PRESENT AT THE BEGINNING

Both editors of *The Autoimmune Diseases*, 5th edition, were present when it happened in the mid-1950s. The topic of autoimmune disease emerged from the “dark ages,” as Silverstein characterizes it in Chapter 2. One of us (I.R.M.) was collaborating with F.M. Burnet as the current foundations of modern immunity were laid, based on the requirements for self-recognition and cellular selection of immune repertoires. The other editor (N.R.R.) studied with Ernest Witebsky, who devoted a lifetime to delineating the antigenic characteristics of differing normal and malignant cells. If some of the wisdom and vision of these giants, on whose shoulder the editors stood, is evident in this book, they will be especially pleased. In a foreword to *The Autoimmune Diseases*, 1st edition, in 1985, Burnet concluded: “Every chapter of this book represents a fusion of acts and ideas from both the clinical and experimental fields. It is both inevitable and essential that this cooperation go on indefinitely.”

Grateful acknowledgments go to a number of individuals who made completion of this volume possible. On the side of the publisher, Elsevier, Mary Preap has been a critical member of the team from the beginning. More recently, Melissa Read and Marion Stockton provided the final touches. It was indeed an international team effort. Each of the editors received editorial support from skilled secretarial administrators including Kathleen Spinnato and Starlene Murray at Johns Hopkins, and Elaine Pearson at Monash University. As in previous

editions, the Editors record that successful completion of this fifth edition depended upon the encouragement, forbearance, and keen sense of humor of our wives. I.R.M. thanks Monash University through the Dean of the Faculty of Medicine, Professor Christina Mitchell, for ongoing provision of full academic and scholarly facilities via an appointment as Adjunct Professor. Most of all, the editors thank the many contributors. They not only submitted learned chapters but graciously withstood the rigor of editorial review. Many chapters were revised multiple times before the “picky” editors released them to the publisher.

The editors have the sad need to tender particular tribute to two of the authors, highly esteemed colleagues and huge contributors to knowledge of autoimmune diseases George Eisenbarth and Lloyd Mayer. Both died during the later stages of preparing this book. George’s last communication to the editors, sent a few weeks before his death, was to reassure them that his contribution would be submitted in due time. Lloyd’s chapter was completed before his untimely death, but his co-author took on the challenges of editorial corrections. Their energy and insights will be greatly missed by all who strive to reduce the burden of autoimmune disease.

“...the best test of a physiological concept is its application to pathological conditions”

F.M. Burnet, 1959

EVOLUTION OF THE AUTOIMMUNE RESPONSE

The goal of this book, like the previous editions, is to promote and promulgate newer knowledge and deeper understanding of the family of autoimmune diseases. Progress towards that goal is enhanced by considering the evolution of immunity itself. Diverse as they are in their clinical manifestations, all of the autoimmune diseases are related by the fact that host-directed immune responses play a significant role in their etiology and pathogenesis. The proper function of the immune response entails maintaining a careful balance between vital effector activities with judicious regulation. As challenges, both internal and external, arise continuously, the immune system must be highly adaptable. An understanding of the physiology of the immune system presupposes recognition of its evolution over the long term and its plasticity in the short term.

A century and a half ago, Charles Darwin and Alfred Russel Wallace taught us that survival of life depends upon adaptation of an organism to its ever-changing

environment. On a populational level, successful adaptation leads to natural selection and permits propagation of a species. Among individuals, successful adaptation is measured as survival and reproduction. On both individual and population levels, the immune system needs to distinguish components of the environment that promote survival from those that threaten it. For example, an evolutionary connection between nutrition, the ability to recognize and take in substances needed but not manufactured by the host, and protection of the host, based on recognition and disposal of pathogenic agents, was described by Metchnikoff in Darwinian terms (Tauber and Chernyak, 1991) and liberal use was made by F.M. Burnet (1959) of the concepts of variation and survival of the fittest, and homeostatic processes, in formulating his clonal selection theory of acquired immunity.

Throughout evolutionary time, organisms have devised more and more mechanisms that fit them for survival, devices that must be robust enough yet flexible enough to facilitate survival despite internal changes and external threats. The term homeostasis was foreshadowed by use of *milieu interne* by Claude Bernard (1865), and further developed by Walter Cannon (1932) who described homeostasis as the requirement for a harmonious interaction among these many devices, ultimately providing the optimal conditions for various physiologic

functions. Continued existence of an individual organism or propagation of a population depends upon maintaining and adjusting homeostasis, even in the presence of a hostile environment. “Normality” of any organism, including members of our own species, can be defined as the condition at that moment when the homeostatic requirements imposed by evolution are best satisfied.

Among all of the agents of the external environment that may adversely affect human survival, microorganisms are among the most common threats. Highly diverse and ever changing, they surround and cohabit our bodies and thrive in a symbiotic relationship in the intestinal tract. Consequently, the immune system in fulfilling its core function for providing protection has developed multiple strategies to recognize and manage microorganisms that may enter the body, especially the pathogenic ones that have the ability to upset normal homeostasis, yet tolerate others that confer benefit on the host.

A PHYLOGENETIC PERSPECTIVE

The tools employed by the human immune system for recognition have been increasingly refined, specialized, and expanded during the long evolution of multicellular organisms. Many of the elements of the human immune system have been reshaped from invertebrate predecessors. Some immunologic devices recognize the broad array of potential pathogens. Among these are barriers such as skin and mucous membranes which daily present the most effective protective measures available to the host. If they are disrupted, invasion of the body by microorganisms is a common, but unwelcome outcome.

The Innate Immune System

If these covering barriers fail in their function, the immune system draws on additional resources defined collectively as the innate immune system (Chapter 5). A limited number of pattern recognition receptors (PRRs), accumulated during evolution, are inherited to some extent by all members of our species. The PRRs of the innate immune system, capable of acting immediately, are designed to recognize a broad array of molecules present on or secreted by different invading microorganisms. The receptors are hard wired to signaling pathways that drive cell metabolism to produce mediators affording host protection. Included among the generators of these prompt responses are specialized cells such as granulocytes (Chapter 14), monocytes (Chapter 11), natural killer (NK) cells (Chapter 13), soluble products such as the complement system (Chapter 15), and naturally occurring polyreactive antibodies secreted by the special B1 subset of B cells (Chapters 9 and 10). The components of the innate immune system, resulting from many eons of

evolution, are borrowed in one form or another from the many species lower on the evolutionary timescale.

Our long evolutionary history has seen the components of the innate immune system capable of injuring tissues of the host selected against and effectively silenced. However, the cells of the innate immune system, like any other rapidly multiplying cells, are subject to the vicissitudes of mutation which, if not lethal, can become established in the germline. Some of these genetic traits can result in products like IL-1 β that induce inflammation after exposure, not only to unwanted intruders, but as well to native cells of the host. These increasingly recognized genetically determined deviations in inflammation are now well described as autoinflammatory diseases (Chapter 4). Some hitherto have been considered as genuine examples of autoimmunity, but they lack evidence of an adaptive autoimmune response. Because these diseases also share inflammatory mediators with the autoimmune diseases, they may lend themselves to similar modes of treatment.

The Adaptive Immune System

In its strategy to produce such a broad, all-encompassing recognition system, the innate immune response sacrifices potency, precise specificity, and memory for breadth and immediacy. The more recently evolved adaptive immune system seen in jawed vertebrates builds upon many of the same constituent cells and cell products represented in the innate immune system. For example, inflammatory processes that accompany innate immunity may provide the costimulatory signals that act as adjuvants for the adaptive response (Nhu and Rose, 2013). The adaptive response has developed a strategy of focusing recognition on specified, molecular structures such that the outcome of an adaptive response is highly directed reactivity. The generation of this huge diversity of specific receptors is the job of the lymphocytes and their antigen receptors. To recognize a virtually infinite number of potential antigens, the lymphocyte population depends upon the well-studied post-genetic mechanisms, including hyper-mutation and recombination activating genes (RAG)-dependent recombination (Chapters 6 and 10). Finally, there has evolved a very necessary guidance system to position the appropriate defensive lymphocyte to exactly where it is needed to fulfill its particular purpose—this is the task of the adrenergic and chemokine receptors that engage chemokine ligands (Chapter 22).

Random recombinations inevitably lead to receptors on some lymphocytes that recognize antigens of the host. Such lymphocytes represent a clear and present danger, and must be carefully regulated. Some of these lymphocytes are eliminated during their birth and others are controlled later by the active and passive processes that jointly contribute to “self tolerance” (Chapters 7, 9,

and 10). When the controlling measures fail, diseases caused by the adaptive immune system—the classical autoimmune diseases—ensue. These represent prototypic examples of homeostatic dysregulation within the adaptive immune system and point to a need to be rebalanced repeatedly through the lifespan as environmental changes occur.

SELF AND NON-SELF, AND THE NATURE OF AUTOANTIGENS

Any discussion on autoimmunity necessarily raises the issue of distinction of self–non-self, and the structure and nature of autoimmune epitopes. Historically “self” was regarded as an entity fixed during early development and responsible for imposing and maintaining natural immune tolerance in the primary lymphoid tissues, thymus (Chapter 7) or bone marrow (Chapter 9), “central tolerance.” It depended on precise processes that entailed physical deletion of lymphocytes capable of autoimmune reactivity. These theoretical ideas were made real, in the case of T cell tolerance, by the discovery of the *AIRE* genes, which encode an autoimmune regulator protein that facilitates the deletion of autoreactive lymphocytes in the thymus and possibly in peripheral lymphoid tissues too (Kyewski, 2008). The “immunologic self,” then, represents all host antigens presented in the thymus, or otherwise inducing unresponsiveness. However, over recent years self–non-self distinctions have become blurred. Can immunologic self include the intestinal microbiota, thereby justifying “autoimmune” for the colonic inflammatory diseases (Chapter 60)? Products derived from aberrant apoptotic cell death can induce systemic autoimmunity (Chapter 17), while tumor-derived autoantigens from primary neoplasms of ovary, breast, or lung (which are also represented in normal brain tissue) can evoke devastating neurological syndromes (Chapters 57 and 58). Self-tolerance clearly needs to be redefined.

A related issue is the nature of reactive sites—epitopes—for antibodies and T cells on autoantigenic molecules. In the case of thyroglobulin, a large glycoprotein produced and stored in the thyroid glands, patients with autoimmune thyroid disease react with epitopes that differ from the many recognized by normal individuals (Caturegli et al., 1994). Taking the example of glutamic acid decarboxylase, a pancreatic islet autoantigen, epitope sites, identifiable by use of specifically reactive monoclonal antibodies and crystallographic data, are quite limited in number, with most of the surface-exposed sites being immunologically silent (Fenalti et al., 2008). The degree to which such information can clarify how autoimmune disease is initiated remains to be seen.

AUTOIMMUNITY AND AUTOIMMUNE DISEASE

In the decade since the publication of the fourth edition of *The Autoimmune Diseases* in 2006, our understanding of the homeostatic regulation of the adaptive immune system has expanded greatly. These changes have required that most of the chapters on underlying immunologic principles be extensively rewritten. Some topics are entirely new. For example, we now recognize a population of large lymphocytes that bear the signature markers of NK cells, but produce the T cell receptors of very limited variability. These receptor-invariant NKT cells, like other cell systems of the immune response, are becoming subclassifiable, as described in Chapter 8. A greater understanding of the pathways that carry the signals from antigen-specific binding of receptors to induce nuclear changes has begun to explain the concurrence of events that leads to an escalating autoimmune response. The role of epigenetic changes (heritable or non-heritable) in the immune process continues to provide fresh understandings of how the immune system operates (Chapter 28), including how substances in the environment can actually lead to immune dysregulation and autoimmune disease (Chapter 21). The distinction between autoimmunity as the everyday consequence of ongoing clonal diversification and autoimmune disease as an exceptional pathologic outcome has been greatly advanced by investigating the various nuances of antigen presentation by differing subtypes of dendritic cells and macrophages (Chapters 11 and 12). Investigations of effector mechanisms dependent on infiltrating cells and their products provide clues for potential biologic therapies (Chapters 23 and 81). The progression from autoimmunity to autoimmune disease also follows the chance accumulation of particular genetic alleles, many of which help to maintain immunologic homeostasis on a day-to-day basis. The coincidence of these genetic traits leads to a wide spectrum of autoimmune disease susceptibility (Chapters 26 and 27). On the brighter side, however, greater knowledge of these genetic traits combined with functional early warnings such as appearance of multiple autoantibodies and presence of key cytokine or other mediators in the blood provide the first hope for earlier diagnosis, more effective interventions and a real possibility for prediction and prevention (Chapters 78 and 79).

THE COMMON THREADS

The reader will note that the number of diseases included in the current edition of the book exceeds that in previous editions. In fact, that number has increased with each succeeding edition since the first in 1985 as more diseases are seen as sharing the common threads of autoimmune

pathogenesis. Broadly, we define an autoimmune disease as one in which autoimmunity demonstrated by self-reactive T cells or antibodies plays a causative or a significant contributory role (Rose and Bona, 1993). In humans, the evidence to support autoimmunity as a pathogenetic agent can be determined with varying degrees of certainty. In a few instances, there is direct evidence that a human disease is caused by autoimmunity based on disease transfer. At this time, T cell transfers between humans are not feasible and this metric pertains to instances where transfer of antibody is possible. The situation prevails mainly in cases of maternal to fetal exchange, as in neonatal lupus (Chapter 35), myasthenia gravis (Chapter 54), and Graves' disease (Chapter 40). Pertinent here as well is transient autoantibody-mediated thrombocytopenia in human volunteers after serum from a patient with immune-mediated thrombocytopenia, as in Harrington's classic experiment in 1951 (Chapter 47). In some instances a human pathogenic autoantibody can transfer features of a particular disease to a rodent recipient (Chapter 57).

If no evidence is available to show a direct causative effect of autoantibodies, indirect evidence can be marshaled. It depends on the creation or identification of a model in experimental animals where the appropriate antibody or adoptive cell transfers can be carried out. The availability of a genetically engineered rodent has opened new opportunities to explore mechanisms of induction and pathogenesis (Chapters 30 and 31). The great majority of autoimmune diseases are defined on the basis of such indirect evidence, even though the model may not completely mimic the human condition.

In many other instances, only inferential or circumstantial evidence is available based on the appearance of the common features of autoimmune diseases such as the presence of relevant autoantibodies at an unquestionable level, co-occurrence (clustering) with better established autoimmune disorders and shared genetic traits. Genetic markers are becoming more informative with widening applicability of genome-wide searches that are increasingly showing single-nucleotide polymorphisms (SNPs) common to autoimmune diseases as well those that are disease unique (Chapters 26 and 27). In some situations, regrettably, the now-appealing concept of autoimmunity is becoming applied to odd diseases that actually fail to qualify, perhaps furthered by a lack of stringency of results for autoantibodies reported by immuno-diagnostic laboratories (Chapter 77). Some of these diseases are described in a special chapter by Mackay (Chapter 75).

In reviewing the human diseases attributable to effects of autoimmunity, our emphasis has been placed heavily on the common features that underlie these clinically varied disorders (Rose, 1997). The common threads uniting the autoimmune diseases represent shared maladaptations

of the adaptive immune response to changes in internal or external environments. The common threads often represent particular inadequacies in the homeostatic control measures that normally prevent the progression of benign autoimmune responses to the far less common pathogenic autoimmunity. These maladaptations can sometimes be traced to specific genetic traits (Chapter 26), to environmental stresses, or to hormonal changes (Chapters 21 and 24), but most often result from all of them combined.

There is an intimate relationship between the endocrine system and the immune system based on their co-evolution (Chapter 3). They even share some mediators and signaling messengers. Hormonal changes explain much of the sex bias and the age dependence of autoimmune diseases. Although the autoimmune diseases predominantly occur in females, a few such diseases are seen mainly in males. This finding supports the view, now well established, that multiple mechanisms come into play in determining the female to male ratio (Chapter 24). Another set of common threads characteristic of the family of autoimmune diseases is their dependence on an environmental initiator. With a few striking exceptions, (Chapter 29) heritability alone is insufficient to explain the occurrence or expression of an autoimmune disorder. In outbred humans autoimmune disease depends on exposure to some endogenous or exogenous influence, be it infection or some chemical or physical agent. The importance of greater study of environmental triggers rests on the demonstration in a few instances that an autoimmune disease can be arrested or actually prevented even in a genetically disposed individual if separated from that environmental agent. A telling example is the virtual disappearance in developed countries of rheumatic carditis associated with elimination of endemic beta-hemolytic streptococcal infections (Chapter 69).

The internal environment, represented in part by the microbiome, is acquired at or soon after birth and their "pattern" tends to remain throughout life (Chapter 25). These microorganisms, especially bacteria, live harmoniously and may even benefit the host. For reasons only partly understood, the pattern may become "destabilized" and changes in the microbial population can have great impact on the host immune response. But allowing for effects of physical or chemical agents in some cases, infection with a microorganism is in general seldom out of the picture and can influence the immune response in almost countless ways to incite autoimmune disease (Chapter 19).

THE "PROPER STUDY. . ."

Accepting that the "proper study of mankind is man," an appropriate investigation of autoimmune disease begins with a careful assessment of the disease itself, starting

with a patient's present illness, its history, social setting, and familial occurrences (Rose, 2013). A large array of immunologic tests and radiologic imaging procedures is presently available. As individuals with similar histories and exposures are collected, epidemiologic studies reveal common environmental and genetic risks. These population-based investigations are now being expanded by multinational consortia, allowing for the assembly of many thousands of cases for valid statistical analysis. Clinical presentation and epidemiologic aspects are dealt with in each disease-related chapter of the book. Sometimes patient-based information obtained from carefully studied patients is sufficient in itself to identify the pathogenetic mechanisms underlying an autoimmune disease, especially if there are laboratory procedures that can reproduce the essence of the pathology outside of the body. Examples are seen in the hematologic cytopenias (Chapters 46–48) and antireceptor diseases such as myasthenia gravis (Chapter 54) or cerebral neuroreceptor diseases that are attracting increasing interest among neurologists and neuropathologists (Chapters 57 and 58). As mentioned above, experimental models have proved to be of great value in determining the precise effector mechanisms of disease, even though the initiation of the disease in the model can be quite different from the human counterpart. For this reason, as well as the well-known intrinsic differences in the physiologic basis of immunity in different species, the principal findings obtained from experimental models need to be referred back to the human equivalents often in the form of immunologic comparisons and clinical trials. Importantly, particular interventions devised in animal models form the basis of preclinical data needed before undertaking clinical trials.

Data emerging from extensive studies in animals provide a template for understanding the steps leading to human autoimmune disease; specifically its initiation, progression, and injury. With respect to initiation in experimental animals, studies have informed us how the delicate normal balance of the immune response—homeostasis—can be perverted by a multitude of influences. In broad terms, an autoimmune response can exceed the bounds of the normal homeostatic controls because it is too strongly induced, too long maintained, or too inadequately regulated, singly or in combination. An autoimmune response may be strengthened by an external antigenic mimic, by an agent with the properties of an adjuvant, or by one of the many non-antigen-specific costimulators of immune responses. Very likely, both antigen-specific and non-antigen-specific regulatory pathways are needed for an autoimmune disease to get started.

Once the threshold of homeostatic adaptation has been exceeded, an autoimmune response can progress on to its

pathologic outcome. That process may—in fact usually does—take weeks or even years, well recognized in the extensively studied example of autoimmune diabetes mellitus in humans and in rodent models (Chapter 41). During that time it is often characterized by an escalation or augmentation of the autoimmune response. This may involve spread of the response from a single to multiple epitopes (designated as epitope spreading) on an original antigenic molecule or, in the case of inflammatory diseases, production of additional autoantibodies to different organ-specific antigens (Chapter 78). This escalation of the autoimmune response is often the first clinical clue that a well-regulated autoimmune reaction has progressed to a dysregulated immune reaction in the form of overt autoimmune disease (Rose, 2007).

In recent years, much progress has been made in studies of cellular injury during autoimmune responses (Chapter 17). For instance, defects in processes of apoptosis can allow emergence of autoimmunogenic derivatives of nuclear or cytoplasmic constituents of the cell. Ironically, the damaging effector mechanisms during autoimmune disease are generally the same ones as those that confer protective immunity in infections. Many new specifically targeted modes of treatment of autoimmune disease are based on careful dissection of the various effector mechanisms. Thus, blocking particular cytokines or their receptors promises winning strategies for treating the deleterious effects of an autoimmune response (Chapter 76). The recent prodigious progress in this area is comprehensively described by Chatenoud (Chapter 81).

Important as these advances have been in benefiting patients by arresting and even reversing progression and so providing symptomatic relief, they do not necessarily change the underlying cause(s). The expectation is that as homeostasis is re-established, the sufferer becomes separated from some of the exogenous causal factors, perhaps “a triumph of hope over experience.” Thus cures or elimination of autoimmune disease mostly remain in the future excepting, perhaps, instances like celiac disease (Chapter 59) and rheumatic carditis (see above) where the initiating agent can be confidently determined.

A requirement for homeostasis in the immune system was envisioned early on by Burnet (1959, p. 122) while recognizing that ‘there was no experimental evidence whatever on the point’. This has changed, with homeostasis now becoming more widely understood by immunologists to describe various functional activities of the immune system. One example is seen in the fine balance between the “positive” effector processes mediated by autoantibody-producing B lymphocytes and Th1/Th17 CD4⁺ T lymphocytes counterbalanced by the “negative” effector processes mediated by B lymphocytes (Chapter 10) and maybe by anti-idiotypic antibody, and by T lymphocytes with regulation by several T cell types among

which we see the CD4⁺ CD25⁺ Fox p3 Treg subset as being the one of major prominence.

TOWARDS THE FUTURE

Much of the research on the autoimmune diseases conducted during the latter part of the 20th century has been based on the reductionist principle of isolating a single variable within a complex background. The overall success of this approach is evident in the remarkable advances described in this and prior editions of the book. Yet, all biologists realize that evolution has produced a highly integrated and interactive immunologic network: changes in any one component alter the entire network. The availability of new tools based on microarray platforms with capabilities for managing large amounts of biologic data have made it possible to construct an image of such complex physiologic system. The fruits of a systems approach are already visible in looking at large panels of autoantibodies (Chapter 77). Combining an initial systems analysis with subsequent reductionist research on precise mechanisms promises fresh visions into the complex biologic reactions underlying autoimmune responses.

Progress in research on the autoimmune diseases will certainly accelerate over the next decade. One major imperative of the numerous population studies in progress is explaining the striking temporal increase in incidence of many of the autoimmune diseases, in particular autoimmune diabetes, multiple sclerosis, celiac disease, and Crohn's disease, as analyzed in the corresponding Chapters 41, 52, 59, and 60. Better recognition could be only a partial explanation. It is unlikely that most of the rise can be assigned to an accumulation of genetic susceptibilities, leaving environmental pressures as the main drivers of the increase. One popular but still hotly debated idea is that the current overly hygienic lifestyle in developed countries is not conducive to optimal development for an "under-challenged" maturing immune system. However, there are many alternative possibilities such as the so-called "Western" diet with its relatively low fiber content, which yields an insufficiency of diet-derived ligands; this is exemplified by short-chain fatty acids to engage "metabolite sensing receptors" such as G protein-coupled receptor (GPR) 43 situated on immune (and other) cell types so favorably modulating immune homeostasis and the character of the intestinal microbiome (Maslowski et al., 2009; Maslowski and Mackay, 2011).

Whatever the case, environmental changes may be induced within the immune system itself, in interrelated physiologic systems, or to the microbiome. Since the changes operative through the environment still rest on the foundation of host genetics, they will be highly personal. Thus, knowledge of a person's genome and microbiome may be critical in explaining the diversity of

individual responses to changing environmental provocations. As it broadens to meet the changing environment, medicine in general and immunology in particular will have to become more individualized.

Another lesson gained from 20th century research is the likelihood that there is a long incubation period in the development of many of the autoimmune diseases as judged by the presence of signal autoantibodies in archived sera. So, when does an autoimmune disease actually begin? What happens on "day 1?" This information is of the greatest importance in devising a cure or attaining the ultimate goal of prevention. Animal models have clearly shown that in most cases it is considerably easier to arrest or even reverse an injurious autoimmune response by intervening before the immune response is fully under way and "memory" populations of effector lymphocytes have settled in. Later interventions are more problematic and associated with much greater risk of adverse outcomes, particularly after novel interventions. Given sufficient personal, quantitative information on risk based on genetic data combined with early immunologic and biochemical signs, it may well become acceptable practice to intervene actively to primarily prevent autoimmune disease before it is clinically evident or has secondarily extended to avoid recurrence.

THE LAST WORD

We are far from writing the last word on the pathways to autoimmune disease. An immune system, charged with sensing an ever-changing environment and making appropriate modifications, requires constant recalibration. Environmental changes needed to sustain life on this planet (and perhaps other planets) are likely to increase. It will be the task of the ever-evolving immune system to gather new tools to accommodate new demands. The risk of biologic errors will remain even in the best regulated system. Accordingly, autoimmune disease will remain a problem as long as variation and natural selection remain laws of nature. Our continuing goal remains to nullify the destructive effects of immunity while maintaining its vital protective functions.

We face the future with cautious optimism. In a forthcoming work on the historical foundations of autoimmunity (Anderson and Mackay, 2014) there is cited the apt phrase of the English historian of science J.W.N. Sullivan (1921): "This spirit is chiefly a sense of unlimited possibilities."

Autoimmunity as a cause of human disease is well established as a clinical reality, shifting so many formerly enigmatic diseases out of the idiopathic category. The clinical laboratory has given us remarkable tools for earlier, more precise diagnosis and the research laboratory

has provided rational targets for intervening successfully in many formerly unmanageable diseases. By considering the autoimmune diseases as a category of related disorders and concentrating on their core causes, possibilities of true cures and eventual preventions are slowly emerging. Most important, the size of the autoimmune disease problem is gaining increasing attention from the medical profession and, ultimately, from the public, the best prognostic for future progress.

"...1955–1965 [was] the decade marked by the question, Does autoimmunity exist?"

(Rose and Mackay, 1985)

It is one of the curious situations in science that certain well-demonstrated facts are refused entry into the body of accepted knowledge, and may become so effaced from the collective memory that they must be rediscovered many years later in order to gain acceptance. Such was the case in immunology with Donath and Landsteiner's (1904) discovery that paroxysmal cold hemoglobinuria (PKH) is an autoimmune disease, or with Clemens von Pirquet's (1910) explanation of immune complex disease. The cause of this selective amnesia may merely be an earlier contradictory pronouncement by a respected leader in the field; sometimes it lies in an inability to fit the new finding into the working paradigm that guides thought in the field, as the historian of science Thomas Kuhn (1970) has suggested. In the end, it may be that Ludwik Fleck (1979) was right when he proposed that acceptance of a fact in science depends less upon its truth than upon its acknowledgment by the leaders in the discipline (whom Fleck called the *Denkkollektiv*). Ultimately the truth in science will emerge, although sometimes it takes a very long time.

The earliest discoveries in immunology were made in the context of the battle to ward off infectious diseases. These included Louis Pasteur's (1880) preventive vaccines, Ilya Metchnikoff's (1884) bacteria-eating phagocytes, and Behring and Kitasato's (1890) curative antidiphtheria and antitetanus sera. It seemed evident that these efficient mechanisms for the protection of the body were Darwinian adaptations designed to prevent or control infectious disease, a widespread view in the 1890s even after it was demonstrated that specific antibodies might be formed against such innocuous antigens as egg albumin, bovine serum proteins, and sheep red cells. It seemed unthinkable at the time that a grand mechanism designed to prevent disease might turn the tables and cause disease. This concept of a benign immune system became so well established that demonstrations that antibodies might cause disease were either disregarded entirely, or else ascribed to "aberrant" antibodies acting under the influence of a "misdirected" immunity (Silverstein, 2009). This was how the early discoveries of serum sickness, hay fever, asthma, and a variety of immunopathological phenomena were treated by mainstream immunology during the first half of the twentieth century.

It is beyond the scope of this chapter to discuss the entire history of the unwillingness to accept that the

immune response might lead to a variety of harmful outcomes (which we now describe under the rubric “immunopathology”). We shall limit the present discussion to the way in which a subset of the whole, autoimmune diseases, was regarded (or rather disregarded) during the first half of the twentieth century. This sample should provide a quite adequate representation of the way that early immunologists dealt with the paradox presented by the almost oxymoronic word *immunopathology*.

THE SEARCH FOR AUTOANTIBODIES

Horror Autotoxicus

It was Richard Pfeiffer (1894) who discovered a new mechanism that functions to mediate immunity—the destruction of bacteria by humoral antibodies. Jules Bordet (1899) showed that not only were bacteria lysed by thermostable antibody and a thermolabile substance that he called *alexine* (later termed *Komplement* by Paul Ehrlich), but that mammalian erythrocytes could be hemolyzed specifically by two similar agents. Here was a technique that would see broad application in many areas of immunology (Silverstein, 1994), not least in connection with the question of whether an individual could form antibodies against its own self.

Two consequences of Bordet’s report were immediately apparent. Karl Landsteiner (1900) became interested in red cells and discovered blood groups in humans (for which he received the Nobel Prize in 1930). Then Paul Ehrlich and Julius Morgenroth (1900, 1901) launched a series of studies of immune hemolysis in order to develop additional support for Ehrlich’s (1897, 1900) side-chain theory of how antibodies are produced and how they function. It was Ehrlich’s interpretation of his hemolysis experiments that would play a major role in the early history of autoimmunity. These hemolysis experiments are described and analyzed in detail by Silverstein (2002).

During the course of these experiments, Ehrlich and Morgenroth immunized many different species with the red cells of other species. They also immunized animals with the red cells of other members of their own species, and even tried to immunize animals with their own red cells. In every case, they were able to demonstrate the production of xenohemolysins and isohemolysins, but autohemolysins were never observed. This led inexorably and logically to the conclusion that animals could not make autotoxic antibodies to any self-antigens, a postulate that Ehrlich named *horror autotoxicus*. Indeed, he would conclude that, “It would be dysteleological in the highest degree, if under these circumstances self-poisons of the parenchyma—autotoxins—were formed” (Ehrlich, 1902).

But Ehrlich was not the only one who responded to Bordet’s publication on immune hemolysis. If red cells

could stimulate an immune response, why not other tissues and organs? In no time, attempts were undertaken to immunize animals with all types of cells and tissue extracts, especially at the Pasteur Institute in Paris where Bordet had worked. As expected, cytotoxic xenoantibodies against a variety of tissues were reported; indeed, volume 14 of the *Annales de l’Institut Pasteur* was largely devoted to these studies, including a review of antitissue antibodies by Metchnikoff (1900). Most surprising was a report by Metalnikoff (1900) that some animals were able to form antibodies against their own spermatozoa. But while these autoantibodies could destroy the sperm *in vitro*, they seemed to have no effect *in vivo* on the viable sperm in the immunized animal.

Ehrlich was not impressed! These are not “autocytotoxins within our meaning” said he, since they do not cause disease (Ehrlich and Morgenroth, 1901). Here was the true meaning of *horror autotoxicus*: not that autoantibodies cannot be formed, but that they are prevented “by certain contrivances” from exerting any destructive action (Goltz, 1980). Due in part to Ehrlich’s worldwide prestige and to the fact that an autoantibody seemed so obviously counter-intuitive, *horror autotoxicus* found broad acceptance as a guiding principle. Indeed, so firm was the conviction that autoimmune disease was impossible that everyone soon forgot Ehrlich’s suggestion that an autoantibody might exist without causing disease. It would be some 80 years before the important distinction would be made between autoimmunity and autoimmune disease (Rose and Mackay, 1985).

The Nature of Ehrlich’s “Contrivances”

Paul Ehrlich was nothing if not logical. He proposed one of his typical thought-experiments to examine the possible outcomes (Ehrlich and Morgenroth, 1900). Suppose the existence of a self-antigen α . Then, since antibody formation results from the interaction of antigen with preformed cell receptors according to the side-chain theory (the first selection theory!), two possibilities are seen:

- The host possesses no anti- α cell receptors. Therefore no autoantibody response and thus no disease can occur. (Here is, in embryo, Burnet’s later clonal deletion idea!)
- The host does possess anti- α cell receptors on its cells. Therefore autoanti- α is formed. But the host also possesses the self-antigen α on its cells, with which the anti- α may react to stimulate the formation of anti-anti- α . (Remember, Ehrlich knew nothing about lymphocytes, and conceived that all cells possess receptors, and thus may be stimulated to form antibodies.) But the specific site on the anti-antibody should be identical with that on the original antigen, since they are both able to react specifically with the

antibody combining site! Ehrlich therefore concluded that a self-regulating equilibrium would be established between autoantibody and antigen (=anti-antibody) to suppress the development of autoimmune disease. (Here was a regulatory network theory 70 years before Niels Jerne's (1974) idiotype—anti-idiotypic theory!)

CHALLENGES TO THE THESIS

Lens Autoantibodies

The initial flurry of interest in antitissue antibodies quickly subsided as the implications of *horror autotoxicus* gained broad acceptance. In 1903, however, Paul Uhlenhuth (1903) demonstrated the existence of organ-specific antigens by showing that the proteins of the lens are unique to that tissue; they are found nowhere else in the body. Moreover, these antigens are shared by the lenses of different species. Ophthalmologists seized upon this finding to suggest that an immune response to one's own lens might be responsible for the development of senile cataract (Römer, 1905). They showed further that an intraocular inflammation may be induced by the experimental rupture of the lens in the eye of a lens-immunized animal (Krusius, 1910).

Here were observations that would fascinate both ophthalmic clinicians and a later generation of immunopathologists interested in the possible workings of autoimmune disease. First, there was this early preview of what would later be called the “sequestered antigen” concept. Since “self” antigens by definition cannot elicit an immune response, then such antigens as do must be “foreign”—in this case isolated from the immunologic apparatus of the host, like sperm and lens. Secondly, Römer and Gebb (1912) concluded that if indeed disease does result from the formation of autoantibodies, this would represent a most unusual occurrence and must be considered as an aberration due to a malfunction of Ehrlich's “contrivances.” Here they showed that unlike a future generation, they understood Ehrlich's “law of immunity research” completely.

Interest in the possibility that autoimmunity to lens might lead to disease did not disappear in the years that followed. But whereas the initial studies had been done in the context of the new immunology and was known to all workers in the field, further work was restricted to ophthalmologists and eye departments. Thus, a broad clinical study led Verhoeff and Lemoine (1922) to identify numerous cases of lens-induced inflammatory disease, to which they gave the name phacoanaphylaxis, a process which would later be accepted as a true autoimmune disease. Thenceforth, the description would appear routinely in textbooks of ophthalmic pathology, and clinical diagnoses would be made.

Paroxysmal Cold Hemoglobinuria

Fast on the heels of the lens antigen demonstration came an even more convincing case involving erythrocyte antigens. PKH was a rare disease presenting with signs of intravascular red cell lysis and a resulting hemoglobinuria, following exposure of the patient to the cold. Donath and Landsteiner (1904, 1906) published reports that reproduced *in vitro* all features of the disease. They demonstrated beyond question that it was due to a peculiar autoantibody in the patient's serum that affixes to his own red cells only in the cold, and mediates hemolysis with complement when the sensitized cells are rewarmed.

It was clear from the outset that Landsteiner fully understood the implications of this discovery and its meaning for Ehrlich's *horror autotoxicus*. Indeed, even Ehrlich's student Hans Sachs gave a somewhat grudging acceptance of the phenomenon and its interpretation (Sachs, 1909). But again, the implication seemed to be that this was an unusual exception to the regular scheme, and the implications of PKH as the prototypical autoimmune disease soon vanished almost completely from view.

Sympathetic Ophthalmia

It had always seemed odd to clinicians that after traumatic injury to one eye, the second eye might spontaneously develop a blinding inflammatory disease even years later. Soon after the discovery of cytotoxic antibodies, the proposal was advanced that sympathetic ophthalmia might be caused by the formation of “autocytotoxins” (Santucci, 1906). The concept was picked up and given broad currency by one of the foremost ophthalmologists of the day, Elschnig of Prague (1910a, b). As with autoimmunity to lens, work on the immunology of sympathetic ophthalmia continued, but only in ophthalmology departments. Woods (1921, 1933) reported the presence of antiuveal antibodies in patients with perforating injuries of the globe, and uveal pigment was implicated as the causative antigen (Woods, 1925; Friedenwald, 1934).

The Wassermann Antibody

The discovery of the role of complement in immune hemolysis was soon followed by the finding that *any* antigen—antibody interaction would fix complement nonspecifically (Bordet and Gengou, 1901). The ability to measure this uptake using a hemolytic assay meant that antibody could be titered if specific antigen were available. With the recent identification of *Treponema pallidum* as the cause of syphilis, a serological test for this disease was sought. But since the organism could not be grown in culture, Wassermann and colleagues (1906) and,

independently, [Detré \(1906\)](#) used extracts of tissues from syphilitic patients as the antigen, and a valuable diagnostic test was born.

Most perplexing, however, was the report from many laboratories that positive tests for syphilis might be obtained as well, using extracts of normal tissues as antigens. This ran counter to the prevailing view that only *specific* antigens can interact with antibodies to fix complement. It appeared necessary to conclude, therefore, that the “Wassermann antigen,” being native, must be measuring an autoantibody rather than an anti-treponemal antibody. This suggestion was made, in fact, by [Weil and Braun \(1909\)](#) who speculated that the Wassermann antibody is an autoantibody specific for the tissue breakdown products generated in the syphilitic lesions. They suggested further that these autoantibodies exacerbate the disease, and that the brain lesions in tertiary syphilis (paresis) may represent an autoimmune disease directed against neural antigens. (A century later, the antigen involved in the Wassermann reaction has been identified as a lipid named cardiolipin, but why these antibodies are formed is still a mystery, as is their role in the disease process!)

THE SHIFT TO IMMUNOCHEMISTRY

Despite all these hints that autoimmune diseases might exist, interest in the question waned in mainstream immunology—indeed almost disappeared—for some 40 years, from just before the First World War to the mid to late 1950s. This was due in part to the continuing sway of Ehrlich’s *horror autotoxicus*. But there was another factor at play—the change in the overall direction of the field of immunology.

During the quarter-century prior to the First World War, immunology had been concerned chiefly with medical problems, and was pursued almost exclusively by physician-researchers. It had achieved notable successes in the prevention of some infectious diseases (vaccine development), their cure (serotherapy), and their diagnosis (serology). It had even begun to define several immunogenic diseases (anaphylaxis, serum sickness, hay fever, and asthma). But most of the easy problems had been solved, and further successes in these areas became disappointingly rare. Vaccines were sought, generally unsuccessfully, for the remaining great scourges of mankind: syphilis, tuberculosis, typhus, and the many serious tropical diseases. Few diseases were caused by exotoxins like diphtheria and tetanus, and thus new serotherapeutic approaches were rare. Yet other forces were at work. The Wassermann test and its offshoots became so widespread for the diagnosis of disease that it moved from the immunological research laboratory to the clinic. A new discipline, serology, arose that soon became independent of the mother discipline, immunology. In the same way, experimental anaphylaxis and its human

disease relations, hay fever and asthma, stimulated the interest of clinicians, who soon took over work in this field and called their new discipline “allergy.”

When in a science one research direction reaches the point of severely diminishing returns, its practitioners will usually move to more productive pursuits. So it was with immunology, beginning shortly after the end of the First World War. Karl Landsteiner started working with haptens, and soon devoted himself almost entirely to a chemically-oriented study of the structural basis of immunological specificity and crossreactions ([Landsteiner, 1962](#)). Then Michael Heidelberger ([Heidelberger and Avery, 1923](#)) studied the immunochemistry of pneumococcal polysaccharides and introduced a variety of quantitative methods for the estimation of antigens and antibodies, best typified by the popular text written by his students, *Quantitative Immunochemistry* ([Kabat and Mayer, 1949](#)). For more than three decades, the field was devoted largely to studies of structure, specificity, and the thermodynamics of antigen–antibody interactions. The texts and monographs were primarily chemically oriented, and the practitioners were either chemically trained or at least chemically oriented. Even the theories of antibody formation that guided the field, [Breinl and Haurowitz’s \(1930\)](#) and [Pauling’s \(1940\)](#) antigen-instruction concept, were chemical (i.e., nonbiological and non-Darwinian) in spirit. It was easy to assume that a protein might be synthesized according to external instruction; for the chemist, molecules have no evolutionary history.

Given the continuing influence of Ehrlich’s dictum, and the generally nonmedical orientation of the most prominent immunological investigators, it is not surprising that autoantibodies and autoimmune diseases were not among the most popular topics in the research laboratory. This is not to say, however, that there was absolutely no work along these lines. As we have seen, ophthalmologists reported findings in lens-induced disease and in sympathetic ophthalmia, but these were published in specialty ophthalmic journals. In the early 1930s, Rivers and coworkers published a series of papers on the production of an experimental encephalomyelitis ([Rivers et al., 1933](#); [Rivers and Schwentker, 1935](#)) that only later would be shown to represent an autoimmune process. While these studies are viewed today as important milestones in autoimmunity research, they attracted little attention at the time among immunologists.

The contemporary view of autoimmunity during the 1940s and early 1950s is perhaps best exemplified by the position of Ernest Witebsky, trained in immunology by Ehrlich’s student Hans Sachs and himself a disease-oriented physician. He could say as late as 1954 at the celebration of the centenary of the birth of Ehrlich that, “The validity of the law (sic!) of *horror autotoxicus* certainly should be evident to anyone interested in blood transfusion and blood

disease. Autoantibodies—namely, antibodies directed against receptors of the same individual—are not formed” (Witebsky, 1954). This from the individual who, only two years later with his student Noel Rose, would help refocus interest on autoimmunity with the demonstration of the production of experimental autoimmune thyroiditis! (Rose and Witebsky, 1956; Witebsky et al., 1957).

THE RETURN OF IMMUNOBIOLOGY

During the late 1930s and 1940s, a series of observations began to question the assumptions that had guided recent thought and experiment in immunology. How could one explain in chemical terms the enhanced booster antibody response, or the change with time in the specificity and affinity of the antibodies formed? How to explain the persistence of antibody formation in the apparent absence of antigen? Even more troubling was the lack of relationship between immunity to certain viral diseases and the titer of antiviral antibodies, or the absence of a correlation between antibodies and “delayed” hypersensitivity skin tests. Here were basic biological questions that demanded answers—questions with which current theory was unable to cope, and for which it could not even provide experimental approaches. But even more difficult questions arising from biology and medicine would pose further challenges.

Peter Medawar’s (1945) experiments showed that the rejection of tissue grafts was somehow mediated by immunological mechanisms. Then Ray Owen (1945) described the paradoxical situation in which dizygotic twin cattle might share one another’s red cells without being able to mount an immune response to these foreign antigens. Macfarlane Burnet, biologist *par excellence*, called attention to all of these inexplicable phenomena and hypothesized the existence of a fundamental biological mechanism to explain Owen’s finding—an embryonic interaction that

would suppress the ability to respond to one’s own native antigens (Burnet and Fenner, 1949). This was soon confirmed by Medawar’s group (Billingham et al., 1953), and would be termed immunological tolerance. Yet other observations would emphasize the awakening biomedical movement in immunology—the description of a group of immune deficiency diseases. Taken together, these new questions and phenomena foretold a radical change of direction—what I have termed elsewhere as the “immunobiological revolution” (Silverstein, 1991). Not only did these questions challenge the accepted dogma but they also served to stimulate the entry into the field of a new group of investigators. These were basic scientists from such fields as genetics and physiology, and clinicians from a variety of medical disciplines. They were unfettered by any allegiance to earlier ideas and techniques, and thus could entertain iconoclastic ideas and design novel experiments.

Perhaps the best illustration we may provide of the long period during which immunologists showed little interest in disease may be seen in Table 2.1. Here we list for each organ or disease entity the interval between the last significant study during the “classical” period and the first significant contribution of the “modern” era. The average hiatus, for those for which both ending and restarting dates can be identified, is about 44 years! This is an extremely long interlude for a field that was only some 70 years old in 1950.

In the context of a growing interest in the more biomedical aspects of the immune response, work on autoimmunity thus became respectable. This was also due to the increasing use of Freund’s adjuvant, which made animal models of the various autoimmune diseases more readily available and more reproducible. Advances came rapidly. Coombs, Mourant, and Race (1945) showed with the antiglobulin test that many cases of

TABLE 2.1 The “Dark Ages” of Autoimmunity

| Disease/Organ | Last “classical” contribution | First “modern” contribution |
|------------------------|-------------------------------|--|
| Hemolytic disease | 1909 | 1945 (Coombs et al., 1945) |
| Sperm and testicular | 1900 | 1951 (Voisin et al., 1951) |
| Encephalomyelitis | 1905 | 1947 (Kabat et al., 1947) |
| Sympathetic ophthalmia | 1912 | 1949 (Collins, 1949) |
| Phacoanaphylaxis | 1911 | 1957 (Halbert et al., 1957) |
| Thyroid | 1910 | 1956 (Rose and Witebsky, 1956; Roitt et al., 1956) |
| Wassermann antibody | 1909 | — |
| Platelet disease | — | 1949 (Ackroyd, 1949) |

Adapted from Silverstein (2009).

acquired hemolytic anemia were due to “incomplete” (non-agglutinating) antibodies. [Kabat, Wolfe, and Bezer \(1947\)](#) refocused attention on the immunopathogenesis of “allergic” encephalomyelitis. [Collins \(1949\)](#) introduced a reproducible animal model of sympathetic ophthalmia. [Voisin, Delaunay, and Barber \(1951\)](#) showed how to produce an experimental allergic orchitis. Finally, [Rose and Witebsky \(1956\)](#) demonstrated in experimental animals and [Roitt et al. \(1956\)](#) in human Hashimoto’s disease that some forms of thyroid disease might be based upon autoimmune processes. In addition, an understanding of the pathogenesis of some of these diseases was made easier by the increasing appreciation of the fact that not all were mediated by circulating antibodies; some involved the action of subclasses of lymphocytes that originate in the thymus.

These new findings not only opened wide the floodgates of autoimmunity studies, but stimulated further interest in the more general field of immunopathology as well. This new movement was provided with a theoretical base with [Talmage’s \(1957\)](#) suggestion and Burnet’s Clonal Selection Theory ([Burnet, 1959](#)), which emphasized for the first time the biologically important role of cell dynamics in the antibody response. It is no accident that the late 1950s saw the first international conferences on immunopathology ([Miescher and Vorlaender, 1958](#); [Grabar and Miescher, 1959](#)) and on the fundamentals of hypersensitivity ([Lawrence, 1959](#); [Shaffer et al., 1959](#)). For the first time, in 1963, there appeared a textbook aimed at medical students ([Humphrey and White, 1963](#)), and then two comprehensive descriptions of immunological diseases aimed at clinicians ([Gell and Coombs, 1963](#); [Samter et al., 1965](#)). It was in the spirit of the new immunology that [Mackay and Burnet \(1963\)](#) could summarize contemporary knowledge in the increasingly active field of the autoimmune diseases.

CONCLUDING REMARKS

This, then, is the story of the early stirrings of interest in the possibility that disease might result from an immune response to one’s own autochthonous antigens. Perhaps the initial reports were too premature to be incorporated into the received wisdom of the young field of immunology, just as the discovery of the several allergic diseases could not at first be integrated. Certainly Paul Ehrlich’s dictum of *horror autotoxicus* contributed to an unwillingness to recognize the full significance of the initial findings of a response to spermatozoa, erythrocytes, and retina. But the mounting challenges to the dogma would eventually prove irresistible and the field of autoimmunity would finally flourish. The more modern history of autoimmunity, resulting from the remarkable modern advances in our understanding of the cellular, molecular,

and genetic contributions to the field, will be found in the accompanying chapters in this volume.

A host of diseases are characterized by activation of the immune system in the absence of an external threat to the organism. In these diseases, inflammation and tissue damage occur in the absence of infection, toxin exposure, or tumor growth. These diseases can be characterized as those that display activation of the innate immune system and an excess of inflammatory mediators, but no evidence of an antigen-specific immune response; familial Mediterranean fever and other inflammasome diseases, Behçet disease, even atherosclerosis, can be considered to fall within this category. Alternatively, there are diseases characterized by an activation of the adaptive immune response with T and B lymphocytes responding to self-antigen in the absence of any detectable microbial assault or tumor invasion. These diseases constitute the vast majority of diseases considered to be autoimmune in origin. There are over 80 defined autoimmune diseases in composite affecting 5–7% of the population. Moreover, their incidence is increasing (Patterson et al., 2009).

INNATE IMMUNE ACTIVATION

Activation of the innate immune response is a feature of many, perhaps all, autoimmune diseases (Mills, 2011). This activation may be the primary event involved in triggering the disease process. One example is activation of the innate immune system in systemic lupus due to complement deficiencies that permit excess accumulation of proinflammatory apoptotic debris (Manderson et al., 2004). Increased production of type 1 interferon is present in first degree relatives of some lupus patients, suggesting that this enhanced innate immune activation may be a triggering immune abnormality in these patients (Niewold, 2011). Likewise, inflammatory bowel disease (IBD) is associated with genetic alterations in the inflammasome pathway, leading to increased production of proinflammatory cytokines (Hamilton et al., 2012; Zaki et al., 2011). It is also apparent that the innate immune system can be activated secondarily in autoimmune disease. Immune

complexes containing endogenous Toll-like receptor (TLR) ligands such as DNA, RNA, or citrullinated proteins can activate dendritic cells and other myeloid cells to amplify inflammatory pathways (Green and Marshak-Rothstein, 2011; Sokolove et al., 2011). Tissue injury also leads to activation of innate immune cell networks (Kawai and Akira, 2010; Miyake and Yamasaki, 2012); thus, once autoimmune-triggered tissue injury is ongoing, the innate as well as the adaptive immune system is always engaged.

A low threshold for activation of myeloid cells and differentiation of monocytes to dendritic cells predisposes to autoimmune disease in animal models, and blockade of pathways of the innate immune system can ameliorate many autoimmune diseases. In particular, TLR signaling seems to be a critical feature of many autoimmune diseases as deletion of MyD88, a common component of the signaling cascade for several TLRs, and neutralization of high mobility group protein B1 (HMGB1), a cytokine which synergizes with many TLR agonists, can prevent or treat murine models of diabetes, rheumatoid arthritis, systemic lupus, IBD, and more (Andersson and Tracey, 2011; Herlinds et al., 2008; Pagni et al., 2010; Rivas et al., 2012). The success of IL-1 and more recently IL-6 inhibition in rheumatoid arthritis and IL-12 inhibition in IBD also attest to the involvement of the innate immune response in autoimmune diseases.

Interestingly, the innate immune response, and more specifically monocyte activation, is under the control of the cholinergic anti-inflammatory pathway. This pathway is initiated in the central nervous system, is mediated through the vagus nerve (cholinergic) and the splenic nerve (adrenergic), and culminates in the induction of acetylcholine production by splenic T cells that then inhibits the production of inflammatory cytokines by monocytes that express an $\alpha 7$ cholinergic receptor (Rosas-Ballina and Tracey, 2009). The identification of this pathway has provided a potential therapeutic target that regulates multiple cytokines simultaneously.

CELLS OF THE ADAPTIVE IMMUNE SYSTEM

There is a coordinated interplay among the cells of the adaptive immune system with dendritic cells (DCs), T cells, and B cells interacting to generate the effector response of the immune system. DCs activate T cells and B cells. T cells activate DCs and B cells. B cells activate T cells. This cascade leads to an immune response that recognizes a broad spectrum of epitopes of microbial pathogens and enlists multiple effector mechanisms (Blanco et al., 2008; Goodnow et al., 2010; O'Shea and Paul, 2010; Shlomchik, 2008; Steinman, 2007).

DCs are antigen-presenting cells (APCs) that are the intermediary between the innate and the adaptive immune systems. DCs can be tolerogenic in their resting

state (Kalantari et al., 2011; Morel and Turner, 2011), but when activated they are critical in initiating an immune response. Similarly, monocytes clear the apoptotic debris generated from the billions of cells that die daily in a tolerogenic fashion but, when exposed to inflammatory mediators, they differentiate into macrophages or DCs (Dominguez and Ardavin, 2010). Activation of the innate immune system, therefore, can establish a population of immunogenic DCs for activation of the adaptive immune system. Like essentially all cells, monocytes and DCs display surface expression of class I major histocompatibility complex (MHC) molecules, which permit the presentation of intracellular antigens to T cells. DCs and some macrophage subsets also express class II MHC molecules, which are present on a much more restricted set of cells and permit the presentation of extracellular antigens (Banchereau and Steinman, 1998). Multiple alleles of class I and II molecules exist and thus each individual has a unique set of MHC molecules (Beck and Trowsdale, 2000). DCs also express an array of nonpolymorphic receptors, such as TLRs, and pattern-recognition receptors that bind microbial antigens, products of tissue injury, and nucleic acids (Kawai and Akira, 2010, 2011). Engagement of these receptors causes the DCs to upregulate expression of costimulatory molecules and to deliver an obligatory second signal for activation (Dzopalic et al., 2012; Engels and Wienands, 2011; Vincenti and Luggen, 2007). It is important to note that each DC can recognize and respond to a broad spectrum of microbial antigens.

Each T cell and each B cell express a single receptor for antigen. These antigen receptors are acquired by gene rearrangements that occur in somatic cells (Gellert, 2002); thus, there is no inheritance of the T or B cell repertoire. T cells mature in the thymus (Stritesky et al., 2012). Each T cell expresses a unique receptor (TCR) that recognizes a molecular complex on the surface of an APC consisting of a class I or class II MHC molecule associated with a small peptide derived from an intra- or extra-cellular protein antigen, respectively. Signaling through both the TCR and costimulatory molecules is needed to effect activation of mature T cells (Engels and Wienands, 2011; Vincenti and Luggen, 2007; Weinstein et al., 2012). B cells also express a single receptor for antigen, but the B cell receptor (BCR) recognizes native antigen rather than processed antigen. B cell activation also requires signaling through both the BCR and costimulatory molecules (Crow, 2004). Activated B cells not only secrete antibody, but can also function as APCs to engage a greater number of T cells in the immune response. B cells also secrete molecules that are essential for lymphoid organization, and can secrete a variety of cytokines (Leon et al., 2012; Lipsky, 2001; Marino and Grey, 2012).

A critical feature of both T and B cells is that they proliferate in response to antigenic stimulation to create clonal expansions of cells with a unique antigenic specificity and to develop cells with a memory phenotype (Bishop et al., 2003; Grossman et al., 2004; McKinstry et al., 2010). Memory cells have an accelerated and enhanced response following re-exposure to antigen. B cells have the added feature of undergoing class switching of the immunoglobulin heavy chain gene and random somatic mutation of the BCR followed by selection of those B cells with improved affinity for the eliciting antigen (Li et al., 2004; Victora and Nussenzweig, 2012). Thus, there is a progression from low-affinity IgM antibodies to high-affinity IgG antibodies during the course of an immune response. The memory response reactivates the high-affinity IgG-producing B cells, whose repertoire is unique to each individual.

For the immune system to function effectively there must be a sufficient number in both the naïve and memory repertoires of T and B cells that can respond to an enormous diversity of microbial antigens, and a means of regulating those cells that respond to self-antigen.

DEFINING AUTOIMMUNE DISEASE

An autoimmune disease is a condition in which tissue injury is caused by T cell or antibody reactivity to self. The immune activation may be initiated by infection, but then persists in the absence of any detectable microbial antigen (Davidson and Diamond, 2001). It is important to state that although many diseases considered autoimmune display anti-self-reactivity, evidence may still be lacking that the self-reactivity is, in fact, responsible for tissue damage. It is sometimes possible to determine whether autoantibodies are pathogenic by transferring them to a rodent host; however, T cell reactivity is not transferable from humans to rodents because T cell activation and T cell effector function occur only in the context of self-MHC molecules. Thus, demonstrating the pathogenicity of the autoimmune response has not been accomplished in all autoimmune diseases. In some instances, a disease is presumed to be of autoimmune origin only because B and T cells are present in affected tissue.

Animal models of autoimmune disease have been enormously useful in aiding our understanding of both disease inception and disease pathogenesis (Bar-Or et al., 2011; Billiau and Matthys, 2011; Howell, 2002; King, 2012; Lam-Tse et al., 2002; Mandik-Nayak and Allen, 2005; Peutz-Kootstra et al., 2001; Wooley, 2004). Some models develop spontaneous disease. Others represent genetically modified mice that target a particular pathway in the immune response. Finally, some autoimmune diseases can be triggered in animals by

immunization with self-antigen. While all these animal models have been very important in informing our understanding of autoimmunity, it is important to recognize that we do not know how closely they reflect human disease (Bodaghi and Rao, 2008; Kollias et al., 2011). Some of these models may be more similar to human disease in the effector mechanisms of tissue injury than in the mechanisms of induction of autoreactivity. Indeed, autoantibody-mediated tissue damage is probably most alike in human disease and animal models (Monach et al., 2004). It is also important to consider that there may be extensive heterogeneity in human disease and that the animal models we study intensively may reflect only a subset of individuals with a given disease. A challenge that confronts us is to understand which animal models are most similar to human disease, and can teach us most about the genetic predisposition to disease, disease pathogenesis, and effective therapy.

PREVALENCE OF AUTOIMMUNITY

It is striking that while each autoimmune disease individually affects only a small number of people, the prevalence of all autoimmune diseases is approximately 5–7% (Jacobson et al., 1997). Two critical facts about autoimmune disease are important in understanding the high frequency of these diseases. First, autoreactivity is an aspect of every normal immune system. In fact, the repertoire of immunocompetent lymphocytes that provides protective immunity is selected based on autoreactivity (Gu et al., 1991; Nobrega et al., 2002; Vallejo et al., 2004). Regulation of autoreactivity helps shape the immune system so that it does not become the pathogenic autoreactivity associated with tissue damage: this requires constant vigilance. The immune system maintains a precarious balance between the two: too little response leads to potential neglect of danger, while an overexuberant response can potentially lead to autoreactivity. How this balance is maintained is discussed below. Second, there is a genetic predisposition to autoimmunity and aspects of this predisposition may be similar for many different autoimmune diseases (Cho and Gregersen, 2011). Autoimmune disease requires not just autoreactivity, but may also be influenced by target-organ vulnerability (Liao et al., 1995; Liu et al., 2009). Some of the recent studies of the genetic basis of autoimmunity show that the genetic factors governing specific organ vulnerability are distinct from those governing autoreactivity. Thus, individuals may share pathways promoting autoreactivity, yet present with different autoimmune diseases (Cho and Gregersen, 2011; Cotsapas et al., 2011).

GENETICS OF AUTOIMMUNITY

Association of Single Gene Defects with Autoimmunity

It is clear from epidemiologic studies and studies of animal models of autoimmune disease that there is a genetic component to essentially every autoimmune disease. A few autoimmune diseases appear to be monogenic diseases (Chapters 29 and 50). The human disease autoimmune-polyendocrinopathy-candidiasis-ectodermal-dystrophy (APECED), an autoimmune disease of multiple endocrine organs, is a consequence of a deletion in the AIRE gene that encodes a protein that causes tissue-specific genes to be expressed in medullary epithelial cells in the thymus (Akirav et al., 2011; Anderson and Su, 2011). These cells mediate negative selection of T cells reactive with peptides that derive from tissue-specific proteins. In the absence of AIRE expression, a spectrum of autoreactive T cells fails to be deleted; these cells mature to immunocompetence and mediate an immune attack on various organs. The absence of the AIRE gene appears sufficient for autoimmunity, although the phenotype of the disease that emerges, even within a single family, can be quite variable. Similarly, a defect in the Fas gene can also lead to autoimmunity. The Fas protein is expressed on activated lymphocytes. Engagement of Fas by Fas ligand leads to the death of the Fas-expressing cell, a process critical for downregulating the immune response. Individuals deficient in Fas expression have a disease called autoimmune lymphoproliferative syndrome (ALPS) characterized by an excess of T and B cells and by autoantibody production (Fleisher et al., 2001; Grodzicky and Elkon, 2002; Madkaikar et al., 2011). Of note, not all individuals with deficient Fas expression display ALPS; thus, even in this disease other genes must modulate disease phenotype. Deficiency in certain complement components also results in a high incidence of the autoimmune disease systemic lupus erythematosus (SLE). In this case the mechanism is thought to be a failure of clearance of immune complexes and apoptotic material, resulting in an overload of immunogenic necrotic material that can activate the immune system through engagement of TLRs and other innate receptors (Lewis and Botto, 2006; Pettigrew et al., 2009). Finally, deficiency in Foxp3 that is required for the development of regulatory T cells is associated with severe autoimmunity affecting the bowel and endocrine organs (Ochs et al., 2007).

Genome-wide Association Studies (GWAS) Identify Multiple Gene Loci that are Associated with Autoimmunity

For most autoimmune diseases, multiple susceptibility loci contribute to the disease phenotype. Studies from

mouse models of autoimmune disease have also revealed the presence of loci that suppress the autoimmune phenotype (Wakeland et al., 2001). Thus, an individual's risk of developing an autoimmune disease depends on a summation of susceptibility and resistance loci. A major advance in the last 5 years has been the application of genome-wide association scans (GWAS) that evaluate large numbers of common single nucleotide polymorphisms (SNPs) as genomic markers to type increasingly large datasets of well-defined patient and control populations. Studies in multiple autoimmune diseases have definitively linked a number of genetic variants to disease susceptibility (Deng and Tsao, 2010; Fleisher et al., 2010; Harley et al., 2008).

MHC Associations with Autoimmunity

Despite the identification of a large number of autoimmunity associated genes using the GWAS approach, the polymorphic locus most closely linked to autoimmunity in studies of virtually every autoimmune disease is the MHC locus, an association that has long been known. For example, anti-cyclic citrullinated protein (CCP) positive rheumatoid arthritis in the white population is highly associated with the expression of a set of DR4 alleles that have a particular structural motif, called the “shared epitope” (Winchester, 2004). Reactive arthritis occurs in individuals expressing B27 or, less commonly, B7 class I MHC molecules. In type 1 diabetes both pathogenic and protective DR and DQ alleles have been identified and the *trans*-complementing heterodimer encoded by DQA1*0501 and DQB1*0302 confers very high risk. In celiac disease, 98–99% of affected individuals bear a susceptibility DQ allele—thus DQ testing can be used clinically to exclude disease with a high degree of certainty (Wolters and Wijmenga, 2008). Multiple sclerosis and systemic lupus display particular human leukocyte antigen (HLA) associations, as do many other autoimmune diseases (Fernando et al., 2008; Tomlinson and Bodmer, 1995; Winchester, 2004; Wong and Wen, 2003). The basis for the association of MHC polymorphisms with autoimmune disease is still for the most part unknown but might be due to T cell recognition of particular pathogenic peptides that can bind within the peptide binding cleft of certain MHC molecules, cross-reactivity of peptides derived from infectious organisms with self-peptides, or alterations in the T cell repertoire that result in a decrease in regulatory T cells.

Other Genes Identified by GWAS Studies

A number of non-MHC genes within or in linkage disequilibrium with the MHC locus could help regulate the immune response and may also contribute to a genetic

predisposition to autoimmunity. Genetic studies are allowing an exploration of this question. In rheumatoid arthritis, for example, virtually all the risk for CCP positive disease within the MHC locus is attributable to variations within the peptide binding groove of HLA DR with a lesser contribution from two MHC class I alleles and virtually none from non-MHC genes (Raychaudhuri et al., 2012).

With the exception of the MHC, the other genetic risk loci for autoimmunity that have been identified by GWAS involve a conglomeration of approximately 150–200 relatively common alleles (Cho and Gregersen, 2011), each of which confers only a modest risk, with odds ratios <1.5–2. Some of these polymorphisms are shared between autoimmune disorders and some, but not all, cross major racial groups. In mouse models there is evidence that genetic susceptibility can be a consequence of combinations of genes within each gene locus, and not the consequence of a single gene in each locus. For example, a region on chromosome 1 that is implicated in autoimmunity in SLE has several sub-loci which contribute to various aspects of the disease (Morel, 2010; Morel et al., 2001).

Clinically, it has long been appreciated that autoimmune diseases cluster in families. The biologic basis for this observation is now clear; the same susceptibility genes can influence many different autoimmune diseases. For example, a polymorphism of CTLA-4, an inhibitory costimulatory molecule present on activated T cells, conveys risk for insulin-dependent diabetes, autoimmune hemolytic anemia, and Graves' disease (Ueda et al., 2003), while the CARD15 (NOD-2) gene is associated with both IBD and psoriasis (Bene et al., 2011; Rahman et al., 2003; Russell et al., 2004; Zaki et al., 2011). Similarly, polymorphisms in PTPN22, a molecule that regulates lymphocyte receptor signaling, is associated with type 1 diabetes, SLE, RA, and Crohn's disease but not multiple sclerosis (Burn et al., 2011). The differences in disease phenotype may lie in associated genes, those governing target organ susceptibility or those that modulate disease severity (Russell et al., 2004) or in different environmental exposures. Indeed, the genetic association of HLA and Ptpn22 with CCP-positive rheumatoid arthritis is considerably magnified in smokers, leading to a postulated pathogenetic mechanism whereby damage to the lung by cigarette smoke induces autoimmunity to citrullinated proteins specifically in genetically susceptible individuals (Mahdi et al., 2009).

GWAS Studies Identify Common Pathways for Autoimmunity

One of the most striking advances made as a result of the GWAS analyses has been the identification of immune pathways associated with autoimmune tendencies, some

of which are shared across diseases. A meta-analysis of the autoimmunity associated genes identified thus far suggests that individual diseases can be clustered in groups that share pathogenetic mechanisms. For example, using this type of methodology, disease associations with polymorphisms in IL-2 can be distinguished from those associated with IL-21 that are within the same genetic locus (Cotsapas et al., 2011). The genetic studies in sum suggest that autoimmunity can result from a defect in almost any pathway of immune homeostasis and affect thresholds for innate immune cell activation and for selection and activation of autoreactive lymphocytes.

Application of Data from GWAS Studies to Clinical Practice

Applying this new information to individual patients represents a major challenge since attribution of an SNP identified by GWAS to a single gene often requires extensive resequencing of large regions of DNA from many patients. Furthermore, since the GWAS approach (Cantor et al., 2010) identifies only common polymorphisms with frequencies within the population of >1–5%, the risk variants identified by this method account for only a small proportion of the overall heritability of the disease (Deng and Tsao, 2010). New methodologies to identify rare variants or copy number variations are being developed, but these variations will only be seen in a small fraction of those who are affected. Finally, establishing a link between genetic variations, gene function, and disease pathogenesis has not been easy. Many of the risk alleles identified by GWAS are common variants with subtle effects that are compatible with normal immunological function; in many cases the variation is not even within the gene coding region. Even for genes with coding region mutations such as Ptpn22, functional studies may yield conflicting results (Rieck et al., 2007; Zhang et al., 2011). More studies will be required to understand how the disease-associated variants affect immune responses and interact with each other to contribute to the risk of a particular disease. Nevertheless, as the function of the variants is clarified and potentially pathogenic pathways are identified, personalized interventions may become possible.

Epigenetic Alterations Associated with Autoimmunity

Despite the advances in understanding the genetics of autoimmunity, concordance in monozygotic twins remains below 50% for most diseases, indicating a contribution from random and/or environmental factors. Epigenetic alterations that change the access of DNA regions to the transcriptional machinery through methylation or

acetylation, or silence transcription through inhibitor miRNAs, or alter protein longevity or processing within the cell through ubiquitination or citrullination, may all influence immune system function. T cell differentiation, for example, is influenced by epigenetic mechanisms that reinforce the T cell cytokine-producing phenotype (Nakayamada et al., 2012). While it is clear that epigenetic alterations may profoundly influence cell phenotype, the application of this concept to autoimmunity is in its early phases (Chapter 28). Abnormalities of methylation or acetylation or of expression of particular miRNAs has been demonstrated among peripheral blood cells of patients with several autoimmune diseases (Ceribelli et al., 2011a, b; Ghosh et al., 2012) and there are several examples of deficiencies of particular enzymes or miRNA species causing spontaneous autoimmune disease in mice (Glasmacher et al., 2010; Namjou et al., 2011).

HORMONES AND AUTOIMMUNITY

Since many autoimmune diseases occur more commonly in women than in men, and autoimmunity in general is almost three times more common in women than in men, there have been several investigations of the role of sex hormones in autoimmune disease (Chapter 24). Animal studies have shown multiple effects of sex steroids on the immune system (Rubtsov et al., 2010); studies in mice lacking an estrogen receptor have clearly attributed estrogen effects to signaling through the estrogen receptor α . However, it has been difficult to extrapolate the conclusions from these studies to autoimmunity. Not all autoimmune diseases are more common in women. Some, such as ankylosing spondylitis, have a much higher incidence in men. Furthermore, the predisposition to autoimmunity can be sex determined or hormonally modulated; thus, the higher incidence of disease in women may not always reflect the influence of female hormones on the immune system. The X chromosome in fact harbors many genes of immunologic interest. In gonad matched mice the presence of XX confers a greater susceptibility to pristane induced lupus than does XY (Smith-Bouvier et al., 2008). Similarly, in humans, the XXY phenotype is associated with an increased prevalence of SLE. Nevertheless, the genetic components of the XX chromosome complement associated with lupus risk are not yet clear. The evidence also shows that the effects of sex hormones differ in different diseases. While there is significant evidence that estrogen can exacerbate systemic lupus, estrogen seems to protect against rheumatoid arthritis. Additionally, estrogen or other sex hormones might affect target-organ antigen display or target-organ susceptibility to immune-mediated damage. Thus, there is no simple paradigm to explain the relationship between sex and autoimmunity (Grimaldi et al., 2005).

AUTOIMMUNITY AND CENTRAL TOLERANCE

The hallmark of autoimmune disease is the activation of self-reactive T and B lymphocytes. A major mechanism of self-tolerance is the elimination of self-reactive immature lymphocytes by antigen ligation of the T cell receptor (TCR) or BCR at critical stages of development. For autoimmunity to develop there must be a lack of stringency in the elimination of autoreactive cells. Because TCRs and BCRs are generated by random gene rearrangements that occur within the nucleus of the cell and are not determined by knowledge of the world of self or foreign antigen, autoreactive T and B cells arise routinely. To eliminate autoreactive cells and maintain self-tolerance, T and B cells routinely undergo a selection process during their maturation in primary lymphoid organs, the thymus and bone marrow, respectively (Alexandropoulos and Danzl, 2012; Goodnow et al., 2010; Rajewsky, 1996; Vallejo et al., 2004; von Boehmer and Melchers, 2010). B cells again undergo a second process of selection after somatic mutation of immunoglobulin genes, as somatic mutation routinely generates autoreactivity (Goodnow et al., 2010; Shlomchik, 2008).

T cells that mature in the thymus and enter peripheral lymphoid organs must display TCRs with some affinity for self-peptide–self-MHC complexes in order to receive the necessary signals for survival, termed positive selection. T cells arising in the thymus that express TCRs lacking any affinity for the self-peptide–self-MHC complexes fail to undergo positive selection and die. T cells that are strongly reactive to self-peptide–self-MHC complexes are eliminated in a process termed negative selection. The threshold for both positive and negative selection represents a continuum. As the peptide–MHC complexes present in the thymus differ in each individual and the threshold for negative selection varies from individual to individual, each individual releases a different repertoire of antimicrobial and antiself reactive T cells to the periphery, each reflecting a different spectrum of foreign and self-peptide specificities (Bommhardt et al., 2004; Vallejo et al., 2004; Werlen et al., 2003). It is also probable that certain stimuli can rescue T cells.

B cells similarly undergo a process of negative selection prior to achieving immunocompetence. This process occurs in the bone marrow and continues in the spleen where B cells migrate as transitional cells after exiting the bone marrow. Whether B cells require positive selection on self-antigen for survival and need to display some degree of autoreactivity remains an area of active investigation. It is clear, however, that highly autoreactive B cells are negatively selected on self-antigens encountered during early maturation, and again the threshold for deletion is different for each individual (Monroe et al.,

2003). Deletion occurs with the highest extent of BCR cross-linking; anergy occurs with less cross-linking. Thus, the degree of autoreactivity in the B cell repertoire is also variable. B cell selection is influenced not only by the strength of the signal received through the BCR but also by the availability of the tumor necrosis factor (TNF) like cytokine BAFF. In late transitional B cells the interaction of BAFF with BAFF-R cooperates with signals received through the BCR to promote B cell survival and metabolic fitness. Since the availability of BAFF depends to a large extent on the number of B cells, B cell depletion can result in high levels of BAFF leading to relaxation in the stringency of selection and the escape of autoreactive B cells to the periphery (Liu and Davidson, 2011; Mackay and Schneider, 2009). Anergic autoreactive B cells may also be rescued in a proinflammatory setting by engagement of costimulatory molecules on the B cell membrane or by signaling through TLRs (Monroe and Keir, 2008). Thus, the repertoire of naïve B cells will vary over time within an individual, with higher-affinity autoreactive B cells present during times of infection, inflammation or lymphopenia, and fewer, lower-affinity autoreactive cells present during times of immunologic quiescence (Goodnow et al., 2010; Liu and Davidson, 2011; Shlomchik, 2008).

This paradigm must be understood in the context of our knowledge that autoimmunity is often accompanied by some degree of immunodeficiency. A failure of proper selection may lead to a repertoire that includes too many antigen-reactive T or B cells. This might result in a secondary failure to focus on those clones that mediate protective immunity. The presence of autoreactivity in individuals who are immunosuppressed is more straightforward. For example, the increased levels of BAFF that result from B cell lymphopenia will lead to a failure to appropriately select the B cell repertoire. Some defects that affect T cell activation also impair expansion of regulatory cells or T cell apoptosis and may therefore impair both responses to pathogens and self-tolerance. In the presence of T cell lymphopenia, homeostatic expansion of self-reactive cells can occur.

AUTOIMMUNITY AND PERIPHERAL TOLERANCE

Negative selection of T and B cells occurs in the periphery as well as in primary lymphoid organs, permitting the removal of autoreactive cells that do not encounter autoantigen in the thymus or bone marrow. This process of negative selection is termed peripheral tolerance. Like central tolerance, it is mediated by engagement of the TCR or BCR in a noninflammatory setting (Goodnow et al., 2010; Walker and Abbas, 2002). Although it has

been traditional to debate whether autoimmunity results from a defect in central tolerance in the thymus or bone marrow, or in peripheral tolerance in secondary lymphoid organs, current knowledge of tolerance induction suggests that this may be an artificial distinction. Engagement of the antigen receptor is critical to both central and peripheral tolerance, although there are some differences in antigen receptor signaling pathways, expression of co-receptors and costimulatory molecules that exist between immature T or B cells and their mature counterparts. Mouse models of autoimmunity suggest that defects in negative selection can be limited to central or peripheral tolerance (Anderson and Su, 2011; Linterman et al., 2009; Vinuesa et al., 2005) whereas others may paradoxically impair central tolerance and enhance peripheral activation (Seo et al., 2003). Thus, some autoimmune-prone individuals might exhibit a general lack of stringency in B or T cell tolerance while others might have a defect that is stage specific. This distinction has important therapeutic implications; learning to subset patients based on their tolerance impairment mechanism might permit a better pairing of patient with therapy, in short more personalized medicine. In summary, the thresholds for survival and deletion need to be set within appropriate limits at multiple times in the maturation and activation of a lymphoid cell (Goodnow et al., 2010; Liu and Davidson, 2011; von Boehmer and Melchers, 2010). Too little deletion at any stage and autoreactivity ensues; too much deletion and the protective repertoire may be compromised. Any genetic change that reduces deletion or enhances activation may be a risk factor for autoimmunity.

TRIGGERS OF AUTOMMUNITY

Environmental factors are important triggers for expression of autoimmunity. Autoimmunity may develop following sterile tissue damage. Smoking, drug exposure, diet, chemical exposure, and sunlight have all been implicated as risk factors for particular diseases (D’Cruz, 2000; Debandt et al., 2003; Knip and Akerblom, 1999; Moriyama and Eisenbarth, 2002; Price and Venables, 1995; Steen, 1999; Vaarala, 2012). Molecular pathways for some of these have been established (Chapter 21). Smoking and periodontal disease lead to the generation of citrullinated proteins; these are a target of autoantibodies in rheumatoid arthritis (Klareskog et al., 2011; Routsias et al., 2011). Notably, PAD, the gene encoding peptidyl arginine deiminase involved in the citrullination of proteins, contains a susceptibility allele for rheumatoid arthritis (Bang et al., 2010; Kochi et al., 2011). UV light causes apoptosis of keratinocytes, liberating cellular debris which is then bound by SLE-associated autoantibodies, initiating an inflammatory response in the skin

(Bijl and Kallenberg, 2006; Kuhn and Beissert, 2005). It is now appreciated that pattern recognition receptors for microbial pathogen-associated molecular patterns (PAMPs) also bind to endogenous ligands, DAMPs, or damage-associated molecular patterns. The release of DAMPs in damaged tissue can establish a proinflammatory milieu leading to immunogenic presentation of self-antigens that are normally sequestered from the immune system, such as many intracellular antigens (Zhang et al., 2010). Once these become targets of an immune response, ongoing inflammation may be sustained. For example, the ongoing inflammation in some diseases, such as autoimmune myositis, targets regenerating tissue, preventing tissue repair and resolution of inflammation (Mammen et al., 2011; Suber et al., 2008).

Clearly, infection can also precipitate autoimmune disease. It has even been suggested that most autoimmune diseases represent the late sequelae of an infectious process (Christen et al., 2012; James and Robertson, 2012) (Chapter 19). Proving this hypothesis has, however, been difficult. For some diseases, such as rheumatic fever, the causal connection between microbial infection, the antimicrobial response, and autoimmune disease is clearly established (Cunningham, 2003; Guilherme and Kalil, 2004). For other diseases, there is suggestive epidemiologic evidence in humans or evidence from animal models that autoimmunity can follow microbial infection, or T cell or antibody cross-reactivity with both microbial and self-antigen has been identified (James and Robertson, 2012; Kuon and Sieper, 2003; Strassburg et al., 2003). In general, researchers have sought to implicate particular infections in the pathogenesis of particular autoimmune diseases, but it is possible that for some autoimmune diseases there is more than one possible microbial trigger. Importantly, the interaction of the TCR with a peptide–MHC complex must be of higher affinity to activate a naïve T cell than a memory T cell. Thus, a microbial peptide may initiate a response that can then be sustained by self-peptide. Moreover, once a response to self-antigen is initiated, epitope spreading to other epitopes on the same protein or on associated proteins occurs, often through B cell-mediated antigen presentation (Shlomchik et al., 2001).

Recent studies have provided remarkable information on the progression of autoimmunity, demonstrating that the autoantibodies characteristic of a given autoimmune disease are present as long as 10 years before the onset of clinical disease (Arbuckle et al., 2003). Moreover, cytokine abnormalities can also be observed before the onset of clinical symptomatology (Deane et al., 2010). These observations suggest there may be an opportunity to abort or retard the progression to disease in predisposed individuals.

Finally, the adipocyte has joined the ranks of immunomodulatory cells. It can secrete a variety of cytokines that promote a proinflammatory, proimmunogenic milieu (de Heredia et al., 2012). Thus, increasing obesity may be one contributor to the increasing incidence of autoimmune disease.

ACTIVATION OF THE IMMUNE SYSTEM

Activation of both T and B cells in the periphery requires that the cells receive two signals, one derived by ligation of the antigen receptor and the other by engagement of a costimulatory receptor. In general, when antigen enters the system, there is an activation of DCs, the critical APC in a primary immune response. This occurs because microbes express molecules that bind to pattern-recognition receptors or TLRs on the DC. The consequence of this binding is upregulation of the costimulatory molecules CD80 (B7.1) and CD86 (B7.2) on DCs, and transformation of the DC from resting, or tolerogenic to activated, or immunogenic. T cells recognizing microbial peptide in either class I or class II MHC molecules on the immunogenic DC will be activated. Because some degree of autoreactivity is present in all T cells, each time a T cell is activated by a foreign-peptide–self-MHC complex, that activated T cell may also recognize a self-peptide–self-MHC complex. It is a feature of memory T cells that they can be activated by a lower-affinity interaction with the TCR than is required to activate primary T cells; this is due to epigenetic changes and alterations in the structure of lipid rafts in the membrane that facilitate rapid receptor cross-linking with much less requirement for costimulatory signals (Weng et al., 2012). Thus, a T cell that is not activated by a self-peptide–self-MHC complex while still a naïve cell may be activated self-antigen once it becomes a memory T cell. Memory T cells may therefore be autoreactive in a proinflammatory setting. In addition, the signaling cascades within activated lymphocytes may differ in autoimmune vs. healthy individuals. For example, peripheral T cells from SLE patients have altered signaling and a faster T cell calcium flux than those of healthy individuals due to replacement of the principal signaling molecule of the TCR complex, CD3 ζ , by the FcR γ chain (Moulton and Tsokos, 2011). This results in use of the adaptor molecule Syk rather than the usual ZAP70 and activation of the downstream kinase calcium/calmodulin-dependent protein kinase type IV (CaMK4) that, via the transcription factor Crem α , enhances production of IL-17 and blocks production of IL-2. B cells activated in an inflammatory setting may also recruit aberrant signaling pathways that amplify the inflammatory phenotype of the cell (Doreau et al., 2009).

There are many examples in the literature of a T cell derived from an individual with autoimmune disease that

recognizes both a microbial peptide and a self-peptide. This cross-reactivity is termed molecular mimicry, and represents a mechanism by which autoimmunity can be triggered by infection (Cusick et al., 2012). The hypothesis that molecular mimicry predisposes to autoimmunity clearly has validity in rodent models of autoimmune disease, and suggests that laxity in selection of the naïve T cell repertoire can be a major contributor to autoimmunity. Those individuals with less stringent negative selection will have multiple T cells that can be activated by foreign antigen and will also display pathogenic autoreactivity.

The activated T cell provides T cell help or costimulatory signals to B cells that are encountering microbial antigen. B cells that bind both microbial antigen and self-antigen will ingest, process, and present epitopes of self-antigen, which can then be recognized by T cells. Because B cells often process antigen to different peptides than do DCs, the B cells can present novel epitopes of self-antigen and activate T cells with novel autospecificities (Bockenstedt et al., 1995; Sercarz et al., 1993; Yan et al., 2006). These cross-reactive B cells will, therefore, contribute to a cascade of autoreactivity, as they activate an expanded repertoire of T cells. Memory B cells are also potent antigen presenting cells that can activate naïve T cells. The B cell repertoire, therefore, critically influences the T cell repertoire (Whitmire et al., 2009). The fewer autoreactive B cells present, the less presentation of self-antigen to T cells.

There is much complexity in the cytokine expression patterns of activated T cells with at least four subsets of well-described helper T cells (Th1, Th2, Th17, and T_{FH}) as well as regulatory cells that help to restrain immune responses. The balance of transcriptional regulators expressed in each T cell will help determine its precise function, whereas epigenetic changes will help to reinforce a particular phenotype through subsequent rounds of proliferation. Nevertheless, there is emerging evidence that helper T cells have a substantial amount of flexibility with respect to their phenotype. Signals from the innate immune system can be drivers of T cell reprogramming, suggesting that inflammation or infection may have a profound effect on T cell function, converting T cells with a protective phenotype to those that amplify inflammation (Nakayamada et al., 2012).

Much is now known about the signaling pathways that are downstream of receptor and costimulatory molecule mediated stimulation and that are required for B and T cell activation and cytokine production. Since activated lymphocytes are major mediators of the effector inflammatory response, some of these pathways are targets for immune interventions with small molecules. Both inhibitors of Syk and of Jak3 have been used clinically in autoimmune diseases and other kinase inhibitors are in development (Kontzias et al., 2012). In addition, because

the high rate of cell growth and proliferation occurring in expanding clones requires a large amount of energy, there is increasing recognition that immune responses are linked to metabolism and that different types of effector and regulatory T cells have different metabolic requirements (Gerriets and Rathmell, 2012).

ROLE OF ANTIGEN AS A DRIVER OF AUTOIMMUNITY

A major question in autoimmune disease is whether the process is autonomous or driven by antigen, and, if the latter, whether the antigen is self-antigen or foreign antigen. Animal models of disease definitively show that molecular mimicry following activation by microbial antigen can initiate autoreactivity (Cunningham, 2003; Cusick et al., 2012; Kuwabara, 2004).

There are also data suggesting that self-antigen drives the autoimmune response. First, in animal models of systemic lupus, it appears that an excess of apoptotic cells or a problem in their clearance can result in a lupus-like serology with antichromatin reactivity (Peng and Elkon, 2011; Peng et al., 2007). Current understanding would suggest that an excess of apoptotic debris can activate TLRs and transform tolerogenic DCs into immunogenic APCs, as well as activate B cells (Filardy et al., 2010).

Second, extensive tissue damage can lead to the presentation of normally sequestered self-antigen in a proinflammatory setting (Bratton and Henson, 2011; Horwitz et al., 2002; Vezy and Lefrancois, 2002) or post-translational alteration of self-antigen such that it is now immunogenic (Doyle and Mamula, 2012). The proinflammatory setting may be enhanced by apoptosis of cells following tissue insult. This can clearly lead to an autoimmune response. Whether in some individuals this response is perpetuated because of a lack of appropriate restoration to homeostasis is an important question.

Finally, polymorphisms in autoantigens may also constitute risk factors for autoimmune disease (Pauza et al., 2004; Suzuki et al., 2003). As the genetic susceptibility to autoimmune disease is further explored, the degree to which molecular mimicry, aberrant expression of autoantigens, or exposure to previously sequestered antigen in an immunogenic setting contributes to disease will become more apparent.

A variety of environmental exposures might also non-specifically accelerate disease by activating the innate immune system resulting in the release of proinflammatory cytokines that initiate autoimmunity. In mice, for example, type I interferons can initiate SLE in susceptible strains (Koutouzov et al., 2006) and may be responsible for the Koebner phenomenon observed in psoriasis. Tissue damage also results in the release of soluble

mediators such as HMGB1, defensins and heat shock proteins that can activate DAMPs and TLRs and further amplify immune activation pathways.

DEFECTIVE DOWNREGULATION OF AN IMMUNE RESPONSE

The induction of an immune response needs to be followed by a downregulation or elimination of most of the cells that have undergone clonal expansion. A major observation of recent studies of autoimmune disease is that a defect in the restoration of immune homeostasis, or in downregulation of an immune response, can be a risk factor for autoimmunity. Since all reactivity with foreign antigen includes reactivity to self-antigen, anti-self-responses are routinely generated in the process of mounting an immune response to foreign antigen. The potential pathogenicity of the autoimmune response will vary from individual to individual. In general, however, the mechanisms that exist to dampen the immune response also diminish the autoreactivity, and even potentially pathogenic autoreactivity is downregulated. B and T cells are routinely downregulated as soon as they are activated. For the B cell, this occurs, in part, by cross-linking of the BCR and FcRIIB by antigen–antibody complexes. When FcRIIB is absent or deficient on B cells, as occurs in many individuals with SLE, autoantibody production is poorly controlled (Bolland and Ravetch, 2000; Fukuyama et al., 2005). Multiple coinhibitory molecules are expressed on activated T cells. Interaction with their receptors either within lymphoid organs or in the peripheral site of inflammation transduces an inhibitory signal to the T cells, signaling them to downmodulate their response (Francisco et al., 2010; Scanduzzi et al., 2011). There is also some evidence that engagement of CD80 (B7) on the APC by the T cell coinhibitory molecule CTLA-4 transduces an inhibitory signal to the APCs. Mutations in two coinhibitory molecules, PD1 and CTLA-4, are associated with several autoimmune diseases (Chen, 2004; Khoury and Sayegh, 2004). Both B and T cells are also susceptible to activation-induced cell death mediated through Fas–Fas ligand interactions (Brunner et al., 2003; Li-Weber and Krammer, 2003). Defects in this process can lead to autoimmunity.

Thus, controlling the immune response is critical to normal homeostasis of the immune system and is mediated by multiple inhibitory pathways. A major component of autoimmune disease in some individuals may be a defect in the suppression of immune activation.

REGULATORY LYMPHOCYTES

Another area of intensive study is the characterization and mechanisms of action of CD4⁺ positive T regulatory

cells, some of which arise during thymic development and others after antigen exposure in the periphery (Wing and Sakaguchi, 2010). These cells regulate immune responses in a variety of ways that include secretion of inhibitory cytokines, promotion of apoptosis of effector lymphocytes, depriving effector T cells of cytokines or essential amino acids leading to apoptosis, or inhibition of dendritic cell function. Absence of Tregs in mice results in lymphoproliferation and fatal multi-organ autoimmunity, demonstrating the need for the ongoing regulation of pathogenic self-reactive cells that escape into the periphery. A population of CD4⁺/CD25^{hi} (γ chain of the IL-2 receptor) naturally occurring T regulatory cells (nTregs) arises in the thymus in response to TCR encounter with self-antigens with an avidity lower than that required for negative selection; their development depends on both CD28 and IL-2. Tregs can also be generated after antigen exposure in the periphery from naïve T cells in a manner that is dependent on IL-2 and TGF β and may be enhanced by the vitamin A metabolite retinoic acid. Both these types of Tregs express the master transcriptional regulator Foxp3; its expression is stabilized by epigenetic modifications of DNA that reinforce the transcriptional availability of suppressive cytokines while preventing access of transcription factors to DNA encoding inflammatory cytokines (Hsieh et al., 2012; Josefowicz et al., 2012a).

Cells expressing immunosuppressive cytokines such as transforming growth factor (TGF)- β or IL-10 (Tr1 cells) (Pot et al., 2011) arise under particular conditions of antigen exposure and once activated, mediate suppression through both cytokine secretion and contact mediated lysis of effector cells. Tr1 cells are present in large numbers in the gut where they help to protect from colitis and they can also protect against multiple sclerosis in mice. Tr1 cells are Foxp3 negative and can be induced by IL-27 (Wojno and Hunter, 2012) but have been difficult to study due to lack of a clear phenotype. Nevertheless, the transcriptional program of these cells is being unraveled and recent studies have suggested that both IFN β and galectin 1 induce DCs to produce IL-27, suggesting a way in which Tr1 cells can be induced therapeutically.

Other studies have identified a population of CD8 suppressor cells that may directly lyse autoreactive cells or may secrete immunosuppressive cytokines (Cortesini et al., 2001; Jiang et al., 2010). In lupus models these cells can be induced by autoantigen or by idiotype peptides (Sawla et al., 2012). CD8⁺ regulatory T cells have recently been described during adaptive immune responses where they serve to regulate humoral responses in the germinal center by lysing B cells (Kim and Cantor, 2011). Another group of Tregs expresses neither CD4 nor CD8 and its function is dependent on IFN γ .

The balance between effector cells and regulatory cells may determine whether an autoreactive response

that arises in the course of microbial exposure is terminated or perpetuated. However, application of this new knowledge to the treatment of autoimmunity is still in its earliest stages. One approach has been to use inhibitors of the mammalian target of rapamycin (mTOR) to induce or stabilize Foxp3 expression (Chinen and Rudensky, 2012; Josefowicz et al., 2012b). Another is to use low-dose IL-2 or IL-2 anti-IL-2 complexes to enhance Treg development. This strategy has recently been successfully applied to the treatment of graft versus host disease (GVHD) and cryoglobulinemic vasculitis in humans in which an increase in Tregs was associated with a therapeutic response (Oo et al., 2012). *In vitro* expansion and delivery of a stable population of Tregs or *in vivo* activation of antigen-specific Tregs by tolerogenic self-peptides have been problematic since the precise TCR affinity or antigen dose required for Treg generation are not known and many factors in the microenvironment may influence the survival or stability of transferred Tregs or the outcome of TCR peptide encountered *in vivo*. Clinical trials directed at tolerance induction in new onset type 1 diabetes by manipulation of Tregs have failed to cure disease despite an increase in Treg numbers, although several approaches have had partial effects (Gallagher et al., 2011).

B cells may also have regulatory functions (Klinker and Lundy, 2012). One such B cell subset produces IL-10 and can regulate autoimmunity in mice. The phenotype of these cells has not been fully elucidated but they may derive from immature or innate B cell populations (B1). The human counterpart of these cells and an understanding of how and where these cells regulate autoimmunity remains to be clarified. Another way in which B cells can regulate immune responses is by post-transcriptional modification of antibodies. Alterations in galactosylation and sialylation of the Fc region of Ig molecules may have a profound effect on immune responses. Sialylated immunoglobulin suppresses immune responses by binding to DC-SIGN on macrophages and DCs and initiating a suppressive program that results in upregulation of the suppressive Fc receptor FcRII on macrophages (Anthony et al., 2011). Specific IgM antibodies that have low affinity autoreactivity can also suppress immune responses by promoting opsonization of apoptotic material and promoting non-inflammatory clearance (Chen et al., 2009).

Since intense immunosuppression may inactivate both effector and regulatory T cells and B cell depletion may deplete both effector and regulatory B cells, improved strategies to inhibit effector cells, while allowing regulatory cells to expand, are being actively pursued. The success of this strategy will depend on a better understanding of the origins and growth requirements of the various regulatory cell types and the development of mechanisms to target them specifically and reinforce their stability *in vivo*.

THE ROLE OF THE GUT MICROBIOTA IN AUTOIMMUNITY

An emerging theme in autoimmunity is the heretofore unrecognized role of the gut microbiota in regulating immune responses (Atarashi and Honda, 2011) (Chapter 25). A vast colony of bacteria of multiple species is found in the human gut and can be changed by diet and other environmental exposures. One of the most important observations in this field is that the induction of TH17 cells in mice requires segmented filamentous bacteria; absence of these bacteria prevents the induction of experimental forms of arthritis and multiple sclerosis in normal mice and the spontaneous onset of type 1 diabetes in a susceptible mouse strain (Romano-Keeler et al., 2012). The bacteria provide TLR ligands and induce other inflammatory genes that trigger DCs and are also a source of ATP that helps to activate TH17 cells. The precise function of these cells, either as pathogenic cells, or as regulatory cells that also produce IL-10, will depend on other factors in the gut environment. Pathogenic bacteria may be found in some types of autoimmunity. For example, transfer of commensal bacteria from diseased to normal mice can transmit inflammatory bowel disease, suggesting that the initiating trigger for this disease may be communicable (Garrett et al., 2007). Importantly, susceptibility to colitis may be altered by dietary changes that prevent the emergence of the pathogenic bacteria suggesting that fecal transplants or probiotics are therapeutic strategies that should be tested. Gut microbiota also appear to be required for the generation of gut Tr1 cells and this may be mediated by different bacterial species than those that induce TH17 cells. Conversely, the absence of regulatory T cells can affect the composition of the gut microbiota (Chinen and Rudensky, 2012; Josefowicz et al., 2012b). How the balance of pro- and anti-inflammatory gut microbiota is maintained and how this might be manipulated for the prevention or treatment of autoimmunity remains an important question.

MECHANISMS OF TISSUE DAMAGE

Studies over the past decade have clearly demonstrated that the mechanisms that incite autoimmune disease may differ substantially from the mechanisms that propagate tissue damage. Autoreactive T and B cells that are activated in secondary lymphoid organs and initiate disease may be activated in a different microenvironment and may have a different cytokine profile from the effector cells that migrate into target organs and cause tissue fibrosis (Campbell et al., 2001; Gerriets and Rathmell, 2012; Katzman et al., 2011). Thus, it is clear that at each stage of autoimmune disease, induction of autoreactivity and tissue destruction need to be separately explored, and that the previous characterization of certain cytokines as

proinflammatory and others as anti-inflammatory may be misleading. While TGF- β may dampen the induction of autoreactivity, it may hasten tissue fibrosis (Valluru et al., 2011). Similarly, IL-10 is anti-inflammatory during disease initiation through its inhibitory effects on APCs, but may lose its anti-inflammatory properties (Herrero et al., 2003) and even drive T cell proliferation, immunoglobulin class switching, and antibody production later in disease (Mocellin et al., 2004). Even the proinflammatory cytokine interferon- γ can have anti-inflammatory properties in the early stages of some autoimmune diseases (Billiau, 1996; Grohmann and Puccetti, 2002; Rosloniec et al., 2002) perhaps by antagonizing the differentiation of T cells secreting IL-17. It is important, as we move forward in studies of autoimmune disease, to consider the mechanism of both immune activation and tissue destruction, and to be aware that cytokines, hormones, or other mediators may exhibit differential effects in each process. Studies of animal models have now clearly shown that it is possible to intervene in disease progression to protect organs from immune-mediated destruction, even while autoreactivity continues unabated (Clynes et al., 1998; Schiffer et al., 2003).

Recent studies emphasize the role of innate immune cells in tissue injury, particularly neutrophils and macrophages that are recruited to sites of ischemic injury. Macrophages have a complex program in which they first release proinflammatory mediators to fight pathogens but may then initiate programs to help in the clearance of dead tissue and tissue repair. While the latter response is beneficial if short-lived, continued activation of the repair program may be detrimental if it becomes chronic (Bethunaickan et al., 2011).

FLARES AND REMISSIONS DURING DISEASE

The vast majority of animal models of autoimmune disease develop chronic progressive disease activity. Once the autoimmune disease becomes manifest, it progresses to organ failure or death. Much human autoimmune disease, in contrast, is characterized by periods of disease remission and flare. Little is known in human disease about the cellular events that lead to disease remission. It is also true that little is known regarding the cause of disease flares. In mouse models of multiple sclerosis, disease flares can result from epitope spreading with sequential recruitment of T cell populations that recognize different epitopes of myelin (Mallone et al., 2011; Vanderlugt et al., 1998). Similarly in humans, epitope spreading has been observed among cohorts of lupus patients from whom pre-diseased serum was available (Arbuckle et al., 2003; Deshmukh et al., 2003). Nevertheless, a major area of ignorance

concerns the cell type responsible for disease flares. It is not known for most autoimmune diseases whether flares represent a *de novo* activation of naïve autoreactive cells or a reactivation of quiescent memory cells and whether these flares are due to a new environmental exposure or to failure of regulation, or both. Our ignorance in this regard derives largely from the difficulty of sampling a large enough repertoire of autoreactive T or B cells. Often, these cells are poorly represented in peripheral blood (Bischof et al., 2004; Newman et al., 2003; Reddy et al., 2003). The development of MHC class I and class II tetramers containing peptides of known autoantigens is beginning to facilitate analysis of pathogenic T cells in human autoimmune diseases and animal models in which the autoantigens are known (Mallone et al., 2011; Massilamany et al., 2011). Similarly, the development of single cell PCR technology is allowing the analysis of the frequency and binding specificity of autoreactive B cells from peripheral blood (Meffre and Wardemann, 2008). These studies have shed light on how autoreactivity is regulated in human B cells during B cell development and have demonstrated abnormalities in regulation of the B cell repertoire in individuals with a variety of immune deficiencies and autoimmunity related genetic polymorphisms (Isnardi et al., 2010; Meffre and Wardemann, 2008; Menard et al., 2011).

THERAPEUTIC ADVANCES

A major advance in the last decade has been the application of new knowledge about immune system function to the treatment of autoimmune diseases (Chapter 81). New therapies target innate immunity, adaptive immunity and even tissue injury. As these new drugs have entered clinical practice it has become clear that the pleomorphic and stage-specific functions of particular molecules can result in both beneficial and adverse therapeutic effects of the drugs that target them. TNF inhibitors, for example, while highly therapeutic in RA and IBD, can induce SLE, multiple sclerosis, and vasculitis (Kollias, 2005). Another important lesson has been that some therapies are highly effective for some diseases but not others. These responses have, however, been difficult to predict based on our current understanding of disease pathogenesis. For example, global B cell depletion using an antibody to CD20 is therapeutic in RA and multiple sclerosis (Barun and Bar-Or, 2012; Buch et al., 2011), diseases that were initially thought to be T cell dependent, but has much less, if any, effect in SLE, a prototypic B cell disease (Merrill et al., 2010). Variability among patients results in response rates that rarely reach more than 70% even for the best of the new therapies. Finding ways to identify responders and non-responders before initiating an expensive and potentially toxic new therapy is a task that is

being actively pursued using large patient databases and genetic and “omics” studies.

New drugs to treat autoimmune disease are constantly in development. Many of the current approaches are based on a perceived need to institute immunosuppression and anti-inflammatory therapy at the time of autoimmune tissue destruction. Multiple pathways of immune activation, including innate TLR and pattern-recognition receptor signaling pathways, costimulatory pathways and T and B cell activation and cytokine signaling pathways are being targeted to reduce activation of the immune system (Rosenblum et al., 2012). Our most updated understanding of autoimmunity would suggest that it might also be appropriate to consider treating disease during times of disease quiescence. The goal of this therapeutic approach would be to alter T and B cell repertoire selection or to drive the expansion of regulatory cells and enhance regulation (Daniel and von Boehmer, 2011). Currently, antigen-specific therapies remain a dream even for those diseases in which causative antigens have been identified (Michels and Eisenbarth, 2011).

Protecting target organs and preventing irreversible tissue damage will require different therapeutic strategies from blocking systemic autoreactivity (Katschke et al., 2007; Sica et al., 2011; Szekanecz et al., 2009). These new therapeutic approaches offer the hope of maintaining immunocompetence while eliminating the consequences of pathogenic autoreactivity.

Finally, the observation that autoimmunity and immunodeficiency can be linked suggests that effective treatment of autoimmunity will lead to enhanced immunocompetence, and the reversal of developmental defects in lymphoid cells should reduce autoreactivity. This is the metric against which therapeutic interventions should be judged.

GOALS FOR THE FUTURE

Over the past several years, new technologies have been developed that will substantially increase our understanding of autoimmune disease. High-throughput technologies to examine genetic polymorphisms, epigenetic changes, gene expression and protein expression and modifications, linked with the collection of well-characterized databases of patients make it possible to determine the level of expression of a very large number of genes or proteins in defined populations of patients and subpopulations of cells. These data may provide new insights into disease pathogenesis and new ways to phenotype patients with autoimmune disease. These technologies may also provide sets of biomarkers that will help determine risk for developing a particular disease, characterize current activity of the disease and disease prognosis, and assess response to therapy at an earlier time point than current

clinical endpoints. It is reasonable to predict that patterns of gene and protein expression will reveal differences and similarities among autoimmune diseases.

The development of biomarkers will, undoubtedly, improve the therapy of autoimmune disease. It may be possible to identify early those patients whose disease is likely to be severe and to monitor disease activity without waiting for clinical symptomatology. Furthermore, the recognition that autoimmunity can be detected before clinical symptomatology and that the likelihood of development of disease in individual patients can be predicted with more certainty will allow testing of therapies that have the potential to prevent or cure autoimmune disease before tissue damage occurs. Ultimately, it may be possible to customize therapy for each patient, thereby enhancing efficacy and avoiding unnecessary toxicities and expense.

CONCLUDING REMARKS

The past several years have witnessed a change in our understanding of autoimmunity and a clear new direction in our approach to the study of autoimmunity. Multiple genetic polymorphisms contribute to autoimmunity risk and more remain to be identified. The complexity of regulation of gene expression suggests several other mechanisms by which gene expression may be aberrantly regulated in autoimmunity. It is clear that activation of the innate immune system can act as a trigger for the initiation of autoimmunity in susceptible individuals and can amplify tissue damage in target organs. Autoimmunity can result from either a failure in T and B cell repertoire selection or a failure in the regulation of activated T and B cells. Autoimmune B and T cells can be identified years before the emergence of clinical disease, suggesting that multiple triggers act sequentially to precipitate disease. It is also clear that autoimmunity needs to be coupled to target-organ vulnerability to immune attack for autoimmune disease to be present and that inflammatory cascades can be interrupted or regulated in the periphery. This understanding suggests new therapeutic targets and new therapeutic strategies.

The focus on new technologies to provide biomarkers of immune function represents an exciting opportunity to treat disease prior to tissue damage and to customize therapy for each patient. Furthermore, studies of gene and protein expression will help elucidate those mechanisms of immune dysfunction that are shared among multiple autoimmune diseases and those that are unique to a particular disease. Thus, there are reasons to be optimistic, but acquiring the necessary new knowledge and translating that knowledge to therapy will take time and will require more clinical trials.

The Concept of Autoinflammatory Diseases

Monique Stoffels and Anna Simon

Department of Medicine, Radboud University Nijmegen Medical Centre; Nijmegen Centre for Infection, Inflammation and Immunity Centre for Immunodeficiency and Autoinflammation; Nijmegen Centre for Molecular Life Sciences, Nijmegen, The Netherlands

Chapter Outline

| | | | |
|---|-----------|---|-----------|
| Historical Perspective | 39 | Polygenic or Acquired Autoinflammatory Disorders | 46 |
| Definition | 40 | Autoinflammatory Mechanisms of Disease in Common Disorders | 46 |
| Spectrum from Autoimmune to Autoinflammatory Disease | 40 | Type 2 Diabetes Mellitus | 46 |
| Mechanisms in Autoinflammation | 40 | Atherosclerosis | 46 |
| Classical Hereditary Autoinflammatory Disorders | 41 | Newest Developments: Rare Hereditary Disorders with Autoinflammatory Aspects | 46 |
| Common Phenotype | 41 | Proteasome Defects | 47 |
| Cryopyrin-Associated Periodic Syndrome | 43 | PLC γ 2 Deficiency | 47 |
| Familial Mediterranean Fever | 44 | HOIL | 47 |
| TNF Receptor-Associated Periodic Syndrome | 44 | Conclusion | 48 |
| HIDS (also Known as Mevalonate Kinase Deficiency) | 45 | References | 48 |

Autoinflammation is increasingly recognized as a distinct mechanism of disease, not only in rare monogenic syndromes, but also in more heterogeneous inflammatory disease as well as in common disorders such as atherosclerosis. This chapter will give an overview of autoinflammation with a focus on pathophysiology.

HISTORICAL PERSPECTIVE

The term “autoinflammatory syndrome” was first coined in 1999, in connection with the discovery of the genetic background of an autosomal dominantly inherited disorder that subsequently became known as tumor necrosis factor (TNF) receptor-associated periodic syndrome (TRAPS) (McDermott et al., 1999). Starting off in the niche group of so-called “hereditary periodic fever syndromes,” concerning relatively few patients and physicians, it has in the past decade gained more interest and a bigger audience. This is partly due to the advent of biologicals inhibiting specific cytokines, particularly

interleukin-1 β (IL-1 β). Before, these diseases were curiosities with no treatment options and as such there was no great incentive for a correct diagnosis. When very effective treatment became available, diagnosis became of new importance (and pharmaceutical companies suddenly began to show interest as well).

At the same time, this increasing interest has paralleled the increasing interest and insight into innate immunity in general (Medzhitov and Janeway, 2000), which revealed a much more important role for the innate immune system than had previously been thought. With the discovery of multiple receptors for recognition of pathogens and endogenous danger signals, as well as newly recognized innate immune cell types and intricate effector mechanisms, their role in human disease (either when too active or too inactive) could quickly be recognized.

By now, “autoinflammatory disease” has become established as a recognized category of disease, and is used in daily clinical practice—and even abused, as most

medical terms will be, just as “autoimmune disease” became the mantra for many immunological disorders. However, some degree of inflammation can be detected in almost any disease. So what defines a disease as “autoinflammatory”?

DEFINITION

The original 1999 definition for an autoinflammatory disease from the group of Daniel Kastner was: “seemingly unprovoked inflammation without high-titer autoantibodies or antigen-specific T-lymphocytes” (McDermott et al., 1999). This is useful to distinguish the group of diseases from autoimmune disorders, but consists mainly of negative definition: prescribing what is not part of it (no provocation, no autoantibodies), and not what is. Also, with our greater understanding of autoinflammatory disorders, we are able to recognize factors that can provoke the inflammatory episodes of these diseases, such as vaccination in hyper-IgD syndrome (HIDS) or cold in cryopyrin-associated periodic syndrome (CAPS), thus “seemingly unprovoked” became misleading.

Therefore, 11 years later, Kastner et al. proposed a new formulation: “abnormally increased inflammation, mediated predominantly by the cells and molecules of the innate immune system, with a significant host predisposition” (Kastner et al., 2010). This definition is broad enough to encompass both the original Mendelian-inherited fever syndromes, as well as the more complex polygenic or acquired disorders (Kastner et al., 2010). It again distinguishes these disorders from autoimmune disorders because of the focus on the innate immune system versus the adaptive immune system. Also, the latter part of this definition implies that there should be some intrinsic defect in the innate immune system underlying the disease. This is important because increased inflammation can of course be seen in many diseases. A pneumococcal pneumonia (in a previously healthy person) will be accompanied by a lot of inflammation but will not fall under this definition, since the inflammation is an adequate response to the infection. A systemic inflammatory reaction upon exposure to cold is not an adequate response, and occurs in CAPS because of an intrinsic defect in the innate immune system—and therefore does fall under this definition.

Despite the difficulty of definition, recognizing autoinflammatory disease as a category in clinical medicine has its clear usefulness. First, it can be used when working on the differential diagnosis in a complex patient. Many of these disorders are rare, and patients go undiagnosed for years, due to lack of awareness about these disorders. Recognizing the possibility of a category of disease increases the chances of reaching a definite diagnosis. Second, it increases the chances of finding an

effective treatment, even in cases where the specific diagnosis remains elusive. Recognition of an autoimmune clinical phenotype will warrant treatment with prednisone or other immune suppressive therapy directed against T cell immunity. In the same way, recognition of an autoinflammatory phenotype will make treatment with an inhibitor of cytokines or innate immune cells more rational. Third, the recognition of autoinflammatory disorders, or autoinflammatory aspects of disorders, supports the existence of common features in the underlying pathogenesis. This facilitates research into the pathogenic background of these diseases, which will in future support diagnosis and treatment.

Several classifications within the group of autoinflammatory disorders have been proposed in recent years (Masters et al., 2009; Kastner et al., 2010), based on pathogenic mechanism or clinical phenotype or a combination of these.

SPECTRUM FROM AUTOIMMUNE TO AUTOINFLAMMATORY DISEASE

The innate and the adaptive immune system can of course not be seen as two completely separate entities. There are many areas in which the distinction is hard to make, for example in several types of regulatory T cells. In the same way, the disease categories “autoimmune” and “autoinflammatory” should in many cases not be seen as completely separate. McGonagle and McDermott (McGonagle and McDermott, 2006) suggested the idea of a spectrum of disease, ranging from autoimmune to autoinflammatory, in which many of the disorders have some aspects of both (Figure 4.1). The relative importance of the innate versus the adaptive immune system in the pathogenesis of a disorder determines its place on the spectrum. To fully comprehend this categorization, it is important to understand the mechanisms that play a role in innate immunity. In the ensuing paragraphs, we will first give a general overview of pathophysiological mechanisms in autoinflammation, followed by a number of examples from this spectrum.

MECHANISMS IN AUTOINFLAMMATION

As per the definition, the pathogenic defect in autoinflammation is located in the innate immune system. A key step in the innate immune response is the processing of the proinflammatory cytokines IL-1 β and IL-18. In many diseases in this category, the defect is primarily located in the regulation of IL-1 β .

IL-1 β is an extremely potent inflammatory cytokine. Therefore, its production, secretion and signaling need to be tightly regulated at multiple levels (Figure 4.2). IL-1 β signaling is controlled by means of expression of multiple

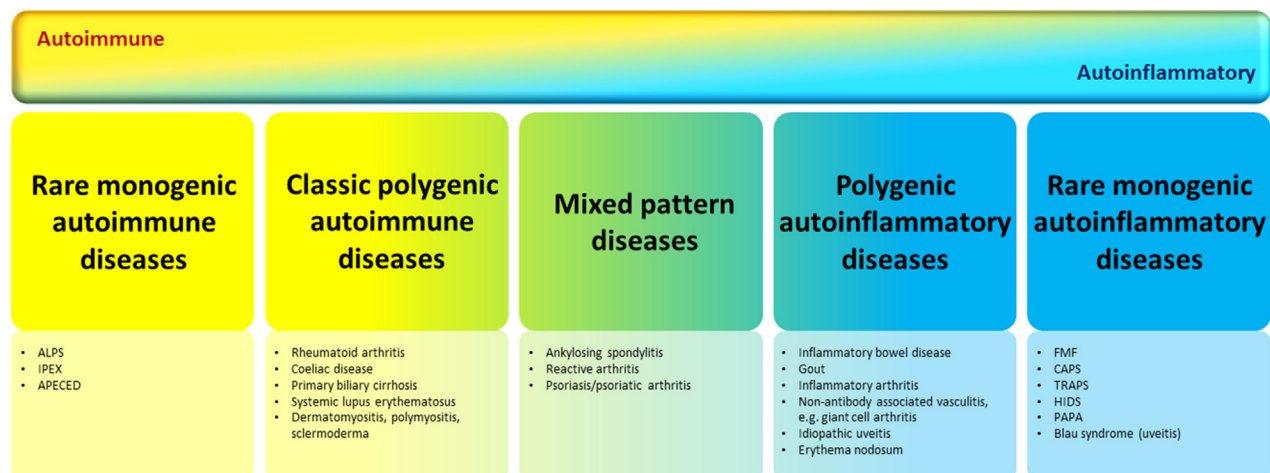

FIGURE 4.1 Spectrum from autoimmune to autoinflammatory disease. In between the two extremes of monogenic autoimmune and autoinflammatory disorders is a continuum of disease phenotypes comprising, to a different degree, characteristics from both autoimmune and autoinflammatory disease. This list serves as an example and is not complete. *Figure adapted from McGonagle and McDermott (2006).*

IL-1 receptors and the existence of an IL-1 receptor antagonist (IL-1Ra). For IL-1 β production and secretion two distinct signals are required. The first is triggered by Toll-like receptor (TLR) activation. This leads to the production of pro-IL-1 β . In the presence of the second signal, mediated by ionic perturbations, pro-IL-1 β can be cleaved into active IL-1 β by the so-called inflammasome. This is a concept first coined by Jurg Tschopp (Martinon et al., 2002), which holds that a scaffold of multiple proteins is formed to activate pro-caspase-1 into caspase-1, which in turn can cleave and activate pro-IL-1 β . The existence of this inflammasome as an actual multi-protein complex has only definitely been demonstrated in overexpression models; but it has been shown that the components of this complex are at least all required for intracellular IL-1 β activation *in vivo*. Several types of inflammasome have been described so far; the main function of each of these appears to be activation of IL-1 β . The most studied inflammasome is the so-called NLRP3 inflammasome (for clarity reasons, only this is depicted in Figure 4.2, for more details on other inflammasomes we refer to Box 4.1). Several proteins and mechanisms can either directly or indirectly modify inflammasome activation. Some of these will be detailed in the following paragraphs about the associated diseases. There are also inflammasome-independent ways of activating IL-1 β , but these fall outside the scope of this chapter.

IL-1 β is mainly a paracrine and autocrine acting cytokine. Serum concentrations of IL-1 β are always very low, and are therefore not a good indicator of its importance in the pathogenesis of a disease. For example, the IL-1 β serum concentration is not always clearly increased in CAPS, despite its hereditary defect in the inflammasome. The role of IL-1 β can be better examined by *ex-vivo*

stimulation of relevant cell types (especially peripheral blood mononuclear cells (PBMCs)), or by the therapeutic effect of inhibitors of IL-1.

Some authors almost equate autoinflammation with IL-1-related disease, maintaining that this inflammatory cytokine is always at the heart of the pathogenesis. However, defects in other parts of the innate immune system have been described, such as NF- κ B and NOD2. And although inhibition of IL-1 is a good therapeutic option in many autoinflammatory diseases, it is not true for all of them.

CLASSICAL HEREDITARY AUTOINFLAMMATORY DISORDERS

Common Phenotype

At the far extreme of the spectrum are the monogenic hereditary autoinflammatory disorders, previously known as hereditary periodic fever syndromes. The genetic defect in each of these disorders is directly located in a protein of the innate immune system. Familial Mediterranean Fever (FMF) is the hallmark example of a classic hereditary autoinflammatory syndrome, but several others exist (Table 4.1) (Lachmann, 2011; Park et al., 2012). The common phenotype of these disorders is a lifelong recurrence of systemic inflammation, which can manifest itself as fever and/or various skin lesions, serositis, abdominal pain, myalgia, arthralgia or arthritis, lymphadenopathy, aphthous ulcers, and more. In some of these disorders, the inflammatory episodes are clearly demarcated by symptom-free intervals, in others the inflammation is fluctuating in severity but almost continuously present. In all of these, the systemic inflammation

FIGURE 4.2 Schematic overview of mechanisms that play a role in autoinflammation. For detailed description of these mechanisms the reader is referred to the text and to the references in [Box 4.1](#). Briefly, upon TLR signaling in combination with a second stimulus, the inflammasome (A) is formed, pro-IL-1 β is activated and IL-1 β will be secreted (B). Pyrin (C) can interact with and influence the activation of the inflammasome. In its turn, PSTPIP1 (D) binds to pyrin, thereby indirectly influencing activation of the inflammasome. IL-1 β secretion can, through autocrine or paracrine binding of IL-1 receptor, stimulate more cytokine secretion, including TNF and IL-1 β itself. (E) Upon TNF secretion, the extracellular domain of the TNFR is shed to prevent overstimulation of the cell. The IL-1R is inhibited when IL-1Ra (F) binds to it. PLC γ 2 activation (G) leads to increased [Ca²⁺]_i and as a consequence increased inflammasome activation. NEMO is a modulator of NF- κ B, and a complex called LUBAC targets it via ubiquitination to signalosomes of IL-1R1, TNFR, and TLRs (H). *Location of disease pathology in this schematic overview:* (A) in CAPS, mutations in NLRP3 cause an overactivation of the inflammasome, (B) in HIDS, MK activity is drastically decreased and leads to increased IL-1 β secretion, (C) in FMF, mutations in pyrin result in more IL-1 secretion, (D) in PAPA (pyogenic arthritis, pyoderma gangrenosum, and acne) mutations in PSTPIP1 change its binding properties to pyrin, thereby indirectly influencing inflammasome activation, (E) in TRAPS, mutations in TNFR1 result in distorted TNF signaling, and consequently disturbed IL-1 signaling, (F) in DIRA, the absence of (functional) IL-1Ra leads to overstimulation of the IL-1 signaling route, (G) in (A)PLAID, deletions in PLC γ 2 result in failure of autoinhibition and thus constitutive phospholipase activity, (H) in HOIL, mutations in one of the LUBAC components impair this process, and dependent on the cell type result in diminished NF- κ B activation or hyper-responsiveness to IL-1 β , (I) in PSMB8 related disorders, immunoproteasome activity is compromised, leading to accumulation of ubiquitinated and oxidized proteins.

is always accompanied by an acute phase response (e.g., raised C-reactive protein or erythrocyte sedimentation rate). They have a varying risk for the development of AA-type amyloidosis. All have an autosomal inheritance pattern and almost all are directly or indirectly caused by a relative surplus of IL-1 β .

Apart from this common phenotype, these disorders each have their own characteristics ([Table 4.1](#)).

A physician with experience in these disorders can generally make a preliminary diagnosis based on the clinical phenotype, although not in all cases. The four most common and well described of these syndromes will be briefly discussed in the following paragraphs, focusing on symptoms and signs distinguishing them from the common phenotype, and on pathophysiology.

TABLE 4.1 Major Monogenic Autoinflammatory Disorders: Molecular Pathology and Features

| Disease | Gene | Protein | Inheritance | Mechanism | Distinctive symptoms | Duration and frequency of attacks |
|---------------|-----------------|----------------------------------|-------------|--|--|--|
| FMF | <i>MEFV</i> | Pyrin | AR | Gene-dosage and ASC dependent, NLRP3-independent, inflammasome activation | Colchicine responsive, erysipelas-like erythema, serositis | 1–3 days, variable |
| TRAPS | <i>TNFRSF1A</i> | Tumor necrosis factor receptor 1 | AD | Abnormal aggregation and intracellular accumulation of TNFR1, ligand-independent signaling; mitochondrial ROS, MAPK activation | Prolonged symptoms, migrating skin rash and severe myalgia | >week, may be very prolonged |
| MKD | <i>MVK</i> | Mevalonate kinase | AR | Reduced geranylgeranylation of proteins leading to increased IL-1 β secretion | Diarrhoea, lymphadenopathy, aphthous ulcers | 3–7 days, 1–2 monthly |
| CAPS | <i>NLRP3</i> | NLRP3 | AD | Abnormal oligomerization, spontaneous activation of caspase-1 activity | Cold-induced fever, urticarial rash, sensorineural deafness, aseptic meningitis, deforming arthropathy, mental retardation | 24–48 h, depending on environmental factors (FCAS) continuous |
| PAPA | <i>PSTPIP1</i> | PSTPIP1 | AD | Distorted pyrin function due to PSTPIP1 binding | Pyogenic arthritis, pyoderma gangrenosum, cystic acne | Intermittent attacks with migratory arthritis, may be continuous |
| Blau syndrome | <i>NOD2</i> | NOD2 | AD | Affected nucleotide binding domain might cause increased NF- κ B activation | Granulomatous polyarthritis, iritis, dermatitis | +/- continuous |
| DIRA | <i>IL-1RN</i> | IL-1 receptor antagonist | AR | Absence of or non-functional IL-1 Ra leads to unregulated IL-1 signaling | Sterile multi-focal osteomyelitis, periostitis and pustulosis | continuous |

FMF: familial Mediterranean fever, TRAPS: TNF receptor-associated periodic syndrome, MKD: mevalonate kinase deficiency, CAPS: cryopyrin-associated periodic syndrome, PAPA: pyoderma gangrenosum, acne and pyogenic arthritis, DIRA: deficiency of IL-1ra, NLRP3: NACHT, LRR and PYD domains-containing protein 3, PSTPIP1: proline-serine-threonine phosphatase-interacting protein 1, NOD2: nucleotide-binding oligomerization domain-containing protein 2, AD: autosomal dominant, AR: autosomal recessive, ASC: apoptosis-associated speck-like protein containing a CARD, ROS: reactive oxygen species, MAPK: mitogen-activated protein kinase.

Adapted from Lachmann et al. (2011), Park et al. (2012).

Cryopyrin-Associated Periodic Syndrome

One of the clearest examples of dysregulation of IL-1 β is CAPS, a hereditary disorder caused by mutations in the NLRP3 protein which lead to easier NLRP3

inflammasome activation and secretion of IL-1 β (Hoffman et al., 2001; Aksentijevich et al., 2002; Feldmann et al., 2002; Goldbach-Mansky, 2012). CAPS is the current name for three previously recognized

clinical syndromes with an autosomal dominant inheritance pattern: the relatively mild Familial Cold Autoinflammatory Syndrome (FCAS); the intermediate Muckle–Wells syndrome (MWS); and the far more severe NOMID (also known as CINCA). Distinguishing clinical features of these disorders include an urticaria-like skin rash, progressive perceptive hearing loss, inflammatory episodes provoked by systemic exposure to cold, and in severe cases joint deformations and aseptic meningitis, resulting in developmental delay and significant disability. Genetic studies revealed a common genetic background in these patients, i.e., an activating mutation in the gene for NLRP3 (upon discovery, this protein was named cryopyrin, resulting in the name of the disorder CAPS; but NLRP3 is now recognized as the official name for the protein) (Bertin and DiStefano, 2000; Fairbrother et al., 2001; Martinon et al., 2001; Ting et al., 2008). NLRP3 is the central protein in the most important inflammasome, and mutations result in an increased production of active IL-1 β (Figure 4.2A) (Agostini et al. 2004). Since the discovery of the common genetic background, it has been recognized that rather than three separate entities, the clinical phenotype should be seen as a continuous spectrum ranging from mild to very severe disease. There is no conclusive phenotype–genotype correlation, and disease severity can even vary within families—so it is likely that there are other contributing (genetic) factors. Treatment with inhibitors of IL-1 is very effective and has dramatically improved quality of life for these patients in recent years (Dinarello et al., 2012).

Familial Mediterranean Fever

The most prevalent of these rare disorders, and the one which has been recognized for the longest time, is FMF. This was already recognized as a distinct familial syndrome with autosomal recessive inheritance more than a century ago. Patients suffer from recurring episodes of serositis. A classic FMF attack presents as peritonitis, with or without fever, lasting for 2–3 days. Before the patient is diagnosed as having FMF, these episodes are frequently mistaken for appendicitis or other acute abdomen, resulting in unnecessary abdominal surgery. Other presentations of the FMF-associated serositis can be pleuritis, pericarditis, arthritis, and more rarely meningitis or acute scrotal inflammation (Masters et al., 2009).

The name FMF is derived from the epidemiological observation that many patients have an ethnic background originating from the countries around the Mediterranean Sea (Sohar et al., 1967). Until the 1970s, FMF was considered a disease with a significantly reduced life expectancy, mainly due to the high prevalence of renal failure due to AA-type amyloidosis. This changed with the

discovery of the high efficacy of prophylactic use of colchicine. In more than 90% of FMF patients, chronic use of a sufficiently high dose of colchicine (1–2 mg per day) will either prevent the occurrence of inflammatory attacks or greatly reduce their severity and frequency. It also prevents the occurrence of AA-type amyloidosis, and renal failure is now very rare in patients who are compliant with therapy (Ozturk et al., 2011).

In 1997, two groups practically simultaneously discovered the genetic background of FMF, and raced each other for publication and for the naming of the protein involved, which was previously unknown (International FMF Consortium, 1997; French FMF Consortium, 1997). The gene was named *MEFV* (Mediterranean FeVer gene), and the protein is now known as pyrin. Pyrin has a regulatory function; mutations in pyrin affect the function of the NLRP3 inflammasome, leading to increased IL-1 β (see Figure 4.2C) (Masters et al., 2009; Stoffels et al., 2013). Most mutations are missense mutations, and most patients are compound heterozygous for two different missense mutations. There is some information on phenotype–genotype correlations; the mutation associated with most severe disease and the highest prevalence of amyloidosis is M694V (Masters et al., 2006). A clear founder effect has been proven for this mutation, which explains its prevalence in communities around the Mediterranean Sea and Jewish populations. There has been some speculation on a survivor advantage for carriers of one *MEFV* gene mutation, such as increased survival of certain infectious diseases, to explain the relatively high prevalence in some areas, but this is hard to prove (Masters et al., 2009).

TNF Receptor-Associated Periodic Syndrome

Distinguishing clinical features of TRAPS are a migrating painful erythematous skin rash, severe myalgia, and particularly prolonged inflammatory episodes, of weeks rather than days (Masters et al., 2009; Cantarini et al., 2012).

TRAPS is one of the autoinflammatory disorders that is not caused by a direct effect of IL-1 β signaling. It is caused by autosomal dominant heterozygous mutations in *TNFRSF1A*, which encodes the TNF- α receptor 1, a transmembrane protein and member of the TNFR superfamily. The ligand for this receptor is TNF- α , which is produced mainly by monocytes and macrophages, and is involved in systemic inflammation, apoptosis, and cell proliferation (Bazzoni and Beutler, 1996). The intracellular signaling subsequent on binding of TNF- α to its receptor is complicated, and can include activation of NF- κ B, c-Jun/activator protein 1 (AP-1), apoptosis, and protein–kinase pathways activated by mitogens (Wajant et al., 2003).

TRAPS mutations almost exclusively affect the extracellular domain of TNFRSF1A. Initially, it was hypothesized that the mutations would have an activating effect. However, there is no increased binding of TNF- α , no spontaneous activation of the receptor, and no increased receptor expression (McDermott et al., 1999). Another hypothesis was that TNFR mutations would lead to a defect in receptor shedding (Mullberg et al., 1995), the process in which a receptor is cleaved off the membrane to prevent constitutive signaling, and to act as a decoy for excess extracellular ligand. But this shedding hypothesis could not hold true, because shedding defects could only be detected in some TRAPS-associated TNFR1 mutations and only in certain cell types (Aksentjevich et al., 2001; Huggins et al., 2004).

Recent studies have shed new light on the pathophysiology. TRAPS-related mutations actually have several characteristics of function inhibiting mutations: impaired membrane trafficking, and as a consequence retention of the receptor in the endoplasmic reticulum (ER) (Todd et al., 2004, 2007; Lobito et al., 2006); no oligomerization of mutant- with WT-receptors (Lobito et al., 2006), and decreased binding of TNF- α (Todd et al., 2004). It was shown that accumulated mutant receptors result in increased spontaneous activation of mitogen-activated protein kinase (MAPKs), thereby priming the TRAPS cells to become more susceptible to low doses of inflammatory stimuli and responding by secreting more proinflammatory cytokines, in particular IL-1 β (Simon et al., 2010). This effect is mediated by increased mitochondrial-derived reactive oxygen species (ROS) (Bulua et al., 2011).

Initially, treating patients with etanercept, a synthetic version of soluble TNF receptor (sTNFR), seemed most appropriate, to substitute the deficiency of sTNFR. However, the clinical efficacy of etanercept in TRAPS can be disappointing, and actually the inhibition of IL-1 is more effective than the inhibition of TNF—supporting the observation that even TRAPS symptomatology is mediated more by increased IL-1 β than TNF- α .

HIDS (also Known as Mevalonate Kinase Deficiency)

In 1984, van der Meer et al. described an autoinflammatory disease that was different from FMF, and named the disease after the high serum IgD concentrations that were found in these patients: hyperimmunoglobulinemia D and periodic fever (HIDS) (van der Meer et al., 1984). The common clinical phenotype as described above is seen, distinguished by an age of onset around 3 months, with characteristic accompanying symptoms such as lymphadenopathy, hepatosplenomegaly and aphthous

ulcers, and the fact that any vaccination can trigger an inflammatory attack.

In the early days, the diagnosis was made solely based on careful clinical observation. Elevated serum IgD concentrations are characteristic, but not related to disease severity, presence or absence of a fever attack and it is not present in all patients; therefore the original name can be misleading.

In 1999, the genetic defect causing this rare disorder was found: mutations in the MVK gene lead to amino acid substitutions in mevalonate kinase, an enzyme in the isoprenoid pathway (Drenth et al., 1999; Houten et al., 1999). Patients with the far more severe mevalonic aciduria (MA) also have a defect in mevalonate kinase (Berger et al., 1985). These patients have the same symptoms as HIDS patients, but in addition suffer from growth retardation, dysmorphic features, and neurological symptoms such as ataxia and mental retardation. There is a spectrum of clinical phenotypes related to mevalonate kinase deficiency (MKD), with HIDS at the mild end of the spectrum and MA at the other end (Simon et al., 2004). Recently, Zhang et al. found MVK mutations in disseminated superficial actinic porokeratosis (Zhang et al., 2012), and we have found them in patients with isolated retinitis pigmentosa (Siemiakowska et al., in press), diversifying this spectrum even further. There is some correlation between residual MK enzyme activity and disease severity, and some correlation between enzyme activity and certain MVK mutations, but the genotype–phenotype correlation is not perfect.

It is intriguing how an enzyme defect in a pathway that seemingly has nothing to do with inflammation can cause these phenotypes. MK is a major enzyme in the mevalonate pathway (also called isoprenoid pathway), from which the end products are, for example, cholesterol and isoprenoids. The enzyme 3-hydroxyl-3-methylglutaryl-coenzyme A (HMG-CoA) reductase converts HMG-CoA to mevalonate, which is then phosphorylated by mevalonate kinase. Further down in the pathway the end products are formed; these metabolites are important for various cellular functions. For example, protein prenylation can regulate the activation status of proteins, such as some small GTPases of the Ras super family (Henneman et al., 2010). Mutations in MVK result in decreased enzyme activity, sometimes even below detection level, and therefore the formation of end products, including isoprenoids, is compromised. The exact link between MKD and inflammation is at present still unknown (Figure 4.2B), although it is likely to be the defect or dysregulation of protein isoprenylation. *In vitro* studies showed that shortage of isoprenoids, mainly geranyl-geranyl, induced increased caspase-1 activation and hypersecretion of IL-1 β in monocytes (Mandey et al., 2006; Stoffels and Simon, 2011).

POLYGENIC OR ACQUIRED AUTOINFLAMMATORY DISORDERS

This can encompass a large and very diverse group of disorders, similar to the autoimmune diseases (see Figure 4.1).

For some of these, the designation autoinflammatory is clearly more apt than the term “autoimmune.” Examples of these include gout, in which the pathogenic role of IL-1 β and the NLRP3 inflammasome has become clear. A rare disorder with a clear autoinflammatory background is the syndrome of periodic fever with aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA), a childhood disease characterized by episodes of the symptoms described in its name, which is often self-limiting within a number of years. PFAPA is suspected to have a polygenic background (Stojanov et al., 2011).

It could also be argued that the inflammatory bowel diseases are part of this group of polygenic autoinflammatory disorders. Although many aspects of the etiology are still unclear, there are certainly features of increased inflammation. This is also supported by the link with mutations in the NOD2 gene. For a more detailed discussion of the pathophysiology of these diseases, see Chapter 60.

More to the middle of the spectrum are the disorders for which an approximately equal contribution of innate and adaptive immunity is suspected in the pathophysiology. For example, IL-17 dysregulation is important in the pathophysiology of psoriasis, leading to dysregulation of both innate and adaptive immunity. The importance of the innate immune system is underscored by the recent finding of mutations in the IL-36 receptor antagonist as the cause of a rare hereditary subgroup termed generalized pustular psoriasis (Marrakchi et al., 2011; Onoufriadis et al., 2011).

AUTOINFLAMMATORY MECHANISMS OF DISEASE IN COMMON DISORDERS

The effects of IL-1 β are not restricted to a small group of rare autoinflammatory diseases. In some common diseases there is also an autoinflammatory component. Below we will describe two of those examples: type 2 diabetes and atherosclerosis.

Type 2 Diabetes Mellitus

Obesity and inactivity are high risk factors for acquiring type 2 diabetes, leading to insulin resistance, where the insulin-producing β cells cannot adapt to increasing insulin demands. A role for IL-1 β has been suggested in this pathophysiology. Low IL-1 β concentrations have been shown to be selectively toxic for insulin-producing

pancreatic β -cells, supporting a causative role for IL-1 β in the loss of β cell mass (Dinarello et al., 2010) (see Chapter 66). The autoinflammation is driven by glucose, free fatty acids, leptin, and IL-1 β itself; caspase-1 is also required for the release of free fatty acids from the adipocyte. Treatment with IL-1 receptor antagonist in patients with type 2 diabetes in clinical trials resulted in improved glycemia and β cell function (without effect on weight or insulin sensitivity). These data show potential for long-term glycemic control and reduced risk for cardiovascular events (Dinarello et al., 2012).

Atherosclerosis

It is clear that atherosclerosis can be viewed as an inflammatory disease; inflammatory lesions in arteries result in vascular plaques, and rupture of these plaques can result in the complications associated with this common disorder. Chapter 71 of this book deals in great detail with the current knowledge on the pathophysiology of atherosclerosis; the authors argue that this fits with an autoimmune basis for the disease. However, as they show in their Table 71.1, a large role is played by cells of the innate immune system. A direct role for the NLRP3 inflammasome in atherosclerosis has also been suggested by numerous studies: e.g., NLRP3 inflammasome activation is required for vascular smooth muscle cell calcification (Wen et al., 2013), apolipoprotein E deficient mice, a model for vascular inflammation, developed significantly less atherosclerosis when crossed with caspase-1 deficient mice (Usui et al., 2012), and cholesterol crystals, as found in atherosclerotic plaques, activate NLRP3 in primed immune cells (Düwell et al., 2010), resulting in IL-1 β secretion (Grebe and Latz, 2013). Thus, atherosclerosis is likely located more to the right of the autoimmune–autoinflammatory spectrum (Figure 4.1), with increasing evidence for autoinflammatory mechanisms of disease.

NEWEST DEVELOPMENTS: RARE HEREDITARY DISORDERS WITH AUTOINFLAMMATORY ASPECTS

With the rise of next generation sequencing techniques, disease discovery has significantly speeded up. Diseases that previously could not be distinguished or of unknown origin are now being unraveled at a higher rate. Some of these newly discovered syndromes belong somewhere in the middle of the autoinflammation–autoimmunity spectrum. Others combine aspects of both autoinflammation and immunodeficiency, or other defects such as lipodystrophy, which were not recognized as part of these disorders before. Below we discuss a few of the recently discovered syndromes, which are not only worthy of

mention because they are new, but even more because they extend the range of mechanisms that are involved in autoinflammation.

Proteasome Defects

From the 1980s, several hereditary syndromes have been described with largely similar phenotype, although with small variations. These each received their own name, and became known as Nakajo–Nishimura syndrome (NNS (Kitano et al., 1985; Tanaka et al., 1993; Kasagi et al., 2008), recently named JASL (Kitamura et al., 2011)), JMP (Megarbane et al., 2002; Garg et al., 2010), and CANDLE (Torrelo et al., 2010; Ramot et al., 2011). They are characterized by marked lipodystrophy, which seems to be induced by panniculitis, and muscular atrophy, as well as episodes of fever and inflammation, skin rash, violaceous swollen eyelids, hypochromic or normocytic anemia and joint contractures.

More or less at the same time, several groups discovered that autosomal recessive mutations in PSMB8, encoding the inducible proteasome subunit beta-type-8, are the cause of all of these syndromes (Agarwal et al., 2010; Arima et al., 2011; Kitamura et al., 2011; Liu et al., 2012). The different mutations result in a reduced activity of the immunoproteasome. Consequently, ubiquitinated and oxidized proteins accumulate in cells expressing these immunoproteasomes, instead of being degraded (Figure 4.2I). This also results in an increase of IL-6 and IFN- γ inducible protein (IP)-10 serum concentrations.

These high concentrations of IP-10 and a prominent IFN- γ signature distinguish these disorders from IL-1-mediated disorders (Agarwal et al., 2010; Arima et al., 2011; Liu et al., 2012). It remains to be seen whether these provide a link to pathogenesis and whether this can point to effective treatment strategies (Goldbach-Mansky, 2012).

PLC γ 2 Deficiency

In 2012, two groups reported defects in the *PLCG2* gene, encoding a signaling molecule expressed in B cells, natural killer cells, and mast cells: phospholipase C γ 2. Its activation leads to increased intracellular [Ca²⁺], which turn can activate the inflammasome (Brough et al., 2003; Lee et al., 2012; Murakami et al., 2012; Rossol et al., 2012; Haneklaus et al., 2013). *PLCG2* mutations lead to a spectrum of PLC γ 2-related phenotypes that combine both autoinflammatory and immunodeficiency properties.

Initially, three families with a dominantly inherited complex of cold-induced urticaria, antibody deficiency, and susceptibility to infection and autoimmunity were described, and the phenotype was coined as PLAID (Ombrello et al., 2012b). Affected family members

suffered from atopy, granulomatous rash, autoimmune thyroiditis (with the presence of antinuclear antibodies), sinopulmonary infections, and hypogammaglobulinemia (including reduced serum concentrations of IgA and IgM). This was accompanied by reduced circulating natural killer cells and class-switched memory B cells. Genetic analysis in these families revealed *PLCG2* deletions of exon 19, and exons 20–22, located in the autoinhibitory domain, rendering PLC γ 2 constitutively activated. At physiologic temperatures, cells had diminished signaling; however, at subphysiologic temperatures, signaling was enhanced. So *PLCG2* deletions can lead to gain of PLC γ 2 function, causing signaling abnormalities in multiple leukocyte subsets, and a phenotype that consists of both excessive and deficient immune function.

In the same year, a missense mutation in PLC γ 2, p.Ser707Tyr, located in an autoinhibitory SH2 domain, causing enhanced PLC γ 2 activation, was found in another patient (Zhou et al., 2012). The p.Ser707Tyr substitution is responsible for a phenotype that is not provoked by cold, and includes recurrent blistering skin lesions, bronchiolitis, arthralgia, ocular inflammation, enterocolitis, absence of autoantibodies, and mild immunodeficiency. The authors considered this to be a very distinct phenotype and suggested their own name for the disease: APLAID (autoinflammation and PLC γ 2-associated antibody deficiency and immune dysregulation). Very likely, PLAID and APLAID are part of a continuum of inflammatory diseases related to PLC γ 2 defects.

Heme-Oxidized IRP2 Ubiquitin Ligase

Recently, Boisson et al. provided the clinical molecular description of a new fatal human disorder, characterized by chronic autoinflammation, invasive bacterial infections, and muscular amylopectinosis (Boisson et al., 2012; Ombrello et al., 2012a). Patients combine symptoms of both autoinflammation and immunodeficiency, and very early in life develop recurrent episodes of fever and systemic inflammation with an acute-phase response, hepatosplenomegaly and lymphadenopathy.

Again, the underlying pathophysiology turned out to be surprising. Loss-of-expression and loss-of-function mutations in heme-oxidized IRP2 ubiquitin ligase-1 (HOIL-1), a component of the linear ubiquitin chain assembly complex (LUBAC), are responsible for this disease. LUBAC is a multiprotein complex that attaches linear chains of ubiquitin molecules to protein substrates (Kirisako et al., 2006), which is important for targeting proteins for proteasomal degradation, protein-protein interactions, and protein trafficking to cellular locations (Tokunaga et al., 2009). An example is targeting NEMO (modulator of NF- κ B) to signalosomes of IL-1R1, TNFR, and TLRs.

The described mutations in HOIL1 resulted in impaired LUBAC stability, and as a consequence NF- κ B activation in response to IL-1 β was diminished in patient fibroblasts. On the other hand, monocytes were hyper-responsive to IL-1 β , explaining the appearance of both autoinflammation and immunodeficiency in the patients. These data show that LUBAC differentially regulates NF- κ B-dependent IL-1 β responses in different cell types (Figure 4.2H). It remains to be elucidated which mechanisms underlie the diversity in effects observed.

CONCLUSION

Autoinflammation and autoimmunity are part of a spectrum of immunological diseases, in the same way that innate and adaptive immunity are part of an immunological continuum. Recognizing autoinflammation as a distinct mechanism of disease helps in unraveling the pathophysiology, and also in finding the right therapeutic approach. It is likely that the definition of “autoinflammatory disease” will continue to evolve over the next decades, just as that of autoimmune disease has done, to match our increased insight.

INTRODUCTION

The cells of the immune system are derived from self-renewing hematopoietic stem cells (HSCs) which give rise to multipotent progenitors (MPPs) that are no longer able to self renew (Boisset and Robin, 2012). Cytokines and other signals lead to the expression of different patterns of transcription factors (Sarrazin and Sieweke, 2011) which drive the MPPs down particular differentiation pathways, ultimately leading to the generation of lymphocytes, natural killer (NK) cells, dendritic cells (DCs), neutrophils, eosinophils, basophils, mast cells, monocytes, macrophages, megakaryocytes, and erythrocytes.

THE INNATE AND ADAPTIVE RESPONSES

The immune system can mount innate responses that occur to the same extent, however many times the antigen is encountered, and adaptive (acquired) responses that generate immunologic memory leading to quantitatively and qualitatively enhanced responses upon re-encounter with the antigen. Both types of response detect a threat using receptors that recognize molecules associated with pathogens (Table 5.1). Innate responses exhibit broad specificity based upon detection of pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs) by pattern recognition receptors (PRRs) (de Wet and Gordon, 2007; Moresco et al.,

2011), and the binding to complement receptors and Fc receptors of opsonized antigens coated with complement or antibody. Only the lymphocytes, the dedicated cells of the adaptive response, bear antigen-specific receptors which permit exquisitely refined recognition of individual antigens. Each lymphocyte possesses approximately 10^5 antigen receptors of identical specificity. While the B cell receptor (BCR) recognizes structures (epitopes) on the surface of native antigen, the epitopes recognized by the T cell receptor (TCR) are short peptides (Figure 5.1). The peptides are produced by proteolytic processing of antigen within cells and are presented to T cells by highly polymorphic major histocompatibility complex (MHC) class I and class II cell surface molecules. The main human class I molecules are HLA-A, B, and C and the class II comprise HLA-DP, DQ, and DR. Thus an individual who is heterozygous at each locus will express 12 variants, although cross-pairing of some class II chains can increase this number. MHC class II, which presents 8–30 amino acid long peptides to the TCR on CD4⁺ helper T cells, is expressed on DCs, macrophages, B cells, activated human (but not mouse) T cells, thymic epithelial cells, and can be induced on a variety of other cell types. In contrast, MHC class I molecules, which present peptides of 8–9 amino acids in length, are ubiquitously expressed on nearly all nucleated cells in the body and are concerned with alerting CD8⁺ cytotoxic T lymphocytes (CTL) to the presence of intracellular infection.

TABLE 5.1 Innate and Adaptive (Acquired) Responses Detect a Threat using Receptors that Recognize Molecules Associated with Pathogens

| Receptor | PRR | MHC | TCR | Antibody (BCR) |
|------------------------------------|---|--|---|---|
| Location | Cell surface, cytoplasmic, secreted | Cell surface | Cell surface | Cell surface, secreted |
| Recognition | PAMPs and DAMPs | Each MHC variant can bind many different peptide sequences | Highly peptide-MHC specific | Highly antigen specific |
| Protein diversity in an individual | 10 s–100 s | ~12 for classical MHC | Millions | Millions |
| Genes | Each protein individually encoded. Low polymorphism | Each protein individually encoded. Extremely polymorphic | Genetic recombination creates diversity | Genetic recombination creates diversity |

The cells of the immune system need to detect a threat and do so using four main groups of receptors. Pattern recognition receptors (PRR) are predominantly employed by cells of the innate response (although they are also present on lymphocytes) and collectively are found on cell surfaces, intracellularly or as secreted molecules. They recognize pathogen-associated molecular patterns (PAMPs) and danger-associated molecular patterns (DAMPs). MHC class I is present on all nucleated cells in the body although MHC class II is highly restricted in its expression. The TCR is restricted to T lymphocytes. The transmembrane version of antibody, the BCR, is only present on the surface of B lymphocytes, but antibody is also present throughout the body both as a soluble molecule and held on the surface of cells by Fc receptors.

FIGURE 5.1 Antigen recognition by lymphocytes. Dendritic cells take up external (exogenous) antigen (Ag), process it, and then present it on their cell surface in the form of a peptide fragment bound to MHC class II molecules. This peptide–MHC complex is recognized by the T cell receptor (TCR) on CD4⁺ helper T cells (Th). Antigens lurking inside cells (endogenous antigens, e.g., viruses) can be processed within the cell and then presented on the surface of the infected cell in the form of a peptide fragment bound to MHC class I molecules. This peptide–MHC complex is recognized by the TCR on CD8⁺ cytotoxic T cells (Tc). Cross-presentation can also occur whereby exogenous antigens are presented by MHC class I and endogenous antigens by MHC class II. The B cell receptor (BCR) is a transmembrane version of the antibody (Ab) molecule. This directly detects intact antigen, a process which can be assisted by follicular dendritic cells holding complexes of Ab–Ag and complement (C) bound to their surface by Fc receptors (FcR) and complement receptors (CR).

INNATE RESPONSES

Cellular Components

Cells of the innate immune response include neutrophils, eosinophils, monocytes, macrophages, and DCs, all of which to varying degrees can act as phagocytic cells, together with the non-phagocytic basophils, mast cells, and NK cells. All of these cell types are capable of producing inflammatory mediators. Detection of infection or tissue injury can result in the activation of intracellular molecular complexes referred to as inflammasomes (Figure 5.2), leading to the secretion of proinflammatory mediators such as the cytokines interleukin (IL)-1 β and

IL-18 (Strowig et al., 2012). The immediate consequence of an encounter with an entity that is deemed to pose a threat is the generation of an acute inflammatory response in which cells and molecules of the immune system are rapidly recruited to the site of the stimulus. Inflammatory mediators and microbial products cause the upregulation of adhesion molecules on vascular endothelium, thereby alerting inflammatory cells to the presence of a local infection (Figure 5.3). Histamine released from mast cells causes smooth muscle contraction and an increase in local vascular permeability, facilitating the passage of neutrophils from the blood to the tissues. Activation of the complement system (Chapter 15) plays a pivotal role in this

FIGURE 5.2 The inflammasome. Inflammasomes comprise multi-protein cytoplasmic complexes that promote inflammation by converting the IL-1 β precursor into active IL-1 β , and additionally by stimulating the generation of IL-18. The proinflammatory caspase-1, complexed with NOD-like receptors (NLR) such as NLRP3 and with the apoptosis-associated speck-like (ASC) adaptor protein, becomes activated in response to danger signals resulting from infection or tissue damage.

FIGURE 5.3 Entry of neutrophils into tissue during an inflammatory response. Microbial products such as lipopolysaccharide (LPS), together with inflammatory mediators such as histamine, thrombin, and the cytokines IL-1 β , IL-17 and tumor necrosis factor (TNF)- α , lead to the increased expression of vascular endothelial adhesion molecules. This alerts neutrophils and other inflammatory cells to the presence of an infection in the underlying tissues. P-selectin becomes expressed on the surface of the endothelium and captures neutrophils due to their possession of PSGL-1 (P-selectin glycoprotein ligand-1). Initially the neutrophils are slowed down and roll along the blood vessel wall. Signaling through PSGL-1 causes the neutrophils to activate β_2 integrins. Additional vascular endothelial adhesion molecules become expressed such as ICAM-1, which binds to the β_2 integrins LFA-1 and/or CR3, and E-selectin which binds to ESL-1 (E-selectin ligand-1), PSGL-1 and CD44 on the neutrophils (Zarbock et al., 2011; Muller, 2011). Eventually the neutrophils are brought to a halt and squeezed out of the blood vessels, a process known as diapedesis which is greatly facilitated by the deformable nature of the multi-lobed nucleus in these polymorphonuclear leukocytes.

process, triggering mast cell degranulation and chemotactically attracting the neutrophils (Chapter 14). Chemotactic cytokines (chemokines) help guide the neutrophils to the site of the infection (Sanz and Kubes, 2012). The presence on the neutrophil cell surface of both Fc receptors for antibodies and complement receptors greatly facilitates phagocytosis if the antigen is opsonized

with these agents (Underhill and Ozinsky, 2002). Engulfed microorganisms are killed within the neutrophil by a plethora of toxic molecules including superoxide anions, hydroxyl radicals, hypochlorous acid, nitric oxide, proteases, defensins, and lysozyme. Neutrophil extracellular traps (NETs) prevent microbial spreading and focus released microbicidal substances onto any

non-phagocytosed pathogens in the immediate vicinity of the neutrophil (Borregaard, 2010; Remijnsen et al., 2011).

Although eosinophils (Chapter 14) are able to phagocytose microorganisms, their role in protection against infection is perhaps more specialized towards the release of granules containing cationic proteins in order to destroy extracellular parasites such as helminths. Eosinophils are also involved in immune regulation, secrete leukotriene C₄, platelet-activating factor and an array of cytokines, and can be induced to express MHC class II and thereby act as antigen-presenting cells for T cell activation (Rothenberg and Hogan, 2006; Kita, 2011). Blood basophils and tissue mast cells are not phagocytic and share many features. They become sensitized with IgE antibodies bound to their high affinity Fcε receptors (FcεRI) and, when antigen cross-links the IgE, release preformed inflammatory mediators including histamine, platelet-activating factor, and many different cytokines. Newly synthesized leukotrienes, prostaglandins, and thromboxanes are also released. Two populations of mast cells have been described in humans, those that contain both tryptase and chymase (MC_{TC}) and those which lack chymase (MC_T) (Galli et al., 2011). A number of immunoregulatory roles have been proposed for mast cells based upon the particular cytokines and other mediators they secrete (Galli et al., 2011).

The tissue macrophages (Chapter 11) and their circulating precursors, the blood monocytes, possess both Fc receptors and complement receptors, and contain similar microbicidal substances to neutrophils. However, they live much longer than neutrophils and are able to process antigens for presentation to helper T cells. An additional role of the macrophage is the removal of the body's own dead or dying cells. While tissue damage associated with necrotic cell death triggers inflammation, cells dying due

to apoptosis are removed much more quietly. Loss of membrane symmetry is a feature of apoptotic cell death and exposes the molecule phosphatidylserine on the cell surface, marking the cell for phagocytosis by macrophages expressing phosphatidylserine receptors (Devitt and Marshall, 2011). Macrophages are key players in inflammatory responses, releasing cytokines such as IL-1β and TNFα, and are particularly characteristic of chronic inflammation.

Sets of activating and inhibitory receptors are expressed on NK cells (Chapter 13). They enable the NK cells to detect cells that have either lost or altered their expression of self MHC molecules as a result of infection or oncogenesis. A dominant signal through the activating receptors will lead to the induction of apoptosis in the target cell (Figure 5.4). NK cells can also mediate antibody-dependent cellular cytotoxicity (ADCC) of antibody-coated target cells, and are a rich source of certain cytokines, particularly gamma interferon. This latter activity bestows an important immunoregulatory role upon the NK cell (Shi et al., 2011).

A key interface between innate and adaptive responses is provided by DCs, a heterogeneous population which include the Langerhans cell in the skin. DCs (Chapter 12) sample extracellular antigens by endocytosis and become activated to an antigen-presenting mode when their PRRs (Table 5.1), which include Toll-like receptors (TLRs), NOD-like receptors (NLRs), and various C-type lectin receptors, recognize PAMPs such as LPS, terminal mannose, and microbial CpG motifs (unmethylated cytosine-guanosine dinucleotide sequence flanked by two 5' purines and two 3' pyrimidines). Endogenous DAMPs such as uric acid and heat shock proteins can also activate these cells (Ueno et al., 2007). The activated DCs travel to the local draining lymph node where they present antigen

FIGURE 5.4 Natural killer (NK) cells possess both activating and inhibitory receptors. The activating receptors recognize a number of different activator ligands constitutively expressed on many cells in the body (e.g., CD112) or expressed in response to factors such as cell stress (e.g., MICA). Activation of killing is usually blocked by the engagement of inhibitory receptors that recognize the MHC class I molecules normally expressed on all nucleated cells in the body. Cells lacking MHC class I are not able to engage the inhibitory receptors, are therefore deemed abnormal, and are killed by the NK cells. Even in the presence of MHC class I, if sufficient activating signals are received (because infection, cancer, or other types of cell stress has caused the cell to express higher levels of activators), the inhibitory signal is subdominant and the target cell will be killed.

to T cells. During their migration through the afferent lymphatics, they upregulate their cell surface MHC class II molecules and the CD80 (B7.1) and CD86 (B7.2) costimulatory ligands for CD28 on the T cell (Ueno et al., 2007). Such costimulation is required, together with antigen, for T cell activation (Figure 5.5). Within the DC the antigen is processed into short peptides and then expressed on the cell surface together with the MHC class II molecules for presentation to CD4⁺ helper T cells and regulatory T cells (Tregs). DCs are also able to cross-present exogenous antigens by transferring them into the MHC class I processing and presentation pathway for recognition by CD8⁺, mostly cytotoxic, T cells (Amigorena and Savina, 2010). Conversely, cytoplasmic antigens can undergo autophagy and be cross-presented to CD4⁺ (mostly helper) T cells following delivery to the MHC class II presentation pathway (Pierdominici et al., 2012).

DCs can also act to limit immune responses. T cell interactions with DCs lacking the expression of the crucial CD80/CD86 costimulatory molecules induce anergy (functional inactivation) in the T cell. Immunosuppression by DCs can be mediated via their production of the tryptophan-depleting enzyme indoleamine 2,3-dioxygenase (tryptophan being required for T cell proliferation) or by

the preferential stimulation of Tregs (Maldonado and von Andrian, 2010).

Although B cells are able to recognize antigen without the intervention of any other cell type, recognition is more efficient if multiple copies of the antigen are “presented” to the B cell in the form of immune complexes held on the surface of follicular dendritic cells (FDCs) (Aguzzi and Krautler, 2010). These are an entirely different cell type to the DCs discussed above. Unlike DCs they are not phagocytic, and they lack MHC class II molecules. Furthermore, they appear not to be bone marrow derived, probably arising from fibroblastic reticular cells in the B cell areas of lymphoid tissues. They can present immune complexes to B cells very efficiently by virtue of their FcγRIIB receptors for IgG and CR1 and CR2 receptors for complement.

The role that erythrocytes perform in immune responses should not be overlooked. Their possession of CR1 complement receptors for C3b, C4b, and iC3b confers on these cells an important role in clearing immune complexes from the circulation, rapidly transporting them to the liver and spleen where they are destroyed by Kupffer cells and splenic macrophages (Birmingham, 1995).

FIGURE 5.5 T cell activation. Interaction of costimulatory molecules leads to activation of resting T lymphocytes by antigen-presenting cells (APC) on engagement of the T cell receptor (TCR) with its cognate antigen–MHC complex. Engagement of the TCR without accompanying costimulatory signals leads to anergy (functional inactivation). Note, a cytotoxic rather than a helper T cell would involve coupling of CD8 to MHC class I. Costimulation is delivered to a resting T cell primarily through engagement of CD28 on the T cell by B7.1 (CD80) or B7.2 (CD86) on the APC. Other molecules involved can include intercellular adhesion molecule-1 (ICAM-1), lymphocyte function-associated molecules-1/3 (LFA-1/3), vascular cell adhesion molecule-1 (VCAM-1), and very late antigen-4 (VLA-4). Modified from Delves, P.J., Martin, S.J., Burton, D.R., Roitt I.M. 2011. *Roitt's Essential Immunology*, 12th ed. Wiley-Blackwell.

Soluble Mediators

The complement system (Chapter 15) is based upon an enzymic amplification cascade which can be triggered using one of three pathways; classical, lectin, and alternative (Ehrthaller et al., 2011). These all lead to the cleavage of complement component C3 by a C3 convertase which “converts” C3 into C3a and C3b (Figure 5.6). The classical pathway is activated by IgG and IgM antibodies when they bind antigen, thereby creating an array of closely associated immunoglobulin Fc regions to which complement component C1q binds, followed by C1r and C1s. This event initiates a series of enzymic reactions leading to the generation of the classical pathway C3 convertase, C_{4b}2a. The lectin pathway, which is essentially an antibody-independent variant of the classical pathway, leads to the generation of the same C3 convertase when microbial carbohydrates interact with mannose binding protein (MBP) which then binds to the two MBP-associated serine proteases MASP-1 and MASP-2. The initially quite separate alternative pathway is activated when complement component C3b becomes stabilized by binding to microbial cell walls. The C3b then combines with factor B which is cleaved by factor D, generating a different C3 convertase, C_{3b}Bb. This C3 convertase is further stabilized by properdin. Both proteolysis and thiolester hydrolysis of C3 constitutively generate very low levels of C3b. However, in the alternative pathway, it is only when C_{3b}Bb is generated that there is substantial splitting of C3

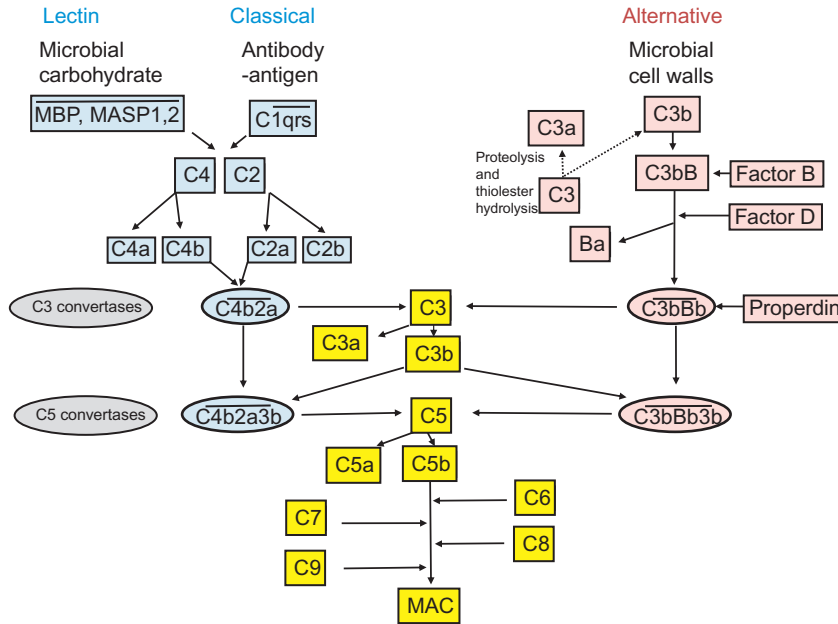

FIGURE 5.6 The complement system. For simplicity complement regulatory proteins have been omitted. The classical and lectin pathways (pale blue) are very similar. Like the alternative pathway (pink), these pathways generate C3 and C5 convertases, leading to shared post-C3 events (yellow). For details see text.

into C3a and C3b. Subsequently, a C5 convertase, either $C4b2a3b$ (from the classical and lectin pathways) or $C3bBb3b$ (from the alternative pathway), is produced by addition of C3b to the C3 convertase. This splits C5 into C5a and C5b, ultimately leading to the generation of the membrane attack complex (MAC) composed of complement components C5b, C6, C7, C8, and C9. Because complement activation consists of a series of sequential enzyme reactions, there is a tremendous amplification of the initial response and along the way a number of complement components with potent immunologic activities are generated.

A major function of C3b (and its cleavage products iC3b and C3d) and of C4b is to enhance the engulfment of antigens by phagocytic cells bearing the complement receptors CR1 and CR3. The C3a, C4a, and C5a components act as anaphylatoxins triggering the release of inflammatory mediators from mast cells. C5a is also a potent neutrophil chemoattractant. The MAC generates pores in cell membranes, ultimately leading to the demise of the target cell by apoptosis. Because of these many potent activities, the complement cascades are tightly controlled by a number of complement regulatory proteins including C1 inhibitor (which dissociates the C1qrs complex), factor H and factor I (which cooperate to break down C3b in the alternative pathway), CD46 (membrane cofactor protein) and CD55 (decay accelerating factor) both of which limit the formation and function of the C3 convertases, and CD59 (homologous restriction factor, an inhibitor of MAC formation) (Kim and Song, 2006).

Complement components C3, C9, and factor B are classed as acute phase proteins. This diverse group of

mediators, which also include C-reactive protein, serum amyloid A protein, proteinase inhibitors and coagulation proteins, share an ability to undergo a rapid change in plasma concentration in response to infection, inflammation, and tissue injury. Collectively the acute phase proteins facilitate host resistance to infection and promote the resolution of tissue damage (Gabay and Kushner, 1999).

Another group of proteins, which function in both the innate and adaptive response, are the cytokines (Fitzgerald et al., 2001) (Chapter 16). These soluble mediators facilitate communication both within the immune system and between the immune system and other cells of the body. In order to respond to a given cytokine a cell must express the relevant cytokine receptor. One subset of cytokines, the chemokines (Juan and Colobran, 2009), are important in ensuring that immune system cells end up in the correct location as already mentioned in the context of an acute inflammatory response. In addition to acting as communication molecules, some cytokines play a more direct role in immune defense. For example, the interferons produced by virally-infected cells establish a state of viral resistance in surrounding non-infected cells, thereby acting as a “firebreak” against the spread of the infection (Randall and Goodbourn, 2008).

ADAPTIVE IMMUNE RESPONSES

The adaptive responses involve the clonal expansion of antigen-specific B and T lymphocytes. B cells differentiate into plasma cells which secrete the antigen-specific antibodies responsible for the elimination of extracellular

antigens. T cells help other cells in the immune response, kill infected cells, or suppress undesirable immune responses.

T Cell Development

T cell precursors migrate from the bone marrow to the thymus, an organ essential for their production. T cell development occurs in the thymus throughout life, despite the fact that it undergoes significant atrophy during aging (Dooley and Liston, 2012). The TCR on T cells comes in two different versions, either a $\alpha\beta$ or a $\gamma\delta$ heterodimer; each chain of the dimer having one variable domain and one constant domain. Collectively, T lymphocytes are capable of producing vast numbers of different TCR variable regions by recombining variable (V) and joining (J) gene segments from the pools of α and γ TCR genes and V, diversity (D) and J gene segments from the pools of β and δ TCR genes (Ciofani and Zúñiga-Pflücker, 2010). There are a number of different sequences for each segment and one out of each V(D)J set is utilized in the rearrangement event (Figure 5.7). Recombination-activating

genes encode the enzymes RAG-1 and RAG-2 which mediate these processes following the recognition of the recombination signal sequence (RSS) nucleotide motifs flanking the V, D, and J gene segments (Jung et al., 2006). Splicing inaccuracies and the insertion of additional nucleotides around the V(D)J junctions by the enzyme terminal deoxynucleotidyl transferase (TdT) further increase diversity (Benedict et al., 2000).

Recombination, and subsequent expression, of the TCR genes does not occur until the precursor T cells reach the thymus. Developing $\alpha\beta$ T cells switch on expression of both CD4 and CD8 cell surface molecules and are therefore referred to as “double positive” T cells. This dual expression permits $\alpha\beta$ T cells to potentially interact with both MHC class I and MHC class II molecules. CD4 binds to conserved (nonpolymorphic) residues on the MHC class II molecule, whilst CD8 binds to conserved residues on MHC class I. Positive and negative selection of the $\alpha\beta$ T cells then occurs (Starr et al., 2003). At this relatively early stage in their differentiation $\alpha\beta$ T cells are programmed to undergo apoptosis (Chapter 17) and are only rescued from this default “death by neglect” if their

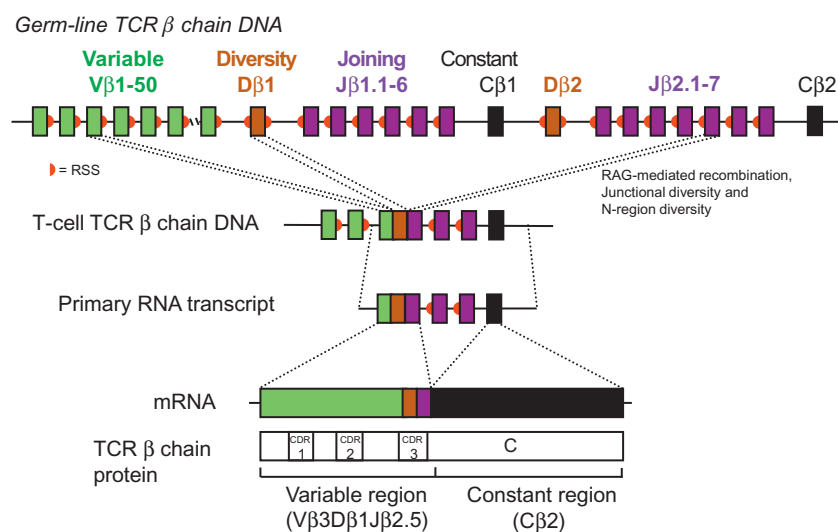

FIGURE 5.7 Diversity of antigen receptors. As an example, the recombination of the TCR β chain genes is shown. Early in T cell development the recombination-activating genes RAG-1 and RAG-2 are expressed. Random rearrangement of either the diversity (D) β 2 gene segment next to any one of the seven joining (J) β 2 gene segments, or of the D β 1 gene segment to any one of the 13 J β 1 or J β 2 gene segments, is followed by recombination of any one out of approximately 50 variable (V) gene segments next to the already rearranged DJ segment. The RAG enzymes recognize recombination signal sequences (RSS) found 3' of each V gene segment, both 5' and 3' of each D gene segment, and 5' of each J gene segment. Different T cells will recombine a different segment out of each pool, thereby creating one level of diversity. Additional heterogeneity is brought about by junctional diversity due to splicing inaccuracies and by the fairly random incorporation of nucleotides (N-region diversity) mediated by the enzyme terminal deoxynucleotidyl transferase (TdT). The primary RNA transcript is processed into messenger RNA (mRNA), with splicing of the rearranged VDJ next to the downstream C β constant region gene. This mRNA will encode a TCR β chain which is placed on the surface of the pre-T cell together with an invariant pre-T α chain. As the pre-T cell undergoes further maturation the TCR α gene segments (for simplicity not shown in the figure) rearrange to produce the TCR α chain. This replaces the pre-T α chain in order to produce a mature $\alpha\beta$ TCR on the cell surface. The complementarity-determining regions CDR1 and CDR2 within the α and β chain variable regions bind to MHC while CDR3 binds to the peptide. Although the detailed organization of the germ-line genes for the TCR α chain, Ig heavy chain, Ig κ light chain and Ig λ light chain are somewhat different to each other, they all consist of pools of V, J, and, for IgH as well as TCR β -chain and TCR δ -chain, D gene segments that undergo recombination to create antigen receptor diversity. The same general principles regarding the rearrangement process therefore apply to the generation of the $\gamma\delta$ TCR on $\gamma\delta$ T cells and to the BCR on B cells.

TCR is capable of binding to self peptide + self MHC on the thymic epithelial cells (Figure 5.8). Positive selection ensures that the randomly generated $\alpha\beta$ TCR is able to interact with self MHC molecules (i.e., those allelic variants of the MHC that are present in the individual). The T cells lose expression of either CD4 or CD8 to become “single positive” CD4 or CD8 cells during positive selection. The majority of the $\alpha\beta$ T cells fail at this first hurdle and are therefore eliminated. For the remaining cells apoptosis is induced in any lymphocytes capable of high affinity binding to self peptide + self MHC on DCs, macrophages, and thymic epithelial cells. Negative selection by clonal deletion in the thymus constitutes central tolerance of self-reactive T cells (Chapter 7). Peptides are generated from a number of organ- and tissue-restricted self antigens ectopically expressed in the thymus and peripheral lymph nodes under the transcriptional control of the autoimmune regulator (AIRE) protein (Metzger and Anderson, 2011). Negative selection, like failure to be positively selected, results in extensive T cell death within the thymus. T cells that successfully pass through these hurdles exit the thymus and enter the periphery, a term used to denote any location outside of the primary lymphoid organs (bone marrow and thymus). These mature naive $\alpha\beta$ T cells will be capable of recognizing foreign peptides presented by self MHC. Generally, $\gamma\delta$ T cells, although also arising in the thymus, do not express either CD4 or CD8 and they recognize antigen directly rather than in the form of peptide–MHC.

Functional Activities of T Cells

The $\alpha\beta$ and $\gamma\delta$ TCRs are not by themselves able to transmit activation signals into the cell, this function being

assigned to the CD3 molecules (CD3 γ , CD3 δ , CD3 ϵ) and the CD3-associated ζ chains. Receptor aggregation occurs within lipid rafts which also incorporate a number of adhesion and costimulatory molecules including LFA-1, CD2, CD28, and CD45 to form the immunological synapse (Fooksman et al., 2010). Stimulation through the synapse results in the phosphorylation of tyrosines within immunoreceptor tyrosine-based activation motifs (ITAMs) present on the cytoplasmic tails of the CD3 complex and the ζ chains. A number of protein kinases including Lck, Fyn, and ZAP-70, together with the adaptor proteins SLP-76 and LAT, are involved in initiating the signaling cascade (Smith-Garvin et al., 2009). The CD45 phosphatase also plays a critical role in both T and B cell activation by its ability to act as both a positive and negative regulator of Lck and Fyn (Saunders and Johnson, 2010).

Broadly speaking, CD4⁺ T cells act as helper or regulatory T lymphocytes, while CD8⁺ T cells are usually cytotoxic (Chapter 6). However, some CD4⁺ cells can exhibit cytotoxic activity (van de Berg et al., 2008), while CD8⁺ cells secrete cytokines that can help in the generation of immune responses, be cytotoxic, or be immunosuppressive (Woodland and Dutton, 2003).

The TCR on CD8⁺ CTL binds to peptide–MHC class I on target cells. Endogenous antigens, including self antigens and viral proteins, are broken down into peptides by a proteolytic structure known as the immunoproteasome (Krüger and Kloetzel, 2012). If the TCR recognizes the peptide–MHC combination and receives costimulation then the CTL becomes activated to kill the target cell, for example a cell infected with a virus or a tumor cell (Dustin and Long, 2010). It does this by inducing apoptosis in the target via engaging the Fas molecule on the

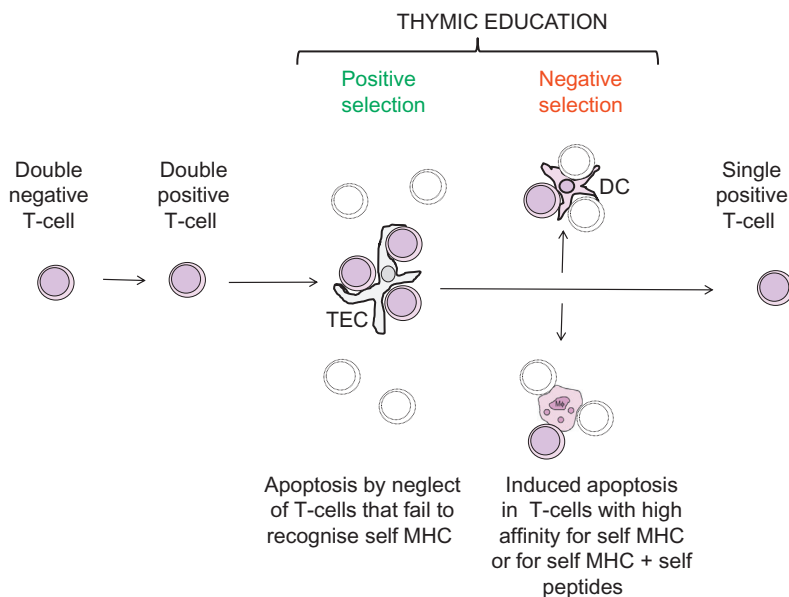

FIGURE 5.8 Positive and negative selection in the thymus. Following a productive recombination of their TCR α -chain and TCR β -chain genes T cells express a cell surface TCR together with both CD4 and CD8 to become double-positive T cells. Positive selection on thymic epithelial cells (TEC) that express both MHC class I and MHC class II will rescue T cells from a default pathway of apoptosis which occurs if these cells are neglected. As long as they have generated a TCR able to recognize self MHC they are saved from neglect. The rescued cells are then protected from apoptosis unless they actively undergo negative selection due to high affinity interaction of their TCR with self MHC or self MHC + self peptides present on DCs and macrophages. The CD4⁺ CD8⁻ and CD4⁻ CD8⁺ single-positive T cells that exit the thymus therefore possess an $\alpha\beta$ TCR with the potential to detect foreign peptides presented by self MHC. *Modified from Delves, P.J., Martin, S.J., Burton, D.R., Roitt I.M. 2011. Roitt's Essential Immunology, 12th ed. Wiley-Blackwell.*

target cell with Fas ligand on the CTL or by using the perforin/granzyme pathway (Figure 5.9).

In contrast to the ubiquitously expressed MHC class I, MHC class II is only present on a few specialized cells, including DCs, macrophages and B cells (“professional antigen-presenting cells”). These cells generate peptides by proteolytic cleavage of engulfed antigens within endosomal vesicles and then present the peptide–MHC class II combination to CD4⁺ T cells. Helper T cells can be divided into different populations based upon the cytokines they produce. Cells secreting IL-2, interferon- γ (IFN γ) and tumor necrosis factor β (TNF β , lymphotoxin) but not IL-4 and IL-5 are designated Th1 cells, those secreting IL-4, IL-5, IL-10, and IL-13 but not IL-2 and IFN γ are classified as Th2 cells, and those secreting IL-17 and IL-22 are termed Th17 cells (Mosmann and Sad, 1996; Littman and Rudensky, 2010) (Figure 5.10). In general, cytokine production by Th1 cells facilitates cell-mediated immunity, involving macrophage activation and T cell mediated cytotoxicity, and assists in the production of some humoral responses. Cytokines produced by Th2 cells are mostly involved in humoral immunity, particularly involving IgE and IgA responses, and cytokines from Th17 cells mediate inflammatory and a variety of other

responses (Fitzgerald et al., 2001; Peters et al., 2011). IL-12 from DCs drives T cells towards a Th1 phenotype (Moser and Murphy, 2000) and Th1/Th2 responses tend to become polarized because the IFN- γ from Th1 cells downregulates Th2 activity, whereas IL-4 and IL-10 from Th2 cells downregulates Th1 cells.

A population of CD4 lymphocytes exist which have some properties of NK cells and some properties of T cells. Many of these NKT cells (Chapter 8) express an invariant TCR which recognizes lipid antigen presented by the non-classical MHC molecule CD1d. NKT cells are multifunctional and secrete a range of cytokines (Godfrey and Berzins, 2007; Godfrey et al., 2010).

The antigen specificities and functions of $\gamma\delta$ T cells are less well characterized than that of $\alpha\beta$ T cells (Chapter 6), but some $\gamma\delta$ TCRs recognize molecules that are upregulated in response to cellular infection or stress. $\gamma\delta$ T cells take up residence throughout the body, being particularly prevalent in epithelia including the mucosal tissues. They can function as cytotoxic cells, and mediate both inflammatory and suppressive activity via their ability to secrete a diverse range of cytokines including TNF α , IFN γ , TGF β , IL-4, IL-5, IL-10, IL-13, and IL-17 (Bonneville et al., 2010).

FIGURE 5.9 Cytotoxic T lymphocytes. Cytotoxic T cells (Tc or CTL) can kill target cells by the granule-dependent pathway in which the CTL inserts perforin into the target cell membrane to act as a channel for the passage of granzyme B and other serine proteases into the target cell. They can also kill target cells by engaging Fas on the target using their cell surface Fas ligand (FasL). Both pathways result in the activation of caspases leading to apoptotic cell death in the target cell. *Modified from Delves, P.J., Martin, S.J., Burton, D.R., Roitt I.M. 2011. Roitt's Essential Immunology, 12th ed. Wiley-Blackwell.*

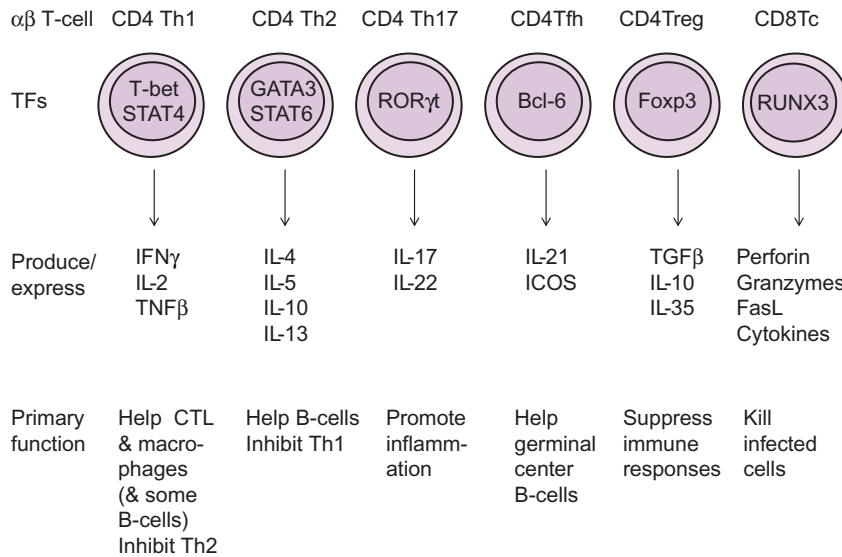

FIGURE 5.10 T cell subpopulations. The major subpopulations of $\alpha\beta$ T lymphocytes are shown with key transcription factors, characteristic secreted or cell surface molecules and functional attributes that distinguish them. Note that cytotoxic T cells can also be subdivided on the basis of cytokine production into Tc1, Tc2, etc. Abbreviations: ICOS, inducible T cell costimulator (cell surface molecule); Tc, cytotoxic T cell, TFs, transcription factors; Tfh, follicular helper T cell; Th, helper T cell; Treg, regulatory T cell.

B Cell Development and Functions

A minor population of B cells (Chapter 9), B1 cells, develop early during ontogeny and often express the CD5 cell surface molecule (Berland and Wortis, 2002). These cells secrete low to moderate affinity IgM antibodies which can exhibit polyreactivity, i.e., recognize several different antigens, often including common pathogens and autoantigens. Such antibodies are often referred to as natural antibodies because of their existence in the absence of an obvious antigenic stimulus. The majority of B cells, B2 cells, lack CD5 and develop slightly later in ontogeny. Like T cells, these B cells are collectively capable of producing a huge number of different variable regions on their antigen receptors. They achieve this by recombining the immunoglobulin heavy and light chain gene loci in a process analogous to the rearrangement of TCR genes in T cells.

Early in B cell development, pro-B cells mature into pre-B cells, at which stage they express RAG-1 and RAG-2. Random rearrangement of any one of 25 D gene segments next to any one of six J gene segments is followed by rearrangement of any one out of approximately 50 V gene segments next to the already recombined DJ segment. As with the TCR in T cells, additional diversity is brought about by splicing inaccuracies and the action of terminal deoxynucleotidyl transferase (TdT). The heavy chain primary RNA transcript is processed into mRNA, with splicing of the rearranged VDJ next to the C μ constant region gene. This mRNA will encode a μ heavy chain which is placed on the surface of the pre-B cell together with the surrogate light chain Vpre-B λ 5 encoded by two non-recombining genes termed VpreB and λ 5. Expression of this pre-BCR on the immature B

cell leads to ligand-independent signaling which drives B cell differentiation towards the mature naïve B cell coexpressing conventional IgM and IgD antibodies on the cell surface (Geier and Schlissel, 2006). As the pre-B cell undergoes maturation the immunoglobulin light chain V (which number about 40 for V κ and 30 for V λ) and J (of which there are five for each light chain isotype) gene segments rearrange to produce a κ or λ light chain. This light chain replaces the surrogate light chain in order to produce a mature IgM BCR the cell surface. Expression of RAG-1 and RAG-2 is now switched off. Once the B cells express a mature antigen receptor their survival and further differentiation becomes antigen dependent. The BCR at this stage also comprises IgD antibodies of the same specificity, produced by alternative splicing of the rearranged VDJ to either the C μ or C δ constant region genes.

The cell surface immunoglobulin is associated with several molecules including Ig α (CD79a), Ig β (CD79b), CD19, CD21 (the CR2 complement receptor), CD81 (TAPA-1), and CD225 (Leu13), which collectively transmit activation signals into the cell when receptor aggregation occurs following cross-linking of the antibody by antigen (Chapter 10). This signaling initially involves phosphorylation of ITAM sequences on Ig α and Ig β by the protein tyrosine kinase Lyn with subsequent recruitment of additional kinases including Syk and Btk (Harwood and Batista, 2010). Upon binding to the BCR, the antigen is endocytosed and then processed within acidified endosomes for presentation by MHC class II to CD4⁺ helper T cells (Clark et al., 2004). In addition to an antigen-presenting role, B cells secrete a variety of cytokines including IL-10, IL-12, IL-13, TNF α , TNF β (lymphotoxin), transforming growth factor- β (TGF β), and

granulocyte-macrophage colony-stimulating factor (GM-CSF) (Fitzgerald et al., 2001). Following an encounter with the antigen in the presence of costimulatory signals the B cells undergo rounds of proliferation and then differentiate into memory cells or alternatively into plasma cells which produce high levels of soluble antibody. Many plasma cells are short-lived, but others survive for long periods of time, particularly in the bone marrow (Oracki et al., 2010).

Antibodies

The immunoglobulin antibody molecules are composed of two identical heavy polypeptide chains and two identical light polypeptide chains, held together by interchain disulfide bonds. All immunoglobulins are glycoproteins, containing between 2 and 14% carbohydrate depending on the antibody class (Arnold et al., 2007). The N-termini of the light and heavy chains are each folded into a variable domain containing three hypervariable loops, constituting the complementarity determining regions (CDRs) responsible for non-covalent binding to the antigen. Most epitopes recognized by antibodies are discontinuous, comprising amino acids that are only brought together upon protein folding (Muller and Jacoby, 2009). The heavy chain C-terminal domains form the constant region which specifies the class/subclass of antibody. The light chain constant domain determines the κ or λ isotype. The human antibody classes are IgG, IgA, IgM, IgD, and IgE, with four IgG (IgG1–4) and two IgA (IgA1–2) subclasses (Schroeder and Cavacini, 2010) (Table 5.2). Each antibody can be produced either with a hydrophobic transmembrane sequence to anchor the molecule in the B

cell membrane where it functions as the BCR or as a secreted molecule lacking the transmembrane sequence.

The basic antibody monomer (biochemically a tetramer) is bivalent with two antigen-binding arms of identical specificity. Secretory IgA at mucosal surfaces is a tetravalent dimer, whereas circulating IgM is most frequently a decavalent pentamer with a minor proportion of hexamers and tetramers. IgA and IgM polymerization is stabilized by a polypeptide J chain (Johansen et al., 2000).

Antibodies that are capable of inhibiting the binding of microorganisms or biological molecules (toxins, hormones, cytokines, and so forth) to their cellular receptors exert their effect independently of other immune system components and are referred to as neutralizing antibodies. Usually, however, antibodies do not function in isolation but are employed to activate the classical complement pathway and/or link antigen to Fc receptor-bearing cells. Antigens opsonized with IgG, IgA, or IgE bind to the appropriate Fc receptors (Fc γ R, Fc α R, or Fc ϵ R) on phagocytic cells (Powell and Hogarth, 2008). Alternatively, both IgG and IgE can mediate ADCC in which NK cells, monocytes, macrophages, and neutrophils bearing Fc γ receptors or macrophages, eosinophils, and platelets bearing Fc ϵ receptors are focused onto antibody-coated target cells or parasites (Graziano and Guyre, 2006). The target is destroyed by apoptosis using perforin and granzymes. IgE antibodies are also able to sensitize mast cells and basophils via the high affinity IgE receptor Fc ϵ RI and if cross-linked by antigen will trigger the release of inflammatory mediators.

The epithelial cell poly-Ig receptor transports dimeric secretory IgA produced by plasma cells underlying

TABLE 5.2 The Main Properties and Approximate Serum Concentration of Human Antibodies

| Antibody class/subclass | Serum conc. (approx.) | Major features include: |
|-------------------------|-----------------------|---|
| IgM | 1.5 mg/ml | Constitutes, together with IgD, the BCR on naïve B-cells. Secreted IgM acts mainly in the circulation and is the first antibody class to be produced in an immune response. Activates complement. Powerful agglutinin |
| IgG1 | 9 mg/ml | Most abundant antibody in the blood. Activates complement and enhances phagocytosis. Can cross the placenta |
| IgG2 | 3 mg/ml | Activates complement. Poorly transported across placenta |
| IgG3 | 1 mg/ml | Activates complement and enhances phagocytosis. Can cross the placenta |
| IgG4 | 0.5 mg/ml | Main effector function unclear. Can cross the placenta |
| IgA1 | 3 mg/ml | In secretory form protects mucosal surfaces |
| IgA2 | 0.5 mg/ml | In secretory form protects mucosal surfaces |
| IgD | 30 μ g/ml | Constitutes, together with IgM, the BCR on naïve B cells |
| IgE | 0.05 μ g/ml | In presence of antigen triggers release of inflammatory mediators from mast cells and basophils |

mucosal surfaces (Johansen and Brandtzaeg, 2004). On the luminal side of the epithelium the IgA is released by proteolytic cleavage of the receptor, leaving a fragment called secretory component still attached to the IgA. Secretory IgA acts to prevent microbial adhesion to the epithelial cell surface (Corthésy, 2010).

Another type of receptor, FcRn, is expressed on vascular endothelium where it is involved throughout life in the recycling of IgG in order to increase the circulating half-life of this class of immunoglobulin. It is also present in the placenta, where it transports IgG from the maternal to the fetal circulation, and on the intestinal epithelium of the neonate where it is involved in the uptake of IgG from maternal milk (Roopenian and Akilesh, 2007).

Secondary Lymphoid Tissues

The primary lymphoid organs, the bone marrow and thymus, are where fully differentiated mature naïve T and B cells are generated. However, activation of lymphocytes occurs in structurally organized B and T cell compartments in the secondary lymphoid tissues; the mucosa-associated lymphoid tissues (MALT), lymph nodes, and spleen. Large numbers of lymphoid cells are also present throughout the lung (Bienenstock and McDermott, 2005) and in the lamina propria of the intestinal wall (Dahan et al., 2007). Because only a handful of lymphocytes will be specific for a given antigen, T and B cells recirculate through the different lymphoid tissues in order to increase the chances of encountering antigen. While responses to blood-borne antigens are usually initiated in the spleen, those to antigens in the tissues are stimulated in the local draining lymph nodes.

Lymphoid follicles within the secondary lymphoid tissues contain germinal centers where B cell activation occurs within a meshwork of FDCs displaying immune complexes on their surface (Figure 5.11). T follicular helper cells are specialized for providing help to germinal center B cells (Vinuesa and Cyster, 2011). Germinal centers are at the heart of the generation of adaptive responses for it is here that B cells proliferate, class switch, undergo affinity maturation, and differentiate into memory cells and into plasma cell precursors (Gatto and Brink, 2010). B cells can increase the binding affinity of their BCR by somatic hypermutation of the V(D)J genes. Higher affinity clones will then be preferentially selected by antigen. Class switching from IgM to IgG, IgA, and IgE involves switch sequences composed of highly repetitive nucleotide motifs present immediately upstream of each constant region gene (except C δ , IgM and IgD being co-expressed as the BCR on naïve B cells). Both somatic hypermutation and class switching require the expression of activation-induced cytidine deaminase (AID) and the utilization of the nonhomologous DNA end-joining

(NHEJ) machinery (Lieber, 2010; Stavnezer, 2011). A process referred to as receptor editing enables self-reactive B cells to replace the variable region gene in the recombined VDJ heavy or VJ light chain sequence with a different variable region gene in order to eliminate auto-reactivity (von Boehmer and Melchers, 2010).

Most pathogens enter the body through mucosal surfaces. The palatine tonsils and adenoids are the sites for the induction of responses to intranasal and inhaled antigens (Brandtzaeg, 2011). Antigens from the gut are taken up by specialized epithelial microfold (M) cells which transport the antigens across the epithelium for access to the Peyer's patches where mucosal responses are initiated (Corr et al., 2008). Activated lymphocytes exit the Peyer's patches via the efferent lymphatics, traffic through the blood, and then home to the lamina propria and other mucosal effector sites (Brandtzaeg, 2009) (Chapter 22). Intraepithelial lymphocytes (IEL) are interspersed between the gut epithelial cells, have a diverse phenotype, and can be either cytotoxic or immunoregulatory (Cheroutre et al., 2011).

Lymphocytes enter lymph nodes, tonsils, and Peyer's patches either via the afferent lymphatics or from the blood via high endothelial venules (HEV). L-selectin is constitutively expressed on lymphocytes and constitutes a ligand for adhesion molecules referred to as peripheral lymph node addressins (Rosen, 2004). If increased expression of LFA-1 (lymphocyte function-associated antigen-1) is induced on the lymphocytes their adhesion to HEV is enhanced and they migrate across the HEV into these lymphoid tissues. Lymphocytes leave the lymph nodes via the efferent lymphatics. Although the spleen lacks HEV, circulating lymphocytes can directly access the marginal zone of this organ from the blood vessels. T cells locate mostly to the periarteriolar lymphoid sheaths, while B cells enter the lymphoid follicles. Lymphocytes exit the spleen via the splenic vein.

When naïve lymphocytes first encounter antigen in the secondary lymphoid tissues they mount a primary immune response, generating both effector and memory cells. The memory cells are responsible for the quantitatively and qualitatively superior secondary immune response that occurs upon any subsequent encounters with the same antigen (Zielinski et al., 2011). Memory cells have a lower activation threshold than naïve cells and the secondary response is more rapid, involves larger numbers of lymphocytes, and, for B cells, produces higher levels of antibody with a superior affinity for antigen.

The term T-independent antigen is used to refer to antigens which are capable of generating an antibody response without a requirement for helper T cells. Polysaccharides, polymerized flagellin, and a number of other antigens have repetitive determinants which can extensively cross-link the BCR and thereby directly activate the B cell (Möller, 2001). Because they do not

FIGURE 5.11 The germinal center. During the initiation of the acquired immune response, these structures form in the secondary lymphoid tissues in order to generate a microenvironment where all the necessary antigen-specific and innate antigen-presenting cells can interact. Antigen-stimulated B cell proliferation occurs in the dark zone and is accompanied by affinity maturation, due to somatic hypermutation (SHM) of the immunoglobulin V(D)J genes, and class switch recombination (CSR). Both SHM and CSR are associated with the expression of activation-induced cytidine deaminase (AID) in the B cell. Upon passage into the basal light zone, high affinity antigen-specific B cells are positively selected by interaction with antigen, which is present in the form of immune complexes on the surface of follicular dendritic cells. B cells which fail to be positively selected undergo apoptosis and are phagocytosed by macrophages. The positively selected cells migrate to the apical light zone where proliferation continues, and memory cells and plasma cell precursors are generated. *From Delves, P.J., Martin, S.J., Burton, D.R., Roitt I.M. 2011. Roitt's Essential Immunology, 12th ed. Wiley-Blackwell.*

recruit T cells, T-independent antigens fail to provoke the formation of germinal centers and therefore are unable to induce B cell memory, class switching, or significant amounts of affinity maturation. Thus, low affinity IgM antibodies are produced in response to T-independent antigens and, although involving B cells, the response does not go on to exhibit the characteristics of adaptive

immunity. The majority of antigens that stimulate B cells are, however, T cell dependent in that the B cell response requires help from T cells. As mentioned earlier, the BCR on the surface of the B cell internalizes bound antigen which is then processed into peptides for presentation by MHC class II molecules. Upon recognition of the peptide–MHC complex by the T cells in the secondary

lymphoid tissues, the costimulatory molecule CD154 (CD40 ligand) on the T cell engages CD40 on the B cell, leading to class switching (Ford and Larsen, 2009). In addition to cell surface molecules, cytokines play a key role in the mutual activation of the T and B lymphocytes. T cell help can also be recruited by DCs and macrophages presenting the relevant peptide–MHC class II combination to the helper T cell.

Resolution of the Immune Response

Antigen stimulates the immune response and therefore, for a foreign antigen, its clearance by the immune system will naturally lead to a waning of the response. However, there are additional mechanisms which initially amplify and subsequently downregulate the response. Once high levels of class-switched antigen-specific IgG are produced, the antibody can inactivate the antigen-specific B cells in a manner reminiscent of classical negative feedback loops in the endocrine system. Cross-linking of the BCR to Fc γ RIIB on B cells by immune complexes results in the transmission of inhibitory signals into the B cell (Smith and Clatworthy, 2010). A number of signals from cytokines and cell surface molecules can also be inhibitory. Ligation of the T cell surface molecule CTLA-4 by CD80 and CD86, and of PD-1 by PD-L1 and PD-L2, provide downregulating signals (Bour-Jordan et al., 2011). Some Foxp3⁺ regulatory T cells secrete IL-10, IL-35 and transforming growth factor β (TGF β) which can act in an immunosuppressive capacity, while others suppress responses by cell-contact-dependent mechanisms (Josefowicz et al., 2012).

Neuroendocrine interactions with the immune system provide a further level of regulation (Butts and Sternberg, 2008). For example, TLR ligands and inflammatory mediators such as IL-1 β result in efferent nerve signaling in the spleen, triggering the release of acetylcholine from splenic T cells which in turn inhibits the release of proinflammatory cytokines from macrophages in order to maintain immune homeostasis and thereby avoid an excessive inflammatory response (Andersson and Tracey, 2012).

INTRODUCTION

The immune system has evolved to defend against a wide array of pathogens, and optimal immune function requires coordinated responses from both the innate and adaptive systems. While the innate immune system utilizes a relatively small number of invariant receptors specific for conserved microbial products, such as the cell wall components of bacteria, the adaptive immune system makes use of a nearly unlimited repertoire of receptors generated by random recombination of the T and B cell receptor loci. Although random recombination allows for incredible lymphocyte receptor diversity, it comes at the price of generating potentially autoreactive receptors. The risk for self-reactivity is in part mitigated by checkpoints during lymphocyte development that eliminate most self-reactive clones (referred to as central tolerance) as well as mechanisms that limit the ability of self-reactive clones to mount responses in the periphery (referred to as peripheral tolerance). However, the existence of lymphocyte-dependent autoimmune disease is a clear indication that these mechanisms are imperfect and some self-reactive

lymphocytes are able to initiate destructive autoimmune inflammation.

Self-reactive CD4⁺ T helper cells (Th) play a crucial role in the pathogenesis of many human autoimmune diseases. This is in part due to the unique ability of Th cells to undergo further differentiation into distinct subsets that are specialized at recruiting and coordinating different immune effector mechanisms, largely via the secretion of particular sets of cytokines and chemokines (Figure 6.1). The differentiation of naïve Th cells into distinct subsets is dependent both upon recognition of cognate antigen—major histocompatibility complexes (MHC) as well as environmental cues, particularly cytokines, that drive different transcriptional modules. Although multiple factors are important for Th differentiation, in many cases a single transcription factor is crucial for initiating and stabilizing expression of the transcriptional module that defines a given Th subset (Figure 6.1). Additionally, there is a complicated interplay between the different Th subsets, as factors that are produced by one subset may inhibit the differentiation of another. Thus, understanding the factors that drive differentiation of Th subsets and the

FIGURE 6.1 Generation and function of Th subsets. Naïve CD4⁺ T cells are capable of differentiating into various effector and regulatory subsets. Th subsets are shown, along with the cytokines critical for differentiation, lineage-defining transcription factors, and effector cytokines.

effector mechanisms those Th subsets utilize to promote or inhibit tissue inflammation is important for understanding the pathophysiology of autoimmune disease.

TH1 CELLS

Approximately 20 years ago, Tim Mosmann and Robert Coffman (1986) published a seminal paper describing the heterogeneity of the effector CD4⁺ T cells that can be divided into two distinct subsets, Th1 and Th2 cells, so named because they were the first two to be described. Th1 cells play a critical role in inducing protective immune responses to extracellular pathogens such as *Mycobacterium tuberculosis* or intracellular pathogens like *Listeria monocytogenes* (Mosmann and Coffman, 1989a, b; Geginat et al., 1998; Neighbors et al., 2001; Viegas et al., 2007; Wan and Flavell, 2009). In response to certain microbial stimuli, dendritic cells and macrophages produce cytokines, including interleukin (IL)-12, IL-18, and type 1 interferons, that promote Th1 development by inducing expression of the transcription factor T-bet, the key transcriptional regulator of Th1 cells (Nakanishi et al., 2001; Szabo et al., 2003;

Wan and Flavell, 2009). While multiple cytokines are important for Th1 differentiation, IL-12 is particularly crucial. Thus, mice deficient for either IL-12 or the IL-12 receptor (IL-12R) chains have impaired Th1 differentiation and are extremely susceptible to intracellular pathogens (Mosmann and Coffman, 1989a, b). Upon binding to its receptor, IL-12 promotes Th1 lineage commitment by activating STAT4, which then enhances production of interferon (IFN)- γ , the hallmark cytokine of Th1 cells (Mucida and Cheroutre, 2010; Oh and Ghosh, 2013; Yamane and Paul, 2013). IFN- γ feeds back in an autocrine manner via activation of STAT1 to enhance T-bet expression thus further promoting Th1 polarization. T-bet then promotes further IFN- γ production by inducing chromatin remodeling of the IFN- γ locus (Szabo et al., 2003; Mucida and Cheroutre, 2010; Oh and Ghosh, 2013; Yamane and Paul, 2013). Finally, IFN- γ also inhibits the differentiation of naïve CD4⁺ T cells into other subsets, such as Th2 or Th17 cells (Schoenborn and Wilson, 2007). Thus, Th1 differentiation can be viewed as a feed forward loop, in which IFN- γ is first induced and then stabilizes lineage commitment.

The role of Th1 cells in inflammation and autoimmune pathology has been extensively studied and Th1 cells have been shown to play an important role in many organ-specific autoimmune diseases, including type 1 diabetes, multiple sclerosis (MS), inflammatory bowel disease (IBD), and rheumatoid arthritis (RA) (Szabo et al., 2003). Prior to the discovery of Th17 cells, an imbalance between Th1/Th2 subsets was proposed to be a key driver of autoimmunity, with skewing towards a Th2 phenotype being considered protective while Th1 predominance was felt to be pathogenic (Adorini et al., 1996a, b). For instance, animal studies revealed that transgenic expression of IL-4 on the pancreatic islets protected non-obese diabetic (NOD) mice from developing insulin-dependent diabetes mellitus (IDDM), while adoptive transfer of Th1 cell clones promoted diabetes (Katz et al., 1995; Mueller et al., 1996). IFN- γ producing Th cells were often found within the target tissue in multiple other organ-specific human autoimmune diseases, thereby implicating Th1 cells in disease pathogenesis. Subsequent studies in animal models of human diseases have further validated the importance of Th1 cells in causing immunopathology (Kuchroo et al., 1993; Lafaille, 1998; Oppmann et al., 2000; Neurath et al., 2002; Szabo et al., 2003).

In an animal model of MS, experimental autoimmune encephalomyelitis (EAE), Th1 cells have been shown to induce disease and play an important role in propagating epitope spreading, whereby infiltrating Th1 cells in the CNS induce inflammation and demyelination causing the release of new, previously sequestered antigens (Katz-Levy et al., 2000; Yin et al., 2001; Mack et al., 2003). Newly released antigens are then picked up and presented by antigen presenting cells (APCs) to induce activation of additional autoreactive T cells (McMahon et al., 2005). It is unknown how myelin-specific T cells are initially activated, particularly as myelin-associated antigens are sequestered within the CNS by the blood–brain barrier. One potential mechanism is that a viral infection may induce the activation of T cells that cross-react with myelin, a mechanism termed molecular mimicry. These cross-reactive T cells then attain a pathogenic effector phenotype, traffic to the target organ, and induce inflammation and tissue destruction, resulting in CNS autoimmunity (Schreiner et al., 2007; Chastain and Miller, 2012). Furthermore, IFN- γ has been shown to enhance effector function of scavenger APCs which may promote molecular mimicry as well as epitope spreading by the auto-reactive T cells and enhance autoimmune pathology (Karni et al., 2006; Smith and Miller, 2006; Schoenborn and Wilson, 2007). However, there is evidence to support that IFN- γ may not be the key cytokine responsible for pathogenic effector functions of Th1 cells in many autoimmune

conditions (Matthys et al., 1999; Chu et al., 2000; Trembleau et al., 2003; Zhang et al., 2012).

TH17 CELLS

Discovery and Differentiation

Although Th1 cells were thought to be the main drivers of organ-specific autoimmunity, animals lacking the Th1 signature cytokine IFN- γ or other molecules involved in the Th1 differentiation pathway, including IFN- γ R and STAT-1, are not resistant, but more susceptible to multiple autoimmune diseases including experimental autoimmune encephalomyelitis (EAE), experimental autoimmune uveitis (EAU), and collagen-induced arthritis (CIA) (Ferber et al., 1996; Jones et al., 1997; Matthys et al., 1998). Even more surprising, mice deficient for the IL-12 chain p35 were also more susceptible to EAE, whereas loss of the other chain of IL-12, p40, made mice highly resistant to EAE. This conundrum was solved when it was shown that p40 does not only pair with p35 to form IL-12, but can also pair up with another cytokine chain p19 to form a novel cytokine called IL-23 (Oppmann et al., 2000). In a seminal study, Cua and colleagues showed that loss of both p40 and p19 (IL-23) protected animals from EAE, whereas IL-12-p35-deficient animals, which lacked IL-12 and Th1 responses, remained susceptible to EAE (Cua et al., 2003; Langrish et al., 2005). These data provided the foundation for the hypothesis that IL-23 rather than IL-12 is crucial for the development of autoimmunity. It was later revealed that IL-23 is involved in the generation of a unique T cell subset, named Th17 cells, owing to their production of the effector cytokine IL-17.

Although generation of Th17 cells was initially thought to be driven by IL-23, naïve T cells do not express the receptor for IL-23 (IL-23R); rather, Th17 differentiation requires the presence of the cytokines TGF- β and IL-6 (Bettelli et al., 2006; Mangan et al., 2006; Veldhoen et al., 2006). In addition, IL-21 also induces Th17 differentiation, particularly in the absence of IL-6, and promotes self-amplification of Th17 cells in a feed-forward loop (Korn et al., 2007; Nurieva et al., 2007; Zhou et al., 2007). Finally, IL-1 β can synergize with IL-6 to induce murine Th17 cell differentiation (Chung et al., 2009), and, in conjunction with TGF- β , IL-6, and IL-21, has also been described as a critical differentiation factor for human Th17 cells (Manel et al., 2008; Yang et al., 2008a).

Upon engagement with their respective receptors both IL-6 and IL-21 induce phosphorylation of STAT3, which is crucial for proper Th17 differentiation (Yang et al., 2007). IL-6 and TGF- β signals ultimately lead to the expression of the Th17 lineage-specific transcription

factors ROR γ t and ROR α , which transactivate many Th17 signature genes including IL-17A and IL-17F, IL-23R, and the Th17-specific chemokine receptor CCR6 (Zhou and Littman, 2009; Yang et al., 2008b; Ciofani et al., 2012). In addition, the transcription factors IRF4 and BATF mediate the effects of IL-21 on Th17 differentiation and self-amplification and are required for the induction of ROR γ t (Huber et al., 2008; Schraml et al., 2009; Brüstle et al., 2007). A recent study demonstrated that BATF and IRF4 cooperatively bind to DNA and regulate chromatin accessibility, allowing subsequent binding of pSTAT3 and ROR γ t and initiation of the Th17-specific transcriptional program (Ciofani et al., 2012). Another factor that is involved in certain aspects of Th17 cell differentiation and regulation is c-Maf, which both enhances the production of IL-21 in Th17 cells, thereby contributing to the amplification of Th17 cells (Bauquet et al., 2009), and also increases production of IL-10 and represses production of IL-22, thus modulating Th17 effector functions (Rutz et al., 2011). The identification of ROR γ t as the Th17-lineage-specific transcription factor, together with the observation that transcription factors of other lineages, including T-bet and GATA-3, are dispensable for Th17 cell differentiation, established Th17 cells as an independent lineage (Bettelli et al., 2008). Moreover, recent studies examining transcriptional networks induced during Th17 differentiation have shown that antagonist transcriptional modules promote Th17 differentiation while at the same time suppressing development of other T cell subsets (Ciofani et al., 2012; Yosef et al., 2013).

Function

The Th17 signature cytokines IL-17A and IL-17F can form homo- or heterodimers and are partly redundant in their effector functions. They signal through a receptor complex composed of IL-17RA and IL-17RC, which is expressed on both hematopoietic cells and non-hematopoietic cells. IL-17 receptor signaling induces production of proinflammatory cytokines and chemokines, including IL-6, IL-1, TNF, CXCL1, CCL20, GCP-2, and IL-8, as well as anti-microbial peptides and matrix-metalloproteinases. Thus, Th17 cells promote tissue inflammation and neutrophil recruitment (Bettelli et al., 2008). Th17 cells are important for host defense against a variety of pathogens, most notably bacteria like *Citrobacter*, *Klebsiella pneumoniae*, and *Staphylococcus aureus*, as well as fungi such as *Candida albicans* (Bettelli et al., 2008). In humans, the critical role of IL-17 and Th17 cells in host defense is evident in the susceptibility of patients with genetic defects in the *IL17RA*, *IL17F*, or in the *STAT3* gene to *C. albicans* and *S. aureus* infections (Cypowyj et al., 2012).

Aside from host defense, Th17 cells have been primarily associated with autoimmune tissue inflammation. Thus, elevated levels of IL-17 were detected in several autoimmune diseases including MS (Matusevicius et al., 1999), RA (Aarvak et al., 1999), and psoriasis (Teunissen et al., 1998). In EAE, treatment with IL-17 neutralizing antibodies ameliorated disease (Hofstetter et al., 2005) and IL-17 deficient animals developed attenuated CIA and EAE (Nakae et al., 2003; Ishigame et al., 2009). Furthermore, therapies targeting Th17 cells or Th17 effector cytokines in humans have yielded positive results as ustekinumab, a human anti-p40 antibody, ameliorates both Crohn's disease and psoriasis (Papp et al., 2008; Sandborn et al., 2008), and anti-IL-17A antibodies were shown to be effective in the treatment of psoriasis, RA, and uveitis (Genovese et al., 2010; Hueber et al., 2010; Leonardi et al., 2012). In addition, proof-of-concept studies indicate that anti-IL-17 antibody may also be effective in reducing gadolinium-enhancing lesions in MS patients (Havrdová et al., 168, 28th ECTRIMS congress, Lyon, 2012). These studies established the importance of Th17 cells as a therapeutic target in several human autoimmune diseases.

Reciprocal Relationship with Tregs

Exposure of naïve T cells to TGF- β leads to expression of the transcription factor Foxp3 and differentiation into immunosuppressive regulatory T cells (Tregs). However, in combination with the proinflammatory cytokine IL-6, TGF- β induces ROR γ t and promotes Th17 differentiation (Bettelli et al., 2006; Veldhoen et al., 2006). The molecular basis for the reciprocal relationship between Tregs and Th17 cells lies in the ability of ROR γ t/ROR α and Foxp3 to physically bind to each other and antagonize each other's function (Zhou et al., 2008; Du et al., 2008). Thus, many factors have been shown to have opposite effects on Tregs and Th17 cells and modulate immune responses by shifting the balance between Tregs and Th17 cells. For example, IL-2 acts as a growth factor for Tregs while inhibiting Th17 cell differentiation, whereas IL-21 amplifies Th17 responses, but inhibits Treg expansion (Laurence et al., 2007; Liu et al., 2011). Similarly, retinoic acid promotes Treg differentiation, but inhibits Th17 cells (Mucida et al., 2007). Another example is the aryl hydrocarbon receptor (AhR), which promotes Th17 differentiation upon engagement with the natural ligand FICZ (Veldhoen et al., 2008a), but upon interaction with TCDD, a synthetic ligand, seems to primarily expand Tregs by enhancing Foxp3 expression (Quintana et al., 2008). Finally, recent studies reported that Hif-1 α , a metabolic sensor of hypoxia, enhances Th17 differentiation on a transcriptional level, while simultaneously attenuating Treg development by targeting Foxp3 for proteasomal

degradation (Dang et al., 2011; Shi et al., 2011). Importantly, the reciprocal relationship of Th17 cells and Tregs offers attractive opportunities for therapeutic interventions in autoimmunity, as future therapies may be able to simultaneously weaken Th17 and strengthen Treg responses.

The Role of IL-23 in the Generation of Th17 Cells

Although initial *in vitro* and *in vivo* differentiation of naïve T cells into Th17 cells does not require IL-23, generation of pathogenic Th17 responses *in vivo* is impaired in both IL-23 and IL-23R deficient mice (Langrish et al., 2005; Awasthi et al., 2009; McGeachy et al., 2009). Furthermore, several studies have demonstrated genetic linkage of *IL23R* to susceptibility to human autoimmune diseases including psoriasis, ankylosing spondylitis, and Crohn's disease (Duerr et al., 2006; Burton et al., 2007; Cargill et al., 2007; Liu et al., 2008), suggesting that IL-23 is also crucial for autopathogenic T cell responses in humans. Expression of the receptor for IL-23, which is composed of IL-12R β 1 and the specific chain IL-23R (Parham et al., 2002), is induced by IL-6 and TGF- β during Th17 differentiation and is further upregulated by IL-23 itself (Awasthi et al., 2009). IL-23 induces pSTAT3 and thus enhances IL-17 production and reinforces the Th17 transcriptional program. In addition, IL-23 also induces *de novo* production of the Th17 effector cytokine IL-22 (Liang et al., 2006; Zheng et al., 2007), which promotes epithelial growth and induces expression of acute-phase reactants and β -defensins, thus promoting barrier function (Wolk et al., 2010). Recent data also show that IL-23 drives re-expression of IL-7R α on Th17 cells (McGeachy et al., 2009), thus rendering Th17 cells responsive to IL-7, which may be important for terminal differentiation and survival/expansion of pathogenic Th17 cells (Liu et al., 2010). In addition to expanding and stabilizing Th17 cells, IL-23 is essential for inducing pathogenic effector functions in Th17 cells (see below). However, to date the signaling network downstream of IL-23R is not completely understood.

Th17 Pathogenicity and Plasticity

Numerous studies indicate that Th17 cells may come in different flavors and vary in terms of gene expression, effector functions and pathogenicity. Thus, adoptive transfer studies in EAE have shown that Th17 cells generated with TGF- β 1/IL-6 in the absence of IL-23 are non-pathogenic despite their production of IL-17 (McGeachy et al., 2007; Ghoreschi et al., 2010). In contrast, Th17 cells generated in the presence of TGF- β 1/IL-6/IL-23 or IL-1 β /IL-6/IL-23 or TGF- β 3/IL-6 are capable of inducing

severe autoimmune tissue inflammation (McGeachy et al., 2007; Jäger et al., 2009; Ghoreschi et al., 2010; Lee et al., 2012), indicating that abundance of TGF- β 1 together with relative lack of IL-23 during differentiation favors the generation of non-pathogenic Th17 cells, while the presence of IL-23 promotes the generation of pathogenic Th17 cells. In addition, other factors like IL-1 β fine-tune the effector phenotype of Th17 cells: thus, it was shown recently that IL-1 β enhances IL-23R expression via MyD88 and mTOR and thus promotes responsiveness of Th17 cells to IL-23 (Gulen et al., 2012; Chang et al., 2013). At the molecular level, the Th17 effector phenotype is a result of transcription factors that are differentially expressed in pathogenic vs. non-pathogenic Th17 cells. Thus, a recent study has identified pathogenic signature and non-pathogenic signature genes in Th17 cells, which determine the pathogenic properties of Th17 cells (Lee et al., 2012).

A prominent example for a pathogenic signature gene is *Csf2*, which encodes the cytokine GM-CSF. Importantly, GM-CSF has been associated with Th17 pathogenicity during EAE in two independent studies, and IL-23 and IL-1 β were shown to drive GM-CSF production in Th17 cells (Codarri et al., 2011; El-Behi et al., 2011). GM-CSF prompts antigen presenting cells to produce proinflammatory cytokines including IL-6 and IL-23, which amplify Th17 responses, and it also attracts a wave of secondary cells, primarily macrophages, which further propagate tissue inflammation (Codarri et al., 2011; El-Behi et al., 2011). In contrast, important examples for non-pathogenic signature genes are *cMaf* and *Il10*. Consistent with the role of IL-23 in promoting pathogenicity, expression of c-Maf and IL-10 is diminished by IL-23 and enhanced by TGF- β 1 (McGeachy et al., 2007; Ahern et al., 2010). IL-10 can limit autoimmune tissue inflammation by enabling Tregs to suppress Th17-induced inflammation (Chaudhry et al., 2011) and also by directly inhibiting proliferation of Th17 cells (Huber et al., 2011).

The Th1 transcription factor Tbet, which controls expression of IFN- γ , is also part of the pathogenic signature in Th17 cells. Although Th17 cells do not produce much IFN- γ *in vitro*, IL-17⁺IFN- γ ⁺ double producers are commonly seen in target organs of various autoimmune disease models, including the CNS during EAE (Ivanov et al., 2006; Abromson-Leeman et al., 2009) and the colon during colitis (Hue et al., 2006; Kullberg et al., 2006). Whether these cells arise from Th1 or Th17 cells has been much debated; however, fate-mapping experiments now indicate that IL-17⁺IFN- γ ⁺ double producers are derived from Th17 cells in an IL-23-dependent fashion (Hirota et al., 2011). Additionally, Th17 cells generated in the absence of IL-23 lose expression of IL-17 relatively easily and switch over/dedifferentiate into IFN- γ producers (Shi et al., 2008; Bending et al., 2009;

Lee et al., 2009 Jäger et al., 2009), while Th17 cells generated in the presence of IL-23 maintain stable IL-17 production, but often co-produce IFN- γ in the target organ (Mangan et al., 2006; Jäger et al., 2009; McGeachy et al., 2009; Liu et al., 2010). The co-production of the Th1 cytokine IFN- γ by Th17 cells emphasizes that Th17 cells are potentially more plastic than other Th subsets. However, whether production of IFN- γ by Th17 cells is beneficial or detrimental for the development of tissue inflammation and autoimmunity remains unclear. Analogous to the variety of Th17 effector phenotypes described in mice, human Th17 cells also show different effector phenotypes depending on the microenvironment. For instance, *C. albicans* infection generated an IL-1 β -rich cytokine milieu that prompted Th17 cells to co-produce IL-17 and IFN- γ , whereas *S. aureus* infection primed Th17 cells to produce IL-17 together with IL-10 (Zielinski et al., 2012). Similarly, different microenvironments in different tissues and target organs may cause Th17 cells to have slightly different cytokine profiles and effector functions in the various human autoimmune diseases.

Th17 Regulation in the Intestine

Under non-pathologic conditions, a population of Th17 cells exists in the small intestine, where they protect the organism from infections. Th17 cell differentiation in the intestine is triggered by certain commensal microbiota, especially by segmented filamentous bacteria (Ivanov et al., 2009; Huber et al., 2012), and under steady-state conditions Th17 populations in the intestine are kept in check by Tregs and immunosuppressive cytokines such as IL-10 (Huber et al., 2012). However, if not controlled, Th17 cells in the intestine may induce autoimmune tissue inflammation both directly in the intestine (Huber et al., 2012) as well as in distant organs. Indeed, recent studies demonstrated that Th17 differentiation triggered in the intestine by commensals can promote autoimmune tissue inflammation in the CNS during EAE and in the joints during arthritis (Wu et al., 2010; Berer et al., 2011). These data suggest that environmental factors such as diet can influence Th17 differentiation in the gut either directly or by modulating the composition of microbiota and thereby increase susceptibility to autoimmune diseases. In support of this hypothesis, two recent studies showed that a high salt diet increases Th17 differentiation in the gut and exacerbates development of autoimmune tissue inflammation during EAE (Kleinewietfeld et al., 2013; Wu et al., 2013). Importantly, the strong connection of Th17 cells with the gut also offers attractive therapeutic opportunities, as it might be possible to manipulate the effector phenotype of Th17 cells and reduce their pathogenicity with enterally targeted

therapeutics. Indeed, a recent study suggested that proinflammatory Th17 cells can be redirected to the gut and tolerized (Esplugues et al., 2011). A similar approach could potentially be beneficial in the therapy for human autoimmune diseases.

REGULATORY CD4⁺ T CELLS

While Th1 and Th17 CD4⁺ T cell subsets have been implicated in inducing autoimmune disease, regulatory CD4⁺ T cells (Tregs) represent a distinct Th cell subset that maintains self-tolerance and controls immune responses. The importance of T cells for controlling autoimmunity was first suggested by neonatal thymectomy experiments carried out by Nishizuka & Sakakura (1969), who found that thymectomy prior to day 7 of life led to the development of multi-organ autoimmune disease. Subsequent adoptive transfer studies found that transfer of purified populations of CD4⁺ T cells (CD45RB^{hi} or CD5^{lo}) into lymphopenic rodents led to the development of T cell-mediated autoimmunity that could be mitigated by co-transfer of CD45RB^{lo} or CD5^{hi} CD4⁺ T cells, suggesting the existence of a subset of CD4⁺ T cells with regulatory properties (Sakaguchi, et al., 1985; Powrie and Mason, 1990). Sakaguchi and colleagues further demonstrated that within the CD5^{hi} CD45RB^{lo} CD4⁺ T cell population the CD25⁺ subset was uniquely able to inhibit the development of organ-specific autoimmunity, whereas depletion of CD25⁺ cells was sufficient to cause multi-organ autoimmune disease (Sakaguchi et al., 1995). Subsequently, it was demonstrated that CD4⁺CD25⁺ T cells express Foxp3, the lineage defining transcription factor for Tregs (Hori et al., 2003), and spontaneous mutations in Foxp3 lead to the development of severe, multi-organ autoimmunity in both mice (*scurfy*) and humans (immunodysregulation polyendocrinopathy enteropathy X-linked syndrome) (Bennett et al., 2001; Wildin et al., 2001; Khattri et al., 2003). Thus, Foxp3-expressing CD4⁺CD25⁺ Treg cells are critical for maintaining peripheral self-tolerance in both mice and humans.

The number of genes directly regulated by Foxp3 is relatively small and does not encompass the majority of the genes that regulate Treg development, suggesting that other factors are equally critical to maintaining the Treg transcriptional program (Hill et al., 2007). Additionally, naïve human Th cells can upregulate Foxp3 upon activation without acquiring regulatory function (Gavin et al., 2006). Fate-mapping experiments in mice have also demonstrated a population of “ex-Tregs” that once expressed Foxp3, but no longer do so and readily produce effector cytokines such as IFN- γ and IL-17 (Zhou et al., 2009). Intriguingly, adoptive transfer of such “ex-Tregs” leads to rapid development of autoimmune disease, consistent with loss of regulatory and acquisition of effector

function. Thus, while expression of Foxp3 is a defining characteristic of Tregs, Foxp3 expression alone is not sufficient for stable regulatory function. Several groups have recently shown that Tregs possess a unique epigenetic pattern of DNA methylation (Floess et al., 2007; Schmidl et al., 2009; Wei et al., 2009; Ohkura et al., 2012). Acquisition of this methylation pattern begins during thymic development and does not require Foxp3 expression, although it does help to maintain Foxp3 expression and regulatory function *in vivo* and *in vitro* (Ohkura et al., 2012). Therefore, stable Treg differentiation depends upon both Foxp3 expression and a unique pattern of DNA methylation.

Tregs can develop both in the thymus (tTregs, formerly natural, or nTregs) and in the periphery (pTregs, formerly induced, or iTregs). While tTregs appear to primarily maintain peripheral tolerance to organ-specific antigens, pTregs are thought to be important in maintaining tolerance to exogenous but innocuous antigens the immune system encounters at mucosal sites. The neonatal thymectomy studies of Nishizuka and Sakakura highlighted the importance of thymus-derived tTregs in preventing organ-specific autoimmunity and raised the question of what drives their development in the thymus. One clear factor appears to be some degree of self-reactivity, as demonstrated by studies utilizing mice engineered to transgenically express T cell receptors (TCRs) of defined antigen specificity. On a recombination activating gene (RAG)-deficient background, foreign antigen-specific TCR transgenic mice had no tTregs, whereas on a RAG-sufficient background, tTregs were present and showed evidence of endogenous TCR α chain rearrangement (Itoh et al., 1999). Moreover, ectopic thymic expression of cognate foreign antigen was sufficient to allow tTreg differentiation in RAG-deficient TCR transgenic mice (Kawahata et al., 2002). Finally, the unique DNA methylation pattern seen in Tregs depended on TCR recognition of cognate peptide (Ohkura et al., 2012). These data therefore suggest a model in which tTreg development requires recognition of self-peptide/MHC complexes.

While specificity for self-antigen appears to be a critical factor in tTreg development and differentiation in the thymus, pTreg differentiation is controlled by the molecular context in which T cells are activated. Thus, the cytokine TGF- β has been shown to be important for development of pTregs both *in vivo* and *in vitro* via activation of SMAD3, which in turn binds to the CNS1 regulatory element within the Foxp3 gene and promotes pTreg differentiation in concert with other factors (Chen et al., 2003; Fantini et al., 2004; Kim and Leonard, 2007; Zheng et al., 2010). Interestingly, TGF- β can also promote Th17 differentiation in conjunction with inflammatory cytokines such as IL-6 (Bettelli et al., 2006).

Therefore, depending on the context in which the antigen is encountered, a T cell may be driven to differentiate into either a potentially inflammatory Th17 cell or a tolerogenic pTreg.

Treg expression of CD25, which along with CD122 and the common γ -chain (γ_c), makes up the high-affinity IL-2 receptor complex, highlights the importance of IL-2 in Treg biology. Because IL-2 was initially described as a growth factor for activated T cells, the finding that mice deficient in IL-2, CD25, or CD122 developed autoimmune and lymphoproliferative disorders was initially quite surprising (Schorle et al., 1991; Kramer et al., 1995; Suzuki et al., 1995). This apparent conundrum was resolved when mice deficient in IL-2 or its receptor components were found to have markedly reduced numbers of Foxp3⁺ Tregs in the periphery (Papiernik et al., 1998; Almeida et al., 2002; Malek et al., 2002). Subsequent studies clarified a critical role for IL-2 in supporting the peripheral survival and function of Tregs (Thornton et al., 2004; Fontenot et al., 2005). Administration of blocking antibodies to IL-2 or CD25 resulted in a marked decline in Treg cell numbers, whereas administration of IL-2 at low doses augmented Treg numbers (Setoguchi et al., 2005; Grinberg-Bleyer et al., 2010). This strategy has been extended to clinical trials, where administration of low dose IL-2 led to increased Treg frequency and clinical improvement in both graft versus host disease and hepatitis C-associated vasculitis (Koreth et al., 2011; Saadoun et al., 2011). Thus, IL-2 functions to support the peripheral homeostasis and function of Tregs, and is amenable to therapeutic modulation in T cell mediated inflammatory conditions.

The means by which Tregs control effector T cell responses is an area of active inquiry. *In vitro* proliferation suppression assays have demonstrated that Tregs can control effector responses both by acting directly on the responding effector T cell as well as indirectly, by modifying APC function. Regardless of the mechanism of action, Tregs require cell–cell interaction in order to exert their suppressive function *in vitro*. *In vitro* direct suppressive mechanisms include release of inhibitory cytokines, such as IL-10 and IL-35, restricting the bioavailability of IL-2, either by decreasing IL-2 transcription or by preferentially consuming IL-2, and direct granzyme-mediated cytotoxicity (Thornton and Shevach, 1998; Grossman et al., 2004; Collison et al., 2007; Pandiyan et al., 2007). In contrast, Tregs indirectly reduce effector T cell proliferation by altering APC function, either by inhibiting APC maturation (such as via LAG-3/MHCII interactions or catabolizing ATP released on tissue damage via CD39), or by reducing expression of B7-1 or B7-2 (Borsellino et al., 2007; Liang et al., 2008; Onishi et al., 2008). B7-1 and B7-2 downregulation is dependent upon Treg expression of CTLA-4, which

binds B7-1 and B7-2 and physically removes them from the APC via transendocytosis (Wing et al., 2008; Qureshi et al., 2011). Thus, Tregs are able to utilize a variety of molecular mechanisms to both directly and indirectly regulate effector T cell activation and expansion *in vitro*.

An intriguing finding is that while Foxp3-mutant *scurfy* mice uniformly develop spontaneous autoimmune disease, the nature of the pathogenic effector response varies depending upon the genetic background of the mice (Lin et al., 2005; Suscovich et al., 2012). Thus, modifier genes can exert significant influence on the ability of Tregs to control immune responses *in vivo* and suggests that Tregs may utilize distinct molecular mechanisms to control distinct effector responses. The hypothesis that Treg control of different effector subsets requires additional factors has been bolstered by the finding that Tregs can be induced to express transcription factors associated with these subsets and expression of these transcription factors is important for proper *in vivo* regulation of the associated effector subset. For instance, Tregs upregulate Tbet in response to either IFN- γ or IL-27, and Tbet in turn drives expression of CXCR3, facilitating Treg responsiveness to IFN- γ -dependent chemokines, such as CXCL10 (Koch et al., 2009, 2012; Hall et al., 2012a). Interestingly, while Tbet-deficient Tregs had normal *in vitro* suppressive activity (Bettelli et al., 2004), they failed to prevent lethal Th1-mediated autoimmune disease upon adoptive transfer into *scurfy* mice (Koch et al., 2009), suggesting that Treg-specific Tbet expression is crucial for proper regulation of Th1 responses *in vivo*. Similarly, expression of IRF4 or STAT3 appears to be critical for Tregs to properly regulate Th2 or Th17 responses *in vivo* (Chaudhry et al., 2009; Zheng et al., 2009). These findings support the idea that Tregs possess both a core module of regulatory factors that are generally required for their suppressive function, including Foxp3 and CTLA-4, as well as inducible modules specific for control of distinct effector Th subsets (Wing and Sakaguchi, 2012).

The multi-organ autoimmunity seen in both mice and humans with spontaneous mutations in Foxp3 shows that Tregs are vital in restraining potentially autoreactive Th cells and suggests that defects in Treg function may underlie the development of other autoimmune diseases. Supporting this, single nucleotide polymorphisms in multiple genes important for Treg function, including CTLA-4, IL-2, IL-2Ra, and IL-10, have been found to be risk alleles in genome-wide association screens for a number of autoimmune diseases, such as type 1 diabetes, RA, IBD, and MS (Howson et al., 2012; Vandembroeck, 2012). Moreover, there is evidence for some autoimmune diseases that the frequency of Tregs is altered, such as the finding that in IBD Treg frequency in the peripheral blood inversely correlates with disease activity (Takahashi et al., 2006; Saruta et al., 2007). Similarly, by

the careful immunophenotyping of circulating Tregs, Miyara et al. (2009) were able to distinguish resting and activated Treg populations and observed altered population dynamics in patients with active systemic lupus erythematosus (SLE). Finally, impaired Treg-mediated suppression of effector T cell proliferation has been demonstrated in some patients with MS, SLE, and diabetes mellitus (DM) (Viglietta et al., 2004; Alvarado-Sanchez et al., 2006; Kumar et al., 2006; Ferraro et al., 2011). Thus, alterations in Treg frequency and function are observed in human autoimmune disease, and pathways regulating Treg survival and function may represent promising therapeutic targets for treatment of human autoimmune diseases.

TR1 CELLS

Type 1 T regulatory (Tr1) cells are a recently identified Th subset that possesses regulatory function in the absence of Foxp3 expression, in large part via production of IL-10. Tr1 cell differentiation is dependent upon IL-27, a heterodimeric cytokine composed of EBI3 and p28, and additionally Tr1 cell differentiation can be amplified by TGF- β (Pot et al., 2011a; Hall et al., 2012a) IL-27 induces activation of STAT1 and STAT3, which have been shown to be essential for Tr1 differentiation (Hall et al., 2012b). Exogenous IL-27 also promotes transcription of c-Maf, IL-21, and ICOS, and subsequently IL-21 acts as an autocrine growth factor (Pot et al., 2009, 2011a, b; Hall et al., 2012b) indicating that IL-27 and IL-21 cooperate in the generation of Tr1 cells. To date, detailed functional characterization of Tr1 cells has been hampered by lack of specific markers that can reliably differentiate Tr1 cells from other IL-10 producing regulatory and effector T cell subsets. In addition, it is unclear whether Tr1 cells are only generated in the periphery or whether Tr1 cells are also generated through thymic selection, analogous to tTregs (Fujio et al., 2010).

Functionally, IL-27 treatment ameliorated EAE by increasing the frequency of IL-10 producing T cells and thereby suppressing IL-17 producing Th17 cells, suggesting it may be useful therapeutically (Kastelein et al., 2007). Furthermore, IL-27R α deficient mice were shown to develop exacerbated EAE (Batten et al., 2006). Intriguingly, recent clinical trials suggested that IFN- β , which is widely used as a first line treatment for MS, increased serum IL-27 levels (Sweeney et al., 2011). Some MS patients have been reported to have decreased IL-10 production (Ozenci et al., 1999), thus, the clinical efficacy of IFN- β in MS has been attributed to the induction of IL-27, consequently promoting an increased frequency of IL-10 producing Tr1 cells which can then potentially control auto-pathogenic T effector cells (Guo et al., 2008; Ramgolam et al., 2009; Sweeney

et al., 2011). Another area where regulatory cells are of high therapeutic value is organ transplants, such as pancreatic islet transplants in insulin-dependent diabetes mellitus (IDDM), where inadequate immunosuppression gives rise to graft rejection. A strong correlation has been described between transplant acceptance and frequency of circulating tTregs (Berney et al., 2009), as well as IL-10 production by peripheral blood mononuclear cells (Huurman et al., 2009), suggesting that tTregs play an important role in maintaining long-term tolerance. However, generation, expansion, and stability of antigen-specific Tregs remains a major challenge (Sagoo et al., 2008). Thus, an alternative to tTreg therapy is the adoptive transfer of *in vitro* generated IL-10 producing Tr1 cells that can sustain long-term survival *in vivo*. Indeed, the transfer of antigen-specific Tr1 cells prevented islet graft rejection in mouse models of islet transplant (Gagliani et al., 2010). Additionally, preliminary data indicate that adoptive transfer of host-specific Tr1 cells may prevent graft versus host disease (GvHD) in leukemia patients who underwent stem cell transplant (Allan et al., 2008; Bacchetta et al., 2010; Hippen et al., 2011; Roncarolo et al., 2011) supporting the potential value of Tr1 therapy in generating tolerance.

TFH CELLS

T cell-dependent antibody responses occur in germinal centers (GC) of lymphoid follicles and require interaction between antigen-specific B cells and Th cells (MacLennan et al., 1997; Garside et al., 1998). Recent evidence suggests that this interaction is mediated by a distinct Th subset, termed follicular T helper cells (TFH). These TFH cells are activated by antigen in the T cell zone of lymphoid tissues, and then migrate specifically to the outer edge of the B cell follicles in order to encounter antigen-specific B cells that have also migrated to this location (Vinueza and Cook, 2011). The homing of the TFH cells to the GC is dependent on a two-step chemotactic process that begins with the downregulation of CCR7, the receptor for the chemokines CCL19 and CCL21, which are produced in the T cell zone of the lymphoid tissue (Gunn et al., 1998; Ansel et al., 2000; Luther et al., 2000), followed by the induction of CXCR5, which allows TFH cells to migrate into the GCs (Breitfeld et al., 2000; Haynes et al., 2007). The downregulation of CCR7 and upregulation of CXCR5 is driven by the B cell lymphoma 6 protein (Bcl6), the master transcription factor regulating TFH cell differentiation. The stable induction of Bcl6 is also critically dependent on the physical interaction of T and B cells (Liu et al., 2012, 2013). In addition to CXCR5, TFH cells express the costimulatory molecule ICOS (inducible costimulator) and interaction of ICOS with ICOS ligand on B cells promotes the

differentiation of T cells to TFH cells (Ramiscal and Vinueza, 2013). TFH cell development also requires expression of the signaling molecule SAP and SLAM, an adaptor protein, as these are crucial for the induction of Bcl6 (Ramiscal and Vinueza, 2013). Deletion of Bcl6 prevents the generation of TFH cells and inhibits GC reactions, including affinity maturation, isotype switching, B cell proliferation, and generation of memory B cells and plasma cells (Nurieva et al., 2009a). The differentiation of TFH cells is mediated by IL-21 and IL-6, and TFH cells require STAT3 (Nurieva et al., 2008) and c-Maf for their generation (Bauquet et al., 2009). With the activation of Bcl6, TFH cells begin secreting their signature cytokine, IL-21, which has been shown to be essential for B cell survival and promoting germinal center reactions (Nurieva et al., 2008; Nurieva et al., 2009b). While other T helper subsets also produce IL-21, the amount of IL-21 produced by TFH cells is far greater compared to both Th1 and Th2 cells (Chtanova et al., 2004).

Immune responses that drive differentiation of other Th subsets may also give rise to distinct subtypes of TFH cells (King et al., 2008). For example, *in vitro* generated Th1 and Th2 cells have been shown to develop into TFH cells upon adoptive transfer. Consistent with the important role of cytokines in regulating isotype switching, TFH cells can secrete IFN- γ , IL-4, and IL-17, though at levels lower than conventional Th1, Th2, or Th17 cells. Thus, during the early stages of TFH cell development some cells may have upregulated CXCR5 but not yet turned on Bcl6 (Crotty, 2011). However, with entry into the follicle and upon interaction with B cells, Bcl6 expression increases, and TFH lineage commitment stabilizes, commensurate with downregulation of the Th1, Th2, and Th17 associated genes (Crotty, 2011). Thus, the ability of other Th subsets to give rise to TFH cells is likely crucial to appropriately coordinate humoral and cellular immune responses (Crotty, 2011). Collectively, TFH cells have emerged as a distinct T helper subset that provides critical help to B cells and regulates GC reactions, and as a result ultimately controls humoral immune responses.

A number of autoimmune diseases are characterized by the presence of self-reactive autoantibodies. It has been suggested that GCs may drive the pathogenic generation of autoantibodies. In animal models for SLE, for example, spontaneous generation of GCs correlated with increased serum concentration of autoantibodies (Luzina et al., 2001; Hsu et al., 2008). Cognate help from TFH cells has been demonstrated to promote the survival, expansion, and differentiation of self-reactive B cells, which ultimately resulted in autoantibody production and promoted tissue injury (Zhang et al., 2013). In addition, aberrant TFH cell function has been shown to promote development of disease in animal models of SLE and

RA, and is characterized by GC expansion, increased IL-21, and TFH cell expansion in extra-follicular sites (Zhang et al., 2013). In human autoimmune diseases, expansion of circulating TFH cells in patients with juvenile dermatomyositis, RA, SLE, and Sjögren's syndrome has been observed to strongly correlate with increased plasmablasts and serum concentrations of anti-dsDNA and antinuclear antibodies (Morita et al., 2011; Ma et al., 2012; Zhang et al., 2013). These observations are highly suggestive of the role that aberrant TFH cells may play in the pathogenesis of autoimmunity.

TH2 CELLS

Initially described for their distinct pattern of cytokine expression and their ability to promote IgE class-switching (Mosmann et al., 1986), Th2 cells are critical for amplifying and sustaining inflammation marked by eosinophil recruitment and mast cell activation. Th2 responses may be either protective, in the case of host defense against helminthes and other extracellular parasites, or detrimental and lead to the development of asthma and environmental allergies (Paul and Zhu, 2010; Pulendran and Artis, 2012). Th2 differentiation is induced by IL-4, which, upon binding a heterodimeric receptor consisting of IL-4R α and the γ_c -chain, results in the phosphorylation and activation of STAT6 and in turn induces expression of GATA-3. GATA-3 then transactivates many Th2-specific cytokines, most notably IL-4, IL-5, and IL-13, all of which share a common genetic locus (Zheng and Flavell, 1997). Th2 development results in significant chromatin remodeling at the *Ii4* gene locus, such that IL-4 production by established Th2 cells can be seen even after the conditional deletion of GATA-3 (Baguet and Bix, 2004; Zhu et al., 2004). The same molecular pathways that promote Th2 differentiation simultaneously counter-regulate the development of other effector Th subsets, particularly Th1 cells. For instance, GATA-3 can downregulate expression of Th1-promoting genes such as STAT4 and IL-12R β 2 (Zheng and Flavell, 1997). Additionally, the transcription factor c-Maf both transactivates the *Ii4* locus and induces downregulation of IFN- γ (Ho et al., 1996, 1998). Th2 differentiation is thus a powerful counter-regulator of Th1 differentiation.

The role of Th2 cells in autoimmune disease is complex. They have been implicated in facilitating isotype switching in SLE (Singh et al., 2003) and high levels of IL-4 and IL-13 are commonly seen in patients with systemic sclerosis, although the role of these cytokines in the pathogenesis of this disease is still unclear (O'Reilly et al., 2012). In contrast, many inflammatory autoimmune diseases show marked bias towards Th1 and Th17 responses and prior infection with a Th2 skewing pathogen can ameliorate EAE in mice (Sewell et al., 2003).

Moreover, many inflammatory autoimmune diseases have lower incidences in areas where parasitic infections are more common and longitudinal studies of MS patients with asymptomatic intestinal parasitemia suggest these patients have milder disease than uninfected controls (Correale and Farez, 2007). These observations have been extended to clinical trials assessing the efficacy and safety of administering ova from *Trichuris suis*, a pig nematode that is unable to productively infect humans, to patients with ulcerative colitis. Early studies showed clinically significant improvement in over 40% of patients with severe ulcerative colitis, compared to a placebo response rate of 17% (Summers et al., 2005), and larger scale trials are underway (Weinstock and Elliott, 2013). Additionally, glatiramer acetate, an immunomodulatory agent approved for use in MS, appears to be efficacious in part due to skewing the immune response towards a Th2-biased response (Arnon and Aharoni, 2004). Thus, Th2 counter-regulation of other Th effector subsets can be utilized clinically in inflammatory autoimmune disorders.

TH9 CELLS

Th9 cells, a recently identified Th subset generated by activating naïve Th cells in the presence of TGF- β and IL-4, produce both IL-9 and IL-10 (Dardalhon et al., 2008; Veldhoen et al., 2008b). The requirement for IL-4 in Th9 differentiation raises the question of whether Th9 cells represent a distinct lineage or are a subset of specialized Th2 cells, particularly given that both Th2 and Th9 cells can readily induce allergic airway inflammation (Chang et al., 2010; Staudt et al., 2010). Similar to Th2 cells, Th9 cells also require the transcription factors IRF4 and STAT6; however, IL-9 production is uniquely dependent upon the TGF- β -induced transcription factor PU.1, which, although expressed by other Th subsets, is not required for Th2 differentiation (Chang et al., 2010; Staudt et al., 2010; Goswami et al., 2012). Moreover, while myelin-specific *in vitro* differentiated Th2 cells failed to induce EAE upon adoptive transfer, transfer of Th9 cells resulted in robust disease, suggesting Th9 cells have distinct functional properties from Th2 cells (Jäger et al., 2009). However, Th9 cells do show considerable plasticity after adoptive transfer (Dardalhon et al., 2008; Jäger et al., 2009), leaving open the question of whether they represent a truly terminally differentiated Th subset.

CONCLUDING REMARKS

The functional diversity and plasticity of CD4⁺ T cells is crucial for successful host defense against diverse environmental pathogens but can also go dangerously awry in the setting of autoimmune disease. Recent years have

seen the identification of novel Th subsets as well as a remarkable growth in our understanding of the molecular mechanisms that underlie Th cell differentiation. In particular, the identification of Th17 cells and Tregs as distinct lineages has greatly furthered our knowledge of the pathobiology of a variety of autoimmune disorders and allowed the identification and development of novel therapeutic approaches. Recent work investigating the complex transcriptional networks involved in Th17 differentiation clearly illustrates the dynamic tension between transcriptional modules that enhance Th17 cell differentiation and inhibit development of other T cell subsets, thus providing the molecular basis for counter-regulation between Th subsets (Ciofani et al., 2012; Yosef et al., 2013). Although impairment of counter-regulatory mechanisms may lead to autoimmune tissue inflammation, these same pathways are amenable to modulation and offer opportunities for the development of novel immunomodulatory therapies for autoimmune diseases.

EARLY STUDIES SUPPORTING THE INDUCTION OF TOLERANCE

Some of the earliest evidence for immune tolerance came from studies examining the epidemiology of lymphochoriomeningitis virus (LCMV), a natural, non-cytopathic mouse pathogen. Traub observed that mice infected with LCMV *in utero* became lifelong carriers of the virus without producing significant quantities of anti-virus neutralizing antibodies (Traub, 1936, 1938). This observation suggested that a host could become tolerant to foreign antigens, as long as they had been “seen” early enough in development. A study published by Ray Owen in 1945 supported this idea. He found that non-identical twins became hematopoietic chimeras *in utero* and, as a result, they remained tolerant to antigens expressed on the other’s red blood cells (Owen, 1945). In 1953, a transplant surgeon by the name of Peter Medawar extended Owen’s observations by noting that non-identical twin cattle could also accept skin grafts from each other, suggesting that this tolerance was maintained throughout the life of the

non-identical twins. In 1953, Medawar et al. provided the most compelling evidence for immunological tolerance to date. In this study they injected allogeneic blood cells from one inbred mouse strain into newborn mice from a different inbred strain. They found that the donor blood cells engrafted, resulting in lifelong chimerism such that the recipient mice demonstrated significant tolerance to skin grafts that was specific for the foreign tissue antigens encountered neonatally (Billingham et al., 1953). Medawar went on to describe this phenomenon as actively acquired tolerance. The importance of actively acquired tolerance was highlighted in 1960 when Medawar shared the Nobel Prize in medicine with Frank MacFarlane Burnet for their collective work in acquired tolerance.

THYMIC TOLERANCE

Brief Overview of Thymocyte Development

The development of immature thymocytes into mature T cells can be followed by the expression of the cell surface

proteins CD4 and CD8 (Figure 7.1a). Initially, bone marrow-derived progenitors that enter the thymus do not express CD4 or CD8 and are referred to as CD4⁻CD8⁻ double negative (DN) thymocytes. Following T cell receptor (TCR) β chain rearrangement, only thymocytes expressing a functionally rearranged TCR β chain continue to mature. These thymocytes then upregulate both CD4 and CD8 to become CD4⁺CD8⁺ double positive (DP) thymocytes. At this DP stage, TCR α chain rearrangement is initiated and functionally rearranged TCR α chains are expressed on the cell surface with the TCR β chain. The production of TCR α and TCR β chains involves random rearrangement of gene segments, and, together with the additional diversity created by the rearrangement process, gives rise to thymocytes that have the potential to recognize a wide array of antigens including self-molecules (Starr et al., 2003). Thymocytes expressing TCRs that are unable to productively engage self-major histocompatibility complex (MHC) molecules die within a few days (death by neglect). Thymocytes expressing a TCR that is able to interact with low to intermediate affinity with self-MHC molecules are rescued from death and instead undergo positive selection (Shearer, 1974; Zinkernagel & Doherty, 1974). However, a strong interaction between the TCR and self-MHC molecules leads to the elimination of self-reactive thymocytes by a process referred to as negative selection (clonal deletion) (Werlen et al., 2003).

Mechanisms of Thymic Tolerance

Several events that occur in the thymus are critical for establishing and maintaining tolerance. Thymocytes that express receptors that are capable of recognizing self-antigens may undergo clonal deletion or clonal inactivation (anergy). In addition, an important subset of T cells known as regulatory T cells (Tregs) are selected in the thymus. These cells are essential for limiting the function of autoreactive cells and preventing the onset of autoimmunity.

Clonal Deletion

One of the major processes that occurs during thymocyte development is the elimination of many autoreactive T cells via clonal deletion. While clonal deletion had long been proposed to be a mechanism of self-tolerance, it wasn't until the generation of TCR-specific antibodies that Kappler et al. were able to provide the first definitive evidence of this (Kappler et al., 1987). Using a monoclonal antibody specific for the V β 17 segment of the TCR, they showed that V β 17⁺ T cells react with the class II MHC molecule I-E and are not present in the periphery of mice expressing I-E. They further found that immature DP thymocytes expressing the V β 17⁺ I-E reactive TCR were present in the

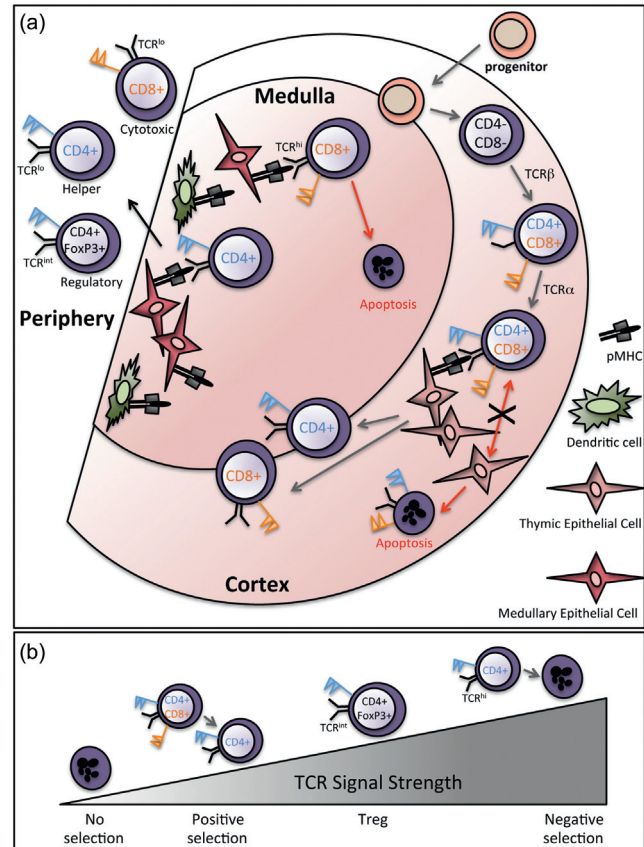

FIGURE 7.1 Thymocyte development in the thymus. (a) The development of thymocytes into mature T cells can be followed by the expression of surface markers including CD4 and CD8. Bone marrow-derived progenitors that enter the thymus do not express either CD4 or CD8 and are referred to as CD4⁻CD8⁻ double negative cells. Thymocytes expressing a functionally rearranged TCR β chain upregulate both CD4 and CD8 to become CD4⁺CD8⁺ double positive thymocytes. At this CD4⁺CD8⁺ DP stage, TCR α chain rearrangement is initiated and functionally arranged TCR α chains are expressed on the cell surface with the TCR β chain. The diverse array of TCRs now expressed by the developing thymocytes interact with self-MHC molecules expressed by thymic epithelial cells in a process referred to as positive selection. During this stage of development, thymocytes that do not interact with self-MHC molecules undergo apoptosis within a few days (death by neglect), while thymocytes that express TCRs able to functionally interact with self-MHC molecules with low to intermediate affinity are rescued from death and instead continue on in development to become CD4⁺ or CD8⁺ single positive thymocytes. However, thymocytes that bind to self-MHC molecules with high affinity are deleted in a process called negative selection. (b) The random rearrangements resulting in the TCR α and β chains result in a TCR repertoire with an array of specificities, and the affinity of the TCR with self-MHC determines the fate of the developing thymocytes. Those with TCRs not able to recognize or bind to self-peptides presented by self-MHC (pMHC) do not receive any signal through their TCR and die within a few days via apoptosis (death by neglect). Cells that receive extremely strong signals through their TCR due to high affinity interactions with self-MHC are deleted during negative selection so as to eliminate potentially autoreactive T cells. Thymocytes with TCRs that can recognize and bind to self-MHC with low to intermediate affinities (do not recognize “self”) during positive selection finish development and enter the periphery as mature, naïve T cells. T cells with high affinity TCRs that survive negative selection differentiate into CD4⁺FoxP3⁺ regulatory T cells (Tregs).

thymus of I-E⁺ mice suggesting that the I-E reactive thymocytes were deleted at later stages of development.

Further evidence for clonal deletion was provided by the use of TCR transgenic mice (Kisielow et al., 1988). In this model, the TCR α and β chains were taken from a CD8⁺ T cell clone that was specific for the male antigen H-Y presented by the MHC class I molecule H-2D^b. In female transgenic mice, the H-Y specific CD8⁺ T cells were positively selected by H-2D^b. However, there was a striking reduction in the number of DP thymocytes and mature CD8⁺ T cells in the male mice suggesting that H-Y-specific thymocytes were negatively selected during the DP stage of development. Many subsequent studies using monoclonal antibodies and TCR transgenic models supported the principle of clonal deletion as a key mechanism of tolerance (MacDonald et al., 1988; Sha et al., 1988; Pircher et al., 1989).

Anergy as a Mechanism for Self-Tolerance

In addition to clonal deletion, anergy has been proposed as an alternative mechanism of self-tolerance. The term anergy describes a T cell that is present but unable to respond to its cognate antigen because of earlier exposure to the same antigen (Nossal, 1983). Ramsdell et al. developed a novel model that supported anergy as a mechanism of thymic tolerance *in vivo* by following the induction of T cell tolerance to a minor antigen known as Mls-1^a. The Mls (minor lymphocyte stimulating) group of molecules was originally described by Hilliard Festenstein and these antigens were later shown to be derived from endogenous retroviruses (Festenstein and Kimura, 1988; Frankel et al., 1991; Marrack et al., 1991). Fowlkes' group generated chimeric mice in which Mls-1^b bone marrow was transplanted into irradiated Mls-1^a/Mls-1^b hybrid recipients (Ramsdell et al., 1989). The recipient bone marrow cells are sensitive to irradiation while the thymic epithelial cells are resistant, leading to the selective depletion of the bone marrow in the irradiated recipient. Thus, in the resulting chimeras, expression of the tolerizing Mls-1^a was limited to the thymic stroma. They found that the Mls-1^a reactive V β 6⁺ T cells, which were normally deleted in an Mls-1^a host, could mature and were found in the periphery. However, these mature V β 6⁺ T cells were unresponsive to activation by either Mls-1^a antigen or activating monoclonal antibodies, therefore demonstrating that T cells could be rendered unresponsive to antigen in the thymus and that anergy could be an alternative mechanism of self-tolerance.

Thymic Development of Regulatory T Cells Maintain Tolerance

Early work by many groups supported the presence of a population of cells known as the suppressor T cell that

could inhibit immune responses. However, in-depth molecular studies disputed the existence of this subset (Shevach, 2002). Nonetheless, strong evidence remained that a population of cells existed that could negatively regulate immunity, and this population was “reborn” as the Treg. Tregs (Figure 7.1a, b) develop in the thymus when CD4⁺ T cells receive a relatively strong signal that is below the threshold required to induce deletion (Feuerer et al., 2009). Thymus-derived Tregs are a cell population that prevents autoimmunity and plays an important role in modulating inflammatory immune responses. Early work found that neonatal thymectomy of some inbred lab rodent strains led to the development of autoimmunity (Nishizuka & Sakakura, 1969; Penhale et al., 1973), which eventually led to the identification of a subset of cells that could protect against autoimmunity. These studies showed that transfer of naïve CD4⁺ T cells into immunodeficient rats resulted in autoimmune diabetes and inflammatory bowel disease but that this autoimmunity could be blocked by the co-transfer of CD4⁺ T cells that expressed memory T cell surface markers (Powrie & Mason, 1990). This work was extended to mice when it was found that transfer of CD4⁺CD25⁻ T cells into young BALB/c mice resulted in autoimmune inflammation in several tissues, which could be suppressed with co-transfer of CD4⁺CD25⁺ T cells (Sakaguchi et al., 1995).

One key discovery in the field identified a gene that was critical for the development of Tregs by studying autoimmune disorders of mice and humans. FoxP3 was identified as the essential transcription factor required for the differentiation of CD4⁺CD25⁺ Tregs (Brunkow et al., 2001), and was shown to be the mutation that drives an autoimmune phenotype in scurfy mice. Importantly, FoxP3 mutations were also identified in patients with the severe and potentially fatal inflammatory disorder Immune dysregulation, Polyendocrinopathy, Enteropathy, X-linked (IPEX) syndrome (Chatila et al., 2000; Bennett et al., 2001; Wildin et al., 2001). Clinical symptoms vary between patients but commonly include type 1 diabetes, enteropathy, and eczema (Ochs et al., 2005). Subsequently, FoxP3⁺ thymus-derived Tregs, referred to as natural Tregs (nTregs), have been shown to suppress autoimmunity, allergy, and inflammation (Fontenot et al., 2003; Hori et al., 2003; Allan et al., 2005).

During T cell selection in the thymus, variations in TCR signaling events are central for T cell lineage fate determinations. It is therefore not surprising that there are particular requirements in TCR signaling for the induction of FoxP3 expression and Treg lineage commitment. Direct evidence indicating that Tregs are exposed to high affinity TCR signals came from studies using transgenic mice expressing a TCR specific for myelin basic protein in the absence of any endogenous TCR rearrangements

(RAG deficient). These mice developed inflammatory lesions in the brain, while a subset of T cell expressing endogenous TCRs was able to prevent this inflammatory disease in RAG-sufficient mice (Lafaille et al., 1994; Olivares-Villagomez et al., 1998). These studies and others point to a critical role of TCR specificity in the development of nTregs. In addition to TCR stimulation, CD28 costimulation is important for the differentiation and peripheral survival of nTregs as Treg frequencies are significantly reduced in CD28 or CD80/CD86-deficient mice (Salomon et al., 2000).

Expression of Tissue-Restricted Antigens in the Thymus

Negative selection of T cells in the thymus is essential for the elimination of self-reactive T cells during development. However, one of the conceptual caveats associated with negative selection was how T cells could be tolerized in the thymus to self-antigens expressed by tissues outside the thymus. This led to the possibility that negative selection would be incapable of establishing tolerance to self-antigens that are expressed only in peripheral tissues; for example, insulin in the pancreas. However, it has become increasingly clear that cells of the thymic stroma, originally dubbed “peripheral antigen expressing cells” (Jolicoeur et al., 1994; Smith et al., 1997), can express tissue-specific antigens (TSAs) to facilitate negative selection of autoreactive T cells. While it has since been shown that the thymic medullary epithelial cells (mTECs) express a wide array of self-antigens (Derbinski et al., 2001, 2005), it was still not known how this was regulated.

Work done by human molecular geneticists led to the discovery of a novel gene called the autoimmune regulator (AIRE). Mutations in this gene were responsible for a disorder called autoimmune polyendocrinopathy-candidiasis ectodermal dystrophy (APECED) or autoimmune polyendocrinopathy syndrome (APS-1), which is characterized by the progressive development of multiple, organ-specific autoimmune diseases (Aaltonen & Consortium, 1997; Nagamine et al., 1997). Initial analyses of AIRE indicated that it functioned by binding DNA based on the presence of conserved domains and clustering of disease-inducing mutations within those domains (Aaltonen & Consortium, 1997; Nagamine et al., 1997; Bjorses et al., 2000). Later, AIRE expression was shown in mTECs, suggesting a role for AIRE in regulating tolerance in the thymus, either by maintaining normal thymic architecture or by regulating interactions with T cells undergoing negative selection (Heino et al., 1999). Finally, studies showed that AIRE existed primarily as a nuclear protein in the mTECs (Aaltonen & Consortium,

1997; Nagamine et al., 1997; Heino et al., 1999), suggesting that it may ultimately be functioning as a transcription factor. Since both AIRE and peripheral tissue antigens were expressed in mTECs, it was speculated and later confirmed that AIRE is a transcription factor that controls the expression of many TSAs.

To further study the function of AIRE and its role in tolerance, two independent groups generated AIRE-deficient mice (Anderson et al., 2002; Ramsey et al., 2002). Similar to what was seen in the human disease setting, these mice developed spontaneous, organ-specific autoimmune disease, characterized by lymphocytic infiltrates and autoantibodies directed against a variety of peripheral organs and tissues including the salivary gland, retina, stomach, thyroid, and ovaries. These mice had no defects in T cell subsets or T cell function and the use of bone marrow chimeras and thymus grafts demonstrated that while AIRE expression in the radio-resistant cells of the thymic stroma was crucial for negative selection, loss of AIRE in the hematopoietic compartment did not significantly affect autoimmunity (Anderson et al., 2002). Having demonstrated that AIRE expression in the thymus was critical for the prevention of autoimmunity, Anderson et al. went on to show that AIRE promotes the expression of a multitude of TSAs in the mTECs. Accordingly, AIRE-deficient mice were shown to have severely disrupted expression of a variety of tissue-restricted antigens in the mTECs, which resulted in defective negative selection of tissue-specific T cells (Liston et al., 2003). However, it is also worth noting that the AIRE does not control the expression of all TSAs.

More recently, a transgenic mouse was made where AIRE expression can be repressed with the administration of doxycycline (Guerau-de-Arellano et al., 2009). This study found that perinatal expression of AIRE was crucial for its role in tolerance as these mice only developed autoimmunity if AIRE expression was repressed before the pups were weaned. Conversely, loss of AIRE expression after 21 days of age did not result in autoimmunity.

Therefore, AIRE can contribute to central tolerance by driving the expression of tissue-specific antigens to provide negatively selecting ligands to developing self-reactive thymocytes.

PERIPHERAL TOLERANCE

Not all self-reactive thymocytes are deleted during development and, as a consequence, various peripheral tolerance mechanisms are in place to control self-reactive T cells (Figure 7.2a, b). Perhaps the most compelling evidence for peripheral tolerance comes from studies exploring the importance of Tregs. Elimination of Tregs results in autoimmune disease demonstrating that there are a multitude of self-reactive T cells that must be kept in

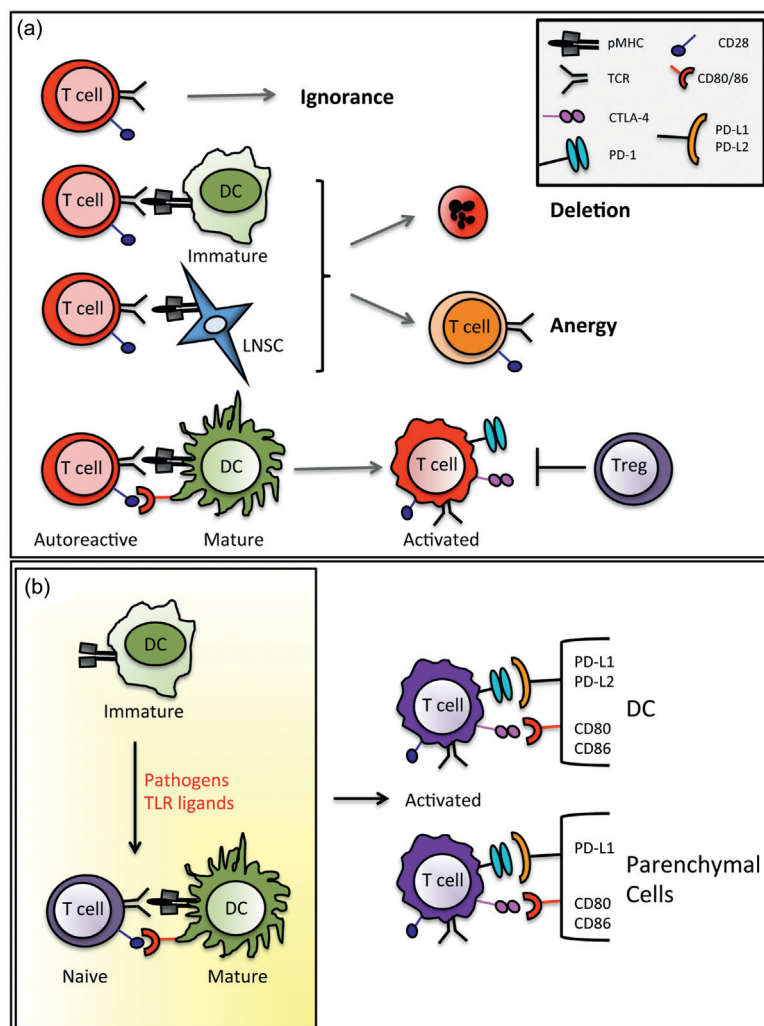

FIGURE 7.2 Mechanisms of peripheral tolerance.

(a) Not all self-reactive thymocytes are deleted in the thymus during central tolerance and as a consequence, peripheral tolerance mechanisms have evolved that allow mature T cells to be eliminated or rendered unresponsive to self-antigens to avoid autoimmunity. $CD4^+FoxP3^+$ Tregs can inhibit the activation or activity of activated, autoreactive T cells via a variety of mechanisms. Alternatively, if a T cell encounters antigen presented on a resting dendritic cell (DCs) or TSAs presented on lymph node stromal cells, the autoreactive T cells can be deleted or rendered unresponsive or anergic. If naïve, autoreactive T cells do not encounter antigen then they remain ignorant. (b) Interactions between naïve T cells and mature DCs is essential for both the initiation of an effective immune response as well as inducing tolerance. Engagement of Toll-like receptors, for example, on DCs leads to their maturation, which includes the upregulation of B7 family members such as B7-1/CD80 and B7-2/CD86. These are able to bind to the costimulatory receptor CD28 expressed on the surface of naïve T cells, leading to T cell activation. Coinhibitory receptors such as CTLA-4 and PD-1 are upregulated on the surface of activated T cells. CTLA-4 competitively binds to the B7-1 and B7-2 with higher affinity than CD28, thus contributing to the inhibition of active T cells. PD-1 binds to PD-L1 (B7-H1) and PD-L2 (B7-DC), which also sends an inhibitory signal to activated T cells. B7 family members are expressed on a variety of cells to contribute to immune homeostasis including DCs and tissue parenchymal cells.

check. This section will describe the various mechanisms that maintain self-tolerance, including deletion, anergy, ignorance, as well as control by suppressor cell populations such as Tregs. Importantly, one of the pivotal cells that regulates the decision between T cell tolerance and activation is the dendritic cell (DC). Therefore, DC biology plays a critical role in the induction and maintenance of tolerance.

Impact of Dendritic Cells

Dendritic Cells: Directors of Peripheral Immune Tolerance

In the thymus, engagement of high affinity TCR and peptide/MHC (pMHC) interactions generally lead to clonal deletion or anergy, while strong TCR signals in mature T cells are required to induce an effective immune response. How, then, can a mature T cell distinguish between a TCR-specific interaction that leads to activation vs.

tolerance? Solving this problem holds tremendous potential for solving clinical problems such as transplant rejection, autoimmunity, and tumor immunology.

Early work suggested that the induction of an immune response required the presence of adjuvants such as lipopolysaccharide (LPS). When LPS (a component from Gram-negative bacteria) was given with antigen *in vivo*, a functional immune response was induced, while antigen administered in the absence of LPS resulted in tolerance induction (Dresser, 1961; Claman, 1963). Further work studying allograft rejection and tolerance led to the “passenger leukocyte concept,” which suggested that APCs from the donor were critical for eliciting graft rejection (Lafferty & Cunningham, 1975; Talmage et al., 1976; Lafferty et al., 1983). Other models proposed that the adaptive immune system is induced by two signals, an antigen-specific signal 1 with a costimulatory signal 2. This model predicted that signal 1 alone led to the induction of tolerance. The discovery of CD28, a T cell costimulatory receptor constitutively expressed on the surface

of most T cells, fulfilled the role of signal 2 (Linsley et al., 1990; Harding et al., 1992).

DCs have been shown to be the key APC that can activate T cells (Steinman & Cohn, 1973). Groundbreaking work by many groups has demonstrated that adjuvants such as LPS can cause DCs to mature, via receptors known as the Toll-like receptors (TLRs) (Medzhitov et al., 1997; Poltorak et al., 1998; Akira et al., 2006). DC maturation is now known to occur downstream of many stimuli, such as NOD-like receptor (NLR) or RIG-like receptor stimulation. Various studies subsequently demonstrated that the maturation state of the DC determines the outcome of T cell tolerance vs. activation (Figure 7.2a, b) (Garza et al., 2000; Dhodapkar et al., 2001; Hawiger et al., 2001). TCR-specific interactions between resting DCs and T cells result in tolerance (anergy and/or deletion), while antigens encountered on mature DCs induce immunity. Importantly, upon DC maturation, a number of molecules including the ligands for CD28, CD80 (B7-1), and CD86 (B7-2), are upregulated, which contributes to optimal T cell activation (Figure 7.2b) (Linsley et al., 1990; Azuma et al., 1993; Freeman et al., 1993; Steinman et al., 2003). Additionally, DC maturation invokes the upregulation of other costimulatory and coinhibitory ligands that control T cell activation, as well as the induction of proinflammatory cytokines such as IL-12, IFNs, TNF, and chemokines, which all impact the function, survival, and migration of cells of the adaptive immune response (Reis e Sousa, 2006; Iwasaki & Medzhitov, 2010; Kawai & Akira, 2010).

Molecular Programming of Resting DCs is Critical for Preventing Autoimmunity

Previous evidence suggested that resting DCs were a default state and that adaptive immunity was controlled by various signals that led to DC maturation. However, recent studies have provided compelling evidence that the resting or immature DC state is programmed by molecular pathways. Perturbing these pathways by removing negative regulatory molecules leads to an altered DC state that is able to activate T cell responses and contribute to autoimmunity *in vivo* (Figure 7.3).

The first evidence that DCs are not tolerogenic by default, but are instead actively maintained in a resting state, came from a study investigating the functions of NF- κ B1 in DCs (Dissanayake et al., 2011). NF- κ B1 belongs to a family of transcription factors that are critical regulators of both the innate and adaptive immune systems (Vallabhapurapu & Karin, 2009). This family is composed of homo- and heterodimeric protein complexes containing RelA, RelB, c-Rel, as well as p50 and p52 which are processed by the proteasome from the precursor proteins NF- κ B1 and NF- κ B2, respectively. In unstimulated cells, NF- κ B complexes are sequestered in the cytoplasm by inhibitory I κ B proteins. NF- κ B activating signals trigger the degradation of I κ B allowing NF- κ B to translocate to the nucleus. The function of NF- κ B1 in DCs was of particular interest as it has linked to both the initiation and inhibition of gene transcription. Upon TLR stimulation, NF- κ B1 p50 can heterodimerize with p65 to promote the transcription of proinflammatory genes

FIGURE 7.3 Molecular programming of resting DCs. Resting DCs can mature in response to a variety of stimuli including pathogens or other TLR ligands. After maturation, DCs upregulate several cell surface receptors including MHC and B7 family members such as CD80 and CD86. Mature DCs can contribute to autoimmunity, in part through the activation of autoreactive T cells. Alternatively, if the molecular programs that normally maintain DCs in their resting state are perturbed then these deregulated DCs can also interact with autoreactive T cells to induce autoimmunity. An example of this is NF- κ B1. In normal, resting DCs, the p50–p50 homodimers act as transcriptional repressors and prevent the expression of proinflammatory cytokines such as TNF- α . However, in the absence of NF- κ B1, the repressive p50 homodimers are lost and p50–p65 heterodimers are now able to bind the TNF- α promoter to induce its expression, ultimately resulting in the induction of autoimmunity.

(Sha et al., 1995). Conversely, p50 is also found in transcriptionally repressive homodimers in many unstimulated cells, including DCs (Carmody et al., 2007).

Ohashi et al. developed a novel *in vivo* system that can evaluate the role of defined pathways and genes in DC function in which the induction of CD8⁺ T cell-mediated autoimmunity is dependent upon self-antigen presentation by DCs that have been matured by TLR stimulation (Dissanayake et al., 2011). Using this model they found that NF- κ B1-deficient DCs do not require TLR-induced maturation to initiate self-reactive CTL activity *in vivo*. These “immature” NF- κ B1-deficient DCs did not express increased levels of classic DC maturation markers (CD80/CD86/CD40) or IL-12. Furthermore, the immature NF- κ B1-deficient DCs spontaneously expressed TNF- α , which is normally seen only after maturation. Ultimately, these DCs were able to induce autoimmunity *in vivo*, suggesting that NF- κ B1 is required to maintain DCs in a quiescent state. The importance of these findings may be highlighted by an identified polymorphism in the NF- κ B binding site on the TNF promoter region (Udalova et al., 2000) that results in reduced binding by p50 homodimers. This polymorphism has been linked to autoimmune disease in humans including type 1 diabetes (Seki et al., 1999; Li et al., 2008; Stayoussef et al., 2010) and may be the result of aberrant DC maturation leading to activation of autoreactive T cells.

The idea that DCs are actively maintained in a resting state was supported by other studies that found that the absence of the ubiquitin-editing molecule A20 in DCs also resulted in spontaneous DC maturation resulting in activation and expansion of CD8⁺ T cells and autoimmunity (Hammer et al., 2011; Kool et al., 2011).

A20 is an ubiquitin-binding protein that also has deubiquitinating and E3 ligase activity. It is upregulated in most cell types in response to proinflammatory cytokines and can inhibit the activation of NF- κ B in response to TNF- α or IL-1 (Jaattela et al., 1996; Song et al., 1996). In addition to TNF- α -mediated inflammation, A20 can restrict activating signals from TLRs and NLRs, as well as from CD40, by limiting NF- κ B signaling (Lee et al., 2000; Wertz et al., 2004). A20-deficient mice spontaneously develop a lethal, multi-organ inflammatory condition and die perinatally (Lee et al., 2000). Additionally, these mice were extremely sensitive to other inflammatory stimuli, as well as sub-lethal doses of TNF- α , IL-1, or LPS. These studies have clearly established A20 as a critical negative regulator of NF- κ B that is essential in the maintenance of immune homeostasis. Given the critical role for A20 in restricting diverse activating signals that are important for DC maturation, a conditional knockout in which only the DCs are A20 deficient was generated to determine if DC-derived A20 was important for regulating immune homeostasis (Hammer et al., 2011).

This study demonstrated spontaneous maturation and activation of A20-deficient DCs, as well as the spontaneous development of lymphocyte-dependent colitis, seronegative ankylosing arthritis, and enthesitis, conditions that mimic inflammatory bowel disease (IBD) in humans, suggesting that A20 in DCs is required to retain them in their quiescent state, preventing spontaneous autoimmunity. Again, the importance of these findings may be highlighted by the identification of single-nucleotide polymorphisms (SNPs) in the human A20 gene, which have been associated with several human autoimmune diseases, including systemic lupus erythematosus, rheumatoid arthritis, psoriasis, and celiac disease (Plenge et al., 2007; Musone et al., 2008; Elder, 2009; Trynka et al., 2009). The identification of these mutations suggests that altered A20 function contributes to autoimmunity.

Collectively, these studies identify intrinsic factors within DCs that are programmed to inhibit the ability of the DC to activate the adaptive immune system. They further demonstrate that the functions of DCs are regulated even in the absence of external stimulation and that the removal of these repressive mechanisms can result in the activation of autoreactive T lymphocytes.

Mechanisms of Peripheral Tolerance

Clonal Deletion

If T cells recognize antigens presented by resting DCs, tolerance may occur by clonal deletion (Figure 7.2a). This mechanism of peripheral tolerance was demonstrated *in vivo* by a number of different groups. Collectively, these studies showed that TCR stimulation of mature, peripheral T cells in the absence of costimulatory and proinflammatory signals results in several rounds of proliferation. This proliferative burst is short-lived, however, and tolerance is ultimately induced. Either the daughter cells were deleted or they failed to form into fully functional helper, cytotoxic T cells or memory cells.

In one of the earliest studies analyzing peripheral T cell tolerance, Mls-1^a-expressing splenocytes were infused into thymectomized Mls-1^b mice (Webb et al., 1990). The Mls-1^a reactive V β 6⁺ T cells initially expanded but were eliminated from the T cell repertoire. Studies looking at T cell responses to exogenous antigens such as Staphylococcal enterotoxin B (SEB) found similar observations (Kawabe & Ochi, 1990). Collectively, these studies suggested that while exposure of T cells to exogenous antigens in the absence of microbial or adjuvant costimulation resulted in limited T cell activation, the response was generally aborted and ultimately led to the deletion of reactive cells.

Further studies using transgenic models showed that self-antigen specific T cells were tolerized by presentation

of self-antigen in lymph nodes that drain particular tissues. For example, in a study by Kurts et al., OVA-specific CD8⁺ T cells were transferred into recipients expressing a membrane-bound form of the OVA antigen on their pancreatic islet cells and in the kidneys (Kurts et al., 1997, 1998). The OVA-specific T cells underwent expansion in the pancreatic and kidney draining lymph nodes where they had encountered antigen cross-presented by immature DCs. Additionally, the expanded OVA-specific CD8⁺ T cells displayed an active phenotype and had CTL activity. Nevertheless, the OVA-specific T cells were subsequently almost entirely deleted from the T cell repertoire, demonstrating deletion as a mechanism of peripheral tolerance. Importantly, these studies demonstrated that cross-presentation of self-antigens *in vivo* leads to cross-tolerance.

Anergy as a Mechanism of Peripheral Tolerance

While engagement of the TCR on mature T cells with cognate antigen in the periphery can result in deletion, some antigen-specific T cells remain in the peripheral T cell repertoire in a hyporesponsive state (Figure 7.2a). The first direct evidence for anergy as a tolerance mechanism came from *in vitro* studies in which antigens expressed on chemically fixed APCs were used to induce T cell anergy. These studies found that when T cells were incubated with high concentrations of their cognate peptide antigens in the absence of APCs, the T cells became unresponsive to restimulation with the same antigen presented by stimulatory APCs. However, these hyporesponsive T cells could be rescued through the addition of exogenous IL-2, a cytokine known to drive T cell proliferation (Jenkins & Schwartz, 1987; Mueller et al., 1989).

This *in vitro* work was extended to *in vivo* models by a number of groups. Rammensee et al. transferred Mls-1^a-expressing cells into Mls-1^b positive recipients (Rammensee et al., 1989). After the initial expansion and deletion of the Mls-1^a-reactive Vβ6⁺ T cells, the authors noted that Vβ6⁺ T cells remained in the periphery but were unable to respond to restimulation by Mls-1^a antigen. In the early 1990s, Rocha et al. furthered this work by utilizing the male-specific antigen (H-Y). Rocha et al. transferred H-Y-specific CD8⁺ T cells isolated from female TCR transgenic mice into nude male mice (Rocha and von Boehmer, 1991). After deletion of most of these cells in the male recipients, the authors noted that any H-Y-specific T cells that remained in the peripheral repertoire failed to respond to restimulation with male cells or anti-H-Y TCR antibodies, suggesting that they had been inactivated. They also noted that if these anergic T cells were transferred into female mice that do not express the H-Y antigen, the anergic T cells recovered and could now

respond to and proliferate in response to antigen. This suggested that anergy induced during tolerance requires persistent exposure to antigen.

Ignorance

Not all autoreactive T cells are deleted or inactivated in the thymus or in the periphery. Instead, if T cells are unable to detect self-antigen then they may remain in the peripheral repertoire in an “ignorant” state (Figure 7.2a) (Ohashi et al., 1991; Oldstone et al., 1991).

Ignorance was first clearly demonstrated by Ohashi et al., in which a viral glycoprotein (LCMV-gp) was expressed in the pancreatic islet cells under the control of the rat insulin promoter (RIP-gp) (Ohashi et al., 1991). These mice were crossed to the P14 TCR transgenic mice, expressing a TCR specific for the LCMV-gp. Examination of the mature T cell repertoire in both the RIP-gp and P14/RIP-gp mice clearly showed that the islet-specific T cells were not deleted in the thymus or tolerized in the periphery. Despite the presence of mature, islet-specific T cells in these mice, they did not develop spontaneous autoimmunity. However, LCMV infection of either RIP-gp or P14/RIP-gp mice resulted in the induction of diabetes, due to the activation and cytotoxic activity of the LCMV-gp-specific CD8⁺ T cells. Other studies have shown similar results in which autoimmunity can be induced by immunizing animals with tissue-specific antigens in the presence of adjuvant, leading to the activation of autoreactive T cells (Kuchroo et al., 2002). Collectively, these studies suggest that T cells are not all tolerized in the presence of antigen and instead may remain “ignorant.” Immunological ignorance may be a consequence of undetectable or low levels of self-antigen presentation (Kurts et al., 1999).

Induced Regulatory T Cells and the Maintenance of Peripheral Tolerance

FoxP3⁺ Tregs were originally identified as a population of cells that arise in the thymus. However, it is now appreciated that Tregs also develop in the periphery from naïve CD4⁺ T cells and are commonly referred to as induced Tregs (iTregs) (Josefowicz et al., 2012). While the essential role for nTregs in the control of dysregulated immune responses has been well characterized, the role of iTregs has been harder to understand, in part due to the existence of subsets of iTregs that are distinct in both their development and mechanisms of action. While both nTregs and iTregs limit inflammation, several key differences have been reported.

Several specialized subsets of iTregs have been identified, the best characterized of which are FoxP3⁺ iTregs and the IL-10-producing type 1 Tregs (Tr1). Tr1

cells were first described in severe combined immunodeficient SCID patients who had long-term tolerance to stem cell allografts but have since been described in a variety of settings (Battaglia et al., 2006) and their importance in tolerance is well appreciated. Tr1 cells develop when a naïve T cell encounters a tolerogenic APC in the presence of IL-10 (Levings et al., 2005) and function through the inhibition of T cells and other immune cells in an IL-10 and TGF- β -dependent manner. Currently Tr1 cells are defined by their cytokine profiles. These cells express exceptionally high levels of IL-10, an immunosuppressive cytokine that is critical in the maintenance of tolerance, and are a central mediator of cytokine-dependent immune regulation in both humans and mice (Bacchetta et al., 1994; Groux et al., 1997; Roncarolo et al., 2006). In addition to IL-10 and TGF- β , Tr1 cells express low levels of IL-2 and variable levels of IL-5 and IFN- γ (Gregori et al., 2012). In contrast to FOXP3⁺ iTregs, Tr1 cells only transiently express FOXP3 following activation (Allan et al., 2008), a phenomenon observed in all human CD4⁺ T cells (Allan et al., 2007). Although Tr1 cells require TCR activation to acquire suppressive function, they are able to mediate “bystander suppression” against cells that recognize other antigens. Tr1 cells specific for self-antigens can be isolated in a variety of settings including desmoglein3 in pemphigus patients (Veldman et al., 2004) and islet antigens in diabetes patients (Tree et al., 2010). Foreign antigen-specific Tr1 cells have also been observed in celiac disease and allergy patients (Cavani et al., 2000; Akdis et al., 2004; Gianfrani et al., 2006; Meiler et al., 2008).

FoxP3⁺ iTregs are phenotypically and functionally similar to thymus-derived nTregs. While they may only contribute minimally to peripheral tolerance under homeostatic conditions (Almeida et al., 2006; Wong et al., 2007), FoxP3⁺ iTregs are a natural consequence of protective immunity and develop in parallel to that of effector CD4⁺ T cells. The resulting FoxP3⁺ iTregs likely control the escalating T effector cell responses and limit damage to tissues (Kang et al., 2007). These cells express typical nTreg markers including FoxP3, CD25 and TGF- β (Tran et al., 2007; Horwitz et al., 2008). However, surface expression of Helios on nTregs may differentiate them from FoxP3⁺ iTregs (Thornton et al., 2010). FoxP3⁺ iTregs suppress a wide variety of immune cells including naïve and memory CD4⁺ and CD8⁺ T cells, B cells, monocytes, and DCs (Lin et al., 2002; Lim et al., 2005; Miyara & Sakaguchi, 2007; Tiemessen et al., 2007). Therefore, while many different subsets of Tregs have been described, they likely work together to maintain immune homeostasis. It is also clear that both nTregs and iTregs contribute to the induction and maintenance of tolerance.

FoxP3 expression appears to be induced at particularly high levels at mucosal sites, possibly due to the presence of specialized tolerogenic DCs and cytokines. CTLA-4, which is not required for nTreg differentiation, is required for TGF- β -mediated induction of FoxP3 expression *in vitro* (Zheng et al., 2006). Conversely, CD28 cross-linking was shown to inhibit FoxP3 expression (Kim & Rudensky, 2006; Benson et al., 2007). Collectively, these studies indicate that high-affinity TCR signaling, in conjunction with suboptimal costimulation, favors induction of FoxP3 expression and conversion of peripheral CD4⁺ T cells into iTregs.

The cytokine environment is also important for development of iTregs. TGF- β is able to induce FoxP3 expression in CD4⁺ T cells *in vitro* and *in vivo* (Chen et al., 2003; Selvaraj & Geiger, 2007). However, there is debate as to whether TGF- β alone converts naïve CD4⁺ T cells into stable iTregs. There is also a subset of peripheral CD4⁺FoxP3-negative cells that upregulate FoxP3 in response to IL-2 alone (Schallenberg et al., 2010) and many studies have determined that IL-2 cooperation with TGF- β promotes the differentiation of stable iTregs *in vitro* (Davidson et al., 2007; Horwitz et al., 2008). Additionally, retinoic acid, in conjunction with TGF- β and chronic antigen exposure in some tissues promotes iTreg development (Benson et al., 2007). Clearly, the microenvironment is an important contributor to iTreg differentiation.

While the importance of Tregs to immune homeostasis is clear, the mechanisms whereby they suppress immune responses have been widely debated (Schmidt et al., 2012). Tregs inhibit the proliferation and inflammatory cytokine production of effector T cells by both direct and indirect mechanisms and can suppress the activation and maturation of APCs (Allan et al., 2008). While suppression of T cells requires cell contact *in vitro*, *in vivo* many mechanisms have been reported including the production of immunoregulatory cytokines IL-10, IL-35, and TGF- β (Ostroukhova et al., 2004; Von Boehmer, 2005; Uhlig et al., 2006; Collison et al., 2007), induction of indoleamine 2,3-dioxygenase in target cells (Fallarino et al., 2003), adenosine (Bopp et al., 2007; Deaglio et al., 2007), and by inducing apoptosis in target cells (Grossman et al., 2004). Additionally, studies have proposed that Tregs consume IL-2 in the local microenvironment, thus depriving effector T cells of IL-2 (Pandiyani et al., 2007). While various molecular mechanisms of suppression have been described, there is so far no agreement on a universal mechanism. It is likely that there are multiple suppressive mechanisms that can be employed by Tregs and will depend on the local microenvironment, the site of the immune reaction, as well as the type and/or activation status of both the Treg and the target cell.

Despite the difficulties in defining their precise mechanism of suppression, the ability of Tregs to dampen harmful immune responses is clear and has led to great interest in utilizing them in cell-based therapies for transplantation and autoimmunity.

Negative Regulatory Mechanisms that Impact Tolerance

Studies have clearly shown that costimulatory and coinhibitory molecules play important roles in both T cell activation and in maintaining peripheral tolerance (Figure 7.2b). CTLA-4, PD-1, and PD-L1-deficient mice all develop spontaneous autoimmune diseases to varying degrees and have been proposed to regulate tolerance through the control of autoreactive T cells (Tivol et al., 1995; Waterhouse et al., 1995; Nishimura et al., 2001; Probst et al., 2005; Schmidt et al., 2009).

Similar to CTLA-4, PD-1 is expressed on mature T cells after activation and is constitutively expressed on Tregs. It has two known ligands, PD-L1 (B7-H1) and PD-L2 (B7-DC). PD-L1 has broad expression and is found on T cells, B cells, DCs, macrophages, as well as non-hematopoietic parenchymal cells. Conversely, PD-L2 expression is limited to macrophages and DCs. Tregs have been shown to express both PD-1 and PD-L1 (Fife & Bluestone, 2008). Signaling through PD-1 blocks the function and survival of effector T cells and expression of PD-L1 on parenchymal cells has been suggested to be important for maintenance of tolerance (Keir et al., 2006). Collectively, these studies suggest that tolerance is maintained, in part, by negative regulation of the immune system.

Figures 7.2 and 7.3 summarize the different mechanisms of peripheral tolerance. If T cells detect antigen, then tolerance may occur through deletion or anergy. If T cells are unable to detect TSAs then T cells may remain ignorant. Therefore, the level of self-antigen can determine the fate of autoreactive T cells. However, tissue-specific T cells can escape both central and peripheral tolerance and can potentially cause autoimmune disease. Autoimmunity may be prevented through the function of Tregs and DCs.

Expression of Tissue-Specific Antigens by Lymph Node Stromal Cells

Peripheral tolerance has been shown to result from cross-presentation of tissue antigens to naïve, self-reactive lymphocytes by quiescent, tissue-resident DCs that migrate to the local lymph node (LN), leading to anergy or deletion (Lukacs-Kornek & Turley, 2011). The prevailing models of peripheral tolerance therefore rely on both resident and incoming DCs to provide the signals for determining activation vs. tolerance and requires trafficking of DCs to

peripheral tissue draining LNs or cell-independent transfer of TSAs from organ to LN (Allan et al., 2006; Lukacs-Kornek et al., 2008). However, recent studies have suggested an alternate mechanism of peripheral tolerance in which, similar to the mTECs, the non-hematopoietic stromal cells in secondary lymphoid tissues can present TSAs to induce tolerance (Fletcher et al., 2011).

Like many stromal populations, lymph node stromal cells (LNSCs) were assumed to primarily provide parenchymal support. However in 2007, Lee et al. provided the first evidence of peripheral tolerance mediated by LNSCs (Lee et al., 2007). In this study they used a transgenic model with a truncated OVA protein expressed in the intestinal epithelia under the control of the intestinal fatty acid-binding protein (iFABP) promoter. This study demonstrated that the gut-restricted OVA was ectopically expressed by the LNSCs in non-draining lymph nodes. It further showed that transfer of OVA-specific TCR transgenic CD8⁺ T cells into these mice resulted in a proliferative burst of the transferred cells followed by their eventual deletion from the peripheral T cell pool. This “activation” of the OVA-specific T cells occurred even in the absence of functional hematopoietic APCs, such as DCs, suggesting that the LNSCs could directly present the OVA antigen to CD8⁺ T cells. These results were confirmed and extended in subsequent studies (Nichols et al., 2007; Gardner et al., 2008; Cohen et al., 2010). While these earlier studies relied on transgenic antigens expressed under the control of tissue-specific promoters, Cohen et al. went on to evaluate tolerance in response to an endogenous tissue antigen (Cohen et al., 2010). This study examined tolerance to the melanocyte-specific antigen tyrosinase and found that tolerance depended on expression of tyrosinase in non-hematopoietic LNSCs. While tyrosinase mRNA was detected in the thymus, autoreactive T cells were not deleted efficiently when tyrosinase-sufficient thymi were transplanted into tyrosinase-deficient albino mice. Furthermore, tyrosinase was expressed in peripheral LNs, where CD8⁺ T cell deletion occurred, but not in the spleen. Tyrosinase-specific CD8⁺ TCR transgenic T cells that were adoptively transferred into tyrosinase-sufficient mice were shown to traffic to LNs, where they were initially activated and subsequently tolerized by LNSCs directly presenting antigen. This study therefore supported the previous conclusions that peripheral tolerance can be induced by expression and direct presentation of TSAs by the LNSCs to CD8⁺ T cells. This study further demonstrated that tyrosinase-derived antigens were not cross-presented by either radiosensitive DCs or radio-resistant Langerhans cells under steady-state conditions, suggesting that unlike the thymus, classical APCs are not able to cross-present tissue antigens to induce tolerance.

While it is increasingly clear that peripheral tolerance can be induced by LNSCs, the tolerogenic cell type within the LNSC population had not been clearly identified. It was initially assumed that a single, specialized cell type was responsible but collectively these studies have instead demonstrated that this is not the case. For example, in the iFABP-OVA transgenic model, only fibroblastic reticular cells expressed OVA (Lee et al., 2007), whereas Cohen et al. found that only lymphatic endothelial cells directly expressed tyrosinase-derived antigens (Cohen et al., 2010), suggesting that there is no specialized tolerogenic cell type in the LNs. Instead, tolerance induction is a function shared between cells of various lineages that can interact directly with T cells (Fletcher et al., 2011).

LNSCs can express a wide array of tissue antigens but little was known about how their expression was regulated. As was discussed previously, AIRE regulates expression of peripheral tissue antigens in the thymus and as AIRE has also been detected in peripheral tissues (Heino et al., 2000; Kogawa et al., 2002), it was assumed that it was regulating expression of TSAs in the LNSCs. This was initially supported by Gardner et al. who developed a mouse model in which a GFP-fused pancreatic protein (IGRP) was expressed in the *AIRE* locus in a bacterial artificial chromosome (BAC) (Gardner et al., 2008). The authors found expression of AIRE in a population of LNSCs (EpCAM⁺MHCII⁺UEA-1-gp38 stromal cells) that did not express costimulatory markers such as CD80 and CD86 but could induce tolerance of transgenic T cells specific for IGRP. Interestingly, this study also demonstrated that AIRE-induced TSAs expressed in mTECs and in extrathymic AIRE-expressing cells are largely distinct, suggesting that AIRE-induced tolerance in the thymus and periphery are not redundant (Gardner et al., 2008; Fletcher et al., 2011). While there is clearly a role for AIRE in driving expression of TSAs in LNSCs, it is increasingly clear that it does not drive expression of all TSAs in the periphery. For example, tolerance to tyrosinase is AIRE-independent (Cohen et al., 2010). In addition to AIRE, deformed epidermal autoregulatory factor 1 (DF1) has also been linked to the expression of tissue antigens in the pancreatic draining LN of aged NOD mice (Yip et al., 2009). Furthermore, DF1 transcripts have been identified in each of the different LNSC populations suggesting a role for it in driving peripheral tolerance (Fletcher et al., 2010).

In addition to mediating deletion of autoreactive T cells through the AIRE-dependent and -independent expression of TSAs, there is also evidence that LNSCs can contribute to peripheral tolerance through the induction of Tregs. For example, LNSCs present in the mesenteric LNs produce retinoic acid, which is known to promote the differentiation of Tregs (Coombes et al., 2007).

Several groups have reported expression of TSAs in peripheral cells other than LNSCs. For example, initial

studies on the role of AIRE in tolerance had noted that epithelial cells from tissues other than the thymus can constitutively express tissue-associated antigens and may be tolerogenic (Heino et al., 2000; Kogawa et al., 2002). Furthermore, there is evidence for a tolerogenic role of stromal cell populations outside of the secondary lymphoid compartments. For example, cancer associated fibroblasts (CAFs) are phenotypically similar to gp38⁺ FRCs found in LNs and are functionally associated with an immunosuppressive microenvironment (Egeblad et al., 2005). Mesenchymal stromal cells, which are found in most tissues, can induce tolerance and reduce inflammation seen in inflammation-associated pathologies such as graft versus host disease (GVHD) and colitis (Tyndall & Uccelli, 2009). Additionally, myofibroblasts found in the colon exhibit a suppressive phenotype in the absence of inflammation (Pinchuk et al., 2008). These cells express PD-L1, PD-L2, and MHCII but lack expression of costimulatory molecules and have been shown *in vitro* to suppress the proliferation of CD4⁺ T cells (Pinchuk et al., 2008).

Collectively, these studies clearly demonstrate that tolerance can be induced when autoreactive T cells encounter their cognate antigen presented by various LNSC populations and that expression of TSAs by LNSCs was both necessary and sufficient for tolerance induction. They further suggest that induction of peripheral tolerance is a complex process that involves many different cell types.

CONCLUDING REMARKS

While research over the last decades has led to a better understanding of how T cell tolerance is regulated in the thymus and periphery, much remains unknown. As we benefit from the genomics era, a clearer understanding of the molecular pathways that regulate the cellular functions that keep tolerance in check will undoubtedly lead to a detailed understanding of human autoimmunity. Ideally, key discoveries will provide novel strategies to utilize the physiological processes of immunological tolerance to prevent transplant rejection, allergies, and autoimmunity and to promote rejection of tumor cells.

ACKNOWLEDGMENTS

We would like to thank Dylan Johnson and Anne Brüstle for their critical reading of this manuscript. PSO holds a Canada Research Chair in Autoimmunity and Tumor Immunity.

THE CURIOUS CASE OF *i*NKT CELLS

The Many Names of NKT Cells

Natural killer T (NKT) cells are a unique subset of T lymphocytes found in mice, humans, and other mammals that phenotypically and functionally resemble NK cells as well as T cells, and thereby exhibiting features of the innate as well as the adaptive immune system (Kronenberg and Gapin, 2002; Taniguchi et al., 2003; Godfrey and Kronenberg, 2004; Kronenberg, 2005; Wingender and Kronenberg, 2006; Bendelac et al., 2007; Tupin et al., 2007; Cerundolo et al., 2009; Godfrey et al., 2010).

They were originally defined by co-expression of a T cell antigen receptor (TCR) and NK cell receptors, especially

NK1.1 (NKR-P1C) in certain mouse strains (Watanabe et al., 1995) and CD56 or CD161 (NKR-P1A) in human (Lanier et al., 1994; Exley et al., 1998; Doherty et al., 1999). This classification, however, is an oversimplification, as conventional T cells can express NK receptors, especially after activation (Hammond et al., 1999; Assarsson et al., 2000; Slifka et al., 2000; McMahon et al., 2002) and the expression of NK markers by NKT cells varies with their maturity, activation state, and in mice, with the genetic background (Kronenberg and Gapin, 2002; Kronenberg, 2005; Bendelac et al., 2007).

Although the term “NKT cell” is still sometimes used in this broad sense, nowadays it usually refers to T cells expressing an $\alpha\beta$ TCR that are reactive to antigens presented by CD1d, a non-polymorphic major

histocompatibility complex (MHC) class I-like antigen-presenting molecule. CD1d reactive $\alpha\beta$ T cells are often divided into Type I and II NKT cells, based on the TCR they express (for reviews see [Kronenberg and Gapin, 2002](#); [Taniguchi et al., 2003](#); [Godfrey and Kronenberg, 2004](#); [Kronenberg, 2005](#); [Wingender and Kronenberg, 2006](#); [Bendelac et al., 2007](#); [Tupin et al., 2007](#)).

Type I NKT cells are the largest and best-studied fraction of NKT cells and they carry a canonical $V\alpha 14$ to $J\alpha 18$ TCR rearrangement ($V\alpha 14i$) in mice and an orthologous $V\alpha 24$ - $J\alpha 18$ TCR chain ($V\alpha 24i$) in humans. This invariant TCR α chain (i TCR) pairs predominantly with $V\beta 8$, $V\beta 7$ or $V\beta 2$ in mice, and almost exclusively with $V\beta 11$ in human, although these β chains have highly diverse rearrangements to $J\beta$ segments ([Matsuda et al., 2001](#); [Ronet et al., 2001](#)). Considering the β chain variability, and the near complete absence of variability in the α chain, in reality these cells have a semi-invariant TCR. However, they are typically referred to as invariant NKT (i NKT) cells, a designation we will use herein. The specificity of i NKT cells is remarkably conserved over at least 50 million years of evolution, since the divergence of hominids and rodents. In fact, there is a surprising degree of interspecies cross-reactivity, with mouse i NKT cells recognizing human CD1d and vice versa ([Brossay et al., 1998](#); [Brossay and Kronenberg, 1999](#); [Kronenberg, 2005](#)). This conservation suggests an important function for these cells in the mammalian immune system.

In contrast to i NKT cells, type II NKT cells, also termed variant NKT (v NKT) cells, encompass all other CD1d reactive T lymphocytes that utilize a more variable TCR ([Wingender and Kronenberg, 2008](#)). However, there is a degree of oligoclonality in these cells, with enrichment for some TCRs such as: $V\alpha 3.2$ and $V\alpha 8$ ([Park et al., 2001](#)). The specificity of these cells is largely unknown, although some recognize sulfatide, a self glycolipid antigen ([Jahng et al., 2004](#); [Blomqvist et al., 2009](#)).

Sometimes, especially in earlier literature, a third group (type III) of NKT cells is listed. This group is more heterogeneous, as it subsumes all non-CD1d reactive T lymphocytes that express NK receptors ([Kronenberg and Gapin, 2002](#); [Taniguchi et al., 2003](#); [Wingender and Kronenberg, 2006](#); [Wingender et al., 2006](#)). Furthermore, it should be noted that several other non-conventional T cell subsets have been defined based on their TCR α chain repertoire. Mucosal NKT (m NKT) or mucosal associated invariant T (MAIT) cells express a fixed $V\alpha 19i$ TCR in mice, and a homologous $V\alpha 7.2i$ in humans ([Shimamura and Huang, 2002](#); [Treiner et al., 2003](#); [Wingender and Kronenberg, 2008](#); [Le Bourhis et al., 2010, 2011](#)). They are reactive to MR1, a highly conserved MHC class I homologue ([Treiner et al., 2003](#); [Le Bourhis et al., 2011](#)). Additionally, $V\alpha 10$

expressing NKT cells have recently been described ([Pellicci et al., 2011](#)). These cells are also CD1d reactive, and have a specificity similar to i NKT cells, although the CDR3 regions of their α chains are not invariant ([Pellicci et al., 2011](#)).

The focus of this review is exclusively i NKT cells in rodents, non-human primates (NHP) and humans and their roles in autoimmune disease pathogenesis and prevention.

The Many Faces of i NKT Cells

Phenotype

Even as they differentiate in the thymus (for reviews see [Das et al., 2010](#); [Hu et al., 2011](#); [Engel and Kronenberg, 2012](#)), i NKT cells begin to express a pattern of surface markers ($CD69^+$, $CD44^{\text{high}}$, $CD11a^{\text{high}}$, $CD62L^{\text{low}}$, $CD122^+$) typically associated with activated or memory T cells ([Bendelac et al., 1997](#); [Dutton et al., 1998](#); [Godfrey et al., 2000](#); [Kronenberg and Gapin, 2002](#); [Sprent and Surh, 2002](#)). This effector/memory phenotype is also displayed by i NKT cells that are derived from umbilical cord blood ([van der Vliet et al., 2000](#); [D'Andrea et al., 2000](#)) or from germ-free animals ([Park et al., 2000](#); [Wingender et al., 2012b](#)), and they maintain this pattern as mature cells.

Additionally, these cells constitutively express detectable mRNA for IL-4 and $IFN\gamma$ ([Matsuda et al., 2003](#); [Stetson et al., 2003](#)), although these transcripts increase dramatically following activation. Taken together, these data suggest that i NKT cells undergo a strong antigenic stimulation during their differentiation, consistent with the hypothesis that true TCR agonists mediate their positive selection ([Kronenberg, 2005](#)). However, two reports indicated that peripheral TCR-CD1d interactions aid the full maturation and reactivity of i NKT cells ([McNab et al., 2005](#); [Wingender et al., 2012b](#)).

Distribution

$V\alpha 14i$ NKT cells have the highest representation within the total T cell population in the liver and the bone marrow (>10%), followed by significant numbers in thymus, peripheral blood, and spleen (1–3%), whereas they are relatively rare in all other organs (<0.5%), including sites where conventional T lymphocytes are numerous, such as the lymph nodes and intestinal tissue ([Kronenberg and Gapin, 2002](#); [Kronenberg, 2005](#); [Bendelac et al., 2007](#)). Interestingly, in humans the frequency of i NKT cells is generally much lower, although a high degree of inter-individual variability in peripheral blood mononuclear cells (PBMC) has been reported ([Prussin and Foster, 1997](#); [van der Vliet et al., 2001](#); [Gumperz et al., 2002](#); [Kita et al., 2002](#)). Although the reason for this variability is unknown, nonetheless, the frequency of i NKT cells in

the PBMC of an individual appears to be stable over time (Lee et al., 2002b; Wither et al., 2008). *i*NKT cells are also relatively infrequent, compared to mice, in human intrahepatic lymphocytes (Kita et al., 2002; Kenna et al., 2003), but recent evidence indicates they may be much more abundant in adipose tissue (Lynch et al., 2009) and also to some extent, in peritoneal fluid (Wingender et al., 2012a).

The Many Effector Functions of *i*NKT Cells

Activation

*i*NKT cells recognize glycolipid antigens presented by CD1d (Bendelac, 1995; Bendelac et al., 1995; Kawano et al., 1997; Zeng et al., 1997), and one of the best-studied antigens is the glycolipid α -galactosylceramide (α GalCer). α GalCer is a synthetic glycosphingolipid, a category of glycolipids that contains ceramide as the lipid portion. Glycosphingolipids are natural compounds found in many organisms, including mammals. α GalCer was originally purified from a marine sponge, and was optimized by medicinal chemistry to yield its exceptionally strong agonistic potential (Morita et al., 1995). α GalCer contains an unusual α -anomeric linkage of the sugar to the ceramide lipid, unlike mammalian glycosphingolipids (Morita et al., 1995) and this α -linkage is crucial for its great stimulatory capacity (Bendelac et al., 1997; Kawano et al., 1997). Numerous synthetic derivatives of α GalCer have been studied (East et al., 2012), and natural antigens that can stimulate the majority of *i*NKT cells have been characterized from a few bacteria as well, including glycosphingolipids from environmental bacteria *Sphingomonas* spp. (Kinjo et al., 2005; Mattner et al., 2005). Because the *Sphingomonas*-derived antigens are similar to α GalCer, and *Sphingomonas* bacteria are found in aqueous environments (White et al., 1996), it is widely believed that the original α GalCer compound derived from a bacterium associated with the sponge. Antigens from pathogenic microbes include diacylglycerols from *Borrelia burgdorferi*, the causative agent of Lyme disease (Kinjo et al., 2006), and diacylglycerols from *Streptococcus pneumoniae* and group B *Streptococcus* (Kinjo et al., 2011). The biochemistry of lipid antigen binding to CD1d and recognition of the antigen CD1d complex by the TCR is very well understood as a result of biophysical and X-ray crystallographic studies. This topic has been reviewed recently (Zajonc and Kronenberg 2009; Pei et al., 2012; Rossjohn et al., 2012).

Activation of *i*NKT cells by TCR-mediated recognition of antigen bound to CD1d has been referred to as direct or antigen-dependent activation (Kinjo and Kronenberg, 2005; Parekh et al., 2005). It is known,

however, that memory T cells can be activated by cytokines alone in a TCR-independent manner (Berg and Forman, 2006). Considering their constitutively activated phenotype, it therefore is not surprising that a similar cytokine-dependent activation was reported for *i*NKT cells as well (Nagarajan and Kronenberg, 2007; Tyznik et al., 2008). This so-called indirect or antigen-independent activation (Kinjo and Kronenberg, 2005; Parekh et al., 2005) can be induced by several proinflammatory cytokines, such as IFN α , IFN β , IL-12, and IL-18, alone (Leite-de-Moraes et al., 1999; Biron and Brossay, 2001) or more effectively, in combination (Dao et al., 1998; Ogasawara et al., 1998; Leite-de-Moraes et al., 1999, 2001). Dendritic cells (DCs) and macrophages produce these cytokines following the engagement of Toll-like receptors (TLR) or other stimuli for the innate immune system, like early after bacterial or viral infections.

One has to keep in mind, however, that the direct, TCR-driven and the indirect, cytokine-driven pathways of *i*NKT cell activation are not exclusive. The innate cell-derived cytokines IL-12 and IFN α/β have been reported to augment CD1d-dependent *i*NKT cell activation (Brigl et al., 2003; Mattner et al., 2005; Malleveay et al., 2006; Paget et al., 2007), which was especially crucial for stimulation with presumably weak antigens.

Furthermore, in some cases, it has been shown that *i*NKT cells require the recognition of endogenous or self-ligands presented by CD1d for activation in a cytokine-dependent context (Brigl et al., 2003). This is exemplified by the activation of *i*NKT cells following *Salmonella* infection, which is not only dependent on IL-12, but also on CD1d (Brigl et al., 2003; Mattner et al., 2005; Malleveay et al., 2006). As *Salmonella* is not known to express antigens that activate *i*NKT cells, these data demonstrate that self-antigens presented by CD1d acted in concert with IL-12 to activate *i*NKT cells. In line with the idea of recognition of “self” by *i*NKT cells is the observation that mature *i*NKT cells can under some circumstances display autoreactivity (Salio and Cerundolo 2009; Hegde et al., 2010). Additionally, data with tumor-derived glycolipids suggest (Behar et al., 1999; Gumperz et al., 2000; Metelitsa et al., 2003; Rauch et al., 2003; Wu et al., 2003; Metelitsa, 2010) such self-antigens could provide an “altered-self” for *i*NKT cell activation.

The structure of such self-antigens important for the activation of mature *i*NKT cells is still controversially debated, and there could be several types, but currently the best candidates are lysophospholipids (Fox et al., 2009), at least for human *i*NKT cells and β -D-glucopyranosylceramide (Brennan et al., 2011). A lysophosphatidylethanolamine with an ether bond or plasmalogen has been suggested to be important for *i*NKT cell positive selection (Facciotti et al., 2012).

Cytokine Production

In accordance with their constitutively activated phenotype is the remarkable ability of *i*NKT cells to rapidly (<1 hour) exert effector functions such as cytokine production and cytotoxicity (Wingender et al., 2010). After antigenic, TCR-driven activation they rapidly produce copious amounts of various cytokines such as T helper type 1 (Th1; e.g., IFN γ , TNF) and Th2 cytokines (e.g., IL-4, IL-10, IL-13) (Kronenberg, 2005; Wingender and Kronenberg, 2006; Bendelac et al., 2007), with a subset capable of producing IL-17 A (Michel et al., 2007, 2008; Coquet et al., 2008; Pichavant et al., 2008; Doisne et al., 2009, 2011; Milpied et al., 2011) and IL-22 (Paget et al., 2012). This explosive production of cytokines is more similar to innate immune cells or a memory T cell response, as a conventional naïve T lymphocyte would take days of stimulation to produce these cytokines. In contrast to naïve T cells, *i*NKT cells are somewhat resistant to cytokine polarization (Matsuda et al., 2003) and the response towards a strong TCR agonist is always a mixed IFN γ /IL-4 or Th0 response (Sullivan et al., 2010).

In contrast to this manifold array of cytokines following TCR-driven activation, the indirect, cytokine-driven activation, for example by IL-12 and IL-18, leads exclusively to the production of IFN γ by the stimulated *i*NKT cells (Nagarajan and Kronenberg, 2007; Tyznik et al., 2008). Similarly, IL-1 β and IL-23 stimulate the IL-17 A producing subset to secrete IL-17 (Moreira-Teixeira et al., 2011; Doisne et al., 2011), and some *i*NKT cells are stimulated by IL-25 to produce IL-13 (Terashima et al., 2008).

Downstream Effects

Due to their cytokine production, *i*NKT cells have a pronounced impact on other lymphocytes, amplifying responses of DCs (Kitamura et al., 1999; Chen et al., 2005; Kojo et al., 2005), macrophages (Flesch et al., 1997; Denney et al., 2012), neutrophils (Li et al., 2007; Michel et al., 2007; Wintermeyer et al., 2009; De Santo et al., 2010; Emoto et al., 2010), NK cells (Eberl and MacDonald, 2000; Smyth et al., 2000a,b), B and T cells. However, in some cases the interaction has been shown to be in part cell–cell contact dependent (Novak et al., 2005; Baev et al., 2008; Caielli et al., 2010; Yang et al., 2011).

Moreover, activated *i*NKT cells can skew or polarize the character of the entire immune response either towards a Th1- (Denkers et al., 1996; Cui et al., 1999; Kitamura et al., 1999; Gonzalez-Aseguinolaza et al., 2002) or a Th2- (Yoshimoto et al., 1995a,b; Bendelac et al., 1996; Burdin et al., 1999; Singh et al., 1999; Hong et al., 2001; Sharif et al., 2001) direction. This can be

promoted by the stimulating antigen utilized, with some synthetic glycolipids, like C-glycoside (Schmiege et al., 2003), leading to a Th1 bias and others like OCH (Miyamoto et al., 2001) and C:20 (Yu et al., 2005), leading to a Th2 bias (East et al., 2012; Pei et al., 2012). Interestingly, this bias is not reflected in the initial *i*NKT cell cytokine response, which remains Th0 (Sullivan et al., 2010), but instead reflects the interactions between networks of cells including the presentation of the antigen on antigen-presenting cells (APC) (Im et al., 2009; Arora et al., 2011). For example, Th1 skewing of the cytokine response reflects enhanced IFN γ production by NK cells (East et al., 2012; Pei et al., 2012).

Consequently, by orchestrating the ensuing immune response, with regard to its strength and properties, *i*NKT cells can act as a bridge between innate and adaptive immune responses. Therefore, it is not surprising that *i*NKT cells have been reported to be crucially involved in the early phases of a dazzling variety of different immune reactions, ranging from self-tolerance and autoimmunity to include responses to pathogens and tumors (Bendelac et al., 1997; Kronenberg and Gapin, 2002; Godfrey and Kronenberg, 2004; Kronenberg, 2005; Kinjo and Kronenberg, 2005; Parekh et al., 2005; Godfrey et al., 2010).

The Many Kinds of *i*NKT Cells

There is increasing evidence that the functionally diverse roles of *i*NKT cells are partly due to functional *i*NKT cells subsets with distinct homing properties and cytokine profiles. These may be pre-programmed in the thymus, or induced in the periphery under the influence of particular stimulatory conditions. At first, *i*NKT cells subsets were defined by the expression of surface molecules, such as CD4 (Gumperz et al., 2002; Kim et al., 2002; Lee et al., 2002a), NK1.1 (McNab et al., 2007), IL17RB⁺ (Terashima et al., 2008), Ly49 receptors (Hammond et al., 1999; Skold and Cardell, 2000) and CD49b/DX5 (Hammond et al., 1999; Pellicci et al., 2005), among others.

However, with very recent advances, it now seems feasible, at least in the mouse, to attempt to define some *i*NKT cell subsets based on transcription factor usage (Table 8.1): (a) NKT1 are Tbet^{high}, PLZF^{low}, GATA3^{low}, ROR γ t^{neg} and they characteristically produce IFN γ . (b) NKT2 are PLZF^{high}, GATA3^{high}, Tbet^{low}, ROR γ t^{low} and produce IL-4. (c) NKT17 are ROR γ t^{pos}, GATA3^{high}, PLZF^{int}, Tbet^{low} and are characterized by IL-17A production (Michel et al., 2007, 2008; Coquet et al., 2008; Pichavant et al., 2008; Doisne et al., 2009, 2011; Milpied et al., 2011) (transcription factor usage in (a–c) based on Kristin A. Hogquist, personal communication). These subsets can be identified in the thymus and therefore may

TABLE 8.1 Features of CD1d-reactive NKT Cell Subsets

| Name | Invariant (<i>i</i>)NKT | | | | | | Variable (<i>v</i>)NKT | | | |

The table does not include the V α 10⁺ NKT cells or other non-conventional T cells. nd = not determined or not clear.

be considered preprogrammed. (d) T_{FH}-NKT cells are induced by strong antigenic stimulation and are characterized by the expression of the transcription factor Bcl6 and the surface markers CXCR5 and PD-1 (Chang et al., 2011; King et al., 2011; Tonti et al., 2012). (f) FoxP3⁺ *i*NKT cells acquire FoxP3 expression following strong antigenic stimulation in the presence of high amounts of TGF β (Moreira-Teixeira et al., 2011, 2012).

In contrast, in humans *i*NKT cell subsets are not yet as well defined. However, expression of CD4 has been correlated with functional differences. Following antigenic stimulation the cytokine production of CD4⁺ V α 24*i* NKT cells follows a Th0-pattern, whereas CD4^{neg} *i*NKT cells are biased towards to a Th1-pattern (Gumperz et al., 2002; Lee et al., 2002a). Furthermore, an IL-17 producing subset of human *i*NKT cells exists, but unlike

in mice, it requires exposure to inflammatory cytokines as well as TCR activation for IL-17 production (Moreira-Teixeira et al., 2011).

Altogether, these data demonstrate that *i*NKT cells are heterogeneous. Because the prevalence of functional *i*NKT cell subsets may differ between inbred mouse strains or individuals, some of the current controversies regarding the roles of *i*NKT cells could depend on subset prevalence or selective activation of subsets under certain conditions.

Technical Problems and the Species Divide

Several technical problems complicate the interpretation of the reported human data on *i*NKT cells and autoimmunity that we summarize below. Human *i*NKT cells can be

identified by CD1d/ α GalCer tetramers, which may be the most inclusive and accurate method. A clonotype-specific antibody that recognizes the CDR3 α region formed by the invariant V α 24-J α 18 rearrangement is also available (Montoya et al., 2007), but may miss some human α GalCer and CD1d reactive cells that do not use V α 24 (Gadola et al., 2002; Brigl et al., 2006). In one study, these α GalCer reactive cells with this non-canonical TCR α chain were up to 20% of the tetramer binding population (Brigl et al., 2006). Interestingly, the TCRs expressed by these cells are related to the canonical TCR, as they express V β 11 and the predominant V α -segments they express (V α 3.1 and V α 10.1) are rearranged to the same J α 18 expressed by V α 24i NKT cells (Gadola et al., 2002; Brigl et al., 2006). The combination of V α 24 and V β 11 antibodies is also sometimes used, but this might leave out some V α 24 negative *i*NKT cells, as well as including some non-*i*NKT cells. However, frequently less accurate methods to define *i*NKT cells are used, including: (a) V α 24-specific antibodies alone, (b) $\alpha\beta$ TCR and expression of one of several NK cell markers (e.g., CD161, CD56, CD16), (c) CD4⁻CD8⁻ (DN) $\alpha\beta$ T cells, and (d) RT-PCR for the *i*TCR, which does not allow for a direct assessment of cell frequency. Altogether, this means that different human studies are difficult to compare, as different populations may have been investigated. Here we will focus on reports using CD1d/ α GalCer tetramers, the 6B11 antibody or V α 24⁺V β 11⁺ cells. Furthermore, the depths of the characterization of *i*NKT cells in humans remains limited, especially regarding functional subsets, as analysis is usually confined to CD4 expression, one of the NK receptors, IFN γ , and IL-4. However, a “global” look at *i*NKT cells might miss important phenotypic and functional changes by a so far overlooked subset, which might be relevant in a particular disease. Also, most information about human *i*NKT cells is, for obvious reasons, derived from PBMCs. How human *i*NKT cells in peripheral blood relate to tissue *i*NKT cells, especially in affected organs, is largely unknown. For mice it has been reported that *i*NKT cells in blood poorly reflect the cells in other tissues regarding frequency, phenotype, and function (Berzins et al., 2004). Finally, when the frequency or function of *i*NKT cells during autoimmune diseases was reported, this was usually done at a single time in an individual, rather than longitudinally, which could be misleading in cases wherein the relevance of *i*NKT cells changes at different stages during disease progression.

The Species Divide

Most of the work on *i*NKT cells has been done in mouse models. Apart from the quip that “mice are not humans,” and the obvious fact that the genetic background in human subjects is much more varied than in the few

inbred mice strains commonly used, there are a few other aspects worth noting that complicate the translation of findings from mice to humans. A striking difference is in the relative distribution of *i*NKT cells in different organs. In mice the highest frequency of *i*NKT cells is found in liver, followed in descending order by adipose tissue, thymus/spleen/bone marrow/PBMCs, and lymph nodes. In humans *i*NKT cells are abundant in adipose tissue, but not especially abundant in liver/peritoneum and generally lower in frequency than in the commonly studied inbred mouse strains. Additionally, in human *m*NKT and type II NKT cells are more frequent than in mice and they contain additional non-conventional T lymphocytes reactive to CD1a, CD1b, and CD1c (Kronenberg and Gapin, 2002; Kronenberg, 2005; Bendelac et al., 2007). So, whereas in many cases the role of *i*NKT cells in animal models of autoimmunity is well established, controversy to varying degrees remains with regard to their role in human autoimmunity.

THE JANUS-LIKE CHARACTER OF *i*NKT CELLS IN AUTOIMMUNITY

In line with the diversity of *i*NKT cells, cytokine and effector responses, and their involvement in shaping immune responses, it is not surprising that *i*NKT cells have also been reported to participate in autoimmune disease pathogenesis (for earlier reviews on this topic see Ronchi and Falcone, 2008; Balato et al., 2009; Wu and Van Kaer, 2009; Berzins et al., 2011; Novak and Lehuen, 2011; Simoni et al., 2012). Despite conflicting data, we try here to distinguish those autoimmune diseases in which *i*NKT cells seem to promote pathogenesis in the majority of reports from those in which they tend to prevent it. Given the vast literature in the field, not all details can be described here, but rather we summarize the major findings, emphasizing the underlying mechanisms and focusing on recent developments.

Too Much of a Good Thing: Detrimental Roles of *i*NKT Cells

For diseases in this section, the data are most consistent with roles for *i*NKT cells in initiating and/or aggravating pathogenesis (Table 8.2).

Atherosclerosis

Atherosclerosis is a chronic inflammatory disease within the vessels, driven by responses to accumulated lipids in the arterial intima. A contribution of the adaptive as well as the innate immune system, and an autoimmune component, has recently become apparent (Shi, 2010; Grundtman and Wick, 2011; for earlier reviews on the

TABLE 8.2 Detrimental Involvement of Human *i*NKT Cells in Selected Autoimmune Diseases

| Disease | <i>i</i> NKT cell frequency* | <i>i</i> NKT cell cytokines | Effects of treatment | Etc. |
|-------------------------------------|--|---|--|---|
| Atherosclerosis | <ul style="list-style-type: none"> decreased in PBMCs: Kyriakakis et al. (2010). | <i>i</i> NKT cell lines derived from atherosclerotic plaques were more sensitive to antigen stimulation than lines derived from PBMCs (Kyriakakis et al., 2010). | | CD1d expression is enhanced in the atherosclerotic plaques (Melián et al., 1999; Bobryshev, 2005; Chan et al., 2005; Kyriakakis et al., 2010). *The table only lists reports in which *i*NKT cells were identified by CD1d/ α GalCer tetramers or 6B11 antibodies or the combination of V α 24⁺V β 11⁺. Comments: [1] NKT-cell like (CD3⁺CD161⁺) cells are found in atherosclerotic plaques (Bobryshev, 2005; Chan et al., 2005). [2] Differing results by Wither et al. (2008).

role of *i*NKT cell in atherosclerosis see [Braun et al., 2010](#); [Getz et al., 2011](#), see also Chapter 71).

In PBMCs of human patients, *i*NKT cell numbers were decreased ([Kyriakakis et al., 2010](#)) and NKT cell-like (CD3⁺CD161⁺) cells were found in atherosclerotic plaques, where they represented up to 2% of the lymphocytes ([Bobryshev, 2005](#); [Chan et al., 2005](#)). Interestingly, CD1d expression was enhanced in the atherosclerotic plaques ([Melián et al., 1999](#); [Bobryshev, 2005](#); [Chan et al., 2005](#); [Kyriakakis et al., 2010](#)). *i*NKT cell lines derived from atherosclerotic plaques produced proinflammatory cytokines following α GalCer stimulation and did this with an approximately 10-fold higher antigenic sensitivity than PBMC-derived cell lines ([Kyriakakis et al., 2010](#)).

In mouse models of atherosclerosis, *i*NKT cells could also be found in the atherosclerotic lesions ([Tupin et al., 2004](#); [Nakai et al., 2004](#); [Aslanian et al., 2005](#)) and data with reporter mice suggest that CXCR6 signaling might be required for this accumulation ([Galkina et al., 2007](#)). Interestingly, when serum lipids from atherosclerosis-prone LDL-receptor deficient mice were fed to DCs, this led to a CD1d-dependent stimulation of *i*NKT cell hybridomas ([VanderLaan et al., 2007](#)). *i*NKT cell deficient mice developed a greatly ameliorated disease ([Major et al., 2004](#); [Nakai et al., 2004](#); [Tupin et al., 2004](#); [Aslanian et al., 2005](#); [Ström et al., 2007](#); [Rogers et al., 2008](#); [To et al., 2009](#)) and transfer of CD4⁺*i*NKT cells could transfer susceptibility ([VanderLaan et al., 2007](#); [To et al., 2009](#)). The reduced plaque formation in *i*NKT cell deficient animals correlated with an approximately 90% decrease in IFN γ mRNA in the atherosclerotic lesions ([Rogers et al., 2008](#)). Consequently, activation of *i*NKT cells either by antigens ([Tupin et al., 2004](#); [Nakai et al., 2004](#); [Major et al., 2004](#)) or with lipopolysaccharide (LPS) ([Ostos et al., 2002](#); [Andoh et al., 2012](#)) aggravated disease. This is in line with the observation that microbial infections enhance the development of atherosclerosis in both human and animal models ([Hansson et al., 2006](#)). Despite this, one study reported a protective effect of *i*NKT cell stimulation on atherosclerosis ([van Puijvelde et al., 2009](#)). Several proteins involved in lipid metabolism have also been shown to be involved in CD1d lipid antigen loading and *i*NKT cell development, including apoE ([Elzen et al., 2005](#)), sphingolipid activator protein (SAP) ([Zhou et al., 2004](#)), microsomal triglyceride transfer protein (MTTP) ([Brozovic et al., 2004](#)), and ABCG1 ([Sag et al., 2012](#)). For example, apoE can bind α GalCer and aid in its uptake ([Elzen et al., 2005](#); [Allan et al., 2009](#)).

Asthma

Asthma is multi-factorial disease that could in some cases have an autoimmune component. Several studies have

implicated V α 24i NKT cells in the pathogenesis of asthma in humans ([Matangkasombut et al., 2009b](#); [Rijavec et al., 2011](#); [Thomas et al., 2010](#); [Umetsu and DeKruyff, 2010](#)). A decreased frequency in PBMCs from asthmatic patients, at least in the CD4⁺ subset of *i*NKT cells, has been reported by some ([Koh et al., 2010](#); [Yan-ming et al., 2012](#)), but not by others ([Magnan et al., 2000](#); [Akbari et al., 2006](#)). Interestingly, upper respiratory tract infections, which often exacerbate asthma, were correlated with a decrease of *i*NKT cells in PBMC ([Koh et al., 2012](#)), suggesting potential recruitment to the lung. In line with this notion, *i*NKT cells are almost undetectable in the airways of healthy controls, either in lung biopsies ([Akbari et al., 2006](#); [Vijayanand et al., 2007](#); [Reynolds et al., 2009](#)) or in the bronchoalveolar lavage fluid (BALF) ([Akbari et al., 2006](#); [Thomas et al., 2007](#); [Matangkasombut et al., 2009a](#)), but can be detected in samples from asthmatic patients. However, controversy remains about the magnitude of this increase within the lungs of asthmatics. For BALF only two studies reported a frequency of more than 2.5% of *i*NKT cells within total T cells ([Akbari et al., 2006](#); [Matangkasombut et al., 2009a](#)) with most studies reporting frequencies between 0.6 and 2.5% ([Thomas et al., 2006, 2007](#); [Vijayanand et al., 2007](#); [Bratke et al., 2007](#); [Heron et al., 2007](#); [Mutalithas et al., 2007](#); [Matangkasombut et al., 2009a](#); [Brooks et al., 2010](#)). For lung biopsies the values ranged from 1.7 ([Vijayanand et al., 2007](#)) to 9.8 ([Reynolds et al., 2009](#)) to over 50% ([Akbari et al., 2006](#)). Importantly, it was noted that the frequency of *i*NKT cells in the lung increases with the severity of symptoms ([Akbari et al., 2006](#); [Hamzaoui et al., 2006](#); [Matangkasombut et al., 2009a](#); [Reynolds et al., 2009](#); [Koh and Shim, 2010](#)). Most forms of asthma are associated with Th2 cytokine profile, but conflicting data were reported regarding the presence of a Th2 skewed cytokine production by restimulated *i*NKT cells from PBMC of asthma patients ([Sen et al., 2005](#); [Yan-ming et al., 2012](#)). However, antigen stimulated *i*NKT cells from BALF of asthmatic patients produced IL-4 and IL-13, but hardly any IFN γ ([Akbari et al., 2006](#)), in line with the hypothesized Th2 bias.

In mouse airway inflammation models, the evidence is strong for a major pathogenic role for *i*NKT cells in airway hypersensitivity. The potency of *i*NKT cells in airway inflammation is illustrated by the fact that airway challenge with *i*NKT cell glycolipid antigens alone, like α GalCer, induces many of the pathological features of asthma, even in MHC class II deficient mice that lack conventional CD4⁺ T cells ([Meyer et al., 2006](#)). This suggests that asthma might be induced directly by airway exposures to *i*NKT cell antigens present in inspired air. Clearly, weak environmental *i*NKT cell antigens found in house dust can act as potent adjuvant in the sensitization to a model antigen ([Wingender et al., 2011](#)). Even in the

absence of known *i*NKT cells antigens, several groups have found that *i*NKT cells are required in mouse models of asthma initiated by ovalbumin (OVA) sensitization (Akbari et al., 2003; Lisbonne et al., 2003; Kim et al., 2004, 2009), ragweed (Bilenki et al., 2004), or ozone (Pichavant et al., 2008). This is best illustrated by the clearly reduced airway inflammation in *i*NKT cell deficient animals in several models, and the restoration of susceptibility by *i*NKT cell transfer (Cui et al., 1999; Akbari et al., 2003; Lisbonne et al., 2003; Pichavant et al., 2008; Wingender et al., 2011; Kim et al., 2012).

In the allergen-induced model of airway hypersensitivity, IL-4 and IL-13 secretion by *i*NKT cells has been implicated (Akbari et al., 2003; Meyer et al., 2006; Terashima et al., 2008), while the ozone-induced model depended upon IL-17A as well as IL-4 and IL-13 (Pichavant et al., 2008).

Two studies in macaques were in line with the findings in mouse models in showing that a glycolipid antigen for *i*NKT cells could induce hypersensitivity and that an allergen challenge could lead to *i*NKT cell infiltration into the lung (Matangkasombut et al., 2008; Ayanoglu et al., 2011).

IBD/Colitis

Inflammatory bowel disease (IBD) denotes a spectrum of T cell-dependent chronic disorders of different parts of the gastrointestinal tract. The inflammatory response is triggered by antigens derived from the gut lumen, which may follow a perturbation of the epithelial layer, caused either through genetic alterations or the administration of exogenous agents. Several reviews on the role of *i*NKT cells in colitis models have been published (Zeissig et al., 2007; Wingender and Kronenberg, 2008). Some types of intestinal bacteria are probiotic, in that they prevent inflammation of the intestine. It is therefore of note that *i*NKT cells can influence the microbial colonization and the composition of intestinal bacteria (Nieuwenhuis et al., 2009). Furthermore, the activation state of *i*NKT cells, and their influence on the mucosal immune response, is highly altered in germ-free mice (Olszak et al., 2012; Wingender et al., 2012b).

Ulcerative colitis is an inflammation of the superficial layers of the colon that has been attributed in some studies to an exaggerated Th2 response. *i*NKT cells were decreased in the PBMCs of ulcerative colitis patients (van der Vliet et al., 2001; Grose et al., 2007b). Additionally, there was a reduction in V α 24 mRNA in the intestine of colitis patients (Grose et al., 2007a), but the majority of these V α 24⁺ cells might not be *i*NKT cells, as judged by V β 11 expression (O'Keefe et al., 2004). Interestingly, in ulcerative colitis patients, it was found that *v*NKT cells, rather than *i*NKT cells, were the major CD1d-dependent

producers of the deleterious IL-13 (Fuss et al., 2004). This is in contrast to results obtained using the oxazolone-induced mouse model of colitis, where it was shown that the pathogenic IL-13 was derived from *i*NKT cells (Heller et al., 2002). In this model, interfering with *i*NKT cell activation prevented disease development (Heller et al., 2002; Brozovic et al., 2004; Camelo et al., 2012).

Primary Biliary Cirrhosis (PBC)

PBC is characterized by portal inflammation and immune-mediated chronic destruction of intrahepatic small bile duct epithelial cells (i.e., cholangitis) (for earlier reviews on *i*NKT cell activity in this disease see Camelo et al., 2012; Uibo et al., 2012).

*i*NKT cells are increased in PBMCs as well as in the liver of PBC patients (Kita et al., 2002) and these livers contain higher IFN γ levels (Omenetti et al., 2009). The increase of *i*NKT cells in the liver coincided with an increase of CD1d expression levels on epithelial cells of the small bile duct of PBC patients (Tsuneyama et al., 1998; Kita et al., 2002). The cross-reactivity of antibodies to several bacteria with the lipidated mitochondrial protein PDC-E2 has been implicated in the genesis of PBC (Selmi et al., 2003; Bogdanos et al., 2004; Bogdanos and Vergani, 2009; Yanagisawa et al., 2011).

One bacterium in particular that is the target of these cross-reactive antibodies from PBC patients is *Novosphingobium aromaticivorans* (Selmi et al., 2003; Olafsson et al., 2004). This bacterium is of interest because of its relation to *Sphingomonas* bacteria, which bear known *i*NKT cell antigens (Kinjo et al., 2005; Mattner et al., 2005). Most importantly, *N. aromaticivorans* can induce a PBC-like disease in a mouse model in an *i*NKT cell-dependent fashion (Mattner et al., 2008; Mohammed et al., 2011). The crucial role for *i*NKT cells in initiating PBC-like disease in mice has been supported by other reports (Chuang et al., 2008; Wu et al., 2011).

Rheumatoid Arthritis

In rheumatoid arthritis (RA) autoreactive Th1 and Th17 T cells cause inflammation of small and large synovial joints, leading to joint deformation and loss of movement (for earlier reviews on the role of *i*NKT cells in RA see Coppieters et al., 2007a; Drennan et al., 2010; Sowden and Ng, 2012).

Human RA patients display reduced *i*NKT cell frequencies in PBMCs (Kojo et al., 2001; van der Vliet et al., 2004; Parietti et al., 2010; Tudhope et al., 2010) and the rheumatoid synovium (Maeda et al., 1999; Linsen et al., 2005). Although the *i*NKT cell frequency did not correlate with clinical disease severity (Parietti et al., 2010;

Tudhope et al., 2010) it was noted that the frequency increased following treatment (Parietti et al., 2010; Tudhope et al., 2010). *i*NKT cell lines derived from RA patient PBMCs expanded less *in vitro* following α GalCer stimulation (Kojo et al., 2001; Linsen et al., 2005; Tudhope et al., 2010) and produced reduced cytokines, although with a Th1 bias (Kojo et al., 2001; Linsen et al., 2005), when compared to control lines. In contrast to PBMCs, no impairment of *i*NKT cell expansion and function was observed in synovial derived *i*NKT cell lines (Linsen et al., 2005). Even though the expression levels of CD1d on PBMCs might not be altered (no change: Kojo et al., 2003; higher on DCs: Jacques et al., 2010) it was reported that RA patients have decreased levels of soluble CD1d in the serum (Kojo et al., 2003; Segawa et al., 2009).

Without delineating the details of the different mouse models for RA that have been studied, the role of *i*NKT cells overall is pathogenic. The frequency of *i*NKT cells increased with disease progression (Chiba et al., 2005; Postigo et al., 2012), they upregulated activation markers (Kim, 2006; Jung et al., 2009; Miellot-Gafsou et al., 2010) and they were recruited to the joints (Kim et al., 2005) where they could be activated directly by aggregated antibodies (Kim et al., 2005). Furthermore, the percentage of IL-17A⁺*i*NKT cells increased with disease progression (Jung et al., 2009). Injection of blocking α CD1d antibodies ameliorated arthritis (Chiba et al., 2005; Miellot-Gafsou et al., 2010) and in *i*NKT cell deficient mice the disease was less severe (J α 18^{-/-}: Chiba et al., 2005; Ohnishi et al., 2005; Yoshiga et al., 2008; CD1d^{-/-}: Ohnishi et al., 2005; Kim et al., 2005; Kim, 2006; Jung et al., 2009; Teige et al., 2010). Such diseased *i*NKT cell deficient animals had higher IL-10 production by collagen-specific T cells (Chiba et al., 2005; Jung et al., 2009) and proinflammatory cytokines tended to be lower (Chiba et al., 2005; Ohnishi et al., 2005; Yoshiga et al., 2008; Jung et al., 2009). Additionally, they had reduced antigen-specific antibody titers (Jung et al., 2009; Ohnishi et al., 2005) with an elevated IgG1/IgG2a ratio (Chiba et al., 2005), suggesting a Th2 deviation. Furthermore, injection of *i*NKT cell antigens generally ameliorated disease (Chiba et al., 2004; Miellot et al., 2005; Takagi et al., 2006; Coppieters et al., 2007b; Kaieda et al., 2007; Yoshiga et al., 2011). The disease amelioration could be attributed to the impairment of the pathogenic Th17 response, rather than to a Th2 cytokine deviation (Chiba et al., 2004; Kaieda et al., 2007; Yoshiga et al., 2011). By contrast, only two studies implied a beneficial role of *i*NKT cells in mouse models of RA. In one, tolerogenic DCs were only effective ameliorating arthritis when they were CD1d⁺ (Jung et al., 2010), suggesting a role for type I and/or type II NKT cells. Also, Teige et al. (2010) reported a protective role

of *i*NKT cells. Intriguingly, it has recently been suggested, that V α 14i NKT cells might recognize a mouse collagen II derived peptide (mCII₇₀₇₋₇₂₁) in a CD1d-dependent manner (Liu et al., 2011). This report is one of very few indicating that peptides, in addition to lipids, can be presented by CD1d (Castano et al., 1995; Zeng et al., 1997; Lee et al., 1998; Tangri et al., 1998). Further studies will be required to understand the mechanism of peptide binding into the hydrophobic CD1d groove, and to confirm that *i*NKT cells are in fact reactive to a peptide bound to CD1d.

Skin Disorders

Psoriasis is a local inflammation of the skin driven by a mixed Th1/Th17 T cell response (Lowe et al., 2008; Zaba et al., 2009) leading to abnormal proliferation and differentiation of keratinocytes (for earlier *i*NKT cell reviews see Balato et al., 2009; Peternel and Kastelan, 2009; Tobin et al., 2011). There are numerous reports of T cells expressing NK cell markers in skin (Bonish et al., 2000; Nickoloff, 2000; Cameron et al., 2002; Gilhar et al., 2002; Koreck et al., 2002; Curry et al., 2003; Langewouters et al., 2007) and increases in these cells in psoriatic plaques (Zhao et al., 2008). For *i*NKT cells, one report showed a decreased frequency in PBMCs from psoriasis patients (van der Vliet et al., 2004). Furthermore, CD1d expression is upregulated in the inflamed skin (Gober et al., 2008; Zhao et al., 2008). Specifically, IFN γ pre-treated keratinocytes upregulate CD1d and can induce IFN γ , but not IL-4, production by *i*NKT cell lines (Bonish et al., 2000).

In systemic sclerosis NKT cells from patient PBMCs have been reported to be decreased (Kojo et al., 2001; van der Vliet et al., 2001) and to display a Th1-bias (Kojo et al., 2001).

Similarly, in contact dermatitis NKT cells from patient PBMCs, especially the DN subset, were decreased in most (Oishi et al., 2000; Takahashi et al., 2003; Ilhan et al., 2007; Gyimesi et al., 2011), but not all (Magnan et al., 2000; Prell et al., 2003; Wu et al., 2010) reports. Whereas skin from control subjects did not contain detectable *i*NKT cells, they could be found in patient skin biopsies (Gober et al., 2008; Simon et al., 2009; Wu et al., 2010; Balato et al., 2012), consistent with a possible migration from the blood to the site of inflammation. *i*NKT cells, all CD4⁺, were found within the dermal infiltrating cells and made up 6–9% of the T cells, although none were found in the epidermis (Gober et al., 2008; Simon et al., 2009). After stimulation of PBMC *i*NKT cells two reports noted a Th2 bias (IL-4 > IFN γ) of the cytokine response in patient *i*NKT cells (Takahashi et al., 2003; Gyimesi et al., 2011), whereas one report observed a Th1 bias (Oishi et al., 2000).

Furthermore, production of IFN γ and IL-4 by *i*NKT cells was also detected within the affected skin of patients (Gober et al., 2008; Simon et al., 2009). Interestingly, thymic stromal lymphopoietin (TSLP), a cytokine that is produced by activated keratinocytes (Soumelis et al., 2002) and is elevated in patient lesions (Nakamura et al., 2008; Wu et al., 2010) can bias cytokine production by activated *i*NKT cells towards a Th2 pattern (IL-4, IL-13) (Wu et al., 2010; Jariwala et al., 2011).

In an animal model of contact hypersensitivity (CHS), the majority of studies demonstrated the involvement of *i*NKT cells (Campos et al., 2003, 2006a,b; Nieuwenhuis et al., 2005; Dey et al., 2011; Askenase et al., 2011), although two reports did not (Elkhal et al., 2006; Goubier et al., 2012). Furthermore, *i*NKT cell deficient animals showed an impaired CHS response (Nieuwenhuis et al., 2005; Askenase et al., 2011). Interestingly, topical application of a CD1d-binding non-stimulatory glycolipid reduced the severity of the CHS response, likely by blocking the presentation of antigenic lipids by CD1d (Nieuwenhuis et al., 2005). The pathogenic role of *i*NKT cells could be attributed to their rapid production of IL-4 (Campos et al., 2003, 2006b).

Missed so Sadly: Beneficial Roles of *i*NKT Cells

Here we outline cases where the current consensus points to a beneficial role of *i*NKT cells in preventing disease development (Table 8.3).

Diabetes

Type 1 diabetes mellitus (T1D), also called insulin-dependent diabetes mellitus, is a Th1 autoimmune disease caused by the selective destruction of insulin-producing β -cells in the islets of Langerhans in the pancreas, leading ultimately to the loss of glucose homeostasis (for earlier *i*NKT cell reviews see Fletcher and Baxter, 2009; Wu and Van Kaer, 2009; Lehuen et al., 2010; Berzins et al., 2011; Novak and Lehuen, 2011).

Conflicting data on the frequency and function of *i*NKT cells from patient PBMC have been reported. Whereas some reports observed lower *i*NKT cell frequencies, at least of the CD4⁺ cells (Wilson et al., 1998; Kukreja et al., 2002; Kis et al., 2007; Montoya et al., 2007), others found equal (Lee et al., 2002b; Michalek et al., 2006; Tsutsumi et al., 2006; Oling et al., 2007; Zhang et al., 2011) or even more *i*NKT cells (Oikawa et al., 2002) in patient PBMCs compared to healthy controls. Furthermore, whereas some authors noted reduced cytokine production of *i*NKT cell (lines) and/or a Th2 bias (Wilson et al., 1998, 2000; Kukreja et al., 2002; Kis et al., 2007), others did not find such differences (Lee et al., 2002b; Roman-Gonzalez et al.,

2009). Importantly, one study analyzed *i*NKT cell lines derived from the draining pancreatic lymph node and observed reduced IL-4 production following antigen stimulation (Kent et al., 2005).

Non-obese diabetic (NOD) mice develop spontaneous T1D and have been studied extensively. *i*NKT cells in NOD mice are reduced in frequency (Berzins et al., 2004; Chen et al., 2011) and produce fewer cytokines following α GalCer (Gombert et al., 1996; Lehuen et al., 1998; Falcone et al., 1999; Hong et al., 2001; Sharif et al., 2001) or after stimulation of the innate immune system (Falcone et al., 1999). Increasing the *i*NKT cell frequency in NOD mice, either by cell transfer (Baxter et al., 1997; Hammond et al., 1998; Lehuen et al., 1998; Beaudoin et al., 2002; Chen et al., 2005; Cain et al., 2006; Simoni et al., 2011) or by overexpression of the *i*TCR (Lehuen et al., 1998), or by overexpression of CD1d on pancreatic island cells (Falcone et al., 2004), prevented or ameliorated symptoms. Consequently, *i*NKT cell deficient NOD mice showed increased frequency and earlier onset of disease (Naumov et al., 2001; Shi et al., 2001; Wang et al., 2001; Fletcher and Baxter, 2009). Furthermore, the repetitive injection of α GalCer ameliorated disease progression, even when treatment was started after the onset of insulinitis (Hong et al., 2001; Naumov et al., 2001; Sharif et al., 2001; Wang et al., 2001). Other α GalCer derivatives were similarly effective (Mizuno et al., 2004; Forestier et al., 2007; Ly et al., 2010). The original explanation for the therapeutic effect of α GalCer was the shift to a Th2 response (Hong et al., 2001; Naumov et al., 2001; Sharif et al., 2001), but not all studies observed such a shift (Shi et al., 2001; Wang et al., 2001; Beaudoin et al., 2002) and work with congenic NOD lines demonstrated that such a shift is not required for protection (Rocha-Campos et al., 2006; Jordan et al., 2007). Furthermore, the results from a number of papers are not in agreement as to which cytokine is essential for the protection from diabetes. IL-10 (Hammond et al., 1998; Hong et al., 2001; Naumov et al., 2001; Sharif et al., 2001) and/or IL-4 (Hong et al., 2001; Naumov et al., 2001; Sharif et al., 2001) were claimed to be important, but not in every case (Beaudoin et al., 2002; Mi et al., 2004; Novak et al., 2005; Chen et al., 2006), and even IFN γ elicited by *i*NKT cell activation was implicated as protective in one study (Cain et al., 2006). However, it was shown that activated *i*NKT cells can directly interact and influence T cells and DCs in multiple ways. Activated *i*NKTs were reported to impair the differentiation of pathogenic islet-specific CD4⁺ T cells, leading to T cell anergy (Beaudoin et al., 2002; Hugues et al., 2002; Novak et al., 2005). This was dependent on cell–cell contact between the *i*NKT and CD4⁺ T cells (Novak et al., 2005) and independent of CD4 T cell CD1d expression (Novak et al., 2007). Although overall numbers of regulatory T (Treg) cells in the NOD/ α GalCer model did not differ

TABLE 8.3 Beneficial Involvement of Human *i*NKT Cells in Selected Autoimmune Diseases

| Disease | <i>i</i> NKT cell frequency* | <i>i</i> NKT cell cytokines | Effects of treatment | Etc. |
|----------------------------------|--|---|--|--|
| Asthma | <ul style="list-style-type: none"> decreased in PBMCs? (a) yes: Koh et al. (2010); Yan-ming et al. (2012). (b) no: Magnan et al. (2000); Akbari et al. *The table only lists reports in which *i*NKT cells were identified by CD1d/ α GalCer tetramers or 6B11 antibodies or the combination of V α 24*V β 11*.

Comments: [1] differing results in Magnan et al. (2000); Prell et al. (2003); Wu et al. (2010); [2] NKT-like (CD3⁺CD57⁺) cells accumulated in the bile ducts of PBC patients (Harada et al., 2003).

Reference: Harada, K. et al. 2003. Accumulating CD57⁺ CD3⁺ natural killer T cells are related to intrahepatic bile duct lesions in primary biliary cirrhosis. Liver Int. 23(2), 94–100.

(Sharif et al., 2001; Ly et al., 2006; Forestier et al., 2007) their activity has been implicated by some (Ly et al., 2006; Diana et al., 2011), but not by others (Beaudoin et al., 2002; Cain et al., 2006). Tolerogenic effects on CD8⁺ T cells have been reported too (Chuang et al., 2011). Furthermore, *i*NKT cells in NOD mice treated with α GalCer could affect several DC populations leading to a tolerogenic outcome (Naumov et al., 2001; Chen et al., 2005; Saxena et al., 2007; Driver et al., 2010; Diana et al., 2011). Interestingly, this also required cell–cell contact (Baev et al., 2008; Caielli et al., 2010) but required CD1d expression on the DCs as well (Caielli et al., 2010). These tolerogenic DC were reported to induce Tregs (Diana et al., 2011) and migrate to the pancreatic lymph node to tolerize T cells locally (Chen et al., 2005). The diverse outcomes in the NOD mouse could reflect the different experimental systems used, for example, the transfer of different NOD mouse cell populations to recipients.

IBD/Crohn's Disease

Crohn's disease is characterized by a chronic and discontinuous inflammation deep in the tissues of both the small and large intestines, with high levels of Th1 cytokines. *i*NKT cells are reduced in PBMCs of affected patients (van der Vliet et al., 2001; Grose et al., 2007b). Additionally, V α 24 mRNA and the numbers of V α 24⁺ cells were reduced in the intestine (Grose et al., 2007b).

In Th1 cytokine-mediated mouse colitis models, stimulation of *i*NKT cells could ameliorate disease (Saubermann et al., 2000; Numata et al., 2005; Ueno et al., 2005). The data are consistent with the conclusion that this activation shifted the immune response from the deleterious Th1 cytokine pattern to a protective Th2 response (Saubermann et al., 2000; Numata et al., 2005; Ueno et al., 2005).

Multiple Sclerosis/EAE

Multiple sclerosis (MS) is a chronic, Th1/Th17 T cell-driven inflammatory disease directed against myelin antigens in the central nervous system (CNS), leading to progressive paralysis.

The frequency of *i*NKT cells was reduced in patient PBMCs in most (Illes et al., 2000; van der Vliet et al., 2001; Araki et al., 2003; Demoulins et al., 2003), but not all studies (Gigli et al., 2007; O'Keefe et al., 2008). This reduction was especially prominent in patients under remission (Illes et al., 2000; Araki et al., 2003). Furthermore, when *i*NKT cell lines derived from patient PBMCs were analyzed for cytokine production, one study found no difference (Gigli et al., 2007), one study observed a Th1 bias (Gausling et al., 2001), whereas two studies noticed a Th2 bias

of the *i*NKT cell lines (Araki et al., 2003; O'Keefe et al., 2008;). Interestingly, MS patients under treatment (IFN β : Gigli et al., 2007) or patients in remission (Araki et al., 2003) displayed an increased frequency of *i*NKT cells in PBMCs and increased cytokine production by them.

MS-like features can be replicated in mice by immunization with CNS peptides creating a model now called experimental autoimmune encephalomyelitis (EAE). Most (Jahng et al., 2001; Teige et al., 2004; Oh and Chung, 2011), but not all studies (Singh et al., 2001; Furlan et al., 2003) reported that *i*NKT cell deficient animals display exacerbated disease. Additionally, an increased *i*NKT cell frequency, due to expression of a V α 14*i* transgene, ameliorated disease (Mars et al., 2002, 2008). Importantly, activation of *i*NKT cells with α GalCer or Th2 biasing glycolipids related to α GalCer (Miyamoto et al., 2001; Zhang et al., 2008) protected mice against EAE. Protection correlated with a Th1 to Th2 cytokine diversion (Jahng et al., 2001; Miyamoto et al., 2001; Pal et al., 2001; Singh et al., 2001; Furlan et al., 2003; Zhang et al., 2008; Oh and Chung 2011) and a reduction of the Th17 T cell response (Mars et al., 2009; Yokote et al., 2010; Oh and Chung, 2011). However, which *i*NKT cell cytokines are important for these changes is not known. IL-4 and/or IL-10 have been suggested (Jahng et al., 2001; Miyamoto et al., 2001; Singh et al., 2001; Oh and Chung, 2011), but some data contradict this (Mars et al., 2002; Furlan et al., 2003); similarly divergent results have been reported role for IFN γ (Pro: Furlan et al., 2003; Mars et al., 2009 Con: Jahng et al., 2001; Oh and Chung, 2011). Although, *i*NKT cells can enter the CNS (Jahng et al., 2001; Mars et al., 2008; Oh and Chung, 2011) it is not certain if this is required for protection. Likewise, the importance of CD1d, beyond the primary *i*NKT cell stimulation, has been disputed (Wiethe et al., 2007; Mars et al., 2008). Recently, it was shown that *i*NKT cells activated by α GalCer in an EAE model skewed the CNS-infiltrating macrophage population towards a protective M2 type (Denney et al., 2012).

Systemic Lupus Erythematosus (SLE)

SLE is characterized by the production and deposition of autoantibodies against multiple nuclear antigens, leading to chronic inflammation of various tissues. The autoantigens are thought to derive from a defective clearance of apoptotic cells (see Chapter 17). According to one hypothesis, *i*NKT cells suppress autoreactive B cells in a CD1d-dependent fashion (for earlier *i*NKT cell reviews see Ronchi and Falcone, 2008; Gabriel et al., 2009; Chuang et al., 2012).

*i*NKT cells from patient PBMCs were reduced in frequency (Sumida et al., 1995, 1998; Kojo et al., 2001; van der Vliet et al., 2001; Wither et al., 2008; Wong et al., 2009; Parietti et al., 2010; Cho et al., 2011; Yu and Wang, 2011; Bosma et al., 2012) and proliferated less after stimulation *in vitro* with α GalCer (Kojo et al., 2001; Cho et al., 2011; Yu and Wang, 2011). Furthermore, resulting *i*NKT cell lines (Kojo et al., 2001; Cho et al., 2011; Yu and Wang, 2011; Bosma et al., 2012) or fresh *i*NKT cells from PBMCs (Bosma et al., 2012) displayed a Th2 bias but produced fewer cytokines overall. The frequency of *i*NKT cells in PBMCs correlated in most studies with disease severity (yes: Parietti et al., 2010; Cho et al., 2011; no: Wither et al., 2008) and serum levels of autoreactive IgGs (Green et al., 2007; Wither et al., 2008). Interestingly, the frequency of *i*NKT cells in peripheral blood increased following therapy (Oishi et al., 2001; Bosma et al., 2012). Whereas CD1d expression levels on APCs from patient PBMCs and healthy subjects did not differ, a decrease of CD1d surface expression was observed on patient B cells (Cho et al., 2011), and it was suggested that B cells in SLE patients were responsible for most of the *i*NKT cell defects (Bosma et al., 2012).

SLE in mice is studied either with mouse lines genetically prone to develop lupus-like diseases spontaneously, or in induced models by injection of either the hydrocarbon oil pristane, LPS, or apoptotic bodies in selected mouse strains (see Chapter 30). Most data are in line with the idea of a protective role of *i*NKT cells. Crossing lupus-prone mouse lines onto an *i*NKT cell deficient background led to exacerbated disease (Chan et al., 2001; Yang et al., 2004, 2007), although this was more pronounced for some organs than others (Chan et al., 2001; Yang et al., 2004). Interestingly, aged $J\alpha 18^{-/-}$ mice by themselves have been shown to develop lupus-like symptoms (Sireci et al., 2007). Similarly, in the induced lupus models *i*NKT cell deficiency exacerbated symptoms (Yang et al., 2003, 2011; Wermeling et al., 2010). However, the effect of antigenic stimulation of *i*NKT cells led to conflicting outcomes in the different models. In the (NZB/NZW)F1 mouse model of spontaneous SLE, injection of α GalCer into young mice was beneficial, but detrimental in aged animals (Zeng et al., 2003; Major et al., 2006; Yang et al., 2007). In line with a switch to a pathogenic role later in the disease is the observation that *i*NKT cells numbers increased with lupus progression in these (NZB/NZW)F1 mice (Morshed et al., 2002; Forestier et al., 2005; Yang et al., 2007). Furthermore, in aged mice *i*NKT cells become hyperactive (Forestier et al., 2005) and interfering with their activation by means of blocking glycolipids (Morshed et al., 2009) or anti-CD1d antibodies (Zeng et al., 2000, 2003; Takahashi and Strober, 2008) ameliorated disease. Not surprisingly, strain differences are also important as the effects of

α GalCer treatment in the spontaneous models affected lupus nephritis in one mouse line, but not the other (Zeng et al., 2003; Forestier et al., 2005), and likewise a strain dependence was observed for the induced models (Singh et al., 2005).

GOOD OR BAD PERFORMERS?

In some autoimmune diseases, *i*NKT cell number and/or function are altered, but it is much less certain if they play a role in pathogenesis or in regulation/prevention of disease. We consider two examples here.

Sjögren's syndrome is mediated by an autoimmune destruction of exocrine glands and *i*NKT cells in PBMCs from patients are reduced in numbers (Kojo et al., 2001; van der Vliet et al., 2001) and tend to show a Th1 cytokine bias following antigen stimulation (Kojo et al., 2001).

Celiac disease (CeD) is a chronic inflammation of the small intestine driven by the adaptive immune system and triggered by dietary gluten (Stepniak and Koning, 2006). As there is to date no animal model, data on the role of *i*NKT cells are still very limited. In PBMCs from CeD patients a decrease of *i*NKT cells has been reported in three out of four studies (yes: Grose et al., 2007a; Cseh et al., 2011; Calleja et al., 2011; no: van der Vliet et al., 2001). Additionally, fewer $V\alpha 24^+$ T cells were found in the intestine of CeD patients (Grose et al., 2007a), but again, it is uncertain how much of this expression was derived from *i*NKT cells (O'Keefe et al., 2004). Furthermore, it has been suggested that patient *i*NKT cells produced less cytokine following *in vitro* stimulation (Grose et al., 2007a). In patients the adherence to a gluten-free diet normalizes symptoms and, interestingly, this improvement correlates with a normalization of the *i*NKT cell numbers in PBMCs (Bernardo et al., 2008; Calleja et al., 2011; Cseh et al., 2011).

The Far End of the Question?

What emerges from this survey is that unlike some other T lymphocyte subsets, for example $Foxp3^+$ Tregs, *i*NKT cells have diverse effects on autoimmune disease pathogenesis. How can we account for this, considering their limited TCR diversity and essentially clonal specificity? Two main questions capture the potential involvement of *i*NKT cells during autoimmune diseases: What draws *i*NKT cells in, and what effect do they initiate?

What Activates *i*NKT Cells During Autoimmune Responses?

It is likely that *i*NKT cells need some form of activation to be involved in disease progression and like conventional T cells this could be modulated by differences in

signal 1 (TCR), signal 2 (costimulation), and signal 3 (cytokines).

- Signal 1 (TCR): Beyond the inherent autoreactivity of *i*NKT cells, CD1d-mediated activation of *i*NKT cells could conceivably be augmented in inflammatory settings by several means: (a) upregulation of CD1d on APCs, (b) the increased presentation of stimulatory self-antigens, e.g., following metabolic changes in activated APCs, (c) the presentation of stimulatory neo-antigen, and (d) so far unknown foreign antigens, e.g., from commensals or opportunistic pathogens. Furthermore, heterogeneity in the outcome of *i*NKT cell activation could arise from the fact that different glycolipids can elicit divergent cytokine responses and also different *i*NKT cell subsets respond differently to the same antigen.
- Signal 2 (costimulation): Besides these “classical” means of *i*NKT cell activation, additional pathways of activation have been described, some of which are known to be important for T cell costimulation. Well-known costimulatory molecules like CD28 (Kawano et al., 1997; Hayakawa et al., 2001; Wang et al., 2009) and CD154 (CD40L) (Kawano et al., 1997; Hayakawa et al., 2001) can affect *i*NKT cell activation, but so can other members of the TNF superfamily such as 4-1BB (Kim et al., 2008) and OX40 (Diana et al., 2009). The Ig superfamily molecule PD-1, known as a coinhibitory molecule, plays a role in modulating *i*NKT cells in mouse asthma models (Akbari et al., 2010). In addition, there are other receptors that can modulate *i*NKT cell stimulation, including NK receptors (Arase et al., 1996; Exley et al., 1998; Ortaldo et al., 2006), Fc γ RIII during arthritis (Kim 2006), adenosine receptors (Lappas et al., 2006), and β -adrenergic receptors (Wong et al., 2011). Some of these, such as the NK receptors, can act independently of TCR stimulation, while others apparently act in concert with the TCR. Although there is still limited information, as different subsets will likely express a different set of these receptors, they will respond differently. As these affects are cell–cell contact dependent, they are also dependent on migratory behavior of *i*NKT cells, which allows them to interact with a given APC.
- Signal 3 (cytokines): Activation of *i*NKT cells by cytokine combinations like IL-12/IL-18, IL-1 β /IL-23, IL-25, and TGF β have been outlined above. Additional cytokines have been suggested to modulate *i*NKT cell responses, including IL-2 (Sakuishi et al., 2007), IL-7 (Hameg et al., 1999), IL-15 (Li et al., 2006), IL-33 (Smithgall et al., 2008), GM-CSF (Crough et al., 2004), the prostaglandin D₂ (PGD₂) (Torres et al., 2008), and TSLP (Wu et al., 2010;

Jariwala et al., 2011). Many of these cytokines can be secreted in affected tissues during autoimmune-mediated inflammation. Therefore, different combinations of local cytokines could induce diverse responses from *i*NKT cell subsets that express the appropriate cytokine receptors.

Therefore, the *i*NKT cell-mediated influence on the immune response depends on the means by which a particular *i*NKT cell gets activated. This reflects a complex “information input” that depends on the subset characteristics of the *i*NKT cell, the particulars of the local cytokine milieu, and the type and activation status of the APC they interact with.

Which iNKT Cell Effector Functions Orchestrate the Development of Autoimmune Responses?

The different “inputs” causing the activation of *i*NKT cells lead to different “outputs” or *i*NKT cell responses that will affect autoimmune disease pathogenesis in different ways. Whereas the bias towards Th2 cytokines imparted by *i*NKT cells seems to be most often raised as the mechanism for the effects of *i*NKT cells in autoimmune diseases, newer data paint a more complex picture. *i*NKT cells can impact the Th1/2 balance via their cytokine production, whereby IL-4 and IL-13 promote Th2; IFN γ and TNF promote a Th1 response; IL-10 and TGF β suppress pathogenic Th1 responses; and under some circumstances even IFN γ has been shown to contribute to the development of Th2 responses (Bocek, 2004). However, the Th2 bias is clearly not sufficient to explain all observations and other factors play a role, dependent on the particular disease, its stage, and many other circumstances. Importantly, beyond the Th1/2 paradigm Th17 responses can be pathogenic (Weaver et al., 2007) and *i*NKT cells have shown to be effective at suppressing Th17 responses, as exemplified by their role in rheumatoid arthritis.

Additional *i*NKT cell-driven mechanisms have been suggested. For example, IFN γ can aid in the induction of anergy or apoptosis in antigen-specific Th1 T cells and this was suggested to be important in diabetes (Beaudoin et al., 2002; Hugues et al., 2002; Novak et al., 2005). Furthermore, IL-4, IL-10, and/or GM-CSF can promote the differentiation/recruitment of tolerogenic DCs. In addition, *i*NKT cells can under some circumstances aid in the induction of Tregs, either via tolerogenic DCs or via cytokines like IL-2, IL-10, and TGF β (Kojo et al., 2005; Liu et al., 2005; Cava et al., 2006; Ly et al., 2006). Furthermore, cell–cell contact-dependent mechanisms are important, and the activation of the above outlined receptor/ligand pairs is often mutual. Additionally, the

timing of *i*NKT cell action might be critical, as there are indications, for example in rheumatoid arthritis (Coppieters et al., 2007b; Kim et al., 2005), that the impact of *i*NKT cell activation can be beneficial and detrimental at different stages of the disease. Also, the diverse means by which distinct *i*NKT cell subsets are activated, and the different responses they make, are of course not mutually exclusive. This complexity surely contributes to some of the contradictory results on the role of *i*NKT cells in particular autoimmune diseases.

CONCLUSION

As outlined here, *i*NKT cells have been shown to be crucially involved in a wide range of autoimmune responses. Whereas it seems at first puzzling that a relatively small population has so many effects, one should keep in mind that even if present at less than a 1% frequency, *i*NKT cells are as abundant as typical CD4 memory cell populations, and they can exert their pivotal role due to their clonal specificity and explosive cytokine production. However, despite the vast literature on the role of *i*NKT cells in autoimmune diseases, much remains to be learned.

One important question, of course, is the extent to which the knowledge gained from animal models can be applied to humans. Although data from human patients are still relatively scarce, in several contexts they do suggest roles for *i*NKT cells that are comparable to the ones observed in mice. This is indeed very promising. Furthermore, we expect that soon functionally distinct *i*NKT cell subsets will be better characterized in humans, which most likely will help to readdress more specifically the role of *i*NKT cells in autoimmune diseases. A related issue is the potential of stimulating or inhibiting *i*NKT cells for therapeutic purposes. Despite the fact that α GalCer is already used in clinical trials for cancer, and other glycolipids and approaches for manipulating *i*NKT cells are in trial or are being planned, the therapeutic potential of *i*NKT cells remains to be validated.

INTRODUCTION—WHAT HAS TO BE GENERATED IN B CELL DEVELOPMENT TO MAKE IT TO MATURITY?

One B lymphocyte makes one antibody, which it displays on the cell surface in 10^4 to 10^5 copies as antigen-recognizing B cell receptors (BCRs). This central dogma of immunology (Jerne, 1955; Burnet, 1959) is observed in 98–99% of all B cells for the immunoglobulin heavy (IgH) chain locus, and in 95–97% of all Ig light (L) chain loci. Hence, in the majority of all B cells only one of two IgH, and only one of four (in the mouse), or six (in humans) IgL loci are expressed. This choice of only one IgH and one IgL allele for expression of protein is called “allelic exclusion” (for reviews see Melchers and Rolink, 1999, 2006).

The repertoires of different antigen-specific BCRs can maximally contain the number of Ig-producing B lymphocyte-lineage cells that produce one Ig heavy (H) and one light (L) chain. From the cellular dynamics of

B cell development one can try to estimate how many B lineage cells are generated in the lifetime of a mouse or a human, how many of these B lineage cells make it to a successful, Ig-producing B cell, and how many of these Ig⁺ B cells make it into the pools of peripheral, mature, antigen-reactive B cells. The antibody repertoire which is generated from progenitor cells by V(D)J rearrangements in the IgH and IgL chain gene loci is so diverse that many of the developing B cells can recognize autoantigens, and some are even polyreactive to several antigens (Zhou et al., 2007). At a first, immature stage of B cell development these autoreactive B cells are eliminated (Lederberg, 1959) in the primary lymphoid organ in a process termed “negative selection” (during adult life in bone marrow), at cellular sites yet to be discovered, before they can reach the peripheral sites of mature B cells. Pools of mature B lymphocytes are found at different sites in the body in different numbers and at different stages of differentiation from newly generated cells to antigen-experienced memory cells and

antibody-secreting plasma cells. In a 6- to 8-month-old inbred strain of mice, such as C57BL/6, such mature cells are predominantly found at two types of sites of the body that accommodate either B1 or B2 B cells.

FOLLICULAR B CELLS

In the follicular regions of spleen and lymph nodes, B cells aggregate in “B cell-rich” areas (Pillai and Cariappa, 2009), and find themselves surrounded, in the neighborhood of follicular helper T lymphocytes (King, 2009), ready to react to foreign antigen, but—in the absence of foreign antigen—over 98% are in a non-stimulated, resting, G0 cell cycle state. Clearly, they are not stimulated by autoantigens present in their neighborhood. Newly generated B cells are short-lived, with half-lives of less than a week. Experience by exposure to stimulation (e.g., by antigen) induces a longer half-life, in some cases of weeks and months. T cell-dependent stimulation in expanding germinal centers (Klein and Dalla-Favera 2008) at the interphase between T cell- and B cell-rich regions induces not only longevity, but also hypermutations of V regions of IgH and L chain genes at rates of 10^{-3} per base pair per division of the proliferating B cells, so that every cell division generates a somatic mutant in the variable regions of IgH and IgL chain genes. Hypermutating B cells in the dark zone of germinal centers divide at least once every 18 hours, and maybe even more rapidly, e.g., with cell cycle times of 6 hours, a finding that is paradoxical if DNA replication during the S phase of the cell cycle takes 8 hours and needs further investigation. Therefore, this proliferative expansion generates at least 1000 V region mutant B cells from one antigen-stimulated B cell in a week.

It is not the subject of this review, but should be noted that such hypermutations are likely to generate long-lived, autoantigen-reactive mature B cells that need to be silenced, not to elicit an autoaggressive response. It is also clear that the antigen-driven expansion of mutant B cells increasingly contributes to the total B cell repertoire as life goes on.

T cell-dependent stimulation of follicular B cells also induces IgH class switching and B cell differentiation to Ig-secreting plasma cells, followed by the migration of resting, long-lived, hypermutated, and Ig class-switched “memory” B cells and Ig-secreting plasma cells (Shapiro-Shelef and Calame, 2005) out of the follicular regions of spleen and lymph nodes, maybe even out of the secondary lymphoid organ and into specific sites (“niches”) within spleen and bone marrow (Tokoyoda et al., 2010; Weill et al., 2013). It has been estimated that a 6- to 8-week-old C57BL/6 mouse has around 5×10^8 of these B2 cells, but a more detailed quantitation of the sizes of

these different B cell subpopulations with age is missing for mice and humans.

INTRAEPITHELIAL B CELLS

In the gut- (and lung-associated) epithelia B lymphocytes are located at two distinct sites: in the gut they are found in follicular structures, surrounded by T lymphocytes not unlike in spleen and lymph nodes, near flat epithelial cells which are suspected to allow permeation of food- and commensal bacteria-derived antigens from the lumen into these lymphoid cell aggregations. Separate from these aggregations single B lymphocytes and Ig (predominantly M and A)-secreting plasma cells are dispersed in the lamina propria of the gut, from where their secreted IgA can traverse the epithelium and the mucous membranes into the lumen to interact with antigens of food and with commensal bacteria. Many of these so-called B1 lymphocytes (Tung and Herzenberg, 2006; Baumgarth, 2011; Montecino-Rodriguez and Dorshkind, 2012) appear somehow activated (as they are slightly larger and, occasionally, enter cell cycle), and it has been suggested that these B cells are reactive, or at least crossreactive, to autoantigens and such “quasi-autoantigens” as food and commensal bacteria. B1 cells need the spleen to develop (Wardemann et al., 2002). It is, therefore, possible that these B1 cells are positively selected by autoantigens by a low affinity reaction of their BCRs with these autoantigens present at these sites. Many of them can respond to antigens in the absence of helper T cells and, hence, to T cell-independent antigens. Many of them can activate activation-induced cytidine deaminase (AID) (Muramatsu et al., 2000; Revy et al., 2000) for Ig class switch recombination, again apparently without the help of T cells, but this class switch is almost entirely to IgA, and their capacity to hypermutate their V regions is very limited. It is not clear whether both populations of B cells in the gut, those organized in aggregates and surrounded by T cells near flat epithelium, and the others, the single B cells in the lamina propria, are B1-type cells.

Furthermore, and in contrast to conventional, B2-type B cells, B1 cells are able to repopulate their compartments after adoptive transfers and show strong clonal persistence *in vivo*. Thus, they can be considered to have “stem cell”-like properties, e.g., the capacity of migration to the right sites (e.g., gut) and the property of long-term self-renewal. Many of the B lymphocytes at these sites can be characterized as B1-type cells. In a 6- to 8-week-old C57BL/6 mouse around 5×10^8 cells may be found, i.e., as many as there are conventional B2-type cells in follicular regions of spleen and lymph nodes, but these numbers vary considerably with the health of the animal. B1 cells are considered to be the main source of so-called “natural antibodies” (Hooijkaas et al., 1984; Bos

and Meeuwesen, 1989; Bos et al., 1989). Again, a more precise quantitative analysis of the sizes of these B1 compartments with time is missing.

All these B cell sites are connected by blood and lymph vessels. Hence, when B lymphocytes are first generated in primary lymphoid organs, they enter the peripheral immune system via the blood, mainly through the central artery in the spleen from where they distribute themselves via the marginal zone to the different locations. Some marginal zone B cells probably continue their travel to gut- and lung-associated lymphoid regions where many of them establish themselves as B1-type B cells. Other marginal zone B cells begin to migrate continuously from the marginal zone into the follicular regions of spleen and back (Arnon et al., 2013). Eventually they also emigrate from the marginal zone to peripheral lymphoid organs, such as lymph nodes. In the peripheral lymphoid organs B cells can become experienced by antigenic stimulation, then circulate back, and reappear in the marginal zone of the spleen. This may, on rare and ill-understood circumstances, even allow them to change their preimposed preference to circulate back to the peripheral lymphoid site from whence they came, and redistribute themselves into another site in the system. For a site-specific distribution into B1- or B2-rich areas they need to be directed by specific chemokines, but it remains unclear whether (low affinity) recognition by autoantigens influences their choice of the B1 compartments, and whether ignorance (lack of any affinity) of autoantigens allows their aggregation in follicular B2 zones in spleen and lymph nodes. In addition, autoantigen recognition at non-lymphoid sites (such as, for example, in the articular synovial fluid of joints during active phases of rheumatoid arthritis) may contribute to the formation of lymphoid follicular structures capable of performing germinal center reactions at unusual, normally non-lymphoid sites in the body.

TWO TYPES OF MEMORY B CELLS

The distinction between B1 and B2 cells is particularly striking in the way memory is maintained in antibody-producing B cells. Longevity in the B1 compartment appears to be connected to continuous presence of the antigen, and to its stimulation to maintain an antigen-specific, long-lived, modestly activated state. Whenever such B1 cells show long-term repopulation potential upon transplantation, with longevity and persistence in the areas of the gut-associated lymphoid tissues, continued low-level antigenic stimulation via the BCR is suspected to be the selecting and survival-inducing signaling force. Food- or commensal bacterially-derived antigens, maybe with low level cross-reactivity with autoantigens, could

be such B cell receptor-mediated selecting forces. It is suspected that this cross-reactivity to autoantigens is beneficial to positively selecting and expanding a first line of B cells that encounter microbes which colonize the body after birth.

Memory B2 (classical) B cells and long-lived plasma cells have properties of long-term repopulating hematopoietic stem cells (LT-pHSCs) (Wagers and Weissman 2004; Luckey et al., 2006; Eliasson and Jönsson, 2010; Lesinski et al., 2012). They can migrate to, and become resident in, “niches” of spleen and bone marrow as long-term resting cells for long, in some cases life-long, periods of time. They retain this property when they are transplanted. We expect memory B2 cells not to rely on continuous low level stimulation via B cell receptors for survival. Their long-term resting persistence should be independent of the presence and continuous stimulation by antigen. Antigen-dependent restimulation mobilizes these resting B2 cells to leave their “niches,” and it remains to be seen how antigen specific this mobilization really is, i.e., whether memory cells specific for other, unrelated antigens are co-mobilized. Once the mobilized B2 memory cells have arrived at a peripheral lymphoid organ (e.g., a lymph node), the rechallenging antigen will activate the antigen-specific memory B2 cells to a memory-type B cell response, while those mobilized memory cells that are not specific for the challenging antigen may remain resting, and may return to their sites of rest in spleen and bone marrow.

Once the peripheral, mature, B lymphoid sites in the body have been formed and filled, a constant number of cells appear to maintain a given size by (largely unknown) mechanisms of homeostasis. Since the large majority of B cells are expected to turn over within days, weeks, or months, it follows that these B cell populations must be continuously replenished during life. However, the relative, and even the absolute, sizes of different B cell compartments change with age.

The description of the different B cell compartments, restricted to a few inbred strains of mice at a restricted time in their life, is far more detailed than that of humans—not to mention other species such as other mammals, fish, or birds. B1 and conventional B2 compartments, comparable but not necessarily identical to mouse, have been found and defined in humans (Descatoire et al., 2011). Very generally summarized, humans with a thousand-fold higher body size than mice have a thousand times more B cells with similar sites of cellular organization of similar subpopulations with similar functions. However, we lack a more systematic comparison with age and immunological experience of the two species, as these are studied for different reasons—mice, because of the tremendous experimental opportunities to study and interfere with its immune system, and humans, often because of self-centered, health-minded interests.

The limitations of the description of B cell development that follows should be seen in this light.

B LYMPHOPOIESIS BEFORE IG REPERTOIRE GENERATION—DEVELOPMENT OF PROGENITOR AND PRECURSOR CELLS

Lymphocyte development occurs in two phases. In the first phase cells are developed in sufficient numbers to the stage at which they first express an antigen receptor. Obviously, this phase is independent of any influence by antigen, because the antigen receptors have not yet been made. Developing hematopoietic cells on their way to B lineage cells enter a series of decisions which are influenced by their interactions with an inductive microenvironment. Once they are committed to the B lineage cells they begin the second phase when they begin to express BCRs.

DEVELOPMENT IN WAVES DURING ONTOGENY, AND IN NICHEs THROUGHOUT LIFE

Three waves of hematopoietic cell developments colonize the mouse embryo (Cumano et al., 2001; Godin and Cumano, 2002; Ling and Dzierzak, 2002). The first wave (primitive hematopoiesis) begins at embryonic day (E) 7.5 in yolk sac, i.e., extra-embryonically. This wave does not develop B lymphocytes, but only fetal-type hemoglobin-expressing erythrocytes, megakaryocytes, platelets, and special types of myeloid cells—the latter with unusual longevity (Irión et al., 2010; Schulz et al., 2012). The second and third waves of (now definitive) hematopoiesis originate intra-embryonically at E10.5 from the aorta–gonad–mesonephros area (Cumano et al., 1996; Medvinsky and Dzierzak, 1996), from where undifferentiated pHSCs (Ohmura et al., 2001; Huber et al., 2004; Cumano and Godin, 2007; Yokomizo et al., 2011) migrate through embryonic blood to developing rudiments of fetal liver, omentum, thymus, and bone marrow.

B cells develop in fetal liver, omentum, and bone marrow, probably in a process involving the transmigration of pHSCs from inside the blood vessels through vascular endothelium, to further differentiate on the other side in contact with mesenchymal and epithelial microenvironments (Tsuneto et al., 2013). Since B1 cell development in fetal liver occurs in one wave between E12.5 and birth of a mouse this organ never establishes a niche for long-term residing pHSCs.

By contrast, bone and its marrow—which generates B1 and B2 cells throughout life—is capable of developing

“niches” of long-term resting pHSCs in the neighborhood of, and in close contact with, non-hematopoietic stromal cells. It secures continuous, life-long generation of new hematopoietic cells, hence also B lymphocytes (Lu et al., 2011). The niches for pHSCs appear localized at sub-endosteal sites near intra-bone surfaces that allow the long-term residence of pHSCs with the capacity to long-term (LT) reconstitute a lethally irradiated host with all lineages of hematopoietic cells, including B lymphocytes. LT-pHSCs exist in different states of the cell cycle. In one state they are activated into cell cycle, i.e., they divide. One of the two asymmetrically dividing daughter pHSCs keep their stem cell status, hence they self-renew, while the other daughter cell differentiates to short-term (ST) repopulating HSCs that retain hematopoietic pluripotency, i.e., capacity to differentiate to multipotent myeloid/lymphoid progenitors (MPP), to common myeloid progenitors (CMP), and to common lymphoid progenitors (CLP), from which B lineage cells develop (Akashi et al., 1999).

In the other state they are resting in a G0 state of the cell cycle, and consume low levels of energy in a subosteal, hypoxic microenvironment. From this resting state a small number of cells can be mobilized (stem cell mobilization) to enter the cycling state. However, cycling LT-pHSCs might also revert back to a long-term resting state. Bone marrow microenvironments appear uniquely specialized to harbor resting, long-time residing cell types, such as long-term repopulating pHSCs, memory lymphocytes, and plasma cells. Among all LT-pHSCs in the resting cell population, only a minor subfraction of cells is “mobilized” at any time to enter asymmetric cell divisions and, because of this, only a part of all long-term resting pHSCs participate in hematopoiesis at any given time. This might allow the hematopoietic cell system to continuously refresh its pHSC pools by new, unused pHSCs, thereby preserving its genetic integrity and protecting itself from adverse somatic mutations in actively proliferating pHSCs—mutations that could contribute to breaking tolerance to autoantigens. On the other hand, if cycling LT-pHSCs can revert back to the G0 long-term resting state their somatically mutated genetic constitution might increase the chances for abnormal hematopoiesis and B lymphopoiesis with age (Rossi et al., 2007).

CELLULAR ENVIRONMENTS OF THE FIRST PHASE OF EARLY, ANTIGEN-INDEPENDENT B CELL DEVELOPMENT

Early embryonic phases of the first wave of B cell development in fetal liver of the mouse can be studied *in situ* in histological sections as the organ develops with time. Attracted by the chemokine ligands CXCL10 and CXCL12, produced by non-hematopoietic vascular

endothelial cells and mesenchymally-derived stromal cells, CXCR3 and CXCR4-expressing pHSCs and other early progenitors transit from embryonic blood through vascular endothelium into the developing fetal liver and migrate inside to mesenchymally-derived stromal cells. These non-hematopoietic cells provide the hematopoietic and B-lymphopoietic progenitors with interleukin-7 (IL-7), the cytokine which is mandatory to interact with IL-7 receptors (IL-7 R) on the hematopoietic progenitors to induce the early, antigen-independent stages of B1 cell development (Tsuneto et al., 2013). Thymic stromal lymphopoietin (TSLP) has been implied as an alternative stimulating cytokine in fetal liver (Montecino-Rodriguez et al., 2006).

Microenvironmental influences of these early phases of B cell development during the second, continuous wave of B cell development in developing bone are mostly yet to be discovered, but it appears reasonable to expect that, by similar modes, pHSCs will have to transit from embryonic blood into the environment of developing bone and marrow, and that IL-7, again, is the major force that drives the early phases of B cell development. While fetal liver generates almost exclusively B1a cells, bone marrow develops B1- and B2-type B lymphocytes, but the B1 cells, called B1b, differ from the embryonically developed B1a cells. Transplantation of E13.5 fetal liver pHSC-like cells repopulate the host preferentially with B1 cells, while transplantations of pHSCs and progenitors from adult mice repopulate the host preferentially with B2 lymphocytes. Bone marrow retains this capacity, though the numbers of pHSCs decrease with increasing age by at least 100-fold in 1 year of the life of a mouse.

B1a cells generated in fetal liver also differ in some properties from B1b and B2 cells generated in bone marrow. Since the enzyme terminal deoxynucleotidyl transferase (TdT)—which inserts N-region nucleotides at VDJ joints during Ig gene rearrangements—is not expressed in fetal liver (but only in bone marrow) the repertoires of newly generated B cell receptors are less diverse. How much that influences the capacities of these early embryonic repertoires to recognize and distinguish foreign from autoantigens is still not clear. B1a cells from fetal liver express CD5, a cell surface marker indicating cell activation, while most bone marrow-derived B1b cells do not. Furthermore, micro-RNAs play regulatory roles in the development of fetal liver-derived B1a and bone marrow-derived B cells. Thus the gene *Lin28b* is selectively expressed in hematopoietic progenitors of fetal liver, but not of adult bone marrow. It downregulates the expression of a family of miRNAs, the *let7* miRNA cluster. Ectopic expression of *Lin28* in bone marrow-derived pHSCs and progenitors reprograms B cell development, so that B1a cells are generated. These results argue for the existence of two B cell lineages, B1a and B2 (including, maybe, B1b), that are developed as two consecutive layers of B

cell repertoires (Tung et al., 2006; Montecino-Rodriguez and Dorshkind, 2012).

EARLY COMMITMENTS TO ANTIGEN-INDEPENDENT B CELL DEVELOPMENT

The initiation and maintenance of the development of B lymphoid lineage cells from pHSCs, MPP, CLP, and pro-/pre-B cells to pre-B1 cells, before the generation of sIgM + immature and mature B cells, is controlled externally by a microenvironment of non-hematopoietic (and maybe also hematopoietic) cells that provide cell contacts, cytokines, and chemokines for their mutual attraction, proliferation, and differentiation. After ST-pHSCs have been induced from LT-pHSCs by the action of FLT3 ligand, acting on *flt3*, to become MPPs, and after IL-7 has induced IL-7 R-expressing progenitors to enter the lymphoid pathway of differentiation. Inside the hematopoietic cells signal transducing and gene transcription-controlling factors regulate these processes of proliferation, cell survival, and differentiation. Three transcription factors, E2A, EBF, and Pax5 (Bain et al., 1994; Zhuang et al., 1994; Sigvardsson et al., 1997; Kee and Murre, 1998; Roessler and Grosschedl, 2006; Kwon et al., 2008), control B cell development from CLP. By contrast, little is known how microenvironments influence the choices of a multipotent progenitor to become myeloid or lymphoid, and how an oligopotent common lymphoid progenitor is influenced to become either a natural killer (NK) lineage, T lineage, or B lineage cell. While these decisions should have no influence on the repertoires of IgH and IgL chains that are generated, they may well be important for the efficiencies with which B cells are provided among the mature pools of cells. Over- or underproduction of B lineage cells could well have an influence on the functions of these B cell pools.

The molecular details of the transcriptional activation of B cell development have been clarified in remarkable detail (Decker et al., 2009; Ebert et al., 2011; Medvedovic et al., 2011; Revilla-I-Domingo et al., 2012; Vilagos et al., 2012). First, E2A begins to be transcribed as early in hematopoiesis as in pHSCs. In these cells the promoter of Pax5 remains silenced while its enhancer is activated. One developmental stage later, in MPP, E2A directly activates the expression of early B cell factor (EBF). This remains the pattern of gene activation, until the Pax5 promoter is activated in pro-/pre-B cells. This allows EBF to bind to the Pax5 promoter, and PU.1, IRF-4, IRF-8, and nFkB to bind to the activated Pax5 enhancer. EBF-complexed promoter and PU.1/IRF-4/IRF-8/nFkB-complexed enhancer form a supercomplex that allows the expression of Pax5. Pax5 then induces a large number of genes involved in early and late steps of B cell development, while

downregulating the expression of genes involved in myelopoiesis (Schebesta et al., 2007). Finally, Pax5 expression is terminated when differentiation to Ig-secreting plasma cells is induced (Shapiro-Shelef and Calame, 2005; Delogu et al., 2006; Ochiai et al., 2013).

Targeted deletions of the genes encoding these transcription factors result in blocking of B cell development at different developmental stages. E2A-deficient progenitor B cells have not yet entered DH to JH rearrangements at the IgH chain locus (Ikawa et al., 2004), whereas EBF-deficient and Pax5-deficient progenitors have done so, the latter on both alleles (Rolink et al., 1999). Both EBF- and Pax5-deficient CLP-like pro-/pre-B cells from bone marrow can be established as stable cell lines proliferating for long periods of time, like pre-BI cell lines (Rolink et al., 1991), identifiable as clones of cells by their individual sets of DHJH-rearranged IgH chain alleles on stromal cells (providing stem cell factor (SCF), the ligand of c-kit, and IL-7), added in sufficient quantities *in vitro* by the recombinant cytokine.

The Pax5-deficient progenitors are remarkably flexible cells. Clones of these cells, genetically marked by individual sets of DHJH/DHJH rearrangements at their IgH chain alleles, respond to different cell contacts and cytokines by different differentiation programs. Thus, *in vitro* they can be induced to macrophages by macrophage colony-stimulating factor (M-CSF), to dendritic cells by granulocyte-macrophage colony-stimulating factor (GM-CSF) and M-CSF, to granulocytes by GM-CSF and G-CSF, to natural killer cells by IL-2 and IL-15, to osteoclasts by TRANCE expressed on mesenchymally-derived stromal cells, and to thymocytes by mesenchymally-derived stromal cells expressing the NOTCH ligand DELTA1 in the presence of FLT3 ligand and IL-7, while their development to B cells—which is induced by stromal cells in the presence of FLT3 ligand and IL-7 in Pax5^{+/+} cells—is blocked by the Pax5 deficiency (Nutt et al., 1999; Rolink et al., 1999; Höflinger et al., 2004; Radtke et al., 2004).

Removal of the cytokine IL-7 *in vitro*, or transplantation into suitable recipient mice *in vivo*, induces the differentiation to VHDHJH/VLJL-rearranged, sIgM + immature B cells—however, only of wild-type-, but not of EBF- or Pax5-deficient cells. *In vivo* mature B1 cells (Hayakawa et al., 1985) develop from fetal liver- as well as bone marrow-derived wild-type cell lines, detectable in spleen and peritoneum of recombination activating gene (RAG)-deficient recipient mice. From fetal liver cell lines, B1a cells develop, while bone marrow-derived cells generate B1b cells (Hayakawa et al., 1985; Vegh et al., 2010).

In the presence of T cells, as in JH-T mice, or in RAG-deficient mice co-transplanted with CD4⁺ (and CD4⁺25⁺ T cells), there are also formed B2-type follicular B cells, mainly in spleen. These wild-type-, fetal liver-, or bone marrow-derived, wild-type Pax5-expressing cells do not

repopulate the bone marrow. By contrast, Pax5-deficient pro-/pre-B cells do migrate and reside after transplantation to bone marrow (Schaniel et al., 2002a,b), and this homing to bone marrow, also characteristic of earlier cellular stages of hematopoiesis (including pHSCs), is controlled by miR221 (Knoll et al., 2013). Expression of externally added, i.e., retrovirally transduced Pax5 induces B cell differentiation to CD19⁺ pre-BI cells, but not beyond, since the Pax5-deficient pro-/pre-B cell lines express an endogenously VH(7183)DHJH-rearranged IgH chain that apparently affects allelic exclusion (Simmons et al., 2012). It is still not clear whether such premature IgH chain rearrangements also occur during normal B cell development *in vivo*, and, if so, how such cells overcome the arrest due to allelic exclusion—maybe by VH gene replacements.

The long-term proliferating pro-/pre-B and pre-BI cell lines have been successfully used in experiments that have investigated the transgenic expression of genes active in B cell development and their functions *in vivo*, such as graded Pax5 expression in Pax5^{-/-} cells to biphenotypic myeloid/lymphoid cells, or miR221 expression in pre-BI cells, inducing cell migration to bone marrow, or the synergistic transforming activities of two oncogenes, one, pim-1, inhibiting apoptosis, the other, c-myc, inducing proliferation of pre-B cells to form pre-B lymphomas (Bouquet and Melchers, 2012). Unfortunately, such transduced expression of individual antibody genes has not yet been achieved, because the IgH chain gene cannot be expressed at the appropriate stage of B cell development, but is induced too early, blocking normal B cell development due to allelic exclusion.

THE SECOND, EVENTUALLY AUTOANTIGEN-SENSITIVE, PHASE OF B CELL DEVELOPMENT TO SIGM⁺ IMMATURE B CELLS

In the second phase of B cell development, Ig genes are rearranged, Ig H and L chains are made, deposited as pre-BCRs and BCRs on the cell surface and molecularly linked to intracellular signaling pathways. V(D)J rearrangements at the Ig loci occur stepwise at different cellular stages of B cell development. The emerging repertoires of IgH and L chains are screened successively at two checkpoints, at the first for their fitness by pre-BCR formation, and at the second for autoantigen recognition after BCR formation.

After IL-7 has induced IL-7R-expressing lymphoid/myeloid progenitors to enter the lymphoid pathway of differentiation, the rearrangement-active genes RAG1 and 2 and TdT (the latter only in bone marrow, not in fetal liver), as well as the genes encoding the Ig membrane

anchoring molecules Ig alpha and beta, and the components of the surrogate light chain (SLC), Vpre-B and lambda5, become expressed in CLPs. Vpre-B and lambda5 associate non-covalently to form an IgL chain-like structure in pro-/pre-B cells.

As soon as IgH chains become expressed, this SLC can form, between the IgL chain constant region domain-like lambda5 and the first μ H domain, S-S-bonded Ig(BCR)-like structures, called pre-B cell receptors (pre-BCR) (Melchers, 2005).

In SLC a carboxy-terminal peptide of Vpre-B and an amino-terminal peptide of lambda5 protrude at the location of the third complementarity-determining region of a normal VL domain. These non-Ig parts control the turnover of pre-BCRs with opposite effects on the cell surface: Vpre-B stabilizes surface deposition, while lambda5 downregulates pre-BCR by internalization. As pre-BCR signaling is dependent on the quantity of molecules on the surface, they appear to modulate pre-BCR signaling in opposite ways (Knoll et al., 2012).

When CLPs enter the B lymphoid pathway they open the IgH chain loci for DH to JH rearrangements and become $c\text{-kit}^+ \text{flt}3^+ \text{CD}19\text{-pro-/pre-B}$ cells, not yet expressing Pax5. Pax5^{-/-} pro-/pre-B cells appear arrested in B cell development at that stage.

In pro-/pre-B cells of mice, but not of humans, B cell development with DHJH rearrangements in reading frame 2 results in the expression of a DJ- μ protein that can assemble with SLC to form a VH-deficient pre-B cell receptor (pre-BCR)-like molecule on the surface of such cells. This appears to result in negative signaling to induce the deletion of these pre-BCR-like expressing cells (Haasner et al., 1994). This state of negative selection may extend into that phase of development when VH to DHJH rearrangements are initiated. In Pax5^{-/-} pro-/pre-B cell lines we have found VHDHJH-rearranged IgH loci, expressing IgH chains containing VH segments within the 7183-VH cluster (most frequently the VH81X segment), which are located at the 3' end of the clusters of VH segments in the IgH locus, but which cannot pair with SLC, thereby apparently evading this negative signaling by a pre-BRR (Wolf, I. and Melchers, F., unpublished). If IgH chains were made that could pair with SLC, such IgH chain loci might enter VH replacement reactions to generate an SLC non-pairing H chain to evade this negative selection (Nakajima et al., 2009). It has been estimated that, in the mouse, between 1 and 7% of all VHDHJH-rearranged IgH loci result from such editing of VH replacements (Davila et al., 2007). It is not known whether a possible specificity of the VH to autoantigens influences this negative selection, but an autoreactive (transgenic) IgH chain has been shown to induce VH editing in pro-/pre-B cells without having to form a functional pre-BCR (Nakajima et al., 2009).

At the chromosomal level of organization the IgH locus is controlled by contractions of large regions (Feeney et al., 2011; Guo et al., 2011a,b). In cells not yet expressing Pax5 the parts of the regions of the IgH locus containing DH segments are brought into proximity to the JH region for rearrangements.

Once these Pax5-negative cells have undergone DH to JH rearrangements, DH proximal VH regions (VH7183 and Q52) can also be brought near to the DHJH-rearranged regions, and rearranged, even before Pax5 is expressed. Strikingly, one VH segment, VH81x, is rearranged as the first VH segment most frequently. When rearranged “in-frame” with N-region insertions in bone marrow μ H chains are made which, in the vast majority of instances, cannot pair with SLC. Hence, in the adult, the B2 repertoire is selected against inclusion of these VH81x-expressing pre-B and B cells. By contrast, VH81x-containing μ H chains, produced in fetal liver without N-region insertions, can pair with SLC and appear in the peripheral, mature B1a cell repertoire. This “useless” function of the earliest VDJ rearrangements for the developing adult B cell repertoire in bone marrow has long been an enigma. However, the recent discovery that the IgH locus is further subdivided for additional control of VH rearrangements suggests a more differential usage of VH segments for the total process of VDJ rearrangements at the IgH locus. In the chromosomal region of the IgH locus between the DH and the JH segments a CTCF-cohesin binding site is located that further regulates the order of VH to DHJH rearrangements. Deletion of this site on the IgH locus increases proximal (VH7183, especially VH81x) over distal (VH J558) rearrangements (Giallourakis et al., 2010). As the 3'-located VH segments have been found to be used preferentially, as B cells begin VHDHJH rearrangements, we can speculate that the VH regions of the IgH locus are opened in a step-wise fashion. In the first step, accessibility of the locus may be more important than productivity for μ H chains.

THE FIRST CHECKPOINT FOR THE EMERGING B CELL REPERTOIRE—PROBING THE FITNESS FOR A GOOD BCR

Once the locus is open at all VH regions, distal VH rearrangements induced by Pax5 can be made. They are induced when Pax5-negative $\text{flt}3^+ \text{CD}19\text{-pro-/pre-B}$ cells differentiate to Pax5-expressing $\text{flt}3^- \text{CD}19^+$ pre-BI cells (Ebert et al., 2011). At this first checkpoint the emerging repertoire of μ H chains is probed for fitness of pairing with SLC. Pre-B cells expressing an SLC-fitting μ H chain can display the resulting pre-BCR on the surface. Cross-linking of the pre-BCRs by ligands provided either by the microenvironment or by the pre-B cells themselves induce proliferation of large pre-BII cells, signal

downregulation of the rearrangement machinery (RAG1 and 2) and of SLC expression, thereby limiting the supply of SLCs for pre-BCR formation, and hence limiting pre-BCR-induced proliferation. The VH repertoires of early pre-B cells before SLC-mediated proliferative expansion and of large pre-BII cells during proliferative expansion have been found to use VH segments at different frequencies, suggesting that the fitness for SLC pairing may be different for different VH families. This VH repertoire shift is delayed in surrogate light chain-deficient bone marrow (ten Boekel et al., 1997).

Only between 20 and 50% of all IgH chains can pair to form a pre-BCR on the surface of pre-BII cells, and they do so with varying degrees of fitness (ten Boekel et al., 1997, 1998; Kawano et al., 2006). The better they fit, the longer they proliferate. Cross-linking of pre-BCRs through positively charged arginine residues in the non-immunoglobulin portion of $\lambda 5$, possibly mediated by repetitive negative charges on molecules such as nucleic acids and other molecules on stromal cells, or by molecules expressed in pre-B cells themselves (Bradl et al., 2003; Ohnishi and Melchers, 2003), initiates pre-BCR signaling. Some μ H chains have been found that enter proliferation as large pre-BII cells even in the absence of a functional SLC. They carry charged amino acids (arginines, lysines) in the CDR3 regions of their VH domains, not unlike the carriage of non-Ig parts of SLC. This suggests that the charged amino acids in CDR3s can function in place of SLC to signal proliferative expansion of pre-BII cells. It remains to be seen what terminates this proliferation that is normally limited by SLC expression.

Pre-BII cells also close the second, often DHJH-rearranged IgH allele for further rearrangements, thereby securing allelic exclusion at the IgH locus. Since triple-deficient $V_{\text{pre-B1}}^{-/-}$, $V_{\text{pre-B2}}^{-/-}$, $\lambda 5^{-/-}$ B lineage cells still show allelic exclusion of expression of their IgH loci, pre-BCRs cannot be involved in signaling for allelic exclusion, leaving it open just how the successful expression of an IgH chain mediates allelic exclusion in such situations (Shimizu et al., 2002). Since double productively VHDHJH-rearranged B lineage cells have been found in numbers expected from a random process of in- and out-of-frame rearrangements at the IgH alleles, and since in all these cases only one of the two productively rearranged alleles could form a pairing IgH chain (ten Boekel et al., 1998), it remains to be seen just which is the SLC analogous partner to sense the pairing capacity of a newly made IgH chain.

Those heavy chains unfit to pair with surrogate light chains do not induce proliferation of pre-BII cells through pre-BCRs. In situations where pre-BCRs cannot be formed, such nonproliferating pre-BII cells nevertheless proceed towards differentiation (Grawunder et al., 1993,

1995; Rolink et al., 1996). However, because such pre-BCR-defective pre-B cells do not proliferate, their contribution to the developing B cell compartment should be at least 20- to 40-fold lower than that of their pre-BCR-expressing counterparts (Rolink et al., 1993).

In conclusion, the pre-BCRs do not use the classical complementarity-determining regions (CDRs) of the V_H domain of their IgH chains to bind ligands that could induce proliferation. Therefore, the newly generated V_H domain repertoire is not screened for antigen, i.e., autoantigen binding, but merely for fitness to pair, first with SLC and eventually with conventional IgL chains. In this way, there is exclusion of unfit H chains that may have other unwanted deleterious properties, such as the formation of self-aggregating immune complexes that might confer the danger of glomerulonephritis and vasculitis (Melchers, 2005).

EXPRESSION OF IgL CHAINS

When large pre-BII cells have terminated their proliferative expansion, they become resting, small pre-BII cells, just as the SLC non-pairing, non-proliferating pre-BII cells do. The IgL loci are opened, RAG1 and 2 become re-expressed and VL to JL rearrangements are initiated, in the mouse five times more frequently at the kL locus than the λ L loci, whereas in the human equally frequently at the kL and λ L loci. Only 10% of all potentially rearrangeable Vk segments, spread over the entire Vk region, are used in these first rearrangements, and they use the most 5'-located Jk most frequently. Vk segments, which are located in both orientations in the locus, are equally frequently rearranged by deletions and inversions. Two-thirds of the emerging in-frame rearranged immature sIgM⁺ B cells are immediately selected, such that further IgL loci rearrangements are terminated by downregulation of the RAG genes, the second kL allele remains in germline, non-rearranged form, and all λ L loci remain non-rearranged (Melchers et al., 2007). The immature B cell is likely to sense the production and surface deposition of a BCR, probably by "tonic" signaling and without recognition by an autoantigen binding to the VH/VL domains of the BCRs.

In the remaining pre-BII cells secondary and even subsequent rearrangements occur, probably for two reasons. One reason is that two of three VL to JL rearrangements end up out of frame, and hence do not allow translation into IgL chains. Hence the cell remains in the pre-BII stage, does not express BCRs, keeps the RAG genes expressed and all IgL alleles open for secondary and subsequent rearrangements, until it either manages a productive rearrangement to produce an IgL chain and, hence, a BCR and becomes an immature sIgM⁺ B cell, or

until it runs out of opportunities to rearrange, when all J_L segments have been used up.

The other reason is that, either after the first, or after any subsequent productive V_L to J_L rearrangement, the resulting BCR is autoantigen reactive. This immature autoreactive B cell is then recognized at the second checkpoint by autoantigens existing in bone marrow, and presented by a specialized microenvironment. It has been found that such autoantigen recognition keeps RAG expression upregulated, giving the immature B cell the opportunity to “edit” its BCR by secondary and subsequent V_L to J_L rearrangements, in an attempt to abrogate the recognition of autoantigen and enter the resting, immature sIgM⁺ B cell compartment, ready for exit from the bone marrow to the periphery, through blood via the central artery into the spleen. Hence, “edited” B cells contain signs of secondary rearrangements, as circles of DNA containing the excised intervening sequences between the V_L and the J_L segment used in the rearrangement, and by an increased frequency of V_λ to J_λ-rearranged alleles.

In human B cell development, most of the polyreactive cells (Wardemann and Nussenzweig, 2007) and some, but not all, autoreactive cells are lost during the transition from pre-B2 to immature B cells. In patients with systemic lupus erythematosus (SLE) and rheumatoid arthritis, however, these autoreactive and polyreactive BCRs are not lost at this checkpoint (Witsch et al., 2006), pointing to a role of this checkpoint in preventing autoimmune disease. By contrast, Köhler et al. (2008) found a subset of polyreactive pre-BCRs, expressed in pre-B2-like cells, to induce proliferation *in vitro*, suggesting positive selection by polyreactive pre-BCRs. However, other experiments indicate that pre-BCR cross-linking in fetal liver organ culture does not boost pre-B cell proliferation (Ceredig et al., 1998).

During the process of light chain editing, evolutionarily selected “editor” immunoglobulin light chains with low isoelectric points can “neutralize” the DNA-binding properties of certain heavy chains. Such IgL chains may preclude diseases, e.g., SLE that is mediated by antibody–DNA complexes (Li et al., 2001). Continued V_L to J_L rearrangement can also lead to the expression of two or even more different light chains in a single immature B cell (Gerdes and Wabl, 2004; Doyle et al., 2006; Khan et al., 2008). Immature B cells with one autoreactive and one non-autoreactive BCR can become unreactive to autoantigen because of dilution of the autoreactive with the non-autoreactive BCR. Dual-IgL-expressor B cells can enter the mature B cell pool while remaining potentially autoreactive. Light chain replacement can also lead to polyreactivity (Witsch et al., 2006). Interestingly, some human B cells co-express Vpre-B and conventional light chains together with μ chains containing CDR3 regions enriched in positively

charged and/or aromatic amino acids. Two-thirds of these cells are autoreactive and appear to have escaped central tolerance. Although human Vpre-B, which has an isoelectric point of 5.67, may act as an “editor” by neutralizing positively charged CDR3 regions, mouse Vpre-B proteins have an isoelectric point of 9.37 and thus may not be able to perform this function (Meffre et al., 2004).

THE SECOND CHECKPOINT: SITES AND MECHANISMS OF SELECTION OF NEWLY GENERATED SIGM⁺ B CELLS

While V_H repertoires expressed in immature B cells in the bone marrow and in immature and mature B cells in spleen are not significantly different, almost 90% of the newly formed immature B cells never leave the bone marrow (Rolink et al., 1999). They have half-lives of less than a week, probably for two reasons: they might have an intrinsic cellular program to enter apoptosis, unless selected to transit out of bone marrow into the periphery, and they might be subject to autoantigen-induced mechanisms of cellular deletion. In essence, a 6–8-week-old mouse continuously generates from around 10⁴ pHSCs over 2.5 × 10⁶ pre-BI cells, and 5 × 10⁷ small pre-BII 2 × 10⁷ immature sIgM⁺ B cells, into a pool of around 10⁸ such immature B cells, only to discard 9 × 10⁷, i.e., the vast majority of them, mostly in fear of autoreactivity. The invention of nature to generate diversity of recognition by V(D)J rearrangements must have been an accident in evolution that was developed as the adaptive branch of the immune system to be advantageous for the defense of the individual against unexpected aggressors, yet a dangerous weapon that could destroy this individual. No wonder, then, that most of the BCRs on immature B cells ever made have to be eliminated.

In this establishment of “central” tolerance in B cell repertoires by negative selection, neither the cellular microenvironments in the bone marrow nor the molecular mechanisms of deletion are well known. This is all the more remarkable since the processes of negative selection to establish central tolerance for the T cell repertoires in the thymus have been so well investigated. While the studies in the thymus have been aided by the realization that autoantigens should be presented by major histocompatibility complex (MHC) I and II molecules, nothing comparable is evident from the genetics of B cell development that would guide the search for the autoantigen-presenting modes that establish central B cell tolerance. However, the rapidly expanding cases of genetically identified immunodeficiencies leading to early blockages of B cell development should help to clarify the means whereby central B cell tolerance is established. Thus, it has been realized for some time that

the complement components C1q, C4, serum amyloid protein, complement receptor-2, or secreted natural serum IgM could be involved, as deficiencies of any one of these lead to SLE.

Two models for the selection of the emerging B cell repertoires have been proposed. In one model (Carroll, 2004), the maturing B cells are protected from the stimulatory influence of autoantigens released from apoptosing, blebbing cells in the primary lymphoid organ because macrophages expressing complement receptors (CIqR for CIq, CRI for C4) efficiently take up, and thereby remove, apoptosing cells bound by natural serum IgM and complexed with CIq and C4b. This model, however, does not explain how the developing repertoire of immature B cells is purged of autoreactive cells, nor does it take into account that immature B cells are sensitive to induction of apoptosis rather than to proliferation and development of Ig-secreting plasma cells and memory B cells.

In contrast, the second model (Melchers and Rolink, 2006) (Figure 9.1, redrawn from Figure 2 in von Boehmer and Melchers, 2010) proposes that autoantigens from dying cells are presented to the emerging repertoire of B cells by stromal cells in the primary lymphoid organ, i.e., bone marrow. The presenting cells are expected to express receptors for natural serum IgM that can bind via its Fc to IgM-Fc receptors. IgM via its variable regions could bind to autoantigens, possibly even in solution, then fix CIq and create a bridge between the CIqR, CRI, and FcR on the presenting cells. In this way autoreactive BCR on the immature B cell would then be brought together by CIq, C4, serum IgM, and autoantigens. Depending on the strength of the interaction of the BCRs with autoantigens, and possibly also on the nature of the presenting stroma cell, this autoantigen-induced signaling can have different outcomes. It can lead to apoptosis of the B cell, if the avidity of autoantigen-BCR binding is high, leading to negative selection of the B cell repertoire. Such negative selection has been documented in a variety of experimental settings. If BCR downregulation and re-expression of a secondary BCR due to editing of a new L chain, thus leading to a new, nonautoreactive BCR, occurs fast enough, this apoptosis may be avoided. Since approximately 90% of the 2×10^7 sIgM⁺ immature B cells that are made each day in the bone marrow of a mouse never arrive at the immature sIgM⁺ B cell pool of the spleen, it is likely that this negative selection engages the vast majority of the newly generated immature sIgM⁺ B cell repertoires in bone marrow, and before their transit to spleen (Rolink et al., 1999).

Alternatively, the interaction of the newly generated immature B cells can lead to positive selection, maybe into the B1b compartment, if the avidity of BCR-mediated interaction is low. Those B cells expressing BCRs with no avidity to autoantigens present in bone marrow will be “ignored,” and will be allowed to exit to

the periphery, as long as they show their “passport” specifying an unrecognized BCR on their surface. It is truly remarkable that, despite this extensive effort to avoid autoimmunity, the peripheral, mature B cells continue to be an autoimmune threat.

Further, it remains equally remarkable just how many cells are made, and then discarded, to generate the few that are finally allowed to leave the bone marrow to face the world of foreign antigens. This fate of the majority of all newly generated B cells reminds me of a fable, told by Anatole France (1893), of a young Persian king who asked his academicians to write the history of mankind—as this article is written to describe the history of B cells. Their initial rendition was carried to the king on 20 camels with 500 books each. The king complained that he would not have the time to read it all, and asked for a shorter version. Even the shorter versions were always too long to be read by the king in his remaining lifetime. Finally, a lone academician arrived with only one book, but the king responded by saying: “So I will die without knowing human history.” To which the academician replied: “I can summarize it for you in three words: ‘Ils naquirent, ils souffrirent, ils moururent’ (‘They are born, they suffer, they die’).”

FUTURE APPROACHES TO UNDERSTANDING CENTRAL B CELL TOLERANCE

A better understanding of the modes of central tolerance induced by apoptosis, editing, anergy, and ignorance still requires an identification of all of the relevant antigen-presenting cell populations. A strikingly similar model has been proposed for the establishment of peripheral B cell tolerance, i.e., negative selection of autoreactive B cells which are randomly, hence accidentally, generated by somatic hypermutation and class switching of a follicular helper T cell-driven immune response within germinal centers (Vinuesa et al., 2010). In this model the hypermutated, autoantigen-recognizing IgG takes the role of the natural IgM antibody proposed in our model (above) for the establishment of central tolerance of B cells.

In contrast to T cell development, in which only MHC-restricted, i.e., self MHC I- or II- plus autoantigen peptide-recognizing, T cells that recognize self MHC-I or MHC-II are allowed to exit the thymus and enter the periphery, B cells just need to show surface-bound IgM that does not recognize any autoantigen in bone marrow, and that has been “ignored” by the selecting environment to gain exit from the bone marrow. Once in the periphery, particularly the spleen, hardly any further cell loss is detected during the transition from immature (including transitional T1 and T2 B cells) to mature B cells in the spleen. In humans

Selection of the Primary B Cell Repertoires in Bone Marrow

FIGURE 9.1 Proposed Site for Autoantigen-Mediated Selection of Immature B Cells. A hypothetical microenvironmental cell, non-hematopoietic?, follicular dendritic?, expresses Fc- μ -receptors, C1q receptors, and complement receptor 1 (CR1). Note that several cells close to each other could also express these different receptors. Fc- μ -R bind natural IgM antibodies, which bind C1q when complexed with autoantigen. That allows binding of C1q to C1qR. C4 bridges the immune complexes with CR1. Newly generated immature sIgM⁺ B cells bind autoantigens with different avidities. High avidity binding induces apoptosis (negative selection), possibly aided by signaling from unknown cytokines. Low avidity binding induces survival and selection into B1 pools (not aided by BAFF). No avidity (ignorance) induces BAFF-mediated transfer into the periphery of mature follicular B2 cell pools (via T1 and T2 intermediates) expressing MHC II and CD40. Adapted from von Boehmer and Melchers (2010), and redrawn by Justin Hewlett, MNHS Multimedia Unit, Monash University.

there is a further reduction of the percentage of autoreactive cells (40 to 20%) across this transition, whereas the percentage of polyreactive cells remains at the low level (6%) already achieved during the transition from pre-B to immature B cells (Wardemann and Nussenzweig, 2007). Patients with, say, SLE or rheumatoid arthritis fail to establish recessive tolerance even at this second checkpoint, indicating that failure of several mechanisms for establishing tolerance likely contributes to these diseases (Yurasov et al., 2005). The genetics of autoimmune diseases and immunodeficiencies are now investigated by full genome analyses (Mackay et al., 1999; Rolink et al., 2002; Kumar et al., 2006; Deane et al., 2007; Liu et al., 2007; Xie et al., 2007; Shlomchik, 2008). It is predictable that an ever-increasing number of mutant molecules involved in (often also epigenetic) regulation of gene expression, of signal transductions from a variety of receptors involved in the interactions of B lineage cells with their inducing microenvironments, controlling proliferation, differentiation, migration and survival on their way to mature B cells will be found to change the normal course of B cell development.

Finally, it is unclear how the affinity for antigen of a BCR decides what it signals to either the immature or later the mature B cell. Of relevance here, a monoclonal, autoreactive, dsDNA-binding, SLE-propagating, hypermutated IgG autoantibody was isolated from an SLE patient. The corresponding VH and VL domains of the IgH and IgL chain genes were then “back-mutated” to the germline-encoded VH/VL sequence, and expressed as an antibody (Schroeder et al., 2013). In this back-mutated form, the antibody remarkably failed to bind to dsDNA any longer. The corresponding immature B cell expressing this antibody as a BCR was evidently not negatively selected by dsDNA, which is abundantly present in bone marrow throughout life. How, then, did the mature BCR⁺ B cell ever become autoreactive? Possibly the cell entered a germinal center reaction, hypermutated, and that a dsDNA-binding somatic mutant B cell then evaded negative selection in the process of peripheral tolerance induction—but who or what triggered it?

It is fully possible that we do not understand how a cell surface-bound BCR establishes contact with the autoantigen (in bone marrow) or antigen (in the periphery),

possibly presented (as occurs for T cells in thymus and periphery) by antigen-presenting cells. To quote Huppa and Davis (Huppa et al., 2010; Huppa and Davis, 2013) on their studies of the interaction of T cells with antigen-presenting cells in immunological synapses: “There is increasing evidence that the molecular dynamics of receptor–ligand interactions are not only dependent on the intrinsic properties of the binding partners but also become transformed by cell biological parameters such as the geometrical constraints within the immune synapse, mechanical forces, and local molecular crowding. To appreciate the complete picture, we think a multidisciplinary approach is imperative, which includes genetics, biochemistry, and structure determination and also biophysical analyses and the latest molecular imaging techniques.” It seems therefore not unreasonable to expect that similar dynamics of antigen recognition by BCRs on immature and on mature B cells, and of costimulatory or co-inhibitory surface-bound ligands and receptors will become evident, which will lead to redefinitions of the distinction between “self” and “non-self” in B cell repertoires at different stages of development.

All these examples should make it clear that we are merely at the very beginning of a vision of the control of autoimmunity, or better, the lack of it, in the genetic variants of nearly 7×10^9 human individuals with a functional immune system. Moreover, it will not only be the genetics of B cells, but also their environment, that will be found to exert control. Kurt Tucholsky (1890–1935), German journalist and satirical writer, unwillingly but farsightedly defined what appears to become so important to understand about the functioning of the immune system of lymphocytes in their environments: “Ein Loch ist da, wo etwas nicht ist. . . Das Merkwürdigste an einem Loch ist der Rand. Er gehört noch zum Etwas, sieht aber beständig in das Nichts, eine Grenzwache der Materie. Das Nichts hat keine Grenzwache: während den Molekülen am Rande schwindlig wird, weil sie das Loch sehen, wird den Molekülen des Lochs ‘fest-lig’?” (Zur soziologischen Psychologie der Löcher, 1931). (Translated: “A hole is there where something is not. . . The most remarkable thing about the hole is its rim. It belongs to the something, but looks into the nothing, as a border control of the material. The nothing has no border control, while the molecules at the rim of the hole get dizzy, because they see the hole, do the molecules of the hole get ‘stabilized’?” (The Sociological Psychology of the Holes, 1931).

ACKNOWLEDGMENTS

It should be clear to the reader that my description of B cell development is highly personal, often biased, and incomplete in the quotation of relevant literature, particularly of opposing views. I apologize to all those whom I might have disappointed or even offended. During my attempts to assemble it, I was often ready to

give up. Only the patient persistence of the editors has brought this article to its present status. To once more quote Anatole France (as I was alerted to him by one of the editors, I.M.): my article is less than 500 books in size, and more than the final format of the one sentence quoted above, in the hope that the king does have the time to read it.

I thank my long-time scientific friends, especially Jan Andersson and Ton Rolink at the no-longer-existing Basel Institute for Immunology, for the never-ending discussions of the scientific subject that has united us for so many years. Finally, I thank the Max Planck Society and its Institute for Infection Biology in Berlin for the many years of support as a Max Planck Fellow, well beyond the limits of my official retirement from the Basel Institute for Immunology.

B CELL ACTIVATION

B cells form an important part of the immune system by helping the host to fight against pathogens. In pursuit of their mission of surveillance for foreign antigens, B cells must: (1) gain access to the area where antigens are available (migration); (2) recognize and bind to antigen (antigen specificity); (3) increase antigen-specific cell numbers (proliferate); and (4) mature into terminally differentiated cells including *plasma cells* that secrete antibodies to neutralize antigen and *memory cells* that remember previous encounters with antigen and aid subsequent recognition of the same antigen during future infections. The process controlling this series of events is referred to as B cell activation.

T-dependent activation of B cells occurs in two distinct phases: first, B cells are activated by foreign protein antigen, and second, antigen-specific B cells interact with activated helper T cells with the same antigen specificity.

Antigen-Triggered Activation

Engagement of the B cell antigen receptor (BCR) initiates two interdependent processes, signaling and receptor internalization (information on the mechanisms driving the assembly of the BCR is provided in [Box 10.1](#)). Cross-linking B cell surface receptors (IgD or monomeric IgM on naïve B cells) leads to a cascade of reactions, comprising the first step of B cell activation. When two or more receptor molecules are cross-linked by multivalent antigens, the cytosolic subunit Ig α -Ig β dimers, which are covalently linked to the BCRs, initiate intracellular signaling. The conserved signaling motifs (immunoreceptor tyrosine-based activation motifs or ITAMs) contained within the cytosolic tails of Ig α -Ig β are tyrosine phosphorylated by Src-family tyrosine kinases (Lyn, Fyn, and Btk). These initial events lead to the activation of intracellular signaling molecules and transcription of genes involved in the regulation of B cell activation ([Harwood & Batista, 2010](#)).

Box 10.1 Basic Understanding of B Cell Receptors (BCR)

- B cells share with T cells the ability to recognize specific antigens through their expression of antigen receptors that are expressed early in B cell development through the rearrangement of immunoglobulin genes.
- Diversity in BCRs is achieved through the random recombination of the Ig heavy and light chain genes that encode the BCR and the antibody produced.
- Rearrangement of Ig genes to bring heavy chain variable region genes into proximity with different heavy chain constant region genes also determines the isotype of antibody the B cells produce, either IgM, IgG, IgA, or IgE.
- The isotype of antibody produced, and the nature of the constant region of the BCR, can change over the course of an immune response, allowing the B cell to make the appropriate antibody response for the particular threat.

Secondary Signals for B Cell Activation

However, since BCR cross-linking by antigen alone is not sufficient to fully activate B cells, several pathways exist to deliver additional signals that boost the BCR activation signal. A second set of signals is delivered when the BCR becomes closely associated with the BCR–coreceptor complex (Harwood & Batista, 2010). This complex comprises three main components: CD19 (containing the cytoplasmic signaling domain of the BCR), CD81 (of unknown function), and CD21 (complement receptor CR2 which binds to iC3b, an inactive derivative of C3b, C3dg, or C3d) (Carroll, 1998). Microbes possess antigens rich in polysaccharides that activate the complement system directly through binding C3b. Despite further degradation of C3b its derivative C3d continues to bind to the microbial surface. The BCR–coreceptor complex will bind to complement components on microbial surfaces via CD21, leading to further receptor clustering which significantly enhances the BCR activation signal in response to antigen.

The importance of complement-mediated activation of B cells is shown in mice with a disrupted CR2 gene. These mice display a reduced number of B cells in the spleen, a defect that is reversed upon reconstitution with bone marrow from CR2 expressing wild-type mice (Ahearn et al., 1996). Similarly, mice lacking CR2 expression are unable to generate antigen-specific plasma cells, or to maintain antibody production, in response to viral infection, as CR2 mediated costimulation is required to induce the transcriptional regulators Blimp-1 and XBP-1, molecules driving plasma cell differentiation (Gatto et al., 2005).

The Immediate Consequences of B Cell Activation

B cells process antigen through a series of orderly steps. The endocytosis of receptor-bound antigen is the first in a series of signaling-mediated events that ensures that antigens are efficiently captured, processed, and presented to cognate T cells. These include the prompt transfer of internalized antigens to the endosome and then to the lysosome where the BCR–antigen complex is degraded into peptides. Peptides coupled with major histocompatibility complex (MHC) class II molecules are transported to the cell membrane for presentation to T-helper cells. The intracellular trafficking of BCR–Ag complexes is mediated via the reorganization of actin cytoskeleton and involves the synergistic action of small proteins that promote cell contraction (e.g., Myosin II), and “chaperone molecules” that escort the BCR–Ag complexes to lysosomes (Vascotto et al., 2007). Signaling via the BCR enhances the synthesis of MHC class II molecules and increases expression of costimulatory molecules CD80, 86 (B7-1, B7-2). Any defects in the molecules or mechanisms involved with the transport of antigen or its degradation, or involved in the coupling with MHC class II, result in impaired antigen presentation to T cells and consequently abnormal B cell activation.

B CELL ACTIVATION REQUIRES INTERACTION WITH HELPER T CELLS

The process of mutual stimulation between B and T cells is known as costimulation and requires specificity of both B and T cells for the same antigen. It is possible that B and T cells will recognize different epitopes on the same antigen. Nevertheless, although B cells recognize intact antigen and T cells recognize antigen-derived peptides presented in MHC, the antibody produced by the B cells will be specific for the same antigen as the T cells recognize. T cells activate B cells both by direct contact and indirectly through secretion of cytokines (Guy & Hodes, 1989).

Cell Surface Molecules Involved in B Cell–T Cell Interactions

Activated T cells express high levels of CD154 that binds to CD40, a molecule constitutively expressed on the surface of B cells. The engagement of CD40 by CD154 leads to a further upregulation of CD80/86 on B cells, which in turn bind to CD28 on T cells, resulting in further activation of T cells. The interaction between CD40 and CD154 is also important for class switch recombination (CSR) (discussed later), the clinical relevance of which became apparent when defects in the CD40 (*CD154L*) gene were

found to be associated with the development of X-linked hyper IgM syndrome type 1. These patients present with excessive production of IgM at the expense of IgG, IgA, and IgE, and have increased susceptibility to common infections including pneumonia, sinusitis, and otitis (Noelle, 1996). Blocking the CD40–CD154 pathway using an anti-CD154 monoclonal antibody has been shown to be effective in reducing the severity of autoimmune diseases such as experimental collagen-induced arthritis in rodents (Durie et al., 1993) and immune thrombocytopenia in humans (Kuwana et al., 2004), further reinforcing the importance of this pathway in B cell activation.

Cytokines Involved in B Cell–T Cell Interactions

Activation of costimulatory pathways not only stabilizes and strengthens the communication between T and B cells but also leads to the transcription of several genes by both B and T cells, including the upregulation of cytokine receptors on the surface of B cells. Activated T cells will release several cytokines including IL-2, lymphotoxin, interferon- γ , and IL-10. IL-2 induces proliferation of B cells, whereas IL-4 and IL-10 are needed for their further differentiation into mature B cells (Mingari et al., 1984; Rousset et al., 1992). These accumulated signals will activate the transcription of immunoglobulin (Ig) genes and at this stage some of the B cells will differentiate into plasma cells producing antibodies.

It is important to note that the profile of cytokines secreted by T cells also influences the isotype of antibody produced. For example, abundant IL-4 induces production of predominantly IgG1 and IgE, whereas IFN- γ favors IgG2a production, and TGF- β favors IgA production (McHeyzer-Williams & McHeyzer-Williams, 2005).

Therefore, interaction with a specific antigen of high affinity and effective cross-linking of the BCR, followed by cognate interaction with activated cytokine-producing helper T cells, is required for full activation of B cells. The absence of any of these signals during T–B cell interactions results in B cell anergy. As discussed in more detail later in this chapter, anergic B cells in the periphery are unable to proliferate or to develop further into mature B cells.

A better understanding of the costimulation pathways involved in the activation of B cells and their further maturation to antibody producing plasma cells (or autoreactive antibody) has led to the development of therapeutic agents to treat autoimmune diseases. For example, abatacept, a CTLA4-Ig fusion protein, was developed to block costimulation of B and T cells and its safety and therapeutic efficacy have been demonstrated in the treatment of rheumatoid arthritis (Genovese et al., 2012).

ACTIVATION AND MATURATION OF B CELLS OCCURS IN LYMPHOID ORGANS

In the previous section we learned how activation of B cells requires highly synchronized processes initiated by the recognition of antigen and by interaction with T cells. But where do B cells encounter T cells with the same antigen specificity?

Where Do B Cells become Antigen Activated?

In the bone marrow, B cells carrying an antigen receptor develop from pluripotent stem cells. Only cells that do not react against self-antigens progress through distinct developmental stages. Immature B cells migrate from the bone marrow and through the blood and lymphatic system to a designated location (primary lymphoid follicle) in the spleen or lymph nodes where they mature into naïve B cells (B cells that are yet to encounter a foreign antigen). In addition to B cells, this area is enriched with follicular dendritic cells (FDC), which are cells of mesenchymal origin that help organize lymphoid architecture. FDCs capture opsonized antigen (antigen bound with antibody and complement components) on their cell surfaces via the expression of complement and Fc receptors, which facilitates B cell antigen recognition. Naïve B cell migration through the lymph nodes is guided by the release of chemokines by both FDCs and stromal reticular cells. The chemokine molecules CCL21 (expressed by stromal cells) and CXCL13 (expressed by stromal cells and FDCs) guide CCR7 and CXCR5 expressing B cells through the follicles (Cyster, 2010). The expression of the chemoattractant-type receptor Epstein-Barr virus-induced G-protein coupled receptor 2 (EBI2) by naïve B cells is also important for their migration through lymph nodes; however, the ligand for EBI2 is not yet established (Cyster, 2010). This is a dynamic process as B cells that have not been primed within the initial 24 hours of arriving in the lymphoid tissue recirculate back to the blood in search of cognate antigen (Gonzalez et al., 2011).

To facilitate an encounter with antigen, naïve B cells travel among the FDCs to the outer follicle attracted by CXCL13 and EBI2L. After eventual encounter with their specific antigen, B cells upregulate the expression of adhesion molecules promoting interaction with FDCs, and of integrins that drive their migration towards the T cell zone (Spaargaren et al., 2003). Similarly, CCL21 and CCL19 expression by fibroblastic reticular cells in the T cell zone encourages the B cells to recirculate to the interface between the B and T cell zones. Subsequent upregulation of chemokine receptors (e.g., CCR7, a receptor for CCL19 and CCL21) traps the B cells in this area.

Antigen Activation of B Cells Leads to the Selection of High Affinity Class-Switched Antibody

Once in the T cell zone, some B cells further proliferate and differentiate directly into plasma-blasts, the direct precursor of antibody producing plasma cells. This provides for a “quick fix” to control the spread of infection and is usually referred to as the primary response. However, some of the antigen-activated B cells migrate into the primary lymphoid follicle and form germinal centers (GC). GCs comprise dividing B cells and a small proportion of antigen-specific T cells that provide help to B cells (Cyster, 2010). Several important events related to activation occur in GCs, including *somatic hypermutation*, a process altering the V-regions of Ig genes; *affinity maturation*, which involves selecting the B cells with high antigen specificity; and *class switching*, whereby the selected B cells change the classes of antibodies they secrete to exert their distinct functions.

Somatic hypermutation (SHM) is the initial step. Here site-directed point mutations are induced in the variable (V) regions of the Ig genes of activated B cells, resulting in the expression of BCRs with potentially altered specificities. The mutated B cells are selected based on their affinity for the antigen. If SHM results in a BCR with a high affinity for the original antigen, the B cell expressing this BCR will outcompete antigen-specific B cells with lower BCR antigen affinities for cognate interactions with helper T cells. The B cells with higher affinity BCRs will then receive survival signals provided either by CD154 (CD40L) expressed on the helper T cells or by FDCs. This process, called affinity maturation, will lead to a pool of antigen-specific B cells secreting higher affinity antibody than those secreted by the initial antigen-specific B cell pool (Di Noia and Neuberger, 2007).

CSR occurs after SHM and affinity maturation have taken place (Muramatsu et al., 2000). Transcriptional gene rearrangements lead to the recombination of the Ig genes so that the IgM heavy chain gene is excised from the Ig locus and the constant region for another Ig heavy chain is joined to the heavy chain Ig variable region. The variable region of the Ig heavy chain remains unchanged. As a result of these processes (SHM and affinity maturation), cells switch the class of Igs they secrete from low affinity IgM to a high affinity IgG isotype (Di Noia and Neuberger, 2007). A genetic defect in any gene involved in CSR results in the development of hyper IgM syndrome type 2. These immune-deficient patients are characterized by the absence of immunoglobulin CSR, the lack of immunoglobulin somatic hypermutations, and lymph node hyperplasia caused by the presence of enlarged GCs (Revy et al., 2000). These events occurring

in the GCs prepare the B cell for the production of a long-term targeted response to a foreign antigen.

The Germinal Center

The GC can be divided into three zones: the dark zone, the light zone, and the mantle zone. Within the dark zone of the GC, antigen-activated B cells evolve to form large rapidly dividing cells, the centroblasts (Figure 10.1(2)). It is at this stage and in this location that centroblasts diversify their IgV genes by SHM. Centroblasts move out from the densely packed dark zone and enter the light zone (FDC area) where they differentiate into centrocytes, which then form the outer rim or mantle zone of the GC. Although most centrocytes die *in situ*, those receiving appropriate help from surrounding T cells will differentiate into memory or plasma cells. The end result of GC formation is the production of antigen-specific plasma cells that secrete high affinity antigen-specific Igs, and generate memory cells to counteract any subsequent infection with the same antigen. Memory B cells are long-lived cells, surviving sometimes for up to many years, as also is the case for some plasma cells (Klein & Dalla-Favera, 2008).

T CELL-INDEPENDENT ANTIBODY RESPONSES

B cell responses to non-protein antigens, including polysaccharides and lipids, do not require T cell help and are defined as T-independent responses. Such responses are of two types, 1 and 2. The type-1 response (TI-1) involves engagement by antigens of additional receptors expressed by B cells that regulate innate immune responses, e.g., Toll-like receptors (TLR). TLRs play an important role in regulating the innate immune response and recognize highly conserved molecules expressed by microorganisms. Type-2 responses (TI-2) are against antigens that contain repeating epitopes, such as the cell wall polysaccharides of *Streptococcus*, which simultaneously cross-link multiple BCRs and deliver prolonged signals to the B cells. The cumulative intracellular signaling following engagement of BCRs, TLRs, and B cell coreceptors provides the necessary signal strength to promote B cell activation, proliferation, and plasma cell differentiation in the absence of T cell help. B cells express varying levels and types of TLRs, among which TLR9 is the most highly expressed. TLR9 recognizes CpG motifs in bacterial DNA. The expression of TLR9 by B cells is particularly relevant in the context of autoimmune diseases such as systemic lupus erythematosus (SLE). TLR9 and TLR7 bind to endogenous DNA and RNA respectively and, following BCR recognition and internalization of these autoantigens, there is enhanced release of autoantibodies

Box 10.2 Pathways of Breakdown in Self-Tolerance Leading to Autoimmune Diseases due to a Primary Defect of B Cells (A, B, and C) or Secondary Immune Dysregulation (D and E)

- T-independent antigens such as lipopolysaccharides and DNA CpG motifs can activate autoreactive B cells through TLR 4 and 9 to secrete rheumatoid factors and anti-DNA antibodies.
- Foreign antigen, modified by infection or drugs, can activate “ignorant” autoreactive B cells. Examples include rheumatic fever following streptococcal infection and autoimmune hemolytic anemia associated with α -methyl dopa.
- Tonic signals and intrinsic B cell defects and/or polymorphisms of BCR, $Fc\gamma RIIb$, Lyn, CD22, and CD45 might influence B cell activation and tolerance and lead to the development of systemic autoimmune diseases.
- Impaired extrinsic regulatory mechanisms such as defective complement pathways and regulatory T cells are associated with systemic autoimmune diseases, rheumatoid arthritis and SLE.
- Autoreactive B cells present self-antigens to T cells, with the same antigen specificity, leading to multiple organ-specific autoimmune disease.

against nuclear components, a hallmark of SLE (Green & Marshak-Rothstein, 2011) (summarized in Box 10.2).

B CELL TOLERANCE: A TRADITIONAL AND NEW CONCEPT

The immune system is highly efficient in defending the host against continuous exposure to foreign antigens while halting the maturation of B cells that recognize self-antigens—autoreactive B cells. This latter process (among others) provides for B cell tolerance. Defects in any of the component parts of this process contribute to the development of a group of diseases wherein various organs in the body come under misguided attack from its own defense system. The profound discrepancy between the frequency of autoreactive cells generated in the thymus or bone marrow, some 90% of all new cells, and the rarity of autoimmune diseases highlights the efficacy of tolerance mechanisms for purging the immune system of autoreactive B cells. Tolerance acquired during the development of B cells in the bone marrow constitutes “central tolerance,” whereas mechanisms halting the maturation of autoreactive B cells in the peripheral lymphoid tissues constitute “peripheral tolerance.” Fifty to seventy-five percent of antibodies produced by early immature B cells isolated from human bone marrow are autoreactive or polyreactive (Wardemann et al., 2003); however, multiple checkpoints throughout B cell development

usually prevent mature B cells from producing autoantibody. In addition to the classical view of B cell tolerance as a process that has evolved to prevent production of autoantibodies, we will introduce a new concept in which B cells can serve as effector cells that actively suppress autoimmune responses.

B Cell Tolerance is Acquired by at Least Three Different Processes

First, if a B cell expresses an autoreactive BCR, particularly at an early stage of development, then the B cell can alter its BCR genes in order to express a non-autoreactive version, a process called “receptor editing.” Second, if “receptor editing” fails, autoreactive B cells can be removed while still in the bone marrow by a process termed “clonal deletion.” Third, autoreactive B cells that nevertheless escape to the periphery may acquire tolerance by entering a state of unresponsiveness to antigen, termed “anergy” (Figure 10.1).

Receptor Editing and Clonal Deletion

The generation of adaptive immune responses relies on the random rearrangement of antigen receptor genes to produce a diverse repertoire of antigen receptor specificities. Successful in frame V, (D) J recombination leads to the expression of a productive BCR, followed by suppression of RAG 1 and 2 genes to prevent further rearrangements (Nussenzweig et al., 1987). However, if these rearrangements produce an autoreactive BCR, the B cells may undergo receptor editing. Receptor editing is a second rearrangement of the VJ genes encoding the Ig light chains that results in the expression of a BCR with a new specificity and has been reported to be the main mechanism of B cell central tolerance towards high avidity membrane bound antigens. If rearrangement of the light chain genes results in the expression of a productive BCR with no autoreactive specificity then B cells are allowed to survive and reach maturity (Halverson et al., 2004). For instance, Gay et al. generated mice that were transgenic for Ig heavy and light chain genes that encoded a BCR that was specific for dsDNA, an autoantigen in murine and human lupus. As these genes were already rearranged they would be the first heavy and light chains to be transcribed and, in the absence of receptor editing, all B cells should have been clonally deleted due to their autoreactive BCRs. However, the adult mice had a normal number of mature B cells due to the fact that, while all their B cells expressed the heavy chain transgene, all mature B cells expressed an endogenous light chain, demonstrating that receptor editing had taken place to produce a non-autoreactive BCR (Gay et al., 1993).

FIGURE 10.1 Following the journey of B cell from the bone marrow to the periphery. (1) In the bone marrow, B cells develop from common lymphocyte progenitor (CLP) cells that originate from hematopoietic stem cells (HSC). The random rearrangement of Ig genes results in expression of the B cell receptor (BCR). Immature B cells bearing non-self-reactive BCR (IgM) survive and emigrate from the bone marrow. Clones of autoreactive cells that recognize multivalent membrane bound self-antigen may be deleted or undergo receptor editing in an attempt to express non-autoreactive BCRs. Autoreactive B cells that bind monovalent or oligovalent soluble antigen become anergic. (2) Naïve B cells reach the peripheral lymphoid tissues (lymph nodes and spleen) via the blood and lymphatic systems, where they migrate, following chemo-attractant gradients, to areas where they can interact with follicular dendritic cells and T cells. Interaction with antigen results in B cell activation. In the absence of T cell help antigen-activated B cells undergo apoptotic death. However, if the antigen-activated B cells receive T cell help then some will give rise to short-lived IgM plasma blasts and plasma cells, while others will become rapidly dividing centroblasts (found in the dark zone) that proliferate to become centrocetes (found in the mantle zone). With further T cell help B cells may mature to become memory cells and plasma cells. (3) Additional regulatory systems exist to control the potential damage that maturation of autoreactive B cells may have on the immune system. In response to activation with autoantigen, and/or upon interaction with lipopolysaccharides (LPS), some B cells may differentiate into regulatory B cells (Bregs). Bregs limit tissue damage in certain autoimmune conditions by dampening inflammatory responses. This is achieved by the secretion of anti-inflammatory cytokines such as interleukin (IL)-10 and Transforming Growth Factor (TGF)- β , and/or via inhibition of the development of proinflammatory T cells (T helper-1/T helper-17), and/or by promoting the development of regulatory T cells (Tregs) which in turn inhibit the production of autoantibody.

Receptor editing usually occurs early during B cell development and predominantly, although not exclusively, in the bone marrow. Secondary rearrangements may also occur in the periphery although their importance in maintaining tolerance remains to be fully defined. RAG genes are re-expressed in germinal centers, and it

has been demonstrated in mice that mature follicular B cells that are autoreactive and anti-dsDNA specific can undergo receptor editing in germinal centers following antigen activation, which removes dsDNA specificity (Rice et al., 2005). However, receptor editing, or revision of light chains at this stage of development may have a

role in the generation of high affinity antibodies rather than a role in B cell tolerance (Wang et al., 2007).

If receptor editing in the bone marrow fails to produce B cells with functional BCRs that are not autoreactive then the B cells may be eliminated by apoptosis, a process termed “clonal deletion.” Clonal deletion was originally thought to be the major mechanism of B cell central tolerance to high avidity membrane bound or multivalent self-antigens; however, later studies have suggested that receptor editing is the primary mechanism for removing autoreactive B cells. Clonal deletion provides a final failsafe when receptor editing fails (Pelanda & Torres, 2012).

Defective Receptor Editing Can Promote Autoimmunity

Although receptor editing is the main process contributing to the removal of autoreactive B cells, this system is not perfect. The Ig heavy chain often has the dominant contribution to BCR specificity and if the heavy chain is autoreactive the rearrangement of the light chain may not fully remove the autoreactivity (Luning Prak et al., 2011). In addition, light chain rearrangement does not always lead to the abrogation of expression of the initial light chain and when the B cells reach the periphery the initial autoreactive light chain may be re-expressed (Li et al., 2002b).

Defective receptor editing has been associated with autoimmunity in both mice and humans. Both excessive and inadequate receptor editing can be seen in mice with autoimmune conditions, extensively reviewed by Luning Prak et al. (2011). Excessive receptor editing can result in the generation of B cells with autoreactive BCRs. For example, lupus-prone MRL/lpr.56R mice that are transgenic for an autoreactive Ig heavy chain have an increased production of autoantibodies compared to non-transgenic MRL/lpr mice. However, the majority of the autoantibodies in the transgenic mouse do not use the transgenic Ig heavy chain, suggesting that excessive receptor editing has led to the generation of autoreactive BCR (Li et al., 2002a). Nevertheless, inadequate editing can allow the escape to the periphery of autoreactive B cells; lupus-prone non-transgenic MRL/lpr mice display less efficient receptor editing compared to non-lupus-prone controls (Lamoureux et al., 2007). Furthermore, it has been hypothesized that inefficient receptor editing in autoimmune-prone mice might allow the escape to the periphery of B cells with two types of Ig heavy or light chain. These dual reactive B cells are rare in healthy mice but increased in number in autoimmune strains and are frequently more autoreactive than B cells expressing only one heavy and light chain (Fournier et al., 2012).

Anergy

Despite the efficiency of receptor editing and clonal deletion, B cells carrying self-reactive BCRs may still escape central tolerance and reach the periphery. Here, tolerance can be achieved by inducing a state of unresponsiveness to antigen, known as anergy, in the autoreactive B cells. Anergy results from B cell binding to low avidity or soluble antigen without receiving adequate additional signals to support their activation. Anergic B cells are unable to interact effectively with helper T cells and do not participate in immune responses against their cognate antigen. It was initially demonstrated that B cell tolerance to antigens could arise through anergy rather than clonal deletion (Nossal & Pike, 1980), as follows. Treatment of newborn mice with a soluble molecule, fluorescein-human gamma globulin (Flu-HGG), resulted in tolerance to this molecule in the adult mice. After treatment, adult mice were tolerant to Flu-HGG but unexpectedly this was not as a result of clonal deletion, rather the mice retained normal numbers of Flu-HGG-specific B cells, but these B cells were unable to respond to the antigen. Subsequently, Hartley et al. elegantly demonstrated that it is the nature of the antigen, rather than the affinity of BCR–antigen interactions, that is responsible for whether tolerance comes from clonal deletion or anergy (Hartley et al., 1991). Hartley et al. generated two transgenic mouse models with both carrying B cell receptors that were specific for hen egg lysozyme (HEL); the first expressed membrane-bound HEL as well as the transgenic BCR, and the second expressed soluble HEL as well as the transgenic BCR. The results demonstrated that clonal deletion of the HEL-specific transgenic B cells occurred when mice expressed membrane-bound HEL, whereas clonal anergy occurred in mice expressing soluble HEL. Thus, immature B cell binding to high avidity multivalent membrane-bound antigen mainly leads to receptor editing, or clonal deletion, while binding to low avidity monovalent, or oligovalent, soluble antigen mainly leads to anergy.

Characteristics of Anergic B Cells

Anergic B cells are characterized by a low expression of BCR on their cell surface due to reduced BCR recirculation from the endoplasmic reticulum. This low expression of the BCR is an important feature of anergic B cells. First, it prevents signaling through the autoreactive BCRs. Second, anergic B cells show an increased recruitment of negative signaling regulators, including SHP1 and SHIP, to the BCR complex. Increased SHP1 and SHIP expression can inhibit BCR-mediated B cell activation by the dephosphorylation of signaling molecules downstream of the BCR and Ig α /Ig β . Defects in SHP1 or SHIP are associated with increased autoantibody production (Huang et al., 2003). Third, anergic B cells have a half-life of 1–5 days in contrast to

non-autoreactive naïve B cells with a half-life of around 40 days (Fulcher & Basten, 1994). The short half-life of anergic B cells adds an additional brake to B cell autoreactivity.

SURVIVAL FACTORS AND TONIC SIGNALS MODULATE B CELL TOLERANCE

Tonic Signaling in B Cell Development

Immature B cells with fully functional BCRs leave the bone marrow and emigrate to the periphery where they further mature into transitional 1 (T1) and transitional 2 (T2) B cells. Transitional B cells survive for around 3.5 days, and only 10–30% of them will become mature marginal zone (MZ) or follicular (FO) B cells. Two factors are critical for this transition: tonic BCR signaling, and stimulation by the B lymphocyte activating factor (BAFF) (Pelanda & Torres, 2012). Signaling that occurs in the absence of antigen engagement with the pre-BCR or BCR is called tonic BCR signaling (Monroe, 2006). Stochastic interactions between CD45 in the BCR signaling complex and SRC family protein tyrosine kinases (PTKs) lead to the phosphorylation of ITAMS associated with $Ig\alpha$ and $Ig\beta$ and initiate signaling downstream of the BCR (Monroe, 2006). Tonic BCR signaling is held in a dynamic equilibrium with negative signals from BCR coreceptors such as CD5, CD22, and CD72. SRC PTKs that are activated by tonic BCR signals also phosphorylate inhibitory immunoreceptor tyrosine-based inhibitory motifs (ITIMs) on molecules such as CD22, which in turn recruit protein tyrosine phosphatases that dephosphorylate the ITAMs on $Ig\alpha/\beta$ to inhibit BCR signals. Thus, tonic signaling does not in itself lead to full B cell activation but for immature B cells plays a role in development and survival (Rowland et al., 2012). Tonic signaling positively regulates the expression of BAFF receptor (BAFF-R), and the combination of tonic signaling and BAFF/BAFF-R signaling drives immature B cell maturation to transitional and mature B cells (Rowland et al., 2012). The requirement for both BAFF-R expression and tonic signaling for immature B cell maturation provides a checkpoint for preventing the escape of autoreactive B cells into the periphery; binding of autoantigen by autoreactive B cells leads to the internalization of the BCR and thus a loss of both tonic signaling and BAFF-R expression (Rowland et al., 2010; Pelanda & Torres, 2012).

Tonic Signaling and Autoimmunity

Defects or deficiencies in tonic signaling can lead to autoimmunity. A failure of tonic signaling at an immature B cell stage leads to a developmental regression that can restart the process of Ig gene recombination and potentially break allelic exclusion (Tze et al., 2005). This may

result in B cells that express both autoreactive and non-autoreactive BCRs; the tonic signals from the non-autoreactive BCR provide the developmental and survival signals that allow the escape of dual specific autoreactive B cells (Pelanda & Torres, 2012). Deficiencies in the molecules that negatively regulate tonic, and antigen-dependent, BCR signaling can also lead to autoimmunity. CD22 deficient mice produce high affinity anti-dsDNA antibodies suggesting that defects in CD22 function may support B cell-mediated autoimmunity (O’Keefe et al., 1999). $Fc\gamma RIIb$, an inhibitory Fc receptor, which also contains an ITIM on its intracellular domain, plays a role in regulating BCR signals through the recruitment of tyrosine phosphatases. Mice deficient in this receptor develop spontaneous autoimmune disease characterized by fatal glomerulonephritis and accumulate anti-dsDNA plasma cells (Fukuyama et al., 2005). In humans, polymorphisms in the $Fc\gamma RIIb$ gene that encode molecules with reduced regulatory activity have been associated with SLE (Niederer et al., 2010). In lupus-prone mice, overexpression of $Fc\gamma RIIb$ restored B cell tolerance (McGaha et al., 2005).

BAFF and Autoimmunity

B cell survival depends on the presence of several key chemical mediators. One such mediator is BAFF, which belongs to the tumor necrosis factor (TNF) ligand family, also known as B lymphocyte survival factor (BLyS). As well as its role in promoting B cell maturation, it promotes mature B cell proliferation and differentiation (Schneider et al., 1999). The major sources of BAFF for normal B cell homeostasis are stromal cells in the bone marrow and spleen; however, at sites of inflammation it is mainly produced by monocytes (Gorelik et al., 2003). BAFF binds to three different receptors expressed on B cells at different stages of maturation: BAFF-receptor, BCMA (B cell maturation antigen), and TACI (transmembrane activator and calcium modulator and cyclophilin ligand interactor). The predominant receptor expressed on human peripheral blood B cells is BAFF-R, while BCMA and TACI appear to be preferentially expressed on plasma cells and transitional B cells, respectively (Ng et al., 2004). The importance of BAFF in B cell maturation was elegantly demonstrated by work from the Mackay group. B cells in BAFF and BAFF-receptor-deficient mice were developmentally arrested at the transitional 1 stage of B cell development (Mackay et al., 2002); this group also demonstrated that B cells from BAFF transgenic mice secreted unusually high amounts of rheumatoid factor (RF) antibody and the mice developed lupus-like disease (Mackay et al., 1999). BAFF overexpression rescued autoreactive B cells from deletion in the periphery, but not from the bone marrow, and favored their migration to

follicular and marginal zone areas of lymphoid organs (Thien et al., 2004). Patients with autoimmune diseases such as Sjögren's syndrome and SLE have high levels of BAFF, which may contribute to altered differentiation of B cells (Pillai et al., 2011). Treatment with Belimumab (an anti-BAFF monoclonal antibody) leads to an improvement in symptoms in patients with SLE (Navarra et al., 2011). Thus, whereas BAFF signaling is critical in normal B cell development, when dysregulated it can provoke a breakdown in B cell tolerance leading to systemic autoimmunity.

REGULATORY T CELLS

B cell peripheral tolerance is also maintained by regulatory T cell (Treg) suppression of autoantibody production by B cells. Tregs can suppress autoantibody production indirectly by preventing the maturation of the humoral response by suppression of the T helper cells that would support B cell antibody production (Fields et al., 2005), or directly by inducing apoptosis of autoreactive B cells (Gotot et al., 2012). However, the exact mechanisms by which Tregs suppress autoantibody production remain elusive.

ANTIBODY-INDEPENDENT ACTIVITY OF B CELLS IN TOLERANCE

Cytokine Production by B Cells

As discussed earlier, the generation of B cell tolerance is shaped during the development of B lymphocytes, by receptor editing, clonal deletion, and anergy. However, evidence has emerged for an antibody-independent role for B cells in the maintenance and breakdown of tolerance. B cells can produce a polarized array of cytokines depending on their primary encounter with antigen and T cells so, as for T cells, B cells can be distinguished based on the cytokines that they produce. Naïve B cells that differentiate in the presence of T helper 1 cells release high levels of $\text{IFN}\gamma$, IL-12, and $\text{TNF}\alpha$ and contribute to the clearance of infection, or contribute to the pathogenesis of Th1-mediated autoimmune diseases. In contrast, naïve B cells that differentiate in the presence of T helper 2 cells predominantly produce IL-2, IL-4, and IL-6 and so may play a pathogenic role in allergic reactions (Harris et al., 2000). The contribution of the cytokines released by B cells in the pathogenesis of autoimmune disease is yet to be clearly defined, but recent findings have shown that IL-6 producing B cells promote Th17 responses and contribute to the pathogenesis of experimental autoimmune encephalomyelitis (EAE), and multiple sclerosis (Barr et al., 2012).

Regulatory B Cells

B cells can also produce the cytokines IL-10 and $\text{TGF}\beta$, known to restrain the excessive inflammation associated with autoimmunity. Over the last decade, numerous studies have confirmed the importance of IL-10 producing regulatory B cells (Bregs) in the maintenance of tolerance (Mauri & Bosma, 2012). Studies utilizing chimeric mice, whose B cells alone are IL-10 deficient, have revealed that B cell derived IL-10 limits the severity of inflammation in several autoimmune disorders (Carter et al., 2011; Fillatreau et al., 2002). In the absence of IL-10 producing B cells, chimeric mice present a reduction in the number of Tr1 and Foxp3^+ Tregs, and an increase in inflammatory Th1 and Th17 cells compared to mice with IL-10 sufficient B cells. Thus, Bregs contribute to the maintenance of peripheral tolerance by production of potent anti-inflammatory cytokines (IL-10 and/or $\text{TGF}\beta$), directly by inhibiting the differentiation of Th1 and Th17 cells, and indirectly by converting targeted effector T cells into Tregs (Carter et al., 2011). BCR activation, which is crucial in dictating the specificity of antibody responses and the function of B cells as antigen presenting cells, may also have a role in Breg function. Research has revealed that exposure to an autoantigen leads to an increased IL-10 production by Bregs and an enhanced ability to suppress the pathogenesis of autoimmune disease (Mauri et al., 2003). Similarly, in the field of transplantation, it has been reported that TIM-1^+ Bregs prolonged pancreatic islet allograft survival, but only when the TIM-1^+ B cells are specific for the MHC expressed by the transplanted islet cells, suggesting a role for specific BCR signaling (Ding et al., 2011).

Bregs also play a role in the maintenance of tolerance in healthy individuals. Immature B cells isolated from healthy volunteers produce a higher amount of IL-10 than any other human peripheral blood B cell subset, and can suppress proinflammatory cytokine production by CD4^+ T cells following polyclonal activation with anti-CD3 *in vitro*. Interestingly, in patients with SLE, isolated Bregs failed to upregulate IL-10 in response to CD40 engagement, and failed to suppress the production of proinflammatory cytokine by T cells (Blair et al., 2010). Accordingly rituximab, a B cell depleting anti-CD20 monoclonal antibody which has proved successful in treating some autoimmune conditions, may function not only by depleting autoantibody producing B cells, but also by resetting the balance between pathogenic and regulatory B cells following B cell repopulation (Manjarrez-Orduno et al., 2009; Bosma et al., 2012).

The immune system has several checkpoints to curtail the escape of autoreactive B cells in the periphery and hence prevent autoimmunity. Among these checkpoints are receptor editing, clonal deletion, and anergy. However, it is

becoming clearer that in the periphery tolerance is also maintained by regulatory subsets of cells, including Bregs and Tregs, that control the production of inflammatory cytokines and limit autoreactive responses (Figure 10.1(3)).

FUTURE DIRECTIONS

Knowledge of the mechanisms of B cell tolerance is as yet incomplete. Until recently clonal deletion was thought to be the major mechanism of B cell tolerance; however, it is now clear that receptor editing has a greater influence. Similarly, the exact nature and location of the events that decide whether an autoreactive B cell undergoes receptor editing or becomes anergic warrants further study. Moreover, the majority of the work done to elucidate B cell tolerance has been performed in mice and these results need to be extended to humans.

Whether defects in particular mechanisms of B cell tolerance result in clinically different autoimmune diseases is as yet unanswered. For instance, could defects in receptor editing that lead to the expression of two distinct B cell receptors by mature B cells, one autoreactive and one reactive to a microbial antigen, be important in generating autoantibody to autoantigens that the B cells might otherwise not see? B cells expressing dual BCRs may be activated by the microbial antigen to produce autoreactive antibody and contribute to the pathogenesis of autoimmune diseases despite the offending autoantigen not being generally subject to immune surveillance, e.g., antigens in the central nervous system. Similarly, it is not currently clear what effect the presence of a constantly renewing niche of anergic B cells in healthy humans has on B cell-driven immune responses (Palanichamy et al., 2009). Assuming a large proportion of these anergic B cells are autoreactive they may compete with non-anergic B cells for autoantigen, and thus their presence could prevent the activation of autoreactive T cells. Defects in the generation of anergic B cells may thus lead to autoreactive T cell-mediated autoimmunity. Or indeed an excessively large anergic B cell pool may prevent non-anergic B cells from activating T cells. Defects in individual tolerance checkpoints may thus characterize individual autoimmune diseases.

INTRODUCTION

Although the role of macrophages in innate immunity, and of closely related dendritic cells (DCs) as the bridge to adaptive immunity, has been amply recognized, most recently through the award of Nobel Prizes, their contribution to autoimmunity has been strangely neglected, often reduced to a secondary role in inflammation and tissue injury. A primary role for macrophages in the initiation and perpetuation of autoimmune diseases remains elusive. This is partly due to semantics, if autoimmunity is restricted to antigen-specific drivers of T and B lymphocytes, whereas in many instances the pathogenic role of antigen-activated T and B cells cannot be ascribed only to their own effector cytokines and antibodies, which may themselves be secondary to dysregulated antigen presentation. Moreover, in many classic autoimmune diseases it has not been possible to identify specific autoantigens. The recent delineation of rare but instructive autoinflammatory syndromes, their attribution to genetic abnormalities in intracellular sensing pathways of macrophages, and the dramatic benefits of IL-1 receptor antagonist treatment indicate that there may be a continuous spectrum of genetic and environmental inflammatory diseases that are not strictly autoimmune, but which cannot be easily distinguished from

demonstrably antigen-driven conditions. Furthermore, it is invidious to separate the contributions of myeloid antigen presenting cells (APC, DC, and macrophages), from B and T cell subpopulations, as well as humoral mediators, even interactions with tissue-specific non-hematopoietic stromal cells in the pathogenesis of “autoimmune” tissue injury. In this chapter we review, concisely, the properties of macrophages, and, to a lesser extent DC, which can give rise to autoimmune diseases, and consider particular examples in which macrophage molecules and functions could contribute substantially. We focus on human disease where known. More detailed reviews can be consulted for an overview of macrophage immunobiology (Gordon, 2012).

The classic problem of innate and adaptive immunity is to recognize and discriminate between “self” and “non-self,” such as microbial constituents. This question remains open; the multicellular organism has to distinguish altered/modified self from self to maintain homeostasis, for example by the safe, non-inflammatory removal of dying cells and their products, a major function of specialized phagocytes. Toll-like receptors (TLR) sense ligands of exogenous origin, but also react to endogenous stimuli. Although additional plasma membrane and cytoplasmic sensors and receptors have now

been identified, the structural determinants of their selectivity are not sufficient to account for self/non-self recognition. The answer presumably lies in the complex interactions of receptors, signaling pathways, and gene expression.

From the macrophage viewpoint, their primary function is to maintain systemic homeostasis; in addition to host defense against infection, a range of mechanisms exist to limit potentially deleterious effector responses below a disease threshold; when such a threshold is exceeded, the host response becomes pathological and can give rise to acute or chronic inflammation, especially if the stimulus persists. We therefore pay particular attention to known mechanisms of sensing a threat or abnormality, and the regulation of activation, both by macrophages themselves and in combination with other cells and mediators of inflammation.

Mouse models of genetic manipulation, microbial and sterile host stimulation have been particularly useful in studying autoimmune diseases, including diabetes, colitis, arthritis, multiple sclerosis, and glomerulonephritis, but translation to naturally occurring human autoimmune diseases remains problematic. Recent studies on human genomics, identification of inborn errors and polymorphisms, combined with improved definition of lymphocyte subsets, gene expression and cytokines, have made it

possible to gain insights into diseases such as rheumatoid arthritis, systemic lupus erythematosus (SLE), and uveitis. However, while the macrophage effector mechanisms clearly are integral to these diseases, their study within human tissue, normally and in a range of conditions, remains limited.

ORIGIN AND DISTRIBUTION OF MONOCYTES AND MACROPHAGES

Traditional views of the mononuclear phagocytic system, derived mainly from studies in the mouse, are undergoing change, with current emphasis on the distinct origins of Langerhans cells and microglia, for example, even in the adult, from yolk sac, fetal liver, and bone marrow (Hoeffel et al., 2012). Antigen receptors and chemokine receptors are differentially expressed on distinct subsets of blood monocytes, in humans as well as mice (Figure 11.1) (Ziegler-Heitbrock et al., 2010). Macrophages and closely related DC, which share progenitors and overlapping markers, are widely distributed in lymphohematopoietic and non-hematopoietic tissues throughout life, in the absence of inflammation, as so-called resident cells. Recent studies have reported a novel DC-specific transcription factor zDC which is not

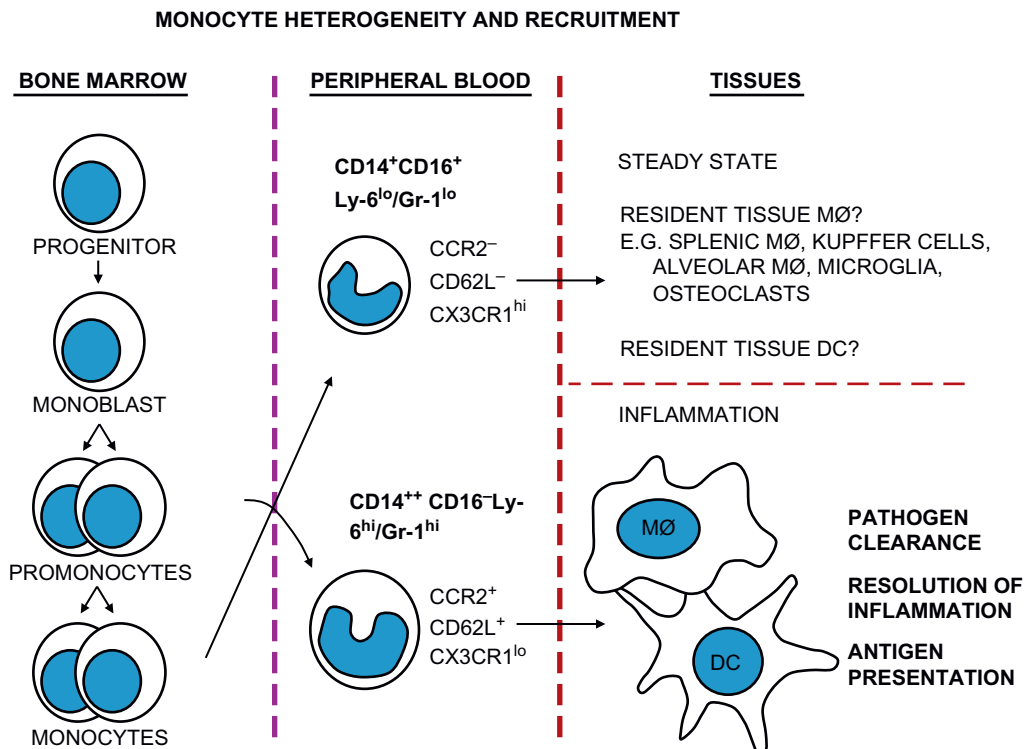

FIGURE 11.1 Schematic presentation of monocyte heterogeneity. Monocytes are present as two distinct subsets which express different surface antigens and chemokine receptors, corresponding to the origin of distinct resident and recruited tissue macrophages. See text for further details.

expressed by monocytes or macrophages (Meredith et al., 2012; Satpathy et al., 2012). Resident macrophages perform phagocytic, clearance, and poorly understood trophic functions; they act as tissue sentinels, able to initiate inflammation and contribute to repair, following injury and infection. A great deal remains unknown concerning their particular functions in different tissues. They arise from hematopoietic progenitors, respond to growth factors such as CSF-1 and GM-CSF, circulate as monocytes, and can be constitutively recruited to tissues such as lung, gut, and brain from early on in development, by poorly understood mechanisms.

In response to injury and infection, a selected monocyte inflammatory subpopulation can be recruited by chemokines and well-defined adhesion molecules to tissues, where they adapt to their local microenvironment. Such recruited cells acquire a new phenotype, including the ability to generate proinflammatory cytokines, to generate a respiratory burst, with release of oxidative radicals, and to serve as APC. Another subpopulation of monocytes appears to patrol the intravascular compartment (Cros et al., 2010).

Apoptosis plays an important part in macrophage turnover especially in an inflammatory milieu, including granulomata, infections such as tuberculosis, and in atherosclerosis. Fas/fas ligand interactions are important as shown in mouse strains that are susceptible to lymphoproliferative as well as myelodysplastic syndromes (Strasser et al., 2009).

The relationship of macrophages to myeloid-derived classical DC is not entirely clear; many genes are expressed in common (Moberg, 2011; Miller et al., 2012), but the mature cells acquire distinct functions; plasmacytoid DC (PDC) differ with regard to marker expression and specialized functions (Hanabuchi and Liu, 2011). Human monocytes can be differentiated by cultivation in different growth factor-containing media to become DC-like APC or acquire macrophage functions. While macrophages and DCs are terminally differentiated, non-proliferating, relatively radio-resistant cells, selected resident and inflammatory recruited macrophages are capable of renewal and local expansion (Jenkins et al., 2011).

Much remains to be learnt about particular resident and newly recruited tissue macrophage populations in humans. The use of marker antigens, F4/80 (Gordon et al., 2011) in the mouse and CD68 in humans as well as the mouse, has made it possible to identify tissue macrophages by immunocytochemistry (Gordon, 2012), and to a lesser extent by FACS analysis. Once within tissues, macrophages are modulated by their local environment, neighboring cells and extracellular matrix, cytokines, and through cell–cell interactions. In mice it is possible to distinguish different phenotypes of activated macrophages as innate, classically activated, or alternatively activated

(Gordon and Martinez, 2010). The signature markers derive mainly from *in vitro* studies with interferon gamma and IL-4/13, respectively, as well as immune complexes (Fleming and Mosser, 2011), which yield distinct regulatory-type macrophages, discussed further below. Markers to identify different forms of activated human macrophages in tissue are still poorly defined.

Granuloma formation is associated with selected infections, e.g., tuberculosis and schistosome egg deposition, and other chronic, persistent inflammatory lesions, such as Crohn's disease. They contain abundant activated, often fused macrophages, as well as lymphoid and other myeloid cells. The determinants of macrophage fusion and giant cell formation have been studied mainly *in vitro* (Helming and Gordon, 2009). *In situ* analysis of phenotype and intravital studies of cell motility (Germain et al., 2012), granuloma formation, and function in mice suggest containment of infection, and promotion of healing. The possible role of macrophages in fibrosis is still obscure (Wynn and Ramalingam, 2012).

Concomitant with activation, a range of deactivating cytokines and arachidonate metabolites downregulate (IL-10) or modulate macrophages (TGF- β , prostaglandin E), thus limiting potentially deleterious inflammatory effects, e.g., after uptake of apoptotic cells, and promoting repair. Plasma membrane glycoproteins, such as CD200/CD200R (Mukhopadhyay et al., 2011) and SIRP α /CD47 (Han et al., 2012), downregulate a range of macrophage responses. Other negative regulators include TLR-related antagonists and the SOCS cytoplasmic proteins.

RECOGNITION, SENSING, AND RESPONSES

Macrophages express a wide range of receptors recognizing pathogenic and host-derived ligands (Figure 11.2). These include opsonic Fc receptors (Nimmerjahn and Ravetch, 2008) and complement receptors (Carroll, 2004); and non-opsonic receptors, such as lectins (e.g., DC-SIGN, Mannose Receptor, Dectin-1), and scavenger receptors (e.g., SR-A I/II, MARCO) (Taylor et al., 2005b). We place particular emphasis on the non-opsonic receptors since their potential role in autoimmune disease is less appreciated, compared with the contribution of Fc and complement receptors.

Fc and complement receptors are heterogeneous in structure and expression, and function by either activating or inhibiting macrophage responses, depending on the receptor and ligand (Carroll, 2004; Nimmerjahn and Ravetch, 2008). Opsonins which promote uptake by these receptors include antibody, IgG complexed with antigens, complement molecules, fibronectin, or milk fat globulins. Macrophages

FIGURE 11.2 Schematic structures of selected macrophage receptors. Macrophages express a wide variety of receptors which mediate recognition of self and non-self molecules. Phagocytic surface receptors include non-opsonic receptors (e.g., C-type lectins and scavenger receptors), as well as opsonic receptors (e.g., complement receptors and Fc receptors). Toll-like receptors (TLRs) are sensors, of which some are expressed on the surface (e.g., TLR4), while others are vacuolar (e.g., TLR9). Sensing receptors are also found in the cytoplasm and these include the NOD-like receptors (NLRs), RIG-like receptors (RLRs) and DNA sensors (e.g., AIM2). Abbreviations: AIM2, absent in melanoma 2; CARD, caspase recruitment and activation domain; CR3, complement receptor 3; Fc γ R, Fc gamma receptor; ITAM/ITIM; immunoreceptor tyrosine-based activation/inhibition motif; MARCO, macrophage receptor with collagenous structure; NLRs, NOD-like receptors; PYD, pyrin domain; RLRs, RIG-like receptors; SR-A, scavenger receptor A; Siglecs, sialic acid-binding Ig-like lectins; TLRs, Toll-like receptors.

express a range of receptors recognizing complement cleavage products, e.g., CR3, which also has a role in the clearance of apoptotic cells. Resident macrophages in liver and pancreas express a newly described CRIG which plays a protective role in autoimmune diabetes (Fu et al., 2012). Fc receptors belong to the immunoglobulin superfamily and have immunoreceptor tyrosine-based activation or inhibitory motifs (ITAMs and ITIMs), which interact with other membrane molecules and cytoplasmic kinases to regulate complex signaling pathways.

The macrophage *scavenger receptors* are a large family of structurally diverse receptors, which recognize a range of ligands including modified low density lipoproteins (LDL), selected polyanionic ligands, and microbial structures (Pluddemann et al., 2007). The Class A scavenger receptor I (SR-AI) was the first to be identified in studies by Brown

and Goldstein who investigated the accumulation of cholesterol from LDL in atherosclerotic plaques. Other Class A scavenger receptors expressed on macrophages include two alternative splice variants of the SR-AI gene, SR-AII, and SR-AIII; and the distinct macrophage receptor with collagenous structure (MARCO). The receptors are all trimeric type II transmembrane glycoproteins generally consisting of several domains including an α helical coiled-coil domain, collagenous domain, and C-terminal cysteine-rich domain, although MARCO lacks the coiled-coil domain and has a longer collagenous domain. For SR-AI and SR-AII the collagenous domain has been shown to be the ligand-binding domain, whereas for MARCO this may lie within the cysteine-rich domain. SR-A are expressed on tissue macrophages and selected endothelia, but not resting monocytes, while MARCO is constitutively expressed on subpopulations

of tissue macrophages (resident peritoneal, spleen marginal zone, and medullary lymph node macrophages). For Class B scavenger receptors CD36 and SR-B, ligand binding is likely mediated via the central part of the extracellular loop structure and these receptors recognize not only modified LDL, but also native lipoproteins (VLDL, LDL, and HDL), and play an important role in cholesterol transport, metabolism, and homeostasis. Other scavenger receptors expressed by macrophages include CD68 and FEEL-1 (predominantly expressed intracellularly), SREC, and SR-PSOX. SREC receptors have been shown to bind molecular chaperones (e.g., calreticulin, gp96, and heat shock protein 70), playing a role in the transport of ligands to the major histocompatibility complex (MHC) Class-I antigen presentation pathway (Berwin et al., 2004). SR-PSOX is the chemokine ligand for a G protein-coupled CXC chemokine receptor 6 (CXCR6) expressed on activated T cells and NKT cells, supporting adhesion of these cells to DCs (Shimaoka et al., 2004).

C-type lectin receptors expressed on macrophages include the mannose receptor (MR), DC-SIGN, SIGNR1, Dectin-1, and Dectin-2 (Gazi and Martinez-Pomares, 2009; Kerrigan and Brown, 2010). These receptors generally have one or more carbohydrate recognition domains and bind ligands in a Ca^{2+} -dependent manner recognizing either mannose- or galactose-type ligands (McGreal et al., 2005). In some cases recognition is independent of the carbohydrate recognition domain or Ca^{2+} . Dectin-1, a β -glucan receptor, bears a cytoplasmic hemi-ITAM, which is coupled to Syk kinase and signals via CARD9, resulting in activation of NF- κ B, thereby contributing to induction of innate and adaptive immunity (Drummond et al., 2011). Collectively, these receptors do not only play a role in pathogen recognition (fungi, bacteria, and viruses), but also recognize endogenous ligands. MR can bind to sulfated carbohydrates found on endogenous glycoproteins (e.g., sialoadhesin and CD45) via a cysteine-rich domain (Fiete et al., 1998) and has been shown to play an important role in the clearance of self-antigens. This receptor has been implicated in controlling levels of the pituitary hormone lutropin, thereby playing a role in fertility (Mi et al., 2002). Dectin-1 also interacts with an endogenous ligand on activated T cells, contributing to T cell proliferation, and can stimulate both CD4^+ and CD8^+ T cells (Ariizumi et al., 2000; Willment et al., 2001). Dectin-1 agonists have been shown to activate DCs, promoting Th1/Th17 differentiation and initiating IL-17 expression by Treg cells (Drummond et al., 2011).

Macrophage receptor recognition of endogenous ligands has been implicated in several *disease processes*. Class A scavenger receptors SR-A and MARCO recognize oxidized and acetylated LDL and play a role in vascular disease by mediating uptake of these modified lipoproteins, leading to the formation of lipid laden foam cells in atherosclerotic lesions (Krieger and Herz,

1994). SR-A and CD36 have also been implicated in the pathology of Alzheimer's disease, where microglia bind β -amyloid fibrils via SR-A and CD36, which stimulates production of cytotoxic reactive oxygen molecules (Santiago-Garcia et al., 2001). Macrophages bind and endocytose advanced glycation end products (AGE) via several receptors including the scavenger receptors SR-AII and CD36, and the AGE receptors 1, 2, and 3 (Lu et al., 2004). AGE are found in many tissues during oxidative stress and inflammation, such as atherosclerotic lesions of arterial walls and kidneys of diabetic patients with chronic renal failure (Nagai et al., 2000), as well as during ageing. Recently, dietary AGE (e.g., from processed food) have also been linked to chronic kidney injury, for example by suppressing AGER1 and inducing oxidative stress and inflammatory responses, thus contributing to pathogenesis and complications of diabetes mellitus (Vlassara and Striker, 2011).

Macrophages play a role in tissue *maintenance and homeostasis*, for example the involvement of several macrophage receptors (e.g., SR-A, CD36, CD14) in the clearance of apoptotic cells, such as apoptotic thymocytes and olfactory sensory neurons, via recognition of cell surface-exposed oxidized phosphatidylserine and phosphatidylcholine (Taylor et al., 2005b). TAM receptor tyrosine kinases Tyro3, Axl, and Mer and their ligands (Gas6 and Protein S) are essential for the phagocytosis of apoptotic cells and membranes. TAM signaling is normally activated by TLR and type I interferon signaling, as part of the innate inflammatory response in macrophages and DCs (Rothlin and Lemke, 2010). The recognition of apoptotic cells by CD36 has been shown to contribute to peripheral tolerance and prevention of autoimmunity by impairing DC maturation (e.g., ligation of cell surface CD36 negatively regulates DC maturation by enhancing IL-10 secretion and reducing the secretion of TNF- α and IL-1 β) (Puig-Kroger et al., 2006). The mannose receptor (MR) is mostly localized intracellularly and is involved in endocytosis, contributing to clearance of mannose-terminal lysosomal hydrolases, neutrophil granule glycoproteins (e.g., myeloperoxidase), hormones (e.g., thyroglobulin), and exocrine secretion products (e.g., amylase) (Gazi and Martinez-Pomares, 2009). Some receptors are specific for recognition of markers of tissue damage and initiate sterile inflammation, for example, the DC-restricted receptor DNGR-1 (Clec9A), a receptor for necrotic cells, recognizes the F-actin component of the cellular cytoskeleton (Ahrens et al., 2012; Zhang et al., 2012).

Some lectins expressed by macrophages, such as Siglec-1, recognize sialic acid molecules and are involved in *cell-cell interactions* (Taylor et al., 2005b). The scavenger receptor CD36 has been shown to mediate adhesion between macrophages and activated platelets via

interaction with the platelet glycoprotein, thrombospondin (Silverstein et al., 1989). This adhesion may, for example, play a role in macrophage recruitment to areas of vascular injury. Ligands for MARCO have been reported on subsets of splenic marginal zone B cells and disruption of these cell–cell interactions was shown to be critical for development and maintenance of the rodent spleen marginal zone microarchitecture (Karlsson et al., 2003; Chen et al., 2005). DCs express high levels of MARCO in response to tumor lysate, inducing specific antitumor responses (Grolleau et al., 2003).

Receptor expression depends on the cell type (monocyte, macrophage, or DC), tissue micro-environment and activation state. For these receptors, ligand recognition generally triggers endocytosis or phagocytosis, depending on the size and nature of the ligand, and receptors can cooperate in the recognition of complex ligands. Phagocytosis/endocytosis triggers complex signaling pathways, membrane and cytoskeleton remodeling, and fusion of phagosomes/endosomes with other intracellular vesicles. Depending on the ligand, secretion of low molecular weight metabolites and pro- and/or anti-inflammatory molecules is triggered. Upon phagocytosis of pathogens, killing mechanisms are initiated, which include oxidative (e.g., the respiratory burst) and non-oxidative methods (e.g., antimicrobial peptides). The ability to activate host immune defense pathways varies among receptors.

Sensing is mediated via TLRs expressed on the macrophage plasma membrane or within endocytic compartments, and cytosolic NOD-like (NLR) and RIG-I helicase (RLR) families of receptors, which form part of multiprotein complexes called inflammasomes (Kanneganti et al., 2007; Kawai and Akira, 2011; Loo and Gale, 2011). The *TLRs* are a family of type I transmembrane receptors with an extracellular domain containing leucine-rich repeats (LRRs) and a cytoplasmic portion homologous to the interleukin-1 receptor family (IL-1R) (O’Neill, 2008). The cytoplasmic domain interacts with adaptor molecules MyD88 (“myeloid differentiation primary response protein 88”), TRAM (“Toll-like receptor adaptor molecule”), TRIF [“Toll-interleukin-1 receptor (TIR)-domain-containing adaptor inducing IFN- β ”], and TIRAP/Mal (“TIR-domain containing adaptor protein”) and the adaptor molecules vary between different TLRs. Interaction with the adaptor molecules induces signal transduction pathways leading to the activation of the transcription factor NF- κ B, MAP kinases p38, and Jun N-terminal kinase (JNK), as well as interferon regulatory factors. Apart from bacterial ligands, TLRs can recognize endogenous ligands, such as heat-shock proteins. TLR signaling has been shown to play a role in the initiation and progression of non-infectious inflammatory processes, e.g., rheumatoid arthritis, experimental autoimmune encephalitis

(EAE), and others (Lin et al., 2011). Recently, an endogenous TLR ligand has been identified, which may play a role in persistent activation of macrophages in chronic inflammatory diseases such as rheumatoid arthritis (Shi et al., 2012). TLR stimulation may also promote inflammatory macrophages in atherosclerosis (Seneviratne et al., 2012) and genome-wide association studies have linked TLR7 and TLR8 to the genetic susceptibility to coeliac disease, a common autoimmune disorder (Netea et al., 2012).

The *NLR family* of receptors consist of a combination of domains, including a central nucleotide-binding and oligomerization (NACHT) domain, which is commonly flanked by C-terminal leucine-rich repeats (LRRs) and N-terminal caspase recruitment (CARD) or pyrin (PYD) domains (Schroder and Tschopp, 2010). Within the NLRs there are three distinct subfamilies, namely the NODs, the NLRPs, and the IPAFs. The carboxy-terminal leucine-rich repeats are thought to sense different microbial and endogenous damage stimuli. Intracellular nucleic acid sensors include the RIG-like helicases RIG-I and MDA5, and the DNA sensor, DAI and AIM2. Recognition of microbial molecules, such as microbial nucleic acids, by these receptors mediates inflammasome activation, which involves assembly of procaspase-1 with different members of the nucleotide-binding domain, leucine-rich repeat (LRR) protein family (NLRs), or absent in melanoma 2 (AIM2)-like receptors (ALRs), or, as recently demonstrated, guanylate-binding protein 5 (GBP5) (Shenoy et al., 2012). This results in caspase cleavage and production of IL-1 β and IL-18 (Schroder and Tschopp, 2010).

PHAGOCYTOSIS, ANTIGEN PRESENTATION, AND SECRETION

Macrophages play an important role in the recognition, phagocytosis, and endocytosis, not only of microbes and foreign particles, but also of modified host components. Macrophages can initiate and perpetuate chronic and acute inflammation, but depending on the ligand and receptors involved, uptake may be silent (clearance) or even suppress inflammation [e.g., uptake of apoptotic cells by macrophages (Henson and Bratton, 2009)]. In general, phagocytosis consists of formation of a phagocytic synapse (Goodridge et al., 2011), phagosome formation, fusion with secretory vesicles from the Golgi, lowering of pH and digestion, and maturation to lysosomes/phagolysosomes (Fair et al., 2009; Mukherjee and Maxfield, 2009; Swanson, 2009). PI3-kinase and phosphoinositides play a role in the initial fusion and association between cellular membranes and cytoskeleton, while membrane trafficking is controlled by small GTPases (Ridley and Hall, 2004; Swanson, 2008). Uptake may

lead to antigen processing and presentation, e.g., SR-A has been shown to mediate uptake of modified antigens for presentation to antigen-specific T cells (Nicoletti et al., 1999). Macrophage cellular responses include inflammasome activation, autophagy, apoptosis, and necrosis. The secretion pathways of pro- and anti-inflammatory cytokines have been extensively described (Kaiser and O'Garra, 2009). Proinflammatory cytokines (e.g., IL-6, TNF) can activate the macrophage itself, recruit other inflammatory cells, or mediate T cell and natural killer cell activation. They induce acute phase proteins, which act as opsonins and pyrogens. Anti-inflammatory cytokines (e.g., IL-4, IL-10, TGF- β) downregulate macrophages and reduce inflammation, affecting different cellular processes, such as proliferation, differentiation, and apoptosis, among others. Interferons (IFNs) inhibit viral replication and cell proliferation, upregulate MHC class I expression, and downregulate MHC class II expression. Recently, interferons have been shown to play a role in autoimmunity, for example SLE and diabetes (Gough et al., 2012). Macrophages also secrete other important growth and differentiation factors, such as enzymes and pro-enzymes, which regulate angiogenesis, as well as antimicrobial peptides, lytic agents, and inhibitory proteins. Resolution of acute inflammation is mediated by specialized proresolving mediators (SPMs), such as lipoxins, resolvins, protectins, and maresins, which are produced by macrophages from the endogenous essential fatty acid, docosahexaenoic acid (DHA) (Campbell et al., 2011). Activated macrophages can exert effector functions by inducing apoptosis in other cells via Fas-ligand and nitric oxide (Strasser et al., 2009). Mutations in Fas have been shown to lead to the development of lymphoproliferation and autoimmune disease and normal expression of Fas in inflammatory macrophages plays an important role in maintaining systemic immune homeostasis (Cuda et al., 2012).

Recognition of cytosolic proteins, nucleic acids, and breakdown products is mediated by inflammasome complexes. As outlined above, these are multiprotein complexes which mediate caspase-1 activation, proteolytic maturation, and secretion of interleukin-1 β (IL-1 β) and IL-18 (Gross et al., 2011). RIG-I-like receptors recognize viral nucleic acids and interact with an adaptor protein located on the mitochondrial membrane, triggering production of type I interferon and induction of NF- κ B (Kato et al., 2011). Apart from microbial molecules, NLRs recognize molecules released during tissue injury, such as recognition of extracellular ATP, hyaluronan, amyloid- β fibrils, and uric acid crystals by NLRP3 (Rathinam et al., 2012). They have been implicated in autoimmune disease, e.g., the association of Nod2 with Crohn's disease (Werts et al., 2011) and the link between polymorphisms in

NLRP1 and SLE (Pontillo et al., 2012). Blocking of IL-1, particularly IL-1 β , is now standard therapy for many auto-inflammatory diseases, such as rheumatoid arthritis, osteoarthritis, Blau syndrome, familial Mediterranean fever (FMF), and type 2 diabetes, among others (Dinarello, 2011).

Autophagy is a mechanism which macrophages can use to capture cytoplasmic components in a double-membrane vacuole for degradation in lysosomes. Autophagy is induced by different families of receptors (e.g., TLRs, NOD-like receptors) and is not only a host defense mechanism against intracellular pathogens, but can also be used as a source of nutrients during starvation. Alterations in the functions of autophagy proteins can lead to enhanced susceptibility to disease and have also been implicated in chronic inflammatory and autoimmune disease processes. For example, mutations in regulators of autophagy have been linked to Crohn's disease (Levine et al., 2011).

ACTIVATION AND DOWNREGULATION: INTERACTIONS WITH T AND B LYMPHOCYTES

Macrophages and DC interact with other hematopoietic cells as well as non-hematopoietic cells in all compartments of the body. In the bone marrow, in addition to developing monocytes, macrophages form a part of the hematopoietic stroma, performing a poorly understood trophic role during hematopoiesis, in addition to clearing erythroid nuclei (Crocker et al., 1991). Specialized adhesion molecules, including Siglec1 (CD169), a sialic acid-binding lectin, and another poorly characterized divalent cation-dependent adhesion receptor, contribute to non-phagocytic interactions with erythroblasts, myeloblasts, and possibly plasma cells (Klaas et al., 2012). In the blood or as sinus-lining cells in liver, spleen, and lymph nodes, monocyte/macrophages interact with endothelium and other circulating cells including erythrocytes, neutrophils, platelets, as well as apoptotic and senescent cells.

The marginal zone in rodent spleen (Martinez-Pomares and Gordon, 2012) and the subcapsular sinus of lymph nodes (Gray and Cyster, 2012) represent important interfaces of blood and lymph-borne circulating cells, antigens, and microorganisms with resident lymphoid populations (den Haan and Kraal, 2012). The marginal zone metallophilic cells are macrophage-like and CD169⁺, but lack F4/80; the outer marginal zone macrophages are phagocytic, express DC-SIGN as well as MARCO, an adhesion receptor for B1 lymphocytes. Red pulp macrophages are responsible for the clearance of senescent erythrocytes and neutrophils, and in rodents provide a reservoir of monocyte/macrophages for recruitment to

peripheral sites of injury, infection, or disturbed metabolism as in atherosclerosis (Swirski et al., 2009). CD68⁺ macrophages are present in the white pulp of spleen, in T cell-dependent areas, but lack the F4/80 antigen; DCs migrate into such areas after antigenic stimulation. In lymph nodes CD169⁺ subcapsular macrophages play a role in antigen capture, interactions with DC and, subsequently, B cells. In germinal centers, tingible body and monocyte-derived macrophages play a role in the activation and affinity maturation of B cells and the phagocytosis of apoptotic cells.

Macrophages and DC are present in thymus, where the DCs contribute to thymocyte selection, whereas F4/80⁺ macrophages remove apoptotic thymocytes. They also associate with viable thymocytes, which are not phagocytosed.

Granulomata contain numerous F4/80⁺ macrophages, which associate with T lymphocytes, other myeloid cells, and connective tissue stroma. The interactions between macrophages, DC, and lymphocytes in granuloma and other lymphoid tissues are still poorly understood, and involve direct cell–cell contact, release, and capture of exosomes and other secretory products.

ROLE OF MACROPHAGES IN ADAPTIVE IMMUNITY AND TOLERANCE

Study of the phagocytic and non-phagocytic interactions of various macrophages with innate and adaptive lymphoid cells is surprisingly neglected, in spite of the clear evidence that cell surface and secreted cytokines, as well as direct contact through plasma membrane receptors and ligands, profoundly, selectively, and reciprocally modulate macrophage and lymphocyte gene expression, cytokine production, and plasma membrane expression of costimulatory and coinhibitory plasma membrane glycoproteins. Particular attention has been paid to the heterogeneity of T cell subsets, Th1, Th2, Th17, and regulatory T cells (Tregs), and their possible macrophage counterparts. Much remains to be done to define the interplay between macrophages and Tregs (Pearson et al., 2012), and with various cytokine producing innate lymphocytes, such as nuocytes (Barlow and McKenzie, 2011). Macrophage activation syndromes, genetic and acquired, e.g., after viral infection, are poorly understood, compared with primary immunodeficiency of T and B cells. This situation may be changing, with the description of a fas/ligand primary defect involving macrophages (Cuda et al., 2012), and the discovery of a novel oncogene mutation in Langerhans histiocytosis.

Apart from their role in phagocytic removal of apoptotic T and B cells, macrophages clear necrotic cell debris, chromatin, etc. from all dying cells, including those killed by CD8⁺ cytotoxic T cells. The DCs (Coquerelle and

Moser, 2010) are uniquely able to activate naïve, resting CD4⁺ T helper cells, through their response to maturation stimuli, e.g., adjuvants, potent antigen capture, processing, and presentation in association with MHC molecules, as well as by MHC I-dependent cross-presentation (Joffre et al., 2012). The role of plasmacytoid DC in antigen presentation is less clear. Macrophages, which may express more labile and lower levels of MHCII, degrade potential macromolecular antigens more completely through their arsenal of digestive hydrolases and can activate primed but not naïve lymphocytes. Resting and activated macrophages are also potent suppressors of T cell activation, e.g., through PGE₂. Macrophages are a prime source of important Th1 and Th2 activating cytokines, IL12, IL18, IL23, as well as of TNF α , IL-10, TGF- β , and IL-6, an important survival and growth factor for B lymphocytes and plasma cells (Kaiser and O'Garra, 2009). Macrophages may regulate antigen access to DC by phagocytosis, digestion, or release of antigen fragments, for cross-presentation, and influence DC maturation by soluble mediators and surface contact.

DCs pay an important role in central and peripheral tolerance, as well as in immune activation. Macrophages have no known role in central tolerance in the thymus, unlike DC; the autoimmune regulator (AIRE) protein is expressed by ill-defined cells (Metzger and Anderson, 2011), possibly APC, in peripheral tissues. In the periphery, the F4/80 antigen, possibly expressed by a subset of DC rather than macrophages, plays a role in the ACAID tolerance model of the eye (Lin et al., 2005), and also in low dose oral tolerance. Further studies are needed to extend these findings to other mouse models of tolerance and to humans.

The marginal zone of spleen, in particular the MARCO scavenger receptor, has been proposed as a regulator of autoantibody formation (McGaha et al., 2011).

ROLE OF MACROPHAGES IN AUTOIMMUNE MODELS AND DISEASES

From the above overview it is evident that macrophages are an integral component of the innate and adaptive cellular and humoral elements of immunity and hence in autoimmunity and autoinflammatory diseases. Evidence for a primary pathogenic role in autoimmunity will depend on implicating molecules that are myeloid, if not macrophage restricted, or disease models in which myeloid-selective gene knockout, e.g., of fas, excludes primary lymphoid cell functions. The efficacy of anti-TNF and IL-1 β treatment indicates that primarily macrophage-derived inflammatory products are major factors in tissue damage, even if part of a more complex immune network. Figure 11.3 and Table 11.1 illustrate

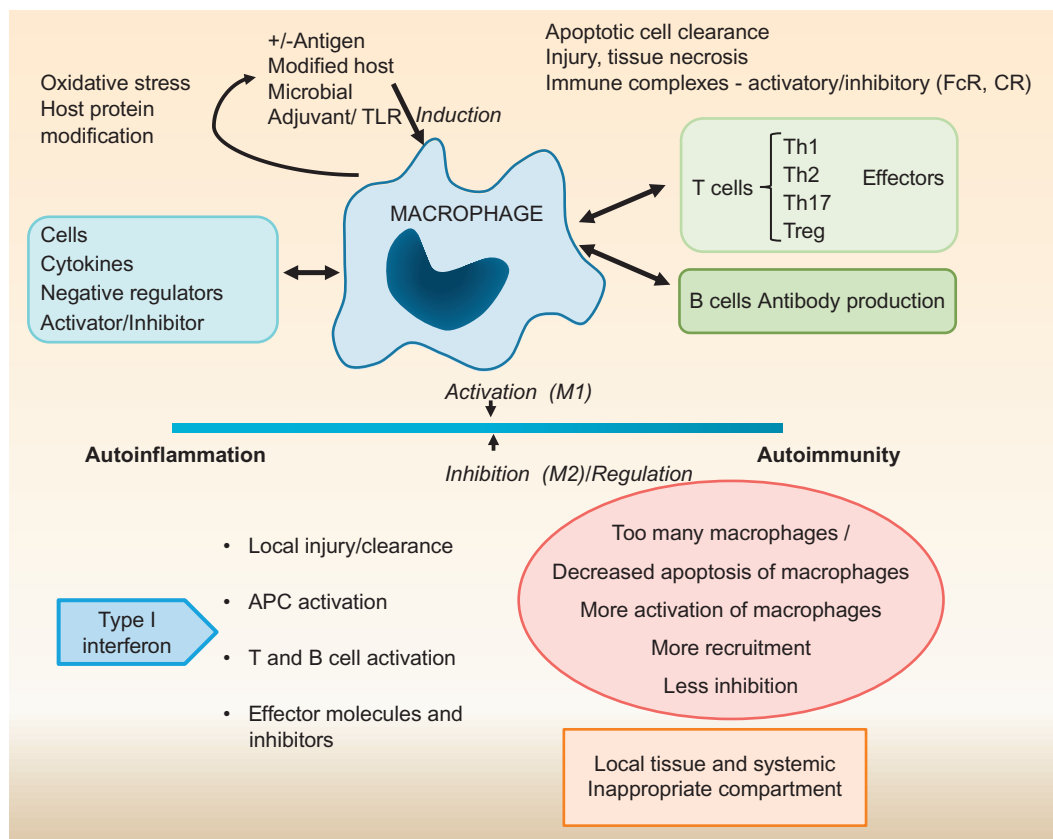

FIGURE 11.3 Overview of macrophage functions which are able to initiate, regulate, and perpetuate autoimmune pathology. Details are discussed in the text.

examples of macrophage function which can initiate and perpetuate autoimmune pathology.

Generation of Autoantigens

Macrophages play a major role in homeostatic clearance of cell debris, and apoptotic bodies generated during cell turnover, physiologically, and in disease. A range of myeloid opsonic and non-opsonic receptors contribute to efficient phagocytosis, endocytosis, and controlled removal, including SR and the family of TAM receptors. C1q deficiency provided an early example of the importance of complement in apoptotic cell clearance (Taylor et al., 2000). A newly described CR1g receptor, expressed by resident macrophages in the pancreas, is protective in the development of early disease in NOD mice (Fu et al., 2012). Host proteins modified by myeloid-induced oxidative injury or amino acid modification, e.g., by citrullination, can give rise to autoantigenicity (Wegner et al., 2010); cross-reaction of host molecules with microbes, for example selected streptococci, contributes to rheumatic fever and heart disease (Cunningham, 2012). The TLR pathway is important in

sensing microbial, adjuvant, and altered host ligands, and interacts with other plasma membrane, endosomal, and cytosolic sensors. Immune complexes, acting via FcR through ITAM/ITIM activatory and inhibitory signaling motifs, have been implicated in SLE (Ivashkiv, 2011).

DC play a major role in uptake, processing, and presentation of peptide antigens in association with MHC molecules and the activation of naïve and primed T and B lymphocytes, as well as of Th17 and Tregs. Macrophages can present antigen to primed T lymphocytes, directly and indirectly, through production of cytokines and auto-crine amplification, especially type I interferon. However, we still know little about the intracellular proteolytic hydrolases in APC which limit degradation of proteins, and the actual peptide antigens associated with MHC molecules from macrophages and DC have not been characterized.

Modulation of Macrophage Activation

Recent studies have drawn attention to the balance between M1 (classically activated) and M2 (alternatively

TABLE 11.1 Examples of Macrophage Functions and their Role in Autoimmune Disease

| Molecule | Role of molecule | Example disease(s) | Reference |
|--|---|--|---|
| Complement C1q | C1q deficiency—importance of complement in apoptotic cell clearance | Systemic lupus erythematosus (SLE) | (Taylor et al., 2000) |
| TAM receptors | Apoptotic cell recognition | SLE | (Rothlin and Lemke, 2010) |
| Toll-like receptors (TLRs) | Sensing receptors—induction of innate immune responses | Type 1 and Type 2 diabetes; SLE, coeliac disease, rheumatoid arthritis | (Lin et al., 2011; Netea et al., 2012) |
| Nod-like receptors (NLRs) | Cytosolic sensors—induction of immune responses, maintenance of homeostasis | Crohn's disease | (Werts et al., 2011) |
| Citrullination and oxidative modification | Autoantigenicity | Rheumatoid arthritis | (Wegner et al., 2010) |
| MARCO | Adhesion, recognition, autoantigen | SLE | (Wermeling et al., 2007; McGaha et al., 2011) |
| Complement receptor of the immunoglobulin superfamily (CRIg) | Inhibition of activation, proliferation, cytokine production | Protective role in autoimmune diabetes | (Fu et al., 2012) |
| Fas | Induction of apoptosis | Autoimmune and lymphoproliferative disorders | (Takahashi et al., 1994; Cuda et al., 2012) |
| Immune complexes | cDC-B cell interactions | SLE | (Joo et al., 2012) |
| | Defect in rho GTPase activity | SLE | (Fan et al., 2006) |
| CD200/CD200R interactions | Negative regulation of cell activation by TLR, NLR, and inflammasome | Autoimmune uveitis | (Taylor et al., 2005a) |
| CD47 | Regulation of cell activation | Experimental autoimmune encephalomyelitis (EAE) | (Han et al., 2012) |
| Indoleamine 2,3-dioxygenase (IDO) | Regulation of immune response to apoptotic cells | SLE | (Ravishankar et al., 2012) |
| Macrophage inhibitory factor (MIF) | Innate immune response regulation—mediates recruitment and retention of monocytes | SLE | (Leng et al., 2011) |
| Colony stimulating factor 1 (CSF-1) | Macrophage growth factor—promotes macrophage survival and maturation | SLE/Lupus nephritis | (Menke et al., 2011; Iwata et al., 2012) |

activated, regulatory macrophages), its importance in dysregulation, and opportunity for therapeutic manipulation of autoimmunity (Fleming and Mosser, 2011; Parsa et al., 2012). This assessment is likely to be simplistic. The heterogeneity of macrophage gene expression and functions is only beginning to be revealed by *in vitro* and *ex vivo* analysis, and the actual phenotypic markers and functions need to be validated *in situ*, taking due regard of the contribution of the local microbiome (Mathis and Benoist, 2012). Activated macrophages often express a mixed phenotype, requiring further population as well as single cell analysis. The studies of Mosser and colleagues (Fleming and Mosser, 2011) have revealed a striking role for immune complexes in modulating the balance between

IL-12/IL-10, and exploited this in the treatment of autoimmune paralysis in mice. Uptake of autoimmune haematopoietic cells, e.g., platelets and erythrocytes, may contribute to dysregulation of pro- and anti-inflammatory cytokine balance in macrophage activation syndromes.

In principle, macrophages can be increased in number, recruitment, activation, fail to undergo apoptosis, or be inadequately inhibited, tilting the balance between tolerance and immune/inflammatory activation. Indoleamine 2,3-dioxygenase (IDO) has been implicated in the maintenance of peripheral tolerance (Ravishankar et al., 2012). Further studies, including models of autoimmunity, are required to extend our knowledge of the F4/80 molecule in immune tolerance. M-CSF has been implicated in

mouse models of renal tubular epithelial injury (Menke et al., 2011; Iwata et al., 2012). Bucala and co-workers have demonstrated a critical role for macrophage inhibitory factor (MIF), a cytokine produced and acting on macrophages, in systemic and local regulation of macrophages (Bucala, 2006; Leng et al., 2011). An intriguing possibility is that anatomic dysregulation of marginal zone macrophages can result in autoimmune activation of B cells, through their interactions with MARCO (Wermeling et al., 2007).

CONCLUSIONS AND QUESTIONS

In order to progress, technical challenges have to be overcome; in humans, improved cell phenotyping and population analysis in tissues, e.g., by laser capture microscopy and immunocytochemistry, before, early, as well as late in the development of autoimmune diseases. Analysis of macrophage-expressed gene polymorphisms in disease-prone individuals should emphasize negative as well as positive controls of macrophage growth, recruitment, activation, and turnover. The identification of biomarkers on readily accessible blood monocytes could improve diagnosis and be used to follow the natural history of systemic autoimmune diseases; a recent example has indicated a correlation between monocyte subsets and Th17 responses (Rossol et al., 2012). In mouse models, better methods are required for selective and efficient macrophage depletion, silencing, and conditional genetic manipulation, distinct from dendritic and other myeloid cells.

The clearance functions of macrophages are mediated by a growing list of plasma membrane receptors. Lectins, such as the macrophage mannose receptor, contribute to the removal of lysosomal hydrolases and degranulation products from the circulation and extracellular space. The proteolytic processing by macrophages and DC and modification of macromolecules by phagocyte oxidation and secretory activities may profoundly affect antigenicity and adjuvanticity.

The balance of activation and inhibition of tissue macrophage phenotypes determines the outcome of many autoimmune diseases, and provides targets for treatment. While the role of macrophage activities and products in diseases like rheumatoid arthritis is established, their possible contribution to systemic autoimmune diseases such as scleroderma, for example, is obscure. The relevance of mouse models to human disease is often problematic. Above all, the predilection of many autoimmune diseases to affect selected tissues such as eyes, joints, and endocrine organs remains obscure. The presence of resident macrophages and possibly organ-specific stromal cells (McGettrick et al., 2012) at these sites and their

response to many types of local injury, make them attractive targets for further investigation.

ACKNOWLEDGMENTS

The authors would like to thank Diane Mathis, Christophe Benoist, Richard Bucala, and Vicki Kelley for their help, and the Medical Research Council (United Kingdom) for financial support.

ANTIGEN PROCESSING BY DENDRITIC CELLS

Dendritic cells (DC) take up antigenic material, soluble and particulate, self and foreign, by a variety of processes including phagocytosis, pinocytosis and receptor mediated endocytosis. Some DC are equipped with receptors for recognition of apoptotic or necrotic cells of the body (Sancho et al., 2009; Zhang et al., 2012). Non-activated (“immature”) DC are especially active in antigen uptake; some uptake processes are shut off once the DC become activated (“mature”). In contrast to other phagocytic cells such as macrophages that rapidly and completely degrade phagocytosed material, DC conserve antigenic material for a prolonged period, allowing continuous processing and presentation of antigen. There are several antigen-processing routes in DC (Trombetta and Mellman, 2005; Wilson and Villadangos, 2005). Exogenous antigens are usually processed in endocytic vesicles, leading to appropriate peptides being loaded onto major histocompatibility complex (MHC) class II molecules. The MHC class II associated antigens then presented to CD4 T cells will include peptides from exogenous foreign antigens, along

with peptides from self components such as recycling DC surface molecules. When conventional DC are activated, the MHC class II–peptide complexes all shift to the cell surface and are no longer recycled, so for their limited lifespan the mature DC present a “snapshot” of the antigenic environment at the time of activation.

DC, along with most other cells, produce, as a by-product of protein synthesis, peptides that are loaded onto MHC class I for presentation to CD8 T cells. Such endogenously derived “self” antigens will include viral antigens if the DC are infected with a virus. Some DC have the additional ability to take up and shuttle exogenous antigens into the MHC class I presentation pathway. This specialized function is only performed efficiently by particular DC subtypes, and has been termed “cross-presentation” (Heath et al., 2004). Cross-presentation of exogenous antigens, including material from dead cells, is important for the generation of cytotoxic T cell responses to intracellular pathogens that do not infect the DC themselves. The pathways of cross-presentation are still being determined, but involve movement of antigen from the endocytic vesicles through the cytosol into the endoplasmic reticulum to join the MHC class I loading pathway.

Only some DC subsets cross-present antigens efficiently and this capacity is induced as a late step in their development (Shortman and Heath, 2010).

PATTERN RECOGNITION RECEPTORS

A unifying feature of all DC is the expression of receptors that recognize microbial products or damaged cells, aspects of the environment often generalized as “danger.” These receptors, collectively called pattern recognition receptors (PRR) are not all expressed on all DC subsets and indeed the differential expression of PRR is a major functional discriminator of DC subsets (Hochrein and O’Keeffe, 2008; Table 12.1).

PRRs exist on the plasma membrane, in the cytoplasm, and on endosomal membranes of cells. They belong to four major families: Toll-like receptors (TLR) 1–13; Rig-like helicases (RLH); C-type lectin receptors; and nucleotide-binding domain, leucine-rich repeat containing (NLR) receptors.

The PRRs recognize a variety of pathogen-derived and self molecules. For recent reviews see: TLR (Uematsu and Akira, 2008; Kawai and Akira, 2010, 2011); NLR (Martinon and Tschoop, 2005, Davis et al., 2011; Elinav et al., 2011); RLH (Barbalat et al., 2011; Loo and Gale Jr., 2011); C-type lectin receptors (Robinson et al., 2006; Diebold, 2009; Kerrigan and Brown, 2009; Osorio and Reis e Sousa, 2011). Most importantly, not all DC express all receptors and in fact there is heterogeneity in the expression of the different receptor families. Particularly relevant for vaccine design, adjuvants induce different immune responses and this is mediated at least in part by the fact that different adjuvants work through different PRR and target different subsets of immune cells such as DC. Likewise, PRR activation in autoimmune disease may involve activation of discrete DC subsets exemplified by the activation of plasmacytoid DC (pDC) in patients with lupus (see below).

It is important to note that the pattern of expression of PRR is not always the same between similar cells of different species and thus caution must be taken in interpreting effects of ligation of different PRR in animal models of disease and their relevance to human disease settings.

DENDRITIC CELL ACTIVATION

The engagement of PRR provides signals that are needed to activate DC to full immunogenic function. The signaling pathways downstream of PRR all converge on the activation of the transcription factor family NF- κ B, leading to the production of cytokines and the upregulation of costimulator molecules and MHC molecules on the DC surface (Kawai and Akira, 2007; Diebold, 2009).

DENDRITIC CELL SUBSETS

DC can be divided into two major categories; conventional (c) DC (sometimes termed myeloid DC) and plasmacytoid (p) DC (sometimes termed lymphoid DC). The cDC can be further divided into migratory and resident subsets based upon tissue location and surface phenotype (Table 12.1: DC subsets, location, PRR expression, known cytokine production). The migratory DC collect antigen in peripheral tissues then migrate to lymph nodes for presentation to T cells. The lymphoid tissue resident DC collect antigen within the lymphoid organs, either directly or as antigen acquired from other cell types including migratory DC. It is also useful to distinguish the DC found in normal, healthy “steady-state” from activated “inflammatory” DC that are generated, sometimes in substantial numbers, in response to inflammation or infection. Inflammatory DC can develop from monocytes; they are modeled by the development of DC in culture when monocytes are cultured with cytokines including GM-CSF, although recent reports suggest that M-CSF may actually be the crucial growth factor required by these DC (Greter et al., 2012). The most detailed information on individual DC subsets comes from studies on laboratory mice. Although the general picture translates to the human immune system, many of the details of surface markers and specialized functions differ, so mouse and human DC subsets will be discussed separately.

MOUSE DENDRITIC CELLS

Mouse spleen, lacking input from the lymphatics, serves as an enriched source of resident DC (Table 12.1). CD8 α has been a useful marker in mice for distinguishing resident cDC subsets, although its function is unknown and it is not expressed on human DC. The CD8 α ⁺ cDC, as well as having the unifying DC function of presenting exogenous antigens on MHC class II, have the additional capacity for “cross-presentation,” i.e., the ability to present exogenous antigen in the context of MHC class I (Villadangos and Schnorrer, 2007). Accordingly, CD8⁺ cDC are particularly efficient at inducing CD8⁺ T cells in response to exogenous antigens. High IL-12p70 production on activation via PRR is another hallmark of CD8 α ⁺ cDC (Reis e Sousa et al., 1997; Maldonado-Lopez et al., 1999; Hochrein et al., 2001) and this leads to a capacity to bias activated T cells to an inflammatory Th1 response. The CD8⁺ DC express high levels of TLR3, recognizing dsRNA, and TLR9, recognizing ssDNA, both located in intracellular endosomes. These PRR equip the CD8⁺ DC to respond to viral and bacterial nucleic acids. The CD8⁺ cDC are also especially efficient in the uptake of dead and dying cells. One PRR involved in dead cell recognition by

Selected pattern recognition receptors, their cellular location, and specificity are shown along with their pattern of expression in the DC subsets of mouse spleen. +/- depicts low or weak expression.

CD8⁺ DC is Clec9A, which recognizes the filamentous form of actin (F actin), exposed when the membrane of a cell is disrupted (Sancho et al., 2009; Zhang et al., 2012). With the dual functions of cross-presentation and dead cell uptake, the CD8⁺ DC are perfectly equipped to present viral and bacterial antigens from infected dead and dying cells. Moreover, it is not hard to imagine that in an autoimmune setting the CD8⁺ DC could be particularly detrimental as they may be activated by self nucleic acids taken up in dead cells and present self peptides present in these cells, leading to activation of cytotoxic T cells.

The CD8⁻ lymphoid tissue resident cDC are more numerous than the CD8⁺ cDC, but recent evidence indicates they consist of two distinct DC subsets separable by expression of several markers including Clec12A, DCIR2, and CD4 (Kasahara and Clark, 2012). However, most functional data so far relate to the unseparated CD8⁻ DC population. All cDC are capable of presenting antigen to CD4⁺ T cells via MHC class II but the CD8⁻ cDC are the most efficient. T cell activation driven by activated CD8⁻ DC may lead to a Th2 response, possibly due to the DCIR2 DC subset. The CD8⁻ cDC express TLR7 (recognizes ssRNA), TLR9, and very high levels of intracellular Rig-like helicase receptors (RLR) that recognize dsRNA in the cytoplasm (Luber et al., 2010). The high expression of RLR and some NLR (Luber et al., 2010), suggests that the CD8⁻ cDC are particularly primed to rapidly respond to intracellular viral and bacterial infection. The CD8⁻ cDC express high levels of chemokines including CCL5 (RANTES), CCL3 (MIP-1 α), and CCL4 (MIP-1 β). These chemokines are elevated upon PRR activation but are also expressed constitutively by CD8⁻ cDC (Proietto et al., 2004).

Lymph nodes, as well as containing similar resident cDC to spleen, also contain migratory DC even in steady state, but the input from peripheral tissues increases markedly on infection or inflammation. These DC that have migrated in from peripheral tissues are more mature than the resident DC in terms of costimulator molecule expression even in the steady state, but are not necessarily immunogenic and do not produce cytokines unless they have received the appropriate PRR signals. Three basic types of migratory DC have been identified (Bursch et al., 2007; Poulin et al., 2007). Langerhans cells in the skin epidermis were identified long before their function as DC was recognized (Merad et al., 2008). They have an exceptionally long lifespan in the epidermis, but turn over rapidly post migration. Recent work suggests they have a predominantly tolerogenic role, even in an activated state (Shklovskaya et al., 2011). DC resembling Langerhans cells also occur in other epithelial tissues. A more rapidly migrating DC population occurs in the skin dermis

and as interstitial DC in other tissues. Recently a minor but important migratory DC subset was discovered in the skin dermis and in other tissues, first distinguished by expression of CD103 and sharing with Langerhans cells the expression of langerin, a pathogen recognition molecule expressed at high levels in Langerhans cells but also at lower levels in some other DC (Nagao et al., 2009). However, this numerically minor DC subset, although not expressing CD8, is similar in functional properties to the resident CD8⁺ DC subset in expressing Clec9A, in processing material from dead cells and in a marked capacity for cross-presentation. It may be considered as the migratory counterpart of the resident CD8⁺ cDC.

The pDC are generally considered as part of the DC “family” but in many respects have similarities to B cells. pDC circulate through the bloodstream much like lymphocytes and have a lymphocyte-like morphology. pDC also normally lack the ability to stimulate naïve T cells (O’Keeffe et al., 2002). The categorization of the pDC as a member of the DC “family” rests upon morphological and phenotypical features that they display upon activation, when the pDC upregulate costimulation markers and MHC molecules to levels resembling the cDC and rapidly acquire the typical stellate morphology of cDC.

The pDC express high levels of TLR7 and TLR9. If given specific PRR stimuli they can induce some T cell division, more than B cells or macrophages but typically in the order of 10-fold or less than that of the cDC (Villadangos and Young, 2008). Unlike cDC the pDC continually present antigens on MHC class II molecules once they are activated and as a result can continue to present new viral antigens during the course of infection (Young et al., 2008). The importance of this function of pDC during an ongoing infection is not yet elucidated. Instead the pDC, also referred to as natural interferon-producing cells (NIPC), are renowned for their production of Type I interferons (IFN-I) in response to viral or bacterial stimuli and mimics thereof (Gilliet et al., 2008; Kadowaki, 2009). The pDC of both mouse and humans recognize ssDNA via TLR9. As a consequence of endoplasmic reticulum to lysosome internal trafficking of TLR9 and differential expression of molecules that are involved in the TLR9 signaling complex, such as high constitutive expression of IRF7, the pDC have the ability to produce extremely high levels of IFN-I upon TLR9 ligation (Gilliet et al., 2008). Synthetic CpG-containing oligonucleotides (ODN), without addition of transfection reagent, are sufficient for the triggering of IFN-I from pDC. The pDC and a recently identified DC in bone marrow (miDC) (O’Keeffe et al., 2012) are the only cell types known to produce IFN-I in response to CpG-ODN alone.

DENDRITIC CELLS IN THE MOUSE THYMUS

Although thymic DC may serve the same sentinel role as in other tissues, their main role is likely to be in the selection of the specificity repertoire of developing T cells, so ensuring tolerance to self components (Ardavin, 1997). Although thymic epithelial cells are the major source of self antigens for thymocyte selection, DC appear to contribute to negative selection and can collect and present antigens originally produced by the epithelial component (Klein et al., 2011). Thymic DC are of two distinct origins. The CD8⁺ thymic DC are produced endogenously, possibly from the same early precursors that give rise to T cells. They resemble the CD8⁺ conventional DC in peripheral lymphoid organs and, being in the immature state, are likely to induce tolerance. However, their cross-presentation capacity is fully developed and this may be important for presentation of self antigens derived from other thymic cells (Gallegos and Bevan, 2004). In contrast, the thymic CD8⁻ conventional DC appear to be a little more mature than the CD8⁺ thymic DC and they enter the thymus preformed from the bloodstream; this may enable them to carry into the thymus peripheral self antigens for induction of central tolerance. These thymic CD8⁻ DC may also contribute to negative selection, but are particularly effective at generation of regulatory T cells (Proietto et al., 2008). The plasmacytoid cells in the thymus also enter the organ directly from the bloodstream. It is not known whether they play any role in thymic T cell selection, or whether they are simply on patrol in case of a viral infection.

DENDRITIC CELL SUBSETS AND TOLERANCE

As discussed above, the CD8⁻ migratory cDC in thymus are particularly efficient in the induction of regulatory T cells (Tregs) in the thymus. This function, together with their ability to carry peripheral tissue antigens into the thymus and to play an important role in the deletion of thymocytes reactive to these self antigens (Bonasio et al., 2006; Proietto et al., 2008) contributes to central tolerance (Proietto et al., 2008).

Migratory DC in the gut also play a major role in inducing tolerance, specifically to oral and commensal bacterial antigens. The CD103⁺ DC in the lamina propria migrate to mesenteric lymph nodes where they produce retinoic acid from dietary vitamin A and induce gut-homing Tregs (reviewed in Scott et al., 2011).

The CD8⁺ cDC of both spleen and lymph nodes can present self-antigen by endocytosis of apoptotic cells *in vivo* in the steady state and tolerize self-reactive T cells in the periphery (Iyoda et al., 2002). This ability to cross-

present exogenous antigen on MHC class I (den Haan et al., 2000) is probably also responsible for the ability of CD8⁺ cDC to induce peripheral tolerance to tissue associated antigens (Belz et al., 2002). Moreover, CD8⁺ cDC produce TGF- β in the steady state and induce antigen-specific Treg cells, further contributing to peripheral tolerance (Yamazaki et al., 2008).

Although the pDC have a remarkable proinflammatory function based on their IFN-I production, they have also been credited with protection from allergy (Lambrecht and Hammad, 2008) and determining oral (Goubier et al., 2008) and transplant tolerance (Abe et al., 2005; Ochando et al., 2006). Mechanisms of tolerance induction and/or immunosuppression by non-activated pDC probably include, but are not limited to, their ability to produce indoleamine-pyrrole 2,3-dioxygenase (IDO, the enzyme catalyzing L-tryptophan to N-formylkynurenine breakdown; Fallarino et al., 2007) and to induce Tregs (Ochando et al., 2006; Hadeiba et al., 2008).

DC differentiated from human monocytes or mouse bone marrow *in vitro* can be rendered tolerogenic by a variety of mechanisms including culture with IL-10 or TGF- β , treatment with drugs such as dexamethasone or BAY 11-7085 that inhibit NF- κ B signaling, vitamin D3 or genetic modification by transduction of IL-4, IDO or treatment with antisense oligonucleotides for costimulatory molecules CD80, CD86, and CD40 (Steinman et al., 2003; Thomson and Robbins, 2008; Stoop et al., 2011). Tolerogenic DC differentiated by these mechanisms are characterized by low expression of costimulatory molecules, low production of proinflammatory cytokines, and high production of IL-10. They can induce tolerance by a variety of mechanisms including promotion of T cell death or anergy, the induction of Tregs, diversion of Th1 and Th17 responses towards a Th2 phenotype, and secretion of immunosuppressive molecules such as IDO (Thomson and Robbins, 2008). Vaccination with tolerogenic DC can prevent disease onset and limit disease severity in the collagen-induced arthritis mouse model, a commonly used model of rheumatoid arthritis. Similarly in NOD mice, transfer of tolerogenic DC prevents the onset of diabetes (Giannoukakis et al., 2008; Mukherjee and D'Iorio, 2010). Several studies have shown a requirement for DC loading with specific autoantigen, e.g., type II collagen for collagen-induced arthritis, or islet beta cell antigens for diabetes, while others have demonstrated better efficacy if DC are not loaded with specific antigen. In the latter case it is presumed that DC acquire autoantigen *in vivo*. These promising preclinical studies in animal models have provided the impetus for the initiation of a number of Phase I studies in humans using tolerogenic DC as a treatment for rheumatoid arthritis or type 1 diabetes (Thomson and Robbins, 2008). Although the main endpoint of these Phase I trials is safety, results based on defined secondary

endpoints are promising in a Phase I rheumatoid arthritis trial, where a decrease in general hyperinflammatory responses was observed in tolerogenic DC-treated patients (Nel et al., 2012) and in a diabetes trial where DC-treated patients showed some evidence of the induction of tolerogenic B cells (Giannoukakis et al., 2011).

HUMAN DENDRITIC CELL SUBSETS IN STEADY STATE

The study of human DC subsets is still in its infancy due to their rarity and lack of distinguishing markers and constraints on accessing human tissue. Most human studies have focused on DC differentiated from blood monocytes after *in vitro* culture in the presence of GM-CSF and IL-4 (MoDC). Their *in vivo* counterparts are currently unclear, but they most likely resemble the mouse inflammatory DC subtype.

Human blood DC comprise approximately 1% of circulating peripheral blood mononuclear cells (PBMC) and are classically defined as Ag-presenting leukocytes that lack other leukocyte lineage markers (CD3, 14, 15, 19, 20, 56) and express high levels of MHC class II (HLA-DR) molecules (lineage⁻HLA-DR⁺). Like mouse DC, these can be broadly categorized into pDC (defined as CD11c⁻CD123⁺ in humans) and cDC (defined as CD11c⁺CD123⁻). Human pDC are functionally aligned with their mouse counterparts and are characterized by expression of TLR7 and TLR9 and their ability to rapidly produce high levels of IFN-I.

Conventional DC in human blood comprise the CD141 (BDCA-3)⁺ and CD1c (BDCA-1)⁺ DC subsets. These have unique gene expression profiles that are distinct from monocytes and MoDC and this predicts that they have different functions (Lindstedt et al., 2005; Robbins et al., 2008).

Human CD141⁺ DC and mouse CD8⁺ DC share features that are essential for the induction of CTL responses against viruses and tumors (Bachem et al., 2010; Crozat

et al., 2010; Jongbloed et al., 2010; Poulin et al., 2010). They express TLR3 (Edwards et al., 2003; Lindstedt et al., 2005), the C-type lectin Clec9A (Caminschi et al., 2008; Huysamen et al., 2008; Sancho et al., 2008), nectin-like protein 2 (Nectl2) (Galibert et al., 2005), and chemokine receptor XCR1 (Bachem et al., 2010; Crozat et al., 2010). Human CD141⁺ DC and mouse CD8⁺ DC subsets produce IFN- β and IFN- λ in response to poly I:C (Scheu et al., 2008; Jongbloed et al., 2010; Lauterbach et al., 2010) and are specialized in their capacity to cross-present exogenous Ag from necrotic cells on MHC class I for the induction of antiviral and antitumor CD8⁺ T cell responses (den Haan et al., 2000; Iyoda et al., 2002; Schnorrer et al., 2006; Crozat et al., 2010; Jongbloed et al., 2010). However, a key difference is that TLR9 is expressed by mouse CD8⁺ DC but not by human CD141⁺ DC and this would predict interspecies differences in the capacity of DC to respond to ssDNA.

The function of the human CD1c⁺ DC subset, and whether it aligns with the mouse CD11b⁺CD8⁻ DC subset as predicted by their transcriptomes, has not been defined. Human CD1c⁺ DC and CD141⁺ DC are also found in lymph nodes, tonsil, spleen, skin, liver, gut, and lung. Table 12.2 shows human DC subsets, aligned with putative mouse equivalents.

DENDRITIC CELL SUBSETS IN HUMAN SKIN: EPIDERMAL LANGERHANS CELLS AND DERMAL DENDRITIC CELLS

Langerhans cells (LCs) are the main DC subset located in the epidermis of human skin. LCs are considered as the classical sentinels that are at the forefront of contact with invading microbial pathogens in the epidermis. They are characterized by expression of langerin (CD207) that functions as a receptor for microbial pathogens, and E-cadherin which facilitates adhesion with nearby keratinocytes (Cunningham et al., 2010). Human LCs are powerful stimulators of CD4⁺ T cell proliferation and induce

polarization towards a Th2 phenotype characterized by production of IL-4, IL-5, and IL-13 (Klechevsky et al., 2008). Human LCs can cross-present antigens and are potent stimulators of naïve CD8⁺ T cell whereas most studies in mice do not support a role for LC in cross-presentation and the induction of antiviral CD8⁺ T cell responses. Although LCs have been implicated in the inhibition of inflammation and the induction of tolerance in mice, these functions are yet to be addressed in humans.

Three separate populations of DC have been found in human dermis (Klechevsky et al., 2008; Nestle et al., 2009; Zaba et al., 2009; Haniffa et al., 2012). The first subset of dermal DC can be defined by expression of CD14. These DC play a specialized role in the development of humoral B cell responses by promoting the differentiation of CD4⁺ T cells into follicular Th cells that prime naïve B cells to become plasma cells (Klechevsky et al., 2008). A subpopulation of CD14⁺ dermal DC constitutively expresses IL-10 and induces Tregs that inhibit skin inflammation (Chu et al., 2012). The CD14⁻ dermal DC can be further subdivided into two populations based on reciprocally high expression of CD141 or CD1c. Like human blood CD141⁺ DC and the mouse lymphoid resident CD8⁺ and migratory CD103⁺ DC, human dermal CD141^{hi} DC share expression of TLR3, Clec9A, XCR1, Necl2, and are superior to other dermal DC and epidermal LC in their capacity to cross-present Ag to CD8⁺ T cells (Haniffa et al., 2012). pDC are rare in healthy human skin but accumulate in inflamed tissue and facilitate disease pathogenesis in systemic lupus erythematosus (SLE) and psoriasis (Blanco et al., 2001; Nestle et al., 2005). Inflammatory myeloid DC infiltrate both epidermis and dermis of psoriatic lesions and are proposed to play a major role in psoriasis pathogenesis by production of the inflammatory mediators, inducible nitric oxide synthase (iNOS), and TNF- α (Lowe et al., 2005; Zaba et al., 2009).

DENDRITIC CELLS AND AUTOIMMUNE DISEASE

The DC subsets show a remarkable dichotomy in function relating to the induction of thymic and peripheral tolerance, as well as the induction of potent inflammatory responses to activation stimuli. Many factors, still mostly unknown, must control this finely tuned balance. Likewise, many factors contribute to autoimmune disease but clearly an imbalance in the tolerizing versus activation states of DC would lead to or enhance autoimmune disease. Two examples of this are discussed below.

Systemic Lupus Erythematosus

B cells and T cells in SLE are autoreactive to self nucleic acids (dsDNA, ssDNA, and RNA) and nuclear proteins,

particularly nuclear antigens, including RNA-binding proteins such as those associated with U1-RNA (Migliorini et al., 2005). The exact mechanisms that drive development and activation of these autoreactive lymphocytes in SLE remain unknown but genetic influences play a major role in determining susceptibility (see Chapter 26). HLA loci have been linked to SLE, as have more than 30 additional genes, including many involved in proinflammatory cascades, e.g., genes encoding Fc γ receptors, TNFSF4, IRAK1, STAT4 (Delgado-Vega et al., 2010; Deng and Tsao, 2010; Sestak et al., 2011). Many of these genes are involved in pathways leading to production of type I interferons (IFN-I) or responses to IFN-I (Deng and Tsao, 2010).

Indeed many patients with SLE typically carry an “IFN signature” (Rönnblom and Pascual, 2008) as evidence of the expression of genes that are dependent on IFN-I for transcription. IFN-I in SLE is predominantly produced by pDC that respond to nucleic acid/autoantibody complexes via signaling through TLR7 and TLR9 (Means et al., 2005; Rönnblom and Pascual, 2008). Delivery of nucleic acid complexes to pDC in SLE depends on FcR that bind antinucleic acid immune complexes (Means et al., 2005) or nucleic acid complexes associated with neutrophils. Dying neutrophils in SLE patients release neutrophil extracellular traps (NETs); these neutrophils die from “netosis,” thereby releasing large amounts of DNA/DNA-binding antimicrobial protein complexes that allow increased uptake of DNA by pDC and subsequent IFN-I production by TLR9-induced activation (Garcia-Romo et al., 2011; see Chapter 11).

IFN-I production in SLE is seen as a major contributor to the etiology of this disease since it greatly enhances activation of DC, self-reactive B cells and T cells, and the production of many other proinflammatory cytokines. Although studies of IFN-I in SLE suggest this as a therapeutic target, it is important to recognize that the same IFN signature can be induced by another family of IFNs produced by pDC, the type III IFNs, also called IFN-lambda (IFN- λ).

As for type I IFNs (particularly IFN- α), pDC are a major source of IFN- λ in response to TLR9 signaling in mice, and to both TLR7 and 9 in humans; pDC also produce large amounts of IFN- λ in response to viral stimulation (Ank and Paludan, 2009). Apart from pDC, the human CD141⁺ DC and mouse CD8⁺ DC also produce large amounts of IFN- λ in response to dsRNA via TLR3. Our unpublished data indicate that, similarly to IFN-I, IFN- λ enhances DC activation and it is thus very likely that IFN- λ production by DC subsets, like IFN- α , will play a role in enhancing proinflammatory responses in autoimmune diseases like SLE and also psoriasis where self nucleic acids are major immunogens.

IBD—Crohn's Disease and Ulcerative Colitis

Inflammatory bowel diseases (IBD) ulcerative colitis (UC) and Crohn's disease (CrD) are not initiated by an endogenous autoimmune event, but the pathology is autoimmune in nature. These diseases are presumed to manifest as a result of dysregulated immune responses to the intestinal microbiota. Mutations in NLR family members NOD2 and NLRP3 are highly associated with CrD (Cho, 2008; Villani et al., 2009). These PRR are mainly expressed by DC and macrophages and emerging evidence suggests they play a crucial role in maintaining immunological homeostasis in the intestine (Strober et al., 2006; Zaki et al., 2011). NOD2 functions as a receptor for the bacterial cell wall component muramyl dipeptide (MDP). Triggering of NOD2 in human MoDC *in vitro* stimulates processing and presentation of bacterial antigens to CD4⁺ T cells, so generating an antibacterial response due to an increased production of antibacterial IL-17 (Cooney et al., 2010; van Beelen et al., 2007). NLRP3 is activated by a wide variety of microbial agonists and drives IL-1 β secretion that activates the antimicrobial functions of innate immune cells such as macrophages and DC, and induces CD4⁺ Th17 immune responses (Schroder et al., 2010). Thus, abnormal signaling by DC in response to the intestinal microbiota, consequent to mutations in these PRR, likely contributes to the pathogenesis of CrD.

Further evidence derived from mice and humans suggests that an imbalance in intestinal DC subsets, distribution, and function plays a crucial role driving inflammation and disease pathogenesis (Ng et al., 2011; Varol et al., 2010). Depletion of DC in mouse models of colitis leads to increased or decreased disease severity depending on the time-point, demonstrating a crucial role for DC in both the downregulation and exacerbation of intestinal inflammation. The balance between the functions of mouse intestinal CD103⁺ and CX3CR1⁺ DC subsets regulates immune homeostasis and controls inflammatory responses. CD103⁺ DC are migratory DC that reside in the lamina propria and transport microbial antigens to the lymph nodes where they play an essential role in the induction of peripheral Tregs and the generation of oral tolerance. In contrast, the levels of CX3CR1⁺ DC are dramatically increased in mouse colitis models and augment the severity of disease. pDC also accumulate in intestinal tissue in mouse colitis models (Karlis et al., 2004) and are contributors to the protective effects of GM-CSF treatment on colitis (Sainathan et al., 2008).

DC (defined as lacking the markers of other cell lineages and having high levels of MHC class II) can be found in the lamina propria of the human colonic mucosa (Ng et al., 2010). They comprise mostly CD11c⁺ cDC

and few pDC, but their phenotype, function, and degree of alignment with mouse DC subsets is poorly characterized. Increased numbers of activated cDC are found in inflamed tissue in CrD compared to non-inflamed tissue, supporting a role for DC in disease pathogenesis (Ng et al., 2011). These DC express CD40 and CD83, TLR2 and TLR4, and produce proinflammatory cytokines including IL-6, TNF, and IL-12. An increased number of pDC are also present in the colonic mucosa and mesenteric lymph nodes of patients with CrD and ulcerative colitis (Baumgart et al., 2011). However, pDC infiltration in the lamina propria is associated with a clinical response and remission in patients with CrD following G-CSF treatment (Mannon et al., 2009). Thus the contribution of pDC to IBD pathogenesis remains unclear.

DENDRITIC CELL IMMUNOTHERAPY AS A TREATMENT FOR AUTOIMMUNE DISEASES

The essential role of DC in inducing immune responses makes them attractive targets for the development of immunomodulatory vaccines. DC loaded *ex vivo* with antigen and activators and administered as vaccines have been used as a treatment for a variety of malignancies (Vulink et al., 2008; Palucka and Banchereau, 2012) and some infectious diseases (García and Routy, 2011). These studies have demonstrated that DC vaccination is safe and to a degree efficacious. While vaccination with activated DC induces proinflammatory B cell and T cell adaptive immune responses, vaccination with immature DC results in the expansion of IL-10-secreting, Tregs (Dhodapkar et al., 2001). These studies provide some rationale for the adaptation of DC immunotherapy to induce a tolerogenic immune response for the treatment of autoimmune diseases.

TARGETING OF DENDRITIC CELLS IN AUTOIMMUNE DISEASE

Ex vivo manipulation of DC is expensive, logistically impractical, complicated by regulations, and needs to be tailored specifically for individual patients. Delivering antigen to DC directly *in vivo* using antibodies specific for DC-associated molecules such as DEC-205 can overcome many of the current limitations of DC therapy (Tacke et al., 2007). This approach is currently in early phase clinical trials for cancer and is just beginning to be explored in preclinical experimental models for autoimmune diseases. In the absence of adjuvant, targeting antigen to DC *in vivo* using antibodies to DEC-205 induces antigen-specific T cell deletion and unresponsiveness to oligodendrocyte glycoprotein (MOG) in a model of autoimmune experimental acute

encephalomyelitis and to model antigens including ovalbumin (Bonifaz et al., 2002; Hawiger et al., 2004). Furthermore, DEC-205 targeting of autoantigens in the NOD and other mouse models of type 1 diabetes prevents disease onset and progression (Bruder et al., 2005; Mukhopadhyaya et al., 2008).

An alternative approach being developed is microspheres carrying CD40, CD80, and CD86 antisense oligonucleotides. Vaccination with these microspheres can prevent and reverse new-onset type 1 diabetes in NOD mice, presumably via uptake by DC *in vivo* and the expansion of Tregs (Phillips et al., 2008).

Targeting the innate functions of DC, such as cytokine production, is also likely to be successful in autoimmune diseases that are known to have a detrimental DC functional component. The example of SLE cited above is a key candidate for pDC targeting. Targeting strategies that block TLR7 and 9, for example, would extinguish the IFN-I production by pDC in response to self-nucleic acids in SLE.

CONCLUSIONS AND FUTURE PROSPECTS

The roles of DC subsets in mice, and mouse models of disease, are steadily being deciphered. The field has really only just begun to understand the complexity of function of different DC subsets in humans and how they may contribute to disease. Unraveling the functions of DC subsets in different anatomical locations will continue to lend insight into their potential roles in disease states. There is a real possibility that directly targeting DC either through harnessing or dampening their specific functions may lead to novel tailored therapies for autoimmune diseases.

It will be a great challenge to induce tolerogenic DC in humans. DC will be targeted with antibodies to specific surface receptors that are directly conjugated either to drugs or to the surface of nanocomplexes. As described above, drugs such as those that inhibit NF- κ B signaling can freeze DC in a tolerogenic state. Drugs that inhibit TLR-7 or 9 signaling would prevent pDC activation in SLE. The combination of antibody, drug, and antigen, delivered in a nanocomplex, will perhaps ultimately create the perfect tolerogenic, DC-targeting vaccine. The challenge is to determine what is the best antibody, the best anti-inflammatory drug, the best antigen, and how best to complex these in a nanoparticle-like delivery system, for different types of autoimmune disease.

In addition, DC may be increased *in vivo* using growth factors, such as Flt-3 ligand, that we know are safe and induce high numbers of DC (Maraskovsky et al., 2000). These DC would then be targeted by a tolerizing vaccine. Large numbers of tolerogenic DC may be extremely efficient at maintaining a tolerogenic state. The challenge here would be in the timing, since any increase in DC

that are amenable to activation in an inflammatory state would presumably only exacerbate disease.

INTRODUCTION TO NK CELLS

Natural killer (NK) cells were described in the 1970s as large granular lymphocytes exhibiting “natural cytotoxicity” against several types of tumor cells (Kiessling et al., 1975). Significant progress has been made since then in the dissection of additional functional traits of NK cells. By their cytotoxic potential they can kill many more types of cells than tumor cells, e.g., virus infected cells and several types of activated immune cells (Vivier et al., 2008). To carry out these functions, and to discriminate target cells from non-activated “normal” cells, NK cells are equipped with a molecular detection system that includes a variety of cell surface activating and inhibitory receptors (Lanier, 2005). Activating NK cell receptors can detect the presence of ligands on cells in “distress,” such as stress-induced self-ligands (Bryceson et al., 2006a). In parallel, NK cells use inhibitory receptors to monitor the presence of constitutively expressed self-major histocompatibility complex (MHC) class I molecules (Long, 2008); MHC class I expressing cells are normally spared while cells lacking these molecules can be targeted by NK cells, a recognition strategy originally referred to as “missing-self” recognition (Ljunggren and

Kärre, 1990). NK cells are also critical components of the innate immune response, because of their ability to produce a variety of cytokines and chemokines (Vivier et al., 2008). Thus, NK cells may drive, shape, and regulate the activities of other immune cells and by these means affect the development of adaptive immune responses. NK cells respond to initial cues from myeloid cells including myeloid-derived dendritic cells (DC), as well as macrophages and plasmacytoid DC. This response is possible because NK cells express receptors for several myeloid-derived cytokines (Caligiuri, 2008; Vivier et al., 2008). Thus, secondary to triggering of myeloid cells by pattern recognition receptors, NK cells can relay and amplify key cytokine signals. Perhaps the best-characterized cytokine produced by NK cells is interferon (IFN)- γ . However, NK cells also secrete a number of other additional cytokines and other factors, including tumor necrosis factor (TNF)- α and immunoregulatory cytokines such as interleukin (IL)-5, IL-10, IL-13, the growth factor GM-CSF, and chemokines CCL3 (MIP-1 α), CCL4 (MIP-1 β), CCL5 (RANTES), and CXCL8 (IL-8). The ability to respond to a variety of cytokines suggests that the local microenvironment in which NK cells exist may shape and modulate

their function (Caligiuri, 2008; Vivier et al., 2008). Consistent with their functions as innate sentinels, NK cells are spread throughout lymphoid and non-lymphoid tissues. In many tissues, they represent a minor fraction of total lymphocytes. However, in other tissues like the liver and pregnant uterus they are abundant (Vivier et al., 2008).

Although important aspects of NK cell biology have been revealed using mice as a model organism, it should be noted that many central NK cell receptors are rapidly evolving in evolutionary terms. Thus, significant differences between the mouse and human immune systems exist, particularly with respect to NK cells (Mestas and Hughes, 2004). Our review is focused on the phenotype and function of human NK cells, highlighting recent advances in understanding their role in autoimmune diseases.

NK CELL DEVELOPMENT AND DIFFERENTIATION

NK cells belong to the hematopoietic system. They are derived from CD34⁺ hematopoietic precursor cells (HPCs). In transcriptional terms, NK cells are most closely related to cytotoxic T lymphocytes (Sun and Lanier, 2011) and in humans typically defined as CD3⁻CD56⁺ lymphocytes. According to a newly proposed nomenclature, NK cells have been categorized as belonging to the family of innate lymphoid cells (ILCs) and more specifically the group 1 innate lymphoid cells (ILC1s) (Spits et al., 2013). In addition to differential transcriptional regulation, NK cells are distinguishable from other ILCs as NK cells do not express CD127. Furthermore, ILCs lack cytotoxic function as well as several functional NK cell markers including NKG2A and NKG2D. However, the exact relationships and plasticity between the NK cells and other ILCs remains to be further elucidated, especially in humans (Spits et al., 2013).

During fetal development, NK cells are among the first immune cells to appear. It is generally accepted that most NK cells develop in the bone marrow, based on evidence from early studies of bone marrow ablation in mice (Haller and Wigzell, 1977). Bone marrow-derived human CD34⁺ HPCs can also be manipulated to differentiate *in vitro* into NK cells (Miller et al., 1992). In this setting, NK cell development is dependent on bone marrow stroma (Miller et al., 1994). Furthermore, it requires IL-2 and/or IL-15 (Miller et al. 1992, 1994) and is potentiated by flt3-ligands (Yu et al., 1998). One important question is: do NK cell precursors, formed in the bone marrow, traffic to distinct peripheral anatomical locations for their final stages of development? Several lines of research support this notion; for example, immune precursor cells with NK cell developmental potential are selectively enriched in human secondary lymphoid tissues (SLT),

such as lymph nodes and tonsil (Freud et al., 2005). These CD34⁺CD45RA⁺ cells represent more than 95% of all HPCs in SLT, but are infrequent in bone marrow and blood.

Based on this, and other insights, a continuous SLT NK cell developmental pathway has been proposed (Freud et al., 2006; Freud and Caligiuri, 2006). In this pathway, “stage 1” NK cells (pro-NK cells) are characterized by a CD34⁺CD117⁻CD94⁻ phenotype, the lack of expression and transcription of CD122 (IL-2/15 receptor β -chain) and unresponsiveness to IL-15. Upon stimulation with flt3-ligand, IL-3, and IL-7, possibly in a stroma cell-dependent manner, these pro-NK cells acquire a “stage 2” NK cell (pre-NK cells) phenotype characterized by upregulation of CD122 that provides responsiveness to IL-15 (Freud et al., 2006). CD34⁺CD117⁺CD94⁻ pre-NK cells are not fully committed to the NK cell lineage and can also give rise to other immune cells such as T cells and myeloid DCs. Furthermore, they lack characteristic NK cell functions, such as cytotoxicity and the capacity to produce IFN- γ . However, with IL-15 stimulation, pre-NK cells develop into “stage 3” NK cells (immature NK cells, iNK cells) characterized by loss of CD34 and a step-wise acquisition of CD56 together with a functional commitment to the NK cell lineage. Finally, these iNK cells progress into “stage 4” NK cells characterized by bright expression of CD56 (CD56^{bright} NK cells). This progression is marked by the acquisition of the inhibitory receptor CD94/NKG2A and such NK cell-associated activating receptors as NKP46 and NKG2D, as well as by the capacity to produce IFN- γ and to release perforin and granzyme-containing granules (Freud et al., 2006). NK cell expression of killer cell immunoglobulin-like receptors (KIR) for self-MHC class I confers NK cells with effector potential in a yet molecularly poorly defined process termed “education” or “licensing” (Kim et al., 2005; Anfossi et al., 2006; Elliott and Yokoyama, 2011). At present, many open questions remain with respect to how NK cell function relates to development and to what extent NK cell differentiation can be regarded as linear or branched.

Key transcription factors that regulate NK cell development and differentiation have recently been characterized (Klose et al., 2012; Cichocki et al., 2013). STAT5B has been implicated in the early stages of NK cell differentiation, alongside E4BP4 that induces ID2 and GATA3. Without any one of these transcription factors, NK cell development is grossly impaired with a block at the pre-NK to iNK stage. Similarly, but in an apparently parallel pathway, TOX is required for the pre-NK to iNK transition. TBX21 (T-bet) is also required for early NK cell development, while expression of EOMES is required for sustenance of NK cells in a mature stage. Importantly, NK cell selective deficiencies have been associated with autosomal dominant mutations in *GATA2* and *MCM4* (Gineau et al.,

2012; Mace et al., 2013). Much more information is needed to get a better view of how transcription factors program NK cell development and differentiation.

PHENOTYPE AND TISSUE LOCALIZATION OF NK CELLS

In humans, “mature” NK cells are divided into CD56^{bright} and CD56^{dim} subsets, defined by expression levels of CD56 (Lanier et al., 1986; Jacobs et al., 1992; Cooper et al., 2001; Caligiuri, 2008). These two subsets are present at varying proportions in different compartments of the human body. In blood, bone marrow, and spleen, CD56^{dim} NK cells dominate, representing around 90% of all NK cells. On the other hand, in tonsils and other SLT CD56^{bright} NK cells dominate. The liver, in contrast, contains nearly equal proportions of CD56^{dim} and CD56^{bright} NK cells. The CD56^{bright} and CD56^{dim} NK cell subsets differ in phenotype and function. In brief, CD56^{bright} NK cells are negative for, or express only low levels of, the low affinity Fc-receptor CD16, express few inhibitory killer cell immunoglobulin-like receptors (KIRs), or cytotoxic molecules such as perforin and different granzymes (Cooper et al., 2001). On the other hand, CD56^{bright} NK cells uniformly express the inhibitory CD94/NKG2A receptor, as well as CD62L and the high affinity IL-2 receptor α chain (CD25). CD56^{dim} NK cells display a variegated expression of KIRs, NKG2A, and CD62L, express high levels of CD16 on their surface, and contain intracellular granules with large amounts of perforin and granzymes (Cooper et al., 2001). With respect to function, CD56^{bright} NK cells were generally believed to produce large amounts of cytokines but have little capacity to perform cytotoxicity, whereas CD56^{dim} NK cells were believed to be efficient killers but poor at producing cytokines (Fehniger et al., 2003; Ferlazzo et al., 2004; Morandi et al., 2006; Burt et al., 2009). However, recent work suggests that CD56^{bright} NK cells also can mediate some cytotoxicity and produce cytokines in response to exogenous cytokine stimuli, whereas CD56^{dim} NK cells both have efficient capacities for performing cytotoxicity and producing cytokines upon specific target cell recognition (Fauriat et al., 2010).

CD56^{bright} and CD56^{dim} NK cell subsets might represent two sequential stages of NK cell differentiation, with CD56^{bright} cells being less mature (Lanier et al., 1986; Caligiuri, 2008). Several lines of (sometimes indirect) evidence support this hypothesis. First, CD56^{bright} NK cells appear earlier in immune reconstitution settings than do CD56^{dim} NK cells, and the former can represent up to 70–80% of all peripheral blood NK cells a few months after hematopoietic stem cell transplantation (Jacobs et al., 2001; Shilling et al., 2003). Second, CD56^{bright} NK cells

have a more immature phenotype compared to CD56^{dim} NK cells with, for instance, expression of CD117 (c-kit) (Matos et al., 1993), which is typically expressed by immature HPCs. CD56^{bright} NK cells also display longer telomeres (25) and, morphologically, constitute both granular and agranular cells, whereas all CD56^{dim} NK cells are granular (Romagnani et al., 2007). Furthermore, in humanized mice purified CD56^{bright} NK cells were recently shown to differentiate into CD56^{dim} NK cells (Huntington et al., 2009). Hence, a substantial amount of evidence suggests CD56^{bright} (“stage 4”) NK cells to be precursors of CD56^{dim} (“stage 5”) NK cells. Until recently, CD56^{dim} NK cells were considered an “end stage” of human NK cell differentiation. However, recent data have demonstrated that even CD56^{dim} NK cells undergo a continuous differentiation process, the latter characterized by a gradual shift from NKG2A⁺CD62L⁺CD57⁻KIR⁻ cells towards more terminally differentiated NKG2A⁻CD62L⁻CD57⁺KIR⁺ cells (Björkström et al., 2010).

Besides CD56^{bright} and CD56^{dim} NK cells, which constitute the majority of NK cells in human peripheral blood and tissues at variable relative frequencies, a distinct population of CD56^{superbright} NK cells has been characterized in the endometrium which becomes the dominant lymphocyte population in the decidua of pregnant women (Manaster and Mandelboim 2010). Such uterine NK cells may represent relatively immature NK cells and display a unique phenotype, expressing the tetraspanin CD9, high frequencies of activation markers CD69 and HLA-DR, as well as inhibitory NKG2A and KIR. Interestingly, they do not express CD16 or CD57.

FUNCTIONAL RESPONSES BY NK CELLS

NK cells and cytotoxic T cells (CTLs) are thought to share mechanisms for target cell elimination. Cytotoxicity by both NK cells and CTLs relies on directed release of their lytic granule contents. These lytic granules are specialized secretory lysosomes that contain perforin, granzymes, and Fas ligand that all contribute to target cell killing (Dustin and Long, 2010; Griffiths et al., 2010). Imaging studies comparing target cell recognition by NK cells and CTLs *in vitro* and *in vivo* suggest some noteworthy distinctions. *In vitro*, CTLs rapidly establish cytoskeletal polarity, whereas NK cells are more tentative in their interactions with target cells (Wulfing et al., 2003). *In vivo*, CTLs form stable contacts with tumor cells expressing cognate antigen, whereas NK cells establish mainly dynamic contacts (Deguine et al., 2010). These observations suggest differences in the molecular machinery underlying NK cell and CTL recognition and elimination of target cells.

Recent studies of NK cell responses have also highlighted considerable heterogeneity among human peripheral blood NK cells, including hierarchies that govern

the strength of activation stimuli needed for induction of specific responses (Bryceson et al., 2005, 2009, 2011). For example, induction of inside-out signals for leukocyte functional antigen (LFA)-1-mediated adhesion exhibits a markedly low threshold for activation. Induction of chemokines such as MIP-1 β requires stronger activating stimuli, whereas degranulation and production of cytokines such as TNF- α and IFN- γ display the most stringent requirements for induction (Bryceson et al., 2011). Some of the functional heterogeneity in different NK cell populations can be accounted for by differences in cellular differentiation (Björkström et al., 2010; Juelke et al., 2010; Lopez-Verges et al., 2010). For example, relatively immature CD56^{bright} NK cells excel at cytokine production in response to exogenous cytokines such as IL-2, IL-12, IL-15, and IL-18. The same cells, however, express low levels of perforin and are, consequentially, less cytotoxic than CD56^{dim} NK cells and do not produce cytokines as readily in response to target cell recognition. In contrast, relatively more differentiated (NKG2A⁺CD62L⁺CD57⁻KIR⁻) CD56^{dim} NK cells produce significant amounts of IFN- γ in response to exogenous cytokines, express higher levels of perforin, and have a stronger ability to mediate cytotoxicity. They can also produce ample amounts of cytokines in response to target cell recognition. Finally, highly differentiated (NKG2A⁻CD62L⁻CD57⁺KIR⁺) CD56^{dim} NK cells express high levels of perforin and display potent cytotoxic capacity. These cells are also strong producers of cytokines in response to target cell recognition. However, the response of these NK cells to exogenous cytokines is comparatively blunted.

In parallel to the continuous maturation process, recognition of self-MHC class I molecules by inhibitory receptors potentiates the NK cell's ability to respond functionally, a process referred to as "education" or "licensing" (Kim et al., 2005; Anfossi et al., 2006; Elliott and Yokoyama, 2011). Superimposing differentiation and education processes on NK cell functionality does not, however, fully explain the heterogeneity in NK cell responses. Studies have revealed that the thresholds for effector responses are highly dynamic. For example, different molecular pathways are likely used depending on activation by different cytokines and triggering of different (combinations of) cellular receptors, and gives rise to differences in response rates (Bryceson et al., 2009, 2011).

NK CELL RECEPTOR SIGNALING AND EFFECTOR FUNCTIONS

A multitude of activating NK cell receptors that belong to different receptor families have been described (Table 13.1). They contain highly divergent cytoplasmic signaling domains. The signaling pathways orchestrated by some activating NK cell receptors are known whereas

others are significantly less well characterized (Bryceson et al., 2006a; Watzl and Long, 2010). In contrast, structurally distinct inhibitory NK cell receptors all contain immunoreceptor tyrosine-based inhibition motifs (ITIMs). The signaling by such motifs has been extensively studied and is mainly mediated through activation of tyrosine phosphatases such as SHP-1 as well as the tyrosine kinase c-Abl (Long, 2008; Peterson and Long, 2008). Some inhibitory receptors engage other negative regulators such as SHIP, an inositol 5-phosphatase, and the Src family tyrosine kinase CSK. Taken together, today's knowledge suggests that potent NK cell effector functions such as cytotoxicity and cytokine production require dynamic integration of signals derived from multiple receptors (Liu et al., 2009). The following sections will focus on advances in our understanding of the molecular processes underlying NK cell effector responses.

NK Cell Contact and Adhesion to Target Cells

A first step in NK cell responses to pathogen-infected target cells or tumor cells involves recruitment of NK cells to the site of inflammation/infection or to the tumor. NK cells express several chemokine receptors. The mechanism of NK cell trafficking to inflamed tissues is fairly well understood and has recently been reviewed elsewhere (Gregoire et al., 2007). During inflammation, NK cells can be recruited by chemokines that bind the CCR2, CCR5, CXCR3, and CX3CR1 chemokine receptors. However, the degree to which NK cells constitutively traffic in normal tissues is relatively less well understood. How NK cells detect and discriminate target cells has recently been studied quite extensively. The initial contact between NK cells and target cells may involve any of a number of different receptors, leading to adhesion mediated by the integrin leukocyte functional antigen (LFA)-1. Activating receptors, including CD16, 2B4, NKG2D, DNAM-1, as well as LFA-1 itself, can rapidly induce necessary inside-out signals for the activation of LFA-1 in freshly isolated human NK cells, promoting the initial signals required for adhesion (Bryceson et al., 2009). As opposed to activating receptors, inhibitory receptor signals can abrogate adhesion to target cells (Burshtyn et al., 2000; Bryceson et al., 2009). The signals for induction of inside-out activation of LFA-1 are not well defined. As the activating NK cell receptors have distinct cytoplasmic domains, their signaling cascades differ. Live cell imaging of NK cells on supported planar lipid bilayers carrying ligands for LFA-1, NKG2D, 2B4, and CD16 has shown that, indeed, these receptors induce quite diverse behaviors by NK cells (Liu et al., 2009). In regards to signals for

TABLE 13.1 Specificity and Signaling of Human NK Cell Receptors

| Receptor | Signaling | Cellular ligand | Function |
|-----------------------|----------------------|---------------------|--|
| FcγRIIIa (CD16) | Activation (ITAM) | IgG | Elimination of antibody coated cells (ADCC) |
| NKp30 (CD337) | Co-activation (ITAM) | B7-H6 | NK cell–myeloid cell cross-talk, tumor recognition |
| NKp44 (CD336) | Activation (ITAM) | ? | ? |
| NKp46 (CD335) | Co-activation (ITAM) | ? | Surveillance of mitotic cells |
| KIR (CD158a, b, etc.) | Activation (ITAM) | HLA class I | ? |
| CD94/NKG2C (CD159c) | Activation (ITAM) | HLA-E | ? |
| NKG2D (CD314) | Co-activation (YxNM) | ULBP, MICA, MICB | Surveillance of tumor cells and genotoxic stress |
| NKp80 | ? (hemi-ITAM) | AICL | NK cell–myeloid cell cross-talk |
| DNAM-1 (CD226) | Co-activation | CD112, CD155 | Surveillance of tissue integrity |
| 2B4 (CD244) | Co-activation (ITSM) | CD48 | Interaction with hematopoietic cells |
| CRACC (CD319) | Co-activation (ITSM) | CRACC (CD319) | Interaction with hematopoietic cells |
| NTB-A | Co-activation (ITSM) | NTB-A | Interaction with hematopoietic cells |
| CD2 | Co-activation | CD58 | Interaction with hematopoietic and endothelial cells |
| KIR2DL4 (CD158d) | ? | HLA-G (soluble) | Trophoblast-induced vascular remodeling? |
| LFA-1 (CD11a/CD18) | Granule polarization | ICAM | Recruitment and activation during inflammation, efficient cytotoxicity |
| KIR (CD158) | Inhibition (ITIM) | HLA class I alleles | Assess loss of MHC class I alleles |
| LIR1, LILR1 (CD85j) | Inhibition (ITIM) | HLA class I | Assess loss of MHC class I expression |
| CD94/NKG2A (CD159a) | Inhibition (ITIM) | HLA-E | Gauge MHC class I expression |
| KLRG1 | Inhibition (ITIM) | E-cadherin | Assess loss of tissue integrity |
| NKR-P1 (CD161) | Inhibition (ITIM) | LLT1 | ? |
| LAIR-1 (CD305) | Inhibition (ITIM) | Collagen | Control activation in extracellular matrix |
| Siglec-7 (CD328) | Inhibition (ITIM) | Sialic acid | ? |
| Siglec-9 (CD329) | Inhibition (ITIM) | Sialic acid | ? |
| IRp60 (CD300a) | Inhibition (ITIM) | ? | ? |

inside-out activation of LFA-1, phosphorylation and activation of VAV1 has been postulated to be a common denominator of signaling pathways downstream of activating receptors including LFA-1 itself. Concomitantly, VAV1 phosphorylation provides a point at which inhibitory receptor signals can oppose signals from activating receptors. Specifically, phosphorylated VAV1 is a substrate of SHP-1 that is recruited by inhibitory NK cell receptors and acts to prevent NK activation (Stebbins et al., 2003). Several other signaling proteins, including

WASP, Cdc42, Ras, Rap1, CrkL, and HS1, have been implicated in signaling for adhesion.

NK Cell Lytic Granule Polarization and Maturation

Besides adhesion, LFA-1 has a key role in promoting perforin-containing granule polarization towards the target cell, facilitating efficient cytotoxicity (Barber et al., 2004; Bryceson et al., 2005). Moreover, such granule

polarization towards the immune synapse is the result of two different molecular processes. First, granules rapidly converge in dynein-dependent, minus-end directed motion to the microtubule-organizing center (MTOC) (Mentlik et al., 2010). In the NK cell line YTS, antibody-mediated blockade of LFA-1 impairs granule convergence at the MTOC upon target cell contact, suggesting that LFA-1-mediated signals facilitate this process (Mentlik et al., 2010). Second, following convergence of the granules and within minutes, the MTOC and granules polarize towards the interaction site in an LFA-1-dependent manner (Bryceson et al., 2005; Mentlik et al., 2010). In regards to the signaling pathways involved in LFA-1-mediated polarization, several key proteins have been identified. Talin, binding to the cytoplasmic tail of LFA-1, is required for the recruitment of WASP, Arp2/3, vinculin, and actin (Mace et al., 2009, 2010). Furthermore, WASP is required for the accumulation of F-actin at the synapse. Moreover, silencing of WASP interacting protein (WIP) in the human NK cell line YTS impaired lytic granule polarization but had no effect on the formation of conjugates with target cells (Krzewski et al., 2008). The second messenger, diacylglycerol, was required for MTOC polarization and cytotoxicity by CTL (Quann et al., 2009); however, the extent to which diacylglycerol regulates LFA-1-mediated MTOC polarization in NK cells remains to be established. Recent evidence indicated that signaling for granule polarization by LFA-1 in IL-2-expanded human NK cells also involved CD3 ζ -chain phosphorylation, SYK recruitment and activation, and PLC- γ activation (March and Long 2011). Activation of PLC- γ resulted in hydrolysis of phosphatidylinositol (4,5)-bisphosphate (PIP₂) to generate the second messengers, diacylglycerol and inositol (1,4,5)-trisphosphate (IP₃). Downstream of LFA-1, PLC- γ activation led to PKC activation, and pharmacological inhibition of PLC- γ abrogated granule polarization (March and Long 2011). Upon recognition of susceptible target cells, the tyrosine kinase PYK2 was also recruited to the immune synapse, and transfection of dominant negative PYK2 blocked MTOC and paxillin movement to the synapse (Sancho et al., 2000). In summary, a number of studies suggest pathways involving talin, WASP, WIP, PYK, JNK, and paxillin, as well as CD3 ζ , SYK, and PLC- γ for granule polarization.

NK Cell Cytolytic Granule Exocytosis

Vesicle exocytosis is a requirement for NK cell cytotoxicity (Bryceson et al., 2006b). Studies of knockout mice have demonstrated an essential role for PLC- γ in granule exocytosis (Tassi et al., 2005; Caraux et al., 2006). Following the activation of PLC- γ , IP₃ can trigger cytoplasmic release of Ca²⁺ from the endoplasmic reticulum (ER). Engagement of

CD16 is sufficient to induce robust intracellular Ca²⁺ mobilization, whereas several other receptors do not. Rather, co-activation receptors trigger intracellular Ca²⁺ mobilization when engaged in specific pair-wise combinations (Bryceson et al., 2006b). Additional data suggest that the molecular basis for such co-activation involves complementary phosphorylation of SLP-76 as well as overcoming a threshold for activation of VAV1 that is set by the ubiquitin ligase c-Cbl (Kim et al., 2010). PLC- γ activation leads to IP₃-mediated Ca²⁺ release from the ER, which ultimately results in depletion of intracellular Ca²⁺ stores and induction of store-operated Ca²⁺ entry (SOCE). NK cells from patients with mutations in either STIM1 or ORAI1 display defective degranulation, demonstrating a requirement for ORAI1 channel-mediated SOCE for lytic granule exocytosis (Maul-Pavicic et al., 2011). Notably, the ORAI1 deficiency does not affect signals for adhesion or granule polarization (Maul-Pavicic et al., 2011). Further downstream, several proteins required for NK cell exocytosis have been identified through studies of patients with hyper-inflammatory syndromes caused by defective lymphocyte cytotoxicity. These proteins include Rab27a that facilitates terminal trafficking of lytic granules to sites of exocytosis, Munc13-4 that primes lytic granule exocytosis, as well as syntaxin-11 and Munc18-2 that facilitate membrane fusion (Stinchcombe et al., 2001; Feldmann et al., 2003; Bryceson et al., 2007; Wood et al., 2011). Furthermore, results suggest that distinct endosomal compartments fuse prior to lytic granule fusion with the plasma membrane, facilitating the exocytic process (Menager et al., 2007; Wood et al., 2009). Finally, for efficient cytotoxicity, lytic granules must traverse the actin-rich immunological synapse to enable exocytosis. The adenosine triphosphate (ATP)-dependent actin motor protein myosin IIA has been shown to associate with lytic granules in NK cells and play a role in mediating lytic granule traversal for exocytosis (Sanborn et al., 2009).

NK Cell Chemokine and Cytokine Production

Target cell recognition by freshly isolated human NK cells induces a set of chemokines, including CCL3, CCL4, CCL5, as well as the cytokines TNF- α and IFN- γ (Fauriat et al., 2010). Chemokines are induced within one hour of stimulation, whereas secretion occurs several hours after activation. Importantly, experiments varying the signaling input for NK cell activation have revealed a hierarchy in requirements for the induction of chemokines and cytokines, with chemokines induced by weakly activating signals, degranulation induced by intermediate levels of activating stimuli, and cytokines requiring the strongest activation. This hierarchy is reflected in the

requirements for induction of different effector responses. PLC- γ is required for all responses (Tassi et al., 2005; Caraux et al., 2006). A deficiency in SOCE, as seen in NK cells from humans with autosomal recessive STIM1 and ORAI1 mutations, results in defective degranulation and cytokine production induced upon target cell recognition, but only partially impairs chemokine production and cytokine production induced upon target cell recognition, but only partially impairs chemokine production (Maul-Pavicic et al., 2011). Notably, NK cells from PI3K p110 δ -deficient mice displayed selectively impaired cytokine production, whereas knockout of both p110 δ and p110 γ was required to impair cytotoxicity (Kim et al., 2007; Tassi et al., 2007). Moreover, PKC θ -deficient mice had defects in IFN- γ transcription and secretion due to impaired JNK, AP-1, and NFAT activation (Tassi et al., 2008). Yet, NK cell-mediated cytotoxicity was not impaired in PKC θ -deficient mice. Curiously, a Rap1b deficiency in mice selectively deters NK cell chemokine and cytokine production, but not cytotoxicity (Awasthi et al., 2010). Thus, a few proteins, including PI3K p110 δ and PKC θ may be specifically required for transcription of cytokine genes. Further studies are required to understand how these proteins are integrated in the signaling pathways for NK cell activation and how the engagement of different activating receptor controls their function.

NK CELLS AND HUMAN AUTOIMMUNITY

Classically, autoimmune diseases typify syndromes caused by an inappropriate activation of cells of the adaptive immune system; i.e., T cells and B cells, resulting in cell-specific, organ-specific, or systemic tissue damage. Typical examples of such diseases include multiple sclerosis, rheumatoid arthritis, and insulin-dependent type 1 diabetes. Autoimmune diseases often display sexual bias. In this respect, several studies indicate somewhat higher NK cell numbers and activity in men than in women, but these differences often do not reach statistical significance with studies of relatively small sample sizes. Autoimmune diseases have been thought to be initiated in steps, including release of self-antigens from the target organ, a priming step in secondary lymphoid organs, and finally immune cell homing to the target organ/tissue and subsequent tissue destruction (Ji et al., 1999). NK cells can likely act at all these steps; i.e., as mediators of initial target damage leading to release of self-antigens, at the level of T cell priming in secondary lymphoid organs, and at the level of the target organ as immunomodulatory or effector cells (Pazmany, 2005; Shi & van Kaer, 2006; Perricone et al., 2008; Flodström-Tullberg et al., 2009) (Figure 13.1).

Most research results pointing towards a role for NK cells in human autoimmune diseases are, obviously, correlative. Associations between NK cell activity and autoimmune conditions appear in several reports, including

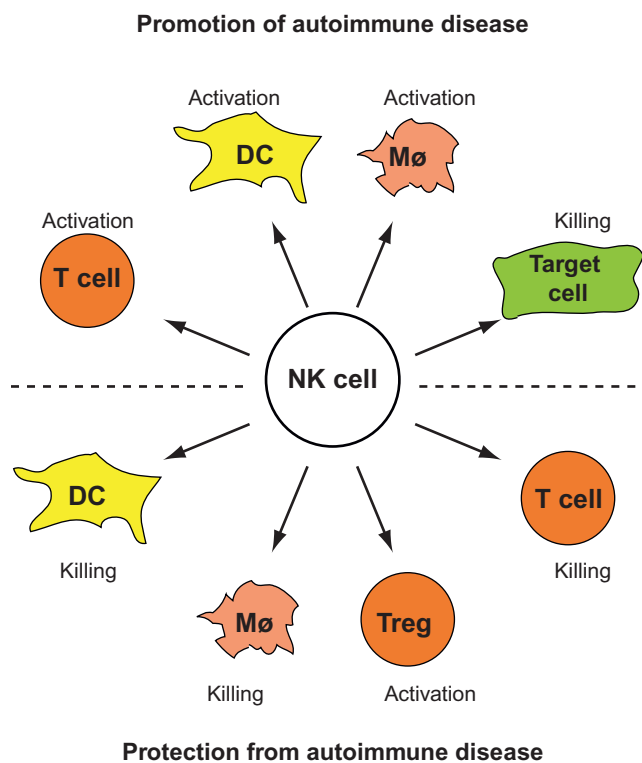

FIGURE 13.1 NK cells may affect autoimmune diseases in many different ways, for example by promoting or preventing functions of other cells, or by killing them. The figure illustrates possible interactions between NK cells and other cells as well as their outcomes. Figure modified from Flodström-Tullberg et al., 2009.

those describing studies finding altered numbers, phenotypes, and functions of NK cells (Shi & van Kaer, 2001; Pazmany, 2005; Perricone et al., 2008; Flodström-Tullberg et al., 2009). Some older studies are, however, difficult to interpret since they fail to distinguish NK cells from regulatory NKT cells or T cells expressing NK cell-associated receptors. An additional problem is determining if abnormalities in NK cell populations are a cause and/or an effect of a given disease state. Finally, most studies rely on assessment of NK cells from peripheral blood, not from appropriate secondary lymphoid organs or affected tissues. Despite these shortcomings, a substantial amount of evidence supports a direct involvement of NK cells in human autoimmunity.

Defective Control of other Immune Cells Links NK Cells to Autoimmune Diseases

The impaired NK cell cytotoxic function frequently observed in some humans with autoimmune diseases and/or other inflammatory conditions highlights the role of NK cells in controlling other cells, e.g., macrophages. Macrophage activation syndrome (MAS) is associated

with several rheumatic diseases, most commonly with systemic juvenile idiopathic arthritis (sJIA) (Villanueva et al., 2005; Kelly and Ramanan, 2007) (Chapter 37). Clinically, this syndrome closely resembles familial hemophagocytic lymphohistiocytosis (FHL), a life-threatening genetic disorder in which NK cell function is absent or depressed (Bryceson and Ljunggren, 2007; Wood et al., 2011). As in FHL, patients with MAS have profoundly decreased NK cell cytotoxic activity (Ravelli et al., 2012). Therefore, impaired NK cell cytotoxicity might be, at least in part, causative of MAS. Supporting this notion, an sJIA patient with low NK cell cytotoxic function was found to harbor compound heterozygous splice-site and missense mutations in *UNC13D*, a gene associated with FHL (Hazen et al., 2008). Another link between NK cells and macrophages comes from studies showing that CD56^{bright} NK cells accumulate in certain inflammatory lesions and, in the appropriate cytokine environment, can engage with monocytes in a reciprocal activation fashion, thereby amplifying the inflammatory response. Moreover, CD56^{bright} NK cells can trigger the differentiation of monocytes into DCs (Zhang et al., 2007). Such positive feedback loops could well promote the pathogenesis of chronic inflammatory conditions such as rheumatoid arthritis (Dalbeth et al., 2004). Moreover, naturally occurring mutations in genes that cause a defect in NK cells are found in patients with abnormalities in TAP-peptide transporters, who typically suffer from chronic infections in childhood and autoimmune manifestations later in life. Notably, although interactions with macrophages are particularly relevant to organ-specific autoimmunity, NK cells also modulate innate and adaptive immunity by interacting with many other cell types, e.g., other lymphocytes including NKT cells as well as effector and regulatory T cells (Carnaud et al., 1999; Assarsson et al., 2004; Ferlazzo et al., 2004; Martín-Fontecha et al., 2004; Ghiringhelli et al., 2006; Shanker et al., 2007).

A specific point at which NK cells cytotoxicity can act to modify immune responses is through killing of activated T cells. Interestingly, upon cytomegalovirus infection in mice, NK cells can kill activated CD4⁺ T cells, thereby affecting CD8⁺ T cell function and exhaustion (Waggoner et al., 2011). In a mouse model of arthritis, blockade of the NK cell receptor NKG2A facilitated NK cell elimination of pathogenic CD4⁺ T cells, arresting disease progression (Leavenworth et al., 2011). Such NK cell-mediated modulation of immune responses may well have implications for human autoimmunity. Moreover, NK cells may limit responses through modes other than cellular cytotoxicity. In studies of lupus, at least *in vitro*, NK cells can potentiate IFN- α production by plasmacytoid DC by up to a thousand-fold. IFN- α is a key cytokine involved in driving the pathogenesis of the disease

(Eloranta et al., 2009). The NK cell-mediated enhancement of IFN- α production by plasmacytoid DC is contact dependent and partially relies on secretion of the chemokine CCL4 (MIP-1 β) by NK cells (Hagberg et al., 2011). Thus, NK cell immunoregulatory interactions may also exacerbate autoimmune responses.

Although less is known in contexts of autoimmunity, roles for NK cells as inducers of organ-specific and systemic tissue damage have also recently been suggested in certain acute and chronic viral infections. For instance, during flares of chronic hepatitis B virus infection, NK cells have been implicated to mediate liver damage via the apoptosis-inducing molecule TRAIL (Dunn et al., 2007). During acute human hantavirus infection, a hemorrhagic fever-inducing virus infection with high mortality, NK cells are highly activated and damage arises to the vasculature system long after the virus has been cleared from the body (Björkström et al., 2011).

Genetic Association Studies Revealing Links between NK Cells and Autoimmune Diseases

Linkage analysis in several autoimmune disease conditions has implicated various NK cell receptors in pathogenesis (Kulkarni et al., 2008). For example, certain *KIR* receptor genes, the products of which are expressed on NK cells and some T cell subsets, have been associated with the development of autoimmune diseases. *KIR* genes are polymorphic and the *KIR* gene complex is polygenic, encoding varying numbers of inhibitory and activating receptors. Interactions of the independently segregating *KIR* and HLA loci are important for NK cell education/licensing and target cell recognition (Jonsson and Yokoyama, 2009). The existence of *KIR*-HLA genotypes that tune NK cells towards activation are favorable in some infectious diseases, but might also predispose to autoimmunity (Kulkarni et al., 2008). A number of associations predisposing to autoimmune diseases have been identified in which activating *KIR* or *KIR*/HLA genotypes are accompanied by lack of inhibition. For example, scleroderma, a disease of tissue fibrosis, inflammation, and vascular injury, has been linked to the presence of activating *KIR2DS2*, in the absence of a corresponding inhibitory *KIR2DL2* (Momot et al., 2004). Likewise, the risk of psoriatic arthritis is enhanced in patients carrying *KIR2DS1* and/or *KIR2DS2*, and this effect is augmented in the absence of ligands for the inhibitory *KIR2DL1* and *KIR2DL2/3*, respectively (Nelson et al., 2004). Similarly, for rheumatoid arthritis, increased risk is associated with a presence of the *KIR2DS2* gene (Yen et al., 2001). Type 1 diabetes is associated with the expression of *KIR2DS2*/HLA ligand pairs in an environment of weak inhibitory interactions (van der Slik et al., 2003, 2007). In primary

sclerosing cholangitis, a claimed autoimmune liver disease characterized by progressive destruction of the biliary tract, homozygosity for HLA-C1, a ligand for KIR2DL3, is associated with increased susceptibility for disease (Karlsen et al., 2007; Hov et al., 2010). Finally, ankylosing spondylitis shows a strong relationship to *HLA-B27*, a ligand for KIR3DL2; NK cells from patients with this disease have predominant KIR3DL2 expression and show an activated phenotype as measured by CD38 expression (Chan et al., 2005). Thus, the interplay between human NK cell inhibitory and activating receptor-MHC class I ligand pairs has provided significant evidence with respect to the involvement of NK cells in human autoimmunity. Noteworthy, however, the function of KIR may in some instances also be exerted at the level of autoimmune T cells, e.g., through augmentation of low affinity activation signals (Björkström et al., 2012).

In addition to receptors that bind MHC class I molecules, a number of other receptors that bind stress-induced ligands or regulate interactions with other immune cells may dictate NK cell specificity. Inappropriate expression of activating receptor NKG2D ligands can lead to detrimental NK cell activation, which in turn may trigger or exacerbate autoimmunity. The best-characterized NKG2D ligands are the MICA/B cellular stress-induced molecules that act as danger signals to alert NK cells and CD8 T lymphocytes (Bauer et al., 1999). Acquisition of MICA/B ligands on the surfaces of potential target cells may cause the breakdown of tolerance. MICA/B molecules, when inappropriately expressed, may thus trigger or worsen an autoimmune response. The involvement of NKG2D and its ligands in autoimmunity was first revealed in patients with rheumatoid arthritis (Groh et al., 2003). It has also been demonstrated that MICA/B are overexpressed on gut epithelium during active celiac disease (Hüe et al., 2004). However, in situations of MICA/B upregulation, these molecules may be targets not only for NK cells but also for T cells, as demonstrated in several studies (Meresse et al., 2004). Polymorphisms of human *MICA* have been associated with a variety of autoimmune disorders. One such example is patients with primary sclerosing cholangitis in whom several studies have identified the *MICA*008* allele in association with increased disease susceptibility (Norris et al., 2001; Wiencke et al., 2001). The functional implications of such polymorphism are, however, far from clear, and *MICA* associations frequently reflect a linkage disequilibrium with *HLA-B* alleles (Field et al., 2008). Still to be established is whether mutations in the NKG2D gene (*KLRK1*) might underlie some autoimmune diseases. Recently, however, a single nucleotide polymorphism (SNP) in *CD226*, conferring an amino acid substitution in the DNAM-1 receptor, was linked to the

development of multiple sclerosis, rheumatoid arthritis, type 1 diabetes, and autoimmune thyroid disease (Hafler et al., 2009). In addition, two intronic SNPs in *CD244*, that likely increase 2B4 receptor surface expression, have been connected with the development of rheumatoid arthritis in a Japanese cohort (Suzuki et al., 2008). However, in a mouse model of lupus, *Cd224*-deficiency exacerbated autoantibody production in an NK cell-independent manner (Brown et al., 2011). Together, these data implicate activating NK cell receptors in susceptibility to multiple autoimmune diseases. We should note, however, that despite the often-used term “NK cell receptors,” these receptors are also expressed on other lymphocyte populations, and it remains to be established to what degree genetic associations are conferred by alterations specifically in NK cell function.

CONCLUSIONS

With the exception of genetic linkage analysis, relatively few studies have been undertaken to explore the role of NK cells in human autoimmunity compared to other diseases where NK cells are more directly implicated. Much knowledge on the role of NK cells in autoimmunity still comes from studies in experimental animal models, and caution must be taken before translating those results directly to human conditions. The emerging view, however, is that NK cells may function as important regulatory cells during the priming phase of adaptive immune responses and as regulatory and effector cells at the sites of target organ during inflammation. NK cell control of macrophage activation may be one important checkpoint at the level of the target organ in the development of autoimmunity. The ability of NK cells to influence adaptive immune responses and to control immune cell homeostasis in humans clearly deserves further attention. Improved comprehension of how NK cells affect numerous autoimmune conditions may furthermore pave the way for new immunotherapeutic approaches towards alleviating or preventing such diseases.

NEUTROPHILS

Basic Biology and Role in Immunity

Neutrophils, the most abundant leukocytes in the human body, have a short lifespan which is balanced by their continuous release from the bone marrow. Neutrophils form part of the innate immune system, the first line of defense against invading pathogens. Neutrophil-mediated inflammatory responses are a complex process, with initial adhesion of circulating cells to the activated vascular endothelium followed by their extravasation and migration towards inflammatory foci and, finally, *in situ* destruction of pathogens (Kaplan, 2011). Microbes are eliminated through various processes including phagocytosis, reactive oxygen species (ROS) generated via the respiratory burst, release of microbicidal substances from cytoplasmic granules (Kobayashi and DeLeo, 2009),

and NETosis, a process characterized by the formation of neutrophil extracellular traps (NETs) (Brinkmann et al., 2004) (see below).

Neutrophils contain various types of granules, enabling the sequential release of hundreds of constitutively expressed proteins into the extracellular environment, including proinflammatory mediators that have effects on antigen-presenting cells and induce dendritic cell maturation (Faurischou and Borregaard, 2003). The proteins contained in primary (azurophilic) neutrophil granules include alarmins, molecules that activate antigen-presenting cells and trigger innate and adaptive immune responses (Kobayashi and DeLeo, 2009). These alarmins include antimicrobial peptides such as α -defensins, lactoferrin, and cathelicidin peptides, such as LL-37, which are chemotactic to various leukocytes. Together with self-DNA release by NETosis, LL-37 also promotes

Box 14.1 Antimicrobial Peptides of NETs

- Neutrophil elastase

- Histones (nucleosome histones, H1)
- Calprotectin

activation of plasmacytoid dendritic cells, increasing their expression of costimulatory molecules and production of type I interferon (IFN) (Lande et al., 2007). Other molecules released by neutrophils, including myeloperoxidase, neutrophil elastase, and cathepsin G, also play a role in activating innate immunity (Box 14.1). Neutrophils also produce inflammatory cytokines and eicosanoids, regulate vascular permeability, and may induce endothelial damage (Murphy et al., 1998; Marzocchi-Machado et al., 2002). They also express toll-like receptors (TLRs) 1–10, with the exception of TLR3, facilitating the initiation of potentially important immune responses when pathogen-associated molecular patterns are recognized.

Neutrophil Extracellular Traps and NETosis: A Novel Form of Cell Death

Stimulated neutrophils may suffer NETosis, an active form of cell death resulting in the release of decondensed chromatin into the extracellular space (Brinkmann et al., 2004; Fuchs et al., 2007). NETs are fibrous chromatin-based structures containing DNA, histones, and granular proteins, including neutrophil elastase and myeloperoxidase (Urban et al., 2009), which are expelled into the extracellular matrix during neutrophil death from NETosis and may immobilize and kill pathogens.

NETs trap many types of microbes *ex vivo*, have been identified in *in vivo* disease models, and are thought to kill pathogens by exposing them to elevated local antimicrobial concentrations (Papayannopoulos and Zychlinsky, 2009). It is not clear how NETs are formed, although the reactive oxygen pathway is involved, as nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and myeloperoxidase are required for NET formation in response to chemical and biological stimuli (Fuchs et al., 2007; Patel et al., 2010; Metzler et al., 2011). Nitric oxide donors can induce NETs via a mechanism that also requires ROS production (Patel et al., 2010), like all

activators of NET formation discovered to date. Upstream of NADPH oxidase, the Raf-MEK-ERK pathway is implicated in NET formation (Hakkim et al., 2011), but later in the process, neutrophil elastase translocates from the granules to the nucleus and degrades histones, leading to chromatin decondensation (Papayannopoulos et al., 2010).

Excess NET formation or impaired NET removal is suggested to be linked to autoimmune diseases, including small-vessel necrotizing vasculitis and systemic lupus erythematosus (SLE) (see below). A recent study found that the cell destructive effect of neutrophils is due to NET components and not to other secreted neutrophil components (Saffarzadeh et al., 2012). NETs induce dose-dependent cytotoxic effects on direct interaction with epithelial and endothelial cells, with NET-mediated cytotoxicity probably being due to histones and myeloperoxidase.

Pathogenic Role of Neutrophils in Autoimmune Diseases

Systemic Lupus Erythematosus

Neutrophil actions normally successfully sequester and resolve inflammatory damage, although their recruitment and activation may provoke disease, resulting in substantial tissue damage. In autoimmune diseases, a potential role for neutrophils in the pathogenesis and associated organ damage of SLE, including description of the LE cell, was described many years ago (Holman, 1960).

Neutropenia and Abnormal Neutrophil Function in SLE

Nearly half the patients with SLE may have neutropenia (Hepburn et al., 2010). The mechanisms driving neutropenia in SLE include: neutrophil-reactive autoantibody-driven cell removal; neutralizing autoantibodies against growth factors that act on neutrophils such as granulocyte colony-stimulating factor; bone marrow suppression; increased neutrophil apoptosis and secondary necrosis; and, possibly, death by NETosis (Arenas et al., 1992). In addition, there is evidence of qualitative abnormalities in some neutrophil functions in SLE. Serum from SLE patients induces increased neutrophil aggregation and impairs phagocytosis and lysosomal enzyme release by normal neutrophils *in vitro* (Brandt and Hedberg, 1969; Abramson et al., 1983). It is suggested that aberrant clearance of apoptotic products by phagocytes, including neutrophils, may play a role in the pathogenesis of SLE (Courtney et al., 1999). Likewise, reduced responsiveness to cytokines such as interleukin (IL)-8 has been reported in SLE-derived neutrophils (Hsieh et al., 2008), as has premature telomere shortening indicative of enhanced

senescence (Wu et al., 2007). Evidence suggests that intravascularly activated neutrophils in SLE patients overexpress various adhesion molecules and tend to form aggregates (Abramson et al., 1983; Molad et al., 1994). Various autoantibodies, including anti- β_2 -glycoprotein I, are involved in neutrophil activation (Arvioux et al., 1995). Likewise, it is suggested that nucleosomes, which are probably major SLE autoantigens, are putative activators and recruiters of neutrophils in SLE, although the mechanisms remain unclear (Rönnefarth et al., 2006). Increased neutrophil apoptosis and aberrant clearance of apoptotic bodies are associated with SLE disease activity (Ren et al., 2003; Donnelly et al., 2006), and the *in vitro* rate of neutrophil secondary necrosis is increased in SLE-derived samples (Ren et al., 2003).

Low-Density Granulocytes in SLE

Low-density granulocytes are a specific subset of aberrant neutrophils that have recently been identified in peripheral blood mononuclear cell (PBMC) preparations from pediatric and adult SLE patients (Kaplan, 2011). Low-density granulocytes display phenotypic characteristics of immature neutrophils with nonsegmented nuclei and greater expression of myeloperoxidase, neutrophil elastase, and defensin-3 (Hacbarth and Kajdacsy-Balla, 1986; Bennett et al., 2003). Low-density granulocytes have a proinflammatory phenotype characterized by augmented secretion of tumor necrosis factor (TNF) and type I and II IFNs after stimulation, which could promote and increase tissue damage. They also have a markedly increased ability to kill endothelial cells upon cell–cell contact (Denny

et al., 2010), and to form NETs compared with normal density SLE-derived neutrophils and control neutrophils (Villanueva et al., 2011) (Figure 14.1). Low-density granulocytes are suggested to account for the increased type I IFN production that leads to abnormal function of endothelial progenitor cells and/or circulating myeloid angiogenic cells *in vitro* and, possibly, *in vivo* in SLE. This aberrant subset of neutrophils has an increased propensity to undergo NETosis (Knight and Kaplan, 2012), and SLE patients with cutaneous involvement and vasculitis have a higher percentage of low-density granulocytes.

NETosis in SLE

As mentioned, NETs may have detrimental effects on the host. They result in autoimmunity by extracellular exposure of self-molecules. In some SLE patients, NET degradation is impaired due to DNase I inhibitors or antibodies to NETs. Recent studies by Lande and colleagues (2011) and Garcia-Romo and colleagues (2011) suggest that NETs and NETosis are the link between INF- α production and neutrophil death through the implication of some peptides such as LL-37 (an antimicrobial peptide that is a key mediator of plasmacytoid dendritic cell activation) and human neutrophil peptide (Bosch, 2011). The hypothesis is that these peptides, in combination with extracellular DNA, are pivotal components of NETs in SLE, and recent studies have suggested that they may be involved in the immunogenicity of self nucleic acids in immune complexes. Lande and colleagues (2011) found high levels of expression of LL-37 in the blood of SLE patients, and suggested that LL-37, together with human

FIGURE 14.1 Circulating low-density granulocytes (LDGs) from SLE undergo increased NETosis. Characteristic images of control neutrophils, SLE-derived neutrophils, and SLE-derived LDGs isolated from peripheral blood and studied at baseline (T0) or after 2 hours' (T2) stimulation with DMSO or PMA. Top panels show merged immunofluorescence images of NETs, which were identified by neutrophil elastase (green). DNA was labeled with Hoechst 33342 (blue). Original magnification, $\times 40$. Scale bar, 20 μm . Abbreviations: DMSO, dimethyl sulfoxide; LDGs, low-density granulocytes; NETs, neutrophil extracellular traps; PMA, phorbol 12-myristate 13-acetate. Permission to reproduce this figure was obtained from *The American Association of Immunologists, Inc.* © Villanueva et al. (2011).

neutrophil peptide, is essential for the immunogenicity of DNA-containing immune complexes in SLE, because free human DNA entered and activated plasmacytoid dendritic cells through TLR9 when complexed with LL-37. Both anti-LL-37 and anti-human neutrophil peptide antibodies activate neutrophils to release NETs; exposure of neutrophils to INF- α *in vitro* is followed by expression of LL-37 and human neutrophil peptide. Lande and colleagues (2007) found a significant correlation between high levels of anti-LL-37, anti-human neutrophil peptide antibodies, and anti-DNA antibody titers, suggesting that neutrophil-derived antimicrobial peptides act as B cell autoantigens in conjunction with DNA. Likewise, autoantibodies in immune complexes interacted with the Fc γ surface receptor II (Fc γ RII) on plasmacytoid dendritic cells and triggered receptor-mediated endocytosis of self DNA. Garcia-Romo and colleagues (2011) also showed that NETs in SLE contain LL-37 and that immune complexes harboring antiribonucleoprotein autoantibodies bonded with Fc γ RIIA on neutrophils suffering death by NETosis, resulting in ROS production. Although the molecular basis of NET formation remains unclear, it is known that ROS trigger activation of neutrophil enzymes and their relocation to the nucleus to initiate the DNA unwinding on which NET formation depends. Increased production of ROS, such as the superoxide anion and hydrogen peroxide, is associated with SLE, as shown by oxidative protein modifications, lipid peroxidation, and lipoprotein oxidation. Ultimately, these events led to plasmacytoid dendritic cell activation and, therefore, the secretion of INF- α . This suggests that, in SLE, anti-self antibodies activate neutrophils, which then release NETs containing DNA–antimicrobial peptide complexes that activate plasmacytoid dendritic cells, leading to INF- α release and worsening or perpetuation of inflammation and disease. Finally, Leffler et al. (2012) have recently found that NETs are a potent complement activator in SLE, and that patients who fail to degrade NETs had a more active disease and lower serum levels of C3 and C4.

Neutrophils and Organ Damage in SLE

A probable etiopathogenic role of neutrophils in SLE-related organ damage has principally been postulated for cardiovascular, renal, and cutaneous involvement. Type I IFNs are reported to play a vital role in the abnormal vascular repair that occurs in SLE through harmful effects on endothelial progenitor cells and circulating myeloid angiogenic cells (Denny et al., 2007; Lee et al., 2007). Depleting low-density granulocytes from SLE proangiogenic cultures restores the ability of endothelial progenitor cells and/or circulating myeloid angiogenic cells to differentiate into mature endothelium (Denny et al., 2010). Thus, low-density granulocytes might play a dual

role in inducing premature cardiovascular damage in SLE patients by promoting endothelial damage and inflammation while inhibiting vascular repair. This hypothesis is bolstered by evidence that high levels of low-density granulocytes correlate with vascular inflammation in SLE (Denny et al., 2010). The probable contribution of neutrophils to the pathogenesis of antibody-mediated lupus nephritis, and especially to acute flares, is confirmed by depletion studies (selective removal of neutrophils from wild-type animals) and adoptive transfer studies (reintroduction of neutrophils into deficient animals) (Cochrane et al., 1965). In several types of glomerulonephritis, neutrophils are predominantly located in the glomerular tuft (Hotta et al., 1996), and release enzymes, including neutrophil elastase, myeloperoxidase and various cathepsins, which can destroy glomerular structures (Camussi et al., 1980; Johnson et al., 1988). Likewise, proinflammatory mediators elicit secretion of B lymphocyte stimulator, which is stored in activated neutrophils (Scapini et al., 2005). Neutrophil infiltration has been associated with some types of cutaneous involvement in SLE. Infiltration of neutrophils and neutrophilic debris beneath the basement membrane zone occurs in acute cutaneous lupus erythematosus (Obermoser et al., 2010). The neutrophilic component is most prominent in bullous lupus erythematosus (an autoantibody-mediated subepidermal blistering disease affecting SLE patients), in which affected skin is infiltrated by neutrophils that then suffer death from NETosis, exposing LL-37, dsDNA, and IL-17 at the tissue level. Furthermore, cutaneous NETosis is associated with increased levels of serum anti-dsDNA (Hacbarth and Kajdacsy-Balla, 1986), while high low-density granulocyte levels in peripheral blood have been associated with skin involvement in SLE patients (Rönnefarth et al., 2006).

Systemic Vasculitides

Antineutrophil cytoplasmic antibody (ANCA) positivity is a hallmark of ANCA-associated vasculitis, which includes granulomatosis with polyangiitis (Wegener), microscopic polyangiitis, and Churg–Strauss syndrome. Myeloperoxidase and proteinase 3 are the main targets of ANCA, which are directed against antigens in the neutrophil cytoplasm.

Neutrophils and Vasculitic Organ Damage

The severity of organ damage in patients with granulomatosis with polyangiitis correlates with the polymorphonuclear infiltrate rather than with other parameters of autoimmunity such as T cell activation or autoantibody titers (Brouwer et al., 1994; Amulic et al., 2012). In addition, ANCA bind myeloperoxidase and proteinase 3 expressed on the surface of activated neutrophils, promoting degranulation and

release of chemoattractants and ROS, which together lead to cyclical tissue damage and inflammation (Gómez-Puerta et al., 2012). In 1990, Falk and colleagues demonstrated that ANCA stimulate respiratory bursts in neutrophils and trigger the release of primary granule constituents (Falk et al., 1990). They also provoke vascular damage *in vitro* by inducing neutrophil effector functions, including cytokine and chemokine release, and produce lysis through adhesion to cultured endothelial cells (Bosch et al., 2006).

NETs in ANCA-Associated Vasculitis

NETs, rather than apoptosis, have been implicated in NETosis in ANCA-associated vasculitis, where they seem to make myeloperoxidase and proteinase 3 available to initiate an autoimmune response. Kessenbrock and colleagues (2009) demonstrated that NET formation could result in endothelial damage and might maintain autoimmune responses against neutrophil components in ANCA-associated vasculitis. After priming neutrophils with purified IgG, they observed that 23% of neutrophils incubated with ANCA-IgG produced NETs after 3 h compared with 11% of IgG-treated neutrophils from healthy controls. Induction of NETs with proteinase 3-specific mouse monoclonal antibodies showed that both proteinase 3 and myeloperoxidase localized with extracellular chromatin fibers and interacted directly with NET-DNA. The finding of NET components near to neutrophil infiltrates in affected glomeruli from renal biopsies of patients with ANCA-associated vasculitis with acutely worsened renal function provides *in vivo* evidence of NET formation. NETs were prominent in samples with strong neutrophil infiltration, suggesting NET formation may occur mainly during active disease. Using myeloperoxidase-specific capture and subsequent DNA-specific detection antibodies, the study identified circulating myeloperoxidase–DNA complexes in patients with ANCA-associated vasculitis but not in healthy controls. NET production resulted in raised levels of proteinase 3 and myeloperoxidase, which are components of NETs, thus providing additional autoantigens to further the autoimmune response. The authors concluded that ANCA might perpetuate cyclical NET production, sustaining the delivery of antigen–chromatin complexes to the immune system.

Rheumatoid Arthritis

Neutrophils are the most abundant leukocytes found in rheumatoid arthritis synovial fluid and show an activated phenotype, suggesting they have undergone activation and have probably released inflammatory mediators (Németh and Mócsai, 2012). Their pathogenetic role has also been demonstrated in animal models of arthritis. In

the K/BxN transgenic mouse model of inflammatory arthritis, neutrophil recruitment into the joints is promoted by the chemotactic lipid leukotriene B4 (LTB4) through its receptor BLT1, both of which are expressed by neutrophils (Chou et al., 2010). Neutrophil activation by immune complexes in the joints promotes IL-1 β production, which then stimulates synovial cells to produce chemokines, thus amplifying neutrophil recruitment into the joints (Chou et al., 2010). Likewise, IL-8 receptor beta [(IL8RB or C-X-C chemokine receptor type 2 (CXCR2)]-dependent neutrophil activation and consequent induction of inflammation is demonstrated in two murine models of multiple sclerosis (Carlson et al., 2008; Liu et al., 2010).

Notably, the K/BxN model of arthritis is critically reliant on spleen tyrosine kinase-mediated Fc γ R signaling, yet the specific cells needed for the signaling events were unknown. Elliott et al. (2011) have recently reported that specific deletion of spleen tyrosine kinase in neutrophils halts the inception of arthritis in the K/BxN model, suggesting that signaling dependent on this enzyme in neutrophils alone is the chief mediator of arthritis in this model.

Studies have recently shown that neutrophils are a major source of cytokines involved in maturation, survival, and differentiation of B cells, including B cell activating factor (BAFF) (Kessenbrock et al., 2009) and the proliferation-inducing ligand APRIL (the molecule most closely related to BAFF) (Mantovani et al., 2011). Neutrophils in rheumatoid arthritis synovial fluid (Gabay et al., 2009) and in various neoplasms including B cell malignancies express and secrete high APRIL levels. Since APRIL promotes the survival and proliferation of normal and malignant B cells, neutrophil-derived APRIL might maintain autoantibody production, as in rheumatoid arthritis (Roosnek et al., 2009), or malignant growth, as in B cell lymphoma (Roosnek et al., 2009).

Neutrophil-derived cytokines are also involved in bone resorption. Human and murine neutrophils upregulate the expression of functionally active, membrane-bound receptor activator of nuclear factor kappa-B ligand (RANKL) following activation *in vitro* and *in vivo* (Chakravarti et al., 2009). Neutrophils from synovial fluid of patients with exacerbated rheumatoid arthritis express high levels of RANKL (Chakravarti et al., 2009), which, after interaction with osteoclasts, activate osteoclastogenesis in a RANKL-dependent manner (Chakravarti et al., 2009). As there are elevated amounts of neutrophils at sites of inflammatory bone loss that express other regulatory factors involved in bone remodeling, including RANK and osteoprotegerin [also known as tumor necrosis factor receptor superfamily, member 11b (TNFRSF11B)] (Poubelle et al., 2007; Chakravarti et al., 2009), neutrophils could, potentially, orchestrate bone resorption in rheumatoid arthritis.

Primary Sjögren Syndrome

Neutropenia is a relevant hematologic finding in primary Sjögren syndrome, with nearly 30% of patients having autoimmune neutropenia (Brito-Zerón et al., 2009), a percentage substantially higher than that for other cytopenias (e.g., leukopenia or thrombocytopenia). Neutropenia is associated with a higher rate of hospital admission due to infection. Agranulocytosis is rare in primary Sjögren syndrome (only about 2% of patients), and is found especially in patients with an underlying hematologic neoplasia (mainly B cell lymphoma). The etiopathogenic role of anti-neutrophil antibodies in these patients, if any, is unclear. Two studies have found no association between autoantibodies to surface neutrophil antigens and agranulocytosis in Sjögren syndrome patients (Lamour et al., 1995; Coppo et al., 2003).

Systemic Sclerosis

Some studies have suggested a possible role of neutrophils in the etiopathogenesis of systemic sclerosis. Activated neutrophils have the potential to release agents capable of endothelial injury, including ROS and proteases, and the ability to affect cytokine signaling. Barnes et al. (2011) have recently demonstrated that serum from patients with systemic sclerosis induces endothelial cell activation and apoptosis in endothelial cell–neutrophil co-cultures, mediated largely by IL-6 and dependent on the presence of neutrophils, suggesting that IL-6 might be a potential therapeutic target in systemic sclerosis. Hussein et al. (2005) have reported increased neutrophilic infiltration in cutaneous biopsies of patients with systemic sclerosis in comparison with controls. Other studies have explored neutrophil function in systemic sclerosis, in particular their ability to contribute to oxidative stress by producing ROS, although the results were contradictory (Maslen et al., 1987; Stevens et al., 1992). However, recent studies have found that neutrophils from patients with systemic sclerosis produce less ROS *in vitro* than unstimulated control neutrophils (Foerster et al., 2006), and that neutrophils from patients with systemic sclerosis are hypofunctional in tests of ROS generation and chemotaxis (Barnes et al., 2011). In addition, proteomic studies show that neutrophils from systemic sclerosis have increased expression of proteins that are also increased on stimulation with lipopolysaccharide or TNF, again indicative of neutrophil activation *in vivo* (Barnes et al., 2011).

Antiphospholipid Syndrome

Women with antiphospholipid syndrome, a systemic autoimmune disease characterized by recurrent thrombosis associated with the presence of antiphospholipid antibodies, often suffer pregnancy-related complications,

including miscarriage. Samarkos et al., 2012 have suggested a close association between neutrophils and complement activation in the fetal losses of patients with antiphospholipid syndrome. Studies have found that C5a induction of tissue factor expression in neutrophils contributed to respiratory burst and trophoblast injury (Redecha et al., 2008; Seshan et al., 2009). Neutrophils from antiphospholipid antibody-treated mice expressed protease-activated receptor 2, whose stimulation led to neutrophil activation, trophoblast injury, and fetal death. Furthermore, simvastatin and pravastatin were found to decrease tissue factor and protease-activated receptor 2 expression on neutrophils and prevent pregnancy loss, suggesting that tissue factor/factor VIIa/protease-activated receptor 2 signaling mediates neutrophil activation and fetal death in antiphospholipid syndrome and that statins might be tested in women with antiphospholipid syndrome-related pregnancy complications.

Autoimmune Skin Diseases

Bullous pemphigoid is a subepidermal blistering skin disease characterized by an autoimmune response against epidermal/dermal proteins. The major autoantigens in bullous pemphigoid are hemidesmosomal proteins such as BP180 or BP230. Sera and purified IgG from patients with bullous pemphigoid are able to recruit neutrophils to the dermal–epidermal junction and to induce *ex vivo* subepidermal separation in human skin cryosections (Sitaru et al., 2002). This response was completely dependent on the Fc portion of the autoantibodies (Sitaru et al., 2002), suggesting a pathogenic role of Fc-receptor-mediated neutrophil activation by bullous pemphigoid-related autoantibodies. Psoriasis is another chronic autoimmune skin disease characterized by hyperplasia of epidermal keratinocytes. Neutrophils are found in skin lesions of psoriatic patients and drug-induced agranulocytosis causes the disappearance of psoriasis vulgaris (Toichi et al., 2000).

BASOPHILS

Basic Biology and Role in Immunity

Basophils, the scarcest circulatory granulocytes, account for 0.3% of nucleated bone marrow cells (Bosch et al., 2011). In the 1990s, it was discovered that human and murine basophils rapidly secrete large quantities of T helper 2 (Th2)-type cytokines, including IL-4 and IL-13, in response to stimuli, including FcεRI mediated signaling (Piccinni et al., 1991; Seder et al., 1991; Schroeder et al., 2001). The number of known factors that positively or negatively regulate basophil activation continues to increase. IL-3 aids differentiation of early precursors into

fully mature basophils in the bone marrow and spleen (Arinobu et al., 2005; Ohmori et al., 2009), and enhances IL-4 production in mature basophils (Le Gros et al., 1990; Lantz et al., 2008; Hida et al., 2009). IL-4 plays a fundamental role in driving naïve T cell differentiation to Th2 cells, which produce Th2 cytokines and contribute to antiparasitic immunity and allergic inflammatory responses (Zhu et al., 2010; Paul and Zhu, 2010).

Basophils also enhance B cell IgE production *in vitro* by producing Th2 cytokines and expressing CD40 ligand (Gauchat et al., 1993; Yanagihara et al., 1998). Basophils efficiently capture intact antigens and enhance B cell activation, particularly B cell proliferation and immunoglobulin production (Denzel et al., 2008). IL-4 and IL-6 produced by basophils optimize CD4 T cell-dependent B cell help (Denzel et al., 2008). *In vivo*, basophil-mediated effects on B cells are vital in providing humoral immunity against bacteria (Chen et al., 2009). Circulating human IgD binds to basophils and induces B cell-stimulating factors, including BAFF, IL-1, and IL-4, as well as antimicrobial and opsonizing factors (Chen et al., 2009).

Basophils in Autoimmune Diseases

Basophils play an immunomodulatory role by provoking Th2 cell differentiation *in vivo*, and therefore may be hypothesized to play a role in immune diseases other than allergies. In addition to evidence of peripheral basophilia and constitutive Th2 skewing of CD4 T cells in lyn (a tyrosine-protein kinase) deficient mice [lyn (–/–) mice], basophil involvement is also reported in autoimmune urticaria, where autoantibodies to the high affinity receptor FcεRIα induce basophil activation (Bischoff et al., 1996; Grattan, 2001). Autoimmune urticaria is known to have a Th2 component, and the immunomodulatory and effector responses of basophils contribute to the development of autoimmune symptoms. Th1 and Th2 cell subsets are suggested to be the primary effector cells involved in chronic inflammation in models of multiple sclerosis (experimental autoimmune encephalomyelitis), human posterior uveitis (experimental autoimmune uveitis), and rheumatoid arthritis (murine collagen-induced arthritis) (Damsker et al., 2010).

Role of IgE in Systemic Autoimmune Diseases

Although IgE is recognized as a human Th2 marker, some studies have found increased levels of IgE in Th1 and Th17 responses in autoimmune diseases (Sekigawa et al., 2003; Veldhoen, 2009). Allergy and autoimmunity share features, including those related to autoantibody production and circulating immune complex formation (Martin and Chan, 2004). Studies suggest that some allergens, including many environmental allergens, and

autoantigens have a common structure (Valenta et al., 2000), which might explain autoimmune diseases such as chronic urticaria. However, increased IgE levels are not associated with increased allergic disease in other autoimmune diseases, such as SLE (Morton et al., 1998).

The pathogenetic mechanisms of lupus nephritis include Th1- and Th17-mediated mechanisms (Crispín et al., 2010). In addition to Th1, Th17, and regulatory T cells, Th2 cells may play a role in SLE (Zeng et al., 2003; Valencia et al., 2007; Pernis, 2009), as suggested by the marked humoral response. Studies show increased IgE and the presence of self-reactive IgE in sera from some SLE patients, without increases in allergy (Tsuiji et al., 2006; Tiller et al., 2007). Patients with SLE without allergy have elevated total IgE and anti-nuclear IgE autoantibody levels, which seem to be linked to disease severity (Charles and Rivera, 2011). In addition, the presence of IgE in glomerular immune complex deposits in renal biopsies of SLE patients and a murine model of systemic autoimmune disease suggests that IgE plays a role in lupus nephritis (Atta et al., 2010). A study of anti-nuclear IgE antibody specificity and cytokine involvement found IgE antibodies against cell autoantigens implicated in protein expression, cell proliferation, and apoptosis in SLE and suggested that IL-10 may downregulate IgE autoimmune responses in SLE (Atta et al., 2010). Charles and colleagues (2010) showed that IgE immune complexes activate basophils and that removing self-reactive IgEs forming functional circulating immune complexes prevents renal disease. As circulating IgE levels are reduced, omalizumab, a monoclonal antibody binding to human IgE and reducing FcεRI expression on basophils (Lin et al., 2004), which is currently used as therapy for asthma and allergic rhinitis (Asai et al., 2001; Charles et al., 2010), may be of therapeutic interest in SLE patients with elevated IgE levels.

Basophils in Lupus Nephritis

Lyn, a Src kinase family member involved in B cell activation, dampens basophil expression of the trans-acting T cell-specific transcription factor GATA-3 (Charles et al., 2009), and B cells from some SLE patients express reduced levels of lyn kinase (Liossis et al., 2001). The lyn (–/–) mouse develops an SLE-like autoimmune disease (Yu et al., 2001), with the production of circulating anti-nuclear and anti-dsDNA antibodies, and glomerular damage caused by deposition of circulating immune complexes that may result in renal failure and death. Lyn (–/–) mice develop early, strong, constitutive Th2 skewing and exacerbated responses to Th2 challenges (Odom et al., 2004; Beavitt et al., 2005) and present basophilia and constitutive Th2 effector CD4 T cells (Charles et al., 2009). Th2-prone immune responses found in these

mice require both basophils and IL-4, further highlighting the importance of IL-4-dependent immune modulation by basophils.

Therefore, lyn (−/−) mice may be a good model to study the effects of the Th2 environment on lupus-like nephritis. Charles et al. (2010) have demonstrated that basophils can promote antibody production and aggravate lupus nephritis, and that a Th2 phenotype contributes to lupus-like nephritis in lyn (−/−) mice and is associated with lupus nephritis in human SLE. Lupus-like disease in lyn (−/−) mice has been related to the presence of IL-4 and IgE, whose absence reversed Th2 skewing. IgG anti-dsDNA and anti-nuclear antibody titers and circulating immune complex levels were also reduced in mice deficient for IgE and lyn, and IL-4 and lyn, respectively, showing that autoantibody production in lyn (−/−) mice was, at least partly, dependent on the Th2 environment. Therefore, the study showed that basophils contribute to self-reactive antibody production in SLE and could enhance pre-existing loss of B cell tolerance. However, the identification of basophils is problematic owing to the lack of specific basophil markers. Since basophils may be found together with plasmacytoid dendritic cells in lesional tissues of SLE patients, these two cellular types share the same forward and sideward scatter properties in flow cytometry, as remarked by Dijkstra et al. (2012), who suggested that, due to their similarities, it may be difficult to analyze either cell type separately or to clearly differentiate between the two.

Basophils in Rheumatoid Arthritis and Vasculitides

Basophils have various immunoregulatory functions, explaining why research into pharmacological modulation by specific inhibitors or regulators is ongoing, particularly in allergic processes and, possibly, soon in autoimmune conditions, as demonstrated by the recent finding of basophil activation by anti-citrullinated protein antibodies (ACPAs) in sera from patients with rheumatoid arthritis (Schuerwegh et al., 2010). Schuerwegh and colleagues (2010) showed that IgE-bearing basophils from patients with ACPA are activated directly on exposure to citrullinated antigens, probably due to FcεRI-bound IgE-ACPAs on basophil surfaces. Identification of this activation pathway mediated by IgE-ACPAs in basophils might lead to new therapies for rheumatoid arthritis. Basophils should also be assessed in diseases driven by immunoglobulins directed against defined renal structures (e.g., anti-glomerular basement membrane disease), deposited in the glomeruli (e.g., membranous nephropathy) or driven by systemic vasculitis (e.g., ANCA-associated vasculitis), as they may help to generate and

maintain high specific immunoglobulin levels and disease progression (Bosch et al., 2011).

Basophils in Autoinflammatory Diseases

Autoinflammatory diseases such as hyper-IgD syndrome are characterized by periodic fever associated with an abnormal release of IL-1 and TNF (Ryan and Kastner, 2008). Human basophils release IL-1β and TNF upon the cross-linking of surface-bound IgD, but not IgE (Chen et al., 2009). These disorders are characterized by elevated amounts of both circulating and mucosal IgD (+) IgM (−) B cells, and more IgD-armed basophils in the mucosa (Chen et al., 2009). Dysregulation of IgD-mediated basophil activation may contribute to the pathogenesis of autoinflammation.

EOSINOPHILS

Basic Biology and Role in Immunity

Eosinophils, although formed elements of the peripheral circulation, are primarily tissue-dwelling cells, of which gastrointestinal eosinophils predominate (Mishra et al., 1999). Eosinophil levels in the gastrointestinal tract are regulated by the constitutive expression of eotaxin-1 and eosinophil chemokine receptor-3 (Humbles et al., 2002; Pope et al., 2005). The eosinophil life cycle has bone marrow, blood, and tissue phases. Eosinophils are produced in bone marrow from pluripotent stem cells. Hematopoietic factors (IL-3, granulocyte-macrophage colony stimulating factor, and IL-5) are important for eosinophil proliferation and differentiation. IL-3 and granulocyte-macrophage colony stimulating factor stimulate proliferation of neutrophils, basophils, and eosinophils. In contrast, IL-5 specifically stimulates eosinophil production (Sanderson, 1992) and synergistically enhances the chemotactic response of eosinophils to chemokines or lipid mediators (Warringa et al., 1992; Schweizer et al., 1994). In addition to producing a number of regulatory or proinflammatory cytokines and chemokines (Hogan et al., 2008; Moqbel and Lacy, 2000), eosinophils secrete mediators that potentially promote Th2-type immune responses.

Identification of key eosinophil regulatory cytokines such as IL-5 and the eotaxin subfamily of chemokines have revealed mechanisms that selectively regulate eosinophil production and localization at baseline and during inflammatory responses. Specifically, an integrated mechanism involving Th2 cell-derived IL-5 regulating eosinophil expansion in the bone marrow and blood and Th2 cell-derived IL-13 regulating eotaxin production explains how T cells regulate eosinophils (Rothenberg and Hogan, 2006).

Eosinophils in Churg–Strauss Syndrome

There is mounting evidence suggesting that eosinophils play a key etiopathogenic role in Churg–Strauss syndrome (CSS), a systemic inflammatory disease characterized by adult-onset asthma, peripheral eosinophilia, and eosinophilic tissue infiltration. Because of the common positivity of ANCA (30–40% of cases), and the main involvement of small vessels, CSS has been categorized as an ANCA-associated vasculitis together with granulomatosis with polyangiitis and microscopic polyangiitis (Pagnoux et al., 2007). The immunopathogenesis of CSS is complex, involving B cells, T cells, eosinophils, and resident epithelial and endothelial cells. Dense eosinophilic tissue infiltration, eosinophilic granulomas, and eosinophilia are characteristic of CSS (Terrier et al., 2010; Vaglio et al., 2012). Infiltrating eosinophils are frequently found in vasculitic lesions (Masi et al., 1990), and peripheral blood eosinophils correlate with the disease course, suggesting they play a role in CSS pathogenesis, although T cells are also involved (Lanham et al., 1984; Masi et al., 1990). Cellular immunity has been inferred from various findings, including the presence of memory T cells in vasculitic lesions (Hattori et al., 1999), increased T cell activation as reflected by cellular and soluble T cell activation markers (Schmitt et al., 1998), and responsiveness of disease activity to treatment with suppressors of cellular immunity (Guillevin et al., 1999).

On a cellular level, a strong shift toward a Th2-like response with massive T cell activation is evident in CSS (Dallos et al., 2010). *In vitro*, T cell lines from CSS patients produce significant amounts of IL-4 and IL-13 (Kiene et al., 2001), as shown by the high serum levels of IgE and IgE-containing immune complexes usually found in patients with active CSS (Manger et al., 1985). Th2 cytokines contribute to eosinophil recruitment, activation, and survival (Romagnani, 1991) and biopsy reveals granulomatous vasculitic lesions filled with eosinophils, macrophages, and lymphocytes (Koss et al., 1981). Chemokines mainly belonging to Th2-skewed pathways are secreted by epithelial and endothelial cells, a mechanism which amplifies CSS-associated inflammation. The chemokine eotaxin 3 [chemokine (C-C motif) ligand 26 (CCL26)] is strongly expressed in affected tissue from CSS patients and is also specifically related to disease activity and eosinophilia (Polzer et al., 2008).

Chemokine (C-C motif) ligand 17 (CCL17)/thymus and activation-related chemokine (TARC) is a CC chemokine secreted by PBMCs and various subsets of monocyte-derived dendritic cells, including thymic dendritic cells and endothelial cells (Imai et al., 1996). Recently, marked CCL17/TARC elevation was found in sera from patients with the lymphocytic subtype of idiopathic hypereosinophilic syndrome, which is characterized

by circulating IL-5-producing clonal Th2 cells (de Lavareille et al., 2002). CCL17/TARC selectively recruits and migrates activated Th2 lymphocytes to affected tissue. Production of CCL17/TARC by dendritic cells is stimulated by Th2 cytokines, providing additional chemoattraction for Th2 cells (de Lavareille et al., 2001). CCL17/TARC expression has been demonstrated in Langerhans cells and keratinocytes in the skin of patients with atopic dermatitis (Kakinuma et al., 2001), considered to be a Th2-dominated disease in its acute phase. CCL17/TARC plays a vital role in Th2-mediated experimental allergen-induced asthma in mice, which may be inhibited by a monoclonal antibody against CCL17/TARC (Kawasaki et al., 2001). Dallos et al. (2010) hypothesized that CCL17/TARC may play a role in recruiting Th2 cells to sites of inflammation in CSS-affected tissue, finding expression of CCL17/TARC by infiltrating cells and occasionally the respiratory epithelium, as in a previous study (Kakinuma et al., 2001). Thus, CCL17/TARC may contribute to trafficking of Th2 cells and eosinophils to affected tissue in CSS. Th2 infiltration may promote activation and degranulation of eosinophils, resulting in tissue damage. In this study, infiltration of Th2 cells in active CSS lesions was demonstrated, as evidenced by the presence of CD294⁺ lymphocytes. Moreover, Dallos et al. (2010) found increased serum levels of CCL17/TARC in patients with untreated CSS compared with healthy controls, although on commencement of therapy, CCL17/TARC concentrations decreased to a level not significantly different from that of controls. Concentrations of CCL17/TARC paralleled the disease course in patients in whom sequential serum samples were obtained. Accordingly, CCL17/TARC concentrations correlated well with IgE levels and eosinophil counts.

A recent study by Terrier et al. (2010) was the first to demonstrate the involvement of IL-25 and its receptor IL-17RB in the pathogenesis of CSS and its correlation with disease activity, suggesting that IL-25 production by eosinophils may play an essential role in promoting Th2 responses in CSS target tissues. IL-25 produced by epithelial cells, eosinophils, basophils, and mast cells enables innate and adaptive immunity by enhancing Th2 cytokine production (Angkasekwinai et al., 2007; Saenz et al., 2008; Wang and Liu, 2009). Elevated expression of IL-25 and IL-17RB was observed in tissues from patients with chronic asthma and atopic dermatitis (Wang et al., 2007), suggesting that IL-25 plays a role in evoking Th2 cell-mediated inflammation that features the infiltration of eosinophils and Th2 memory cells, and may increase allergic inflammation by enhancing the maintenance and functions of adaptive Th2 memory cells. Terrier et al. (2010) found higher levels of IL-25 in the serum of active CSS patients compared with atopic and patients with hypereosinophilic syndrome and with healthy donors.

IL-25 serum level was correlated with CSS clinical activity and the eosinophil count and was more than 10-fold higher in CSS patients than that observed in hypereosinophilic syndrome and atopy. Although the eosinophil count was elevated in patients with hypereosinophilic syndrome, their serum IL-25 level was low. Thus, increased levels of IL-25 in CSS patients may depend on specific priming and differentiation of activated eosinophils. IL-25 was mainly produced in the peripheral blood of CSS patients by eosinophils but not by neutrophils, monocytes, or T cells. IL-25 and IL-17RB were observed within the vasculitic lesions of CSS patients, and IL-17RB colocalized with T cells. Analysis of T cell differentiation in CSS patients pointed toward a polarized type 2 immune response with increased production of IL-4.

CONCLUSIONS AND THERAPEUTIC IMPLICATIONS

Lymphocytes are the white blood cells overwhelmingly implicated in the etiopathogenesis of most systemic autoimmune diseases. However, recent studies have increasingly focused on granulocytes, especially in SLE and systemic vasculitides, and neutrophils are currently under intensive investigation. The dysregulated neutrophil cell death and/or clearance often found in autoimmune diseases (Harper et al., 2001; Ren et al., 2003; Raza et al., 2006) may play a leading role in the pathogenesis of these diseases, as neutrophils release proteolytic and cytotoxic molecules that can trigger organ damage. Neutrophil products act as both targets and mediators of autoimmunity. Self DNA–antimicrobial peptide complexes, LL-37 and human neutrophil peptide, which would seem to be pivotal components of NETs, activate plasmacytoid dendritic cells to produce INF. It is unclear whether NETosis could serve as a biomarker or predictor of tissue damage in SLE or whether enhanced NETosis, which occurs in some vasculitides, could play a role in other autoimmune diseases associated with autoantibody production, INF signatures, or vascular damage, such as Sjögren syndrome, rheumatoid arthritis, or inflammatory myopathies. An attractive hypothesis is that inhibition of NETosis could be a potential therapeutic target in SLE (Knight and Kaplan, 2012). Suppression of NET formation due to ROS scavenging might stop chronic autoimmunity in SLE. Diphenylene iodonium (a potent inhibitor of NADPH oxidase that prevents oxygen-derived free-radical generation in neutrophils) severely impairs NET formation. Glutathione, a hydrogen peroxide scavenger, inhibits neutrophil death; catalase, which reduces hydrogen peroxide to water, delays normal neutrophil apoptosis (Bosch, 2011). Antioxidants such as N-acetyl-cysteine have been shown to block NET formation *in vitro*

(Patel et al., 2010), and N-acetyl-cysteine has been used to treat patients with SLE, Sjögren syndrome, and systemic sclerosis. In addition, antimalarial drugs, a key therapeutic option in SLE (Ruiz-Irastorza et al., 2010), are hypothesized to play a role as endosomal antagonists, and might have the potential to block the processing of NETs through TLR9 in plasmacytoid dendritic cells (Kuznik et al., 2011). Anti-IFN- α drugs are also under development in a phase I trial whose objective is to alter the IFN signature in SLE patients through administration of an anti-IFN monoclonal antibody (Yao et al., 2009), and a phase II study that is underway. The therapeutic hypothesis is that the blockade of IFN- α might help break the aforementioned cycle of NETosis (Knight and Kaplan, 2012). Finally, as activated neutrophils are one of the major sources of the pathogenic soluble IL-6 receptor (Kuznik et al., 2011), the monoclonal antibody tocilizumab may be shown to affect the contribution of neutrophils to autoimmune disease pathogenesis (Németh and Mócsai, 2012).

With respect to basophils, studies show that basophils, IgE, and IL-4 participate in maintaining autoantibody production in lyn (–/–) mice and suggest the Th2 environment contributes to autoimmunity. Basophils seem to amplify lupus nephritis rather than initiate the disease. The essential requirements are self-reactive IgE-dependent basophil activation, IL-4 production by basophils, and promotion of Th2 cell differentiation. Therefore, reducing circulating levels of self-reactive IgE or dampening basophil activity could have therapeutic benefits in lupus nephritis and determining whether basophil reduction or inactivation in early disease could defer or rescue the early development of lupus nephritis is of interest. A recent phase 3 multicenter, placebo-controlled trial in patients with active SLE found that belimumab, a monoclonal antibody against BAFF, is safe and efficacious (Kaveri et al., 2010; Navarra et al., 2011). Belimumab, besides affecting B cells, might deplete basophils (which contain membrane-bound BAFF), and thus could be useful in some patients with lupus nephritis, perhaps combined with treatments suppressing IgE production.

The pathogenic role of eosinophils in CSS is increasingly becoming clearer. As outlined above, IL-5 is a major survival factor for eosinophils, and targeted therapies using monoclonal antibodies directed against IL-5 (e.g., mepolizumab, reslizumab) are now used to treat eosinophilic asthma (Rosenwasser and Rothenberg, 2010). The IL-5-neutralizing antibody mepolizumab is proven to be an effective steroid-sparing agent in patients with hypereosinophilic syndrome negative for the FIP1L1-PDGFR α fusion gene (Rothenberg et al., 2008), and also demonstrated some efficacy in refractory CSS (Kahn et al., 2010). The anti-human IgE monoclonal antibody omalizumab, now used for asthma, has been trialed

in CSS but has also been suspected of causing the development of full-blown CSS, perhaps because it allows (as do leukotriene receptor antagonists) steroid tapering (Wechsler et al., 2009). This may limit a more widespread use of omalizumab for CSS. Finally, IL-25/IL-17RB may be a key molecular pair in the maintenance of inflammation in CSS and therefore could be a potential target for the development of novel therapies.

THE COMPLEMENT SYSTEM AND COMPLEMENT ACTIVATION PATHWAYS

In the 1890s, Jules Bordet observed that bactericidal activity of serum essentially requires two components, one which is present prior to immunization and heat-labile that he named Alexin (from Greek *alexin*: to ward off) and the other component, which is heat-stable and generated by immunization. He demonstrated in 1898 that the same basic mechanisms that compose the bacteriolytic activity of immune sera are responsible for the hemolytic activity of serum towards erythrocytes of other species, a methodology that was used to analyze the biological activities of complement for decades to come. The prevailing name “complement” for this bacteriolytic plasma component was coined by Paul Ehrlich at about the same time to underline that this component was essential for “amboceptors” (the name he proposed for antibodies) to lyse cells and thereby “complement” their function (Dunkelberger and Song, 2010; Schmalstieg and Goldman, 2010). Up to the present day, the bactericidal (or hemolytic) activity of complement mediated through the formation of a lytic membrane attack complex

(formed following the activation of the terminal complement components C5b–C9) is still the most widely known biological activity of the complement system.

Complement is composed of a very complex system of zymogen precursor components, their substrates, fluid phase or cell surface resident regulators/cofactors and receptors for complement activation products comprising altogether more than 40 components (Whaley and Schwaeble, 1997; Carroll and Sim, 2011). Cell surface resident receptors for complement activation products continuously sense the activation state of the complement system and coordinate cellular responses of both the innate and the adaptive immune system. As such, complement activation is involved in the initiation and maintenance of numerous inflammatory reactions and inappropriate control of complement activation can predispose to a wide spectrum of infectious or inflammatory pathologies.

Although the bactericidal or hemolytic activity of complement elicited through the formation of membrane attack complexes is the most popular and widely known function of complement, it is only effective against some bacterial species, while complement-mediated

opsonization which targets bacteria, viruses, yeast, host cellular and bacterial debris and eukaryotic parasites for phagocytosis and elimination through the various phagocytes of the reticulo-endothelial system (via their receptors either for C3b, iC3b, C3d, C4b, or C1q/MBL/ficolins). The cellular receptors on phagocytes responsible for the enhanced uptake of opsonized particles and cells include complement receptors type 1 (CR1 also known as CD35), type 3 (CR3, alias of CD11b/CD18), and type 4 (CR4 CD11c/CD18) (Wagner and Frank, 2010). Phagocytes are directed to the location of complement activation by chemotaxis sensing the release of the potent complement chemotactic factor and anaphylatoxin C5a and the anaphylatoxin C3a, through the receptors C3aR and C5aR (alias CD88) (Van Beek et al., 2003; Wallis, 2007). Complement anaphylatoxins C3a and C5a can also increase vascular permeability aiding the transmigration and extravasation of leukocytes into tissue (Williams, 1983). Various complement deficiencies result in a defective recruitment of leukocytes to the site of damage or infection.

Complement activation products also facilitate transport of antigens to the lymphoid follicles and critical interactions between follicular dendritic cells and B cells in order to promote both B cell memory and the production of specific antibodies (Barrington et al., 2002; Le Friec and Kemper, 2009; Gonzalez et al., 2010). Moreover, complement activation also modulates T cell responses by coordinating the necessary interactions between antigen-presenting cells (APC) and T cells (Zhou et al., 2006; Le Friec and Kemper, 2009; Kwan et al., 2012). The complement system is activated via three activation pathways which all converge through the formation of C3 and C5 convertase complexes and the subsequent formation of the membrane attack complex (MAC).

The Classical Pathway

The first component of the complement C1 is composed of a multimolecular initiation complex that triggers complement activation.

The 790 kDa C1 complex consists of a recognition protein, C1q, and a heterotetramer of C1r and C1s zymogens to form the C1q:C1s:C1r₂:C1s complex (Figure 15.1). C1q is composed of six identical subunits joined together through their collagen-like stalks that end in globular heads. Each subunit consists of three homologous polypeptide chains (Arlaud et al., 2002). Classical pathway activation is initiated either by direct binding of C1q to a target (e.g., bacterial) surface or indirectly by binding of C1q to antibodies deposited on the target (immune complexes). IgM, IgG1, IgG2, and IgG3 bind C1q (Arlaud et al., 2002). Binding of C1q to complement activators leads to a conformational change in the

FIGURE 15.1 Flow diagram of the three activation pathways of complement. Activation step 1 depicts the C1s and MASP-2-mediated cleavage of complement C4 to C4a and C4b, activation step 2 depicts the subsequent C1s and MASP-2-mediated cleavage of C4bC2 to form the C3 convertase of the classical and lectin pathway C4bC2a. With the conversion of C5 into C5a and C5b, all enzymatic steps of complement activation are completed. Both the classical as well as the alternative pathways are thought to correspond with the alternative pathway activation loop through provision of C3b.

collagenous region of C1q which in turn leads to the auto-activation of C1r, which cleaves its only substrate, C1s. C1s in turn cleaves C4 into C4a and C4b and then cleaves C2 bound to the C4b, resulting in the formation of the classical pathway C3 convertase (C4b2a) (Arlaud et al., 2002; Carroll and Sim, 2011).

C4b2a is a protease which activates C3 to form C3a and C3b. C3b, like C4b, can bind covalently to the complement activator, and hundreds of molecules of C3b can be deposited in close proximity to the C3 convertase complex. C3b can bind directly to C4b2a, forming the classical pathway C5 convertase C4b2a3b, in which C4b and C3b form a binding site for C5, orienting it for cleavage by C2a.

The Lectin Pathway

In evolutionary terms, the lectin pathway (LP) of complement activation seems to be the oldest of the three (Dodds, 2002; Wallis, 2007). The LP is initiated by the binding of a multimolecular LP activation complex, similar in structure to the classical pathway C1, to pathogen-associated molecular patterns (PAMPs), mainly carbohydrate structures present on microorganisms, or DAMPS (damage-associated molecular patterns) on damaged host tissue. The LP

recognition molecules are mannose binding lectin (MBL), an MBL-like collectin called CL-11, and ficolins. Like C1q, they are made up of subunits with globular heads and collagenous stalks. Activation is initiated by the binding of the globular heads to carbohydrate structures present on microorganisms or aberrant glycocalyx patterns on apoptotic, necrotic, malignant, or oxygen-deprived cells (Fujita, 2002; Schwaeble et al., 2002). Rodents have at least four circulating LP recognition molecules, with differing, but overlapping, carbohydrate specificities; two mannan-binding lectins (MBL-A and MBL-C), collectin-11 (CL-11), and ficolin A (Fcna) (Schwaeble et al., 2011; Ali et al. 2012). A second murine ficolin, Fcnb, associated with monocyte and macrophage cell surfaces does not activate complement in mice, but may act as a lectin pathway recognition molecule in rats (Girija et al., 2011). Humans have a single MBL (the product of *MBL2*; *MBL1* is a pseudogene), CL-11 (collectin kidney 1, CL-K1), and three ficolins, FCN1 (M-ficolin), FCN2 (L-ficolin), and FCN3 (H-ficolin) (Fujita, 2002; Liu et al., 2005; Hansen et al., 2010). These recognition molecules form complexes with the serine proteases called MASP-1, -2, and -3 (MBL-associated serine proteases 1, 2, and 3). These are homologous to C1r and C1s, and form homodimers (and perhaps some heterodimers). The serine proteases in the CP and LP activation complexes all interact with a highly conserved binding motif within the collagenous region of the recognition subunit, i.e., C1q for the CP and MBL, ficolins or CL-11 for the LP (Wallis et al., 2004). Each recognition molecule can bind one protease dimer. The recognition molecules also interact with MAp19 and MAp44 (alias MBL/ficolin-associated protein 1), which are non-enzymatic, truncated alternative splice products of the *MASP2* and *MASP1/3* genes, respectively. Both truncated gene products lack the serine protease domain and may regulate LP activation by competing for the binding of MASPs to the carbohydrate recognition molecules (Thiel et al., 1997; Stover et al., 1999; Takahashi et al., 1999; Schwaeble et al., 2002; Iwaki et al., 2006; Degn et al., 2009; Skjoedt et al., 2010). Of the three MASPs, only MASP-2 is required and essential to form the LP C3 and C5 convertases (C4b2a and C4b2a3b) (Thiel et al., 1997; Vorup-Jensen et al., 2000; Rossi et al., 2001; Schwaeble et al., 2011).

Like C1s, activated MASP-2 cleaves C4 and C4b-bound C2, generating C4b2a. Neither MASP-1 nor MASP-3 can cleave C4 (Schwaeble et al., 2011). The function of MASP-1 is still uncertain. It may facilitate LP activation by either direct cleavage of complex-bound MASP-2 or cleavage of C4b-bound C2 (Takahashi et al., 2008; Kocsis et al., 2010; Schwaeble et al., 2011). Recent work demonstrated that MASP-1 (and possibly MASP-3) plays a key role in the maturation and initiation of the alternative activation pathway (Takahashi et al., 2008; Iwaki et al., 2011). The LP is probably mainly activated by charge-neutral sugar structures and clusters of acetyl moieties, whereas in the classical pathway,

C1q recognizes mainly charge clusters. The lectin pathway can also respond to immunoglobulins deposited on targets, by binding to glycans on some human IgG, IgA glycoforms, and to the glycans on mouse (but not human) IgM (Carroll and Sim, 2011).

The Alternative Pathway

Factor B, factor D, and properdin (factor P) are specific components of the alternative pathway of complement activation. Unlike the classical and lectin pathways (which are initiated via specific recognition proteins such as C1q or MBL) the alternative pathway is initiated through a spontaneous steady-state hydrolysis of C3 to form C3 (H₂O) which in turn binds to factor B to form a C3(H₂O)B zymogen complex. In this complex, factor B is cleaved by factor D releasing a Ba fragment while Bb remains attached to the complex. The newly formed complex C3 (H₂O)Bb is a C3 convertase enzyme and cleaves C3 into C3a and C3b. Once C3b is generated, it will bind covalently to the surface of pathogens where it can bind to another molecule of factor B and form a new alternative pathway C3 convertase C3bBb (Carroll and Sim, 2011). The alternative pathway also acts as an amplification loop where C3b generated by either the classical or the LP binds to factor B to generate the convertase C3bBb (Schwaeble and Reid, 1999). The C3bBb is homologous to C4b2a (C3 is a homologue of C4, and factor B of C2) and like C4b2a will switch its substrate specificity from cleaving C3 to cleaving C5 upon binding of C3b to the convertase, forming C3bBb3b, the C5 convertase.

The Membrane Attack Complex

The C5 convertases C4b2a3b and C3bBb3b cleave C5 into C5b and C5a. C5b then binds to C6, C7, and C8 to form a C5b-8 complex that can bind to cell surfaces and initiate cell lysis by inserting into the lipid bilayer. Multiple C9 molecules can bind to C5b-8, accelerating lysis and forming the MAC, or C5b-9 (Podack et al., 1982).

CONTROL OF COMPLEMENT ACTIVATION

The complement system is tightly regulated to avoid runaway activation of the enzymatic cascade that would otherwise lead to excess host tissue damage and inflammation. Key events at the center of the cascade are carefully controlled by five closely related complement control proteins, all of which are encoded by genes located in the RCA (regulator of complement activation) cluster on chromosome 1q32 in man. Complement regulatory components include membrane-bound regulators and fluid phase regulators (Kirschfink and Mollnes, 2003; Carroll and Sim, 2011).

Two host membrane proteins, complement receptor type 1 (CR1) and membrane cofactor protein (MCP or CD46), and two fluid-phase regulators, factor H and C4-binding protein (C4bp), act as cofactors for factor I, which inactivates C3b and C4b, preventing formation of the C3 and C5 convertases. C4bp also shortens the half-life of the classical pathway C3 and C5 convertases, while factor H has the same effect on the alternative pathway C3 and C5 convertases. CR1 and another host membrane protein, decay accelerating factor (DAF), act on both the classical and alternative pathway convertases. A truncated splice variant of factor H, factor H-like protein 1 (FHL-1), is also found in serum and has regulatory activity similar to that of factor H (Schwaeble et al., 1987). Prevention of factor H binding results in an increased half-life of C3b containing convertase complexes and overshooting activation of the alternative pathway leading to FHR-C3GN (Ramaglia et al., 2012).

Fluid Phase Regulators

C1 inhibitor (C1 inh), also known as Serpin G1, is a serine protease inhibitor which irreversibly inhibits C1r, C1s, MASP-1, and MASP-2 by forming a covalent complex with the protease active site (Chen et al., 1998; Presanis et al., 2004; Cicardi et al., 2005). Besides complement regulation Serpin G1 can also inactivate serine proteases of the coagulation cascade (FXIa and FXIIa), and of the contact system (kallikrein) (Cicardi et al., 2005; Wagner and Frank, 2010).

Factor I is a protease and a fluid phase regulator of all three pathways. It converts hemolytically active C3b into hemolytically inactive iC3b, in a cofactor-dependent manner. In the fluid phase, factor H, an abundant plasma component, binds to free and complex-bound C3b to allow factor I to convert C3b to iC3b. A further conversion of iC3b to C3c and C3dg by factor I is also cofactor dependent. In a similar fashion, factor I inactivates C4b in the presence of the cofactor C4-binding protein (C4BP) (Seya et al., 1995). Binding of C4BP to C4b inhibits C4b–C2a binding, preventing the formation of the C3 convertase (Blom et al., 2004). Subsequent factor I-dependent conversion of C4b generates the fragments iC4b, C4c, and C4d. Conversion of C3b to iC3b is important in another function: iC3b is a powerful opsonin, recognized by CR3 and CR4, while C3b is a less effective opsonin, recognized by CR1.

Factor H is an important alternative pathway regulator, the main activity of which, besides mediating C3b inactivation by factor I, is to destabilize and also accelerate the decay of the alternative pathway C3 convertase (C3bBb) and C5 convertase (C3bBb3b) (Whaley and Ruddy; 1976, Weiler et al., 1976). Factor H destabilizes the C3 convertase by competitive binding to C3b, which

dislodges Bb from the convertase (C3bBb). Factor H is important for the discrimination of self from non-self cells and therefore preventing autoimmunity. Binding of factor H, for example on sialic acid or glycosaminoglycans of host cells, inhibits alternative pathway activation on the surface of host cells (Pangburn et al., 2000). Carboxypeptidase N (CPN) is an inactivating regulator of the C3a and C5a anaphylatoxins (Bokisch and Muller-Eberhard 1970). Clusterin and S protein are regulators for the terminal activation cascade of complement. They bind to C5b-7 complex and prevent the insertion of C8 and C9 leading to the inhibition of the MAC formation (Jenne and Tschopp, 1989; Wagner and Frank, 2010).

Properdin is the only known and essential positive regulator of the complement system. It is essential for alternative pathway activation as properdin depleted sera lack the ability to activate the alternative pathway (Schwaeble and Reid, 1999). Properdin is produced by monocytes/macrophages, peripheral T lymphocytes and granulocytes (i.e., neutrophils) (Wirthmueller et al., 1997) and acts as a positive regulator by stabilizing the alternative pathway C3 and C5 convertases (Schwaeble and Reid, 1999; Stover et al., 2008).

Membrane-Bound Regulators

Complement activation is also controlled by at least four characterized membrane-bound proteins or receptors, which protect host cells from attack by complement. These comprise the decay-accelerating factor (DAF, also known as CD55), the complement receptor 1 (CR1, also known as CD35), the membrane cofactor protein (MCP, also known as CD46), and CD59 (also known as protectin) (Wagner and Frank, 2010). Like factor H, DAF regulates complement activation by accelerating the decay (dissociation of the convertases) of the C3 convertases (C3b2a and C3bBb) (Lublin and Atkinson, 1989). CR1 and MCP act as cofactors for the cleavage of C3b and C4b by factor I (Wagner and Frank, 2010). CD59 is a regulator of the MAC complex. CD59 binds the nascent MAC complex (C5b-8) inhibiting C9 polymerization and subsequent pore formation on the surface of a cell (Lehto et al., 1997; Farkas et al., 2002). DAF, MCP, and CD59 are found on most cell types, but CR1 has more restricted distribution (erythrocytes, lymphocytes, dendritic cells, and kidney podocytes).

THE BIOLOGICAL EFFECTS OF COMPLEMENT ACTIVATION

Complement activation leads to a multitude of biological activities including opsonization, initiation of a proinflammatory response, immune complex clearance, and direct killing of cells via the membrane attack complex.

Opsonization of pathogens is mediated by the major opsonin C3b or iC3b and C4b to a lesser extent. C3b coats the surface of microorganisms and enhances their phagocytosis by leukocyte via binding to complement receptor type 1 (CR1). iC3b binds to CR3 and CR4. L-ficolin, MBL, and C1q have been reported to initiate phagocytosis directly by binding to pathogens and enhancing phagocytosis by binding to collectin receptors on the surface of the phagocytes (Jack et al., 2001; Aoyagi et al., 2005). In other instances complement can mediate direct killing of bacteria, especially Gram-negative bacteria via the formation of the membrane attack complex which form pores in the cell membrane leading to cell lysis (Nauta et al., 2004). During complement activation, proinflammatory cleavage products anaphylatoxins C4a, C5a, and C3a are released. The release of anaphylatoxins increases vascular permeability and formation of inflammatory exudates. These inflammatory exudates enhance the recruitment of inflammatory mediators and inflammatory cells to the site of injury and efficient elimination of invading pathogens or other inflammatory factors. Increased vascular permeability leads to extravasation of leukocytes to the site of inflammation, which helps in clearing invading pathogens. C5a acts as a potent chemotactic factor that stimulates leukocyte migration. In addition, C5a was found to increase the synthesis of other chemotactic agents like eicosanoids and chemokines. Schindler et al. reported that C5a stimulates the expression of interleukin-1 (IL-1) and tumor necrosis factor (TNF) (Schindler et al., 1990). Complement also plays a major role in the clearance of apoptotic and necrotic cells in addition to immune complexes and microorganisms. The globular head of C1q binds to the surface of apoptotic cells and facilitates the uptake of the cells by macrophages (Taylor et al., 2000). In addition, opsonization of apoptotic cells with iC3b leads to recognition of these cells by CR3 and CR4 on the surface of phagocytes with subsequent engulfment of these cells (Mevorach et al., 1998).

Complement also inhibits the precipitation of immune complexes and enhances their solubility by binding of C1q, C3b, and C4b. This binding inhibits further increase in the aggregation of the immune complex. These complexes bind to CR1 on the surface of erythrocytes which transfer them into the liver and the spleen where they are cleared from the circulation by the resident macrophages (Manderson et al., 2004).

COMPLEMENT INVOLVEMENT IN THE PATHOPHYSIOLOGY OF DIVERSE AUTOIMMUNE DISEASES

As a powerful effector system of both the innate and the adaptive immune response, uncontrolled complement

activation can lead to the loss of antimicrobial immune protection, but can also initiate, feed, and perpetuate inflammatory conditions leading to tissue destruction and autoimmune disease. Uncontrolled, dysregulated complement activation can be caused by inherited or acquired deficiencies of complement components as well as through gain of function or loss of function mutations in complement genes or genes encoding enzymes that further process complement components. An example for the latter is the X-linked phosphatidylinositol glycan class A (PIG-A) gene encoding an enzyme necessary for the synthesis of N-acetylglucosaminyl-phosphatidol, an intermediate required for the membrane anchoring of the membrane protective complement regulatory components decay accelerating factor (i.e., DAF or CD55) and protectin (i.e., CD59) which are attached to the outer cell surface through glycosyl-phosphatidylinositol (GPI) anchoring. A rare inherited or acquired deficiency of the PIG-A leads to the loss of the membrane localization of CD55 and CD59 which in turn renders in particular erythrocytes susceptible to autologous complement lysis cells and presents as a hematological disorder named paroxysmal nocturnal hemoglobinuria (PNH) or Marchiafava–Micheli syndrome. In most cases, PNH is a consequence of a non-malignant clonal expansion of one or more hematopoietic stem cells with an acquired somatic mutation in the PIG-A gene. PNH clinically presents as a chronic hemolytic anemia with both intravascular and extravascular lysis of erythrocytes leading to hemoglobin in the urine and a predisposition of thrombosis. The severity of disease is predicted by the degree of loss of CD55 and CD59 anchoring on blood cells, which can vary between partial loss (PNH type II) and total loss (PNH type III). The condition is potentially life-threatening due to the high risk of thrombotic disease and is presently treated with high-dose applications of a recombinant humanized anti-C5 monoclonal antibody, eculizumab, which prevents C5 activation and MAC formation (Risitano, 2013). This treatment effectively reduces the intravascular lysis, but anemia with the need for blood transfusion persists due to the continuous opsonization of PNH erythrocytes by complement C3 activation products, which makes these erythrocytes susceptible to opsonophagocytosis and extravascular hemolysis. A more effective treatment would be to block complement activation further upstream to avoid C3 deposition. In PNH plasma, the direct antiglobulin test (DAT, or direct Coombs' test) is usually negative, as the hemolysis of PNH is not caused by antibodies. This sets PNH apart from another autoimmune disorder, called autoimmune hemolytic anemia (AIHA), where antibody-mediated complement activation lyses erythrocytes. In most cases of AIHA, the autoantibody is of the IgM class. Treating AIHA with red blood cell transfusions is often

ineffective, since the autoantibodies attach to recipient and donor cells alike. Therapeutic application of C1-esterase inhibitor concentrate was recently shown to protect from complement-induced red blood cell destruction and may offer a safe and effective treatment of AIHA (Wouters et al., 2013).

An extremely strong association has been established between deficiencies of the classical pathway of complement activation and systemic lupus erythematosus (SLE).

The first description of an acquired deficiency of the first component of complement in the serum of an SLE patient was published more than 40 years ago showing the presence of anti-C1q autoantibodies by gel diffusion chromatography (Agnello et al., 1971). The hereditary deficiency of C1q and the predisposition for autoimmune SLE or SLE-like disease represents one of the most powerful associations with over 90% of C1q deficient individuals developing severe SLE. The disease manifestations such as rash, glomerulonephritis, and central nervous system (CNS) disease can vary, but the severity of disease invariably progresses and requires extensive medical care (Walport et al., 1998). A recent report described the successful long-term replacement of C1q through fresh frozen plasma infusions in a young C1q deficient patient for over 9 years (Mehta et al., 2010). Bone marrow transplantation was successfully conducted replacing the bone marrow of a C1q deficient mouse with bone marrow of a syngenic WT mouse (Cortes-Hernandez et al., 2004), restoring normal C1q levels. Interestingly, both inherited or acquired deficiency of each of the classical pathway components C1, C4, C2, and C3 predisposes to lupus-like autoimmune disease (Carroll et al., 2004; Pradhan et al., 2012).

This strongly implies a critical role of the classical pathway in the maintenance of immune tolerance and prevention of autoimmune disease. The present understanding points to the conclusion that the classical pathway fulfills an important scavenger function in removing immune complexes as well as cellular debris and that in the absence of this scavenger system, the clearance of debris is significantly impaired which in turn results in continuous presentation of autoantigens (Arlaud et al., 2002).

A rare but invariably severe autoimmune pathology is caused by an IgG autoantibody directed against the alternative pathway C3, convertase C3bBb. This autoantibody binds to C3bBb and protects this complex from decay by factor H and subsequent inactivation by factor I and thereby increases the half-life of the alternative pathway C3 convertase leading to a continuous activation of the alternative pathway and secondary hypocomplementemia. This perpetual activation of the alternative pathway clinically presents as a form of membranoproliferative glomerulonephritis (i.e., mesangiocapillary glomerulonephritis type II), which earned this autoantibody the name nephritic factor (NeF). Patients suffering from this rare

autoimmune disease frequently show abnormalities in the distribution of their adipose tissue, named partial lipodystrophy (PLD). A recent report provided a plausible explanation showing that NeF can also stabilize the C3 convertase on the surface of fat cells and lyse fat cells through perpetual generation of membrane attack complexes (Mathieson et al., 1993). An even rarer variant of NeF presents as an autoantibody directed against the classical/LP C3 convertase (i.e., C4b2a), called C4 nephritic factor, which stabilizes this convertase causing hypocomplementemia by continuous consumption of C3 (Miller et al., 2012). The majority of the C4-NeF cases were identified in a cohort of lupus nephritis patients. Dysregulated alternative pathway activation caused by deficiencies of the alternative pathway regulators factor H, factor I, membrane cofactor protein and the factor H-related genes (FHR5 and FHR1) predisposes to C3 glomerulopathies (C3GN). The predisposing mutations in the factor H-related genes lead to the formation of FHR dimers which effectively bind and compete with factor H for the binding to C3b. Prevention of factor H binding results in an increased half-life of C3b containing convertase complexes and overshooting activation of the alternative pathway (Ramaglia et al., 2012).

The commonest cause of C3GN is complement factor H-related 5 (CFHR5) nephropathy, which is endemic in Greek Cypriots. Other C3GNs include membranoproliferative glomerulonephritis 1 (MPGN1), fMPGN3, and dense deposit disease (DDD), a rare form of glomerulonephritis characterized by the presence of electron dense deposits within the glomerular basement membrane (GBM) with intense deposition of C3 fragments (De Cordoba et al., 2012).

Hemolytic uremic syndrome (HUS) is a life-threatening condition often following infections with Shiga toxin-producing *Escherichia coli* strains (STEC-HUS; EHEC-HUS). It presents as Coombs' test-negative microangiopathic anemia with severe diarrhea. An atypical form of HUS (aHUS) does not present with diarrhea. It has a poor long-term prognosis as it is recurrent and results in a fatality rate of up to 30%. aHUS can develop in individuals with inherited or acquired predispositions for poorly controlled complement activation, either through mutations in the complement regulatory components factor H, or MCP, factor I or through gain-of-function mutations in factor B and complement C3 (Goicoechea de Jorge et al., 2007), or have autoantibodies against factor H or disease promoting mutations in factor H-related proteins CFHR1 and CFHR5 (see above). Another thrombotic microangiopathy called thrombotic thrombocytopenic purpura (TTP) is pathologically very similar to HUS as it presents with an autoantibody-induced consumption of complement and thrombi in the microcirculation of many organs, including kidney, brain,

heart, lung, liver, and gut (Noris et al., 2012). A majority of TTP patients present with acquired autoantibodies that inhibit a plasma metalloprotease called ADAMTS13 that cleave von Willebrand factor. Inherited forms of TTP are caused by ADAMTS13 gene deficiencies.

In 2005, several independent reports identified a loss-of-function mutation (CHF_{Y402H}) in the complement regulatory component factor H to be a major predisposing factor for age-related macular degeneration (AMD), a degenerative disorder of the retinal pigment epithelium (RPE) and the most common cause of blindness in the Western world (Klein et al., 2005). Interestingly, retinal drusen, the hallmark of AMD, stain positive for complement activation products, indicating that complement activation is involved in drusen formation. *In vitro* models of complement activation on retinal pigmented epithelial monolayers have demonstrated that oxidative stress significantly induced complement activation on the surface of these cells and initiated complement activation in a LP-dependent fashion (Joseph et al., 2013). The sublytic deposition of complement on RPE required the presence of MASP-2 to initiate complement activation, while reduced functional activity of alternative pathway regulators may be critical for the disease process to establish and therefore predispose for the severity and the time of onset of AMD pathology. Most recent work also identified that the loss-of-function mutation (CHF_{Y402H}) of factor H also as a high risk polymorphism for other diseases with autoimmune characteristics such as ocular sarcoidosis, atherosclerosis, and a subgroup of Alzheimer patients (i.e., ApoE4 risk allele carriers) (Thompson et al., 2013).

Complement has also been identified as a critical player in the pathophysiology of diverse autoimmune diseases of the CNS caused by autoantibody-mediated destruction of cells where activation of complement by either the classical or the LP plays a critical role. These diseases include myasthenia gravis (MG) (Romi et al., 2005), Guillain–Barré syndrome (GBS) (Kaida and Kusunoki, 2009), and neuromyelitis optica (NMO) (Asgari et al., 2013). MG is caused by an autoantibody directed against the acetylcholine receptor (AChR), which strongly activates complement and blocks signal transduction at the motor neuron synapse to muscle cells causing muscle weakness and loss of muscle control. In an animal model of MG, experimental autoimmune myasthenia gravis (EAMG) was shown that complement activation is required for the disease to develop, since the disease cannot be induced in absence of C3, C4, or C5 and the application of complement inhibitors ameliorates the severity of established disease (Tuzun and Christadoss 2013). In GBS antiganglioside autoantibodies trigger complement activation leading to a complement-dependent disruption of voltage-gated sodium channel clusters, while in NMO anti-aquaporin-4 autoantibodies trigger complement

activation through the classical and/or the lectin activation pathway.

In other autoimmune pathologies of the CNS, such as multiple sclerosis (MS) (a condition caused by autoimmune destruction of the myelin sheets around the axon of neurons), motor neuron disease (MND) (describing a group of neurological disorders selectively affecting motor neurons), and Alzheimer’s disease (AD) (which was recently defined as an autoimmune disorder triggered by herpes simplex (Wozniak et al., 2007), the involvement of complement in the pathophysiology is somewhat more complex. In experimental autoimmune encephalomyelitis (EAE), a mouse model for MS, the alternative complement activation pathway is essential for the priming of microglial cells. Mice deficient in the C3 convertase regulator complement receptor 1-related protein y (Crry) show an accelerated onset of EAE signs and early microglial priming, but no disease develops in mice deficient in both Crry and C3 and Crry and factor B (Donev et al., 2013). Classical pathway deficiency, however, does not protect from developing EAE. Therapeutic inhibition of factor B in a mouse model does not prevent the onset of EAE, but ameliorates the severity of disease once it is established (Hu et al., 2013). In MND, local complement biosynthesis is increased and therapeutic inhibition of the complement anaphylatoxin C5a reduces inflammatory pathology and survival in a rat model of amyotrophic lateral sclerosis, but at present too little is known to define a definite role of complement in this devastating autoimmune pathology (Woodruff et al., 2008).

In AD the classical pathway recognition component C1q co-localizes with the amyloid- β depositions in the disease lesion areas. In a mouse model of AD, C1q deficient mice show a faster progression of AD neurodegeneration and most recent work demonstrated that C1q is neuroprotective against amyloid- β toxicity (Benoit et al., 2013).

Rheumatoid arthritis (RA) is a highly disabling systemic autoimmune disease characterized by a persistent inflammation of the synovial membrane lining the joint, with associated infiltration of macrophages, granulocytes, T cells, and B cells. Local complement activation is critically involved in the onset and maintenance of this inflammatory disease with a preponderant role of the alternative activation pathway in a mouse model (Dimitrova et al., 2012). Deficiencies of C5 and C6 also protect from RA indicating that the terminal activation cascade essentially contributes to the severity of disease while deficiency of an early component like C2 is a predisposing factor (Jonsson et al., 2005).

Complement-mediated cytotoxicity plays a critical role in the pathophysiology of vitiligo, a common depigmenting autoimmune disorder. Autoimmune antibodies lyse melanocytes through both complement activation and antibody-dependent cellular cytotoxicity (ADCC) (Norris et al., 1988).

Pernicious anemia (PA) is the most common cause of vitamin B12 deficiency. PA patients have complement activating autoantibodies against parietal cells in serum and gastric fluid, but since the antigen H^+/K^+ -ATPase is not expressed on the surface of the target cell, cytotoxicity in PA is unlikely to be complement mediated (De Aizpurua et al., 1983).

Complement does not appear to be involved in the pathophysiology of primary Sjögren's syndrome. It is likely that complement consumption in Sjögren's syndrome patients is caused by concomitant and secondary systemic disease (Lindgren et al., 1993).

Hashimoto's thyroiditis (HT) and Graves' disease (GD) share many common features including the presence of autoantibodies against thyroperoxidase and thyroid stimulating hormone (TSH) receptor. In GD, a subset of TSH receptor antibodies stimulates this receptor and causes the phenotype of hyperthyroidism, the hallmark of GD. The role of the other autoantibodies, however, remains unclear. In HT, immune complexes on the thyroid follicular membrane are often associated with complement deposition indicating a role of complement in the tissue destruction. Previous studies claim that thyrocytes are usually resistant to direct complement lysis as these cells are expressing high levels of membrane-associated complement regulators such as CD59 (Tandon et al., 1992). Non-lytic activation of complement generates soluble membrane attack complexes during the acute phase of HT (Weetman et al., 1989). A more recent study claims that thyroperoxidase on the surface of thyrocytes can also initiate complement activation through the binding of C4 and C4b to a complement control module in the ectodomain of thyroperoxidase leading to direct complement-mediated killing of thyrocytes *in vitro* (Blanchin et al., 2003). This proposed activation mechanism, however, has not been confirmed.

Ischemia/reperfusion injury (IRI) is a complement-mediated post-inflammatory condition leading to major tissue loss. IRI was first thought to be mediated through the classical pathway, since it is less pronounced in IgM deficiency, but more recent work identified that it is predominantly driven by the LP of complement in a MASP-2-dependent fashion (Schwaeble et al., 2011). In experimental models of stroke and myocardial infarction, therapeutic inhibition of MASP-2 reduces infarct sizes by up to 40% and may offer a promising new avenue of treatment to reduce morbidity and mortality in these major ischemic pathologies.

HISTORICAL PERSPECTIVE

Although cytokines are the intermediary intercellular protein signals of the immune system, overproduction of proinflammatory cytokines or deficient production of immunosuppressive cytokine mediators can be a direct cause of autoimmune conditions. Cytokines have been the focus of research for over 60 years and over 500,000 articles have reported on cytokines. This chapter will highlight in brief only those cytokines contributing to autoimmune and autoinflammatory diseases. Fortunately, there are only 27,000 plus references to autoimmunity and only about 6000 relating cytokines to autoimmunity.

The history of cytokine studies was initiated by the report of Menkin (1944) which was the first to propose that “soluble pyrexins” might be responsible for fever by purifying them from inflammatory exudates. However, these pyrexins survived boiling and were contaminated by pyrogenic bacterial endotoxins. Bennett and Beeson (1953) were the first to extract endotoxin-free endogenous pyrogenic from peripheral blood leukocytes. At the same time nerve growth factors were discovered (Levi-Montalcini and Hamburger, 1953). Thereafter, interferons with antiviral activities were distinguished from antibodies (Isaacs and Lindenmann, 1957).

Several reports initiated the studies of lymphocyte-derived factors. Mitogenic factors for lymphocytes were first detected in the supernatants of antigen or alloantigen stimulated mixed leukocyte cultures (Kasakura and Lowenstein, 1965). This was rapidly followed by the detection of immunologically nonspecific macrophage migration inhibitory factors (MIF) in such supernatants (Bloom and Bennett, 1966). The MIF activity was subsequently also found to have macrophage activating activity (MAF) (Nathan et al., 1971) that was subsequently attributed to interferon-gamma (IFN γ). The historic MIF activity is distinct from the more recently discovered MIF, which is produced by the anterior pituitary and is present at detectable levels in normal human serum. This MIF is hormone-like and counters the immunosuppressive effects of corticosteroids as reviewed by Metz and Bucala (2001). These lymphocyte-derived factors were termed lymphokines (Dumonde et al., 1969). Subsequently, it was shown that nonlymphocytes such as macrophages could also produce a thymocyte and lymphocyte activating factor (LAF) (Gery et al., 1971). It was subsequently observed that even fibroblast cell lines could produce factors promoting inflammatory reactions and the term “cytokines” was coined (Cohen et al., 1974). Cytokines serve as signals between every nucleated cell type and

regulate the survival, growth, activation, differentiation, and suppression of both innate and adaptive immune responses involved in host defense and restoration of homeostasis. Although by 1978 over 100 cytokine activities had been reported, in 1979 at a meeting of “cytokinologists” it was decided to call all monocyte/macrophage-derived cytokines interleukin-1 (IL-1) and the lymphocyte-derived ones interleukin-2 (IL-2) (Mizel and Farrar, 1979). This was based on the simplistic presumption that all the activities could be attributed to two molecules. Today we are up to interleukin 38 and there are many more cytokines with idiosyncratic names. For example, over 40 chemotactic cytokines called “chemokines” have been discovered that promote the directional migration of many cell types.

Immunologists at the time were enamored with specific antibodies, and initially considered these nonspecific factors to be “lymphodrek” and to have little merit. However, the advent of the molecular age led to the identification of these molecules as gene products with distinct functions, forever changing immunology research. The first cytokine to be cloned was IFN β 1 (Taniguchi et al., 1980), followed by IFN α 1 (Nagata et al., 1980), and IFN γ (Gray et al., 1982). IL-2 was the first interleukin to be cloned (Taniguchi et al., 1983). The era of “receptorology” was initiated when the first of the three chains of the receptor for IL-2 (IL-2 R α) was identified and cloned (Leonard et al., 1984). We now have hundreds of cloned cytokines.

Thus, cytokines, like hormones, are intercellular regulators of immune cell reactions, but unlike hormones they are more prominent at local inflammatory sites rather than in the serum. Unlike hormones which are usually produced by glands, cytokines are produced at lower (nanomolar) concentrations by a great variety of cells and tissues. Cytokines, like hormones, also interact with selective cell receptors inducing an intracellular signal transduction cascade culminating in gene activation. Cytokines usually have localized “paracrine” effects on neighboring cells or “autocrine” effects on the producing cells, but less often have “endocrine” systemic effects of hormones. The appearance of elevated levels of cytokines in the serum actually has systemic effects such as pyrexia, hypotension, muscle aches and pains, and malaise and is responsible for the systemic symptoms of infections and injury. In the most severe inflammatory states, as in sepsis, this is called a “cytokine storm,” which can be lethal.

Development of technology to delete or modify gene expression yielded “knockout” mice lacking selected cytokine gene activities. This revealed surprising *in vivo* roles and redefined the functions of a number of cytokines. For example, tumor necrosis factor (TNF), which had cytotoxic antitumor activity in tissue culture (Carswell et al., 1975), was identified as a key

proinflammatory host defense cytokine (Nedospasov et al., 2003). IL-2 based on its *in vitro* effects was considered a mitogenic factor, but knockout mice often developed lymphoproliferative autoimmune syndromes based on the absence of the stimulating effects of IL-2 on immunosuppressive T regulatory cells (Tregs) (Hunig and Schimpl, 2003). Thus, studies of knockout mice often revealed specialized and unique roles for many cytokines. Ironically, the advent of knockout mice highlighted the primacy of “*in vivo* veritas” and drove immunologists and molecular biologists from tissue culture studies back to investigating *in vivo* models.

Today we are confronted by a plethora of cytokines, with apparent overlapping redundant activities, in part based on the sharing of receptors. The close interrelationship and apparent overlap in cytokine activities is accentuated by their capacity to induce one another and by their receptors to cross-talk and thus to “trans-activate” each other. Thus, cytokines and their receptors operate in a linked network and inhibition of one often downregulates the effects of other cytokines. It has become apparent over the past two decades that many cytokines mediate inflammatory responses aimed at eliminating invasive organisms and eliminating tissue debris generated by traumatic injuries. However, the identification of Tregs and their immunosuppressive mediators IL-10, transforming growth factor β (TGF β) and CTLA4 have identified a number of anti-inflammatory cytokines that aim to restore homeostasis and mediate tissue repair. Thus, cytokines mediate the immunological balancing act between pro- and anti-inflammatory reactions to pathogenic organisms and tissue damage. They also mediate the discrimination between self and non-self and can enhance or suppress inappropriate reactions to self.

CYTOKINES AND IMMUNITY

The initial “innate” immune responses are preprogrammed in the genome and are based on the induction of proinflammatory cytokine and chemokine production. These signals result in recruiting a rapid inflammatory response to invasive pathogenic organisms or tissue injury by phagocytic neutrophils followed by monocytes, macrophages, and dendritic cells (DC). This cytokine-driven innate immune response is initiated by the interaction of exogenous “pathogen associated molecular patterns” (PAMPs) or so-called stored endogenous “alarmins” with Toll-like receptors (TLRs), nucleotide binding oligomerization domain 2 (NOD2), RIG-like helicases (RLHs), DNA sensors absent in melanoma2 (AIM2), or cell surface c-type lectin receptors (CLRs) present on or in many somatic cell types including inflammatory cells. These pattern recognition receptors (PRRs) enable host cells to

respond to PAMPs and damaged self-proteins (as reviewed in [Bellanti et al., 2012](#)).

The receptors on phagocytic DC internalize, digest, and process the antigens derived from PAMPs yielding peptide fragments that are then presented in conjunction with major histocompatibility complex (MHC) cell surface molecules to T lymphocytes. The presented MHC–peptide complexes activate CD4⁺ T cells that express the appropriate receptors to divide, multiply, and produce lymphokines, thus initiating the adaptive immune response with the capacity to mount specific reactions to invasive organisms and/or damaged cell products. The nature of the stimulant and cytokine response is crucial in determining the type of adaptive response that is generated. The activated CD4⁺ T cells differentiate into subsets that exhibit Th1, Th2, Th17, or Treg cell responses as reviewed by [Zhu et al. \(2010\)](#). As shown in [Figure 16.1 \(O’Shea and Paul, 2010\)](#), the Th1 lymphocytes producing IFN γ favor the production of cellular immune delayed hypersensitivity reactions. Th2 lymphocyte-derived cytokines such as IL-4, 5, 9, and 13 favor humoral antibody-mediated immunity to parasites and allergic reactions. Furthermore, these cytokines reciprocally downregulate the other subset. Thus, IFN γ suppresses the Th2 pathway and IL-4 and IL-13 suppress the Th1 pathway. The lymphocyte-derived Th17 type of cytokines (IL-17, IL-22, IL-23) favor acute inflammatory and autoimmune reactions. Treg cells consist of four subsets known as Th3, cell contact-dependent natural or induced Tregs, or Tr1 subsets which mediate their suppressive effects by expressing cell associated TGF β , CTLA4, and secreting IL-10, respectively. They are all engaged as feedback downregulators of inflammation and adaptive immunity and function to promote tissue repair by reducing inflammation and maintaining tolerance.

Lymphocyte subsets also express lineage specific transcription factors called “master regulators,” such as

Tbet, GATA3, ROR γ t, and FoxP3 for Th 1, 2, 17, and Tregs, respectively, that are responsible for the production of the characteristic cytokines. The CD4⁺ T cell commitment to the production of those cytokines in the case of Th1 and Th2 subsets is largely stable, but the Th17 and Treg subsets do show considerable plasticity and interconvertibility. Despite the fact that cytokines are mediators or “intermediaries,” they can play pivotal direct or indirect roles in the capacity of the immune system to distinguish between self and non-self. Overactivity of cytokines or of their receptors such as members of the IL-17 pathway that play a proinflammatory role can lead to excessive immune responses and decreases in the ability to differentiate between self and non-self. Conversely, failure to produce anti-inflammatory cytokines or defective responses by cytokine receptors such as the IL-10 pathway can result in autoimmune or autoinflammatory conditions, since this usually also results in upregulation and overproduction of proinflammatory cytokines.

The interaction of activated “matured” DC and naïve CD4 T lymphocytes in various cytokine milieu results in phosphorylation of lineage-specific transcription factors and master regulators as follows: The Th1 subset is induced by DC-derived IL-12 and this is markedly augmented by IL-18 and by a positive feedback loop involving IFN γ . IL-4 derived from mast cells and basophils initiates the induction of the Th2 lineage. This can be augmented by IL-33 and thymic stromal-derived lymphopoietin (TSLP). TGF β with the help of IL-6 and/or IL-21 induces Th17 lineage cells. This lineage is augmented by IL-1 and maintained by IL-23. TGF β converts naïve CD4⁺ cells to induced Tregs. Their survival requires IL-2 and they are expanded in numbers by ligands such as TNF interacting with TNFR2. The “augmenting” cytokine ligands upregulate expression of selected cytokine receptors on the subsets enabling them to expand and maintain

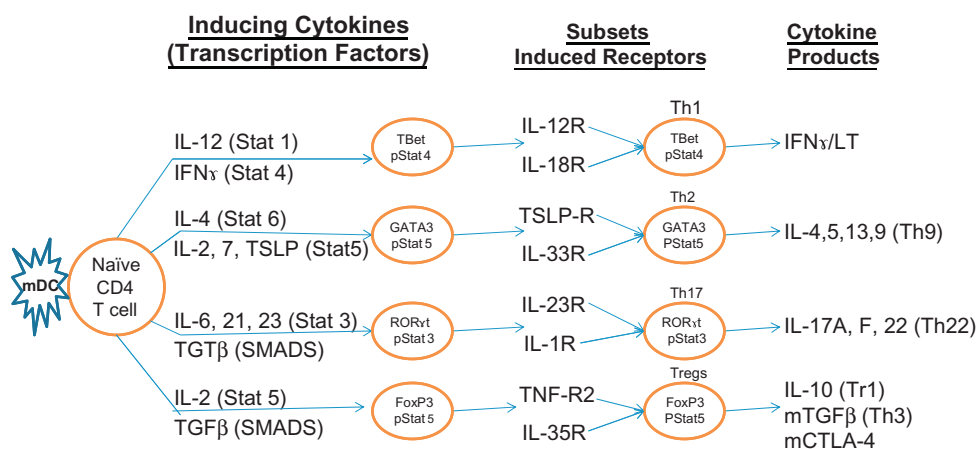

FIGURE 16.1 Helper T cell “differentiation” and Master Regulators. Adapted from [O’Shea and Paul \(2010\)](#).

the lineage and its production of additional characteristic cytokine products. The Th1 and Th2 lineages are largely stable, but the Th17 lineage can develop into dual Tbet and Ror γ t expressing cells that produce both IL-17A and IFN γ . Some of the Th2 subset can become IL-9 producing cells (Th9), while some of the Th17 cells or naïve CD4⁺ T cells can go on to produce IL-22 and have been termed Th22. Some Tregs secrete the immunosuppressive IL-10 cytokine (Tr1 subset), while others express TGF β on their cell membranes (Th3 subset) or membrane associated CTLA4. The Treg subset is the most plastic and can develop into FoxP3 expressing cells that also express Tbet, GATA3, or Ror γ t resulting in effector cells that are no longer suppressive, but function as Th1, Th2, or Th17 cells.

CYTOKINE RECEPTOR SUBSETS

The Common γ c Chain Subset

Cytokines can be classified based on their structure, functions, gene locations, cells of origin, or targets, but such groupings leads to difficulties because of their pleomorphic overlapping effects. Although some cytokines exhibit homologous amino acid sequences, they can best be categorized based on their utilization of related members of receptor families which determines their target cells and effects.

The class I (hematopoietin) family of cytokines includes the common γ c utilizing subfamily of cytokines including IL-2, 4, 7, 9, 15, and 21 as well as the TSLP “stepbrother” of IL-7. Mice with defective γ common chain genes develop severe combined immune deficiency (SCID) syndrome and lack T and B cell immune host defenses against infectious agents (as reviewed in [Liao et al., 2011](#)).

IL-2 was initially discovered as a mitogenic factor for T and B cells, but subsequently also figured prominently in mediating the process of apoptosis (AICD) of lymphocytes. IL-2 is produced by CD4⁺ T cells and uses a receptor consisting of three chains IL-2R α , β , and γ as reviewed by [Akdis et al. \(2011\)](#). The development of IL-2 deficient mice unexpectedly results in hyperplastic lymphadenopathy associated with autoimmune hemolytic anemia. This subsequently was attributed to the crucial role of IL-2 in maintaining the survival and expansion of CD25⁺ (IL-2R α) expressing Tregs. Scurfy mice based on defective Foxp3 genes also lack CD25⁺ Tregs. Consequently, they have hyperactive CD4⁺ T cells and overproduce proinflammatory cytokines. The homologous human autoimmune disease is known as “immune dysregulation, polyendocrinopathy, enteropathy, and X-linked” (IPEX). Thus, the IL-2 function of supporting Tregs is crucial in preventing autoimmune disease.

IL-15 is structurally homologous to IL-2, but is produced by non-lymphoid cells ([Di Sabatino et al., 2011](#)). IL-15 interacts with a heterotrimeric receptor consisting of IL-2 15R β , γ c, and a unique IL-15R α chain. IL15 is a more effective stimulant of natural killer (NK) cells, but less active in stimulating Treg cells than IL-2. Deletion of IL-15 or IL-15R α results in mice deficient in DC, NK cells, and DC8⁺ memory T cells. Defective IL-15 production in mice has also been associated with increased susceptibility to infectious challenges. Conversely, IL-15 overproduction has been shown to play a crucial pathogenic role in a number of autoimmune diseases. Neutralizing antibodies to IL-15 have been shown to decrease inflammation in mouse models of rheumatoid arthritis (RA), psoriasis, and experimental autoimmune encephalomyelitis (EAE).

Another γ c cytokine is IL-7 which serves to maintain a stable number of T and pre-B lymphocytes. This product of stromal cells thus maintains lymphocyte homeostasis by interacting with a receptor consisting of an IL-7 R α and the γ c chains. The absence of a functional IL-7 ligand or IL-7R α chain in mice and humans also yields a SCID phenotype, since IL-7 is required for the generation as well as maturation and survival of all T and B cells. Human polymorphisms of IL7R resulting in excessive inflammatory and immune reactions are a risk factor for a variety of autoimmune diseases. Another gain of function mutation of IL7R is associated with acute lymphoblastic leukemia ([Mazzucchelli et al., 2012](#)).

The deletion of IL-7 R α in mice also inhibits the functions of TSLP, which is produced by epithelial cells and uses a heterodimeric receptor consisting of TSLP-R and IL7R α chains ([Ziegler, 2010](#)). TSLP is a potent inducer of Th2 responses and production of pro-allergic cytokines such as IL-4 and 13 by T and B cells, DC, mast cells, eosinophils, and macrophages. Mutations causing overproduction of TSLP result in mice with severe atopic dermatitis, and TSLP is necessary and sufficient to produce airway inflammatory disease in mice. Although they share a receptor chain, IL-7 functions to maintain the normal level of lymphocytes, while its stepbrother TSLP promotes Th2 immune responses.

IL-21 is a pleiotropic type I cytokine that is a product of CD4⁺ T cells belonging to Th17 and T follicular helper (Tfh) subsets and NK T cells ([Spolski and Leonard, 2010](#)). The Tfh subset of cells has been reported to originate from naïve CD4 T cells by stimulation of Stat 5 and to express Bcl-6 as its master regulator. These T cells express CD4⁺ CXCR5⁺ ICOS⁺ markers and are located in germinal centers (GC) of lymph nodes. Tfh cells produce high levels of IL-21 and B cell antibody production and exhibit considerable plasticity. IL-21 is a potent inducer of proliferation and differentiation of CD4⁺ and CD8⁺ T cells, NK T cells, B cells, DC,

macrophages, and epithelial cells including terminal differentiation and apoptosis. IL-21 interacts with the IL-21 R/ γ_c heterodimer. IL-21 stimulates a wide variety of target cells and contributes to the development of both innate and adaptive immunity. IL-21 does this in part by priming Th17 cells and by upregulating their IL-23R expression. IL-21 can also have feedback downregulatory effects by inducing Tr1 cells to produce IL-10 and by arresting DC in an immature state.

IL-21 along with TGF β and IL-4 may also induce Th9 cells to produce IL-10. IL-21 stimulated B cells also are a rich source of IL-10. Despite these anti-inflammatory effects, studies of IL-21 and IL-21R knockout mice show markedly reduced IL-17 production and reduced development and progression of EAE and systemic lupus erythematosus (SLE). Although IL-21 effects may be tempered by IL-10, overall IL-21 is a proinflammatory effector cytokine.

IL-9 is another pleiotropic cytokine that is produced by a distinct subset of T lymphocytes and mast cells and has therefore been termed a selective product of a unique Th9 pathway (Noelle and Nowak, 2011). However, it is unclear whether IL-9 is a product of stably differentiated cells or whether they exhibit plasticity. IL-9 can also be produced by the Th17 subset and can be co-expressed by IL-17A and by “redifferentiated” Tregs. TGF β in the presence of IL-4 induces stat 6-dependent IL-9 production by GATA3 rather than by Fox3 expressing cells. The PU.1 transcription factor is also essential for the development of Th9 cells. IL-9 utilizes a heterodimeric receptor with IL-9R and γ_c chains. IL-9 behaves like a Th2 cytokine. Mice deficient in IL-9 or IL-9R α are deficient in generating mast cells. In contrast, IL-9 induces mast cells to produce IL-1 β , IL-5, IL-6, IL-9, IL-10, and IL-13. IL-9 is associated with allergic inflammation and immunity to extracellular parasites. Furthermore, adoptive transfer of Th9 polarized cells can promote the development of EAE and experimental autoimmune uveitis (EAU). Conversely, IL-9R α deficiency or neutralizing anti-IL-9 partially ameliorates EAE.

The β_c Utilizing Subset

Another class I subset of cytokines, including GM-CSF, IL-3, and IL-5, interacts with heterodimeric receptors including a β_c chain (Bellanti et al., 2012). In addition, each of these cytokine ligands uses a distinctive receptor chain. GM-CSF is produced not only by T cells and macrophages, but also by endothelial cells and fibroblasts. GM-CSF is a colony stimulating factor that induces progenitor cells in the bone marrow to differentiate into granulocytic and myelocytic lineage cells. Transgenic mice overproducing GM-CSF developed increases in neutrophils, eosinophils, macrophages, and committed

precursors of erythroid and megakaryocytes, which proved lethal because of the excessive inflammatory consequences. *In vitro* culture of monocytes with GM-CSF results in the development of DC, while *in vivo* local injections of GM-CSF or of tumor cells transfected to produce GM-CSF results in the *in situ* accumulation of DC and enhances tumor immunity.

Surprisingly, GM-CSF deficient mice exhibited normal hematopoiesis and myelopoiesis. Only infectious challenge revealed modest defects in granulocyte and macrophage responses. However, GM-CSF deficient mice do develop pulmonary alveolar proteinosis (PAP) and humans with PAP have high titers of anti- β_c antibodies or anti-GM-CSF. Since treatment with GM-CSF benefits such patients, PAP may be due to GM-CSF deficiency, which results in dysfunctional macrophages that fail to clear and metabolize surfactant lipoproteins. The GM-CSF deficient mice did accumulate lymphoid and mononuclear cells around their airways and pulmonary blood vessels. They also developed T cells deficient in IFN γ production and cytotoxicity and decreases in B cell antibody production. GM-CSF knockout mice were resistant to lipopolysaccharide (LPS) challenge and resisted induction of autoimmune arthritis and EAE. Although the hematopoietic effects of GM-CSF appear to be redundant, GM-CSF has considerable proinflammatory cytokine functions.

IL-5, a Th2 cytokine produced by T cells and mast cells, is a critical regulator of eosinophil expansion in the bone marrow and peripheral blood and tissues in response to allergic and parasitic stimuli (Akdis et al., 2011). However, eosinophil migration is regulated by eotaxin (CCL11) and other chemokines and its development by hematopoietic growth factors. IL-5 deficient mice develop reduced numbers of mature functional eosinophils, but there is partial redundancy with other cytokines such as GM-CSF and IL-3.

IL-3 is a product of activated T cells that stimulates the proliferation, differentiation, and activation of multiple hematopoietic progenitor cells, mast cells, basophils, neutrophils, macrophages, eosinophils, and DC. IL-3 thus promotes antigen presentation to T cells and enhances macrophage cytotoxicity. IL-3 deficient mice, however, are normal and its functions are redundant except for a reduced mast cell production in response to stem cell factor (SCF) and parasitic challenge. They also produce fewer basophils in response to parasitic infections and their contact hypersensitivity responses were also diminished.

The gp130 Utilizing Subset (IL-6 Family)

A third subfamily of class I cytokines utilizes a signal transducing gp130 receptor chain in common with a

unique binding chain for each of the nine cytokine ligands in the family. They include IL-6, IL-11, IL-27, IL-31, leukemia inhibiting factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), cardiotropin-1 (CT-1), and cardiotropin-like cytokine (CLC) (Akdis et al., 2011). Although these cytokines share one signaling chain, they have widely divergent functions depending on the cellular location of their unique binding chains.

IL-6 is one of the most important pleomorphic proinflammatory cytokines. IL-6 is produced by macrophages and activated T lymphocytes, but also by fibroblasts, endothelial cells, and other somatic cells. IL-6 interacts with IL-6R α , which is restricted to certain tissues. However, IL-6R α is frequently shed and available in a soluble form that complexes IL-6. These complexes can trigger the widely expressed gp130 receptor and initiate signal transduction by JAK and STAT transcription factors. This enables IL-6 to activate T and B cells, macrophages, megakaryocytes, hepatocytes, endothelial cells neuronal cells, and fibroblasts. This can result in local inflammation, but IL-6 often becomes available in the serum resulting in fever and acute phase responses. IL-6 is a potent inducer of B cell proliferation with the potential of developing plasma cell tumors (multiple myeloma), and growth of neuronal cells. Stimulation by the two other major proinflammatory cytokines, IL-1 and TNF, can induce IL-6 production and IL-6 can synergize with these cytokines. Consequently, IL-6 is a major exacerbator of autoimmune inflammatory diseases (Barr et al., 2012). Neutralizing anti-IL-6 antibodies have been used with therapeutic success to treat Castleman's disease, a form of plasma cell leukemia, but also juvenile idiopathic arthritis (JIA) and rheumatoid arthritis (RA). Anti-IL-6 has been used successfully in some RA patients that were unresponsive to inhibitors of TNF.

Cytokines Sharing either a p35 or p40 Ligand Chain

The so-called IL-12 cytokine family consists of cytokines with an α chain (p19, p28, or p35) and a β chain (p40 or EBI3) as follows: IL-12 (p35 and p40), IL-23 (p19 and p40), IL-27 (p28 and EBI3), and IL-35 (EBI3 and p35) (Akdis et al., 2011).

IL-12 is produced mostly by myeloid DC and macrophages, but also by activated B lymphocytes and neutrophils. IL-12 utilizes a heterodimeric receptor formed by IL-12R β 1 and IL-12R β 2. IL-12R β 2 appears to be the signaling component of the receptor on Th1 lymphocytes and NK cells that becomes tyrosine phosphorylated and activates Tyk2 and JAK2 and subsequently Stat 4. This enables IL-12 to play a crucial role in promoting Th1-dependent cytotoxicity of T cells and NK cells and their

production of IFN γ . IL-2 promotes this pathway by enhancing expression of the IL-12R, while IFN γ promotes the production of more of the IL-12 cytokine; resulting in a positive loop. IL-12 has anti-angiogenic effects by inducing IFN γ , which in turn produces an angiostatic chemokine known as IP-10 CXCL10. Mice defective in IL-12 p40 or IL-12R become much more susceptible to infections by intracellular pathogens such as mycobacteria and even non-pathogenic Bacille Calmette-Guerin (BCG) organisms. Such knockout mice are much more resistant to the induction of autoimmunity, while administration of IL-12 exacerbates autoimmune conditions (Adorini, 2003). These results point out the important contribution of Th1 immune responses to various autoimmune states including EAE, EAU, RA, autoimmune myasthenia gravis, and autoimmune thyroiditis.

An anti-IL-12 antibody has induced clinical responses and remissions in patients with Crohn's disease (Mannon et al., 2004).

IL-23 is a heterodimeric cytokine, which shares a p40 chain with IL-12. Like IL-12, IL-23 is produced by antigen presenting cells such as DCs and macrophages and synovial fibroblasts. IL-23, however, has unique functions of stimulating committed Th17 memory cells that express the heterodimeric receptor for IL-23 consisting of IL-23R and IL-12 R β 1. IL-23 serves to maintain Th17 responses by inducing the production of IL-17A, IL-17F, TNF, IL-6, GM-CSF, IL-22, and some chemokines (CXCL1 and CCL20). Knockout mice with deficiencies in either p19 or IL-23R develop less severe autoimmune inflammatory bowel disease (IBD) and EAE. This presumably is based on the reduced production of Th17 cytokines, which are important contributors to autoimmune inflammatory states. An anti-p40 antibody, which inhibits both IL-12 and IL-23, has therapeutic efficacy in psoriasis (Krueger et al., 2007).

IL-27 is reported to be a product of DC and macrophages as well as epithelial cells that interact with a receptor consisting of an IL-27R and the gp130 chains. Consequently, IL-27 belongs to both IL-6 and IL-12 subfamilies. IL-27 synergizes with IL-12 in activating T cells to produce IFN γ with consequent Th1, antiangiogenic, and antitumor effects. IL-27 also suppresses the development of Th17 cells and can induce considerable IL-10 production with its anti-inflammatory effects (Pot et al., 2011). IL-27 gene deletion results in mice with hyperreactive Th2 inflammatory responses to challenges with pathogenic parasitic organisms. Oral administration of IL-27 expressing lactococci by inducing mucosal IL-10 production suppresses IBD in mice. Thus, the suppressive functions of IL-27 may be less redundant.

IL-35 is reported to be a product of Treg cells and has suppressive effects on Th17 cells and CD4⁺ CD25⁻ T cells. IL-35 is reported to stimulate the proliferation of

Treg cells. It is therefore said to be an immunosuppressive product contributing to the effects of Tregs. However, this cytokine has recently been reported to be produced by TEK factor cells.

Th17 Cytokines and Receptors

It was recently recognized that in addition to the Th1 $\text{IFN}\gamma$ cytokine, a family of IL-17 cytokines is a major contributor to autoimmune reactions; especially IL-17A and IL-17F, which show 50% homology (Iwakura et al., 2011). IL-17 is induced by the combination of $\text{TGF}\beta$ and IL-6 and is maintained by IL-23 and/or IL-1. IL-17 is produced mainly by Th17 CD4^+ and CD8^+ T cells and by NK cells. IL-17 activates neutrophils, T cells, antigen presenting cells (APCs), and fibroblasts, endothelial cells, and stromal cells expressing various IL-17 receptors. IL17A and IL-17F utilize IL-17RA and IL-17RD receptors, respectively, while IL-17B, C, and D use IL-17RB. IL-17 induces many other inflammatory cytokines, chemokines, and prostaglandins. Consequently, IL-17 is important in driving acute inflammatory as well as allergic and autoimmune responses. IL-17 actually has suppressive effects on the Th1 pathway and the production of $\text{IFN}\gamma$. Nevertheless, T cells producing both IL-17 and $\text{IFN}\gamma$ have been detected. IL-17 promotes the production of proinflammatory cytokines such as IL-6, GM-CSF, G-CSF, IL-1 β , TNF, IL-21, IL-22, IL-26, IL-11 various chemokines, and even $\text{TGF}\beta$. Deletion of IL-17A and/or IL-17F or their receptors results in mice with markedly reduced resistance to infectious challenges. Airway hypersensitivity and T cell-dependent antibody production are also considerably reduced. These IL-17A and F knockout mice develop less severe collagen-induced arthritis (CIA) and resist induction of EAE. Attempts to suppress autoimmune diseases in mouse models with neutralizing anti-IL-17 antibodies have not met with resounding success, perhaps because multiple redundant Th1 and Th2 cytokines all are involved in exacerbating the inflammation in these diseases. A humanized anti-IL-17 antibody has been effective in the treatment of RA (Genovese et al., 2010).

IL-25 (IL-17E) is produced by Th2 lymphocytes, mast cells, basophils, eosinophils, and epithelial cells (Akdis et al., 2011). IL-25 utilizes a receptor consisting of IL-17RA and IL-17RB chains. Receptor deleted mice fail to produce IL-5 or IL-13 in response to IL-25. Consequently, IL-25 is an inducer of Th2 and Th9 responses (IL-4, 5, and 13) and actually suppresses Th1 and IL-17 production. In particular, IL-25 is prominently involved in chronic inflammation of the gastrointestinal (GI) tract, including in IBD. IL25 knockout mice show reduced eosinophil infiltration in allergic states due to reduction in Th2 and Th9 responses.

CLASS II CYTOKINE RECEPTOR FAMILY

The class II receptors are utilized by the interferon family ($\text{IFN-}\alpha$, β , γ) and also by IL-10, 19, 20, 22, 24, 26, 28, 29, and 30. The receptors consist of one ligand binding and one signal transducing chain. The interferons are the major host defense cytokines directed against viruses, bacteria, parasites, and fungi. They include $\text{IFN-}\alpha$, β , γ , and λ (consisting of IL-28 and IL-29). The other family members have a diversity of functions.

Type I Interferons α and β

There are actually 13 subtypes of $\text{IFN-}\alpha$ and two subtypes of $\text{IFN-}\beta$ (Huber and Farrar, 2011). $\text{IFN}\alpha/\beta$ both interact with the type I IFN receptor, which consists of two subunits IFNAR1 and IFNAR2 and are widely expressed by all nucleated cells. The type I $\text{IFN-}\alpha/\beta$ are induced by a wide variety of exogenous and endogenous proinflammatory stimulants (especially viral infections) in many cell types. Plasmacytoid DCs are major producers of $\text{IFN-}\alpha$ and $\text{IFN-}\alpha$ is particularly elevated in patients with SLE and psoriasis. Fibroblasts are a greater source of $\text{IFN-}\beta$. Although many functions have been ascribed to $\text{IFN-}\alpha/\beta$, mice knocked out for IFNAR1 exhibit predominantly reduced antiviral host defenses and some reduction in their responses to LPS and CSF-1. However, genetic polymorphisms resulting in the elevation of $\text{IFN-}\alpha$ predispose to the development of human SLE (Niewold, 2011) $\text{IFN-}\alpha/\beta$ are potent stimulators of the maturation of myeloid DC and thus promote adaptive immunity, but this is a redundant function. $\text{IFN-}\alpha$ is used in the treatment of hepatitis B and C. $\text{IFN-}\beta$ is used to treat multiple sclerosis, but the mechanism by which $\text{IFN-}\beta$ suppresses symptoms and signs of MS may be based on suppression of IL-17 producing T cells. $\text{IFN-}\alpha/\beta$ therapy is associated with unpleasant flu-like side effects.

Type II Interferon Gamma

$\text{IFN-}\gamma$ actually has minimal antiviral activity and is the major immunoregulatory product and co-inducer of the Th1 cytokine pathway. $\text{IFN-}\gamma$ enhances autoimmunity (Akdis et al., 2011). It is selectively produced by T lymphocytes, NK cells, and NKT cells. There are reports claiming that $\text{IFN-}\gamma$ is also produced by macrophages, neutrophils and B cells, but their contribution, if any, is minor. $\text{IFN-}\gamma$ utilizes a receptor consisting of IFNGR1 and IFNGR2 expressed by NK cells, macrophages, Th1 lymphocytes, CD8^+ CTL, and B cells. $\text{IFN-}\gamma$ has a major role in protecting against intracellular bacteria, based on its macrophage activating effects. Humans with gene defects in the $\text{IFN}\gamma$ pathway and mice lacking $\text{IFN-}\gamma$ or the IFNGR exhibit markedly reduced resistance to

mycobacteria and other intracellular bacterial, fungal, and parasitic infections. Macrophage production of nitric oxide, TNF, IL-1, IL-12, and IL-6 is impaired. Unexpectedly, the knockout mice were not more resistant to the induction of EAE or uveitis, but more readily developed arthritis. Instead, IFN- γ was found to be critical in suppressing chronic inflammation and restoring T cell homeostasis by promoting T cell apoptosis. Administration of IFN- γ exacerbates multiple sclerosis (MS). IFN- γ is used therapeutically to treat infections in patients with chronic granulomatous disease.

Type III Interferon Lambda

The recently identified subgroup of IFN- λ 1, 2, and 3 are also termed as IL-29, IL-28A, and IL-28B, respectively (Donnelly and Kotenko, 2010). These cytokines utilize a heterodimeric receptor consisting of an IL-28R chain and IL-10R2 chain. The IFN- λ s have both antiviral and immunostimulatory activities. Since the receptors for the IFN- λ are selectively expressed on epithelial cells, they may have fewer undesirable side effects than IFN- α and have demonstrated initial efficacy in the treatment of hepatitis. IL-28 may also have a protective role in EAE and is being investigated as a therapy for autoimmunity.

Non-Interferon Members

IL-10, another family member, has no antiviral activity, but is an active immunodulatory mediator that uses a heterodimeric receptor consisting of IL-10R1 and IL-10R2 chains (Saraiva and O'Garra, 2010). IL-10, a homodimeric cytokine, is produced by many cell types including Th1, Th2 lymphocytes, cytotoxic T cells, B lymphocytes, mast cells, monocytes, DCs, and the Tr1 subset of Tregs. IL-10 has many suppressive effects by inhibiting proinflammatory cytokine production and activities of T cells, NK cells, mononuclear phagocytes, and DC. However, IL-10 also has stimulatory effects particularly for B cells and promotes B cell proliferation, differentiation, and antibody production and induces isotype switching.

By capturing and sequestering antigens, antibodies may suppress inflammation and cellular immune responses, thus further supporting the anti-inflammatory role of IL-10. Stat 3 is essential for the suppressive effects of IL-10 on cytokines, since IL-10 fails to have such an effect on Stat 3 knockout mice. Stat 3 depleted mice become hypersensitive to endotoxin shock and develop chronic enterocolitis (IBD). The suppressive effects of IL-10 also involve the induction of inhibitory SOCS 1 and 3 signal transducers. IL-10 immunosuppressive effects, thus, protect the host from excessive inflammatory responses including allergic reactions. IL-10 knockout mice show normal lymphocyte development and

antibody responses, but they develop runting, anemia, and chronic colitis (IBD) due to excessive production of proinflammatory cytokines in response to enteric bacterial antigens. Polymorphisms reducing the effectiveness of IL-10 have resulted in a variety of human autoimmune diseases. IL-10 has a protective role in autoimmune diseases such as SLE, RA, and type 1 diabetes.

The other members of the class II cytokine receptor family have distinct nonimmunosuppressive functions (Akdis et al., 2011). IL-22 is usually considered a product of the Th17 pathways, although it is also induced by IL-9. IL-22 interacts with receptors consisting of IL-22R1 and IL-10R2. IL-22 is produced by Th17 and NK-22 cells and acts primarily on keratinocytes and epithelial lining cells, which express IL-22R1. IL-22 deficient and IL-22R-deficient mice have increased intestinal epithelial damage and become much more susceptible to *C. rodentium* infection. Thus, IL-22 plays a major role in maintenance and repair of epithelial lining tissues. IL-22 levels are elevated in psoriasis and IBD.

IL-19 shares the IL-20R receptor with IL-24 and IL-26. Since it augments IL-4, but decreases IFN γ production, IL-19 favors Th2 responses. IL-19 is elevated and IL-19 polymorphisms have been associated with psoriasis. IL-20 is also elevated in psoriasis and RA and IL-20 polymorphisms are associated with psoriasis. IL-20 is pro-angiogenic and a keratinocyte stimulant. IL-24 promotes wound healing and is apoptotic for some tumor cells. IL-24 is elevated in melanomas and psoriasis. IL-26 is a proinflammatory cytokine, which is absent in mice and difficult to study. IL-26 is elevated in IBD and polymorphisms of IL-26 are protective of MS and RA.

TNF RECEPTOR FAMILY

The TNF family consists of 19 cytokines, which use 29 structurally related receptors that share intracellular signaling pathways (Aggarwal et al., 2012; Croft et al., 2012). Tumor necrosis factor (TNF) was discovered as a factor in serum that was cytotoxic for tumors (Carswell et al., 1975). TNF is produced by T and B cells, NK cells, and macrophages. Although it interacts with the widely expressed TNFR1 receptor that contains a death domain, TNF acts on immune, endothelial, and other cell types as a major proinflammatory cytokine that mediates acute and chronic inflammatory responses to bacterial infections. TNF stimulates the hypothalamic–pituitary axis to release numerous hormones, induces liver-derived acute phase proteins, activates endothelial cells to express adhesion molecules, and results in egress of TNF activated leukocytes out of blood vessels. Thus, systemic TNF can cause fever, myalgias, malaise, hypotension, vascular leakage, cachexia, osteoporosis, and other signs of inflammation. Nevertheless, studies of mice with deletion of

TNF or TNFR1 receptors showed increased resistance to development of endotoxin shock, resistance to carcinogenesis, reduced resistance to infectious challenges, and partial resistance to induction of EAE. A number of polymorphisms of human TNF gene resulting in excessive activity have been associated with a variety of autoimmune diseases. TNF promotes inflammation and exacerbates autoimmune disorders such as RA, ankylosing spondylitis, Crohn's disease, and psoriasis. This can be countered by treating patients with these disorders with inhibitors of TNF such as anti-TNF antibodies or soluble receptors for TNF. Such immuno-therapies do reduce host resistance and can result in activating latent tuberculosis infections. Despite this TNF blockade has benefited millions of autoimmune patients.

The second receptor for TNF, TNFR2, is expressed only on T lymphocytes and NK cells. TNFR2 is predominantly expressed on all naturally occurring Tregs and activated-induced Tregs (iTregs). Consequently, ligand-induced signals from TNFR2 provide a means of downregulating TNF–TNFR1 proinflammatory effects.

Lymphotoxin (LT α) is the closest relative of TNF and also utilizes TNFR1 and 2. LT β also utilizes two other receptors (LT β R and HVEM). The lymphotoxin name also represents a misnomer based on their initial discovery as *in vitro* cytotoxic activities (Ruddle and Waksman (1967)). LT is produced by activated T cells, NK cells, mast cells, fibroblasts, and endothelial and epithelial cells. Studies of knockout mice yielded the surprising revelation that LT was crucial for the organogenesis and maintenance of peripheral lymphoid tissues. Mice deficient in LT had only rudimentary lymph nodes and Peyer's patches and a disorganized splenic lymphoid architecture. Although LT α also uses TNFR1 and TNFR2, the unique effects of LT are based on the fact that LT α forms heterotrimeric complexes with lymphocyte membrane associated LT β , which then act on LT- β R. In contrast, LT α homotrimers by acting on TNFR1 can mimic the effects of TNF. Consequently, double TNF/LT α knockout mice become even more susceptible to bacterial challenge than single knockout mice. Although the antibody responses and immunoglobulin switching by such mice are defective, their cellular immune responses remain fairly intact based on redundant pathways.

Some of the other members of the TNF superfamily contribute to autoimmune disorders. Humans with disabling heterozygous mutations in the “fragment apoptosis stimulating” (Fas/CD95) receptor develop a disease called autoimmune lymphoproliferative syndrome (ALS) with lymphadenopathy, splenomegaly, and the production of autoantibodies (Lobito et al., 2011). This is based on failure to remove long-lived lymphocytes by the usual Fas-dependent apoptotic mechanism (Strasser et al., 2009). The homotrimeric FasL triggers the Fas receptor, which

contains a death domain, and results in the elimination of senescent lymphocytes. In the absence of normal Fas or FasL functions humans and mice develop B cell lymphomas and autoimmune syndromes based on the accumulation of senescent and defective lymphocytes.

Another family member, “TNF-related apoptosis inducing ligand” (TRAIL), similarly acts on death domain expressing DR4 and DR5 receptors. In addition to mediating antitumor effects, mice with deletion of TRAIL or its receptors develop autoimmune diseases. Analogous to Fas deletion, the absence of TRAIL results in failure to eliminate senescent and defective lymphocytes by apoptosis.

A number of the TNF family of cytokines are potent stimulants of B cells and have been implicated in causing or exacerbating SLE. This is true of the B cell activating factor member of the TNF family known as BAFF or BLYS or BLVS (Vincent et al., 2012). BAFF is a product of activated T cells, macrophages and DCs. BAFF interacts with two receptors known as TACI and BR3 expressed by B and T cells. In addition, BAFF heterotrimerizes with another TNF family member known as APRIL, which interacts with TACI and BCMA receptors (Cancro et al., 2009). Mice with deletion of a functional BAFF show impaired development of B cells, while mice with defective APRIL expression show impaired development of more mature plasma cells. Conversely, transgenic mice that overexpress BAFF have B cell hyperplasia and develop a lupus-like phenotype. Both BAFF and APRIL are elevated in SLE patients and other autoimmune diseases. A monoclonal anti-BAFF antibody that depletes B cells and shows therapeutic benefit has therefore been approved for use in SLE.

Several other TNF family members appear to function as costimulators, which, depending on the context, can enhance inflammatory responses or promote Treg cell activities. These include OX40–OX40L interactions (Ishii et al., 2010), TL1A–DR3 interactions (Ishii et al., 2010; Meylan et al., 2011), and 4-1BBL–4-1BB interactions (Hamano et al., 2011). These interactions can thus either promote autoimmune reactions or can prevent or dampen autoimmune disorders by augmenting Treg activities.

THE IL-1/TLR FAMILY OF RECEPTORS

The IL-1 family has expanded to 11 members, but the three initial members have been most thoroughly studied (Sims and Smith, 2010). They consist of agonistic IL1 α , which is usually cell membrane associated, the soluble IL-1 β , and the soluble IL-1 receptor antagonist (IL-1RA). These ligands interact with the ubiquitously expressed type I IL-1R, which transduces signals that result in proinflammatory effects similar to those of TNF, except they do not induce apoptosis. IL-1RA acts as an

antagonist of IL-1 α and IL-1 β by binding tightly to type I IL-1R and competes with the agonist ligands for this receptor. The type II IL-1R also binds IL-1 β and IL-1 α with high affinity, but fails to signal and is therefore considered a “decoy” receptor, which traps the ligands. Thus, IL-1 is downregulated by these two mechanisms. Furthermore, IL-1 α and β are generated with pro-domains. IL-1 β and IL-18 are generally, but not always, cleaved by caspase-1. This enzyme is generated by the “inflammasome” pathway, which is activated by microbial-derived ligands that interact with nucleotide-binding oligomerization domains (NOD-like receptors NLRs). This provides another means of regulating the activity of IL-1 β as evidenced from the fact that genetically heritable gain of function mutations in the inflammasome pathway result in autoinflammatory periodic fever syndromes such as Muckle Wells syndrome, familial Mediterranean fever, hyper-IgD syndrome, familial cold autoinflammatory syndrome, and others (e.g., NOMID, CINCA). IL-1 α is usually cleaved by calpain and other enzymes, rather than by inflammasome-derived caspase-1. IL-1RA contains a classical signal peptide and is secreted by the endoplasmic reticulum and Golgi apparatus like most other cytokines. The other IL-1 family members all are biologically active as full-length molecules, but enzymatic processing at their N-terminal ends increases their activities. The IL-1 family members all interact with closely related receptors containing extracellular immunoglobulin domains, and they signal through cytoplasmic Toll/IL-1R (TIR) domains using a transduction pathway similar to that of the TLR.

There is another IL-1 family inhibitory receptor, SIGIRR, expressed largely on epithelial cells that decreases the inflammatory responses to IL-1, IL-18, IL-33, IL-36 α , β , γ , and to TLR ligands. This is based on observations showing that SIGIRR deficient mice have enhanced responses to these ligands and develop more severe IBD, asthma, and colon cancer. Thus, SIGIRR also downregulates responses to most of the IL-1 family members.

Despite the plethora of IL-1 activities, deletion of IL-1 α and/or β or of the type I IL-1R has limited deleterious effects on mice with only a modest decrease in cellular and humoral immune responses and decreased resistance to infectious challenges. IL-1/IL-1R deleted mice exhibit greater resistance to induction of autoimmune diseases. In contrast, deletion of IL-1RA yielded dramatic phenotypic effects with hyperinflammatory reactions due to overproduction of inflammatory cytokines, enhanced delayed type hypersensitivity (DTH), humoral immunity, increased resistance to infection, and enhanced induction of autoimmune states including spontaneous development of arthritis. These findings have led to the development of IL-1RA (anakinra) and other inhibitors of IL-1 as therapeutics.

These antagonists are having dramatic benefits in patients with autoinflammatory diseases. They are also benefiting patients with gain of function mutations in TNFR1 (TRAPS syndrome), Behçet’s syndrome, gout, and are being investigated for their utility in type 2 diabetes, congestive heart failure, and other conditions (Dinarello, 2011).

IL-18 also is a member of the IL-1 family that is expressed by a wide range of cell types as an inactive precursor that requires cleavage by caspase-1 generated by the inflammasome pathway. IL-18 interacts with widely expressed heterodimeric IL-18R in which the α chain binds and the β chain signals in response to IL-18. The IL-18 ligand by itself is a weak stimulant of IFN γ (Th1) or IL-13 (Th2) responses, but IL-18 synergizes with IL-12 to produce high levels of IFN γ , or with IL-2 to produce more IL-13. A neutralizing IL-18 binding protein (IL-18BP) has been isolated from the urine of Italian nuns, which binds and inhibits IL-18 with high affinity. IFN γ is a potent inducer of IL-18BP, thus it functions as a negative feedback inhibitor.

IL-18 promotes the development of Th1 responses and functions of NK cells in host defense against bacterial infections. Consequently, IL-18 deficient mice show reduced resistance to parasitic, viral, and bacterial infections. IL-18 is usually elevated in autoimmune diseases and IL-18 deficient mice develop less severe CIA and resist induction of IBD. Moreover, polymorphisms in the promoter regions of the human IL-18 gene have been associated with RA.

IL-33 functions as a nuclear binding transcriptional factor as well as an extracellular cytokine, like IL-1 α . Full-length IL-33, like IL-1 α , is also active, but it can be cleaved by caspase-1 from a 30 kDa to an active 18 kDa cytokine. IL-33 interacts with the ST2 receptor expressed on T helper cells, dendritic cells, and mast cells. Although initially reported as an inducer of Th2 responses, more recent data indicated that IL-33 also can be a potent inducer of Th1 polarized cytotoxic CD8 T cells. A soluble shed form of ST2 has the capacity to bind and inhibit IL-33. Thus, administration of sST2 reduces inflammation in an asthma model in mice and sST2 levels are elevated in autoimmune disorders such as SLE and RA. Mice with defective ST2 receptors have reduced Th2 responses, increased sensitivity to endotoxin challenge, and increased susceptibility to streptozotocin-induced diabetes.

There are some even newer members of the IL-1 family which are proinflammatory, namely IL-36 α , β , and γ (previously named IL-1F6, F8, and F9). Overproduction of IL-36 is reported to induce a psoriatic-like skin disease in mice. IL-1F5, now known as IL-36Ra, is an antagonist of IL-36. IL-37 appears to be an immune suppressive cytokine. It is elevated in tissues of RA patients, where it presumably has an inhibitory feedback effect.

IMMUNOSUPPRESSIVE CYTOKINES/ GROWTH FACTORS

We have already discussed immunosuppressive cytokines that play pivotal roles in preventing exuberant inflammatory reactions against non-self and self antigens such as IL-10, IL-25, and IL-37. The other cytokine that plays a major suppressive role is TGF β . TGF β belongs to a family of over 40 cytokines that utilize serine threonine kinase receptors. Tregs and the subset of Th3 cells, as well as platelets, macrophages, NK cells, epithelial cells, and glial cells, are major sources of TGF β . It is usually classified as a growth factor because it promotes wound healing and fibrosis. Concomitantly, TGF β has antiproliferative and suppressive effects on T and B cells, macrophages, endothelial cells, hematopoiesis, and suppresses inflammatory reactions which interfere with wound healing. Tumor cells often produce considerable TGF β and thus have anti-inflammatory and anti-immune effects supporting Virchow's idea that "tumors are wounds that fail to heal."

Deletion of TGF β in mice is lethal for neonatal mice. They exhibit uncontrolled T cell activation with excessive production of cytokines and die of a "cytokine storm" resembling the effects of "septic endotoxic shock." Conversely, overexpression of TGF β results in renal fibrosis and diabetes. TGF β is crucial in the generation of Treg cells from naïve T cells and in preventing the maturation of DC, which are crucial in preventing the development of autoimmunity. We will not discuss the other growth factors because they are not known to have direct effects on autoimmune responses.

CHEMOKINES

There are over 40 chemoattractant cytokines (chemokines) that interact with over 20 different G α protein coupled receptors (GiPCR). These chemokines play a major role in the trafficking of inflammatory and noninflammatory cells and are responsible for organogenesis of lymphoid and other tissues. Chemokines generally have minimal immune cell activating effects. Deletion of various chemokine or chemokine receptor genes have diverse effects depending on the distribution of their receptors. However, although elevated in autoimmune diseases, chemokines are not directly responsible for any autoimmune disorders. Nevertheless, as key mediators in the pathogenesis of inflammatory, autoimmune, and neoplastic disorders, polymorphisms of various chemokine genes have been associated with a variety of diseases (Colobran et al., 2007). For example, SDF1/CXCL-12 and IL-8/CXCL-8 polymorphisms have been associated with SLE (Wu et al., 2012; Sandling et al., 2011), while defective CCR5 expression has a protective effect on RA.

ALARMINs

There are a number of preformed constitutively available molecules residing in cell granules, cytoplasm, or binding to chromatin that are released by cellular degranulation or necrotic cell death (Yang et al., 2009). These "alarmins" have chemotactic/recruiting activity and also activating effects on mononuclear phagocytes and on dendritic cells resulting in cytokine production and promotion of antigen presentation and adaptive immunity. Thus, alarmins are proinflammatory and enhance both innate and adaptive immunity. Alarmins are produced by a wide variety of leukocytes and non-leukocytes and interact with some GiPCR as well as Toll-like receptors (TLR) to yield chemotactic and activating effects, respectively. Some alarmins such as histamine, IL-33, and eosinophil-derived neurotoxin (EDN) polarize Th2 responses, while others such as HMGB1 and HMGN1 are potent polarizers of Th1 responses. Most other alarmins such as defensins, cathelicidins, IL-1 α , and granulysin promote both Th1 and Th2 responses. IL-1 α and IL-33 as well as HMGB1 and HMGN1 are nuclear binding proteins as well as cytokines with proinflammatory recruiting and activating effects. Many of these alarmins have been experimentally deleted in mice. Deletion of various antimicrobial defensins and cathelicidin results in reduced resistance to bacterial challenges. Deletion of HMGB1 has embryonic lethal effects, while deletion of HMGN1 results in immunodeficient mice with reduced tumor immunity. Studies of the role of alarmins in autoimmunity are limited. Defects in NOD2 with consequent defensin deficiency are associated with enhanced susceptibility to IBD in humans. This NOD2 defect results in overreactive inflammatory responses to gastrointestinal flora in the microbiome. The levels of HMGB1 have been found to be elevated in a number of autoimmune conditions and are correlated with the degree of inflammation. HMGB1 is present in the nucleosomes of SLE serum and autoantibodies to HMGB1 have been detected in SLE sera. However, alarmins have not been implicated as directly causative of autoimmune disorders.

CONCLUSIONS

Cytokines play important roles as either mediators or suppressors of inflammation in autoimmunity. They can, therefore, be targeted therapeutically with beneficial, although non-curative effects. This brief chapter is of necessity incomplete based on our ignorance and on the enormity of the topic. More cytokines and receptors remain to be discovered and some may play central roles in autoimmune processes. More detailed information concerning the role of cytokines in various autoimmune diseases is to be found in many of the chapters in this textbook.

ACKNOWLEDGMENTS

I am grateful to Drs. Scott Durum, Howard Young, O.M. Zack Howard, and Dennis Klinman for their helpful constructive comments and for the secretarial help of Ms. Sondra Sheriff.

APOPTOSIS

History of Apoptosis

In 400 BC Hippocrates used the word “apoptosis” in the book of *Mochlicon* to describe the resulting gangrene from treatment of fractures with bandages (Andre, 2003). Two millennia went by and in the mid-19th century Carl Vogt described cell death for the first time. Shortly after, Rudolf Virchow and Walther Flemming reported two types of cell death and demonstrated that they were the consequence of mechanical or chemical damage (Diamantis et al., 2008). In the early 20th century the seminal work in embryology of several investigators such as Charles Perez and Alfred Glucksmann led to a detailed histological description of cellular death (Diamantis et al., 2008). It was only in 1972 that John F. Kerr coined the word “apoptosis” independently from Hippocrates and after a suggestion from a Greek professor (Kerr et al., 1972). Kerr, along with Andrew Wyllie and Alastair Currie, not only described the “shrinkage necrosis” as a defined pattern and sequence of events during cell death

but also intended to make apoptosis an integral part of cell biology such as mitosis, necessary to the maintenance of life (Kerr et al., 1972). Indeed today, four decades later, this form of cell death has become a fundamental mechanism in all fields of biology. The genetics of cell death had a breakthrough in the late 1970s with the work of John Sulston and Robert Horvitz in the *Caenorhabditis elegans*, a nematode in which a fixed percentage of somatic cells die predictably (Sulston and Horvitz, 1977). This model gave the opportunity to geneticists to dissect the pathways to cell death and to clone several genes called *CED* (*C. elegans* Death). The *CED* genes were eventually shown to be highly preserved in mammals (Lockshin and Zakeri, 2001). Today apoptosis and necrosis are fundamental parts of physiological and pathological processes and are explored as therapeutic venues.

Molecular Pathways of Apoptosis

Two essential components characterize an apoptotic cell: its morphology and the activation of a programmed molecular cascade (reviewed by Kroemer et al. (2009) and Galluzzi

et al. (2012)). Both components can be triggered by *extrinsic* and *intrinsic* mechanisms, hence the concept of extrinsic and intrinsic apoptosis (Riedl and Salvesen, 2007).

Initiation of *extrinsic apoptosis* requires the triggering of a trans-membrane receptor. In the presence of their ligands, such as FasL, TNF- α , or TNF-related apoptosis-inducing ligand (TRAIL) (Takahashi et al., 1994; Wiley et al., 1995), these death receptors (FAS, TNFR1, and TRAILR 1 and 2) trimerize to form the “death-inducing signaling complex” (DISC) (Lavrik and Krammer, 2011). DISC formation depends on a conserved death domain (DD), which can recruit receptor-interacting protein kinase 1 (RIP1) (Varfolomeev et al., 2005), FAS-associated protein with a DD (FADD) (Chinnaiyan et al., 1995), multiple isoforms of c-FLIP, and pro-caspase-8. The triggering of TNFR1 may also lead to activation of NF- κ B or to necrotic death. Once the DISC is formed, activation of caspase-8 ensues (Scaffidi et al., 1999).

In apoptotic lymphocytes (also called type I cells) (Barnhart et al., 2003) caspase-8 activates caspase-3, which initiates proteolytic cleavage of cytoplasmic and nuclear proteins, and the activation of caspase-activated DNase (CAD), which cleaves internucleosomal chromatin (Enari et al., 1998). There is cross-talk between extrinsic and intrinsic pathways. For example, in apoptotic hepatocytes (also referred to as type II cells) there is involvement of the mitochondrial pathway, and caspase-8 instead of activating caspase-3 cleaves BH3-interacting domain death agonist, inducing mitochondrial outer membrane permeabilization (MOMP) and reduction of the trans-membrane potential ($\Delta\psi_m$) (Kroemer et al., 2007). The resulting release of cytochrome c (CYTC) triggers assembly of the apoptosome (CYTC, the cytoplasmic adaptor protein APAF1 and dATP), activation of caspase-9, and finally the initiation of the executioner phase by cleavage of caspase-3 (Bratton et al., 2001).

Intrinsic apoptosis can be triggered by DNA damage, reactive oxygen species, and accumulation of unfolded proteins in the endoplasmic reticulum (ER) (Galluzzi et al., 2012). The pathways that lead to cellular demise share mechanisms intrinsic to mitochondria. Anti-apoptotic pathways are simultaneously engaged, and the fate of a cell depends on which pathway prevailed. As for intrinsic apoptosis, MOMP dramatically reduces adenosine triphosphate (ATP) synthesis, thereby boosting reactive oxygen species (ROS) production (Aon et al., 2006). MOMP also triggers the release of CYTC, DIABLO, apoptosis-inducing factor (AIF), and endonuclease G (ENDOG) (Leibowitz and Yu, 2010). The assembly of the apoptosome leads to the activation of caspase-9 and cleavage of caspase-3, with subsequent cytoplasmic demise and nuclear fragmentation (Bratton et al., 2001). In some circumstances, AIF and ENDOG translocate to the nucleus and initiate chromatin fragmentation in a

caspase-independent manner (Lartigue et al., 2009). Therefore, the mandatory involvement of mitochondria, the dispensable role of caspases and the bioenergetics and metabolic catastrophe are major characteristics of this form of apoptosis.

Apoptotic Cell Morphology

Once an extrinsic or intrinsic trigger has been delivered, the cell starts to round up, mostly due to retraction of pseudopods and reduction of cellular and nuclear volume (pyknosis), accompanied by modification of cytoplasmic organelles and plasma membrane blebbing (Mills et al., 1999). There is preservation of plasma membrane integrity and exposure of phospholipids, a fundamental “eat-me” signal (Darzynkiewicz et al., 1992; Martin et al., 1995). The executioner phase is characterized by nuclear fragmentation (karyorrhexis) and its disintegration into micronuclei surrounded by plasma membrane, called apoptotic bodies and microparticles (Nagata, 2005). An important last step is the engulfment of the apoptotic cell by resident phagocytes (Wang et al., 2003).

APOPTOSIS IN AUTOIMMUNITY

Abnormalities in the apoptotic process have been linked to a variety of autoimmune diseases, both systemic such as systemic lupus erythematosus (SLE) and organ specific such as primary biliary cirrhosis (PBC).

Defective Apoptosis

The inability to control the immune response via cell death can result in autoimmunity; for example, defects in the extrinsic pathway, such as the lack of Fas in MRL/lpr mice renders lymphocytes resistant to cell death with marked lymphadenopathy and lupus-like disease (Cohen and Eisenberg, 1991). MRL/lpr mice succumb prematurely to severe lupus-like disease and accumulate large numbers of lymphocytes, mostly unusual T cells but also B cells (Kono and Theofilopoulos, 2000). Interestingly, the lack of Fas (or caspase-8) in dendritic cells also leads to lupus-like autoimmunity (Chen et al., 2006; Stranges et al., 2007). Human autoimmune lymphoproliferative syndrome, caused by mutations in the Fas death pathway, is a parallel condition (Drappa et al., 1996; Oliveira et al., 2010). Abnormal expression of apoptotic genes in the intrinsic pathway also results in autoimmunity. Overexpression of the anti-apoptotic Bcl-2 gene or deletion of the pro-apoptotic Bim gene lead to accelerated autoimmunity, due to uncontrolled T and B cell proliferation (Tischner et al., 2011; Strasser et al., 1991; Hutcheson et al., 2008). These findings demonstrate the tight control of autoimmunity by cell death.

Excessive Apoptosis and Apoptotic Cells as Sources of Autoantigen

Apoptotic cell excess can result in systemic autoimmunity or in flares of pre-existing disease, presumably by supplying immunogenic nuclear antigens. Injection of UV-irradiated apoptotic cells induces a rise in antinuclear antibodies in normal mice without glomerulonephritis (Mevorach et al., 1998). Injection of dendritic cells that had phagocytosed apoptotic cells accelerates disease onset in lupus-prone mice while inducing transient expression of autoantibodies in normal mice (Bondanza et al., 2003). These and other studies suggest that apoptotic cells may serve as a source of autoantigens.

Generally, an apoptotic cell is non-inflammatory and induces tolerance; nevertheless there are circumstances during which this type of cell death triggers inflammation and amplifies autoimmune response (Green et al., 2009). For example, the redistribution of nuclear contents into membrane blebs and microparticles allows opsonization by autoantibodies. Uptake via proinflammatory Fc receptors and autoantigen presentation may in turn amplify the autoimmune response (Frisoni et al., 2005). Further, during conditions of excessive apoptosis, dying cells may progress into secondary necrosis due to delayed clearance (Munoz et al., 2009). Secondary necrosis allows the release of proinflammatory “danger signals” (Wu et al., 2001).

Autoimmunity toward nuclear components such as chromatin and ribonucleoprotein (RNPs) complexes is one of the most striking characteristics of systemic lupus erythematosus (Rahman and Isenberg, 2008). Yet these autoantigens are generally protected by the nuclear and the cytoplasm membrane, which shield them from the adaptive immune system. Apoptotic cells redistribute their nuclear material into membrane blebs (Casciola-Rosen et al., 1994; Radic et al., 2004), and these apoptotic cell autoantigens, when engulfed by dendritic cells, may be presented to T lymphocytes (Frisoni et al., 2005).

The cellular components released from dead cells, notably nucleic acids, may further stimulate the autoimmune reaction. Indeed lack of toll-like receptors (TLR) TLR7 or TLR9, receptors for ssRNA and dsDNA, abolishes the production of autoantibodies in several models of lupus-like autoimmunity (Green and Marshak-Rothstein, 2011).

Apotopes

Modifications of antigens on apoptotic cells such as cleavage and post-translational modifications (Rosen and Casciola-Rosen, 1997; Utz et al., 1997) lead to the generation of “apotopes,” a term used to designate epitopes displayed on the surface of early or late apoptotic cells and derived from the translocation of intracellular

autoantigens (Reed et al., 2007). Apotopes are recognized by specific autoantibodies, leading to the formation of pathogenic immune complexes such as IgG-apoptotic cells (Cocca et al., 2002), IgG-blebs (Frisoni et al., 2005), or IgG-microparticles (Beyer and Pisetsky, 2010). The recognition of apotopes by autoimmune IgG can also impair clearance of apoptotic cells by neighboring cells (Reed et al., 2008). Primary biliary cirrhosis (PBC), Sjögren syndrome, neonatal lupus (NL) and systemic lupus erythematosus (SLE) are major autoimmune diseases in which this concept has been demonstrated. In PBC, the E2 component of the pyruvate dehydrogenase complex (PDC-E2) is considered a major autoantigen and biliary epithelial cells (BECs) display PDC-E2 as an apotope on blebs during cell death (Lleo et al., 2011). Importantly, PDC-E2 maintains its antigenicity after it translocates to the cell membrane and is recognized by anti-mitochondrial antibodies (AMA). Subsequently, these complexes activate the innate immune system in multiple ways, resulting in increased TNF-alpha production and autoantigen presentation (Lleo et al., 2009). Apotopes have been also demonstrated in NL, a condition in which the passive transfer of anti-SS-A/SS-B (anti-Ro/anti-La) from the mother to the fetus induces congenital heart block (Buyon et al., 2009). Fetal cardiomyocytes expose these antigens during early and late phases of apoptosis, and they are recognized by anti-SS-A/SS-B, inducing further apoptosis (Tran et al., 2002). The apotope of SS-A is normally masked by cytoplasmic Y RNAs, but during apoptosis Y RNA is cleaved and SS-A translocates to blebs and can be recognized by autoantibodies (Reed et al., 2010).

Lupus autoimmunity is arguably the most diverse; nevertheless autoantibodies are usually directed toward chromatin and its individual components (i.e., DNA and histones), making the nucleosome, the basic unit of chromatin, the most frequent target (Arbuckle et al., 2003).

During apoptosis, chromatin undergoes dramatic changes, with fragmentation into the nucleosomes and polynucleosomes (Nagata et al., 2003). These apotope-bearing fragments also redistribute to the cell membrane into blebs and microparticles and may form complexes with antinuclear antibodies (Frisoni et al., 2005; Radic et al., 2004). These complexes may induce and sustain the autoimmune response and may activate TLRs, the best known receptors that activate innate immunity (Marshak-Rothstein and Rifkin, 2007). Apoptotic blebbing requires rho-associated coil-containing protein kinase 1 (ROCK1) (Orlando et al., 2006). Inhibition of ROCK1 inhibits the redistribution of nucleosomes and the binding of autoantibodies (Frisoni et al., 2005). Inhibition of apoptotic nuclear and chromatin fragmentation leads to milder lupus-like disease in inducible models but to worsened autoimmunity in genetically predisposed ones

(Frisoni et al., 2007; Jog et al., 2012). The results suggest that apoptotic autoantigens might serve both as immunogens but also as tolerogens.

NETosis

The formation and release of neutrophil extracellular traps (NETs) may play a key role in stimulating systemic autoimmunity (Knight and Kaplan, 2012; see Chapter 14). These extracellular structures are made of chromatin, histones, and microbicidal granular proteins and are triggered in neutrophils in response to lipopolysaccharides, granulocyte–macrophage colony-stimulating factor (GM-CSF), and IL-8 (Yousefi et al., 2008). NETosis is caspase independent and depends on the production of NADPH oxidase and ROS.

NETs are triggered by granulomatous vasculitis-associated anti-neutrophil cytoplasmic antibodies (ANCA), and contain their target antigens proteinase-3 (PR3) and myeloperoxidase (MPO) (Kessenbrock et al., 2009). Excess NETosis may play a role in SLE (Knight and Kaplan, 2012). They contain histones and DNA, two major lupus autoantigens, and also danger signals such as HMGB1 and proinflammatory cytokines like IL-17 (Garcia-Romo et al., 2011). Moreover LL37, a neutrophil-derived antimicrobial peptide present in NETs, has been found in complexes with anti-DNA and DNA, and its presence triggers type I interferon (IFN-I) production by plasmacytoid dendritic cells (pDC) (Garcia-Romo et al., 2011). Therefore, in SLE, NETs may provide autoantigens and the milieu necessary to amplify the autoimmune response and tissue damage.

NECROSIS

Swelling of the cytoplasm and intracellular organelles, early loss of membrane integrity, and moderate chromatin condensation are the typical morphological changes of a necrotic cell (Kroemer et al., 2009). Molecular steps regulating this process have led to the term programmed necrosis. Two major examples relevant to autoimmunity are described below.

Necroptosis

This necrotic molecular cascade is dependent on the activation of receptor interacting protein kinase (RIP)-1 and/or its homologous RIP-3 (Degterev et al., 2008; Feng et al., 2007). The best-described trigger of necroptosis is TNFR engagement. Trimerization of TNFR triggers the formation of DISC in which RIP-1/RIP-3 phosphorylation is inhibited by caspase-8; in this setting the molecular cascade proceeds toward apoptosis. In contrast, in the absence or inhibition of FADD or caspase-8, there is

reciprocal phosphorylation of RIP-1 and RIP-3, which stimulates oxidative metabolism via activation of NADPH oxidase (NOX1), with production of ROS and consumption of ATP (He et al., 2009). Excess of ROS and decreased availability of ATP lead to energy collapse and necroptosis (Declercq et al., 2009).

Necroptosis in Autoimmunity

Necroptosis plays a role in sterile inflammation such as ischemia/reperfusion injury and neurological disorders (Rosenbaum et al., 2010). Its inhibition benefits models of stroke, myocardial infarction and Parkinson's disease (Vandenabeele et al., 2010). Nevertheless, necroptosis causes release of damage associated molecular patterns (DAMPs), danger signals derived from dead or damaged cells that activate the innate immune system. Necrotic cells stimulate proinflammatory cytokines in SLE and in inflammatory bowel disease (IBD) (Caricchio et al., 2003; Welz et al., 2011). In mice in which caspase-8 was conditionally eliminated, TNF α -induced Crohn's-like lesions with intestinal mucosal destruction and increased expression of RIP-3 kinase (Welz et al., 2011). The lesions were reversed by pretreatment with Necrostatin-1, a RIP-1 inhibitor (Gunther et al., 2011). Similar lesions in patients with Crohn's disease, especially in Paneth cells, demonstrate necroptosis features, without caspase-3 activation and with increased RIP-3 expression (Gunther et al., 2011). This death pathway is likely to be relevant in both activating the immune system and inducing tissue damage, for example in small-vessel vasculitis and glomerulonephritis.

Parthanatos {Par[poly(ADP-ribosyl)ation] and thanatos (death)}

Poly(ADP-ribosyl)ation of nuclear proteins is an early response to DNA damage in eukaryotic cells (Schreiber et al., 2006). Upon DNA damage, often induced during inflammation by ROS, PARP-1 is selectively activated and uses NAD⁺ to catalyze nuclear protein poly(ribosyl)ation (Luo and Kraus, 2012). If the repair is completed, cells survive, while if DNA damage is extensive, PARP-1 is overactivated, resulting in excessive consumption of NAD⁺. As the cell attempts to resynthesize this substrate, it depletes available ATP, resulting in a sudden reduction of cellular energy and necrosis (Bouchard et al., 2003). PARP-1 also induces a forward loop by poly(ribosyl)ation of AIF which translocates to the nucleus and induces DNA damage and further PARP-1 activation (Moubarak et al., 2007). Interestingly, PARP-1 is also part of necroptosis and contributes to the energy collapse (Jouan-Lanhuet et al., 2012).

Parthanatos in Autoimmunity

Parthanatos is characterized by the release of DAMPs, including HMGB1 (Ditsworth et al., 2007). PARP-1 activation and consequent necrosis participates in the pathogenesis of acute and chronic inflammation by facilitating NF κ B activation and production of TNF α , IL6, and iNOS (Krishnakumar and Kraus, 2010). If PARP-1 is absent or inhibited, there is reduced NF κ B activation and disease severity during septic shock, ischemia/reperfusion injury or collagen-induced arthritis (Eliasson et al., 1997; Soriano et al., 2002; Gonzalez-Rey et al., 2007). Because necrotic lesions are often a key feature of immune-mediated nephropathies, parthanatos may be important in inducing tissue damage. Absence of PARP-1 protects from spontaneous and inducible mouse models of lupus nephritis by decreasing necrotic cell death and *in situ* production of TNF α . As the protection only applies to males, females may use a different necrotic pathway, possibly necroptosis (Jog et al., 2009).

CLEARANCE OF DEAD CELLS

One of the most important tasks of the immune system is the removal of the large number of cells that die every day (Ravichandran, 2011). Efferocytosis (decathelineau and Henson, 2003), from the latin root *effero* for “take to the grave,” is the process of phagocytosis and digestion of dying cells that most cell types can perform, including epithelial cells and fibroblasts, although in mammals efferocytosis is also a primary function of “professional” phagocytes, such as macrophages. Efferocytosis removes apoptotic cells before they release harmful intracellular components and stimulates anti-inflammatory factors to preserve a healthy non-inflammatory environment (Erwig and Henson, 2007). Apoptotic cells are normally cleared with extreme efficiency and rapidity, so their detection *in vivo* is usually possible only when there are defects in their clearance (Scott et al., 2001). Failure to remove dead cells promptly has been shown to predispose to inflammation and autoimmunity in a variety of models and in human lupus, where uningested apoptotic cells are evident in lymphoid tissue (Baumann et al., 2002; Cohen and Caricchio, 2004). Deficient phagocytosis may lead to autoimmunity by allowing the apoptotic cells to undergo secondary necrosis and to release autoantigens and DAMPs activating innate immune cells (Ren et al., 2003). In order to accomplish efficient efferocytosis, phagocytes need to be in close proximity to apoptotic cells and to be able to distinguish apoptotic cells from live or necrotic cells. These two functions are promoted by the find-me signals and the eat-me signals, respectively.

Find-me Signals

Macrophages and dendritic cells are recruited by “find-me” signals released by apoptotic cells that promote the directional migration of phagocytes by establishing a chemical gradient (Nagata et al., 2010; Ravichandran, 2011). Lysophosphatidylcholine (LPC) is released by dying cells upon activation of phospholipase A2 in a caspase-3-dependent way. LPC binds the G protein-coupled receptor G2A on phagocytes; mice lacking G2A develop late-onset autoimmunity (Lauer et al., 2003). Another find-me signal is sphingosine 1-phosphate (S1P), an important sphingolipid involved in several biological processes, from lymphocyte trafficking to immunity and cancer (Orr Gandy and Obeid, 2013). S1P is released by apoptotic cells, and its inhibitor FTY720 is attracting interest in various autoimmune diseases like multiple sclerosis and thyroiditis.

Another chemotactic factor is the soluble fragment of the chemokine fractalkine (CX3CL1), which is cleaved in a caspase-dependent way from the plasma membranes of apoptotic cells. Mice lacking fractalkine receptor CX3CR1 have defective migration of macrophages in germinal centers, where many B cells undergo apoptosis (Truman et al., 2008). The latest molecules proposed as find-me signals are ATP and UTP. These nucleotides are released by early apoptotic cells and recruit monocytes upon triggering P2Y2 receptors (Elliott et al., 2009); mice enzymatically depleted of nucleotides or lacking P2Y2 receptors show deficient phagocyte migration and uncleared apoptotic cells. Early apoptotic cells employ the pannexin family of plasma membrane channels to secrete about 2% of the cellular content of ATP and UTP as a find-me signal, much less than the fraction of these nucleotides released by necrotic cells as DAMP upon loss of plasma membrane integrity. Thus, nucleotides either attract non-inflammatory phagocytes or recruit neutrophils and activate dendritic cells, depending on the amount released. Apoptotic cells may also release “keep-out” signals, like lactoferrin, to avoid the recruitment of proinflammatory cells (Bournazou et al., 2009).

Eat-me Signals and their Receptors

Phosphatidylserine

Phagocytes engulf apoptotic cells because they can recognize specific “eat-me” signals expressed by the apoptotic cells. The anionic phospholipid phosphatidylserine is the best known eat-me signal (Fadok et al., 1992). Healthy cells maintain phosphatidylserine hidden in the inner leaflet of the plasma membrane, while apoptotic cells flip the phospholipid content of their membrane through the inhibition of translocases (flippases) and the activation of

scramblases, and thereby expose phosphatidylserine in the outer leaflet (Nagata et al., 2010). Professional phagocytes and neighboring cells can recognize phosphatidylserine through a number of receptors and engage in phagocytosis. The exposure of phosphatidylserine in the outer membrane is a universal marker of early apoptosis, occurring within 1–2 hours from the apoptotic insult, and is detected experimentally by staining with the soluble molecule annexin V (Ravichandran, 2011). The insertion of phosphatidylserine into the plasma membrane of erythrocytes leads to their phagocytosis by macrophages (Tanaka and Schroit, 1983), and the masking of phosphatidylserine with specific antibodies impairs the clearance of apoptotic cells *in vitro* and *in vivo* (Asano et al., 2004). It is still debated whether phosphatidylserine is *per se* sufficient to induce phagocytosis: indeed, contrary to what was observed in erythrocytes, living cells artificially exposing phosphatidylserine are not efficiently phagocytosed, suggesting that either other still unknown eat-me signals are necessary, or that “don’t eat-me” signals, such as CD31 and CD47, protect living cells from removal (Devitt and Marshall, 2011; Ravichandran, 2011). Moreover, phosphatidylserine can be chemically modified during apoptosis and indeed some phosphatidylserine receptors preferentially bind oxidized molecules.

The binding of phagocytes to apoptotic cells requires cooperation with adhesion molecules for firmer binding, a process defined as “tethering and tickling” (Henson et al., 2001); this has been compared to the immunological synapse and therefore termed the “phagocytic synapse” (Devitt and Marshall, 2011). The molecules able to recognize phosphatidylserine can be divided into two categories: receptors on the plasma membrane of the phagocytes that directly recognize phosphatidylserine and those that instead recognize a bridge, i.e., a soluble molecule that opsonizes apoptotic cells. The first category includes the members of the T cell immunoglobulin and mucin (TIM) family. TIM4 is expressed by macrophages and dendritic cells, while TIM3 is expressed in the spleen by CD8a⁺ dendritic cells, which are antigen presenting cells specialized in cross-priming. TIM receptors may allow dendritic cells to engulf dead cells and present their antigens for immunity. TIM4 deficient mice show persistence of apoptotic bodies, hyperactivated T and B cells, and systemic autoimmunity (Rodriguez-Manzanet et al., 2010). Other possible direct phosphatidylserine receptors are the brain angiogenesis inhibitor 1, expressed in neurons, and Stabilin-2, expressed by endothelial cells in lymphoid organs (Nagata et al., 2010).

The second category of receptors for phosphatidylserine includes receptors that recognize soluble molecules bridging phagocytes and apoptotic cells. Milk fat globule EGF factor 8 (MFG-E8) is expressed by most phagocytes, including tingible-body macrophages, by follicular

dendritic cells in germinal centers, and by epidermal Langerhans cells. MFG-E8 binds phosphatidylserine on the apoptotic cells using its two factor-VIII-homologous C-terminal C1 and C2 domains, and to the integrins $\alpha_v\beta_3$ or $\alpha_v\beta_5$ on the phagocytes using an N-terminal EGF domain carrying an RGD motif (Arg-Gly-Asp) (Nagata et al., 2010). During an immune response, mice deficient for MFG-E8 show accumulation of uncleared apoptotic cells in germinal centers, indicating a non-redundant role for MFG-E8 in the removal of apoptotic cells by tingible-body macrophages *in vivo*. MFG-E8 deficient mice also develop spontaneous lupus-like autoimmune disease, with anti-dsDNA and glomerulonephritis (Hanayama et al., 2004).

Gas-6 and Protein S are two other examples of molecular bridges that opsonize apoptotic cells by recognizing phosphatidylserine and promote their phagocytosis. Gas-6 and Protein S bind to members of the TAM family of tyrosine kinases: Tyro3, Axl, and Mer on phagocytes (Rothlin and Lemke, 2010). These kinases are involved in phagocytosis and in the modulation of the immune function of the phagocytes. Mer is expressed by macrophages, dendritic cells, natural killer (NK) cells, and NK T cells (Behrens et al., 2003). Mer-deficient mice show accumulation of apoptotic cells upon a strong apoptotic stimulus and spontaneously develop SLE-like autoimmunity, characterized by anti-DNA, anti-chromatin, antiphospholipid antibodies, and a mild glomerulonephritis (Cohen et al., 2002). This autoimmune phenotype is more severe in mice lacking all three members of the TAMs, with more intense macrophage activation, swollen joints, and glomerular immune complex deposition (Lu and Lemke, 2001; Cohen and Caricchio, 2004). As seen in MFG-E8 deficient mice and other knockout mice (Cohen and Caricchio, 2004), Mer-deficient mice develop severe autoimmunity in the genetic background of the strain 129, while the phenotype is less striking on the C57BL/6 background, presumably reflecting the allelic polymorphisms carried by the 129 strain that promote autoimmunity (Heidari et al., 2006).

Other Eat-me Signals

Many receptors, such as CD14, CD36, CD68, the LDL-receptor-related protein, the oxidized low density lipoprotein recognizing receptors, and the scavenger receptors, bind dead cells independently from phosphatidylserine (Ravichandran, 2011). Natural IgM antibodies can bind phosphatidylcholine exposed by apoptotic cells and enhance the uptake of apoptotic cells by phagocytes by recruiting C1q and mannose binding lectin (MBL). Studies suggest that these natural IgMs protect against autoimmunity and atherosclerosis by promoting clearance of apoptotic cells and regulating immune activation

(Gronwall et al., 2012). Some receptors for apoptotic cells are organ specific, like surfactant A and D, which may be important in the lung: surfactant D deficient mice spontaneously develop emphysema, possibly because the accumulation of intrapulmonary apoptotic cells promotes inflammation and destruction of the pulmonary parenchyma (Vandivier et al., 2002).

Receptors for Necrotic Cells

The C-type lectins are a large family of proteins and some of them are expressed by innate immune cells and recognize damaged and necrotic cells and pathogens (Sancho and Reis e Sousa, 2012). DNGR-1 is a C-type lectin that is expressed by CD8a⁺ dendritic cells and binds a self-protein, the F-actin component of the cellular cytoskeleton, which, like phosphatidylserine, is normally hidden in the cytoplasm of healthy cells and is exposed extracellularly upon necrotic death. Triggering of DNGR-1 marks the phagocytosed cargo as necrotic and shuttles it for cross-presentation (Sancho and Reis e Sousa, 2012).

LOX-1 is another C-type lectin that recognizes molecules from injured or dead cells such as modified LDL and heat shock proteins, and also facilitates other dead cell recognition receptors such as C-reactive protein and C1q. LOX-1 deficient mice show delayed atherosclerosis and reduced ischemia-induced organ damage, possibly because of decreased inflammation (Sawamura et al., 2012).

Complement is an important player in the recognition of necrotic cells. C1q binds to cells in the late stage of apoptosis and possibly to primary necrotic cells and C1q deficient mice develop a lupus-like disease, with anti-DNA and immune complex-dependent renal disease on the 129 genetic background (Mitchell et al., 2002). Furthermore, C1q deficiency in humans leads to lupus-like disease in nearly all homozygous individuals. Autoantibodies against C1q may also cause a functional deficiency of C1q and may block its binding to dead cells and thus exacerbate SLE disease (Cohen and Caricchio, 2004).

Another class of receptors involved in the recognition of dead cells, either apoptotic or necrotic, is the pentraxins (Bottazzi et al., 2010). The short pentraxins, C-reactive protein (CRP) and serum amyloid P (SAP), are acute phase proteins induced by IL-6 in hepatocytes during inflammation, while the long pentraxin PTX3 is expressed by macrophages, myeloid dendritic cells, neutrophils, and some non-immune cells in response to inflammatory cytokines and TLR ligands. CRP, SAP, and PTX3 bind pathogens and dead cells and promote their complement-mediated killing and phagocytosis. Mice deficient in pentraxins show defective clearance of dead cells and develop lupus (Munoz et al., 2010).

ANTI-INFLAMMATORY EFFECTS OF APOPTOTIC CELLS

Apoptotic cells are normally considered anti-inflammatory not only because they preserve their membrane integrity and so do not release DAMPs but also because they actively provide anti-inflammatory signals to the phagocytes (Erwig and Henson, 2007). Apoptotic cells inhibit phagocyte production of proinflammatory cytokines like TNF α and IL-12 and increase the production of the anti-inflammatory cytokines IL-10 (Voll et al., 1997), TGF- β , prostaglandin E₂, and platelet-activating factor (PAF) (Fadok et al., 1998). Phagocytosis of apoptotic cells polarizes macrophages toward the “alternatively-activated” M2 differentiation state, which is reparative and nonphlogistic, through the production of the anti-inflammatory cytokines TGF- β and IL-10 (Sica and Mantovani, 2012). Many receptors may mediate this anti-inflammatory effect of apoptotic cells.

Indeed, ligation of Mer by apoptotic cells can suppress the response of the innate immune cells to TLR stimulation and proinflammatory cytokines, through the autocrine production of type I interferons and the induction of suppressors of cytokine signaling (SOCS) molecules, dampening the innate and adaptive immune response (Rothlin et al., 2007). Therefore, the autoimmunity in Mer-deficient mice could be ascribed to an excess of autoantigens because of their impaired clearance, with these being presented immunogenically because of the DAMPs released by secondary necrotic cells, and also because of the absence of the anti-inflammatory function of Mer on innate immune cells (Rothlin and Lemke, 2010).

CR3, also known as CD11b or Mac-1, is expressed by macrophages and myeloid dendritic cells and, upon binding apoptotic cells opsonized by the complement component iC3b, it signals anti-inflammatory effects in phagocytes (Behrens et al., 2007). CR3 deficient mice have no defects in apoptotic cell clearance or autoimmunity possibly due to the redundancy of anti-inflammatory signals from apoptotic cells.

Some forms of apoptotic cells are instead proinflammatory, such as those killed by ultraviolet irradiation: such cells express IL-1 α (Caricchio et al., 2003) and activate dendritic cells (Rovere et al., 1998).

IMMUNO-STIMULATORY EFFECTS OF NECROTIC CELLS

Necrotic cells activate dendritic cells and stimulate immune responses *in vitro* and *in vivo* (Gallucci et al., 1999; Matzinger, 2002) through the release of endogenous “danger signals” or DAMPs (Miyake and Yamasaki, 2012; Gallo and Gullucci, 2013). Among these signals,

nucleic acids are crucial in lupus pathogenesis because they are important self-antigens and, either in immune complexes with autoantibodies (Leadbetter et al., 2002) or carried by other chaperones (heat shock proteins, HMGB-1, etc.), they activate innate immunity through TLR7 and TLR9 stimulation (Marshak-Rothstein and Rifkin, 2007). Other DAMPs released by necrotic cells include heat shock proteins, uric acid, and degradation products of the extracellular matrix (ECM). These ECM products, such as hyaluronic acid, fibrinogen, and tenascin-C, are upregulated after tissue injury. Their levels are increased in rheumatoid arthritis (RA) tissues, and their administration induces joint inflammation in mice. Mice deficient in tenascin-C show rapid resolution of inflammation (Goh and Midwood, 2011), suggesting a pathogenetic role for ECM molecules in RA.

Finally, HMGB1 is a DNA-binding protein that stabilizes the nucleosome and regulates transcription (Andersson and Tracey, 2011). It is released by necrotic cells and activates innate immune cells by triggering RAGE, TLR2, and TLR4. Necrotic cells lacking HMGB1 are less stimulatory, and neutralizing antibodies ameliorate inflammation (Bianchi and Manfredi, 2007). HMGB1 can participate in the pathogenesis of RA, SLE, experimental autoimmune encephalomyelitis (EAE), and autoimmune diabetes in NOD mice (Andersson and Tracey, 2011). Inhibition of HMGB1 ameliorates arthritis in animals, while its administration into the joints induces arthritis (Kokkola et al., 2003). In RA patients, HMGB1 levels are increased in serum and synovial fluid, and decrease upon therapies that ameliorate joint inflammation (Zetterstrom et al., 2008). SLE patients have anti-HMGB1 autoantibodies and their levels of serum HMGB1 correlate with disease activity; in animals, the injection of HMGB1–nucleosome complexes induces lupus-like autoantibodies.

A GLIMPSE INTO THE FUTURE

The last 20 years have been pivotal in the investigation of the role of apoptosis and clearance of apoptotic cells in the pathogenesis of autoimmune diseases, while only very recently has necrosis been considered a form of programmed cell death with pathogenic relevance in autoimmunity. The discovery of novel kinds of cell death mediated by novel molecular cascades or programs will certainly advance our understanding of the association between programmed cell death and autoimmunity, and may identify therapeutic targets. Next generation deep sequencing studies will indicate the genetic links between novel forms of cell death and disease and identify the subgroups of patients in the affected human population. This chapter will expand to reflect the complex interactions between death, clearance, and recognition of damage by the immune system.

| Autophagy in Lymphocyte Development and Activation | 258 | References | 261 |
| Antigen Presentation for CD4 ⁺ and CD8 ⁺ T Cell Recognition | 259 | | |

Autophagy is a homeostatic process that enables eukaryotic cells to deliver cytoplasmic constituents for lysosomal degradation, to recycle nutrients, and to survive during starvation (Klionsky, 2007; Levine and Kroemer, 2008). The term autophagy, derived from Greek and meaning “eating of self,” was first coined by Christian de Duve over 40 years ago to explain earlier electron microscopic observations of mitochondrial degradation in double-membrane vesicles, a process that had been named autolysis. In keeping with this clearance function, at least one of the autophagic pathways, called macroautophagy, assists in the restriction and elimination of intracellular pathogens as an innate immune response to viral and microbial infection. In addition, macroautophagy regulates CD4⁺ T cell-mediated immune responses to intracellular self and pathogen-derived proteins by delivering intracellular and extracellular antigens major histocompatibility complex (MHC) class II antigen-loading compartments (MIIC) (Schmid et al., 2007b; Nedjic et al., 2008). Here, we provide an introduction to autophagy as an innate immune defense mechanism, highlight its role in the initiation and execution of adaptive immune responses, and discuss its possible role in the development of autoimmune tissue inflammation.

AUTOPHAGY PATHWAYS

Today, three separate pathways have been identified that transport cytoplasmic content into lysosomes for degradation: microautophagy, chaperone-mediated autophagy (CMA), and macroautophagy which has more particular

relevance to autoimmunity and so is the type given attention in this chapter. Microautophagy is characterized by the uptake of cytoplasmic components at the lysosomal membrane via budding into the lysosome, through poorly defined mechanisms. During CMA, proteins are directly imported into lysosomes through the lysosomal-associated membrane protein 2a (LAMP-2a) transporter (Cuervo and Dice, 1996, 2000) assisted by cytosolic and lysosomal heat shock cognate protein 70 (HSC70) chaperones. Substrates of chaperone-mediated autophagy carry signal peptides for sorting into lysosomes, similar to other protein transport mechanisms across membranes (Agarraberes and Dice, 2001). Macroautophagy is the major route of degradation of cytoplasmic constituents; macroautophagy assembles a vesicle around the cargo, which is destined for degradation. This vesicle, called the autophagosome, envelops its substrate with two membranes. The autophagosome fuses with late endosomes and lysosomes to amphisomes and autolysosomes, respectively. In these fusion vesicles, the inner autophagosome membrane and the autophagosome cargo are degraded by lysosomal hydrolysis.

Two ubiquitin-like systems participate in this process which is mediated by evolutionary conserved proteins known as autophagy-related (Atg) proteins. These ubiquitin-like systems can be monitored as well as targeted to investigate the function of macroautophagy in innate and adaptive immune responses. One of these systems, Atg8/LC3, is processed by the cytosolic protease Atg4 to cleave off five C-terminal amino acids and to make a C-terminal glycine residue (G120) accessible. Atg8/LC3 is then activated by the E1-like enzyme Atg7

and conjugated by the E2-like enzyme Atg3 to phosphatidylethanolamine (PE) on the outside and inside of the assembling autophagosome membrane. Whereas Atg8/LC3 gets recycled from the outer membrane after completion of the autophagosome by Atg4, Atg8/LC3, which is coupled to the inner membrane, stays associated with the autophagic vesicle and is degraded with this membrane by lysosomal hydrolysis. This conjugation of Atg8/LC3 to the autophagosomal membrane might serve two purposes. It facilitates membrane fusion during the elongation of the autophagosome membrane (Nakatogawa et al., 2007; Weidberg et al., 2011). In addition, it allows for recruitment of substrates into autophagosomes via Atg8/LC3 binding anchor proteins (Kirkin et al., 2009). In the other ubiquitin-like system, Atg12 gets coupled through its C-terminal glycine residue (G140) to a lysine residue of Atg5 by the E1- and E2-like enzymes Atg7 and Atg10. The Atg12–Atg5 complex associates with Atg16 and then binds to the outer surface of the isolation membrane. This complex mediates Atg8/LC3 conjugation to the autophagosome membrane as an E3-like enzyme (Fujita et al., 2008). Upon completion of the autophagosome, the Atg5–Atg12–Atg16 complex dissociates from the outer autophagosomal membrane and only Atg8/LC3 remains associated with the completed autophagosome. Autophagosomes then fuse with late endosomes and lysosomes for degradation of their cargo and their intravesicular membranes.

AUTOPHAGY IN INNATE IMMUNITY

As an innate immune response to viral and microbial pathogens, macroautophagy participates in limiting pathogen replication in host cells. Bacteria and parasites that either escape from endosomes and replicate in the cytosol or condition the phagosome to serve as their replication niche—by preventing fusion with lysosomes—have been found to be delivered for lysosomal degradation via macroautophagy (Gutierrez et al., 2004; Nakagawa et al., 2004; Singh et al., 2006). Innate immune responses to microbial antigens are mediated through stimulation of pattern-recognition receptors (PRRs) which include Toll-like receptors, nucleotide-binding and oligomerization domain (NOD)-like receptors, retinoic-acid-inducible gene I (RIG-I)-like helicases, and a subset of C-type lectin receptors which endow cells of the innate immune system with the ability to recognize a large number of molecular patterns expressed by bacteria, viruses, or fungi. Recent data have revealed an intricate, mutual interplay between PRRs and macroautophagy, whereby macroautophagy on the one hand facilitates the recognition of cognate ligands by PRRs by fostering their physical interaction, and on the other hand serves as an immune effector mechanism downstream of PRR stimulation. For example, cytosolic

viral replication intermediates of single-stranded RNA (ssRNA) viruses, recognized by PRRs, are delivered to endosomally located TLR7 by macroautophagy, which results in robust type I interferon-dependent innate immune responses by plasmacytoid dendritic cells (pDCs) (Lee et al., 2007). PRR signaling and cytokines such as interferons (IFNs) and members of the tumor necrosis factor (TNF) family can induce or augment macroautophagy, which might represent a feedback mechanism by which activated T cells augment macroautophagy under inflammatory conditions (Orvedahl et al., 2007; Xu et al., 2007; Delgado et al., 2008).

AUTOPHAGY IN LYMPHOCYTE DEVELOPMENT AND ACTIVATION

In addition to mediating innate, cell intrinsic immunity, the pro-survival function of macroautophagy also contributes to the shaping of immune system components. Most of these immune cells originate from hematopoietic progenitor cells (HPCs). This precursor cell population depends on macroautophagy for its survival (Mortensen et al., 2011; Salemi et al., 2012). Not only HPC cell numbers were not maintained upon targeted deletion of the essential macroautophagy gene Atg7 in HPCs, but also myeloproliferations were observed in the affected mice *in vivo* (Mortensen et al., 2011). This expanded myeloid compartment was probably also responsible for the increased reactive oxygen species (ROS) production, resulting in DNA damage and possibly originating from elevated mitochondria numbers. The decreased lymphocyte compartment in mice with deficient macroautophagy in HPCs already indicated that primarily the lymphocyte compartment among the immune system components is affected by macroautophagy loss. Indeed T and B cell development is compromised when macroautophagy deficiency is targeted to these lineages (Pua et al., 2007, 2009; Miller et al., 2008; Arsov et al., 2011). In mice with Atg6/Beclin-1 deficiency in the hematopoietic lineage, T and B cell precursors are diminished in thymus and bone marrow, respectively, while peripheral T and B cell compartments are largely normal (Arsov et al., 2011). The susceptibility of lymphocyte precursors could result from the biphasic expression of Atg6/Beclin-1 and resulting macroautophagic activity during development, while non-activated T and B cells then again seem to have low macroautophagy levels (Arsov et al., 2008). Upon activation, macroautophagy is then upregulated in peripheral lymphocytes, including T cells (Pua et al., 2007; Arsov et al., 2008). Part of the sensitivity of T cell development towards macroautophagy deletion is due to a requirement for mitochondria clearance (Pua et al., 2009). In absence of this clearance during the transition from thymocytes to

mature T cells, elevated ROS levels and an imbalance in pro- and anti-apoptotic protein expression can be observed. The requirement during T cell activation, however, results at least in part from impaired Ca^{2+} mobilization upon T cell receptors engagement (Jia et al., 2011). While the Ca^{2+} storing endoplasmic reticulum is enlarged, influx of this secondary messenger upon T cell activation is impaired, resulting in reduced immune responses. While in developing B cells the transition from pro- to pre-B cells is affected by macroautophagy loss (Miller et al., 2008; Arsov et al., 2011), among mature B cells only the mostly innate B-1a subset is affected (Miller et al., 2008). In contrast to lymphocyte populations myeloid and DCs seem to be much less affected by macroautophagy deficiency. Along these lines conventional and plasmacytoid DCs are found at normal frequencies, if macroautophagy deficiency is selectively targeted to these leucocyte subsets (Lee et al., 2007, 2010). Therefore, primarily lymphocyte development and their activation are compromised upon downregulation of macroautophagy, which could, for example, result from half-life shortening or partial loss-of-function mutations in essential autophagy genes. The resulting changes in immune system responsiveness could also affect tolerizing mechanisms like regulatory T cell populations.

ANTIGEN PRESENTATION FOR $\text{CD}4^+$ AND $\text{CD}8^+$ T CELL RECOGNITION

In addition to regulating T cell development and activation, macroautophagy also contributes to the shaping of the T cell repertoire via self-protein processing for MHC class II presentation. T cells recognize proteolytic fragments of proteins that are presented on MHC molecules. MHC class I molecules present primarily proteasomal products to $\text{CD}8^+$ T cells, while MHC class II molecules present ligands generated by lysosomal degradation to $\text{CD}4^+$ T cells (Trombetta and Mellman, 2005). Among those peptides that can be eluted from affinity purified MHC class II molecules around 20–30% originate from cytosolic and nuclear antigens (Dengjel et al., 2005), which possibly reach lysosomes by an intracellular route. Interestingly, two mammalian Atg8 homologues of higher eukaryotes LC3 and GABARAP are among the source proteins for natural MHC class II ligands (Dengjel et al., 2005; Suri et al., 2008). MHC class II presentation of these peptides derived from cytosolic and nuclear antigens can be increased by 50% upon starvation, a process that also induces macroautophagy (Dengjel et al., 2005). In contrast, starvation did not affect loading of ligands from membrane bound proteins. Indeed, autophagosomes, which could deliver these self-ligands, frequently fuse with MHC class II containing compartments (MIICs),

which are used for antigen loading (Schmid et al., 2007a; van den Boorn et al., 2011). Furthermore, proteins that are incorporated into autophagosomes due to their fusion with Atg8/LC3 are up to 10-fold better presented on MHC class II molecules than their unmodified counterparts (Schmid et al., 2007a; Comber et al., 2011). These studies indicate that cytosolic and nuclear proteins gain access to MHC class II loading via macroautophagy.

The best characterized among these are the nuclear antigen 1 of the Epstein–Barr virus (EBNA1) and the bacterial transposon-derived neomycin phosphotransferase II (NeoR). EBNA1 is intracellularly processed for MHC class II presentation by Epstein–Barr virus infected B cells (Münz et al., 2000). This processing is executed by lysosomes, because EBNA1 accumulates in cytosolic vesicles upon inhibition of lysosomal proteolysis (Paludan et al., 2005). Furthermore, $\text{CD}4^+$ T cell recognition of EBNA1 expressing B cells is compromised upon RNA silencing of essential macroautophagy genes (Paludan et al., 2005; Leung et al., 2010). Inhibition of nuclear import of EBNA1 increases macroautophagy-dependent MHC class II presentation of this antigen (Leung et al., 2010). NeoR on the other hand is a cytosolic antigen, whose processing for MHC class II presentation is sensitive to macroautophagy inhibition (Nimmerjahn et al., 2003). Vice versa, antigens that are fused to NeoR are more efficiently presented to $\text{CD}4^+$ T cells via macroautophagy (Comber et al., 2011). However, in contrast to EBNA1, nuclear import of NeoR does not compromise its presentation on MHC class II molecules after macroautophagic antigen processing (Riedel et al., 2008). Therefore, nuclear localization by itself does not necessarily protect antigens from processing for MHC class II presentation via macroautophagy, suggesting that the subcompartmentalization of the antigen in the nucleus could dictate if this antigen gains access to the cytosol after nuclear envelope dissociation during mitosis and falls prey to macroautophagy.

Recent studies suggest that macroautophagy also seems to contribute to extracellular antigen processing. Atg5 deficient DCs were found to process pulsed antigen less efficiently onto MHC class II, but equally well onto MHC class I molecules when compared to their wild-type counterparts (Lee et al., 2010). This defect correlated with slower phagosome maturation, possibly due to less efficient fusion with lysosomes. Indeed, Atg8/LC3 recruitment to phagosomes has been suggested to facilitate their fusion with lysosomes (Sanjuan et al., 2007; Florey et al., 2011). Alternatively, autophagosomes could also directly deliver processing enzymes to phagosomes to increase antigenic peptide formation. Along these lines it was reported that peptidylarginine deiminase (PAD), which citrullinates endocytosed proteins and thereby gives rise to autoantigens that are recognized in some

autoimmune diseases, like rheumatoid arthritis, reaches phagosomes via macroautophagy (Ireland and Unanue, 2011). Thus, support of extracellular antigen processing by the molecular machinery of macroautophagy could result from Atg8/LC-assisted fusion with lysosomes or processing enzyme delivery to phagosomes by autophagosomes.

While most of the available information points towards a role of macroautophagy for antigen processing towards MHC class II presentation, few studies also implicate this pathway in MHC class I-mediated antigen presentation to CD8⁺ T cells. Along these lines, late during herpes simplex virus (HSV) infection of macroautophages it was observed that autophagosomes engulf viral capsids at the outer nuclear membrane (English et al., 2009). Inhibition of macroautophagy in these cells diminished MHC class I-mediated recognition of these HSV-infected cells by CD8⁺ T cells. Furthermore, antigen donor cells seem to more efficiently package antigen for cross-presentation onto MHC class I molecules via macroautophagy (Li et al., 2008; Uhl et al., 2009). Moreover, aggregated proteins are redirected towards proteasomal degradation and MHC class I antigen processing in the absence of macroautophagy (Wenger et al., 2012). And finally, macroautophagy seems to promote the formation of cross-presenting compartments in macrophages and DCs (Luca et al., 2012). Therefore, macroautophagy seems to contribute to compartments which are beneficial for antigen processing onto MHC class I, namely nuclear membrane-derived autophagosomes, cross-presentation compartments, or exosomes for antigen transfer. Which of these pathways significantly contributes to antigen presentation to CD8⁺ T cells *in vivo* will be an interesting topic for future studies.

AUTOPHAGY IN TOLERANCE AND AUTOIMMUNITY

The first *in vivo* situation that was identified to involve macroautophagy-mediated antigen processing for MHC class II presentation is thymic T cell selection. Recognition of self-antigen-derived epitopes presented by MHC class II molecules on thymic epithelial cells (TECs) is critical for the generation of a functional and self-tolerant CD4⁺ T cell repertoire. TECs shape the T cell repertoire to recognize self-peptide/MHC complexes with low affinity by a process called positive selection and weed out T cells that react to these self-structures with high affinity by negative selection (Kyewski and Klein, 2006). Even though they express MHC class II molecules to fulfill these functions for CD4⁺ T cells, their endocytic capacity is low, but autophagosomes also fuse in these cells frequently with MHCs (Kasai et al., 2009). Indeed,

when positive selection of TCR transgenic T cells through macroautophagy deficient thymi was investigated, only some T cell specificities were correctly selected, while others were deleted and loss of macroautophagy in TECs resulted in severe colitis and multi-organ inflammation (Nedjic et al., 2008). Changes in the MHC class II-presented peptide repertoire were visualized by an elevated presentation of a membrane bound protein in the absence of macroautophagy. In contrast, positive selection of CD8⁺ T cells was not macroautophagy dependent. These data suggest that macroautophagy processes some self-ligands for MHC class II presentation that are involved in positive T cell selection in the thymus and thereby contributes to the generation of a self-tolerant T cell repertoire. In addition to its function in central tolerance induction, we find considerable macroautophagy in immature DCs (Schmid et al., 2007a), which have been implicated in peripheral tolerance induction (Steinman et al., 2003).

Another possible link between macroautophagy and autoimmune tissue inflammation independent from antigen presentation is the role of macroautophagy in the removal of apoptotic cell corpses. Rapid removal of apoptotic cell material is thought to be crucial for the prevention of tissue inflammation. Efficient elimination of apoptotic bodies during programmed cell death involves exposure of phosphatidylserine (PS) on the surface and release of lysophosphatidylcholine (LPC) by apoptotic cells. Apoptotic cells, which did not express Atg5 or Beclin-1 genes, failed to expose PS at the cell surface, and produced lower levels of LPC compared to the wild-type counterpart (Qu et al., 2007). Defective clearance of apoptotic cells has long been suggested to drive autoimmunity in patients with systemic lupus erythematosus and other autoimmune diseases (Bratton and Henson, 2005, and see Chapter 17). Therefore, macroautophagy might prevent inflammatory tissue damage and the generation of autoimmune effector responses owing to sensitization of dying cells for early recognition and non-inflammatory removal. In addition, macroautophagy might be crucial in the induction and maintenance of CD4⁺ T cell tolerance through thymic T cell repertoire selection and by mediating peripheral CD4⁺ T cell tolerance toward self-antigens.

FUTURE PROSPECTS

Macroautophagy in thymic epithelial cells contributes to CD4⁺ T cell selection and is essential for the generation of a self-tolerant T cell repertoire. However, some auto-reactive lymphocytes escape central tolerance induction, exit the thymus and enter the periphery as mature T cells. These circulating autoantigen-specific T cells are thought to play a key role in the initiation and perpetuation of

many autoimmune diseases. Peripheral mechanisms of self-tolerance include deletion or abortive activation of autoreactive lymphocytes by APCs that express low levels of costimulators. It is currently not known whether autophagy, in addition to its function in thymic T cell selection, is involved in peripheral tolerance maintenance and which types of APCs preferentially use autophagy to regulate T cell responses.

Recent studies also suggested a role for macroautophagy in regulating intracellular antigen processing for MHC class I presentation and in packaging antigens for optimal cross-presentation on MHC class I molecules. While these additional pathways require further investigation to understand the underlying mechanisms, autophagy-mediated antigen delivery to both MHC class II and MHC class I molecules should be explored for its potential to limit inflammatory tissue damage in T cell-driven autoimmune disease and to increase the efficacy of antigen-specific tolerization strategies. Future studies might provide a more precise understanding of how and by which mechanisms autophagy regulates T cell immunity and tolerance during health and disease *in vivo* and how this pathway could be harnessed for immunotherapy.

INTRODUCTION

The immune system has evolved multiple mechanisms over millennia that allow it to distinguish between self- and non-self-recognition, which are critical for host preservation. Deficits in self-/non-self-discrimination can result in opportunistic infections or, on the other side of the coin, immunological overreactivity resulting in immunopathology and autoimmunity. It is therefore not surprising that multiple genetic loci that influence activation and regulation of the immune system are associated with triggering autoimmune diseases; however, clinical symptom development may only manifest after viral infections. How infection triggers autoimmunity is likely to involve multiple pathways that converge to trigger overt disease. Unfortunately, this also implies that self-reactive immune responses may be triggered by one or more pathogens. Together these factors make it difficult to associate distinct pathogens and immune response pathways with particular autoimmune diseases. Therefore, this review will discuss mechanisms through which host–pathogen interactions may trigger autoimmune disease and the mechanisms by which autoimmune disease could

alter the ability of the host to control infections and regulate the immune system.

ROLE OF INFECTIONS IN PRIMING OF AUTOREACTIVE IMMUNE RESPONSES

At the level of the innate immune response, defense against invading pathogens is initially mediated by the activation of germline-encoded receptors known as pattern recognition receptors (PRR). These molecules, expressed by various cells of the innate immune system, recognize a multitude of pathogen-associated molecular patterns (PAMPS) and include Toll-like receptors (TLRs), nucleotide-binding and oligomerization domain (NOD)-like receptors (NLRs), (RIG-I)-like helicases (RLH), and a subset of C-type lectin receptors (CLR) (reviewed in Ishii et al., 2008). The signaling pathways triggered by engagement of these molecules culminate in cellular activation, the production of type I interferons, costimulatory molecules, inflammatory cytokines, and chemokines, all of which combine to initiate and direct the antimicrobial immune response. Both pathogenic antigens and

PRR-triggered inflammatory molecules drive the expansion of pathogen-specific T and B cells. Thus, by triggering PRRs, stimulating early cytokine responses by the innate immune system and enhancing the function of antigen presenting cells (APCs), pathogens act as adjuvants for the immune response, while at the same time providing an antigen source to drive T cell activation and effector function. Within this highly inflammatory environment, regulation is critical, with the failure of immune checkpoint regulation potentially resulting in bystander tissue damage and even death. It has been shown that overactive immune responses can cause fatal immune-mediated pathology in viral infections such as those caused by West Nile Virus (WNV) (Terry et al., 2012), or the generation of myelin-specific autoimmunity as observed in mice with cerebral Theiler's murine encephalomyelitis virus (TMEV) infection (Munz et al., 2009). Excluding pathogenic mechanisms driving immune pathology that do not have an antigen-specific component, there are several postulated mechanisms by which pathogenic infections can trigger autoimmune disease, most of which are supported by substantial evidence from animal models.

POTENTIAL MECHANISMS OF INFECTION TRIGGERING AUTOIMMUNITY

Molecular Mimicry

The idea that T cell receptors (TCRs) specific for microbes may cross-react with other self antigens was a concept originally brought forth by Fujinami and Oldstone (Fujinami and Oldstone, 1985, 1989). The degeneracy of antigen recognition by the TCR is now well understood, and the ability of foreign antigens to subsequently stimulate T cells that are also cross-reactive with (mimic) self antigens is very likely (Figure 19.1A). T cells have the capacity to respond to a variety of different peptides that are quite distinct from each other and peptides bound to different major histocompatibility complex (MHC) molecules can lead to cross-reactivity by the same TCR as long as the complexes share similarity in charge distribution and overall shape (Hammer et al., 1993; Gautam et al., 1994; Wucherpfennig et al., 1994; Wucherpfennig and Strominger, 1995; Hemmer et al., 1999; Lang et al., 2002; Gregersen et al., 2006). This has been further highlighted in the transplant setting where allogeneic T cell responses are stimulated by regions of the MHC molecule outside of classical peptide binding motifs critical for TCR restriction. While potentially detrimental, with respect to allograft and autoantigen recognition, this flexibility is central to many homeostatic immunologic processes, including thymic selection and the ability to generate a broad TCR repertoire capable of recognizing pathogen-derived peptides. Notwithstanding, *in vitro* studies have shown that viral peptides having some degree of

homology with self peptides can stimulate autoreactive T cells (Wucherpfennig and Strominger, 1995).

Animal models in which molecular mimicry may be a trigger of autoimmune disease are abundant. These include: Theiler's murine encephalomyelitis virus-induced demyelinating disease (TMEV-IDD), a model of human multiple sclerosis (MS) in which intracerebral TMEV infection of mice leads to an autoimmune demyelinating disorder 30–40 days post-infection (Croxford et al., 2002); *Acanthamoeba castellanii*-induced experimental autoimmune encephalomyelitis (EAE) in Swiss James Lambert (SJL) mice (Massilamany et al., 2010, 2011); herpes simplex virus (HSV) stromal keratitis, in which HSV infection leads to T cell-mediated blindness in both humans and mice; diabetes model(s); autoimmune demyelinating disease and Semliki forest virus (SFV) (Mokhtarian et al., 1999); autoimmune myocarditis associated with coxsackievirus infection (Gauntt et al., 1995); and others (Lawson, 2000). Furthermore, there exist multiple less physiological scenarios that do not necessarily aim to closely model a particular disease but highlight the potential mechanisms through which immune responses to infections could lead to autoimmunity through molecular mimicry (Table 19.1).

Multiple investigations have employed models of molecular identity, in which an exact microbial protein/epitope is transgenically expressed in a particular tissue. Under these conditions, animals are not generally susceptible to development of spontaneous autoimmune disease. Upon infection with the microbe containing the protein, however, autoimmunity in the transgenic protein-expressing organ ensues (Ohashi et al., 1991; Oldstone et al., 1991; von Herrath et al., 1994; Evans et al., 1996). Though some aspects of these approaches are perhaps predictable, they clearly indicate that T cells specific for a “self” antigen can become activated by infection with a microbe containing an identical antigen and which provides appropriate innate immune signals resulting and subsequently results in overt autoimmune disease. Even when the transgene-expressed antigen is also expressed within the thymus, so that normal mechanisms of negative selection significantly diminish the number of high affinity T cells specific for the viral/self antigen, infection eventually results in autoimmunity (von Herrath et al., 1994). These experiments indicate that even T cells with low affinity for a self antigen, as would be the case for many self antigen-specific responses, can be activated through molecular mimicry with a microbial antigen and cause disease. Similarly, in the TMEV-IDD model of MS, a severe rapid-onset central nervous system (CNS) demyelinating disease is induced by intracerebral or peripheral infection with TMEV that has been engineered to express the immunodominant myelin proteolipid protein (PLP)139–151 epitope (Olson et al., 2001).

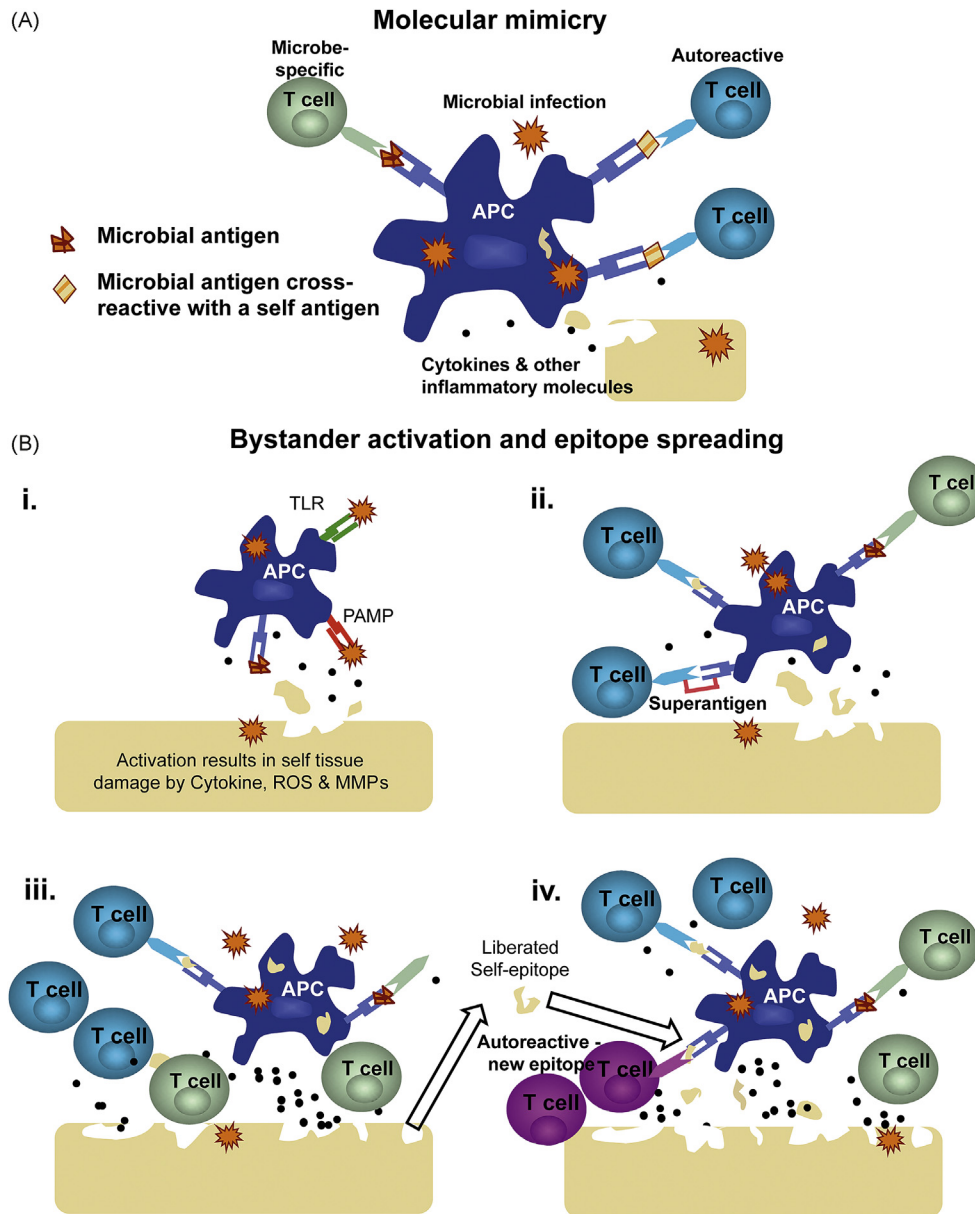

FIGURE 19.1 Mechanisms of infection-induced autoimmunity.

(A) *Molecular mimicry* occurs through cross-reactive recognition between a microbial antigen/self MHC complex and a self antigen/self MHC complex. (B) i, Microbial pathogen associated molecular patterns (PAMPs) stimulate an immune response leading to tissue destruction via inflammatory mediators originating from cells of the innate immune system. ii, During *bystander activation*, engulfment of self tissue debris leads to self antigen presentation to autoreactive T cells (concomitant with presentation of virus antigen to virus-specific T cells). Alternatively an infection can lead to microbial *superantigen*-induced activation of a subset of T cells, some of which are specific for self antigen. iii, T cell-mediated tissue destruction along with innate immune cell-derived inflammatory molecule-mediated destruction leads to release of endogenous self epitopes from tissue. iv, During *epitope spreading*, the response spreads to T cells specific for additional endogenous self antigens. TLR—Toll-like receptor; PAMP—pathogen-associated molecular pattern; ROS—reactive oxygen species; MMP—matrix metalloproteinase.

Several bacterially- and virally-derived peptides that mimic PLP_{139–151} have been identified (Carrizosa et al., 1998), and these have been used in models that more directly address the possibility of molecular mimicry-induced autoimmune disease. TMEV engineered to express peptides derived from *Haemophilus influenzae* (TMEV-HI—sharing 6/13 amino acids) or murine hepatitis virus (TMEV-MHV—sharing only 3/13 amino acids), induces a rapid onset, severe demyelinating disease that is similar to that induced by infection with TMEV containing PLP_{139–151} itself (Olson et al., 2001; Croxford et al., 2006). The *H. influenzae* mimic can also be processed and presented out of its own native flanking sequences

when larger portions of the bacterial protein are expressed in TMEV, more rigorously supporting a potential role for molecular mimicry in a natural infection (Croxford et al., 2005). Relevant to human disease, bacterially-derived peptide mimics of the myelin basic protein (MBP) 85–99 epitope induce demyelinating disease in mice that transgenically express a human MBP_{85–99}-specific TCR as well as a humanized MHC class II molecule (Greene et al., 2008). Molecular mimicry was also demonstrated in a model of diabetes in which lymphocytic choriomeningitis virus (LCMV) nucleoprotein (NP) was expressed under the rat insulin promoter (RIP). Infection with Pichinde virus, which contains an epitope that mimics a

subdominant epitope within the LCMV NP, accelerated autoimmune disease that had already been established by previous infection with LCMV (Christen et al., 2004). HSV-induced stromal keratitis is mediated by anti-corneal antigen-specific T cell responses that are induced upon corneal HSV infection. This is a non-synthetic, natural model of autoimmune disease in which molecular mimicry can occur in the absence of genetic manipulation (Zhao et al., 1998). Though the results from these experiments were called into question by a later study in which HSV-induced stromal keratitis could be induced in mice in the absence of T cell responses against HSV (Deshpande et al., 2001), since different model systems

were used, the strong case for molecular mimicry put forth by the former study, in particular the genetic contribution to it, has yet to be ruled out (Benoist and Mathis, 2001).

In addition to these animal models, patients with autoimmune diseases such as systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), and multiple sclerosis (MS) show higher frequencies, activation states and/or less costimulatory requirements of self-reactive lymphocytes (Lovett-Racke et al., 1998; Markovic-Plese et al., 2001; Bielekova et al., 2004; Samuels et al., 2005; Yurasov et al., 2005). In MS, receptor analysis of T and B cells in CNS tissue and cerebrospinal fluid (CSF) demonstrated

clonal expansions in both populations, indicating clonal reactivity to a restricted number of disease-relevant antigens (Baranzini et al., 1999; Babbe et al., 2000; Skulina et al., 2004) and longitudinal studies provided evidence for long-term persistence of individual myelin-specific T cell clones tracked over several years in the blood of patients with MS (Meinl et al., 1993; Goebels et al., 2000; Muraro et al., 2003), indicating a strong, persisting memory response and/or ongoing autoantigen exposure at least for a subset of myelin-reactive T cells in MS.

These memory responses may reflect, at least in part, persisting clonal expansions of poly-specific T cells recognizing both self and virus antigens that have been found associated with human autoimmune diseases (Table 19.2). For example, the high viral loads that occur during symptomatic primary Epstein-Barr virus (EBV) infection, infectious mononucleosis (IM), are associated with an increased risk of developing MS (Thacker et al., 2006; Nielsen et al., 2007), and could prime these poly-specific T cell responses. Viral titers in circulating blood

cells from patients with MS are, however, similar to those detectable in healthy virus carriers (Lunemann et al., 2006) and patients with MS do not differ from healthy EBV carriers in the rate of EBV-induced B cell transformation or in their ability to control outgrowth of EBV-infected B cells *in vitro* (Lunemann et al., 2008c). This argues against an increased viral replication or impaired immune control of chronic EBV infection in MS. Yet, patients with MS show predominant expansions of T cells specific for the EBV-encoded nuclear antigen 1 (EBNA1), the most consistently recognized EBV-derived CD4⁺ T cell antigen in healthy virus carriers, and EBNA1-specific T cells recognize myelin antigens more frequently than other autoantigens not associated with MS (Lunemann et al., 2008c). Notably, myelin cross-reactive T cells produce IFN- γ but differ from EBNA1-monospecific cells in their capability to produce interleukin-2, indicative of poly-functional T cells, which are thought to be particularly important under conditions of antigen persistence and high antigen load because they are less susceptible to exhaustion or activation-induced cell death (Harari et al., 2007). Consistent with these considerations, a more extensive priming of poly-functional cross-reactive T cells during symptomatic primary EBV infection with high viral loads, and continuous restimulation caused by autoimmune tissue inflammation could potentially establish and maintain a distinct repertoire of myelin-reactive virus-specific T cells, which could predispose to MS.

Bystander Activation of Autoreactive Cells and Epitope Spreading

APCs activated within the inflammatory milieu of a pathogenic infection can stimulate activation and expansion of auto-reactive T or B cells in a process known as bystander activation. In this case, APCs present self antigen, obtained subsequent to tissue destruction and/or uptake of local dying cells, to autoreactive cells (Walker and Abbas, 2002; Zipris et al., 2005) (Figure 19.1B). Related to this concept is the mechanism of epitope spreading, a situation in which an immune response, initiated by any number of stimuli including microbial infection, trauma, transplanted tissue, antitumor responses, or autoimmunity, spreads to include responses directed against a different antigen on the same protein (intramolecular spreading) or on a different protein (intermolecular spreading) (Figure 19.1B). Activating a broader set of T cells through epitope spreading is helpful in an antipathogen or antitumor response, but disease may potentially arise when spread to and within self proteins occurs subsequent to self tissue destruction. Epitope spreading in animal models

proceeds in an orderly, directed, and hierarchical manner, such that more immunodominant epitopes elicit responses first, followed by less dominant responses. This type of spreading has been shown in EAE, a non-infectious model of MS (McRae et al., 1995; Yu et al., 1996), as well as in TMEV-IDD (Miller et al., 1997; Borrow et al., 1998; Katz-Levy et al., 1999, 2000), and in the non-obese diabetic (NOD) mouse model of type 1 diabetes (Kaufman et al., 1993; Prasad et al., 2012).

An even broader bystander activation is achieved by cross-linking T cell receptors of a given V β domain with microbial-derived superantigens presented by MHC class II molecules on APCs. The polyclonal population of T cells stimulated in this fashion could potentially contain a subset of T cells specific for a self antigen (Wucherpfennig, 2001). This mechanism is potentially highly relevant in the human context, where, unlike mice, T cells express human leukocyte antigen (HLA) and can present antigen to each other. In addition, there are multiple examples where superantigens have been shown to influence pathogenesis of diseases such as EAE, arthritis, and inflammatory bowel disease, making superantigens another mechanism by which bystander activation can initiate, or minimally exacerbate, autoimmunity in mouse models (Brocke et al., 1993; Cole and Griffiths, 1993; Dalwadi et al., 2001) (Table 19.1). Furthermore, association of certain genotypes of the superantigen-encoding endogenous retrovirus HERV-K18, which is transactivated by EBV (Sutkowski et al., 2001), with MS has been reported (Tai et al., 2008). However, V β 7 and V β 13 positive T cells, which are stimulated by the retroviral superantigen, do not seem to be selectively expanded in MS patients. Nevertheless, viral antigen-specific and/or superantigen-expanded T cells might participate in the development or maintenance of autoimmune disease.

Emerging Mechanisms of Infection-Induced Autoimmune Disease

Infections affect the immune response in many ways, and mechanisms such as molecular mimicry and bystander activation are certainly not the only ways in which pathogens trigger or accelerate autoimmune disease. A recent study showed that in a spontaneous animal model of SLE, lipid raft aggregation on T cells, which was induced by cholera toxin B from *Vibrio cholerae* in the study but could be induced by a number of microbes or toxins, enhanced T cell signaling and exacerbated SLE (Deng and Tsokos, 2008; James and Robertson, 2012). Furthermore, viral infections could also directly maintain autoreactive effector cells or autoantigen presenting cells (Pender, 2003). For example, EBV immortalizes B cells

and assists in their differentiation to long-lived memory B cells (Thorley-Lawson and Gross, 2004). In addition, even in infected memory B cells that usually do not express latent EBV proteins, non-translated viral RNAs contribute to resistance to cell death (Nanbo et al., 2002). These mechanisms could preserve autoreactive B cells or a reservoir of APCs capable of presenting autoantigens to promote autoimmunity. The reservoir of EBV-infected B cells that were recently described in submeningeal aggregates of MS brains could fulfill these functions (Serafini et al., 2007).

An important consideration is the fact that in most cases viruses and other microbes can infect a host without triggering any clear clinical symptoms. This has further hampered direct linkage of infection with specific autoimmune disease development. This fact, combined with the ever-increasing number of pathways through which pathogens have been shown to be capable of hijacking a host immune response, certainly suggests that consideration of other viral infections and changes in pathogen–host interactions should be considered. One potential pathogen that has spread significantly in the last decade is WNV (King et al., 2007). WNV employs some unusual host evasion strategies that, while designed to circumvent the immune response, may indirectly result in bystander self-reactive T cell activation. WNV replicates about 10-fold greater in cycling cells, but seemingly paradoxically increases MHC expression as well as expression of adhesion molecules like ICAM in quiescent cells (King et al., 2007). This decoy mechanism is thought to promote immune-mediated killing of low virus yielding G_0 cells rather than infected proliferating cells, which support virus replication better. Along the lines invoked for EBV infection, therefore, this raises the possibility that WNV infection generates poly-specific T cells, by increasing the avidity of interaction between T cells and infected cells via increased MHC expression, and that infection activates an array of T cell clones that range from those with high affinity for MHC/virus peptide to those with significant cross-reactivity for self. In the case of WNV, this cross-reactivity of low affinity anti-viral T cells with self has been demonstrated in a mouse model (King et al., 1989; Mullbacher et al., 1991). A direct link between WNV and autoimmunity in humans remains to be made, and is complicated by the fact that over 90% of WNV cases are asymptomatic. Notwithstanding, the WNV example serves to show that there are numerous potential mechanisms through which immune responses to infections result in or accelerate autoimmune diseases. Since evidence of autoimmunity is likely to become clinically apparent only after a considerable period of subclinical autoimmune responses, pathogen-derived triggers may be difficult to identify.

Reciprocal Relationships of Pathogen-Derived Mechanisms of Autoimmunity

All of the above described mechanisms are interrelated, non-mutually exclusive, and dynamic, so the idea of microbial infection eliciting autoimmunity must be viewed not as a defined event that occurs via a particular mechanism, but as a process that can occur through many pathways simultaneously and/or sequentially. For example, epitope spreading can be initiated via molecular mimicry, as illustrated by the activation of PLP_{178–191}-specific T cells in SJL mice in which autoimmunity was induced by infection with TMEV expressing PLP_{139–151} (Olson et al., 2001), or following bystander damage. Molecular mimicry can initially activate autoreactive T cells that then expand and become pathogenic via bystander activation, or vice versa. As a result, it can be difficult to distinguish among all of the postulated mechanisms, even in seemingly simple animal models (Fujinami and Oldstone, 1985; Benoist and Mathis, 2001; Deshpande et al., 2001; Fujinami et al., 2006).

HOW DO THESE MECHANISMS LEAD TO AUTOIMMUNE DISEASE?

Animal model studies have made it clear that, in principle, infections can trigger autoimmune responses. This must be distinguished, however, from the elicitation of overt autoimmune disease as a direct result of microbial infection, which may be more difficult to establish.

Autoreactive adaptive immune cells are unavoidably present in the periphery in humans and animals. These cells may exist because their cognate self antigen was not expressed in the thymus and will therefore only become apparent to the immune system following tissue destruction as a result of infection or trauma. Alternatively, while many autoreactive T cells are deleted in the thymus during development, some T cells that make their way to the periphery may be highly specific for a microbial antigen, but also have lesser affinity for a self antigen. The presence of autoreactive cells in the periphery, however, does not necessarily predispose to clinical autoimmune disease.

It is clear that in many cases an infection is necessary for the development of overt disease, even when abundant autoreactive T cells are present. This is cogently exemplified by the following. Although both priming with PLP_{139–151} peptide in complete Freund's adjuvant (CFA) and infection with TMEV expressing a PLP_{139–151} mimic readily induce demyelinating disease, priming with PLP_{139–151} mimics in CFA does not induce overt disease, despite the fact that T cells from these mice robustly respond to PLP_{139–151} (Carrizosa et al., 1998; Croxford et al., 2006; Walker and Abbas, 2002). Presumably, TLR

engagement and other innate immune stimuli that are present upon infection with TMEV expressing the mimic peptide allow APC to provide the necessary signals for full-blown activation and optimal migration of pathogenic Th1 and Th17 autoreactive T cells (Olson and Miller, 2004). However, the nature of a pathogen, which directs the type of immune response elicited, profoundly influences the potential for development of autoimmune disease, and could in fact enhance *or* inhibit the likelihood of autoimmunity in the presence of autoreactive cells. Also, in the case of molecular mimicry, the virus-encoded mimic itself plays an important role, as a peptide that partially mimics a self antigen (altered peptide ligand), depending on the context of the infection, could have a tolerizing rather than an immunizing effect (Olson and Miller, 2004).

Even the presence of autoreactive T cells along with the presence of an appropriate infection may not lead to autoimmune disease. In the Pichinde virus infection of RIP-LCMV-NP mice, while the mimic-encoding Pichinde virus was not sufficient to initiate overt autoimmunity, it was able to accelerate autoimmune disease that had already been established by infection with LCMV (Christen et al., 2004). Thus, viral “adjuvant” and self mimics may in some cases be able to trigger autoimmune disease only if autoreactive cells are already “primed” to some degree, such that autoreactive T cells that have been previously activated exist at a higher precursor frequency (Hamilton-Williams et al., 2005). The affinity of T cell receptors for various self peptide/MHC complexes may also play a key role in the development of autoimmune disease. Indeed, a threshold level of TCR affinity has been shown to be important for the establishment of autoimmunity (Gronski et al., 2004). In RIP-LCMV mice, whether or not the self antigen was expressed in the thymus during development (thus affecting T cell affinity) has a significant impact on the speed with which autoimmune disease develops (von Herrath et al., 1994). TLR engagement alone can be sufficient for the development of autoimmune disease if autoreactive T cells are of high enough affinity for self antigen (von Herrath et al., 1994; Lang et al., 2005). However, since most T cells will have low affinity for self, studies in which TCR affinity for self antigen is low may have greater relevance to human autoimmune disease.

Thus, the potential for the development of overt disease is dependent on the presence of autoreactive T cells. However, whether overt disease actually occurs may depend on various other coincident events, including the number, avidity, and affinity of autoreactive T cells, and the presence of innate inflammatory signals required for activation and differentiation of those T cells to a pathogenic phenotype. Despite the requirement for all of these elements, it is apparent that these events do not

necessarily need to happen at the same time or in the same place to elicit autoimmune disease.

Autoimmunity Can Occur at a Site Distal to the Initiating Infection

In many animal models, autoimmune responses are triggered during the initial or acute response to an infection, and autoimmune disease occurs exclusively in the infected organ. Along these lines, submeningeal reservoirs of EBV infected B cells have been reported in the brains of patients with MS (Serafini et al., 2007), but it remains unclear if these focus the pathogenic immune response on the diseased tissue. Models, in which infection directs autoreactive responses to distinct tissues, provide a simple system in which to study the pathologic mechanisms of infection-induced autoimmunity. However, in most cases a robust immune response to a pathogenic infection within the target organ is usually not easily associated with the development of autoimmunity in humans. None of the proposed mechanisms for the development of infection-induced autoimmunity exclude the possibility that disease can occur temporally and/or spatially distal from the site of the initiating infection. Animal models that allow study of this aspect of infection-induced autoimmune disease are few, but may provide important insights relative to human disease.

Autoimmune CNS demyelinating disease can be triggered via molecular mimicry when the pathogen containing the mimic epitope does not infect the CNS itself. When mice that express an LCMV protein within the CNS were peripherally infected with LCMV, autoimmune responses occurred within the CNS despite the fact that LCMV was not detectable in that organ (Evans et al., 1996). In non-transgenically manipulated mice, pancreas-tropic coxsackievirus engineered to express PLP_{139–151}, induces CNS demyelinating disease associated with PLP_{139–151}-specific T cell responses, also in the absence of any infection within the CNS itself (S.D. Miller, in preparation).

The fact that the various mechanisms for infection-induced autoimmunity discussed here are non-mutually exclusive make them both more complicated and more plausible as potential causes for human autoimmune disease. As we consider the potentially multi-mechanistic nature of autoimmunity, it is important to remember that an established autoimmune response can also have effects on pathogen-directed immune responses occurring in the same organ or elsewhere in the body.

CONCLUSIONS

Inherent genetic susceptibility plays a major role in determining susceptibility to the development of autoimmune diseases; however, epidemiological and animal studies

have clearly shown that infection is an equally important factor in the generation of autoimmune disease. Potential mechanisms by which infections can induce autoimmune disease include molecular mimicry, bystander T cell activation culminating in epitope spreading, as well as potential roles for microbial toxins and virus-induced decoy of the immune system.

INTRODUCTION

Vaccines are essential components of any public health program. Their beneficial effects have been largely recognized and vaccination is generally considered as the most cost-effective approach in preventive medicine. Therefore vaccines are used extensively and coverage can reach over 90% in a given population. Since autoimmune diseases affect approximately 5–10% of the population in Europe and North America, most people that develop an autoimmune disease are likely to be exposed to some vaccines at some time before or after the onset of the disease process. While earlier vaccines were mainly targeted for pediatric age groups, the development of recent vaccines for adolescents (e.g., human papillomavirus vaccine (HPV)) and older individuals (e.g., pneumococcus and influenza) has increased the probability of coincidental associations of vaccination with autoimmune diseases.

Two major questions are of particular relevance to vaccination and autoimmune diseases. First, can vaccination trigger or enhance autoimmune responses? This

frequently expressed concern is based either on a putative mimicry between vaccines and host antigens or on the fact that vaccination is associated with a transitory and variable activation of innate immunity. The use of adjuvants exploiting the immunostimulatory effect of Toll-like receptors (TLRs) has triggered concerns related to their possible role in autoimmune disease development. Indeed, TLR-related pathways are being independently studied by investigators for their role in autoimmune disease modulation. Second, should patients with chronic autoimmune diseases be routinely vaccinated? Since several infections are known to enhance disease activity in some autoimmune diseases, one can expect that their prevention, when feasible, would be beneficial. However, activation of innate immunity with some vaccines may also bear a theoretical risk of enhancing disease activity. Numerous allegations have been made and it is essential to restrict oneself to evidence-based conclusions rather than focusing on isolated case reports of coincidental events. Therefore it is of importance to define guidelines regarding the use of essential vaccines in patients with autoimmune diseases. Such

guidelines have been proposed by the American College of Rheumatology and the European League Against Rheumatism and will be discussed in subsequent sections in this chapter.

THEORETICAL CONCERNS FOR AUTOIMMUNE DISEASES IN THE CONTEXT OF VACCINATION

Under the generic term of “vaccines,” there is a whole range of products that include complex live attenuated microorganisms as well as purified proteins or polysaccharides. The common purpose of vaccination is to trigger a protective immune response in the host (similar to that seen with naturally acquired infection) but without the host becoming sick. Both in the previous decades for live or non-adjuvanted vaccines and more recently for adjuvanted vaccines, a major safety concern has centered on the possibility of potent stimulators of the immune response increasing the risk of developing an autoimmune disease. In fact, very few cases of vaccine-induced autoimmunity have been clearly demonstrated with past vaccines. The old rabies vaccine that was produced using rabbit brain tissue was associated with the occasional (0.33/1000) development of immune-mediated encephalitis and anti-myelin T cell responses (Swaddiwuthipong et al., 1998). This is no longer observed with modern rabies vaccines produced on cell lines. Measles vaccination is also occasionally associated with a transitory ITP-like thrombocytopenia. However, this syndrome is observed 6–10 times more frequently after natural measles infection (Beeler et al., 1996; Wraith et al., 2003). More recently, an epidemiological association of narcolepsy with the use of an AS03-adjuvanted H1N1 vaccine has been reported in Finland in a group 4–19 years of age representing over 900,000 people (National Narcolepsy Task Force Interim Report, 2011; Statement on Narcolepsy and Vaccination, 2011). The incidence of narcolepsy was 9.0 in the vaccinated as compared to 0.7/100,000 person years in the unvaccinated individuals, the rate ratio being 12.7. However, the pathogenesis of this adverse event is still ill-defined and the respective role of the vaccine and of the concomitant exposure to pandemic influenza remains unclear. This pandemic wave was shown in China to be associated with a 3–4 rise of narcolepsy in the absence of vaccination (Han et al., 2011). The swine influenza vaccine that was used in 1976 was associated with a significant increase in the frequency (incidence of 1 in 100,000) of Guillain–Barré syndrome in the weeks following vaccination (Wraith et al. 2003) but this is not seen after seasonal vaccines (risk of Guillain–Barré reduced to 1 in 1,000,000) (Schonberger et al., 1979; Chen et al., 2001).

CROSSFIRE AND COINCIDENCE

The historical associations described previously remind us of the extent of our current capabilities in identifying risks associated with vaccines—that is, through statistical associations. While identifying causation would be ideal (e.g., a clear and unequivocal link between vaccination and rare adverse events such as autoimmune disease), this is difficult given the individual, environmental, and temporal variables that occur during the window of immunization. While disease incidence in the setting of vaccination can be identified using statistical tools, this analysis can be confounded by the occurrence of “coincidental” associations. There is a background rate of these events that occur despite vaccination and a risk of such event occurring at the same time as the vaccine, by chance alone, which can confound the interpretation of vaccine safety.

One possible but not always practical solution is to collect autoimmune disease prevalence and incidence data in a given population before vaccination to illustrate these coincidental associations. Such an approach was utilized prior to the large-scale introduction of the HPV vaccine where a cohort study of 214,896 female adolescents and 221,472 young adults was carried out to monitor the prevalence of autoimmune disease before vaccine introduction (Siegrist et al., 2007). This elegant approach collected data on the frequency of immune-mediated conditions leading to outpatient visits, the number of women hospitalized, and the most frequently diagnosed autoimmune disease. These data were then used to model temporal associations that would have occurred theoretically had the vaccine been used with 80% coverage. One can quickly appreciate how such population-based efforts enable one to identify, in advance, confounding issues affecting safety perception to avoid a negative impression of an inherently safe vaccine. This approach emphasizes that without better incidence data on autoimmune diseases, the increased large-scale surveillance in vaccine studies may make it incorrectly appear that all vaccines increase the risk of autoimmune diseases.

Table 20.1 has been adapted primarily from autoimmune disease epidemiological data reported in a systematic review (Jacobson et al., 1997) in which four additional categories were added from a study published in 2003 (Cooper and Stroehla, 2003). These combined data represent, to our knowledge, the most comprehensive and conservative estimates to date. Table 20.1 intentionally focuses on the incidence of autoimmune diseases more commonly occurring in adults because the adult population is traditionally enrolled in first-in-human clinical trials with vaccines (the rates of autoimmunity in pediatric patients, though limited, suggest that they are quite different and reflect the contributions of time and

TABLE 20.1 Autoimmune Disease Epidemiological Data Reported in a Systematic Review

| Autoimmune Disease ^a | Incidence ^a (per 100,000 persons per year) | Expected New Diagnoses ^a (persons >18 years of age) |
|-----------------------------------|---|--|
| Adult rheumatoid arthritis | 23.7 | 55,092 |
| Thyroiditis (hypothyroidism) | 21.8 | 50,675 |
| Graves' disease (hyperthyroidism) | 13.9 | 32,311 |
| Type 1 diabetes (age >20 years) | 8.1 | 18,829 |
| Systemic lupus erythematosus | 7.3 | 16,969 |
| Sjögren disease | 3.9 | 9,065 |
| Multiple sclerosis | 3.2 | 7,438 |
| Primary systemic vasculitis | 2.0 | 4,649 |
| Polymyositis/Dermatomyositis | 1.8 | 4,184 |
| Systemic sclerosis | 1.4 | 3,254 |
| Addison disease | 0.6 | 1,394 |
| Myasthenia gravis | 0.4 | 929 |
| Total | | 204,789 |

^aTable obtained with permission from Ahmed, S., Plotkin, S.A., Black, S., Coffman, R.L. 2011. Assessing the safety of adjuvanted vaccines. *Sci. Transl. Med.* 3, 93rv2.

environmental exposure to disease development). These autoimmune diseases, based on previously reported estimates of incidence (Jacobson et al., 1997; Cooper and Stroehla, 2003), would have been responsible for 204,789 new cases of autoimmune disease in a population >18 years of age in the United States based on the 2010 US Census (US Census Bureau, 2011). With this extrapolated table, one rapidly gains a perspective on the risk of coincidental association that can occur when an autoimmune disease is diagnosed in a subject immunized during a vaccine clinical trial (independent of the vaccine's effect). Table 20.2 uses the incidence data from these autoimmune diseases and calculates the probability of observing at least one case of autoimmune disease in clinical trials ranging from 200 to 10,000 subjects. As demonstrated, there is an increase in the probability of observing one patient with autoimmune disease when examining a trial with 200 subjects (15%) versus 3000 subjects (91%) which illustrates why coincidental associations occasionally occur during large phase III vaccine studies and even more during post-licensure monitoring of vaccination adverse events.

CHALLENGES USING ANIMAL MODELS

The existence of animal models in which autoimmune disease is triggered using autoantigen preparations that contain adjuvants may also lead to the misperception that adjuvanted vaccines will trigger autoimmune disease in

subjects. However, one must keep in mind that the adjuvants used in these studies are typically strong adjuvants (e.g., complete Freund's adjuvant (CFA)), and are used on purpose with self or self-mimetic antigen to break immunological tolerance in animals. Furthermore, CFA, which is a mixture containing an antigen and inactivated and dried mycobacteria emulsified in mineral oil, is not approved for use in people because of its local toxicity. What needs to be emphasized here is that vaccine preparations that prevent infectious diseases in humans use adjuvants that are formulated to specifically promote immune responsiveness of vaccine antigens, not break immunological tolerance. Moreover, vaccine antigens are screened for molecular mimicry to exclude autoantigens, using *in silico* and *in vitro* studies, and thus are missing the necessary ingredient to potentially enable breaking of tolerance in the presence of a strong adjuvant.

One Size does “not” Fit All

Thus, suitable preclinical models for predicting relatively rare and delayed adverse events, such as an increase in the incidence of a specific autoimmune disease, have proven elusive. Human autoimmune diseases are diverse and complex, and the nature of the trigger cannot be simplified to the point that one “model” can be reliably expected to predict autoimmune disease induction. For example, many animal models exist for autoimmune

TABLE 20.2 Incidence Data from Autoimmune Diseases

| | Study Sample Size | | | | |
|---------------------------------------|---|----------|----------|----------|------------|
| | N = 200 | N = 1000 | N = 2000 | N = 3000 | N = 10,000 |
| | Probability to Observe at Least One Case ^a | | | | |
| Autoimmune disease^a | | | | | |
| Adult rheumatoid arthritis | 4.6% | 21.1% | 37.8% | 50.9% | 90.7% |
| Thyroiditis (hypothyroidism) | 4.3% | 19.6% | 35.3% | 48.0% | 88.7% |
| Graves' disease (hyperthyroidism) | 2.7% | 13.0% | 24.3% | 34.1% | 75.1% |
| Type 1 diabetes (age >20 years) | 1.6% | 7.8% | 15.0% | 21.6% | 55.5% |
| Systemic lupus erythematosus | 1.4% | 7.0% | 13.6% | 19.7% | 51.8% |
| Sjögren disease | 0.8% | 3.8% | 7.5% | 11.0% | 32.3% |
| Multiple sclerosis | 0.6% | 3.1% | 6.2% | 9.2% | 27.4% |
| Primary systemic vasculitis | 0.4% | 2.0% | 3.9% | 5.8% | 18.1% |
| Polymyositis/Dermatomyositis | 0.4% | 1.8% | 3.5% | 5.3% | 16.5% |
| Systemic sclerosis | 0.3% | 1.4% | 2.8% | 4.1% | 13.1% |
| Addison disease | 0.1% | 0.6% | 1.2% | 1.8% | 5.8% |
| Myasthenia gravis | 0.1% | 0.4% | 0.8% | 1.2% | 3.9% |
| Total | 15.0% | 55.5% | 80.2% | 91.2% | 100.0% |

disease mimicking certain features of a human disease. However, most of these models have been developed on the basis of similarities to end-stage pathology of the human disease instead of similarities in the etiology or pathogenic mechanisms. The widely used mouse models of lupus including (NZBxNZW)F1 and MRL-Fas^{lpr} mouse strains (Kono and Theofilopoulos, 2006) mirror the high levels of autoantibody and consequent lupus nephritis but do not reflect the musculoskeletal or neurological symptoms commonly seen in systemic lupus erythematosus (SLE). Evaluating the effects of a vaccine or adjuvant on one or two disease models would provide no information about the effects on other disease models. Difficulties and limitations with this approach include the differences between animal disease models and human disease clinical manifestations, fundamental genetic and physiological differences between humans and commonly used laboratory animals, and finally the poorly understood etiology of human autoimmune diseases in general. The following section will address these differences in greater detail.

Induced Autoimmune Disease in Animals

So what about animal models of autoimmune disease that are induced experimentally? Given that the etiologies of

human autoimmune diseases remain a mystery, factors that initiate disease in animal models may not be relevant to human disease development. For example, models in which disease is induced by immunization with high doses of autoantigens and adjuvants might reflect the downstream stage of organ pathology, but the upstream induction phase in these models may have little, if any, relevance to disease development in humans. A widely used rodent model for multiple sclerosis, experimental autoimmune encephalomyelitis, is induced by immunizing animals with a homogenate of spinal cords emulsified in CFA (Hemmer et al., 2006). The relevance of these models for shedding light on the potential of a candidate vaccine or adjuvant to influence onset or severity of autoimmune diseases in humans is very little if none. The take home message: the incomplete correlation with human disease and the divergent mechanisms of disease initiation limit the relevance of even the “best” inducible animal models to specific human autoimmune diseases.

Spontaneous Autoimmune Disease in Animals

What about animal models of autoimmune disease that occur spontaneously? Spontaneous models of autoimmunity

may be more relevant to human disease development than induced models, but these models are not without their limitations. Rodent models in which autoimmune disease develops spontaneously reflect a combination of genetic and environmental factors analogous to those thought to determine human autoimmune disease. A good example is autoimmune diabetes in nonobese diabetic (NOD) mice which may be the most similar to its human counterpart in antigenic components, genetic contributions, and pathological features (Kikutani and Makino, 1992). While one could envision using NOD mice to test agents for their potential to accelerate disease development or increase the severity of autoimmune diabetes, one needs to consider that CFA, which typically is used to *trigger* disease in autoimmune models, unexpectedly confers protection against diabetes development in NOD mice (Sadelain et al., 1990; Qin et al., 1993) questioning the utility of data generated in such an animal model. The same holds true for a number of TLR ligands being evaluated as adjuvants for vaccines against human diseases (Aumeunier et al., 2010). Other realities that need to be considered with animal models that spontaneously develop autoimmune disease are that while there may be pathological similarities to human autoimmune disease, the genetic associations and pathogenic mechanism may be quite different. The MRL-Fas^{lpr} mouse is a model known to spontaneously develop renal disease resembling lupus nephritis. A null mutation in the gene encoding Fas is the key element in this model and leads to defective lymphocyte apoptosis (Kono and Theofilopoulos, 2006). However, when attempting to translate these findings to human disease, one will see that genome-wide association studies in systemic lupus erythematosus patients have not demonstrated a link in polymorphisms in Fas to disease susceptibility (Crow, 2008; Graham et al., 2009).

“Of Mice and Men”—The Correct Application of Human Epidemiology and Translation of Human Immunology to Rodent Immunology

The reader should also consider the artificial nature of animal models regarding disease frequency compared to the real-life incidence of autoimmune diseases which, when compared to other medical diseases, are rare! Scientists using animal models to evaluate what in humans is considered a delayed vaccine adverse event (e.g., subsequent triggering of autoimmune disease) are cognizant of the fact that animal models developing autoimmune disease at high frequency (>50%) are not designed to evaluate factors that increase the incidence of rare events in humans. For example, in well-characterized

animal models of autoimmune disease, there is an artificial optimization of the genetic background and immunization conditions to reproducibly generate disease at high frequency. This disease in human populations may occur at a frequency of only 1 in 10,000 to 1 in 100,000 per year. Therefore, current animal models cannot predict an increased incidence in humans due to this artificial optimization. Clinical trials, therefore, may be the only modality to test such risks in that a vaccine that increases the annual incidence of a disease in humans from 1 in 100,000 to 10 in 100,000 (a 10-fold increase) would be considered unacceptable. Furthermore, species-specific differences between rodents and human immunology complicate the utility of preclinical observations for human disease. For example, TLR9 is expressed in human B cells and plasmacytoid dendritic cells (Hornung et al., 2002; Bernasconi et al., 2003; Rothenfusser et al., 2003) but in mice has been demonstrated additionally in macrophages, myeloid dendritic cells, and activated T cells (Gilliet et al., 2002; Gelman et al., 2004; Martin-Orozco et al., 1999; Suzuki et al., 2005). These differences are reflected in the safety and tolerability of inhaled or injected CpG-ODN (a TLR9-dependent agonist) in human and nonhuman primates (Creticos et al., 2006; Fanucchi et al., 2004; Gauvreau et al., 2006; Krieg et al., 2004; Simons et al., 2004; Tulic et al., 2004) and highlight the challenges in interpreting preclinical toxicology studies of CpG-ODN-containing vaccines.

While the development of more appropriate animal models including transgenic, humanized, and nonrodent animal models is warranted, this will need to be balanced with the Animal Welfare Act's focus of reducing, refining, or replacing animal tests (National Institutes of Health Revitalization Act of 1993 and the Interagency Coordinating Committee on the Validation of Alternative Methods Authorization Act of 2000). Clearly, such a focus on animal welfare when juxtaposed with the limited applicability of animal models of autoimmune disease for recapitulating or even predicting human autoimmune disease is likely to limit preclinical studies on rare serious adverse events (e.g., autoimmune disease).

PRACTICAL APPROACH TO VACCINATION IN PATIENTS WITH AUTOIMMUNE DISEASE

What is frequently forgotten, but is commonly observed by clinicians managing patients with autoimmune diseases, is that natural infection, unlike vaccination, is a *more likely and proven risk factor* for triggering (“flare”) and augmenting severity of autoimmune diseases. For example, an influenza vaccine study with 69 patients with SLE and 54 patients with rheumatoid arthritis (RA)

demonstrated that every viral and bacterial infection (seen predominantly in the non-vaccinated cohort) resulted in worsening of the main disease (Stojanovich, 2006). Similarly, a case report described a severe flare of SLE in a patient infected with parvovirus B19 (Hemauer et al., 1999). A recent meta-analysis arrived at a similar conclusion that several vaccine-preventable infections occurred more often in patients with autoimmune disease, that vaccines were efficacious in these patients, and that there did not appear to be an increase in vaccination-related harm compared to nonvaccinated patients (van Assen et al., 2011). Influenza and other acute respiratory infections are also commonly associated with an increased frequency of relapses in patients with relapsing multiple sclerosis (Oikonen et al., 2011). This risk is markedly reduced in patients that received the seasonal influenza vaccine (De Keyser et al., 1998).

The Reality Facing Clinicians Currently

The last 10 years has ushered in several new vaccines which rheumatologists caring for their patients should be familiar with. Some of these vaccines are relevant for the age groups being targeted by vaccination, while others may be live-attenuated vs. being inactivated (thus not capable of replication) and thus need to be considered carefully depending on the clinical interventions being considered for the patient. These new vaccines include those for meningitis (quadrivalent conjugate), pneumococcus (conjugate), papillomavirus (alum and TLR4 adjuvanted), rotavirus, and, lastly, the tetanus, diphtheria, and acellular pertussis vaccine (e.g., DTaP). Yet despite evidence of the impact and benefits of vaccinations, clinicians are not adequately vaccinating their patients according to established guidelines with the most significant barrier to vaccination identified by the Centers for Disease Control being *lack of knowledge* about these vaccines among adult patients and providers (Kroger et al., 2011). This section will provide guidance to the practicing rheumatologist regarding the role for vaccines in the patients that they treat based on 2011 guidelines published by the Advisory Committee on Immunization Practices (ACIP) and detailed guidelines that have been proposed by the American College of Rheumatology and the European League Against Rheumatism (to be discussed below).

Certainty about Vaccines, Uncertainty about Compatibility of Administration in Certain Settings

For those physicians that are aware of the vaccines currently available and recommended for their patients, questions are

sometimes raised regarding what to do where patients are being treated with immunomodulators or the efficacy of vaccines in patients that are immunosuppressed. This concern is based on the observation that immunosuppression resulting from primary or secondarily altered immunocompetence creates the greatest risk for infections in patients. Most patients being managed by rheumatologists are immunosuppressed by drugs prescribed to control their autoimmune disease and, thus, the immunodeficiency is a function of dose and type of therapy. A recent publication from the American College of Rheumatology Drug Safety Committee succinctly addresses this challenge and is the source of the recommendations highlighted in the following sections (Dao and Cush, 2012).

Distinguishing those vaccines that are live from those that are inactivated is critical when considering immunization of patients with autoimmune diseases on immunomodulatory treatments. Examples of live vaccines include the following: smallpox, adenovirus type 4 and 7, Bacille Calmette-Guérin, typhoid (oral), rotavirus, yellow fever, herpes zoster, influenza (live attenuated), varicella zoster, and measles-mumps-rubella. In the case of live vaccines, therapy with low doses of methotrexate and azathioprine are not considered sufficiently immunosuppressive and corticosteroid therapy is not usually a contraindication in the following cases: duration of treatment is less than 2 weeks, use of a dose less than 20 mg per day, duration of >2 weeks but with alternate-day treatment of short-acting formulations, doses that are physiologic, or route of administration is topical or injected within joints, tendons, or bursae. However, the ACIP identifies patients receiving tumor necrosis factor (TNF) inhibitors or doses of prednisone greater than 20 mg/day for longer than 2 weeks sufficiently immunosuppressed to contradict the use of live attenuated vaccines due to the concern for uncontrolled replication of the viral/bacterial microorganism in the host. If higher doses of steroids are used (>20 mg/day for more than 2 weeks), it is recommended to wait a month after immunosuppression before a live vaccine is given as severe complications have been reported following vaccinations with live vaccines. Such concerns do not apply to inactivated vaccines (whether killed whole-organism, subunit, recombinant, polysaccharide, or toxoid vaccines). Examples of inactivated vaccines include the following: typhoid (polysaccharide), tetanus-diphtheria/acellular pertussis, hepatitis A, hepatitis B, human papilloma, influenza (A/B/H1N1), pneumococcal, polio, rabies, and meningococcal. The reader should be aware that some vaccines licensed for immunization and distribution in the United States (e.g., influenza and typhoid) have been developed by different manufacturers as distinct live or inactivated products. A complete list may be found at the following website: <http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/UCM093833>.

Search and You Will Find

Guidance has been published for the use of vaccination in patients with autoimmune diseases. This has been in part due to the increasing awareness of the importance of vaccines in healthy populations and, ironically, also due to the perceived risk with newer vaccines containing adjuvants. Furthermore, more studies are being conducted and published on the value of vaccinations in patients with autoimmune diseases. Recent data obtained from patients with inflammatory rheumatic diseases that were immunized against pH1N1 influenza with an adjuvanted vaccine indicated a lower immunogenicity in RA patients treated with disease-modifying antirheumatic drugs (DMARDs) (Gabay et al., 2011). One should note that in the same study, there were no significant differences between baseline findings and follow-up findings for any of the disease parameters in 82 RA, 28 spondylarthritis, and 18 SLE patients. While studies such as these confirm the safety of vaccination in such patients, they raise questions about immunogenicity in this patient population. However, one should realize that lower “immunogenicity” does not imply lower “efficacy.” Indeed, this is supported by a recent meta-analysis that emphasizes that vaccines are effective in these patients (van Assen et al., 2011). As a result of this meta-analysis, several new recommendations have been published to guide the vaccination of adults with autoimmune disease (Meyer-Olson and Witte, 2011) and the reader is also referred to a web-based article (“How and when to administer inactivated vaccines” at the following website: www.cdc.gov/vaccines/recs/schedules/downloads/adult/adult-schedule.pdf).

CONCLUSION

The primary focus of this chapter is to update clinicians treating patients with autoimmune disease with a concise overview of the challenges facing vaccine development and the best application of this health intervention for their patient population. Those familiar with autoimmune diseases and those involved with vaccine development may already be aware of the common thread to both fields—that is, the triggering of the immune response. However, for those not familiar with these specialties, this common thread has also led to unjustified speculations regarding the relationship between this disease state and this disease intervention. Because this chapter is dedicated to vaccines and their use in patients with autoimmune diseases, the authors thought it would be relevant to mention a few points related to a recently coined syndrome called ASIA. ASIA stands for autoimmune/inflammatory syndrome induced by adjuvants and was first reported in 2011 (Shoenfeld and Agmon-Levin, 2011). While this syndrome attempts to associate a spectrum of immune-mediated diseases with an adjuvant stimulus, the authors coining the term correctly emphasized recently that the clinical proof of causality remains a challenge (Agmon-Levin et al., 2012). There are

some animal models that are being used to try to better understand this rare association (Agmon-Levin et al., 2012) but, in the end, may still be inconclusive for the reasons cited previously on the pitfalls of using animal models for understanding autoimmune disease etiology.

While it is critical to have a high level of scrutiny for the benefit/risk ratio of any prophylactic or therapeutic intervention in human subjects, one needs to keep in mind that vaccines have been responsible for preventing more deaths than virtually any other medicinal product. The value and impact of vaccinations for human health is undeniable—this is the most cost-effective intervention in preventive medicine. Those clinicians not utilizing vaccines routinely in their practices are requested to familiarize themselves in detail regarding vaccines (those with and without adjuvants, live vs. inactivated), the patient populations likely to benefit from such interventions (e.g., young girls and HPV vaccination), and their correct use in patients undergoing immunosuppressive treatments. It is hoped that this review has provided a concise overview that will serve as the basis for more detailed study and prepare the clinicians for the questions posed by their patients about the safety of vaccines.

INTRODUCTION

Although the mechanisms for the development of autoimmune diseases remain obscure, accumulating evidence suggests that these increasingly recognized disorders result from environmental exposures in genetically susceptible individuals (Luppi et al., 1995; Cooper et al., 1999; Miller, 1999; Gourley and Miller, 2007; Miller et al., 2012; Pollard et al., 2010). Despite the great progress that has been made in understanding a number of major histocompatibility complex (MHC) and non-MHC genetic risk factors for autoimmune diseases (see Chapters 26 and 28), relatively little information is now available regarding the role of specific environmental agents in the development of these disorders. This is partly the result of the lack of validated exposure biomarkers and environmental assessment tools, difficulties inherent in defining which of the many environmental exposures are related to disease, the little formal training in environmental medicine, the few resources dedicated to this area, and the lack of consensus approaches for the definition of environmentally associated diseases. As a

result, in the case of most autoimmune conditions, the specific environmental triggers remain unknown.

Just as there are likely to be multiple genes needed to induce autoimmune disease, multiple environmental exposures may need to occur in a particular sequence, or in tandem, to provoke the chronic immune activation that leads to autoimmunity. It is also possible that epigenetics, referring to modifications in gene expression that are controlled by heritable but potentially reversible changes in DNA methylation and/or chromatin structure, may be influenced by environmental exposures (Javierre et al., 2011). In this regard, many lessons might be learned from studies and registries of cancers, which like autoimmune diseases are multifactorial disorders in which multiple genetic and environmental risk factors must interact in a correct sequence, with occasional long latencies, before development of disease (Sarasin, 2003). Thus, in some cases, a change induced by one exposure may be necessary before a subsequent exposure can have its effect. Alternatively, mixtures of exposures, including possible infectious and non-infectious agents, perhaps occurring during critical windows when persons may be more

susceptible to them (i.e., *in utero*, in childhood, during puberty, pregnancy, or lactation) may be necessary in order to overcome tolerance. Other general principles from cancer that might be relevant to autoimmunity include the pathogenetic heterogeneity of currently defined disorders, the likely low effect sizes from many environmental exposures, and the possible requirement for inducers, promoters, and sustainers of disease at different points in the pathogenetic process (Cooper et al., 2002). This is particularly borne out by investigations suggesting that autoantibodies precede the development of clinical disease by months to years and are antigen-driven (Dotta and Eisenbarth, 1989; Miller et al., 1990; Leslie et al., 2001; Arbuckle et al., 2003; Klareskog et al., 2004; Hirschfield and Gershwin, 2013). This suggests that certain environmental exposures may be necessary to overcome tolerance in genetically susceptible individuals and induce autoantibody formation, while other agents may be necessary to promote expression of clinical disease.

If one defines environmental agents as everything outside the genome, then the many exposures that have been suspected of being involved in the pathogenesis of autoimmunity may be divided into two general categories: infectious and non-infectious agents. This chapter will focus on the evidence for the role of non-infectious environmental agents in the pathogenesis of human autoimmune diseases, while infectious agents are reviewed in Chapter 19.

EVIDENCE SUPPORTING THE ROLE OF ENVIRONMENTAL AGENTS IN AUTOIMMUNE DISEASE

Evidence for the role of environmental agents in autoimmune disease comes from a variety of investigative approaches (Box 21.1). Although many of these methods

are indirect, anecdotal, or may be only applicable to single patients, taken together these diverse findings strongly support the contention that most autoimmune diseases do have an important environmental component (Cooper et al., 1999; Smyk et al., 2012).

One line of evidence for the role of the environment is that for autoimmune diseases studied to date there is generally less than 50% disease concordance in monozygotic twins (Leslie and Hawa, 1994; Cooper et al., 1999; Bogdanos et al., 2012). These findings also hint that even if all the genetic risk factors for a given autoimmune disease could be fully identified, this would not allow for prediction of disease with any greater accuracy than the flip of a coin without the incorporation of environmental or other factors.

For certain agents it can be relatively clear when a given exposure is inducing a disease in an individual patient. The definition of an environmental disease in an individual can be accomplished by identifying a new clinical disorder, which develops soon after a novel exposure, resolves when the exposure is removed (dechallenge), and then recurs after reintroduction of the same exposure (rechallenge). This approach is most easily applied in the case of exposures to defined chemical entities such as drugs, foods, topical, or inhaled toxicants. Unfortunately, many xenobiotics (compounds not naturally found in the body) cannot easily be removed from an organism after exposure, and therefore for these agents this approach is not usually helpful. Exposures in this category include inhaled silica, vaccines, fat-soluble oils, and collagen or silicone implants.

The nonrandom distribution in time and space of some autoimmune illnesses also implies that non-genetic factors are important in disease development (Moroni et al., 2012). Studies in these areas are preliminary, and sometimes have not been reproduced, leading critics to posit that referral or other biases might explain some of the findings. Nonetheless, intriguing investigations have

Box 21.1 Lines of Evidence Supporting the Role of Environmental Agents in the Development of Autoimmune Disease

1. Less than 50% disease concordance in monozygotic twins
2. Strong temporal associations with some environmental exposures and disease onset
3. Dechallenge (disease resolution or improvement in an individual after removal of the suspect agent)
4. Rechallenge (disease recurrence or worsening in an individual after re-exposure to the suspect agent)
5. Seasonality in birth dates and disease onset
6. Geographic clustering in disease incidence or prevalence
7. Changes in the prevalence or incidence of disease over time and when genetically similar cohorts move to different geographic locations
8. Major genetic risk factors for autoimmune diseases are polymorphic genes that influence responses to environmental exposures
9. Strong biologic plausibility from animal models
10. Epidemiologic associations between particular exposures and certain diseases

suggested that certain autoimmune disorders have a seasonal onset or that there is a seasonal association with subsets of patients based upon disease-specific autoantibodies. The diseases reported to have seasonal associations include autoimmune myositis (Leff et al., 1991; Miller, 1993; Sarkar et al., 2005), juvenile rheumatoid arthritis (Feldman et al., 1996), type 1 diabetes (Weinberg et al., 1984; Willis et al., 2002), narcolepsy (Han et al., 2011), Wegener's granulomatosis, anti-neutrophil cytoplasmic antibodies associated glomerulonephritis, and systemic vasculitis (Schlesinger and Schlesinger, 2005). Furthermore, studies of type 1 diabetes, myositis, and other diseases have found significant associations with birth dates (Ursic-Bratina et al., 2001; Willis et al., 2002; Vegosen et al., 2007) implying that certain exposures at certain times of the year may alter the target tissues or immune systems of fetuses or neonates resulting in later autoimmunity. While infectious agents are often presumed to be the source of such seasonal or geographic associations, the immune system, like other organ systems, appears to have cyclic or rhythmic patterns (Haus and Smolensky, 1999), possibly related to light exposure and mediated by melatonin or other neurohormones (Nelson and Drazen, 2000). Additionally, many occupational or other exposures are seasonal, including exposures to certain pesticides, chemicals in sunscreens, and some air or water pollutants, so it is possible that non-infectious agents could account for some of these data in ways that have not been accounted for. Geographic clustering or gradients in disease prevalence or incidence have also been found for some autoimmune diseases. These investigations have primarily shown associations with latitude, suggesting a role of ultraviolet radiation in inducing disease, as may be the case for dermatomyositis (Okada et al., 2003; Love et al., 2009), altering mortality, as may be the case in lupus (Grant, 2004), or protecting from disease, as may be the case in multiple sclerosis and type 1 diabetes (Ponsonby et al., 2002).

Measurable increases or decreases in the incidence or prevalence of disease over time imply a non-genetic etiology given the slow rate of genetic change in a population. Although data are limited in this area—and several studies are possibly confounded as a result of improvements in the ability to diagnose some conditions over time—it appears that type 1 diabetes, multiple sclerosis, lupus, and myositis are becoming increasingly prevalent, while rheumatoid arthritis in adults and children may be decreasing in frequency in some populations (Oddis et al., 1990; Onkamo et al., 1999; Uramoto et al., 1999; Cooper and Stroehla, 2003). Changes in living standards and treatment approaches may also have an impact on disease frequency, as in the case of decreasing rheumatic heart disease (Johnson et al., 1975). Some authors believe that as our exposure to microbial agents has decreased in our

modern urban environments, the development of our immune systems has been altered to result in greater frequencies of autoimmune disorders, a concept known as the “hygiene hypothesis” (Rook, 2012).

Studies of genetically similar populations living under different conditions are also illuminating. The incidences of both multiple sclerosis and type 1 diabetes have changed as members of a population move to new regions (Dahlquist, 1998; Noseworthy et al., 2000).

Epidemiologic studies linking specific exposures to autoimmunity are limited and usually consist of relatively small, often underpowered investigations resulting in low effect sizes and large confidence limits. Much larger, well-designed, multicentered, and sometimes international studies, using appropriate controls and collecting adequate information to minimize confounding, will be needed in the future to more fully define the specific environmental risk factors for disease (Miller et al., 2012).

IDENTIFYING AND DEFINING ENVIRONMENTALLY ASSOCIATED AUTOIMMUNE DISEASES

One of the limitations in making progress towards identifying and defining environmental triggers for autoimmune disorders has been the lack of general consensus on the necessary and sufficient evidence needed to define an environmentally associated condition. Medical–legal issues that surround many environmental exposures have further complicated this area. A group of experts in the field—members of the American College of Rheumatology Environmentally Associated Rheumatic Disease Study Group—developed consensus on a general approach to overcome this problem (Miller et al., 2000). In their scheme, the overall process, from the identification of the first possible patient who developed a disease after an exposure, to the refinement of classification criteria for the disease, is divided into four stages (Table 21.1).

The first stage begins with the identification of a single case, or a series of cases, which is suspected of resulting from a given exposure. The consensus proposal is that these cases need to meet certain criteria to assure a minimum number of attribution elements are present (Miller et al., 2000). A total of at least four of all eight possible attribution elements need to be present, including at least three of five primary elements. The five primary elements are: temporal plausibility (taking into account the pharmacokinetics/pharmacodynamics of the agent, minimum induction time, and maximum latency); exclusion of other likely causes for the syndrome; dechallenge (if possible); rechallenge (if appropriate); and biologic plausibility. The additional three secondary elements are: identification of

TABLE 21.1 Proposed Stages for Identifying and Defining Environmentally-Associated Autoimmune Diseases^a.

| Stage | Description | Nomenclature (example) |
|---|--|---|
| Stage 1—Proposing the association | Case reports, defined by ascertainment criteria, propose a possible association of a specific clinical syndrome with a given exposure | Syndrome following exposure (rheumatoid arthritis following hepatitis B vaccination) |
| Stage 2—Testing the association | After a number of such cases are reported, surveillance criteria are proposed and epidemiologic and laboratory studies test that hypothesis | Cardinal signs, symptoms and labs but without the putative exposure (eosinophilia myalgia syndrome) |
| Stage 3—Defining criteria for the condition | If studies above are positive, then specific preliminary classification and other criteria are defined for that specific environmental disease | Exposure-associated disorder (L tryptophan-associated eosinophilia myalgia syndrome) |
| Stage 4—Refining criteria for the condition | Criteria are reassessed and refined as additional data are obtained about the disease | Exposure-induced disorder (hydralazine-induced lupus-like disorder) |

^aModified from Miller et al. (2000).

prior reports of similar cases (analogy); identification of prior reports of nearly identical cases (specificity); and evidence for a dose—response effect. In addition to meeting these criteria, it is suggested that complete information regarding the history and examination, laboratory reports, core demographic data, family history, prior infections, or physiology-altering exposures, all prior diagnoses, and the type/route/ dose/duration of the exposure are detailed in the report.

The second stage involves testing the possible association. This should include epidemiologic studies, using surveillance criteria, to evaluate the relationship between a given exposure and a given syndrome. *In vitro*, *in vivo*, and animal studies should also assess the biologic effects of the agent and plausibility of the development of the syndrome. Other approaches—such as clinical, laboratory, or genetic risk factor studies—could determine in case—control settings if cases of environmental disease differ from those with similar diseases without the exposure or differ from subjects similarly exposed who do not develop disease.

If data from the second stage results in convincing evidence that the association is real, then the third stage will develop preliminary criteria for that environmentally associated disease. Classification criteria will define, with reasonable sensitivity and specificity, groups of patients with one disorder from closely related diseases. Expert committee consensus, mathematical algorithms or other approaches could develop these criteria. Symptom, sign, and laboratory criteria should be expressed in clinically sensible and practical formats with precise definitions of constituent elements. Diagnostic, prognostic, and outcome criteria, and disease activity and damage indexes, should be considered when adequate data exist. The fourth stage repeats the same processes used in the

third stage if new information is collected to warrant a redefinition of the disease.

Although this proposed staging structure has limitations, in that the decisions as to when to progress to the next stage remain somewhat subjective, it nonetheless provides an overall framework to plan for future studies and it allows the classification of the current environmental agents into groups with different levels of evidence for their association with specific syndromes. Unfortunately, most environmental agents suspected of being associated with autoimmune diseases today remain in Stages 1 or 2.

NON-INFECTIOUS AGENTS ASSOCIATED WITH AUTOIMMUNE DISEASES

Drugs

Of all the non-infectious environmental exposures associated with autoimmunity, drugs are the best recognized and most often reported (Table 21.2). This is partly due to their widespread use and careful monitoring by clinicians, the strict regulatory oversight and adverse event reporting systems in many countries, and the ease of collection of dechallenge and rechallenge evidence to make associations in individual patients. Despite the fact that several hundred drugs have been associated in case reports or case series with a number of immune-mediated or autoimmune illnesses, few of the publications have met the consensus criteria described above to allow exclusion of confounding factors and few have been studied in epidemiologic investigations. Chemical agents have been the most often reported drugs preceding the development of autoimmunity, although the increasing use of biologic agents has resulted in more focus on these in recent years.

TABLE 21.2 Selected Drugs Associated in Case Reports or Case Series with Autoimmune Disorders^a.

| Drug | Associated Autoimmune Disorders |
|-----------------------|---|
| α-methyl dopa | lupus-like syndrome, hemolytic anemia, thrombocytopenia |
| allopurinol | lupus-like syndrome, vasculitis |
| bleomycin | scleroderma |
| captopril | lupus-like syndrome, vasculitis, membranous glomerulopathy |
| chlorpromazine | lupus-like syndrome, hemolytic anemia |
| D-penicillamine | lupus-like syndrome, myositis, hypothyroidism, Goodpasture's |
| erythromycins | lupus-like syndrome, myositis, hepatitis |
| estrogens | lupus-like syndrome, myositis |
| gold salts | lupus-like syndrome, membranous glomerulopathy |
| halothane | hepatitis |
| hydralazines | lupus-like syndrome, vasculitis, hepatitis |
| interferon-alpha | lupus-like syndrome, anti-phospholipid syndrome, arthritis, hemolytic anemia, thrombocytopenia, hepatitis, hypothyroidism |
| interferon-gamma | lupus-like syndrome, myositis, arthritis, hypothyroidism |
| interleukin-2 | scleroderma, anti-phospholipid syndrome, arthritis, hypothyroidism |
| iodine | hypothyroidism |
| isoniazid | lupus-like syndrome, arthritis, hepatitis, vasculitis, hypothyroidism |
| L-tryptophan | EMS, scleroderma, myositis, neuropathies |
| lipid-lowering agents | lupus-like syndrome, myositis, hepatitis |
| penicillins | anemia, lupus-like syndrome, hepatitis |
| phenytoin | scleroderma, lupus-like syndrome, hepatitis, thrombocytopenia |
| procainamide | lupus-like syndrome |
| propylthiouracil | lupus-like syndrome, ANCA + vasculitis, myositis |
| quinidine | lupus-like syndrome, arthritis, thrombocytopenia |
| rifampicin | thrombocytopenia, vasculitis |
| sulphonamides | lupus-like syndrome, vasculitis |
| tetracyclines | lupus-like syndrome, arthritis, vasculitis |
| TNF-inhibitors | lupus-like syndrome |

^aReviewed in *Love and Miller (1993)*; *Bigazzi (1997)*; *Mackay (1999)*; *D'Cruz (2000)*; *Hess (2002)*; *Liu and Kaplowitz (2002)*; *Chang and Gershwin (2011)*; abbreviations: ANCA, antineutrophil cytoplasmic antibodies; EMS, eosinophilia myalgia syndrome; TNF, tumor necrosis factor.

The most commonly recognized drug-related syndromes are lupus-like disorders (*Hess and Mongey, 1991*). These are characterized by autoantibodies to histones and single-stranded DNA, rather than autoantibodies to double-stranded DNA as are found more often in non-drug-related lupus. Drug-related lupus also differs from non-drug-related lupus in having more frequent arthritis and less frequent neurologic and renal involvement, as well as having possibly different genetic risk factors. Virtually all of the 80 or more

autoimmune diseases have been anecdotally reported to be associated with one or more drugs. In some of these cases drug-linked disorders differ from the non-drug-related forms in clinical, serologic, or genetic features, while in other cases they do not.

It is noteworthy that although some drugs appear to be associated with a number of autoimmune conditions (*Table 21.2*), there are no common structures, mechanisms of action, metabolites, or other features among them that consistently allow prediction of their toxicity or a

TABLE 21.3 Occupational Exposures Associated with Autoimmune Diseases via Epidemiologic Studies^a.

| Exposure | Disease | Summary of Results |
|-----------------------|---|---|
| Silica | Scleroderma | Three-fold increased risk in four occupational cohort studies; mixed results in five population-based case–control studies |
| | Rheumatoid arthritis | Three-fold (or higher) increased risk in five occupational cohort studies |
| | Lupus | >10-fold increased risk in three occupational cohort studies |
| | ANCA + vasculitis | Four-fold increased risk in three case–control studies |
| Solvents | Scleroderma | Mixed results, but some evidence of two to three-fold increased risk with specific solvents (e.g., paint thinners and removers, trichloroethylene) and with “any” solvent |
| | Undifferentiated multisystem rheumatic diseases | Two-fold increased risk with paint thinners and removers, mineral spirits; three-fold increased risk with specific solvent-related occupations |
| | Rheumatoid arthritis | Weak or no association with specific solvents, but two-fold increased risk among spray painters and lacquer workers |
| | Multiple sclerosis | Two to three-fold increased risk with solvent exposures in most studies |
| Pesticides | Rheumatoid arthritis, lupus | Weak associations (relative risks <2.0) seen with pesticide exposure and in farmers and horticultural workers |
| Ultraviolet radiation | Multiple sclerosis | Reduced risk (OR 0.74) of multiple sclerosis and mortality with increased occupational exposure to sunlight |
| | Dermatomyositis | Positive correlation of the proportion of dermatomyositis with global surface sunlight intensity in international and US studies |

^aData from Cooper et al. (2002, 2010); Love et al. (2009); McCormic et al. (2010); Parks et al. (2011); abbreviations: OR, odds ratio; ANCA, antineutrophil cytoplasmic antibodies.

current understanding of the pathogenesis of these syndromes. The challenge today is to begin to decipher the genetic and other risk factors that interact with exposure to these drugs that result in disease so that they can someday be predicted and prevented.

Occupational Exposures

Limited but growing epidemiologic and experimental data have linked a number of occupational exposures to autoimmune diseases (Table 21.3). The most studied of these include silica, solvents, pesticides, and ultraviolet radiation (Westberg et al., 2009; Cooper et al., 2002, 2010; Parks et al., 2011). One of the first occupationally associated rheumatic diseases identified was Caplan’s syndrome, which is seropositive rheumatoid arthritis associated with a specific form of pneumoconiosis that develops in anthracite coal-miners and in persons exposed to silica and asbestos (Williams, 1991). The strongest occupational associations with autoimmune disease (i.e., relative risks of 3.0 and higher) have been documented in investigations of silica dust and rheumatoid arthritis, lupus, scleroderma and antineutrophil cytoplasmic autoantibody (ANCA) associated glomerulonephritis (Parks et al., 1999; Khuder et al., 2002). Weaker associations are seen, however, for solvent exposures (in scleroderma, undifferentiated multisystem rheumatic disease, and

multiple sclerosis) and for farming or pesticide exposures (in rheumatoid arthritis). Vinyl chloride has been linked to the development of a scleroderma-like disease characterized by skin thickening, Raynaud’s phenomenon, acroosteolysis, and pulmonary involvement. This observation, and the publication of several case reports, stimulated research into associations between scleroderma and other chlorinated solvents (e.g., trichloroethylene and trichloroethane) with varying results (Cooper et al., 2002, 2009).

There are many difficulties in assessing the role of occupational exposures in disease. First, there are few biomarkers for such exposures and essentially none that allow an estimate of lifetime cumulative exposure. Second, there are few validated occupational exposure questionnaires and those that do exist are awkward and costly to apply. Third, most studies in this area have been underpowered given the rarity of the diseases, the likely effects of different genotypes, and the occupations of interest, resulting in imprecise risk estimates. And finally, there is possible confounding from multiple concurrent exposures that makes it difficult to ascertain whether different effects can be attributed to different chemicals. Thus, it may not be surprising that in some cases discrepancies exist in different investigations, making it difficult to assess the true overall risks of most occupational exposures.

TABLE 21.4 Other Exposures Proposed as Possible Risk Factors for Autoimmune Diseases^a.

| Exposure | Disease | Comments (Reference) |
|-------------------|---|---|
| Foods (gluten) | Celiac disease | Celiac disease develops after ingestion of foods containing gluten and related proteins in some genetically susceptible persons (Alaedini and Green, 2005) |
| Cigarette smoking | Rheumatoid arthritis | Studies suggest relative risks of 1.5–3 with a greater effect in men, seropositive disease and those with the HLA shared epitope (Krishnan, 2003; Stolt et al., 2003; Kallberg et al., 2011) |
| | Autoimmune thyroid disease | Meta-analyses suggest two to three-fold increased risks of Graves' and Hashimoto's (Vestergaard, 2002) |
| | Inflammatory bowel disease | Smoking increases risks for Crohn's disease but decreases risks for ulcerative colitis (Timmer, 2003) |
| Heavy metals | Multiple syndromes | "Pink disease" (acrodynia) and glomerulopathy from mercury toxicity; related syndromes with elements of autoimmunity from cadmium and gold salt toxicity; granulomatous pneumonitis from beryllium exposure; support for genetic risk factors in animal models (Bigazzi, 1994; Dally, 1997; Fontenot and Kotzin 2003) |
| Microchimerism | Scleroderma, lupus, primary biliary cirrhosis, autoimmune thyroid disease | Fetal cells detected in maternal blood or target tissue specimens years after pregnancy—not all findings have been reproduced, possibly due to different methodologies with different sensitivities to detect rare microchimeric cells (Sarkar and Miller 2004) |
| | Juvenile myositis | Maternal cells detected in children who developed myositis (Artlett et al., 2000) |
| Vaccines | Multiple syndromes | Arthritis after rubella virus vaccines; thrombocytopenia after measles vaccines; Guillain–Barre syndrome after swine flu vaccine and tetanus; controversy remains over others (Wraith et al., 2003) |
| Collagen implants | Myositis | In one study, OR = 5.05; 95% CI, 2.31 to 9.59 for all forms of myositis (Cukier et al., 1993) |
| Silicone implants | Multiple syndromes | Most studies do not find associations with common autoimmune diseases (Janowsky et al., 2000; Tugwell et al., 2001); rare or atypical multisystem rheumatic diseases and fibromyalgia remain inadequately studied (Brown et al., 1998; Brown, 2002). |
| Stress | Graves' disease | Stressful life events in the 12 months preceding the diagnosis were significantly higher than controls (OR = 6.3, CI = 2.7–14.7 (Winsa et al., 1991); other diseases poorly studied |

^aAbbreviations: OR, odds ratio; CI, 95% confidence interval; ANCA, antineutrophil cytoplasmic antibodies.

Others

A wide variety of other exposures with greatly different properties have been proposed to be associated with autoimmune diseases (Table 21.4). The evidence supporting these proposed associations range from case reports to epidemiologic studies and many are speculative at this time. These are listed below under the major categories into which they may be classified.

Foods

Foods represent some of the better examples of environmental agents associated with autoimmune diseases. The

best example is celiac disease, which is characterized by an immune response to ingested wheat gluten and related proteins of rye and barley that leads to autoantibodies to transglutaminase and inflammation, villous atrophy, and crypt hyperplasia in the intestine (Alaedini and Green, 2005). There is also good evidence for gene–environment interaction in celiac disease with human leukocyte antigens DQ2 and DQ8 being the major known genetic risk factors. Celiac disease is one of the few medical conditions for which dietary intervention is the main treatment modality and a gluten-free diet markedly decreases symptoms in most individuals. Although there is less support for an autoimmune etiology of other food-associated inflammatory disorders—including the L-tryptophan-

associated eosinophilia myalgia syndrome (Sullivan et al., 1996) and the contaminated rapeseed oil-associated toxic oil syndrome (Gelpi et al., 2002)—it is possible that some of these represent cases of food-associated autoimmunity given their frequent autoantibodies and immunogenetic associations (Okada et al., 2009).

Tobacco Smoke

Tobacco smoke has been associated epidemiologically with an increased risk of seropositive rheumatoid arthritis, in which a gene–environment interaction is clear (Bang et al., 2010), autoimmune thyroid disease, and Crohn’s disease in several studies, but inconsistent results were found in studies of smoking and systemic lupus erythematosus, multiple sclerosis, and Hashimoto’s thyroiditis (Miller et al., 2012).

Smoking may be associated with a reduced risk of ulcerative colitis, an inflammatory bowel disease implying that the complex mix of chemicals in tobacco smoke may have different effects in different genetic backgrounds.

Heavy Metals

Exposures to heavy metals, including mercury, cadmium, gold salts, and beryllium, have been associated with a variety of pathologic syndromes, some of which have features of autoimmunity. A recent study of communities in Amazonian Brazil with well-characterized exposures to mercury was the first to document immunologic changes, indicative of autoimmune dysfunction, in persons exposed to mercury (Silva et al., 2004). Additionally, many animal models have documented inflammatory and sometimes highly specific autoimmune responses to the heavy metals, even at subtoxic doses, which appear to differ in different genetic backgrounds (Bagenstose et al., 1999). The mechanisms for these many effects remain unclear, but possibilities include changing the response repertoire by direct and indirect means via changes in cytokine profiles, influencing expression of new antigens, new peptides, and/or antigen presentation by modifying the antigen-presenting complex (Rowley and Monestier, 2005), as has been reported for Abacavir loading of novel self-peptides into HLA-B*57: 01 (Norcross et al., 2012).

Microchimerism

Microchimerism is the persistence of a low level of non-host stem cells or their progeny in an individual. A possible role of microchimerism in the pathogenesis of some (systemic sclerosis, systemic lupus erythematosus, primary biliary cirrhosis, autoimmune thyroid diseases, and juvenile myositis) but not all autoimmune diseases has been suggested by recent studies (Sarkar and Miller,

2004). The initial impetus to explore this exposure was that many of the diseases associated with microchimerism have features that are shared with graft-versus-host disease suggesting a possible mechanism. Although an appealing hypothesis, controversy in the area continues due to the lack of reproducible studies to date and the lack of proof of the role of microchimeric cells in the pathogenesis of these disorders. That cells of multiple origins and different genetic backgrounds may combine to result in functional organ systems, both in mothers and their offspring, requires a re-evaluation of many current paradigms. It is possible that such chimeric mixtures play a role in autoimmunity, tissue repair, and other areas (Fugazzola et al., 2011). Further research—using standardized, sensitive, and validated methods—is needed to address the many questions that the early findings in this field have raised.

Vaccines

Because vaccines are foreign proteins often injected with adjuvants into muscle to induce immune responses, it may not be surprising that immune-mediated adverse events have been reported after a wide variety of immunizations. Although a number of autoimmune diseases have been found to develop following vaccinations, only a few have been deemed to be associated with disease by the Advisory Committee on Immunization Practices (Advisory Committee on Immunization Practices, 1996) and are now compensated by the National Vaccine Injury Compensation Program (<http://www.hrsa.gov/vaccinecompensation/index.html>). These include cases of chronic arthritis after rubella virus vaccines and thrombocytopenic purpura after measles vaccines. There remains significant controversy over other illnesses possibly caused by immunizations, but most of the epidemiologic studies in this area have not shown significant associations (Wraith et al., 2003).

Implants

Bovine collagen implants are biomaterials used for the correction of dermal contour deformities. The use of bovine collagen implants in patients with a personal history of autoimmune diseases is contraindicated by the manufacturer due to concerns that they might induce adverse immune responses, since anti-collagen autoantibodies are present in some patients with multisystem rheumatic diseases. Few epidemiologic studies have been performed in this area, although one study has evaluated the development of myositis in nine patients following collagen implants (Cukier et al., 1993). Eight of the nine patients had a delayed-type hypersensitivity response at the test or treatment sites, and five of six patients tested were found to have increased serum

TABLE 21.5 Possible Mechanisms by which Environmental Agents May Induce Autoimmunity and Promote and Sustain Autoimmune Diseases (Possible Examples in Parentheses)^a.

1. Alteration of target tissue autoantigen structure (bystander drugs, heavy metals)
2. Upregulation or altered locations of normally sequestered autoantigens (UV radiation)
3. Cytotoxic, inhibitory, or stimulatory effects on components of the immune system (interferons, interleukins)
4. Molecular mimicry—structures shared between environmental agent and self (infectious agents)
5. Other effects and combinations of the above

^aInitiators of autoimmunity may differ in action from promoters and sustainers of autoimmune disease.

antibodies to collagen. Compared with the general population, the incidence of dermatomyositis or polymyositis among collagen-treated patients was significantly increased.

Silicone implants remain some of the most controversial environmental agents proposed to be associated with connective tissue disorders. Studies in this area have been hampered by the extensive litigation involved in adverse events following silicone breast implants and the lack of adequate regulatory review prior to their initial use. Most studies have not found associations with common autoimmune diseases (Janowsky et al., 2000; Tugwell et al., 2001); however, some investigators believe that rare or atypical multisystem rheumatic diseases and fibromyalgia remain inadequately studied (Brown et al., 1998; Brown, 2002). Of interest, women who develop myositis after silicone implants appear to be an immunogenetically distinct subgroup with different allelic associations than are seen in women who develop myositis without implants (O'Hanlon et al., 2004).

Stress

Anecdotes have been reported that stressful life events have preceded the development of many autoimmune diseases. A large population-based, case–control study of Graves' disease showed that patients had more negative life events in the 12 months preceding the diagnosis of Graves', and negative life-event scores were also significantly higher (Winsa et al., 1991). Other diseases have not been adequately studied. Although the mechanisms for how stress may play a role remain unclear, it has been hypothesized that, under certain conditions, stress hormones may boost immune responses through induction of tumor necrosis factor (TNF)-alpha, interleukin (IL)-1, and IL-8 and by inhibiting transforming growth factor (TGF)-beta production (Elenkov and Chrousos, 1999). Therefore, conditions that are associated with significant changes in stress system activity may modulate the neuroendocrine-immune axis and perturb systemic cytokine balances resulting in proinflammatory changes and disease induction.

POSSIBLE MECHANISMS BY WHICH ENVIRONMENTAL AGENTS MAY INDUCE AUTOIMMUNE DISEASES

Although the mechanisms for the development of autoimmune diseases associated with non-infectious agent exposures remain poorly understood, a variety of theories have been postulated to explain how xenobiotics may induce disease (Table 21.5). The wide range of these theories emphasizes the lack of understanding of mechanisms even for the most carefully defined environmentally associated diseases. This also suggests that different pathogenic mechanisms are likely at work in different syndromes.

Whatever the specific mechanisms for the development of an autoimmune disease, it has been suggested that an overall framework should include the concept of heterogeneity within the currently defined diseases. A working hypothesis that addresses this issue has been termed the “elemental disorder hypothesis,” which posits that each autoimmune disease as currently recognized contains many elemental disorders (Shamim and Miller, 2000; Gourley and Miller, 2007). In this scenario, an elemental disorder is defined as a unique sign–symptom–laboratory complex (syndrome) that results from a distinct pathogenesis as a result of the interaction of the necessary and sufficient genetic and environmental risk factors. If this concept is true, elemental disorders are likely confounding most studies of disease today by inducing “comparisons of apples and oranges.” If identified, elemental disorders should greatly increase the homogeneity of populations under study and thus decrease the numbers of individuals needed for genetic, environmental, and therapeutic studies. In the future, elemental disorder identification could allow for the prevention of some illnesses by avoidance of environmental risk factors or via gene therapy to correct deleterious genetic risk factors.

OVERVIEW AND FUTURE DIRECTIONS

The multifactorial nature of autoimmune diseases has inhibited understanding of the mechanisms that initiate and sustain them. Autoimmune syndromes are believed to arise, however, from a complex and ill-understood

Box 21.2 Possible Approaches to Enhance Identification of Environmental Risk Factors for Autoimmune Diseases

1. Foster national and international collaborations and coordination to integrate existing and newly developed clinical databases, registries, specimen repositories and other resources, and minimize duplication of effort
2. Develop and validate clinically useful standardized environmental exposure assessment tools
3. Develop and validate standardized biomarkers for environmental exposures
4. Increase support for well-designed, population-based and case–control hypothesis-testing studies for suspected environmental agents
5. Increase support for hypothesis-generating studies to identify new agents and syndromes
6. Collect systematic descriptive epidemiologic data for all autoimmune diseases as a baseline for future comparisons
7. Increase use of information technology and other novel approaches to enhance communications, coordinate efforts, and facilitate clinical studies
8. Improve coordination between animal model and epidemiologic studies
9. Develop novel mathematic, statistical, and bioinformatic approaches to enhance epidemiology studies
10. Define gene–gene, gene–environment and environment–environment interactions
11. Establish an international coordinating committee to oversee and facilitate the above, encourage multidisciplinary research and prepare for and respond to epidemics of environmentally induced, immune-mediated diseases

interplay of predisposing genetic and environmental risk factors. While some progress is being made in defining the multiple genetic risk factors, we are in our infancy in the identification of the environmental risk factors for autoimmune illnesses. Understanding the interactions of those elements that are necessary for disease development offers the promise of preventing or treating autoimmune diseases in novel ways. But before that can be accomplished important questions remain to be answered. Which specific gene–environment interactions lead to which specific clinical syndromes? What are the pathogenic mechanisms involved? Is every autoimmune disease, as currently understood, actually composed of many subsets or “elemental disorders,” each of which may be defined by a unique pathogenesis resulting from interactions of the necessary and sufficient risk factors? Can selected autoimmune diseases be better treated, cured, or even prevented through answers to some of the above questions?

We live in an increasingly complex sea of xenobiotics, which complicates exposure assessments. More than 80,000 chemicals are registered for use in commerce in the United States, and an estimated 2000 new ones are introduced annually to be included in our foods, personal care products, drugs, household cleaners, and a host of industrial processes. The long-term effects of most of these chemicals on human health are unknown, yet we may be exposed to them during the manufacture, distribution, use, and disposal of products or as pollutants in our air, water, or soil. As a result, none of us knows the full range of environmental agents we are exposed to on a daily basis.

The concept of the exposome, which would be all the exposures that an individual has experienced during their lifetime, has been proposed to be a useful construct to focus attention on the critical need for more comprehensive environmental exposure assessments. Currently we

are not able to simultaneously measure the many important components of the exposome—including xenobiotics approved in commerce, the additional thousands of compounds not approved but to which we are exposed in our foods, air and water supplies, plus stressful life events, cigarette smoke or alcoholic drink compositions, drugs and dietary supplements, nanoparticles, biotoxins, cosmetics, hair dyes, ultraviolet and other radiation and climatic factors, electric and magnetic fields—at any single time point in an individual, let alone over a lifetime. Much more work is needed to develop the novel assessment tools that could begin to evaluate these multiple exposures, either directly or indirectly, via their effects on gene expression or epigenetic modification, microRNA levels, or protein composition of various matrices in the body, both in real time and in summation over time.

To summarize, many challenges have prevented further understanding of the environmental risk factors that might trigger autoimmune diseases in genetically susceptible individuals. These include: inadequate validated exposure assessment tools and bioassays; poor training in the evaluation of environmental exposures; the lack of population-based incidence, prevalence, demographic information, and databases or repositories for most diseases; inadequate funding; and the lack of accepted and standardized approaches for defining the minimal criteria for an environmental disease. A number of coordinated initiatives may be useful in overcoming these obstacles and making more progress in the future (Box 21.2). Central to all these efforts are greater attention to and funding for understanding the essential environmental exposures that initiate, promote, or sustain autoimmune disorders. Such investments are likely to be very cost effective since they would have important clinical and financial implications for improving the public health.

MICROVASCULAR DETERMINANTS OF T CELL RECRUITMENT

Specialized microvessels control T cell migration from blood into tissues. In microvascular beds of most tissues except the spleen, lung, and liver, postcapillary venules, but not arterioles or capillaries, bind leukocytes. Because intravascular leukocytes are subjected to extreme physical conditions (shear stress), cells use specialized adhesion receptors, the selectins, which form stable bonds with counter-receptors in the vascular wall (Table 22.1) (Carlos and Harlan, 1994; Springer, 1994). Adhesion receptors on leukocytes and on vascular endothelial cells also function as tissue-specific recognition molecules. For example, the specialized high endothelial venules (HEVs) in lymph nodes and Peyer's patches constitutively express vascular addressins, which support a considerable rate of traffic of "resting" lymphocytes, i.e., naïve T and B cells and some memory T cells, whereas endothelial cells elsewhere permit only minimal leukocyte binding unless they are exposed to inflammatory mediators. Thus, two vascular beds can be distinguished, which support fundamentally different types of leukocyte traffic: those in lymphoid organs which recruit lymphocytes constitutively, and those in normal or inflamed tissues which recruit effector leukocytes whose job is to combat

pathogens (Figure 22.1). The same anti-pathogen effector leukocytes also can mediate tissue damage in autoimmune disease settings.

ADHESION MOLECULES

A central paradigm that underpins leukocyte extravasation is the multistep model of leukocyte binding to endothelium (Springer, 1994). Leukocytes must engage several sequential adhesion steps in order to leave the circulation (Figure 22.2). Initially, tethers are formed by adhesion receptors that are specialized to engage rapidly and with high tensile strength. The most important initiators of adhesion are the three selectins, expressed on leukocytes (L-selectin), endothelial cells (P- and E-selectin), and activated platelets (P-selectin) (Kansas, 1996). All selectins bind oligosaccharides related to sialyl-Lewis^x. The most relevant selectin-binding sugars are components of sialomucin-like glycoproteins (Vestweber and Blanks, 1999). Selectin-mediated binding of leukocytes to endothelium results in a characteristic rolling motion. To stop rolling, cells must engage additional (secondary) receptors (Lawrence and Springer, 1991; von Andrian et al., 1991), members of the integrin family, specifically LFA-1 (CD11a/CD18, aLb2), and the two a4 integrins, a4b1 (VLA-4) and a4b7. a4 integrins can also mediate

TABLE 22.1 Selectins, Integrins, and Their Ligands.

| Adhesion Molecule | Distribution | Ligand(s), Receptor(s) | Role in T-cell Migration |
|------------------------------------|--|---|--|
| Selectins | | | |
| L-selectin (CD62L) | Most leukocytes | PNAd, PSGL-1, MAdCAM-1, E-selectin, others | Homing to lymph nodes and Peyer patches |
| E-selectin (CD62E) | Endothelial cells | PSGL-1, ESL-1, CLA, sLe ^{X+} glycol-proteins and -lipids | Memory/effector cell homing to skin and sites of inflammation |
| P-selectin (CD62P) | Endothelial cells, platelets | PSGL-1, CD24, PNAd | Memory/effector (Th1) cell homing to sites of inflammation; platelet-mediated interaction with PNAd ⁺ venules |
| Selectin Ligands | | | |
| Sialyl-Lewis ^X (sCD15) | Myeloid cells; some memory (Th1) cells; HEVs; other cell types | All selectins | Function depends on presentation molecule |
| PSGL-1 | All leukocytes | P-selectin; also binds L-/E-selectin | Effector cell homing to inflamed tissues |
| Peripheral node addressin (PNAd) | HEVs in LNs and inflamed tissues | L-selectin, P-selectin | Naïve/central memory T-cell homing to LNs |
| Cutaneous lymphocyte antigen (CLA) | Skin-homing T cells, dendritic cells, granulocytes | E-selectin | Memory/effector T-cell homing to inflamed skin |
| b2 Integrins^a | | | |
| aLb2 (LFA-1, CD11a/CD18) | All leukocytes | ICAM-1, -2, -3, -4 and -5 | Homing; inflammation; adhesion to APCs |
| aMb2 (Mac-1, CD11b/CD18) | Myeloid cells, some activated T cells | ICAM-1, factor X, fibrinogen, C3b _i | Unknown |
| aXb2 (p150/95, CD11c/CD18) | Dendritic cells | Fibrinogen, C3b _i | Unknown |
| aDb2 (CD11d/CD18) | Monocytes, macrophages, eosinophils | VCAM-1, ICAM-1 and -3 | Unknown |
| a4 Integrins^a | | | |
| a4b1 (VLA-4) | Most leukocytes except neutrophils | VCAM-1, fibronectin, a4 integrin | Memory/effector cell homing to inflamed tissues, esp. lung |
| a4b7 | Lymphocytes, NK, mast cells, basophils, monocytes | MAdCAM-1, fibronectin, weak binding to VCAM-1 | Homing to gut and associated lymphoid tissues |
| Immunoglobulin Superfamily | | | |
| ICAM-1 (CD54) | Most cell types | LFA-1, Mac-1, fibrinogen | Critical endothelial ligand for b2 integrins |
| ICAM-2 (CD102) | Endothelial cells, platelets | LFA-1 | Unknown |
| VCAM-1 (CD106) | Endothelial cells, BM stroma, FDC, osteoblasts, mesothelium | a4b1, a4b7, aDb2 | Memory/effector cell homing to inflamed tissues |
| MAdCAM-1 | HEVs in gut-associated lymphoid tissues; lamina propria | a4b7, L-selectin | T-cell homing to gut-associated lymphoid tissues |

^aThe integrins are named according to the composition of their constituent *a* and *b* protein chains, which are each identified by a number or letter (e.g., *a4b1* or *aDb2*), but some integrins are often referred to by alternative names, e.g., *LFA-1*, shown in parenthesis.

APC, antigen-presenting cell; BM, bone marrow; CD, cluster of differentiation; CLA, cutaneous lymphocyte antigen; ESL-1, E-selectin ligand-1; FucT-VII, fucosyltransferase-VII; GlyCAM-1, glycosylation-dependent cell adhesion molecule-1; HEV, high endothelial venule; ICAM, intercellular cell adhesion molecule; IL-1, interleukin-1; LFA-1, leukocyte function-associated antigen-1; LPS, lipopolysaccharide; Mac-1, macrophage antigen-1; MAdCAM-1, mucosal addressin cell adhesion molecule-1; NK, natural killer cell; p150/95, protein with 150kDa and 95kDa subunits; PNAd, peripheral node addressin; PSGL-1, P-selectin glycoprotein ligand-1; sgp200, sialylated glycoprotein of 200kD; sLe^X, sialyl-Lewis^X; Th, T-helper; TNF- α , tumor necrosis factor α ; VCAM-1, vascular cell adhesion molecule-1; VLA-4, very late antigen-4.

FIGURE 22.1 Migratory routes of T cells. Naïve T cells “home” continuously from the blood to lymph nodes and other secondary lymphoid tissues. Homing to lymph nodes occurs across high endothelial venules (HEVs), which express traffic molecules for constitutive lymphocyte recruitment. Lymph nodes are percolated by lymph fluid that is channeled to them from peripheral tissues, where dendritic cells (DCs) collect antigenic material. In inflamed tissues, DCs are mobilized to carry antigen to lymph nodes, where they stimulate antigen-specific T cells. Upon stimulation, T cells proliferate and differentiate into effector cells, which express receptors that enable them to migrate to sites of inflammation. While most effector cells are short lived, a few antigen-experienced cells survive for a long time. These memory cells are subdivided into two populations based on their migratory ability (Sallusto et al., 1999): one subset is termed *effector memory* T cells and is localized to peripheral tissues, and the other *central memory* T cells that express a similar repertoire of homing molecules as do naïve T cells and migrate preferentially to lymphoid organs. The traffic signals that direct effector and memory cells to peripheral tissues are organ specific; for example, molecules required for migration to the skin are different from those to the gut; they are modulated by inflammatory mediators and are distinct for different T cell subsets, e.g., Th1 and Th2 cells show differences in their responses to various chemoattractants. *Reproduced from von Andrian and Mackay (2000), with permission.*

tethering and rolling, albeit less efficiently than selectins (Alon et al., 1995; Berlin et al., 1995).

CHEMOATTRACTANTS AND THEIR RECEPTORS

Selectins are constitutively active whereas integrins are activated by signals from chemoattractant receptors

(Cyster, 1999; Kim and Broxmeyer, 1999). Just like adhesion molecules, chemoattractant receptors can be upregulated or lost as cells differentiate, allowing leukocytes to coordinate their migratory routes with their immunologic function. The most extensive family of chemoattractants, particularly for adaptive immune responses, are the chemokines (Table 22.2). While some chemokines trigger intravascular adhesion (Campbell et al., 1998), others

FIGURE 22.2 Essential molecular players in the multistep adhesion cascade. The top of this schematic diagram depicts the four distinct adhesion steps that leukocytes must undergo to accumulate in a blood vessel. Also shown are the predominant molecular determinants of each step with respect to leukocytes (middle of the diagram) and endothelial cells (bottom). A number of molecules can interact with more than one partner, symbolized by arrows. Leukocytes in the bloodstream (arrows at left symbolize the laminar flow profile) tether to endothelial cells and roll slowly downstream. Tethering is greatly facilitated by leukocyte receptors that occur at high density on the tips of microvillous surface protrusions (L-selectin, PSGL-1, and α_4 integrins), whereas subsequent rolling is not influenced by the topography of adhesion receptors (Stein et al., 1999). The most efficient tethering molecules are L- and P-selectin. L-selectin recognizes sulfated sialyl-Lewis^x (sLe^x)-like sugars (PNA^d) in high endothelial venules. It may also interact with other ligands on inflamed endothelial cells (not shown) and with PSGL-1 on adherent leukocytes (broken arrow). PSGL-1 binding to L- and P-selectin requires decoration with an sLe^x-like sugar in close vicinity to an N-terminal motif containing three tyrosines (Y) that must be sulfated. E-selectin can also interact with PSGL-1, but does not require sulfation and also recognizes other sLe^x-bearing glycoconjugates. E-selectin and the α_4 integrins can tether some leukocytes, but their predominant function is to reduce rolling velocities. Rolling leukocytes respond to chemoattractants on endothelial cells because they express specific receptors with seven transmembrane domains (7TMR), which transmit intracellular signals through G proteins. The activating signal induces rapid activation of β_2 and/or α_4 integrins, which bind to endothelial immunoglobulin superfamily members. Note that α_4 integrins can mediate activation-independent rolling interactions as well as firm arrest. However, the latter function requires integrin activation, symbolized by the open conformation of the integrin heterodimer. For a list of abbreviations, see Table 22.1. Reproduced from von Andrian and Mackay (2000), with permission.

TABLE 22.2 Chemoattractant Receptors and Their Ligands in Leukocyte Migration.

| Biologic Activity | Chemoattractant Receptor(s) | Predominant ligands ^{a,b} |
|----------------------------------|-----------------------------|--|
| Naïve T-cell Migration | | |
| To LN and Peyer patch | CCR7 | CCL21 (SLC); CCL19 (Mip-3b) |
| Within lymphoid tissues | CXCR4 | CXCL12 (SDF-1a) |
| Memory T-cell Migration | | |
| To lymphoid tissues | CCR7 | CCL21 (SLC); CCL19 (Mip-3b) |
| To the skin | CCR4, CCR10 | CCL17 (TARC); CCL22 (MDC-1) CCL27 (CTACK) |
| To the gut | CCR9 | CCL25 (TECK) |
| To sites of inflammation | CCR2 CCR5 | CCL2 (MCP-1) CCL5 (RANTES), CCL4 (MIP-1b) |
| Effector T-cell Migration | | |
| Th1 cells | CCR2 | CCL2 (MCP-1) |
| | CCR5 | CCL5, CCL4 (MIP-1b) |
| | CXCR3 | CXCL9, 10, 11 |
| Th2 cells | CCR3 | CCL11 (Eotaxin) |
| | CCR4 | CCL17 (TARC); CCL22 (MDC-1) |
| | CCR8 | CCL1 (I-309) |
| | CXCR4 | CXCL12 (SDF-1a) |
| B-cell migration | | |
| | CCR7 | CCL21 (SLC); CCL19 (Mip-3b) |
| | CXCR4 | CXCL12 (SDF-1a) |
| | CXCR5 | CXCL13 (BLC) |
| Dendritic Cell Migration | | |
| To lymphoid tissues | CCR7 | CCL21 (SLC); CCL19 (Mip-3b) |
| To normal skin | CCR6 | CCL20 (MIP-3a) |
| To sites of inflammation | CCR1 | CCL5, CCL3 |
| | CCR2 | CCL2 (MCP-1) |
| | CCR5 | CCL5, CCL4 (MIP-1b) |
| | CXCR1 | CXCL8 (IL-8) |
| Monocyte recruitment | | |
| | CCR1 | CCL5, CCL3 |
| | CCR2 | CCL2 (MCP-1) |
| | CCR5 | CCL5, CCL4 (MIP-1b) |
| | CCR8 | CCL1 (I-309) |
| | CXCR1 | CXCL8 (IL-8) |
| | CX3CR1 | |
| | C5aR | C5a |
| Neutrophil recruitment | | |
| | CXCR1 | CXCL8 (IL-8) |
| | CXCR2 | CXCL8 (IL-8); Groa, b, g |
| | C5aR | C5a |
| | fmlpR | fmlp |
| Eosinophil recruitment | | |
| | CCR3 | CCL11 (Eotaxin) |
| | C5aR | C5a |

^aThe physiologic function of several chemokine receptors are multiple, since CCR9 promotes prothymocyte homing to the thymus, and T-cell migration to the gut; CXCR4 is widely expressed and appears to have multiple roles.

^bAn established nomenclature for chemokines (Zlotnik and Yoshie, 2000) has superseded older and in many cases duplicate names for a single chemokine. Frequently used alternative names are shown in parenthesis.

CCR, receptor for CC chemokine; CXCR, receptor for CXC chemokine; LN, lymph node, Th, helper T cell.

direct leukocyte migration into and within extravascular spaces. Since lymphocytes must be positioned correctly to interact with other cells, the pattern of chemokine receptors and the type and distribution of chemokines in tissues critically influence immune responses (Cyster, 1999; Sallusto et al., 1999; Syrbe et al., 1999). Over 50 chemokines and some 18 chemokine receptors have been identified (Kim and Broxmeyer, 1999; Zlotnik and Yoshie, 2000). This multitude ensures robust recruitment of inflammatory cells, even if individual pathways are disabled by genetic defects or through subversion by pathogens (Mantovani, 1999). Also, the multitude of chemokines is consistent with the complex nature of the mammalian immune system, the numerous leukocyte cell types, and the distinct microenvironments wherein migration must be regulated. For instance, neutrophils may use different chemoattractant receptors sequentially, to travel from *a* to *b* to *c*, in a process termed *multistep navigation* (Foxman et al., 1997).

Chemokines are divided into four subfamilies based on the position of N-terminal cysteine residues, and are also classified as inflammatory or lymphoid. *Inflammatory chemokines* primarily attract neutrophils, monocytes, and other effector leukocytes. The major sources of these chemokines are activated endothelial cells, epithelial cells, and leukocytes, although virtually any cell has the potential to produce chemokines (and attract leukocytes) when stimulated by lipopolysaccharides (endotoxin) or inflammatory cytokines. *Lymphoid chemokines* are primarily produced in lymphoid tissues. They maintain constitutive leukocyte traffic and compartmentalization within the lymphoid tissue (Cyster, 1999; Jung and Littman, 1999). In addition to the chemokine receptors, the closely related “classical” chemoattractant receptors such as C5aR serve similar functions particularly during inflammatory responses. The very large number of chemokines, and patterns of chemokine receptor expression on subsets of T cells, suggest that this system of chemoattractants evolved to meet the elaborate demands of the adaptive immune system.

MULTISTEP ADHESION CASCADES

A general consideration for drug development is how selective or broad acting an antagonist should be. Chemokine and chemokine-receptor redundancy, and the expression of multiple receptors by cell types such as monocytes, questions whether any single receptor antagonist will always be effective (Mayadas et al., 1993; Arbones et al., 1994; Bullard et al., 1996; Frenette et al., 1996; Wagner et al., 1996; Andrew et al., 1998; Berlin-Rufenach et al., 1999; Forster et al., 1999; Robinson et al., 1999; Stein et al., 2000; Warnock et al., 2000). Deficiencies in any one of the steps, i.e., selectin binding, chemoattractant signaling, or integrin binding, can derail

cell migration. The numerous leukocyte adhesion receptors, endothelial counter-receptor(s), chemokines, and chemokine receptors means that there are hundreds of possible three-step combinations, and thus great flexibility in the regulation of leukocyte migration (Butcher, 1991; Springer, 1994). Indeed, several multistep combinations occur uniquely in specialized tissues and serve to attract very distinct subsets of blood-borne leukocytes (Springer, 1994; Butcher and Picker, 1996; Robert and Kupper, 1999; Stein et al., 2000; Warnock et al., 2000). In considering whether a single receptor antagonist will always be effective, studies *in vivo* using single-receptor antagonists, or with monoclonal antibodies (mAb) to individual chemokine ligands, have actually proved very effective in animal models (Gong et al., 1997; Gonzalo et al., 1998; Ulbrich et al., 2003; Szekanecz and Koch, 2004). Yet, despite this, emergence of effective drugs for human use remains slow. However, we can mention the considerable interest in targeting chemoattractant receptor signaling pathways wherein numerous receptors would be affected: the phosphoinositide 3-kinases (PI3K) are a good example (Ward, 2004). Mice lacking one of the four isoforms, PI3Kg, are viable, but their neutrophils and macrophages show impaired activation through chemoattractant receptors (Hirsch et al., 2000; Li et al., 2000), and poor chemotactic responses.

Organized Lymphoid Tissues: Venues for Naïve T Cell Homing and Dendritic Cell Interactions

The adhesion cascades that mediate homing of naïve T cells to lymph nodes and Peyer’s patches have become well understood (Bargatze et al., 1995; Warnock et al., 1998, 2000; Stein et al., 2000). Circulating lymphocytes gain access to both of these tissues by crossing HEVs (Marchesi and Gowans, 1964; Girard and Springer, 1995). A characteristic feature of HEVs in lymph nodes is the expression of the peripheral node addressin (PNAd), whereas HEVs in Peyer’s patches express mucosal addressin cell adhesion molecule (MAdCAM)-1. L-Selectin binds both of these addressins, but it sustains rolling only on PNAd in lymph nodes, whereas in Peyer’s patches additional binding of a4b7 integrin to MAdCAM-1 is required (Bargatze et al., 1995; Warnock et al., 1998). Cells expressing high levels of a4b7, such as gut-homing effector T cells, tether directly to MAdCAM-1, whereas naïve T cells first engage L-selectin (Bargatze et al., 1995; Kunkel et al., 1998). The chemokines and chemokine receptors important for lymphocyte entry to lymphoid tissues are CCL19 and CCL21 binding to CCR7. CCR7 is expressed at high levels by naïve T cells and central memory T cells, but not effector memory T cells. CCR7 and

another chemokine receptor, CXCR4, are expressed in a reciprocal manner with inflammatory chemokine receptors, such as CCR5 (Bleul et al., 1997), which marks mainly effector memory T cells.

Naïve T cells are normally restricted in their migration to lymphoid tissues. It is here where naïve T cells and other cells necessary for a primary immune response must gather and interact. Dendritic cells (DCs) in lymphoid tissues are usually derived from monocytes, which enter tissues and differentiate to “immature” DCs (see Chapter 12). Both monocytes and immature DCs express receptors for inflammatory chemokines and other chemoattractants that are released during inflammatory responses (Dieu et al., 1998; Sallusto et al., 1998). Langerhans cells in skin also express CCR6 which promotes their constitutive migration through normal skin. Immature DCs patrol tissues and engulf microorganisms, dead cells, and cellular debris. Exposure to inflammatory products stimulates their movement to regional lymph nodes via afferent lymph vessels, with loss of their receptors for inflammatory chemokines, and upregulation of receptors for lymphoid chemokines (Sallusto and Lanzavecchia, 1999). CCR7 expression allows maturing DCs to home to the T cell area of lymph nodes. While in transit, DCs also alter their functional role to that of antigen presentation, and begin producing chemokines that attract subsets of T cells (Sallusto and Lanzavecchia, 1999).

There is a rationale for naïve T cells being restricted in their migration to lymphoid tissues: that is, that the large-scale percolation of naïve lymphocytes, all with different antigen receptors, allows the very rare antigen-specific cell to encounter its cognate antigen. Moreover, lymphoid tissues are the venue for T cell–DC interactions, T–B cell interactions including the germinal center (GC) reaction, and are also a place to which antigen drains and is captured and retained. Perhaps the restriction of naïve T cells to lymphoid tissues facilitates immune tolerance by limiting exposure of naïve T cells to self-antigens in the periphery.

EFFECTOR T CELL MIGRATION

Naïve T cells differentiate to effector cells in lymphoid organs (Figure 22.1). However, the principal sites where effector cells are needed are peripheral tissues, wherein pathogens are encountered. Thus, effector cells upregulate receptors for inflammation-induced endothelial adhesion molecules and inflammatory chemoattractants (Butcher and Picker, 1996). However, different pathogens require different effector responses, e.g., by Th1, Th2, Th17 cells, and Th1, Th2 and Th17 cells express distinct receptors and obey different traffic signals (Syrbe et al., 1999). Tfh cells are another type of effector T cell that provides help to B cells and drives GC reaction. Distinctive chemokine

receptors on Th1 cells include CCR5 and CXCR3 (Bonocchi et al., 1998; Sallusto et al., 1998), which bind inflammatory chemokines (see Table 22.1). In rheumatoid arthritis and multiple sclerosis (both often thought of as Th1/Th17 related), virtually all infiltrating T cells express CCR5 and CXCR3 (Qin et al., 1998). People with a homozygous mutation that disrupts the CCR5 gene (Paxton and Kang, 1998) may also be less susceptible to some inflammatory disorders, including rheumatoid arthritis (Gomez-Reino et al., 1999). Tfh cells express the chemokine receptor CXCR5, as do B cells, and this expression facilitates their co-location and interaction in follicles where the ligand CXCL13 is expressed. Adhesion molecules also play a role; Th1 cells express abundant selectin ligands. P- and E-selectin, which occur on inflamed endothelium, and their ligand, PSGL-1, are critical for Th1 cell migration to inflamed skin (Austrup et al., 1997; Borges et al., 1997) and peritoneum (Xie et al., 1999). Expression of fucosyltransferase-VII is necessary for cells to synthesize selectin ligands (Maly et al., 1996). This enzyme is induced by interleukin (IL)-12, which drives Th1 differentiation, whereas T cell exposure to the Th2 cytokine IL-4 downmodulates selectin ligand expression (Wagers et al., 1998; Lim et al., 1999).

Th2 cells also express distinctive chemoattractant receptors, including CRTh2 and CCR3 (Sallusto et al., 1997). Eotaxin, a ligand of CCR3, has been implicated in eosinophil recruitment into hyperreactive airways and is prominent in mucosal tissues undergoing allergic and anti-parasitic responses (Jose et al., 1994). Eotaxin production is stimulated by Th2 cytokines, such as IL-4 or IL-13, and is absent from Th1-mediated lesions (Ponath et al., 1996). CCR3 is also expressed on basophils and mast cells, which presumably allows these allergy-related leukocytes to co-localize and interact at sites of allergic inflammation (Gutierrez-Ramos et al., 1999). CrTh2 is another chemoattractant receptor also preferentially expressed on Th2 cells.

The trafficking of regulatory T cells (Tregs), now regarded as crucial contributors to immunological homeostasis, is governed by lineage-distinct expressions of chemokines and integrins that facilitate their movement to, and retention at sites where their selective activities are required (Wei et al., 2008).

Homing to Non-Lymphoid Tissues

Antigen-experienced effector T cells often display a bias in their tissue migration patterns in order to enhance their chances for re-encountering antigen. T cells that respond to cutaneous pathogens in skin-draining lymph nodes migrate preferentially to the skin, whereas effector cells that arise in Peyer’s patches in response to enteroviral infections migrate preferentially to the gut (Butcher and

Picker, 1996). Indeed, lymphocytes express different homing receptors when they respond to orally administered antigen, compared to when the same antigen is given parenterally (Kantele et al., 1999). The best understood tissue-selective homing pathways are in the skin and intestine (Butcher and Picker, 1996; Robert and Kupper, 1999), but other selective migration streams may well exist, such as to the lung, joints, and central nervous system (Salmi et al., 1992). Thus, tissue-selective migration streams offer the prospect of selectively inhibiting cell migration through a diseased tissue, such as the gut, and leaving other tissues unaffected. For instance, mAb inhibitors of $\alpha 4\beta 7$ integrin and MadCam have been trialed in patients with inflammatory bowel disease and this pathway remains attractive for the emergence of a new migration inhibitor for inflammatory diseases.

Some Clinical Applications

Chemoattractant receptors and adhesion molecules have long been promising targets for anti-inflammatory therapies (Carlos and Harlan, 1994; Oppenheimer-Marks and Lipsky, 1998; Homey and Zlotnik, 1999; Mackay, 2001; von Andrian and Engelhardt, 2003; Szekanecz and Koch, 2004), and possible antagonists have been pursued vigorously by the biotechnology and pharmaceutical industries (Table 22.3). Numerous antibodies, recombinant soluble adhesion molecules, receptor-blocking mutant chemokines, and small molecules have been tested for clinical application in multiple sclerosis, inflammatory bowel disease, chronic arthropathies, and psoriasis. In general, studies on experimental animals have validated various receptors or ligands in inflammatory disease models, including asthma, rheumatoid arthritis, multiple sclerosis, sepsis, and transplantation (Grant et al., 2002; Haskell et al., 2002; Miller et al., 2003; von Andrian and Engelhardt, 2003; Mackay, 2008). Subversion of immune responses by pathogens also provides a pointer to the best anti-inflammatory strategies. A telling feature of many pathogens is their subversion of host responses through the chemokine system (Alcami, 2003). Chemoattractant receptors probably offer the most promise because the known seven-transmembrane structure of these receptors would favor recognition of agents leading to inhibition with organic small molecules.

Natalizumab (Tysabri) requires particular mention. This mAb to α_4 integrin developed by Biogen-Idec and Elan for the treatment of multiple sclerosis and Crohn's disease, together with the LFA-1 integrin inhibitor, Efaluzimab (Raptiva), validate the effectiveness of migration inhibitors for human inflammatory diseases. Natalizumab binds to both $\alpha 4\beta 1$ (VLA-4) and $\alpha 4\beta 7$. Studies in rodents, indicating that an $\alpha 4$ -integrin inhibitor should be highly effective for human multiple sclerosis

and inflammatory bowel disease, were borne out by results of phase 3 clinical trials, as well as experience from some years of clinical use showing that natalizumab greatly reduced the number of relapses in multiple sclerosis (see Chapter 52). However, a worrisome adverse effect was the development of JC virus-induced progressive multifocal leukoencephalopathy (PML), attributed to the otherwise weakly pathogenic effect of this virus, and resulting in restrictions on the type of patient that can receive this therapy. However, the Food and Drug Administration (FDA) did not require withdrawal of natalizumab from marketing because its clinical benefits appeared to outweigh the risks involved. For efaluzimab, however, the risk of PML did result in the European Medicines Agency and the FDA recommending suspension of the drug in the European Union and the USA.

Fingolimod (Gilenya, FTY720, Novartis) is another interesting new anti-inflammatory agent (Brinkman et al., 2010) which, after natalizumab, is the most established migration inhibitor for use in human autoimmune disease, particularly in multiple sclerosis. Fingolimod works by increasing lymphocyte retention in lymph nodes, with a consequent lymphopenia in blood. This drug is phosphorylated *in vivo* to yield a molecule that mimics sphingosine-1-phosphate (S1P) and acts as an agonist for four of the five members of the S1P family of G-protein coupled receptors (see Chapter 52). The physiological role of S1P receptors on lymphocytes is to control their exit from lymphoid tissues. This exit is very much an active and regulated process, and certain stimuli, particularly antigen challenge, can reduce lymphocyte exit from lymph nodes to almost zero. In two Phase III clinical trials, fingolimod reduced the rate of relapses in multiple sclerosis patients by over one-half compared to a placebo or interferon beta. Fingolimod is now approved by regulatory agencies for use in the USA and in Europe. A potential side effect of fingolimod treatment is bradycardia due to expression of certain S1P receptors, particularly S1P₃, in the heart.

Potent small molecule antagonists have been developed for a number of the chemoattractant receptors (Table 22.3), especially CCR1, CCR3, CCR5, CXCR3, and CXCR4 (Haringman et al., 2003; Szekanecz and Koch, 2004; Mackay, 2008). Chemokine receptor antagonists have proven highly efficacious in animal models, particularly in models of rheumatoid arthritis according to Szekanecz and Koch (2004). One noteworthy example is a small molecule antagonist of both CCR5 and CXCR3, TAK-779, which inhibits ligand binding of these two Th1-type chemokine receptors (Gao et al., 2003), and also inhibits the development of arthritis by interfering with T cell migration to joint lesions (Yang et al., 2002). Effector T cells in the synovium of patients with rheumatoid arthritis express high levels of CCR5 and CXCR3

TABLE 22.3 Adhesion Molecules and Chemoattractant Receptors as Targets for the Treatment of Inflammatory Diseases.

| Target Pathway/ Receptor | Involved in Leukocyte or T- cell Migration to these Sites ^a | Potential Clinical Applications ^b | Comments, Examples of Drug Development ^b |
|--|---|---|---|
| Adhesion Pathways | | | |
| a4b1–VCAM-1 | Numerous inflamed tissues, Th2 lesions | Asthma, MS, vasculitis | Promising phase II data in MS (Miller et al., 2003; von Andrian and Engelhardt, 2003) |
| a4b7–MAdCAM-1 | Non-pulmonary mucosal tissues | IBD using anti-a4b7 mAb | Promising mouse data, disappointing phase II data |
| Mac-1–ICAM-1 | Inflamed tissues? | Ischemia–reperfusion | Anti-ICAM mAb discontinued in phase III |
| LFA-1–ICAM-1 | Most inflamed tissues, T-cell interactions with APCs | Numerous | Promising phase III data with efalizumab for psoriasis |
| Selectins–PSGL-1 | Acute inflammation, Th1 lesions, esp. in the skin | Numerous | Disappointing phase II data, mixed data with various antagonists (Ulbrich et al., 2003) |
| Fucosyltransferase-VII | Acutely inflamed tissues, Th1 lesions | Numerous | Requires intracellular inhibitors, none described |
| Chemokine Receptors/Ligands | | | |
| CXCR1,2–numerous CXC chemokines | Some inflamed tissues, esp. skin | Psoriasis, RA, reperfusion injuries | Efficacy of antagonists not determined in humans |
| CCR1–CCL3, 5 | Numerous inflamed tissues | RA, others | Promising phase Ib data (Haringman et al., 2003) |
| CCR2–CCL2 (MCP-1) | Numerous inflamed tissues | RA, MS | Promising animal data (Gong et al., 1997) |
| CCR3–CCL11 (Eotaxin) | Th2 lesions, allergic inflammation | Asthma, allergies | Promising phenotypes in knock-out mice, but possible redundancy issues |
| CCR4–CCL17, 22 | Skin, Th2 lesions | Asthma, psoriasis, atopic dermatitis | Importance not established <i>in vivo</i> |
| CCR5–CCL3, 4, 5 | Th1 lesions | RA, HIV infection | Promising small molecule antagonists (Baba et al., 1999; Gao et al., 2003) |
| CCR9–CCL25 | Intestine | IBD | Importance not yet established <i>in vivo</i> |
| CXCR3–CXCL9, 10, 11 | Th1 lesions | RA, MS, transplantation | Possible redundancy of Th1 chemokine pathways Promising data with CXCR3 knock-out mice |
| SDF-1a–CXCR4 | Numerous tissues | HIV infection | Critical for embryogenesis; inhibitors may alter hematopoiesis |
| Classical and other Chemoattractant Receptors | | | |
| C5aR–C5a | Neutrophil, mast cells | RA, sepsis, reperfusion injuries | Ongoing clinical trial in RA |
| BLR–LTB4 | Mast-cell initiated inflammatory lesions | RA, asthma | Potent small molecule drugs developed, effectiveness in autoimmune disease unclear |
| S1P receptors (esp. S1P1) i.e., FTY720, effective | Lymphocyte egress from tissues | Numerous | S1P receptor agonist drugs, in animal models of disease (Goetzl and Graler, 2004; Ward, 2004) |

^aMost of these molecular pathways have been targeted with either small molecule antagonists or blocking mAbs, and are currently in clinical trials for various indications. In addition, a substantial amount of animal experimentation has validated these pathways for various diseases.

^bFor reviews of adhesion molecule or chemoattractant receptor antagonists, and their use in preclinical and clinical trials, see Ulbrich et al. (2003), Szekanecz and Koch (2004) and Mackay (2008).

APC, antigen-presenting cell; CCR, receptor for CC chemokine; CXCR, receptor for CXC chemokine; HIV, human immune deficiency virus; IBD, inflammatory bowel disease; ICAM-1, intercellular cell adhesion molecule-1; IL-8, interleukin-8; LAD, leukocyte adhesion deficiency syndrome; LFA-1, leukocyte function-associated antigen-1; Mac-1, macrophage antigen-1; MAdCAM-1, mucosal addressin cell adhesion molecule-1; MS, multiple sclerosis; PSGL-1, P-selectin glycoprotein ligand-1; RA, rheumatoid arthritis; Th, T-helper; VCAM-1, vascular cell adhesion molecule-1.

(Qin et al., 1998), so it is expected that some of these drugs will succeed in clinical trials and prove useful in the treatment of autoimmune diseases. Interactions involving integrins or selectins are more difficult to inhibit with small molecules, but there are promising results with antagonists of $\alpha 4\beta 1$ -VCAM-1 and LFA-1-ICAM-1 interactions (Kelly et al., 1999; Lin et al., 1999). As a general conclusion, cell-migration inhibitors could greatly alleviate the disabling effects of autoimmune inflammation well before the basic nature of autoimmunity is finally understood.

CONCLUSIONS AND FUTURE DIRECTIONS

The disruption of cell-migration pathways has emerged as a new approach to the treatment of inflammatory autoimmune diseases. Well-established examples include multiple sclerosis, rheumatoid arthritis, Crohn's disease, psoriasis, and various others (see Chapter 81). The wealth of data available on trafficking molecules now calls for a more precise understanding of their physiologic and pathologic relevance to human health and disease, with this requiring new experimental and therapeutic entities such as antibodies, recombinant proteins, small molecule inhibitors, screening assays, and, certainly not least, expertly conducted and meaningful clinical trials. One pivotal question is whether to treat autoimmune diseases with broad inhibitors (the sledgehammer approach) using, for instance, an inhibitor of a common signaling pathway of chemoattractant receptors, or whether to treat such diseases with much more specific inhibitors, for instance inflammatory bowel disease with a CCR9 or an $\alpha 4\beta 7$ inhibitor? Further experience should see this question answered.

INTRODUCTION

In the 1960s, pathological reactions produced by an otherwise healthy immune system were subdivided into four groups on the basis of the effector mechanism initiated. More recent advances in our understanding of cellular immunology have led to less prominent use, and critique, of the Gell and Coombs classification system (Rajan, 2003), which cannot be upheld as such in the light of today's knowledge. Nevertheless, it remains a useful introductory way of characterizing some aspects of autoimmune effector mechanisms. Of the four types of “hypersensitivity reactions,” type I represented “conventional” allergic and anaphylactic responses, while the other three contribute to *bona fide* autoimmune pathology.

AUTOANTIBODIES

Autoantibodies are a hallmark of autoimmune disease (Tan, 1991). In fact, their presence is so common in autoimmunity that autoinflammatory disease, which does not involve specific immune recognition, is principally defined by the absence of autoantibodies (Ombrello and Kastner, 2011) (see Chapter 4). In most cases, autoantibodies are important for diagnostic purposes and may not directly influence the outcome of the disease. However, an increasing number of autoantibodies have been directly linked to inflammation,

cell death, or functional problems. Antibody-mediated autoimmune disease is distinguished into two groups by the Gell–Coombs classification system. Type II hypersensitivity reactions that are mediated by a direct effect of the antibody binding its target antigen; examples of pathogenic autoantibody effects are listed in Table 23.1. By contrast, type III hypersensitivity reactions are mediated by the deposition of immune complexes in affected tissues that will almost always result in inflammation, as discussed below.

DIRECT ANTIBODY-MEDIATED DISEASE

Type II hypersensitivity reactions mainly lead to cell death and removal, or disturb physiological functions (Table 23.1).

Autoantibodies leading to cell death include those against thrombocyte membranes in autoimmune thrombocytopenia, to erythrocyte membranes in hemolytic anemia, to various, mostly uncharacterized, antigens in SLE (systemic lupus erythematosus) cytopenias, or, presumably, to endothelial cell antigens in systemic sclerosis. These autoantibodies follow typical antibody function patterns that include antibody-dependent cell cytotoxicity (ADCC) where the antibody recruits an immune (natural killer, NK) cell to induce cells to kill or phagocytose any target that is marked by an antibody. Alternatively, antibodies may destroy their target by recruiting components of the complement system. Essentially all these antibodies are of particular IgG subclasses, and the

TABLE 23.1 Variable Effects of Well-Defined Autoantibodies.

| Antibody to | Disease | Function of Antibody |
|-------------------------|---------------------------------|----------------------------|
| Acetylcholine receptors | Myasthenia gravis | Receptor blockade |
| Aquaporin-4 | Neuromyelitis optica | Cytotoxicity |
| Beta-2 glycoprotein I | Anti-phospholipid syndrome | Activation of coagulation |
| Desmogleins | Pemphigus vulgaris | Binding function blocked |
| Factor VIII | Acquired hemophilia | Coagulation factor removal |
| Glycoprotein IIb/IIIa | Immune thrombocytopenic purpura | Thrombocyte clearance |
| Thyrotropin receptor | Graves' disease | Receptor stimulation |

specific IgG subclass is relevant for their properties. For example, IgG1 and IgG3 activate complement, while IgG2 is a poor complement activator, and IgG4 does not activate complement at all (Daha et al., 2011). The same classes that activate complement, i.e., IgG1 and IgG3, also avidly bind the activating Fc receptor Fc γ R1 (Nimmerjahn and Ravetch, 2010) and mediate ADCC.

Blood cells marked by antibodies will be phagocytosed in the spleen (and liver), and cleared (Cines and Blanchette, 2002; Gehrs and Friedberg, 2002), while immobile cells, such as endothelial cells to which antibodies bind in systemic sclerosis, may be killed by cytotoxic cells (Sgonc et al., 1996). While the former mechanism is usually obvious and can be easily proven, for example by recording clinical improvement following removal of autoantibodies (American College of Rheumatology Ad Hoc Committee, 2004), ADCC often cannot be proven *in vivo*, and is even difficult to prove in an *in vitro* situation. Nevertheless, the latter most probably is the more common process.

In addition to marking cells for ADCC or phagocytosis, autoantibodies can also cause significant pathology by functionally disturbing physiological processes. Important examples of this type of autoantibody-induced mechanism are antibodies to proteins and glycoproteins, such as to factor VIII (Zeitler et al., 2013) in acquired hemophilia or to β 2-glycoprotein I, which induce thrombotic events in the anti-phospholipid antibody syndrome (Giannakopoulos and Krilis, 2013) (see Chapters 51 and 34). Autoantibodies may engage cell receptors, such as the TSH receptor in Graves' disease (Dalan and Leow, 2012), triggering their activation and so leading to thyrotoxicosis or neuromuscular acetylcholine receptors in myasthenia gravis (Levinson, 2013) preventing their activation leading to muscle weakness, or to channel proteins, such as aquaporin 4, which is targeted in neuromyelitis optica/Devic's disease (see Chapter 57 and Papadopoulos and Verkman, 2012). Other examples of antibodies impairing functions are those to desmogleins in the autoimmune blistering disease pemphigus (Stanley and Amagai, 2006), or those mediating psychosis in SLE (Fong and Thumboo, 2010).

IMMUNE COMPLEX DISEASE

Commonly, pathology is not induced by IgG monomers, but by immune complexes consisting of autoantigen and autoantibodies resulting in a type III hypersensitivity reaction. In this case, other antibody classes also play a major role. In particular, this is relevant to the pentameric IgM and the dimeric IgA, due to their cross-linking capabilities. Immune complexes will strongly activate complement, and will be recognized by Fc receptors, thus causing inflammation.

IgM and IgA rheumatoid factors (RF) are characteristic for active seropositive rheumatoid arthritis (RA). RF bind to the Fc portion of IgG, and in this way induce immune complexes, which likely play a major role in RA pathophysiology. In fact, the complement system is clearly activated in rheumatic joints (Olmez et al., 1991). Moreover, beyond disease activity, high titer rheumatoid factors are associated with incurring damage (Aletaha et al., 2013).

Immune complexes also play a major role in organ inflammation in systemic autoimmune diseases, and in SLE in particular. For example, immune complexes of double-stranded DNA (dsDNA) and anti-dsDNA antibodies lead to proliferative glomerulonephritis. These antibodies can directly be detected in glomeruli. However, rather than being deposited from the blood, they may form locally, by antibodies to nucleosomes being caught at the negatively charged glomerular basement membrane (Yung and Chan, 2008; Mjelle et al., 2011).

Similarly, antibodies to the nuclear antigen Ro/SS-A are associated with subacute cutaneous lupus erythematosus (SCLE) (Sontheimer, 2005), where, likewise, immune complexes can be directly detected in the affected skin. While ANCA-associated vasculitides are not immune complex driven, lupus vasculitis is, as are RA vasculitis, cryoglobulinemic vasculitis, IgA vasculitis (Henoch–Schönlein disease), or hypocomplementemic urticarial vasculitis (Jennette et al., 2013).

COMPLEMENT CASCADES

Immune complexes, as well as most antibodies binding to surfaces, activate the complement cascade via the classical pathway (see Chapter 15 and [Daha et al., 2011](#)). Binding occurs via complement component C1, leading to cleavage of C4 and C2 ([Walport, 2001](#)). The activated larger cleavage products C4b and C2a form the convertase for C3, the central complement of the downstream complement cascade, which then leads to the activation of C5 and the membrane attack complex consisting of C5b, C6, 7, 8, and 9. In addition to formation of the membrane attack complex, C1q, C3b, and C4b bound to immune complexes facilitate phagocytosis, a process called opsonization. Mannose binding lectins form an initiating event similar to that of C1, which is not known to play a role in autoimmunity.

In contrast, the alternative complement pathway is commonly involved in autoimmune disease. This amplification pathway is started by cleavage of C3, upon which C3b has to bind to a membrane. Membrane bound C3b then binds to factor B, and together they activate the alternative C3 convertase C3bBb. Antibodies stabilizing the C3bBb complex, called nephritic factor, are associated with type II dense deposit membranoproliferative glomerulonephritis as well as with partial lipodystrophy ([Walport, 2001](#)).

Cells have mechanisms to defend against occasional deposition of C3b. CD59 (membrane inhibitor of reactive lysis) protects autologous cells against the membrane attack complex, and its deficiency leads to paroxysmal nocturnal hemoglobinuria ([Yamashina et al., 1990](#)), where erythrocytes are slowly but continuously destroyed by unrestrained activation of the alternate complement pathway. In addition, the inhibitory plasma protein factor H binds to C3b, leading to its inactivation by factor I ([Walport, 2001](#)). Two membrane proteins, namely CD35 (complement receptor type I) and CD46 (membrane cofactor protein), also play a role in complement inactivation. As another option, cells may be able to eject complement bound membrane by forming microparticles, albeit at the risk of inducing immune complex disease elsewhere ([Pisetsky, 2012](#)).

The classical complement pathway is checked by C1 inhibitor, the deficiency of which causes angioedema. This is related to yet another function of the complement system: The smaller fragments C3a, C5a, and C4a act as anaphylatoxins, inducing the chemotaxis and activation of leukocytes ([Walport, 2001](#)). This may play a role in the kidney disease of ANCA-associated vasculitides, since C5a receptor deficient animals are resistant to this disease ([Schreiber et al., 2009](#)).

Finally, complement may play a role in limiting immune complex disease by aiding the clearance of immune complexes—or of apoptotic cells. Inherited deficiencies of C1–C4 are all associated with an increased incidence of SLE ([Aringer et al., 2012](#)).

MACROPHAGES

Monocytes and macrophages are the main cells to deal with immune complexes (see Chapter 11). They are equipped with both Fc receptors and complement receptors, thus simultaneously recognizing immune complexes and C5a ([Karsten and Kohl, 2012](#)). Under such circumstances, removal of immune complexes (and attached particles) becomes a highly inflammatory process. Not only will these M1 macrophages then present antigen, they will also produce a variety of proinflammatory cytokines. Immune complex recognition leads to the release of tumor necrosis factor (TNF) ([Aringer and Smolen, 2012](#)), but also of other cytokines, including IL-6, IL-1, IL-8, and GM-CSF ([Jarvis et al., 1997](#)). In this way, macrophages link between immune complex deposition and inflammation. Indeed, Fc receptor deficiency was illustrated by uncoupling of immune complex deposition from glomerulonephritis in a lupus mouse model ([Clynes et al., 1998](#)). In addition to their role as essential promoters of inflammation in autoimmune complex disease, macrophages are also an important effector in autoimmune thrombocytopenia and hemolytic anemia, where antibody-loaded cells are cleared in spleen and kidney ([Cines and Blanchette, 2002](#); [Gehrs and Friedberg, 2002](#)).

NEUTROPHILS

As the most common leukocytes, neutrophils are prototypical effector cells of the immune system ([Amulic et al., 2012](#)). In addition to phagocytosis and degranulation, NETosis has more recently been investigated. NETosis is a form of “aggressive” neutrophil cell death that constrains and kills pathogens; in the end it is the physiological background of what has long been known as pus. Neutrophil extracellular traps (NETs) consist of fibrous structures that contain decondensed chromatin, histones, and antimicrobial proteins ([Amulic et al., 2012](#)). NETosis may be importantly involved in autoimmune tissue inflammation, such as in SLE ([Kaplan, 2011](#)) or in ANCA-associated vasculitides ([Kessenbrock et al., 2009](#)). Neutrophils also produce cytokines, including IL-8, IL-1, IL-17, and TNF, as well as chemokines ([Hoshino et al., 2008](#); [Amulic et al., 2012](#)).

Like macrophages, neutrophils carry both Fc and complement receptors, and accordingly react to antibodies and immune complexes ([Hoshino et al., 2008](#); [Nemeth and Mocsai, 2012](#)). In addition, neutrophils are activated by high concentrations of IL-8, which in lower concentrations acts as a chemoattractant ([Amulic et al., 2012](#)). Activated platelets can also activate neutrophils ([Caudrillier et al., 2012](#)). In other inflammatory situations, Toll-like and nonobese diabetic (NOD)-like receptors recognizing pathogen-associated molecular patterns (PAMPs) and danger-associated molecular patterns (DAMPs) play a major role ([Amulic et al., 2012](#)).

MAST CELLS

Principal players in allergic or type I hypersensitivity reactions, there are indications that mast cells also act as effectors in autoimmune diseases. In addition to histamine and serotonin, mast cells also produce the proinflammatory cytokines IL-6 and TNF (Wesolowski and Paumet, 2011). In rheumatoid arthritis, mast cells have been found within the synovial joint (Kiener et al., 1998), and mast cell deficient mice are protected against arthritis in the K/BxN model (Lee et al., 2002). Antibodies to citrullinated peptides, which are fairly specific for rheumatoid arthritis, also exist as IgE antibodies, and are then associated with synovial histamine release (Schuerwegh et al., 2010). Mast cells are also activated by IgG immune complexes, a process that is potentiated by the presence of the inflammatory cytokine, IL-33 (Kaieda et al., 2012).

NATURAL KILLER CELLS AND CYTOTOXIC T CELLS

To protect the organism, virally infected and transformed cells are actively eliminated by NK cells and CD8⁺ cytotoxic T lymphocytes. Cytotoxicity is principally mediated via membrane bound ligands of death receptors, such as Fas ligand, and Granzyme B (Afonina et al., 2010), all of which induce apoptosis in the target cell. Extracellular Granzyme B also has proinflammatory effects in that it enhances IL-1 α activity by processing this cytokine (Afonina et al., 2011). Conversely, IFN γ and TNF made by either cell type increase Fas (CD95) expression on target cells that facilitates their destruction (Bergman and D'Elis, 2010).

Cytotoxic T cells require priming by myeloid cell-dependent antigen presentation in order to be able to kill (Sigal et al., 1999), and recognize specific peptides presented by autologous major histocompatibility complex (MHC) I molecules. These cells are implicated in *H. pylori*-related gastric autoimmunity (Bergman and D'Elis, 2010), type 1 diabetes mellitus (Coppieters and von Herrath, 2011), and autoimmune central nervous system (CNS) disease (Melzer et al., 2009).

In contrast to cytotoxic T lymphocytes, NK cells need no previous activation. NK cells have receptors that have evolved in parallel with the MHC class I proteins they recognize (Parham and Moffett, 2013). This points to their function in recognizing small changes in MHC class I, which may herald an important safety issue with the afflicted cell. In addition, NK cells kill cells targeted by autoantibodies, a process termed ADCC. Whereas circulating cells covered by autoantibodies are removed in spleen and liver, ADCC is the deadly effector pathway of IgG autoantibodies that bind non-circulating cells, such as endothelial cells in systemic sclerosis (Sgonc et al., 1996). This process may thus induce tissue damage anywhere in the body, but this will be difficult to prove *in vivo*.

EFFECTOR T HELPER CELL-MEDIATED AUTOIMMUNE DISEASE

Whereas CD8⁺ cytotoxic T cells act directly to damage target tissues, CD4⁺ helper T cells (Th cells) drive a specific immune attack by employing a variety of additional mechanisms. For any specific immune reaction these cells are of the utmost importance, and need to be addressed when investigating effector mechanisms in autoimmune disease.

A priori, the immune system does not know which kind of pathogens to expect next. Therefore, naïve T cells are entirely flexible. This flexibility changes for determination in the process of activation. Like cytotoxic T cells, naïve Th cells need antigen presentation by myeloid cells in order to be able to mature into effector Th cells. These two groups of T cells mediate delayed type (type IV) hypersensitivity responses; the 24–48 hour delay is due to the required period of antigen presentation. During this process of antigen presentation, the presence of cytokines secreted by the myeloid cell or other nearby immune cell will determine what lineage of effector Th cell will be generated. These include Th1 cells, Th2 cells, and Th17 cells (Tato and O'Shea, 2006; Reiner, 2007).

Th1 cells are important for the clearance of intracellular pathogens (Infante-Duarte and Kamradt, 1999). They are induced by activation in the presence of IL-12 and are characterized by the ability to secrete IFN- γ (Table 23.2), which activates macrophages to kill such organisms and activates NK cells and cytotoxic T lymphocytes, as well as the ability to enhance MHC expression.

Th2 cells are essential for defending mucosal and epithelial barriers against worms and parasites (Paul and Zhu, 2010; Maizels et al., 2012). They are induced in the presence of IL-4 and are characterized by the ability to secrete IL-4, IL-13, and IL-5 when activated. IL-4 stimulates IgG class switching to IgG4 and IgE, and together with IL-13 alternatively activates macrophages towards the M2 phenotype. IL-9 mobilizes mast cells, and IL-5 plays the same role for eosinophils. Together, IL-4, IL-13, and IL-5 increase mucus secretion, which helps eliminate pathogens such as helminths and other parasites. The related, newly identified lineage, Th9 cells, mainly produce IL-9, but do not produce IL-4 (Dardalhon et al., 2008). They emerge in situations where both IL-4 and TGF- β are present.

Th17 cells are highly relevant for the defense against extracellular bacteria, such as *Staphylococcus* or *Klebsiella*, as well as against *Candida* (Annunziato et al., 2009; Peters et al., 2011). They are induced in the presence of TGF β , IL-6, and IL-23 and are characterized by the secretion of IL-17 when activated, which leads to increased neutrophil formation via G-CSF and GM-CSF, and to increased neutrophil recruitment via IL-8 and other chemokines (Zuniga et al., 2013). In addition, IL-17 stimulates the production of defensins and other antimicrobial substances. While Th17 cells also produce IL-22 that induces expression of defensin proteins in target cells,

TABLE 23.2 Characterization of Important Effector Cells by their Receptors and their Mediators.

| Effector Cell | Important Receptors (Receptor Chains) | Important Cytokines and Mediators |
|------------------|---|--|
| Monocyte | Fc γ RI, IIa, IIb; CR1, 3, 4, C5aR | TNF, IL-6, IL-8, GM-CSF |
| Macrophage | Fc γ RI, IIa, IIb, RIIIa; CR1, 3, 4, C5aR | TNF, IL-6, IL-8, GM-CSF |
| Neutrophil | Fc γ RI, IIa; CR1, C3aR, C4aR, C5aR | TNF, IL-1, IL8 |
| Mast cell | Fc ϵ R, Fc γ RIII; C3aR, C4aR, C5aR | Histamine, serotonin, IL-6, TNF |
| NK cell | NCRs; Fc γ RIIIa; CR3, 4; KIRs | IFN γ , TNF, GM-CSF, IL-8, granzyme B |
| Cytotoxic T cell | TCR; KIRs; CTLA-4 | IFN γ , TNF, granzyme B, perforin |
| Th1 | TCR; IL-12R (β 1 + β 2), IL-18R | IFN γ , IL-2, TNF |
| Th2 | TCR; IL-4R (α + γ c) | IL-4, IL-5, IL-9, IL-13, IL-25 |
| Th17 | TCR; IL-23 R (IL-12 R β 1 + IL-23 R) | IL-17, GM-CSF, TGF- β , TNF |

Fc γ RI = CD64, Fc γ RIIa = CD32, Fc γ RIIIa = CD16 activating Fc γ receptors, Fc γ RIIb inhibitory Fc γ receptor; CR1 (complement receptor 1) = CD35, CR2 = CD21, CR3 = CD11b + CD18, CR4 = CD11c + CD18; NCRs natural cytotoxicity receptors; KIRs killer cell immunoglobulin-like receptors; TCR T cell receptor.

there are cells that produce IL-22, but not IL-17, and are therefore termed Th22 cells (Duhon et al., 2009). This subset is particularly prevalent among skin homing cells.

After exposure, the immune system tries to completely eliminate any foreign invader; this process may become protracted. It is therefore not surprising that the T helper phenotype is largely stable. This is achieved by combining several mechanisms. First, lineage-specific transcription factors are stably expressed that drive differentiation. For Th1 cells the critical transcription factor is T-bet, for Th2 cells it is GATA-3, and for Th17 cells ROR γ t.

The Th1 transcription factor T-bet is induced by Stat1 and Stat4 homodimers, activated by IFN γ and IL-12, respectively. T-bet in turn promotes IFN γ production and represses IL-4 production, among many other effects essential for the maturation of Th1 cells (Miller and Weinmann, 2010). The Th2 transcription factor GATA-3 is induced by homodimers of Stat6, the principal signaling molecule of IL-4 and IL-13. GATA-3 induces IL-4, IL-5, IL-13, and GATA-3 itself (Wei et al., 2011). ROR γ t is induced by homodimers of Stat3, the principal signaling molecule of IL-6, IL-21, and IL-23; at the same time T-bet and IFN γ production are inhibited, whether by (low concentrations of) TGF β or by other means (Hirahara et al., 2010; Peters et al., 2011). ROR γ t in a protein complex that includes STAT3 induces the expression of IL-17 and the IL-23R.

In addition, there is a second level of control, namely epigenetic regulation, whereby chromatin accessibility is regulated, further restricting gene expression. Global DNA methylation mapping has demonstrated that the IFN γ locus is open in Th1, but not Th2 or Th17 cells; the IL-4 locus is exclusively open in Th2 cells, and the IL-17 locus is open in Th17 cells only (Wei et al., 2009). Thus epigenetic modifications are one means by which cell differentiation is kept stable during T cell expansion, or, less fortunately, in autoimmune disease or allergy.

EFFECTOR CYTOKINES AND THEIR TARGETS

Essentially all of the immune cells discussed produce significant amounts of cytokines. These are essential for shaping the immune system at any given time. However, some of these cytokines also have important effects on other tissues (Table 23.3), thereby directly contributing to tissue pathology in autoimmune disease. The importance of individual cytokines is highlighted by the success of anti-cytokine antibodies in the treatment of a number of autoimmune diseases.

TNF is a particularly well-known example in this regard. TNF is produced by many immune cells (Table 23.2), and by monocytes and macrophages in particular. Mice transgenic for, and thus overexpressing, human TNF display peripheral and sacroiliac joint pathology indistinguishable from RA and ankylosing spondylitis, respectively (Keffer et al., 1991; Redlich et al., 2004). TNF fosters the development of osteoclast precursors from monocytes and enhances osteoclast activity, which is essential in that osteoclasts are the only cells able to digest bone (Redlich et al., 2002). Conversely, pharmacological TNF blockade blocks radiographic progression in RA even when disease activity is not adequately controlled (Smolen et al., 2006). TNF also activates fibroblasts (Vasilopoulos et al., 2007) and endothelial cells and leads to vascular leakage (Bradley, 2008).

Since both TNF and IL-1 signal via NF- κ B and mitogen-activated protein kinases (MAPKs), it is not surprising that IL-1 in part reduplicates and further enhances such effects, leading to pronounced inflammatory reactions (Dinarello et al., 2012). Unchecked IL-1 effects in infants lacking IL-1 receptor antagonist (IL-1RA) leads to a fatal, highly inflammatory disease with pronounced skin and bone involvement, which can be effectively treated with recombinant IL-1RA (Aksentjevich et al., 2009).

TABLE 23.3 Important Examples of Cytokines Targeting Cells Outside the Immune System.

| Cytokine (Signaling Pathways) | Target Cell | Effects |
|-------------------------------|------------------------|---------------------------------|
| TNF (NF- κ B, MAPK) | Monocytes | Osteoclast formation |
| | Osteoclasts | Bone resorption |
| | Fibroblasts | Activation |
| IL-1 (NF- κ B, MAPK) | Hypothalamic cells | Fever |
| | Pancreatic islet cells | Cell death, diabetes |
| IL-6 (Stat3) | Osteoblasts | Reduced bone formation |
| | Hepatocytes | CRP and hepcidin production |
| IL-17 (NF- κ B) | Epithelial cells | Chemokine production |
| | Osteoblasts | RANKL expression |
| TGF β (Smads, MAPK) | Fibroblasts | Extracellular matrix deposition |
| | Podocytes | GBM thickening |

NF- κ B, nuclear factor- κ B; MAPK, mitogen activated protein kinase; Stat3, signal transducer and activator of transcription 3; GBM, glomerular basement membrane.

Acting systemically, IL-1 is essential for inducing fever by switching on cyclooxygenase in hypothalamic cells. Acting locally, IL-1 may also be key to the death of islet cells in diabetes (Dinarelo et al., 2012).

IL-6 is the third highly inflammatory cytokine that is currently targeted in the clinic. While the full IL-6 receptor is only expressed on leukocytes and hepatocytes, all other cells are able to recruit IL-6 bound soluble IL-6 receptor to the gp130 chain they express (Rose-John et al., 2006). This process is termed trans-signaling. Although IL-6 signals via STAT3, which is distinct from TNF and IL-1 signaling, its *in vivo* effects are less obviously different (Nishimoto and Kishimoto, 2006). Nevertheless, IL-6 has many unique actions including the induction of C-reactive protein (CRP) and other acute phase reactants, the inhibition of iron uptake and use via hepcidin, and is critical for the maturation of Th17 cells. Finally IL-6 is known to influence sleep and fatigue (Rohleder et al., 2012).

IL-17 receptors are found on a variety of non-immune cells, including epithelial cells, endothelial cells, fibroblasts, and adipocytes (Pappu et al., 2011) as well as osteoblasts (Onishi and Gaffen, 2010). Signaling via NF- κ B, albeit less effectively than TNF (Sonder et al., 2011), IL-17 induces epithelial cells to secrete chemokines, a process likely to be of importance in psoriasis (Onishi and Gaffen, 2010), where IL-17 blockade apparently works well (Miossec and Kolls, 2012). On osteoblasts, IL-17 is able to induce the expression of RANKL, which stimulates osteoclast differentiation (Onishi and Gaffen, 2010). IL-17 may also reduce cartilage matrix synthesis by chondrocytes (Hu et al., 2011).

TGF β has a complex role, exerting both anti-inflammatory and profibrotic effects within the immune

system. It is able to inhibit the expression of a number of other inflammatory cytokines and is known to inhibit Th1 and Th2 polarization, and, conversely, in the presence of IL-6, it is known to induce Th17 cells in both mice and humans and in the presence of IL-4 can induce Th9 cells. Furthermore it acts on fibroblasts to produce extracellular matrix, and thus tissue fibrosis in many organs (Pohlers et al., 2009). TGF β has therefore been suggested as a therapeutic target for systemic sclerosis (Varga and Pasche, 2009). Similarly, TGF β may stimulate podocytes to produce extracellular matrix, leading to glomerular basal membrane thickening (Lee, 2012).

CONCLUSIONS

As to be expected given the time the immune system has had to evolve in an environment where pathogens of various kinds threaten the organism, its effector mechanisms are impressive and have the potential to constrain all current and future pathogens. The adaptive immune system, in particular, has developed highly specialized cells and mechanisms for a differential response. Unfortunately, all of these cells and mechanisms can in some way damage the organism when the immune system makes the error of mistaking self for a dangerous intruder. While our understanding on the mechanisms involved has deepened, and while biological and apheresis methods have become more successful in arresting autoimmune disease while preserving immune function, effective non-toxic cures for many autoimmune diseases remain elusive. We hope that further advances in our understanding of the immune system will continue to improve the situation in years to come.

INTRODUCTION

Sexual dimorphism is the term that refers to differences between males and females of the same species, and is most obvious as differences in external appearances. However, there can also be sexual dimorphism of internal organs and biological functions, including the immune system. Sexual dimorphism in the immune system is important in medicine because it can lead to sex differences in the responses to infection and vaccination and sex differences in the development of autoimmune disease (McCombe et al., 2009). This chapter focuses on the effects of sexual dimorphism on immunocompetence, and on some of the possible mechanisms underlying these effects, including the effects of the sex hormones, sex chromosomes, and sexually-dimorphic cultural and environmental effects on immunity. The possible consequences for autoimmunity of sexual dimorphism in the immune system are also considered.

OVERVIEW OF SEXUAL DIMORPHISM

The sex chromosomes evolved many millions of years ago (Livernois et al., 2012). In humans, most males have X and Y chromosomes and most females have two X

chromosomes. In humans, other combinations of sex chromosomes are found, with the most common being a single X chromosome (Turner's syndrome) or XXY (Klinefelter's syndrome). Sexual dimorphism was noted by Darwin (Darwin, 1871) who thought it was due to sexual selection, as, for example, larger, stronger males might have a reproductive advantage. Other possibilities for the evolution of sexual dimorphism include intersexual competition for food (Hedrick and Temeles, 1989). Overall, in humans, males are larger than females, with greater strength, but shorter life expectancy. In medicine, there are sex differences in the prevalence of many diseases, and there can be sex differences in the response to medications.

Sexual dimorphism is related to the sex chromosome complement of an individual (Wijchers and Festenstein, 2011). Many genes show sex-specific differences in expression (Ellegren and Parsch, 2007; Mank, 2009). Sex differences in the immune system are discussed below.

SEXUAL DIMORPHISM IN THE IMMUNE SYSTEM

Immunocompetence is a word used to describe the overall level of function of the immune system, and is a complex

genetic trait (Flori et al., 2011). It has been recognized that females have increased immunoreactivity (immunocompetence) compared to males and it is suggested that this leads to increased autoimmune disease in females (Zandman-Goddard et al., 2007). In the past it has been suggested that the expression of male sexual traits is inversely related to immunocompetence (the immunocompetence handicap hypothesis) (Folstad, and Karter 1992). However, further studies have not confirmed this (Roberts et al., 2004) and others have suggested that the differences in overall immunocompetence between males and females are related to the pressures of selection on the basis of fitness. It is thought that fitness in females is maximized by lengthening the lifespan through greater investment in immune defenses; in contrast, males require fitness early in life to maximize sexual mating, and so do not need to invest in immune defenses to prolong the lifespan (Nunn et al., 2009). There are also differences between males and females in immunosenescence, which is the decline in immune function in later life, with greater decline in males (Das et al., 2008; Yan et al., 2010) (Table 24.1).

Overall immunocompetence is the sum of the elements of the immune system. There is sexual dimorphism of many of the components of the immune system. In terms of cell counts, there are numerical differences between the males and females. In males the total lymphocyte count is similar to that in females (Giltay et al., 2000; Bouman et al., 2004), but the percentage of T cells within the lymphocyte population is lower (Bouman et al., 2004). The ratio of CD4⁺:CD8⁺ T cells is greater in females than in males (Das et al., 2008; Wikby et al., 2008). There are no reports of differences in B cell counts

between females and males; however, there are long-recognized differences in levels of IgM but not in other immunoglobulin isotypes, with females showing increased levels for all ages >6 years (Butterworth et al., 1967; Lichtman et al., 1967).

The reproductive phase of females also influences the immune system, as post-menopausal women, compared to fertile women, have fewer total lymphocytes (as a consequence of decreased numbers of B and helper T cells (Th cells)) (Giglio et al., 1994; Yang et al., 2000). During the reproductive years, there is an increase in the suppressive activity of CD4⁺CD25⁺Foxp3⁺ regulatory T cells (Tregs) during the late follicular and luteal phase of each menstrual cycle, whereas after menopause there is a drop in the per-cell activity of Tregs (Trzonkowski et al., 2001; Prieto and Rosenstein, 2006; Arruvito et al., 2007). The greatest expansion in numbers and per-cell activity of Tregs occurs during pregnancy, both in humans and experimental animals (Aluvihare et al., 2004; Somerset et al., 2004), presumably in order to tolerate the allogenic fetal tissues.

In laboratory animals, there are also sex differences in the structure of primary immune organs: in male rats the thymus is heavier, has a greater yield of cells, and contains a higher percentage of double negative CD4⁻CD8⁻ cells (Leposavic et al., 1996) and catecholamine-containing cells (Pilipovic et al., 2008) than thymi of female rats. However, in humans, in autopsy studies, no difference was found between the weight of adult thymi from females or males, after correction for body weight (Narongchai and Narongchai, 2008). The differences are possibly more clear-cut in inbred laboratory animals.

TABLE 24.1 Summary of Sexual Dimorphism of Immune Functions

| Immune Functions that Show Sexual Dimorphism | Difference Between Males and Females |
|---|---|
| Percentage of lymphocytes in total leukocyte population | Lower in males (Bouman et al., 2004) |
| Immunosenescence | Greater in males |
| IgM levels | Greater in females (Butterworth et al., 1967; Lichtman et al., 1967). |
| Allograft rejection | Greater in females (Kongshavn and Bliss, 1970) |
| <i>In vitro</i> response to mitogens | Greater in females (Santoli et al., 1976; Weinstein et al., 1984) |
| Resistance to the induction of immune tolerance | Greater in females (Bebo et al., 1999) |
| Ability to combat infection | Greater in females (Dos Santos et al., 2005; Lotter et al., 2006). |
| Response to vaccination | Greater in women (Klein et al., 2010) |
| CD4:CD8 ratio | Greater in women (Das et al., 2008; Wikby et al., 2008) |
| Th1 responses | Greater in females (Huygen and Palfliet, 1984). |
| Treg number and per-cell activity | Increased in females during reproductive years |

There are differences in the function of the immune system of males and females. Generally, females produce more vigorous humoral and cellular immune responses than males (Weinstein et al., 1984; Ansar et al., 1985), shown in female mice by an augmented response to a variety of antigens (Terres et al., 1968), the ability to reject allografts more rapidly than males (Kongshavn and Bliss, 1970), and in female mice and humans by better *in vitro* responses to mitogens (Santoli et al., 1976; Weinstein et al., 1984) and relative resistance to the induction of immune tolerance (Bebo et al., 1999). Following trauma-hemorrhage, immune function is severely depressed in young male mice and ovariectomized and aged females, but is maintained in proestrus females (Kahlke et al., 2000; Choudhry et al., 2007). The survival rate in proestrus females following trauma-hemorrhage and the induction of subsequent sepsis is significantly higher than in age-matched males and ovariectomized females.

Furthermore, females are more successful than males in resisting a variety of bacterial, viral, and parasitic infestations and this enhanced immune capability might explain, in part at least, why the life expectancy of females exceeds that of males. For example, female mice have a greater ability than male mice to combat various infections, including leishmaniasis and amebic infection with liver abscess (Lotter et al., 2006), which is thought to be due to sex differences in Th1 and Th2 responses (Mock and Nacy, 1988). Moreover, in Wistar rats infected with *Trypanosoma cruzi*, there is less parasitemia in females than males (dos Santos et al., 2005). Of relevance to autoimmunity, there are gender differences in resistance to inflammation of the heart after coxsackievirus infection, which are inferior in males and related to poorer Treg responses in males than females (Frisancho-Kiss et al., 2007). In immunized mice, females show greater production of the Th1 cytokine interferon (IFN)- γ than males (Huygen and Palfliet, 1984). These differences in Th1 and Th2 response are mediated in part through IL-13 (Sinha et al., 2008).

In humans, the antibody response to a variety of vaccines and test antigens, including flagellin protein (Rowley and Mackay, 1969), influenza, hepatitis B, rubella and tetanus (Cook, 2008) and a variety of other viral vaccines (Klein et al., 2010), is more vigorous in females than in males. In women, the innate immune response is also stronger.

Another, less quantifiable, functional difference between females and males is seen in the immune response to injury, according to reports on greater degrees of immunosuppression in men than in women after physical trauma (Choudhry et al., 2005) and after abdominal surgery (Wichmann et al., 2003), as measured by B lymphocyte, T lymphocyte, T helper cell counts, and natural killer (NK) cell counts and circulating levels of IL-6.

There are many examples of sex differences in biochemical pathways involved in immunity. Sexual dimorphism is also expressed at a cellular level, since stimulation of invariant NKT (iNKT) cells with α -galactosylceramide leads to higher concentrations of interferon gamma in the serum of female mice (Gourdy et al., 2005) and the concentration of serotonin and histamine in white blood cells and mast cells is greater in female than in male rats (Csaba et al., 2003) (see Table 24.1).

EFFECTS OF HORMONES ON THE IMMUNE SYSTEM

Sexual dimorphism in the immune system could be due to the effects of sex and reproductive hormones. These hormones have cognate receptors that are widely expressed on many cell types, including cells of the immune system. There is evidence that sexual dimorphism in immune functions in C57Bl/6 mice are dependent on puberty, which suggests that the effects of the sex hormones are important (Lamason et al., 2006). There are numerous effects of the sex hormones in human immunity (Bouman et al., 2005). The effects of the various sex hormones on immune function are summarized below.

Estrogens

There are three estrogenic hormones, estrogen (E1), estradiol (E2), and estriol (E3), with E3 being produced only in pregnancy. As well as being present at high levels in females, estrogens are also present in males, in whom they have widespread effects (Sharpe, 1998). Estrogens act on intracellular estrogen receptors (ER). The best-known ERs (ER α and ER β) belong to the class known as ligand regulated nuclear transcription factors (Matthews and Gustafsson, 2003). There is also a membrane bound G-protein coupled estrogen receptor (Prossnitz et al., 2007), which is prominent on vascular tissue and has rapid “non-genomic” effects (Simoncini et al., 2004). ER are widespread, and have important effects on the growth of cells. ER α and ER β are expressed on antigen presenting cells (APCs) (Nalbandian and Kovats, 2005), and at higher levels in CD4⁺ T cells and B cells than in CD8⁺ T cells; however, whereas B cells express higher levels of ER β than ER α , CD4⁺ T cells show higher levels of ER α than ER β (Pernis, 2007).

The results of many experiments indicate that estrogen can affect immune function: for example, T lymphocytes from patients with SLE, but not from healthy controls, can be activated via ER α and ER β to increase expression of the T cell activation markers CD154 and calcineurin (Rider et al., 2006). Furthermore, different types of estrogens can have differential effects (Ding and Zhu, 2008). Estrogen induces thymic atrophy by preventing proliferation

of early thymic progenitor cells (Zoller and Kersh, 2006), and this is due in part to the effects of estrogen on the membrane bound estrogen receptor (Wang et al., 2008). Estrogen has effects on dendritic cells (DCs) (Ding and Zhu, 2008), modulates the effects of lipopolysaccharide (LPS) on monocytes (Pioli et al., 2007), and inhibits monocyte adhesion to endothelium (Nilsson, 2007). Such results, however, may not relate to the role of estrogens at physiologic levels. Much of what has been observed *in vitro* is likely to be what occurs in high estrogen states, such as pregnancy, rather than in non-pregnant women.

Estrogen has numerous effects on the function of CD4⁺ T cells (Pernis, 2007). Low doses of estrogen, as would occur in non-pregnant women, enhance Th1 responses whereas high levels, as would occur in pregnancy, enhance Th2 responses. Estrogen also influences chemokine production by activated splenocytes (Lengi et al., 2007) and influences T cell trafficking. E2 can convert CD25⁻ cells to CD25⁺ Treg cells (Tai et al., 2008). Thus enhancement of Th2 responses and induction of Treg cells by high doses of estrogens could ameliorate Th1-mediated autoimmune diseases. It is thought that the drop in Treg activity around the time of menopause is related to estrogen-mediated changes in levels of IL-6 (Rachon et al., 2002). Estrogen enhances antibody production in response to antigen immunization (da Silva, 1999). This effect differs between E3 and E2 (Ding and Zhu, 2008), with E3 strongly stimulating antibody response to bacteria (da Silva, 1999).

There is some evidence that estrogens are more directly involved in autoimmunity. Thus, in patients with myasthenia gravis, there is alteration of expression of ER in the thymus (Nancy and Berrih-Aknin, 2005), a site wherein the disease may be generated (Hill et al., 2008). In SLE, estrogen promotes the survival of B cells with affinity for DNA (as does prolactin) (Grimaldi, 2006). Genetic studies among Japanese show that there are associations with polymorphisms in the ER in rheumatoid arthritis (Takagi et al., 2000), although not in autoimmune diabetes (Ban et al., 2000). In females with multiple sclerosis (MS) who carry HLA-DR2, carriage of an ER α 4 polymorphism conveys the additional risk of developing disease (Mattila et al., 2001).

Progesterone

Progesterone is a steroid hormone that is present in the blood during the menstrual cycle and in high levels in pregnancy. Adult males have levels similar to those in women during the follicular phase of the menstrual cycle. In women, progesterone is produced in the ovary as well as the placenta during pregnancy. In males, progesterone is produced by the adrenal gland and testes. The action of progesterone is mediated through cytosolic progesterone

receptors, of which there are three isoforms, belonging to the nuclear hormone receptor superfamily of transcription factors. The different isoforms are widely distributed and have specific tissue expression patterns that can be modified following exposure to hormones. Ligand binding induces changes in gene expression through direct binding to promoter elements or through protein–protein interactions with other transcription factors (Tait et al., 2008). In some cells, including T cells (Dosiou et al., 2008), progesterone may also act via membrane G-coupled protein receptors that rapidly transduce hormone-induced signals across the cell membrane (Boonyaratanakornkit et al., 2008). Since these additional phenomena do not depend on the genome, these actions are called nongenomic or extranuclear effects (Wehling and Losel, 2006).

Progesterone has immunomodulatory effects (Tait et al., 2008) which are generally anti-inflammatory, including inhibition of glucocorticoid-mediated thymocyte apoptosis (McMurray et al., 2000), reduction of nitric oxide production (Miller et al., 1996), and expression of Toll-like receptors (TLR) (Jones et al., 2008) by macrophages. Progesterone promotes Th2 differentiation *in vitro* (Piccinni et al., 1995) and also influences antibody production, especially production of antibodies that are asymmetrically glycosylated in such a way that they fail to trigger immune effector mechanisms. Such antibodies are thought to be self-protective (Canellada et al., 2002). High doses of progesterone enhance differentiation of human and mouse DCs *in vitro* and expression of the costimulatory molecules CD80, CD86, and CD40, as well as major histocompatibility complex (MHC) II (Ivanova et al., 2005; Liang et al., 2006).

Androgens

Androgens, the best known of which is testosterone, stimulate or control the development and maintenance of masculine characteristics; however, they have other functions, including maintenance of bone mass in both women and men. Androgens are also the precursors of all estrogens. In males, androgens, primarily testosterone, are present at high levels, but these decline with increasing age (Mitchell et al., 1995). In contrast, in females, lower levels of androgens (particularly the adrenal-derived androgens DHEA and DHEA-S) persist throughout life (Davison et al., 2005). The best-known androgen receptors are nuclear receptors, but non-genomic signaling also occurs (Lutz et al., 2003).

The potent and rapidly occurring immunosuppressive effects of testosterone in mice occur at least in part by induction of thymic atrophy, and cessation of testosterone production by castration of males results in thymic hypertrophy; these effects occur via interaction of sex

hormones with receptors on thymic stromal cells (Hince et al., 2008). Testosterone also impairs thymocyte proliferation in response to the mitogen Con A (Yao and Shang, 2005). In men treated with medical castration, there is a reduction in levels of CD4⁺CD25⁺ Tregs and in IFN- γ production following mitogen-induced activation of CD8⁺ T cells (Page et al., 2006). Intriguingly, recent studies using non-obese diabetic (NOD) mice suggest that changing the gut microbial environment can change testosterone levels in these mice, thereby modifying progression to autoimmunity (Markle et al., 2013).

ROLE OF THE SEX CHROMOSOMES IN IMMUNITY

The differences between males and females are due to differences in sex chromosomes. People with a Y chromosome show masculinization, due largely to the effects of the testis forming gene, *Sry*, on the Y chromosome, and the effects of high levels of testosterone. However, the *Sry* gene also has effects other than testis formation, such as controlling concentrations of dopamine (which may explain why there is a higher incidence of dopamine-related disorders such as Parkinson's disease in males) (Wijchers et al., 2010) and other genes on the sex chromosomes play a role in sexual dimorphism, largely through epigenetic effects. Some of the effects of sex chromosomes in immunity are examined below.

X Chromosome

The increased prevalence of autoimmunity in females has generated considerable interest in the X chromosome in immunity, particularly since there was shown to be a direct influence of the overall complement of X chromosomes to the female bias toward autoimmune disease (Smith-Bouvier et al., 2008). Typically, the X chromosome in men is active, whereas women have one active and one inactive copy of each X chromosome, although some genes on the “inactive” chromosome can escape inactivation through the action of epigenetic modifiers. Consequently, females exposed to these modifying agents can have elevated levels of expression of some molecules encoded on the X chromosome. For example, exposure of CD4⁺ T cells to the drug 5-azacytidine leads to elevated levels of CD40 ligand (CD154—which is encoded on the X chromosome) on T cells from females but not males (Lu et al., 2007). There are observations of elevated levels of CD154 in a multitude of autoimmune disorders, including SLE, autoimmune thyroid disease, type 1 diabetes, inflammatory bowel disease, psoriasis, MS, and rheumatoid arthritis (Toubi and Shoefeld, 2004).

Other genes on the X chromosome are also of potential relevance for autoimmunity, including those encoding

the IL-2 R γ chain (also known as the common γ chain because it is shared by receptors for IL-2, IL-7, IL-15, and IL-21) (Alves et al., 2007), and Foxp3, which is important in the development and function of Tregs (Zheng and Rudensky, 2007). Mutations of these genes lead to X-linked severe combined immune deficiency (SCID) (Leonard et al., 1994) and IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome (Bennett et al., 2001), respectively. Additional molecules encoded by genes on the X chromosome that might be important for autoimmunity are: tissue inhibitors of metalloproteinases (TIMPs) 1–4, which are important in inflammation (Anderson and Brown, 2002); the X-linked inhibitor of apoptosis that regulates T cell function (Zehntner et al., 2007); and the pattern recognition receptors TLR 7 and TLR8, both of which are important in the recognition of single-stranded RNA and which have also been associated with asthma and other inflammatory diseases (Fish, 2008; Moller-Larsen et al., 2008). There are also many X-linked genes encoding possible target antigens of autoimmune disease: changes in dosage of these autoantigens could also provide an initiating event for the development of autoimmunity.

Women with Turner's syndrome have one normal X chromosome, but the other X is either missing or structurally altered; these women also have an increased incidence of autoimmune disease overall, and especially thyroid autoimmunity (Wilson et al., 1996). Interestingly, the thyroid disease is associated with the presence of an X isochromosome, in which the short distal arm of one X chromosome (X_p) is deleted and replaced with a copy of the long distal arm (X_q) from the sister chromosome. This suggests that a gene on X_q may play an important pathogenetic role in the development of autoimmune thyroid disease (Elsheikh et al., 2001), or alternatively that genetic elements on X_p help protect against disease.

Males who have SLE in addition to Klinefelter's syndrome (wherein they have at least two X chromosomes and at least one Y chromosome) share many characteristics of the female with SLE (Lahita, 1999), including increased oxidation of androgens, suggesting that there is some role for the two X chromosomes in this process, although exactly what this role is is not yet known.

Y Chromosome

The Y chromosome contains few genes. Most of the DNA is male specific and the remainder is autosomal. The Y chromosome encodes at least 27 proteins, some of which are confined to testis and some of which are more widely expressed (Skaletsky et al., 2003). The most important Y chromosome gene is *Sry*, which is the gene responsible for the formation of testes and masculine features.

There is some effect of Y chromosome genes on the development of experimental autoimmune encephalomyelitis (EAE), the animal model of MS, since female offspring of backcross strains carrying the susceptible SJL/J Y chromosome behaved more like their male siblings than like the female mice from three other birth crosses carrying the resistant C57BL/6 Y chromosome, both in lesion severity (reduced) and clinical sensitivity to central nervous system (CNS) damage (increased) (Teuscher et al., 2006). With increased age, male SJL/J mice show increased susceptibility to EAE, and this has been shown to be due to a polymorphism on the Y chromosome (Spach et al., 2009). Y chromosome candidate genes potentially responsible for these effects in mice include *Hya*, *Yaa*, and *Sry* (Teuscher et al., 2006).

Interestingly, *Yaa*, which predisposes to autoimmunity in mice, is actually a translocation of a cluster of X chromosome genes, including the gene encoding TLR7 (Subramanian et al., 2006). It has been demonstrated that even relatively modest increases in the expression of TLR7 can result in dramatic lymphocyte activation and autoimmunity in mice (Deane et al., 2007). It has been suggested that a similar effect in humans could dictate susceptibility to SLE. However, a study of 190 male and female SLE patients and controls found no lupus-related difference in copy number of the *TLR7* gene, suggesting that human lupus is not commonly due to a *Yaa*-like mutation (Kelley et al., 2007).

ENVIRONMENTAL EFFECTS ON SEX DIFFERENCES IN IMMUNITY

As with many issues in biology, there can be an interaction between genes and the environment. The sex differences noted above are what are observed in humans living in

natural conditions, and it is possible that there is plasticity in the immune responses in response to the environment. It is theorized that the sex differences are a result of the pressures of the environment (availability of food, availability of sexual partners), and that the males and females differ in traits that limit their fitness so the response to the environment will differ. It is possible that alteration of the environment could alter the sexual dimorphism in the immune system. In experiments with *Drosophila*, increased availability of food led to increased female immune function, and increased availability of mates led to decreased male immune function (McKean and Nunnery, 2005). It is possible that gender differences in human immune function could be affected by environmental and social factors. For example, caloric restriction in humans has anti-inflammatory effects (Morgan et al., 2007).

Some environmental effects on sex differences in immunity may relate to differences in the likelihood of exposure of males and females to those effects. For example, recent evidence has implicated UV-induced vitamin D in immune function and protection from development of autoimmunity. Generally, males have more sun exposure and use less sun protection than females, which could help to explain some of the sexual dimorphism in susceptibility to many autoimmune diseases. Similarly, it has been suggested that chemicals in cosmetics act as a trigger for primary biliary cirrhosis (Rieger et al., 2006), which has an overwhelming female predominance.

CONSEQUENCES FOR AUTOIMMUNITY OF SEXUAL DIMORPHISM IN THE IMMUNE SYSTEM

There is a marked sexual dimorphism in the incidence of many autoimmune diseases, ranging from those with a

FIGURE 24.1 Some Human Autoimmune Diseases have a Strong Female Preponderance. The ratio of females to males for a variety of autoimmune diseases is shown. The green line represents a 1:1 ratio. A pink colored top to the bar indicates that the disease is more common in females than in males. CIDP—chronic inflammatory demyelinating polyradiculoneuropathy. SLE—systemic lupus erythematosus.

strong female preponderance (e.g., SLE and primary biliary cirrhosis) to those that show a modest increase in females (e.g., MS and rheumatoid arthritis) to those that are actually male dominated, such as type 1 diabetes, some types of vasculitis and ankylosing spondylitis (Figure 24.1). It is likely that the overall increase in autoimmune disease in females is due, at least in part, to the stronger female immune system. When autoimmune disease occurs in males, this could mean that these individuals have immune systems that are particularly vulnerable to disease. This theory, which is known as the Carter effect (Carter, 1969), is applicable to polygenic disorders and suggests that if a subject has an innate biological resistance to a particular disease then there will be a greater burden of genetic risk factors required to overcome that resistance for disease to occur. Thus, for a male to develop a true autoimmune disorder would require a much heavier load of other contributing elements, be they genetic or environmental: males who do present with diseases such as autoimmune thyroid disorder, primary biliary cirrhosis, or lupus may warrant particular scrutiny, as non-sex-related causal elements might be more readily identifiable.

There may also be other gender-specific differences that indirectly affect immune reactivity and contribute to skewing of susceptibility to autoimmune disease in females (McCombe et al., 2009; Greer and McCombe, 2011, 2012; Borchers and Gershwin, 2012; Nussinovitch and Shoefeld, 2012; Pan and Chang, 2012; Pollard, 2012; Quintero et al., 2012). These differences could include: sexual dimorphism in the vulnerability of the target organ to autoimmune attack; epigenetic effects of the sex hormones or gender-specific environmental or lifestyle exposures on genetic risk factors; differences in genomic imprinting in males and females; and effects related to female reproduction. The future challenge is to determine which of these differences between males and females is most important in the development of autoimmunity, since understanding the influences of sexual dimorphism in autoimmune diseases is likely to provide opportunities for better therapies.

CONCLUDING REMARKS

Sexual dimorphism in the immune system affects the relative immunocompetence of males and females. While the greater immunocompetence of females, as a result of hormonal and X-linked effects, leads to an enhanced ability to fight infection and a lengthening of lifespan, it also increases the risk to females of developing autoimmune disease. Improving our understanding of the underlying causes of sexual dimorphism in the immune system will ultimately improve the potential to successfully treat autoimmune disease.

INTRODUCTION

As soon as the concept of autoimmune diseases emerged, it was suggested that infectious agents have a role in their etiology. In fact, we now know that certain autoimmune diseases, such as rheumatic fever (streptococci) and certain cases of the Guillain–Barré syndrome (*Campilobacter jejuni*), are directly caused by bacterial infection through molecular mimicry.

New insight was gained unexpectedly when it was proposed that the decrease in infectious diseases observed in industrialized countries over the past four decades might cause a parallel increase in the frequency of autoimmune and allergic diseases, suggesting a new role for infectious agents (Bach, 2002). The problem reached an

additional level of complexity when it was found that life-style changes associated with socioeconomic progress, which largely explained the decreased frequency of infectious diseases, also contributed to modifying the intestinal flora (Pflughoeft and Versalovic, 2012). Furthermore, gut flora itself is known to have an effect on the onset of dysimmune diseases such as autoimmune, inflammatory bowel and allergic diseases (Proal et al., 2009; Round and Mazmanian, 2009; Mathis and Benoist, 2011; Cho and Blaser, 2012; Chervonsky, 2013; Shanahan, 2013).

Thus, presently one may wonder, what is the respective role of infectious pathogenic agents and of commensal bacteria in the protection from autoimmune diseases?

THE INTESTINAL MICROBIOME

The expression “intestinal microbiome” is generally understood today as meaning the commensal bacteria of the gut flora.

In addition to intestinal commensal bacteria, every individual is confronted with or lives in symbiosis with many commensal bacteria located outside the intestine (for example, the skin and vaginal microbioma which are discussed below) that are part of the host environment. Innate immunity and, often also, adaptive immunity are continuously challenged by this environment.

Intestinal Microbiome Composition and Genotyping Techniques

Each human being harbors in his or her gut more than 10 trillion bacteria amounting to a weight of over 1.5 kg. They represent a wide diversity of species (200 main species and globally probably more than 1000) (Reid et al., 2011; Molloy et al., 2012). It has become relatively easy to analyze gut flora composition using genetic techniques strongly supported by bioinformatic methods.

Access to modern genetic techniques has opened considerable opportunities in terms of our inventory capacity regarding the intestinal microbiome. The classical techniques of bacterial culture and identification were labor-intensive and not very efficient because many commensal bacteria could not be grown *in vitro*. Gut bacteria are now defined by their genes and designated collectively as “microbiota.” They are referenced by their genetic makeup under the general term “metagenome.”

Two main techniques based on DNA sequencing are used to genotype the gut microbiome:

- The Shotgun sequencing can generate in parallel over 100 million gene sequences (50 to 75 bases) and makes it possible to sequence any given segment of DNA from its two ends (Li et al., 2010). DNA is broken-up randomly into numerous small segments, which are sequenced using the chain termination method to obtain *reads*. Multiple overlapping reads for the target DNA are obtained by performing several rounds of this fragmentation and sequencing. Computer programs then use the overlapping ends of different reads to assemble them into a continuous sequence. The main challenge of using this technique to create a gene catalogue is the assembling of a sufficient number of small sequences of adequate length to obtain contiguous portions of the DNA sequence of interest, the length of which needs to be at least equal to that of a typical bacterial gene.
- The 16S bacterial rRNA gene sequencing generates longer sequences (300–800 bases) and is widely used

for metagenomics analysis (Marguiles et al., 2005). It has been established as the “gold standard” for identification and taxonomic classification of bacterial species mainly due to the lower technical and cost issues. However, the limitation of this technique lies in the sequencing of only one gene for all the samples, with a lower identity percentage than for the whole genome sequencing.

For the two techniques the sequencing can be performed by different technologies, the most largely used being the Illumina dye sequencing and the 454 Pyrosequencing, which differ in the way of detection of the added nucleotides into the sequence.

Several hundred human metagenomes have already been studied, mainly by big international consortiums (such as MetaHit consortium in Europe). A limited number of different profiles (enterotypes) have been identified but the significance of this categorization is not yet clear (Dusko Ehrlich, 2010).

The Microbiome Changes Over a Lifetime

The intestinal flora appears in the days following birth as a consequence of the first intestinal colonization, usually by the mother’s vaginal microbiome in children born through natural delivery (Martin et al., 2010). For those children, and also, of course, also for those born through cesarean section, the initial intestinal microbiome is acquired through feeding, whether the mother breast feeds or not.

Most of the microbiome is fixed in humans as early as the first week of life and is nearly completed by the end of the infant’s first months. Its composition may vary in cases of intestinal infection or antibiotic treatment but reverts to its initial composition with small variations after recovering from illness or the treatment.

The Intestinal Microbiome Depends on the Environment

The composition of the microbiome depends on the host’s environment. Thus sanitary conditions, hygiene, and the medical and nutritional context can have a considerable role on the composition of the microbiome (Pflughoeft and Versalovic, 2012). It has been shown in pigs that rearing animals in sanitary and controlled conditions after delivery by cesarean section significantly altered the composition of the gut microbiome (Mulder et al., 2009). Interestingly, similar results were observed when pigs born by natural delivery were placed in a clean environment by the third day of life, once the first intestinal colonization, mainly of vaginal origin, had occurred (Schmidt et al., 2011).

In humans studies were carried on Italian children living in the Florence region and African children from Burkina Faso. It was found that a number of well-defined bacteria were present in very different amounts in the two groups of children studied (DeFilippo et al., 2010). It is interesting to note in this example the difficulty of knowing which environmental factor is responsible for the observed difference in the composition of the microbiome—diet or hygiene—both of which are very different in these two countries.

Germ-Free (GF) Animals

Several techniques are available to raise germ-free (GF) (also termed axenic) animals throughout their first weeks of life. The first technique consists in raising animals in sterile conditions, in a GF atmosphere in terms of environment and food. The second technique consists of administering at birth, or even to the mother during pregnancy, antibiotics to eliminate most (but not necessarily all) commensal bacteria. Various protocols have been used to successfully eliminate commensal bacteria. Specific antibiotics such as vancomycin or streptomycin have been used, as well as antibiotic cocktails. The results have been different depending on the type of treatment, as determined from microbiome analyses.

Raising animals in a GF environment leads to modifications in the development of the immune system since the intestinal microbiome plays an important role in its maturation (Tlaskalova-Hogenova et al., 2011). It has been known for a long time, in particular from Sterzel's experiments in Prague in the 1980s, that GF animals display severe immune deficiency (Tlaskalova-Hogenova et al., 1983). How intestinal microbiome influences this maturation is still unknown. This partial immunodeficiency essentially affects antibody production and also probably (but this has been less well studied) cellular immunity. Furthermore, a decrease has been observed in intestinal responses to infections that are associated with lymphoid atrophy affecting Peyer's patches (Chinen et al., 2010).

Recently, many studies have focused on identifying the cellular mechanisms underlying this immune deficiency. Particular attention was given to several species of commensal bacteria that can induce regulatory T cells or Th17 cells.

Various studies have shown that commensal bacteria of the *Clostridium* genus can induce regulatory CD4⁺CD25⁺FoxP3⁺ T cells affecting both cell number and function. In particular, the oral administration to GF animals of a bacterial mixture of several *Clostridium* species induced these regulatory T lymphocytes in the colonic lamina propria (Atarashi et al., 2011; Nagano et al., 2012). Simultaneously, a preventive effect on the

induction of inflammatory colitis and the production of IgE was observed.

Similarly, it was shown that the commensal bacterium *Bacteroides fragilis* belonging to the *Clostridium* genus was particularly effective at inducing regulatory T cells that produce interleukin (IL)-10 (Round and Mazmanian, 2010). Kasper and collaborators have shown that in GF animals the same effect could be achieved by replacing the commensal bacterium with one of its polysaccharide constituents, namely polysaccharide A or PSA (Ochoa-Repáraz et al., 2010). It appears that the regulatory T cells induced in the intestine by these bacteria represent a very specific subpopulation of regulatory T cells which, interestingly enough, are not induced in mice invalidated for the IL-10 gene (Ochoa-Repáraz et al., 2010).

It has been observed that GF mice display a deficit of IL-17 producing Th17 cells. Interestingly, it is possible to restore the ability to produce IL-17 in GF mice by colonization with a single bacterium, the segmented filamentous bacterium (SFB) (Ivanov et al., 2009; Gaboriau-Routhiau et al., 2009). In spite of its importance, this observation should not overshadow the fact that other commensal bacteria can also induce Th17 cells in GF mice, in particular *Citrobacter rodentium* and *Salmonella typhimurium* infection (Geddes et al., 2011). These observations have led to important applications in the field of autoimmunity, especially results showing that pathologies involving Th17 cells could be induced by SFB. Thus, the arthritis observed in K/NxB mice (see below) described by D. Mathis et al. could be induced in GF mice, which normally do not develop this disease, after monocolonization by SFB (Wu et al., 2010). Similar results have been observed in experimental allergic encephalomyelitis (EAE) (Ochoa-Reparaz et al., 2009; Lee et al., 2011). Inversely, it has been shown that the presence of SFB in the intestine is positively correlated with protection against autoimmune diabetes in female non-obese diabetic (NOD) mice (but not in male NOD mice) (Kriegel et al., 2011).

EFFECT OF A GF ENVIRONMENT ON EXPERIMENTAL DISEASES

The effect of a GF environment on experimental autoimmune diseases has been mainly studied in four types of models: autoimmune diabetes in NOD mice, EAE, experimental arthritis, and murine lupus.

Non-Obese Diabetic Mouse

Contradictory results were obtained from the study of germ-free NOD mice. The first study led to a significant increase in the incidence of the disease (Suzuki et al., 1985), while other studies could not find any difference

between GF and specific pathogen-free (SPF) housing conditions (Taniguchi et al., 2007; Wen et al., 2008; King and Sarvetnick, 2011). Another study showed increased insulinitis without any worsening of diabetes (Alam et al., 2011). Lastly, recent data showed a major increase in disease incidence in NOD males but not in females with the additional interesting but intriguing observation that transplanting gut microbiome from SPF male mice to SPF females decreased the incidence of diabetes in the recipients, an effect associated with an elevation of testosterone levels (Markle et al., 2013). These different outcomes can be explained by the different GF conditions used in the studies, or more subtly by differences in the sanitary conditions of the control animals. Whatever the cause may be, the important point is that there is a difference between “clean” and less clean animals. Thus, the analysis of GF NOD mice is not very informative. As will be seen below, more information can be obtained by comparing SPF mice and mice raised in fully conventional sanitary conditions.

The question remains open as to when during the life of an animal (at birth or later) bacteria present in the environment have an effect. The involvement of the intestinal microbiome is all the more likely if the effect of the infections occurs early.

Experimental Allergic Encephalomyelitis

The effect of a GF environment on EAE was studied on two types of models:

- Conventional EAE induced by immunization against myelin proteins in normal animals and
- The spontaneous (or antigen-boosted) development of EAE in transgenic mice carrying a T cell receptor that recognizes a myelin protein.

For the first model, it was shown by Ochoa-Reparaz et al. that oral antibiotic treatment can prevent EAE development after immunization against myelin basic protein (MBP) (Ochoa-Reparaz et al., 2009). This study also showed that the antibiotic treatment induced a simultaneous decrease in proinflammatory cytokines and an increase in IL-10 and IL-13 production. The fact that, contrary to orally administered antibiotics, antibiotics administered intraperitoneally did not decrease EAE suggested that oral antibiotics acted on the microbiota (Ochoa-Reparaz et al., 2009).

Two studies involving transgenic mouse models have been published: the first concerned transgenic mice carrying a T cell receptor that recognized MBP (Goverman, 2009) and the second concerned transgenic mice carrying a T cell receptor that recognized myelin oligodendrocyte protein (MOG) (Berer et al., 2011; Lee et al., 2011). In both cases, the mice spontaneously developed EAE when

they were raised under SPF conditions but not when raised in a GF environment. We mentioned earlier that GF mice are deficient in Th17 cells that play a key role for the development of EAE. Transgenic mice carrying an anti-MOG transgenic T cell receptor were shown to have reduced levels of intestinal Th17 cells and increased levels of CD4⁺CD25⁺FoxP3⁺ regulatory T cells (Berer et al., 2011; Lee et al., 2011).

Interestingly, there are no cross-reactions between MOG receptors and commensal bacteria, which suggest that these bacteria induce Th17 cells via an activation signal that is independent of the cognate antigen.

One can consider that EAE onset requires the presence of Th17 cells, itself contingent upon the presence of certain commensal bacteria. This would explain the different effects of the GF status on this autoimmune disease compared to other models such as diabetes where Th17 cells do not appear to be directly involved.

Experimental Arthritis

As early as 1979 it was shown that GF rats developed collagen-induced arthritis at a higher frequency than SPF rats while rats raised under conventional sanitary conditions did not develop the disease (Kohashi et al., 1979). It was confirmed in 1993 that the GF status increased the frequency of collagen-induced arthritis in rats along with an increased level of collagen autoantibodies (Brebant et al., 1993).

These results seemed to be in apparent contradiction with the observation mentioned above made by the group of D. Mathis that K/BxN mice that developed a spontaneous arthritis in SPF conditions did not do so in GF conditions (Wu et al., 2010). This inflammatory arthritis model was based on the serendipitous observation of polyarthritis development in K/BxN mice bred from a cross between transgenic KRN-C57BL/6 mice, carrying a transgenic T cell receptor recognizing a bovine ribonuclease peptide, and NOD mice. The mice suffered from a polyarthritis that was, in many aspects, similar to human rheumatoid arthritis. Most interestingly, the pathophysiology of the disease involved autoantibodies, as proved by the fact that the disease could be induced in other mice by transfer of serum. Furthermore, the ability to develop arthritis in GF K/BxN mice was restored after colonization by SFB, which is known for its capacity to induce TH17 cells. Thus, as in the EAE model discussed above, the fact that this arthritis model is dependent on IL-17 might explain the absence of disease in the GF mice.

Murine Lupus

Two articles published years ago showed that the production of anti-nuclear antibodies and the development of

lupus disease in NZB mice were inhibited under GF conditions (Unni et al., 1975; Mizutani et al., 2005). Why the production of antibodies is inhibited is not yet clearly understood. It can be hypothesized that the presence of commensal bacteria in this particular case could act to stimulate autoantibody production.

MICROBIOME COMPOSITION AND AUTOIMMUNE DISEASES

Metagenomics studies were applied to several diseases other than autoimmune diseases with interesting results. This subject is now the focus of intense research, especially within the last 2 years, as evident from the large number of recent publications.

The numerous data obtained for allergic and inflammatory bowel diseases will not be discussed here, even though some of them might help clarify the role of the microbiome in autoimmune diseases. Nor will we discuss type 2 diabetes, obesity, and the effect on the functioning of the central nervous system, which appear also to be affected by the intestinal microbiome. We shall concentrate herein on observations made within the context of autoimmune diseases. Although the number of patients analyzed is still limited, yet the information is valuable and deserves to be presented. Data are available mainly for two diseases, insulin-dependent (type 1) diabetes and rheumatoid arthritis. Overall, these studies converge on the idea that these two diseases are associated with decreased metagenome diversity.

Type 1 Diabetes

There has been only limited data published on the metagenome in NOD mice (Wen et al., 2008; Markle et al., 2013). None of these studies present a systematic comparison with normal control (non-autoimmune) mice. One article has been published on BB rats. This rat strain is known to develop insulin-dependent diabetes (designated DP rats, for diabetes prone) and is usually compared to genetically similar rats that are diabetes resistant (DR rats). A number of differences were found between the two rat strains; in particular a higher abundance of *Lactobacillus* and *Bifidobacterium* was observed in BB-DR rats (Roesch et al., 2009). The administration of two species of commensal bacteria isolated from the gut of BB-DR rats to BB-DP rats slowed or even inhibited the onset of autoimmune diabetes (Valladares et al., 2010). Interestingly, preliminary data suggested that an inhibition of indoleamine 2,3-dioxygenase (IDO), an enzyme involved in tryptophan catabolism and immune tolerance (Munn and Mellor, 2013), could be involved in the protective effect observed (Valladares et al., 2013). However, these experimental results should be interpreted cautiously since DR rats are

significantly genetically different from DP rats regarding genes other than those involved in diabetes susceptibility.

Four studies have been published on this topic in humans. All of them have found a lower Firmicutes/Bacteroidetes ratio in patients as compared to healthy control subjects. The first study (Brown et al., 2011) found that diabetic patients had a smaller quantity of butyrate-producing bacteria and more short chain fatty acid-producing bacteria resulting in non-optimal mucin synthesis. In another study (Giongo et al., 2011), the same group established a relationship between the composition of microbiota in children at high genetic risk for autoimmune diabetes and the development of the disease over time. The children who developed autoimmune diabetes had a less diverse and stable microbiome. A third study (Murri et al., 2013) showed a correlation between a decrease in the Firmicutes/Bacteroidetes ratio, in the *Bifidobacteria* and *Lactobacillus* species and an increase in plasma glucose levels in children with autoimmune diabetes. In the last study (deGoffau et al., 2013), Vaarala's group found that a smaller quantity of butyrate-producing bacteria such as *Bifidobacterium* was associated with changes in the intestinal epithelial barrier function in recently diagnosed diabetic children.

Rheumatoid Arthritis

Very few studies have examined the composition of the gut microbiota in rheumatoid arthritis (RA) patients. One study published in 2008 found that adult RA patients had fewer *Bifidobacteria* and *Bacteroides* than patients with fibromyalgia used as "controls"; however, the techniques used at the time were less sensitive than those available today (Vaahtovuori et al., 2008). A recent study by Liu et al. found that in patients with early RA the diversity and quantity of some *Lactobacillus* species were lower (Liu et al., 2013).

EFFECT OF PROBIOTICS ON AUTOIMMUNE DISEASES

We discussed in detail above that in some animal models, a GF environment accelerates the onset of an autoimmune disease. Moreover, autoimmune diseases are in some cases associated with a reduced diversity of the gut microbiome. It was therefore logical to study the protective effect of the "preventive/therapeutic" administration of commensal intestinal bacteria, designated as probiotics (by reference to their potential effect), in several experimental models of autoimmune disease. A distinction will be made between studies that use probiotic mixtures, such as those used in a clinical context, and those using a single well-defined probiotic species. This section will refer only to studies carried out on animals raised under physiological (SPF or conventional) sanitary conditions.

Studies involving GF animals, which for obvious reasons are outside the scope of translational approaches, have been discussed in a preceding section.

Probiotic Mixtures

The effect of probiotic mixtures administered orally to 4- to 6-week-old NOD mice was studied by several groups. Calcinaro et al. have shown that such a treatment prevents the onset of insulinitis and diabetes (Calcinaro et al., 2005). Interestingly, this prevention was associated with an increased expression of IL-10 in the intestine and pancreas. Furthermore, the protective effect was shown to be of the active type since it could be transferred to untreated mice using spleen cells of protected treated mice. We ourselves have reported that the administration of probiotics (different from the ones used by Calcinaro et al.) induced an IL-10-dependent diabetes prevention in NOD mice (the prevention was no longer seen in mice treated with antibodies against the IL-10 receptor) (Aumeunier et al., 2010).

Several studies have shown that probiotics have a preventive effect on EAE. The best result was observed with a mixture of probiotics. The presence of several lactobacilli was necessary in this model. When used in isolation, none of the microorganisms was efficient in spite of the fact that some lactobacilli can stimulate certain regulatory IL-10 producing CD4⁺CD25⁺FoxP3⁺ T cells (Lavasanian et al., 2010). Another study confirmed the ability of a mixture of lactobacilli to prevent EAE with the added result that this prevention depended on the lactobacillus strains (Maasen and Claasen, 2008).

Specific Probiotics

Several studies recently demonstrated the beneficial effect of some commensal bacteria in the prevention or treatment of several autoimmune diseases.

As mentioned above, in BB rats, a delay in the onset of diabetes was observed when they were orally administered *Lactobacillus johnsonii* N6.2. There was concomitant suppression of some inflammation markers (like IDO) (Valladares et al., 2010, 2013).

In the EAE model, the administration of *Pediococcus acidilactici*, a lactic acid bacterium, reduced the severity of EAE when administered both prophylactically and therapeutically, mainly by increasing CD4⁺FoxP3⁺ IL-10-producing regulatory T cells in the mesenteric lymph nodes and spleens of treated mice (Takata et al., 2011).

In the collagen-induced arthritis model, two species of lactobacillus reduced the symptoms of the disease, mainly by inhibiting the proinflammatory environment (Amdekar et al., 2011; Nowak et al., 2012).

Inversely, the importance of commensal bacteria contribution to the onset of an autoimmune disease is yet to be determined. Two examples were mentioned in the previous section, EAE and arthritis in K/BxN mice. Their special characteristics compared to the models just discussed are that they involve IL-17-producing Th17 cells. In spontaneous diabetes models and collagen-induced arthritis, the involvement of Th17 cells does not seem to be so prominent, if at all significant. It is relevant to highlight, as we discussed in detail above, that both in EAE and K/BxN mice, probiotics are efficient essentially in GF mice.

Role of Toll-like Receptor Stimulation

A limited number of experimental data show that the probiotic protective effect is not found in mice genetically deficient for Toll-like receptors. Thus, a probiotic mixture lost its therapeutic efficacy in ovalbumine-induced allergy when administered to MyD88^{-/-} NOD mice (Aumeunier et al., 2010). Data in autoimmune diseases are more difficult to collect because of the potential inhibition of the development of these diseases upon blockade of Toll-like receptor signaling, an effect probably due to opportunistic infections in these mice (Wen et al., 2008; Aumeunier et al., 2010).

THE RELATIONSHIP BETWEEN THE INTESTINAL MICROBIOME AND THE HYGIENE HYPOTHESIS

Brief Overview of the Hygiene Hypothesis

The frequency of infectious diseases has significantly diminished in the last four decades in Western countries. In parallel, during the same period of time, the frequency of allergic and autoimmune diseases has considerably increased, more than two-fold in the case of some allergic diseases. It has been tempting to correlate the two observations. This forms the basis of the hygiene hypothesis. According to this hypothesis, improved hygiene and advances in medicine in industrialized countries contributed to a reduction in infectious diseases that resulted in an increase in allergic and autoimmune diseases (Bach, 2002). The hypothesis was substantiated by many epidemiological data that showed in particular the existence of a geographical (north–south) gradient for allergic and autoimmune diseases correlated with socioeconomic conditions. It was also supported by experimental data in spontaneous or induced autoimmune disease models and induced allergy models.

In fact, the hypothesis is essentially based on two types of evidence, which we will discuss below in the case of autoimmune diseases, taking the example of insulin-dependent diabetes. These two types of data are:

the effect of hygiene on the onset of diabetes and the prevention of the disease by infections.

A Clean Environment Promotes the Onset of Autoimmune Diabetes

Experimental Data

The basic observation is well established. NOD SPF mice with a good health status, showing negative results for common microbiological tests, display a very high incidence (over 90%) of autoimmune diabetes, especially in females. The frequency rarely exceeds 50% in males but can reach 60 to 70% in some colonies. However, when mice are not raised in a “clean” (SPF) environment, the frequency of the disease is reduced to levels as low as 10% (Pozzilli et al., 1993; Bach, 2002). An essential point is that when animals are decontaminated at birth by cesarean section and then raised in an isolator, the frequency of the disease shoots up again to 90% in females as early as the first generation (Bach, 2002).

Data are less clear concerning GF mice that immediately after birth by cesarean section are maintained for a prolonged period of time in an isolator and fed a sterile diet. As discussed above in greater detail, depending on the study, a disease frequency comparable to that of SPF mice or higher has been reported (Suzuki et al., 1985; Wen et al., 2008; Alam et al., 2011; King and Sarvetnick, 2011; Markle et al., 2013). This variation in results is not really surprising since the GF status is heterogeneous and depends on the technical details pertaining to the handling of the mice. Furthermore, the GF status significantly affects the development of the immune system, as we discussed. This resulting immaturity of the immune system may interfere with the development of the disease.

Little data are available concerning the effect of antibiotics on the onset of diabetes in NOD mice. The first study published showed, paradoxically in the light of this chapter, a protective effect of vancomycin: However the treatment was applied at the late prediabetic stage (8 weeks), no effect in diabetes incidence was observed (Hansen et al., 2012). Nonetheless, the article published by Chervonsky’s group showed that there was an increase in the frequency of diabetes in NOD MyD88^{+/+} mice, a genetically modified mouse strain that normally does not develop the disease unless they were administered an antibiotic cocktail (Wen et al., 2008).

Human Data

There is a high frequency of the disease in populations with good hygiene.

A north–south gradient is observed for autoimmune diabetes, with a higher prevalence in northern countries, especially in Europe where epidemiological data are well

documented (Bach, 2002). Some regional studies, in particular those carried out in the United Kingdom, have shown that the frequency of diabetes was directly linked to sanitary conditions (Patterson et al., 1996). Of particular interest is a study comparing disease frequency in the Karelian Republic of Russia and neighboring Finland. Although the two populations studied belong to the same ethnic group, the frequency of type 1 diabetes (and allergic diseases) is much lower in Karelian compared to Finnish people who enjoy a much higher social and economic level (Kondrashova et al., 2005). Interestingly, this difference in prevalence of type 1 diabetes is not associated with a different frequency of autoantibodies to β cells (Kondrashova et al., 2007).

In the same vein, data studying the incidence of disease according to the birth order points to the same conclusion. Insulin-dependent diabetes is more frequent in first-borns, who are less exposed to infections, than in the second, third, or fourth child who is, for obvious reasons, more exposed to intercurrent infections (Cardwell et al., 2005). These studies took into consideration the confounding factor represented by the increased diabetes incidence in off siblings (Bingley et al., 2000; Cardwell et al., 2005). The disease is also more frequent in children born by cesarean section than those born by natural birth which exposes them to an immediate contact with the vaginal microbiome of their mother (Cardwell et al., 2008).

Autoimmune Diseases Can be Prevented by Infections With a Pathogen

Experimental Data

Numerous articles have reported prevention of insulin-dependent diabetes in NOD mice by early administration of pathogens (Bach, 2002; Shoda et al., 2005). The pathogens can be bacteria but also viruses and parasites, an important point concerning the intestinal microbiome. Among the bacteria, some are enteric and others not, such as mycobacteria (Sadelain et al., 1990; Qin and Singh, 1997).

The protective effect of infectious agents, in particular bacteria, does not require the administration of live agents. It can be observed using bacterial extracts. In the latter case, it has been shown that protection is maintained in IL-4 genetically deficient mice but not in mice where transforming growth factor (TGF) β has been neutralized by a specific antibody (Alyanikian et al., 2006). Protection can also be observed when using bacterial ligands for many Toll-like receptors (Aumeunier et al., 2010).

Human Data

Prevention of type 1 diabetes by infection with pathogens has not been documented in humans for obvious reasons.

The issue is compounded by the fact that in humans, the onset of the disease is sudden whereas in mice and rats, the natural course of the disease can be monitored and early intervention is possible. Furthermore, an infection can temporarily increase insulin needs and give the impression that diabetes has been triggered when what is revealed is an already existing deficit in insulin production by β cells.

The only data available on humans regarding type 1 diabetes are preliminary. They concern the BCG and Q-fever vaccinations (Elliott et al., 1998; Allen et al., 1999; Faustman et al., 2012). No tangible results were reported in spite of a significant effect observed in NOD mice (Qin and Singh, 1997; Silva et al., 2003). The discrepancy can be explained by differences in the protocols used in humans and mice.

More convincing results have been obtained for other immune diseases in the context of the hygiene hypothesis, in particular for allergic diseases, multiple sclerosis, and inflammatory bowel diseases. Several studies have demonstrated the protective effect of certain porcine parasites (*Trichuris suis*) (Benzel et al., 2012) and probiotic preparations used mostly in the treatment of inflammatory intestinal diseases, atopic dermatitis, and, to a lesser degree, asthma (Kalliomaki et al., 2001; Cordina et al., 2011; Fedorak and Demeria, 2012; Pelucchi et al., 2012).

SYNTHESIS AND CONCLUSIONS

Infectious agents, whether they are commensals or pathogens, may influence the development of autoimmune diseases in a contrasted fashion, either by stimulating, by triggering them or by slowing them down. The stimulatory effect may involve commensal bacteria, as in the example of the SFB in EAE. However, most often the stimulating effect seems rather to involve pathogens, whether bacteria or viruses. The question is more open for the protective effect, since there are strong arguments for both commensal bacteria and pathogenic infectious agents. A possible common denominator of commensal and pathogenic bacteria could be the presence of Toll-like receptor ligands in both types of agents, as indicated by the loss of the protective effect in genetically Toll-like receptor-deficient mice and by the protection afforded by synthetic Toll-like receptor agonists.

The relative loss of this protective effect in recent decades seems due for both commensal bacteria and pathogens to improved hygiene and medicine in developed countries. The fact that environmental hygiene affects both the composition of the intestinal microbiome and the rate of infections in the first years of life in humans, complicates the discussion that is the focus of this chapter, namely, the respective role of commensal bacteria and pathogens in the protective effect.

Another important issue related to the previous one is whether the protective effect operates in the first days or weeks of life or, conversely, if it can also apply later in childhood. Another central question, which concerns both commensal bacteria and pathogens, is to what extent there is a causal link between the qualitative and quantitative variations of bacterial populations and the evolution of the frequency of autoimmune diseases. In other words, do the bacteria directly influence the occurrence of autoimmune diseases or are these two correlated yet independent events, possibly under the control of a single process, most probably of immunologic nature, whose cellular and molecular mechanisms remain to be determined.

The Strength of the Protective Effect of Pathogens

A fact can be taken for granted: pathogens can induce protection *vis-à-vis* autoimmune diseases even if exposure to the pathogen in question occurs after the second or third year of life in humans, without being able to say what the age limit is beyond which the protective effect no longer occurs.

Some epidemiological evidence, particularly in multiple sclerosis, but also in allergic diseases, would tend to suggest that this age limit could be between five to fifteen years. Thus, when one follows the families of migrants from countries with a low incidence of multiple sclerosis to countries with a high incidence, the protective effect of infectious diseases that manifested itself in the country of origin no longer takes place if the migration occurs after the child reached fifteen years of age (Dean and Elian, 1997). Similar studies in allergic asthma have indicated that the age limit is about five years of age (Kuehni et al., 2007).

Importantly, the pathogens responsible for protection do not involve the intestine for some of them, as is the case in particular for mycobacteria and, more generally, for infectious agents affecting the respiratory tract. All is not as clear on this subject as we are still not able to determine among the myriad of potential pathogens, which are the protective ones and, especially, what are the mechanisms involved in their protective effect. The current state of knowledge indicates that there are several possible mechanisms and that they are likely to differ according to the pathogen or, in any case, according to the constituent of the pathogen responsible for the protection. These comments concerning the pathogens are mainly based on experimental models in which there is ample evidence that deliberate infection by a pathogen (bacteria, virus, or parasite) can completely prevent the occurrence of a spontaneous or induced autoimmune disease, even when the infection occurs in animals as adults.

We cannot exclude that commensal agents, which may act as probiotics, may also have a protective effect outside the postnatal period. Clinical trials conducted with probiotics in certain immune diseases provide some arguments in this direction. It must be recognized, however, that the therapeutic effect is modest, challenged in allergic diseases, and virtually undocumented in autoimmune diseases.

The Ambiguous Effect on Autoimmune Disease of the GF or Axenic Status

The increase in the frequency or severity of certain autoimmune diseases in GF or SPF animals compared to conventionally raised animals is, of course, very important for our present discussion. It is, however, subject to different interpretation problems. The question is not so much that of the differences that may exist between GF and SPF animals, insofar as (1) GF and SPF conditions may vary depending on the laboratory and (2) disease frequency often does not differ much in GF and SPF animals.

The main problem, in fact, at least for GF animals, is the already mentioned risk of distorting the interpretation of the results by the consequences of the GF status on the maturation of the immune system. One can indeed think that depending on the nature of the immune deficiency related to the GF status, which may relate to regulatory or effector lymphocytes, there may be a positive or negative change in the severity of the autoimmune disease. This applies to both neonatal antibiotic treatments, which are usually pursued long enough, and to GF mice derived by cesarean section. This is indeed what is seen in experimental models where one can observe in GF mice an increase (diabetes, arthritis) or a decrease (EAE) of the disease.

The Delicate Interpretation of the Reduction in the Diversity of the Intestinal Microbiome

Although the results are still limited, one cannot avoid being struck by the frequency of the reduction in the diversity of the composition of the gut microbiome in autoimmune diseases in humans. The animal data are less numerous due to the limited number of models of spontaneous autoimmune diseases.

These results are impressive, especially when they are compared with those obtained in allergic diseases (Bisgaard et al., 2011; Yap et al., 2011; Abrahamsson et al., 2012). Furthermore, experimental results have shown a clear increase of allergic reactions after neonatal treatment with some antibiotics (i.e., vancomycin but not streptomycin)

that lead to different changes in the gut microbiome composition (Russell et al., 2012).

The case of inflammatory bowel diseases is also interesting yet complicated because these appear to involve immune reactions against intestinal bacteria that cause the lesions and clinical signs observed as well as a protective effect by commensals through mechanisms mentioned above. Some studies have distinguished these two categories of bacteria without dismissing an overlap between them and without clarifying which category each bacterium belongs to (Kverka and Tlaskalova-Hogenova, 2013). A particularly good example is that of ulcerative colitis where clear anomalies in the composition of the metagenome have been observed (Dusko Ehrlich, 2010). Another interesting example is that of Crohn's disease. A study has shown that bacterium *Faecalibacterium prausnitzii* usually found in normal individuals was missing in affected patients. Interestingly, this bacterium has been shown to have an immunomodulating activity inhibiting the progression of experimental inflammatory colitis in mice (Sokol et al., 2008). However, it remains to be proven that an altered microbiome contributes to the pathophysiology of these diseases and is not rather a consequence of the disease or a concomitant characteristic of the disease state *per se* or of the individual.

Perspectives

Following these discussions, beyond the etiological, epidemiological, and pathophysiological considerations, the question arises whether we may expect some therapeutic benefits of the protective effect of commensals or infectious agents in autoimmune diseases.

With regard to commensal bacteria, we can of course discuss the possibility of administering probiotics, either mixtures of probiotics or specific bacteria. It must be recognized, however, that the results currently available, although some are encouraging, were mostly obtained in some experimental models of autoimmunity and in a few allergic diseases in man. Perhaps one could refine the use of probiotics by calibrating mixtures and especially identifying bacteria with abilities well demonstrated to slow the progression of a given autoimmune disease. Maybe we could also consider performing transplants of microbiome as it has already been done in mice presenting spontaneous autoimmune diabetes (Markle et al., 2013). The technique of transplantation of microbiome has been used in humans in cases of serious infection by *Clostridium difficile*, resistant to any treatment (Kassam et al., 2013), and could be extended to other indications, inasmuch the safety has been carefully verified. More simply one could use bacterial extracts, as we did in mice (Alyanakian et al., 2006). One may also consider using synthetic chemicals such as Toll-like receptor agonists for

which we have shown a beneficial effect in autoimmune diseases and allergies in experimental models (Aumeunier et al., 2010).

In brief, a completely new, evolving, and fascinating field based on modern concepts and technologies, which may propel a conceptual revolution in our understanding of the pathophysiology, etiology, and therapeutic management of autoimmune diseases, provided more data are accumulated and validated.

INTRODUCTION

All common autoimmune diseases are complex genetic traits. That is, they result from a combination of many risk factors—genetic, environmental, and stochastic—each contributing a relatively small degree of risk. They are subject to genocopies (a genotype at one locus contributing to the risk of disease in a manner indistinguishable from that produced by another genotype and/or locus) and phenocopies (an environmental factor mimicking the effects of a susceptibility gene). A consequence of this is that the disease phenotype is only a weak predictor of the presence of a particular susceptibility allele. As this association underlies all current genetic approaches, the identification of susceptibility genes in complex disease traits is both practically and technologically challenging.

The main benefits of genetic studies of autoimmunity are to: (1) provide informed genetic counseling; (2) develop improved models for risk prediction; and (3) develop detailed molecular models of etiology and pathogenesis. As a generalization, the first benefit arose from work prior to the 1990s; the second has, in part, been achieved already; and the third remains a major scientific challenge.

DISEASES OF INTEREST

In any genetic study, clinical definition is critical since clinical heterogeneity associated with allelic differences weakens the statistical power. Here, we will concentrate primarily on progress in the genetics of type 1 (autoimmune) diabetes (T1D), multiple sclerosis (MS), and systemic lupus erythematosus (SLE, lupus).

Type 1 Diabetes

T1D is an endocrine disease that results from autoimmune destruction of the insulin-producing β -cells in the pancreas, leading to a loss of insulin secretion and hyperglycemia resulting in osmotic diuresis and the symptoms of polyuria, polydipsia, polyphagia, tiredness, and loss of weight. Potentially fatal complications include ketoacidosis and hyperglycaemic coma. Progression from the pre-clinical stage of β -cell autoimmunity (insulinitis) to established diabetes can take up to a decade (Johnston et al., 1989; Bonifacio et al., 1990). Diagnostically, the major confusion is with latent autoimmune diabetes of adults (LADA), which is of later onset, and type 2 diabetes, which does not have an autoimmune origin (and therefore lacks anti-islet autoantibodies), but is common and of increasing prevalence.

Evidence for a genetic contribution to the risk of T1D includes increased prevalence of disease in first degree relatives (FDR) (2.5–6.0% risk versus 0.1–0.3% in the general population of Western countries) with a λ_s of

about 15 (Tillil and Köbberling, 1987; Pociot and McDermott, 2002). T1D has a high concordance in monozygotic (MZ) twins and intermediate concordance in dizygotic (DZ) twins, 27% and 3.8%, respectively (Hyttinen et al., 2003); and is associated with a lifetime risk for the twin of an affected proband of 44% and 19%, respectively (Kumar et al., 1993). The prevalence of T1D varies markedly between countries and is increasing at a rate of about 3% per year (Onkamo et al., 1999), a change that is associated with alterations in autoantibody profiles and an accelerated onset of disease from the time of identification of autoantibodies. These trends are consistent with changing environmental effects on the pathogenesis of the disease (Ziegler et al., 2011; Long et al., 2012).

Multiple Sclerosis

MS is a chronic and debilitating disease of the central nervous system (CNS) characterized by myelin loss and axonal degeneration, resulting in neurological symptoms and impairment. It primarily affects individuals of northern European descent with a prevalence of approximately 0.1–0.2 %; more females than males are affected, at a ratio of approximately 3:1. Clinically, MS can be divided into two major subtypes: relapsing-remitting MS (RRMS) and primary progressive MS (PPMS). RRMS is characterized by relapses followed by periods of remission of variable duration where there is complete or partial recovery. MS patients with RRMS may eventually progress to secondary-progressive MS (SPMS) characterized by steady decline without remit. PPMS, which affects approximately 5–15% of all individuals with MS, differs from RRMS in that there are no periods of remission. Prior to genetic studies, there was a broad acceptance that RRMS and PPMS were likely to represent pathogenetically different diseases.

Familial aggregation of MS was noted as early as the 1890s and suggested that there was a genetic influence on disease development (Eichhorst, 1896). More recently, the proportion of MS patients who have a blood relative with MS has been shown to be approximately 20% (Compston, 1991), reflecting a 3% risk in siblings of affected individuals and a λ_s (relative risk ratio of disease in siblings of patients) of about 25 (Robertson et al., 1996). Twin studies have demonstrated a concordance of 25–30% between MZ twin pairs, and concordance similar to that of siblings in DZ twins (Ebers et al., 1986; Sadovnick and Baird, 1988; Sadovnick et al., 1993; Robertson et al., 1996; Carton et al., 1997; Montomoli et al., 2002).

Systemic Lupus Erythematosus

Lupus is a highly variable autoimmune disease diagnosed on the basis of a combination of clinical and laboratory

criteria (American College of Rheumatology Ad Hoc Committee on Systemic Lupus Erythematosus Guidelines, 1999). It may be associated with hematologic, musculoskeletal, renal, or neuropsychiatric symptoms. It is generally characterized by the presence in plasma of antinuclear autoantibodies, primarily directed against molecules involved in transcription and translation, such as DNA, the U1 small nuclear ribonucleoprotein/Smith (Sm) complex, and the Ro/SSA and La/SSB ribonucleoprotein autoantigens. The prevalence of lupus is around 40 to 50 cases per 100,000 people, primarily affecting women (F:M ratio is 9:1); the prevalence is much higher, and the course of disease much more pernicious, in Africans and Afro-Caribbeans living in Western countries and particularly in the Aborigines of northern Australia, where the prevalence reaches >90 per 100,000 (Stoll et al., 1996; Bossingham, 2003). Lupus shows familial clustering, with approximately 1.5–3.0% of FDR affected, but the variable and often mixed racial backgrounds of patients complicates the calculation of a λ s, which lies somewhere between 5.0 and 30 (Block et al., 1975; Lawrence et al., 1987; Alarcón-Segovia et al., 2005). In twin studies, 24–69% of MZ pairs and 2–3% of DZ pairs were concordant (Block et al., 1975; Deapen et al., 1992).

HUMAN LEUKOCYTE ANTIGEN (HLA) COMPLEX AND OTHER CANDIDATE GENES

The Major Histocompatibility Complex (MHC) was originally identified by murine allogeneic tumor transplantation (Gorer, 1937). Identification of the analogous gene complex in humans (termed the Human Leukocyte Antigen (HLA) Complex) was made when three groups described antibodies in sera from multitransfused patients or multiparous women that aggregated the leukocytes of many, but not all, donors (Dausset, 1958; van Rood et al., 1958; Payne and Rolfs, 1958). The collaborative dissection of the HLA complex is described elsewhere (Thorsby, 2009). After an association was reported between Hodgkin's disease and the 4c complex (subsequently known as *HLA-B*; Amiel, 1967), many diseases were tested for association with HLA alleles. The strongest HLA association with autoimmune disease found to date is with ankylosing spondylitis (AS); 88–96% of AS patients carry *HLA-B*27* compared with 4–8% of healthy controls (Brewerton et al., 1973; Schlosstein et al., 1973). *HLA-B*27* carries a relative risk of AS of up to 100 (Arellano et al., 1984)—the highest genetic association for any autoimmune disease. The relative risk varies between populations, and is much lower in African Americans (Khan et al., 1977).

Association of Type 1 Diabetes with HLA and other Candidate Genes

The HLA also shows association with T1D (locus termed *IDDM1*; Nerup et al., 1974; Bertrams, 1984; Todd, 1992; Noble et al., 1996; Cucca et al., 2001; Devendra and Eisenbarth, 2003; Kelly et al., 2003; Valdes et al., 2005) and accounts for approximately 40% of the familial aggregation of the disease; the predisposing HLA Class II haplotypes, *HLA-DRB1*04*, *DQB1*03:02* (identified by serology as DR4), and *DRB1*03:01*, *DQB1*02:01* (DR3) are present in 95% of affected individuals. DR3/DR4 heterozygotes carry an absolute risk of T1D of approximately 5% (compared to a cumulative incidence of ~0.3% in Western communities), which rises to about 20% if a haploidentical sibling is affected (Noble et al., 1996; Valdes et al., 2001). DQ amino acid sequences directly correlate to risk of T1D and this association is largely dependent on the identity of residue 57 of the DQ β chain, Asp being protective and Ala conferring susceptibility (Todd et al., 1987), and residue 52 of the DQ α chain (Arg confers susceptibility; Khalil et al., 1990). Khalil et al. (1990) reported that of 50 T1D patients, all expressed the DQ α -52Arg/DQ β -57Ala susceptible heterodimer. Remarkably, the non-obese diabetic (NOD) mouse model of T1D expresses an A β chain homologous to DQ β with a substitution at position 57 (Todd et al., 1987).

INS

Other T1D candidate genes were examined because of their biological relevance to disease. Insulin is primarily transcribed in the beta cells of pancreatic islets, and is a major autoantigen in T1D (Kent et al., 2005). There are three common polymorphisms in strong LD in the insulin (*INS*) gene: –23Hph1 (an A/T polymorphism within the Hph1 restriction endonuclease site 23 bp upstream of the insulin gene transcription start site), +1140 A/C and a variable number tandem repeat (VNTR) locus. The VNTR is the best candidate because it contains binding sites for many transcription factors, including Pur1 (Kennedy et al., 1995), while there is no obvious functional role for either of the two SNPs (Barratt et al., 2004). The promoter of the *INS* gene on 11p15 contains the VNTR locus and the shortest alleles (class I alleles; 26–63 repeats) are associated with T1D in *HLA-DR4*-expressing subjects (odds ratio (OR) 1.9; *IDDM2*; Bell et al., 1984; Julier et al., 1991; Bain et al., 1992; Bennett et al., 1995). Class III alleles (the longest—209 repeats) of the VNTR are associated with marginally lower levels of insulin mRNA expression in pancreata (Bennett et al., 1995), but a two to three-fold higher expression in fetal thymus (Vafiadis et al., 1997). These data are consistent with the hypothesis that protective alleles of the *INS*

VNTR are responsible for increased thymic insulin expression driving more effective induction of central tolerance of insulin-reactive T cells. Although *INS* polymorphisms were associated with T1D in many Caucasian populations, the association was not seen in Chinese subjects because the frequency of the susceptible *INS* allele is approximately 95% in Chinese controls and close to 100% in Chinese T1D patients (Marron and She, unpublished data cited in Marron et al., 1997).

PTPN22

Protein tyrosine phosphatases were thought to be good candidates for autoimmunity susceptibility genes because they are involved in limiting T cell activation by dephosphorylating T cell receptor (TCR)-associated kinases and their substrates. *PTPN22*, on chromosome 1p13, encodes the lymphocyte-specific protein tyrosine phosphatase LYP, which is a negative regulator of TCR signaling via the dephosphorylation of several TCR proximal signaling molecules, including the SRC family kinases LCK and FYN, ZAP70, and TCR ζ . A nonsynonymous single nucleotide polymorphism (SNP) at position 1858 of *PTPN22* was reported to be associated with T1D in many populations (OR for the homozygous TT genotype was 1.7; Bottini et al., 2004; Onengut-Gumuscu et al., 2004; Smyth et al., 2004; Zheng and She, 2005; Steck et al., 2009, reviewed in Steck and Rewers, 2011). This C1858T SNP encodes in a missense mutation that changes an arginine to a tryptophan at position 620 (R620W) causing the inability of LYP to bind its signaling molecule CSK (Vang et al., 2005), resulting in increased phosphatase activity. T cells from T1D patients and healthy subjects carrying the LYP-W620 variant show reduced production of interleukin (IL)-2 and other cytokines following TCR stimulation (Vang et al., 2005; Rieck et al., 2007). This Trp620 variant is also associated with Graves' disease (GD; autoimmune hyperthyroidism; Steck et al., 2006), rheumatoid arthritis (RA; Begovich et al., 2004), and lupus (Kyogoku et al., 2004).

TCR and immunoglobulin loci were also examined as candidates, without consistent evidence of involvement.

Association of Multiple Sclerosis with HLA and other Candidate Genes

Association of MS with the HLA Class I alleles *HLA-A*03* and *HLA-B*07* (identified by serology as A3 and B7) were reported in 1972 (Jersild et al., 1972; Jersild and Fog, 1972; Naito et al., 1972). Further studies found that both of these associations were secondary to those of the Class II alleles *HLA-DRB1*15:01* (DR2) and *HLA-DQB1*06:02* (DQ6), which can be inherited together in strong linkage disequilibrium as the HLA-DR15 haplotype

(*DRB5*01:01, DRB1*15:01, DQA1*01:02-DQB1*06:02*; Fogdell et al., 1995). This haplotype confers a relative risk of MS of between two and four (Francis et al., 1987a,b). Approximately 30% of individuals with MS carry this extended haplotype compared to 15% in the normal population; its effect is dominant and shows evidence of gene dosage (Barcellos et al., 2006). The contribution of *HLA* to total (genetic) susceptibility to MS is estimated to be between 15 and 50% (Haines et al., 1996, 1998).

There is a very strong association between Epstein–Barr virus (EBV) infection and MS: EBV is unique in being the only virus known to have infected virtually all MS patients, in contrast to healthy subjects, of whom only 85–95% are infected (Sumaya et al., 1985; Myhr et al., 1998); EBV seronegativity has an odds ratio (OR) of 0.06 (95% CI 0.03–0.13; $p < 10^{-9}$; Ascherio and Munger, 2007). *HLA-DRB1*15:01* appears to act synergistically as a risk factor with EBV exposure. The risk conferred by *HLA-DRB1*15:01* was 2.9-fold higher in patients with a history of infectious mononucleosis and the risk of MS in *HLA-DRB1*15:01* positive women increased nine-fold in those with elevated anti-EBNA-1 (EBV) antibody titers (Nielsen et al., 2009; De Jager et al., 2008). A confounding problem is the potential effects of *DRB1*15:012* on EBV susceptibility. EBV achieves penetration of the plasma membrane via the binding of its viral glycoprotein gp42 to *HLA-DR* (Li et al., 1997); the *HLA-DR15* haplotype is associated with 15.7-, 5.2-, and 8.3-fold higher expression of DQB1, DRB5, and DRB1, respectively (Alcina et al., 2012), potentially conferring higher infection rates.

MS is also associated with childhood residence at higher geographic latitude (Acheson et al., 1960) and a significant component of this association appears to be mediated by low ultraviolet light exposure resulting in reduced 1,25(OH)₂ vitamin D availability (Nieves et al., 1994; Munger et al., 2006). A functional vitamin D response element (VDRE) has been identified in the promoter region of *HLA-DRB1* and this VDRE is present on the *HLA-DR15* haplotype (Ramagopalan et al., 2009), suggesting these genotypes may be unusual in having vitamin D-regulated MHC Class II expression.

Class I alleles also affect susceptibility to MS: The *HLA-A*03:01* allele increases the risk (OR 2.1) while *HLA-A*02:01* and *B*44* decrease it (OR 0.52 and 0.62, respectively; Fogdell-Hahn et al., 2000; Bergamaschi et al., 2010; Cree et al., 2010; Healy et al., 2010). The presence of *A*02:01* reduces the relative risk of MS conferred by the *HLA-DR15* haplotype from 3.6 to 1.5 (Fogdell-Hahn et al., 2000).

No associations between *HLA* genotypes and specific MS subtypes have been identified (Barcellos et al., 2006), although a significant correlation between the age-of-onset of MS and a SNP tagging the *HLA-DR15* haplotype has

been reported (Masterman et al., 2000; International Multiple Sclerosis Genetics Consortium et al., 2011b); no associations with gender or disease severity were observed.

Other MS candidate genes that have been tested by association or transmission tests were selected largely on the basis of known or predicted roles in pathogenesis. In particular, genes encoding the TCR, IL 1 receptor (IL1R), interferons (IFN) α , β , and γ , and CTLA-4, as well as various cytokine/chemokine genes have been investigated with no consistent results.

Association of Lupus with HLA and other Candidate Genes

*HLA-DRB1*03:01* (identified by serology as DR3) is strongly associated with lupus (Freedman et al., 1993). In African American patients, *HLA-DRB1*03* was found in 62% of lupus patients, but only 20% of controls (relative risk of 6.41); in Caucasian patients, the strength of the association is a little lower: 30% vs. 13% (So et al., 1990). *DRB1*03:01* is part of the 8.1 ancestral haplotype (*HLA-A*01, C*07, B*08, DRB1*03:01, DQA1*05:01, DQB1*02:01*), so named because it includes the class I alleles *HLA-B*8* (B8) and *HLA-A*01* (A1). This haplotype therefore confers susceptibility to both lupus and T1D in Europeans, as does the *H2^{S7}* MHC haplotype in NOD mice (Price et al., 1999; Jordan et al., 2000). It is also associated with celiac disease (Ahmed et al., 1993), myasthenia gravis (Hammarström et al., 1975), chronic active (autoimmune) hepatitis (Strettell et al., 1997), and scleroderma (Kallenberg et al., 1981).

The class II allele *HLA-DRB1*15:01* (serotype DR15, a split of DR2 and usually associated with *DQB1*06:02, DQA1*01:02* (serotype DQ6, a split of DQ1)) is also associated with lupus; it was found in 41% of African American patients and 18% of controls (relative risk of 3.03). Again, in Caucasian patients, the association is a little weaker: 21% vs. 11% (So et al., 1990). The combined relative risk for lupus associated with expression of both haplotypes is 9.0 (Kachru et al., 1984).

TNF

Interest in tumor necrosis factor (*TNF*) genes in humans followed the finding of a polymorphism within the *Tnf* gene of lupus-prone (NZBxNZW)F1 hybrid mice (Jacob and McDevitt, 1988), in which decreased expression of TNF was associated with disease and TNF administration delayed nephritis. The same group applied serotyping and bioassays to determine the relevance of quantitative polymorphisms in *TNF* to lupus and lupus nephritis in patients, reporting that in lupus patients, the DR2-DQ1 serotype (inferred haplotype *DRB1*05:01, DQB1*06:02, DQA1*01:02*) was associated with low levels of induced

TNF expression and an increased incidence of nephritis. In contrast, lupus patients with the DR3 (*HLA-DRB1*03:01*) and DR4 (*HLA-DRB1*04:01*) serotypes had high TNF production and were not predisposed to nephritis (Jacob et al., 1990). One potential explanation for this association is a SNP at position -308 in the promoter of the *TNF* gene: The low expression haplotype has a G in this position, whereas the high expression haplotype has an A (Tan and Arnett, 1998; Hajeer and Hutchinson, 2001). This association with expression, as well as the SNP association with disease has been controversial, in part due to attempts to generalize the original observation to lupus (as distinct from lupus nephritis) and in part due to racial heterogeneity (Rudwaleit et al., 1996). Where an association was found, often it could not be shown to be acting independently of *HLA-DRB1* alleles (Wilson et al., 1994; Rudwaleit et al., 1996).

C4A, C4B

One of the strongest associations with lupus within the HLA is with the C4 genes in the *HLA* class III region (Christiansen et al., 1991). Both the major European DR3-associated haplotypes in lupus patients include disruption of *C4A* or *C4B*. The 8.1 ancestral haplotype common in Western and Northern Europeans contains a null allele of the gene encoding C4A (*C4A*Q0*; Fielder et al., 1983; So et al., 1990). In Caucasians, the relative risk for lupus of carrying two *C4A*Q0* alleles is 16.9 (Howard et al., 1986). Association studies of other *C4A* null alleles in African American and Asian populations, where they are present on haplotypes other than the 8.1 ancestral haplotype, indicate that *C4A* null alleles are lupus risk genes independently of *HLA-DRB1*03:01*, showing a gene dose effect and conferring a relative risk of 2.7 in African Americans (Howard et al., 1986; Yamada et al., 1990).

A null allele of the gene encoding C4B (*C4B*Q0*) is present in the other major European DR3-associated ancestral haplotype (A30::DQ2, consisting of *HLA-A*30:02, C*05:01, B*18, DRB1*03:01, DQA1*05:01, DQB1*02:01*), which occurs with frequencies around 15% in Sardinia and Basque, and between 2 and 10% in Southern Europe. The *C4B*Q0* allele is also relatively common in lupus patients (Fielder et al., 1983), and shows an association with lupus in Australian Aborigines (Christiansen et al., 1991), African Americans (relative risk 2.0; Howard et al., 1986), and Spanish populations (relative risk 6.0; Naves et al., 1998), but not other Caucasians (Howard et al., 1986).

C2

The gene encoding the C2 complement component also lies within the class III region of the HLA, between the

C4 genes and those encoding HSP70, TNF, LT α , and LT β . Null alleles of C2 are likewise associated with lupus and 33% of Europeans with homozygous C2 deficiency develop it (Walport, 1993). Homozygosity for null alleles is present in 0.4–2% of cases compared to 0.01% of the general population; heterozygous C2 deficiencies are present in 2.4–5.8% of cases compared to 0.7–1% of the general population (Sullivan et al., 1994; Lipsker et al., 2000). Patients with C2 deficiency tend to experience photosensitivity and other forms of skin involvement; among C2-deficient patients without lupus, benign cutaneous (discoid) lupus is also common (Agnello et al., 1972; Provost et al., 1983; Lipsker et al., 2000).

C1Q

Hereditary deficiencies of other early complement components (C1q, C1r, C1s) are powerful but rare causes of a lupus-like syndrome. For example, 90% of people with C1q deficiency develop lupus. Onset can occur in childhood (even as early as one year of age) and the disease can be associated with very severe central nervous system (CNS) and renal complications; of 30 patients, 22 died in childhood (Bowness et al., 1994).

FCGR2A, FCGR3A, FCGR3B

In the 1970s a reduction in Fc-rosette formation of red blood cells from lupus patients was identified and attributed to saturation by circulating complexes (Nakai et al., 1977). While it was known that the Fc γ receptors Fc γ RI (CD64), Fc γ RII (CD32), and Fc γ RIII (CD16) contribute to the clearance of IgG and IgG-containing immune complexes, they were not examined as candidates until the 1990s. A SNP in *FCGR2A* results in a His to Arg substitution at position 131 of Fc γ RIIIa and reduces the affinity by which Fc γ RIIIa binds IgG2 (Duits et al., 1995). This substitution also affects the clearance of IgG-coated erythrocytes and has been found to have an inconsistent association with lupus but not to nephritis (Duits et al., 1995; Salmon et al., 1996; Dijstelbloem et al., 2000).

Similarly, a SNP in *FCGR3A* results in a Val to Phe substitution at position 176 of Fc γ RIIIa, reducing, in 176Phe/Phe homozygotes, the binding of IgG1 and IgG3 by natural killer (NK) cells and monocytes, inhibiting NK cell activation and activation-induced cell death (Wu et al., 1997). Homozygosity for this allele is present in a significantly higher proportion of lupus patients than controls (Wu et al., 1997; Koene et al., 1998) and is associated with lupus nephritis, arthritis and serositis, or hematologic cytopenias, depending on the population (Salmon et al., 1999; Dijstelbloem et al., 2000).

Two alleles of *FCGR3B* vary in the encoded amino acid sequence of Fc γ RIIIb, affecting low affinity IgG

binding by neutrophils. The allele associated with decreased phagocytic activity (NA2) is associated with lupus (OR 1.9; Hatta et al., 1999). *FCGR3B* also shows copy number variation and a low *FCGR3B* copy number, in particular complete Fc γ RIIIb deficiency is strongly associated with lupus as well as with Wegener's granulomatosis (Fanciulli et al., 2007; McKinney and Merriman, 2012).

IRF5

Increased production of type I IFNs and expression of IFN-inducible genes is commonly observed in lupus and appears to play a key role in the molecular pathogenesis of the disease (Baechler et al., 2003). Sigurdsson et al. (2005) performed linkage and association studies of 44 SNPs in 13 candidate genes involved in the type I IFN pathway on 679 Swedish, Finnish, and Icelandic patients with lupus, in 798 unaffected family members, and in 438 unrelated control individuals. Two genes were highly significantly associated with lupus: *TYK2* (19p13) and *IRF5* (7q32). Remarkably, despite the relatively low power of the study, the P value for *IRF5* reached a genome-wide level of significance. This finding was quickly and robustly replicated (Graham et al., 2006). The most highly associated SNP in the 7q32 region (*rs2004640*) lies in the splice junction of an alternate first exon. The T allele creates a 5' donor splice site allowing expression of several unique *IRF5* isoforms and is in LD with a cis-acting variant associated with elevated expression of *IRF5*. *IRF5* is a transcription factor that regulates type I IFN gene expression. It is critical for the production of the proinflammatory cytokines TNF, IL-12, and IL-6 following Toll-like receptor (TLR) signaling (Takaoka et al., 2005), and it mediates type I IFN induction in response to some viruses (Barnes et al., 2001). In a genome-wide association study (GWAS) of anti-dsDNA AAb in lupus, *IRF5*, together with the *HLA*, *STAT4*, and *ITGAM*, was found to be significantly associated (Chung et al., 2011).

Mechanisms of Complement and Fc Associations with Autoimmunity

The leading hypothesis explaining the association between lupus and deficiencies in FcR and complement is that these defects impair catabolism of immune complexes by the mononuclear phagocytic system (Walport, 1993). Tracking of radio-labeled immune complexes revealed the following defects in lupus patients: (1) reduced immune complex uptake by the spleen; (2) accelerated clearance of complexes by the liver; and (3) release of those immune complexes from the liver back into circulation (Davies et al., 1992). In similar studies of a patient with C2 deficiency, splenic uptake of immune

complexes was found to be entirely complement dependent, and could be restored by transfusion of fresh frozen plasma (Davies et al., 1993). As C4A binds more effectively to amino groups than C4B does, it has been proposed that it is more efficient at clearing immune complexes (Schifferli et al., 1986). This may explain the stronger association of lupus with C4A deficiencies.

Mechanisms of HLA Association with Autoimmunity

The finding of a single ancestral haplotype (8.1) associated with multiple autoimmune diseases suggests a common mechanism mediating susceptibility. The analysis of HLA recombinant patients indicates that, for many autoimmune diseases, genetic association with the HLA can be primarily attributed to associations with the genes encoding specific peptide-presenting molecules, class I or class II (Thorsby, 1997). The hypothesis arising from this observation is that disease-associated HLA class I and class II alleles permit binding of disease-inducing peptides. The question of why one particular peptide of an autoantigen should be any more disease inducing than another became the driving force behind a supplementary hypothesis: Molecular mimicry, in which it is proposed that bi-reactive TCRs permit the priming of T cells by a microbial peptide and effector activation by autoantigens. The most plausible example of putative molecular mimicry is found in AS, which on microbiologic and serologic criteria is associated with *Klebsiella* infection (Ebringer, 1992). The amino acids 72–77 of the HLA class I molecule B27 are identical to amino acids 188–193 of the nitrogenase of *Klebsiella pneumoniae* (Yu et al., 1989).

Lang et al. (2002) reported bi-reactive TCRs of MS patients that bound both DRB5*0101 presenting a peptide from the DNA polymerase of EBV as well as DRB1*1501 presenting a myelin basic protein (MBP) peptide. Crystal structure determination revealed a marked degree of structural equivalence at the surface presented for TCR recognition. In contrast, T cells from patients with lupus show no such cross-reactivity at the level of TCR/peptide/HLA. In addition to MS and lupus, DRB1*1501 is positively associated with the autoimmune diseases Sjögren's syndrome (Guggenbuhl et al., 1998), Goodpasture syndrome (GS) (Fisher et al., 1997), and juvenile RA (JRA) (Garavito et al., 2004). Such a wide range of tissue specificities renders it most unlikely that a shared autoantigen is responsible, and there is little evidence of any etiological role for EBV in GS or JRA. The cross-reactivity identified in lupus autoantibodies can be explained by B cell polyclonal activation, support of antibody production, and inhibition of apoptosis mediated by EBV, and these activities of themselves probably provide

sufficient explanation for the association between EBV and lupus.

GENE LINKAGE STUDIES OF AUTOIMMUNITY

The availability of dense maps of polymorphic genetic markers (microsatellites and SNPs) revolutionized the localization of non-*HLA*-linked disease genes (Dietrich et al., 1992, 1996; Gyapay et al., 1994; Tsang et al., 2005). Linkage analyses rely on disproportionate transmission of alleles to affected and unaffected progeny.

Linkage Studies of Type 1 Diabetes

The first genome-wide scans for linkage to T1D were performed on large collections of T1D families with pairs of affected siblings (sibpairs) by microsatellite (variable number of tandem repeats) analysis in 1994 (Davies et al., 1994; Hashimoto et al., 1994; <http://www.t1dbase.org>). These studies easily confirmed linkage to the *HLA*, both by their own statistical thresholds, as well as by those of Lander and Kuglyak (1995), which are set to a 5% probability per study of a single genomic region exceeding the significance threshold by chance (i.e., a LOD score >3.6). Davies et al. (1994) calculated that the *HLA* contributes about 42% of the familial clustering of T1D. Neither group showed evidence of linkage at *INS*.

CTLA4

Owerbach and Gabbay (1995) performed a genome-wide linkage analysis in 162 type 1 diabetic families with an affected sibling pair, and subset their data by the *INS* VNTR and *HLA* haplotypes. They identified an additional susceptibility gene located on chromosome 2q31 near *HOXD8* (*IDDM7*; maximum LOD 4.8) in affected sibpairs lacking high-risk *HLA*-DR3/4 haplotypes and expressing homozygous high-risk class I VNTR alleles. This region is homologous to that on proximal mouse chromosome 1 where the *Idd5* T1D gene was subsequently identified in diabetes-prone NOD mice (Cornall et al., 1991) and contains the disease candidate genes *CTLA4* and *CD28*, which encode T cell receptors involved in the control of T cell activation (Walunas et al., 1994).

Candidature of *CTLA4* was also supported by a subsequent linkage analysis in 48 Italian families, transmission disequilibrium testing in 187 Italian families (138 of which had only a single affected child), and 44 Spanish families, and a population based case–control association study of 966 patients and 1058 controls from Belgium (Nisticò et al., 1996). Similar studies in British, Sardinian, and American families did not support *CTLA4*

candidature (Nisticò et al., 1996). A meta-analysis of 33 independent studies showed an odds ratio of 1.45 for the G allele; with a greater effect in cases with onset <20 years of age (odds ratio 1.61; Kavvoura and Ioannidis, 2005). On the basis of *CTLA4* being 10 cM distal of the *IDDM7* linkage peak (*D2S152*), and the lack of disequilibrium between *D2S152* and *CTLA4* in the association study, the locus at 2q33 was designated *IDDM12* (Nisticò et al., 1996).

In addition to T1D, *CTLA4* is associated with GD (Yanagawa et al., 1995; Kotsa et al., 1997; Kouki et al., 2000), Hashimoto's autoimmune thyroiditis (HT) and autoimmune hypothyroidism (Kotsa et al., 1997; Donner et al., 1997), Addison's disease (Blomhoff et al., 2004; Donner et al., 1997), MS (Harbo et al., 1999; Ligers et al., 1999), and RA (Gonzalez-Escribano et al., 1999; Gregersen et al., 2009).

Ueda et al. (2003) examined expression levels of the two major isoforms of the most disease-associated SNP (CT60): the full-length sequence, and a soluble isoform (s-CTLA-4) that lacks exon 3 (Oaks et al., 2000). The disease susceptible genotype was associated with lower expression of s-CTLA-4 in a gene dose-dependent manner. Similarly, sequence-dependent variation in *Ctla4* isoforms were identified in T1D-susceptible NOD mice, and differential expression of one appeared to mediate the allelic variation in T1D risk that maps to this chromosomal region (Oaks et al., 2000; Vijaykrishnan et al., 2004; Araki et al., 2009). CTLA-4 is expressed constitutively on regulatory T (Treg) cells and is thought, at least in part, to mediate their immunosuppressive activities (Manzotti et al., 2002) as interaction of CTLA-4 with CD80 or CD86 inhibits human T-cell activation (Vandenborre et al., 1999). Soluble CTLA-4 also has this activity (Oaks et al., 2000), and a knock-down transgene for sCTLA-4 exacerbated T1D in an NOD congenic strain that expresses the wild-type *Ctla4* allele (Gerold et al., 2011).

CD25

The 10p11-q11 region (designated *IDDM10* in unpublished data by Todd (1995); maximum LOD 2.03; Hashimoto et al. (1994)) contains the putative candidate genes *GAD2* and *CD25* (*IL2RA*). *GAD2* encodes the islet cell specific (65 kDa) form of glutamic acid decarboxylase (GAD65), a prevalent autoantigen in T1D. Association analysis of a highly polymorphic dinucleotide repeat linked to the gene did not support a significant role for *GAD2* (Wapelhorst et al., 1995). In contrast, *CD25* (10p15), which encodes the IL-2 receptor α chain, was supported by a tag SNP approach and a large sample size (7457 cases and controls and 725 multiplex families; Vella et al., 2005). CD25 plays a critical role in the

development and maintenance of regulatory T cells (Treg) and may play a role in Treg expression of CD62L, which is required for their entry into lymph nodes (Malek and Bayer, 2004). In association studies, T1D was associated with two independent groups of SNPs, spanning overlapping regions of 14 and 40 kb, encompassing the first intron of *CD25* and the 5' intergenic region (Lowe et al., 2007; Maier et al., 2009). The T1D susceptibility genotypes were also associated with lower circulating levels of soluble IL2RA (s-IL2RA; Lowe et al., 2007). Dendrou and colleagues (2009) confirmed gene-phenotype correlation at the RNA level: Individuals with one or two protective alleles (G) at *rs12722495* showed an increase in CD25 message (27%) in their CD4⁺ memory T cells when compared to homozygous susceptible individuals (AA) or to those with protective *rs11594456* or *rs2104286* alleles. Allelic variation in *CD25* is also associated with MS (International Multiple Sclerosis Genetics Consortium et al., 2007) and Crohn's disease (Franke et al., 2010). As the most strongly associated SNP in MS is *rs2104286* (OR = 0.85; G, protective, minor allele at *rs2104286*), Dendrou et al. (2009) proposed that while the CD4⁺ memory T cell phenotype is critical for T1D protection, naïve T cell and stimulated CD14⁺ CD16⁺ monocyte phenotypes are important in both diseases.

Other Loci

Other putative diabetes susceptibility loci initially identified using linkage studies were localized to chromosomes: 18q12-q21 (designated *IDDM6*; maximum LOD 3.7; Todd, 1995; Merriman et al., 1997), 6q27 (designated *IDDM8*; maximum LOD 3.4; Luo et al., 1995; Todd, 1995; Luo et al., 1996), 3q22-q25 (designated *IDDM9* (unpublished data, Todd, 1995), maximum LOD 2.4 in DR3/DR4 heterozygotes; Mein et al., 1998; Paterson et al., 1999), 14q24-q31 (designated *IDDM11*; maximum LOD 4.0, 4.6 in families without evidence of HLA linkage to T1D; Field et al., 1994), 2q34-q35 (designated *IDDM13*; maximum LOD 3.3; Morahan et al., 1996), and 6q2 (designated *IDDM15*; identified by an extension of identity-by-descent methods as adjacent to HLA, $p < 5 \times 10^{-5}$; Delépine et al., 1997). The latter locus brings to a total four putative loci on chromosome 6q: *IDDM1/HLA*, *IDDM15*, *IDDM5*, and *IDDM8*, in that order from centromere to telomere over a distance of about 100 cM.

Linkage Analyses of Combined Datasets and the Limits of Linkage Analyses

By 1998, very large collections of families were being analyzed. Mein et al. (1998) studied 356 affected sibpair

families from the UK, but found significant linkage only to three regions: *IDDM1/HLA*, *IDDM10/CD25* (10p13; maximum LOD 4.7), and 16q22-24 (maximum LOD 3.4). Remarkably, most of the previously reported loci were excluded by exclusion mapping at a λ_s of 3 and a LOD of -2 . Similarly, a two-staged analysis of 616 multiplex families from the UK and the USA identified only *IDDM1/HLA* (maximum LOD 34.2) as significant by multipoint analysis, and a single previously unreported locus on 1q of suggestive significance (LOD 3.31; [Concannon et al., 1998](#)). The data were consistent with a locus distal from the *HLA*, at *IDDM15* (6q21) with a maximum LOD 3.8, but its proximity to the *HLA* required correction for linkage disequilibrium, resulting in an adjusted LOD of 2.27. On chromosome 2q, previous studies had proposed three loci (*IDDM7*, *IDM12*, and *IDDM13*) but [Concannon et al. \(1998\)](#) reported a maximum LOD in this region of 1.07, and little evidence for distinct loci. By multipoint analysis, even modest contributions ($\lambda_s \geq 1.5$; LOD < -2) to T1D could be excluded for *IDDM3*, *IDDM4*, *IDDM6*, *IDDM9*, and *IDDM10*. In an identity-by-descent (IBD) analysis of previously reported loci (other than *IDDM1/HLA* and *IDDM2/INS*), only *IDDM7/IDDM12/IDDM13* and *IDDM15* had LOD scores greater than 1; negligible support was found for six of the previously reported loci: *IDDM3*, *IDDM4*, *IDDM6*, *IDDM9*, *IDDM10*, and *IDDM11*.

In an attempt to further increase the power of linkage analyses, multinational consortia were formed, allowing the analysis of combined datasets. The Type 1 Diabetes Genetics Consortium (T1DGC) was established for this purpose in 2002. [Concannon et al. \(2005\)](#) performed, under the auspices of the T1DGC, a combined linkage analysis of four datasets, three previously published ([Concannon et al., 1998](#); [Mein et al., 1998](#)), providing a total sample of 1435 families with 1636 affected sibpairs. By multipoint linkage analysis, only the *HLA* was significant (*IDDM1*; LOD 116; λ_s of 3.35), and four other regions showed suggestive significance (i.e., uncorrected $p < 7.4 \times 10^{-4}$): 2q31-33 (*IDDM7/IDDM12/CTLA4*; LOD 3.34; λ_s of 1.19), 6q21 (*IDDM15*; LOD 22.39; λ_s of 1.56), 10p14-q11 (*IDDM10/CD25*; LOD 3.21; λ_s of 1.12), 16q22-24 (LOD 2.64; λ_s of 1.19). LOD scores above 1 were found at *IDDM2/INS*, and five other regions: 3p13-14, 9q33-34, 12q14-12, 16p12-q11, and 19p13. The 19p13 region contains the insulin receptor gene (*INSR*). In 2009, the T1DGC published a linkage analysis of 2496 multiplex families; again, only the *HLA* was significant at genome-wide significance levels (*IDDM1*; LOD 213), with significance at 6q21/*IDDM15* resulting from an effect partly due to LD with *HLA*. Suggestive linkage was found at *CTLA4* (*IDDM7/IDDM12*; LOD 3.28) and *INS* (*IDDM2*; LOD 3.16) and two regions on chromosome 19: 19p13 (*INSR*; LOD 2.84)

and 19q13 (LOD 2.54; [Concannon et al., 2009](#)). The sample size of this study provided unprecedented power to detect linkage, but provided little support for the majority of loci previously implicated in T1D.

Linkage Studies in Multiple Sclerosis

In contrast to the moderate progress in T1D, attempts to identify MS genes by linkage analysis of families such as affected sibpair analysis or patient and unaffected parent trios were relatively unsuccessful. For example, [Sawcer et al. \(1996\)](#) studied 282 families using a staged approach, but only obtained a maximized LOD score at the *HLA* of 2.8, compared to 8.0 for T1D ([Davies et al., 1994](#)). Only one other locus surpassed the statistical threshold for suggestive linkage, 17q22. In none of the other linkage studies did the *HLA* reach a significant maximized LOD score ([Ebers et al., 1996](#); [Haines et al., 1996](#); [Kuokkanen et al., 1997](#); [Broadley et al., 2001](#); [Coraddu et al., 2001](#); [Ban et al., 2002](#)). [Ebers et al. \(1996\)](#) reported linkage to a region just outside the *HLA* (χ^2 of 10.8 by transmission disequilibrium test), [Kuokkanen et al. \(1997\)](#) reported linkage (maximized LOD 3.6) at 17q22-24 and the Multiple Sclerosis Genetic Group reported suggestive linkage to *HLA-DR* and 7q21-22 ([Haines et al., 1996](#)). Several groups applied a modified threshold for suggestive significance (based on reduced marker density) and identified suggestive linkage at: 1q31 ([Coraddu et al., 2001](#)), 2p13 ([Ban et al., 2002](#)), 4q26-28 ([Ban et al., 2002](#)), 6q26 ([Ban et al., 2002](#)), 10q23 ([Coraddu et al., 2001](#)), 11p15 ([Coraddu et al., 2001](#)), and Xp11 ([Ban et al., 2002](#)).

The issue of why genome-wide linkage studies were relatively successful in T1D but not MS is an important one. Where the effective strength of putative loci could be determined, they were of similar orders between the two diseases. Patient heterogeneity is also an unlikely explanation, because the consolidation of sample sets occurred later for MS than it did for T1D; as a generalization, the MS results reflected samples collected within relatively restricted geographical areas. Similarly, while the power of several of the MS studies was rather low, others used sample sizes comparable to those used in many of the T1D studies. The most likely explanation lies in the relative heritability (the proportion of variation in risk within a community attributable to genetics) of the two diseases: that of T1D is about twice that of MS ([Baxter, 1997, 2007](#); [Hawkes and MacGregor, 2009](#)), an observation consistent with the identification of several environmental factors contributing to the risk of MS (latitude, smoking, EBV).

Linkage Studies in Lupus

Following the identification of linkage to distal chromosome 1 in the NZB/NZW and NZM mouse models of

lupus, Tsao et al. (1997) examined seven markers in the syntenic region of human chromosome 1 (1q31-42) in 52 affected sibpairs and confirmed linkage to lupus.

In 1998, two major genome-wide linkage studies of lupus were published (Gaffney et al., 1998; Moser et al., 1998). Analysis of 105 families with at least two affected siblings identified just two loci surpassing the Lander and Kruglyak (1995) thresholds for significant linkage: 6p11-21 (just centromeric to the *HLA*; maximized LOD 3.9) and 16q13 (maximized LOD 3.6; Gaffney et al., 1998). Both these regions were confirmed in a subsequent reanalysis that included an additional 82 sibpair families (maximized LODs of 4.1 and 3.9, respectively; Gaffney et al., 2000). Two other regions fulfilled the criteria for suggestive linkage: 14q21-23 (maximized LOD 2.8) and 20p12 (maximized LOD 2.6). A peak, albeit nonsignificant, was consistent with linkage to 1q42, as reported in Tsao et al. (1997).

The other major analysis examined 94 African American and European American multiplex extended pedigrees identifying four regions of suggestive linkage: 1q23 (maximized LOD 3.5), 13q32 (maximized LOD 2.5), 20q13 (maximized LOD 2.5), 1q31 (maximized LOD 2.0; Moser et al., 1998). Additional suggestive loci were identified only in African American families—1q41 (maximized LOD 3.5), 11q14-23 (maximized LOD 2.1)—and only in European American families—14q11 (maximized LOD 2.2), 4p15 (maximized LOD 2.2), 11q25 (maximized LOD 2.2), 2q32 (maximized LOD 2.1), 19q13 (maximized LOD 2.1), 6q26-27 (maximized LOD 2.0), and 12p13-11 (maximized LOD 2.0). No linkage to the *HLA* (6p21) was identified, probably reflecting the reduced power of genetic studies in mixed populations. The 1q23 locus is syntenic with the major murine chromosome 1 locus (Vyse and Kotzin, 1998) and contains the lupus candidate gene *FCGR2A*, and the 1q41 linkage is consistent with that found by both Tsao et al. (1997) and Gaffney et al. (1998).

TNFR1, TNFR2, LTBR

The 12p13 locus (Moser et al., 1998) contains the genes *TNFR1* (*TNFRSF1A*) and *LTBR* (*TNFRSF3*), which encode TNF receptor 1 and the LT β receptor, respectively. Similarly, the location of *TNFR2* (*TNFRSF1B*; encoding the TNF receptor 2) on 1p36 was sufficiently close to minor linkage peaks reported by Gaffney et al. (1998) and Shai et al. (1999) for Tsuchiya et al. (2000) to test, and confirm, association of a nonsynonymous coding SNP (587 (T→G)) with lupus in Japanese subjects. Lupus is associated with serum concentrations of soluble TNF receptor (s-TNFR; both type I and type II) sufficient to effectively inhibit the bioactivity of TNF (Aderka et al., 1993). Perhaps the clearest evidence of the

disease's heterogeneity comes from an open label trial of TNF blockade in lupus. While the majority of patients expressed increased titers of high affinity autoantibodies to dsDNA, chromatin and histones over the period of therapy, seven of nine patients with lupus nephritis experienced stabilization of serum creatinine and a reduction in proteinuria of >50%, and all five patients with lupus arthritis underwent remission lasting for weeks after treatment was halted (Aringer et al., 2009).

STAT4

A small genome-wide linkage study of RA identified a region on chromosome 2q33 with significant linkage (Amos et al., 2006). A subsequent high-resolution association study confirmed the involvement of this region in RA and implicated the gene *STAT4*, since the five most significantly associated SNPs all lay within the second intron of *STAT4* (Remmers et al., 2007). *STAT4* is a cytokine-responsive transcription factor that mediates responses to IL12; it plays a critical role in the differentiation of Th1 cells. The authors also genotyped 1039 lupus patients and 1248 controls at the SNP most highly associated with RA (*rs7574865*) and found that the RA susceptibility allele (T) was also associated with lupus (Remmers et al., 2007). In lupus, this SNP was strongly associated with anti-dsDNA particularly severe nephritis, and early onset of disease (Taylor et al., 2008; Chung et al., 2011). The same risk allele confers susceptibility to primary Sjögren's syndrome (Nordmark et al., 2009).

Racial Heterogeneity in Systemic Lupus Erythematosus

Since genome-wide linkage analyses had confirmed the importance of racial heterogeneity in lupus inheritance, Shai et al. (1999) analyzed 80 families with affected sibpairs (43 Mexican American families and 37 Caucasian families) and found no significant loci and only a single suggestive locus: 1q44. An analysis of the data by race made it clear that the linkage could be attributed only to the Mexican American subgroup; there was no support for a gene in this region in the Caucasian families. Lindqvist et al. (2000) analyzed six Icelandic and 11 Swedish pedigrees with multiple affected members. The combined data set showed significant linkage to 2q37 (LOD score 4.24). This region contains the *INPP5D* gene, which encodes an SH2-containing phosphatase which is recruited through tyrosine phosphorylation of Fc γ RIIB, CD19, or CD22 after ligation of the B cell receptor, and is thought to be important in Fc γ RIIB-mediated inhibition of B cell activation. Suggestive linkage was identified at 4p15-13 and 19p13 when the Icelandic subjects were analyzed independently.

The 4p15-13 locus is syntenic with the *Lmb2* murine lupus susceptibility gene. In most cases (14/16 markers), aggregating the data from the two countries eliminated any suggestion of linkage. In many subsequent studies, particularly in the genome-wide association studies that followed, experimental power was improved by restricting racial heterogeneity—generally to populations of European descent.

GENOME-WIDE ASSOCIATION STUDIES OF AUTOIMMUNITY

Genome-wide linkage analyses were limited in resolution by the recombination frequency observable over a few generations, and in power by the relatively low number of multiplex families available. By the year 2000, a reasonable draft of the human genome sequence was completed, millions of SNPs had been deposited into public databases, and high-throughput technologies were under development for SNP genotyping. It was predicted that case–control association studies involving thousands of patients and population-based controls would provide far better resolution and power for the identification of disease-associated genes (Cardon and Bell, 2001). In contrast to linkage studies, association studies can detect alleles with much more modest effects on risk, as long as those alleles are relatively common and the sample size sufficiently large (Wang et al., 2005). In each region of the genome, pre-selected SNPs are chosen that are expected to represent the total genetic variation in linkage disequilibrium with the markers. Kruglyak (1999) estimated that in whole genome association studies, linkage disequilibrium was unlikely to extend beyond an average distance of 3 kb in the general population; this implies that a minimum of 500,000 SNPs would be required for whole genome analysis.

Genome-Wide Association Studies of Type 1 Diabetes

Smyth and colleagues (2006) performed a multi-locus case–control association study of T1D using >6500 coding, non-synonymous (ns)SNPs. Although not discussed in the paper, the rationale for studying nsSNP was the expectation that most alleles affecting common, complex diseases would alter the coding sequence, and therefore the causal variants might be among the markers selected (Weiss and Terwilliger, 2000). The study was underpowered with ~2000 cases and 1700 control samples, and, described as an “interim analysis,” was not corrected for multiple hypothesis testing. The most significantly associated SNP was the previously published and confirmed C1858T SNP in *PTPN22* (Bottini et al., 2004).

IFIH1

The authors referred to the next two most significantly associated SNPs: one in *CAPSL*, which is adjacent to *IL17R*, and the other on chromosome 2q24.3 in *IFIH1* (IFN induced with helicase C domain 1; also known as *MDA5* or Helicard; risk-associated SNP *rs1990760*). The association with *rs1990760* was strengthened by genotyping an additional ~2500 cases and ~4500 controls and by examining an independent collection of parent–child trios. The *IFIH1* protein functions as a pattern recognition receptor for viruses (dsRNA). The T1D-associated A allele of *rs1990760* is also associated with RA (Stahl et al., 2010) and vitiligo (Jin et al., 2010), but is a resistance allele for Crohn’s disease (Barrett et al., 2008).

In 2007, the Wellcome Trust Case Control Consortium (WTCCC, 2007) published a major genetic milestone: a Genome Wide Association Study (GWAS) of seven complex diseases (bipolar disorder, coronary artery disease, Crohn’s disease, hypertension, RA, T1D, and T2D) with about 2000 cases per disease, and a shared group of ~3000 controls, typed at 500,568 SNPs using the Affymetrix GeneChip500k Mapping Array Set. Prior to the genome-wide analysis of the dataset, the authors examined association at previously identified loci for confirmation by association. For T1D, they confirmed association for *HLA*, *CTLA4*, *PTPN22*, *CD25*, and *IFIH1*; *INS* could not be tested because a suitable SNP was not identified. It is sobering to note that the *p*-values obtained for these “proof of principle” associations only exceeded the genome-wide significance level for *HLA* and *PTPN22*. Even more concerning was the finding that even after raising the significance threshold 500-fold, the only other previously reported genetic region identified was *CD25*. The study did, however, identify three new loci significantly associated with T1D: 12q13, 12q24, and 16p13. Two other loci identified by multi-locus analysis were reported, but were unlikely to be significant after correction for the additional hypotheses tested.

In a follow-up study, the WTCCC (Todd et al., 2007) genotyped an additional 4000 cases and 5000 controls (total 6000 affected, 6200 controls) and confirmed significance for 12q24 (gene *SH2B3*), 12q13 (*ERBB3*), 16p13 (*CLEC16A*), and 18p11 (*PTPN2*). Mutations in *SH2B3* have also been associated with celiac disease (Hunt et al., 2008), MS (Alcina et al., 2010), RA (Stahl et al., 2010), and hypothyroidism (Eriksson et al., 2012); polymorphisms in *CLEC16A* are also associated with MS (International Multiple Sclerosis Genetics Consortium, 2009) and primary biliary cirrhosis (Mells et al., 2011); and the T1D-associated risk allele of *PTPN2* is also associated with celiac disease (Dubois et al., 2010).

A combined meta-analysis incorporating cases from the WTCCC studies (Todd et al., 2007) and a combined

British and US GWAS (Cooper et al., 2008) examined a total sample set of 7514 cases and 9045 reference samples (Barrett et al., 2009). At a genome-wide level of significance, they confirmed association with the previously identified regions 1p13 (gene of interest *PTPN22*), 2q24 (*IFIH1*), 2q33 (*CTLA4*), 4q27 (*IL2*), 6q15 (*BACH2*), 10p15 (*IL2RA* and *PRKCQ*), 11p15 (*INS*), 12q13 (*ERBB3*), 12q24 (*SH2B3*), 15q25 (*CTSH*), 16p13 (*CLEC16A*), 18p11 (*PTPN2*), 21p22 (*UBASH3A*), and 22q13 (*CIQTNF6*). In addition, they obtained genome-wide significance for 18 other loci, including *IL10* and *CD69*.

IL2

Within 4q27, the most significant SNP lies in the gene *KIAA1109*, which is about 200 kb 3' of the *IL2* and *IL21* cytokine genes, and is of particular interest because it is syntenic with the NOD mouse diabetes susceptibility gene *Idd3* (Denny et al., 1997).

IL10

The most significantly associated SNP at 1q32 (*rs3024505*) is distal to the *IL10* gene. *IL10* has pleiotropic effects on adaptive and innate immunity. Its ability to inhibit the production of several inflammatory cytokines and chemokines, including *IL1* and *TNF*, contributes to its anti-inflammatory activities. It inhibits expression of MHC class II antigens, as well as the costimulators *CD80* (*B7*) and *CD86* (*B7.2*) on monocytes significantly affecting their T cell-activating capacity. In contrast, it enhances survival and proliferation of B cells and increases antibody production (Moore et al., 2001). While the G allele at *rs3024505* is associated with T1D, the A allele is associated with ulcerative colitis (Anderson et al., 2011) and the T allele with Crohn's disease (Franke et al., 2010). This region also contains genes encoding *IL19* and *IL20*.

CD69

CD69 is encoded at 12p13. Its expression is induced on T cell activation and mediates T cell costimulation. The most significantly associated SNP is in the first intron, which contains a cis-regulatory element (Vazquez et al., 2012). Significantly, *CD69* suppresses Sphingosine 1-Phosphate Receptor-1 (*S1P1*) function (Bankovich et al., 2010). *S1P1* plays a critical role in lymphocyte recirculation; its pharmaceutical downmodulation by the agonist Fingolimod sequesters lymphocytes in lymph nodes, inhibiting relapses of MS.

Genome-Wide Association Studies of Multiple Sclerosis

GWAS of MS soon followed those of T1D and were coordinated through the International MS Genetics Consortium (IMSGC). The first of these was performed in 2007 (International Multiple Sclerosis Genetics Consortium et al., 2007) and involved 931 trios (MS affected individual and non-affected parents) and interrogation of 334,923 SNPs. Analysis for association identified a total of 110 SNPs selected for follow-up in a replication phase consisting of 2322 MS cases, 609 parent-case trios, 789 controls, and genotyping data from two external control datasets resulting in a combined analysis of 12,360 subjects. In addition to the *HLA*, two other genes were found to be strongly associated with MS risk: *CD25* and the *IL7* receptor (*IL7R*) gene.

CD25

The SNP in 10p15 most strongly associated with MS is in the first intron of *CD25*, while that associated with T1D lies about 20 kb upstream. A careful association analysis of *CD25* alleles was performed in a DNA collection of 9407 healthy controls, 2420 MS, and 6425 T1D subjects as well as 1303 MS parent-child trios. Maier et al. (2009a) observed significant complexity at this locus: one allele was associated with T1D but not MS; another was associated with susceptibility to T1D but protection from MS, and a third conferred susceptibility to both diseases. Presence of MS risk-associated variants in *CD25* correlated with increased *sIL2RA* expression; while *sIL2RA* levels were increased in very severe MS, they did not decrease with treatment (Maier et al., 2009b). In contrast the T1D-associated variants correlated with decreased *sIL2RA* expression (Lowe et al., 2007). Although *sIL2RA* inhibits *IL2*-mediated signaling, it promotes T cell activation and proliferation, presumably by reducing activation-induced cell death.

IL7R

IL7R on 5p13 had previously been identified in a small multi-locus case-control association study of MS as associated with the disease (Zhang et al., 2005). In the GWAS by the International Multiple Sclerosis Genetics Consortium et al., (2007) the most significantly associated SNP in the region lies within exon 6, which is alternatively spliced. This SNP has a functional effect on gene expression as it disrupts a putative exonic splicing silencer, influencing the relative proportions of soluble and membrane-bound isoforms of the protein (Gregory et al., 2007). Polymorphisms within *IL7R* are also associated with primary biliary cirrhosis (Mells et al., 2011).

Although not significant, moderate associations were also reported for an additional 13 SNPs, including those located within the genes *CD58* (1p13), *EVI5* (1p22), and *CLEC16A* (16p13). It was not until replication studies were performed in independent cohorts of MS cases and controls that these genes could be confirmed as MS risk-associated variants (Weber et al., 2008; Hoppenbrouwers et al., 2008; Rubio et al., 2008).

CD58

CD58 on chromosome 1p13 encodes the costimulatory molecule LFA-3. Resequencing and fine mapping of the *CD58* gene region in patients with MS and control subjects identified a *CD58* variant that provided further evidence of association with MS. The *rs2300747* SNP lies within the first intron of *CD58*. The protective (G) allele is associated with a dose-dependent increase in *CD58* mRNA expression in lymphoblastic cell lines and peripheral blood mononuclear cells from MS subjects (De Jager et al., 2009a). The possibility that increased LFA-3 expression on circulating mononuclear cells is protective is supported by the finding that *CD58* mRNA expression is increased in MS subjects during clinical remission. A potential mechanism of action is via the engagement of CD2 by LFA-3, which upregulates the expression of transcription factor FoxP3, leading to enhanced function of CD4⁺CD25⁺ Treg cells (De Jager et al., 2009b).

In 2009, an Australian study focused on an MS case versus non-affected control GWAS involving 1618 MS cases in the initial discovery phase, and replication in an independent cohort of 2256 MS cases and 2310 healthy controls (Australia and New Zealand Multiple Sclerosis Genetics Consortium, 2009). This led to the identification of two novel genetic loci, one on chromosome 12q13-14 and the other on chromosome 20q13, and replicated the association of *HLA* and *CD58* at a genome-wide level of significance (Australia and New Zealand Multiple Sclerosis Genetics Consortium, 2009).

CYP27B1

The association with the region on chromosome 12q13-14 could be due to a number of potential candidate genes, and requires further refinement due to the strong linkage disequilibrium in this region. The most strongly associated SNP lies within the 3' untranslated region of *METTL1*, about 2 kb upstream of *CYP27B1*, which encodes the enzyme 25-hydroxy-vitamin D-1 alpha hydroxylase and is involved in vitamin D metabolism (Bailey et al., 2007). Vitamin D plays an important role in immune function, and has also been shown to regulate expression of *HLA-DR15* (Ramagopalan et al., 2009). Other genes in this region include *CDK4* also previously

shown to play a role in immune function and autoimmune disease.

CD40

The SNP most strongly associated with MS on 20q13 lies about 10 kb upstream of *CD40*. In addition to the association with MS, variants within *CD40* are also associated with RA, GD, and Crohn's disease. Of particular interest is a SNP located at -1 bp from the start of translation within the Kozak consensus sequence of the *CD40* gene (*rs1883232*), as the MS resistance allele (C) is associated with RA, GD, and Crohn's disease, and leads to increased efficiency of translation, while the MS susceptibility (T) allele leads to lower *CD40* expression (Blanco-Kelly et al., 2010).

In the same year, De Jager et al. (2009a) published a meta-analysis that combined 895 subjects from the IMSGC's original association study (International Multiple Sclerosis Genetics Consortium et al., 2007), 969 subjects from the Gene MSA consortium (Baranzini et al., 2009), and an additional unpublished set of 860 subjects, totaling 2624 cases and 7220 controls. This study confirmed, at a genome-wide level of significance, *HLA*, *CD58*, *CD25*, and *CLEC16A*. It also identified chromosomal regions at 12p13 (gene of interest *TNFRSF1A*), 16q24 (*IRF8*), and 11q12 (*CD6*) as significantly associated.

TNFRSF1A

The most significantly associated SNP at 12p13 (*rs1800693*) lies at the splice junction at the 3' end of the sixth exon of the *TNFRSF1A* gene, which encodes TNFR1. Analysis of GWAS data in conjunction with the 1000 Genomes Project data identified this SNP as the likely causal variant in the *TNFRSF1A* region. The MS risk allele (C) generates a soluble form of TNFR1 that can block TNF signaling (Gregory et al., 2012), mimicking the effect of TNF-blocking drugs, which exacerbate MS (The Lenercept Multiple Sclerosis Study Group et al., 1999). The MS susceptibility allele at this locus also confers susceptibility to primary biliary cirrhosis (Mells et al., 2011) and this region showed mild linkage to lupus (Moser et al., 1998).

IRF8

The most significantly associated SNP at 16q24 lies ~60 kb 3' of *IRF8*. The *IRF8* gene is a key target of vitamin D, through binding the nuclear vitamin D receptor (Ramagopalan et al., 2010). Administration of exogenous IFN γ exacerbates MS; *IRF8* is upregulated by IFN γ and cooperatively enhances IFN γ -induced apoptosis of oligodendroglial progenitor cells (Horiuchi et al., 2011).

CD6

The most significantly associated SNP in the 11q12 region (*rs17824933*) lies in the first intron of CD6. CD6 is a type 1 transmembrane glycoprotein found on T lymphocytes in association with the signaling components of the TCR. It acts as a costimulator of T cell proliferation via its interaction with the ligand, activated leukocyte cell adhesion molecule (ALCAM; Zimmerman et al., 2006). The MS susceptibility allele is associated with decreased expression of full-length CD6 in T cells and an increase in a splice variant lacking exon 5, resulting in diminished proliferation during long-term activation of CD4⁺ T cells (Kofler et al., 2011). Nevertheless, the role of CD6 in MS is not completely clear, as it can attenuate T cell activation, possibly via regulation of CD5 tyrosine phosphorylation (Oliveira et al., 2012), and appears to play a role in leukocyte trafficking across the blood–brain barrier and into the central nervous system via its interactions with ALCAM on the endothelium trans migratory cups (Cayrol et al., 2008).

The largest GWAS for MS to date was performed by the International MS Genetics Consortium (International Multiple Sclerosis Genetics Consortium, 2011b). This study involved approximately 10,000 MS cases and 20,000 controls collected from throughout Europe, America, and Oceania, and identified a total of 57 genetic loci associated with MS in addition to the *HLA*, of which 28 had not been previously reported (<http://wattle.well.ox.ac.uk/wtccc2/external/ms/>). The genes confirmed as associated with MS at a genome-wide level of significance included *HLA*, *CD58*, *CD25*, *CD6*, *TNFRSF1A*, *CYP27B1*, *CLEC16A*, and *IRF8*. New loci identified included 3p24 (gene of interest *EOMES*), 3q13 (*CD86*), and 5q33 (*IL12B*).

IL12B

The most significantly associated SNP at 5q33 is in the second exon of an uncharacterized open reading frame (ORF; *LOC285626*) about 3 kb upstream of *IL12B*, which encodes the 40 kDa subunit of IL12 and IL23. These cytokines have been strongly implicated in the pathogenesis of both MS and the mouse model of MS, experimental autoimmune encephalomyelitis (Langrish et al., 2005). The gene *IL12A* (3q25), which encodes the 35 kDa subunit of IL12, had been previously implicated as a SNP in its second intron was associated with MS by the IMSGC (International Multiple Sclerosis Genetics Consortium, 2010). IL12 is expressed by activated dendritic cells (DC), macrophages, and monocytes and plays an important role in sustaining IFN γ production and the generation and maintenance of memory/effector Th1 cells. In contrast, IL23 does not promote the development

of Th1 cells, but is essential for the expansion of a pathogenic CD4 T cell population characterized by the production of IL17, IL17F, IL6, and TNF (Thakker et al., 2007). The MS-associated *IL12B* allele is also associated with psoriasis (Ellinghaus et al., 2010). Ustekinumab, a neutralizing anti-IL12 p40 mAb did not show efficacy in reducing the cumulative number of gadolinium-enhancing T1-weighted lesions in MS (Segal et al., 2008).

Once again, outside of the *HLA*, all associations showed only modest OR between 1.1 and 1.3. The majority of associated genes were located either near or within immune-system related genes, and a large proportion had previously been associated with other autoimmune diseases.

Genome-Wide Association Studies of Systemic Lupus Erythematosus

The first GWAS of lupus was performed under the auspices of the International Consortium for Systemic Lupus Erythematosus Genetics (SLEGEM) in 2007 (SLEGEM et al., 2008). It was a phased study with an initial genome-wide analysis of 720 female lupus patients of European ancestry and 2337 controls, with the most significantly associated SNPs typed in an additional 1846 patients. This study confirmed, at a genome-wide level of significance, both the *HLA* and *IRF5*. It also found significant association at four other regions: 16p11 (gene of interest *ITGAM*), 11p15.5 (*PHRF*), 3p14.3 (*PXK*), and 1q25.1.

ITGAM

The most strongly associated SNP in lupus, on 16p11.2, is in the 14th intron of *ITGAM*. This gene encodes the integrin alpha M chain, which together with the beta 2 chain (ITGB2) forms leukocyte-specific integrin CD11b (MAC1, or inactivated complement receptor 3). CD11b is important in the phagocytosis of complement coated particles as well as the adherence and emigration from the bloodstream of neutrophils and monocytes via interactions with a wide range of structurally unrelated ligands, including ICAM-1 and ICAM-2, C3bi, and fibrinogen. In a replication study, the association of lupus with *ITGAM* was confirmed. However, a SNP with stronger association was identified, *rs1143679*, which encodes a nonsynonymous polymorphism that results in an R77H substitution, so altering the conformation of the α I domain, with subsequent consequences for MAC1 ligand binding (Nath et al., 2008). In a GWAS of patients bearing anti-dsDNA autoantibodies in lupus, *ITGAM* together with the *HLA*, *STAT4*, and *IRF5* was found to be significantly associated (Chung et al., 2011).

PHRF1

The most strongly associated gene on 11p15.5 lies within the fourth intron of *PHRF1* (*KIAA1542*). The 3' end of *PHRF1* almost immediately abuts the 3' end of the IFN response gene *IRF7*, which is in the reverse orientation. *IRF7* is a transcription factor that mediates IFN β production in response to viral infection. Genetic variation at this locus is associated with IFN α activity in lupus and titers of anti-Sm autoantibody (Salloum et al., 2010).

Published in the same month as the SLEGEN study, Hom et al. (2008) performed a GWAS on DNA samples from 1311 patients with lupus and 1783 controls, all North Americans of European descent. Strong confirmation at a genome-wide level of significance was found for *HLA*, *IRF5*, and *STAT4*, although there was a partial overlap of subjects included in the original report of *STAT4* association (Remmers et al., 2007). In addition, two other regions of genome-wide significance were identified, 16p11 (*ITGAM*) and 8p23 (*BLK*).

BLK

The most strongly associated SNP on 8p23 is in the promoter region of *BLK*, about 3 kb upstream of the transcription initiation site. This gene encodes a Src tyrosine-kinase that has a role in B cell receptor signaling and B cell development, although *Blk*-deficient mice have no obvious phenotype (Texido et al., 2000). The lupus risk allele is associated with reduced *BLK* mRNA in transformed B cell lines (Hom et al., 2008) but in primary human B lymphocytes, cis-regulatory effects of disease-associated SNPs are restricted to naïve and transitional B cells. The allelic effect has been shown to affect protein levels (Simpfendorfer et al., 2012).

FROM LOCATION TO MOLECULAR MECHANISMS

Although a few tagging SNPs used in GWAS of autoimmune disease affect transcript splicing (Graham et al., 2006; Gregory et al., 2007; Kofler et al., 2011), in general the GWAS approach tests disease associations with individual variants that are unlikely to be causal. Many of the applications of GWAS data are dependent on identifying the functional variants, not just the tagging SNPs with which they are in LD. One approach is to examine protein-coding genes in the vicinity of risk SNPs, in order to identify overrepresented biological pathways. For example, the recent GWAS data obtained for MS were analyzed for enrichment of genes (defined as protein coding regions nearest to the lead tagging SNP) with similar function, as classified in the Gene Ontology (GO) database (Ashburner et al., 2000). The GO terms having the

most significant enrichment included genes involved in “immune system processes” ($p = 8.6 \times 10^{-11}$, OR = 9.12), particularly lymphocyte function ($p = 3.2 \times 10^{-11}$, OR = 35.96), and especially T cell activation and proliferation ($p = 1.85 \times 10^{-9}$, OR = 40.85 (International Multiple Sclerosis Genetics Consortium et al., 2011b)). With this information, one can return to the genomic sequences flagging risk SNPs to identify additional putative causal variants. The sequencing of these, and their associated regulatory sequences, in patients and controls can help validate these candidates.

This approach has provided partial success, but has made it clear that few causal variants affect amino acid sequence of candidate protein coding regions. In many cases, the haplotype block in LD with tagging SNP lies within the first intron, or in regulatory sequences 5' or 3' of a protein-coding gene. Usually, the most important regions that regulate transcription are the promoter and the first intron, although many other regulatory elements are also required for spatiotemporally and quantitatively correct gene expression; enhancer and repressor elements frequently reside in introns up- and downstream of the transcription unit (Kleinjan and van Heyningen 2005). This finding therefore suggests that the linked causal variants in these regions are likely to be expression quantitative trait loci (eQTL), which are loci at which polymorphism affects the expression of one or more transcripts. Indeed, the data obtained on candidate genes for autoimmune diseases strongly support the hypothesis that most of the genetically encoded risk of disease is conferred by eQTL (Jacob et al., 1990; Bennett et al., 1995; Ueda et al., 2003; Graham et al., 2006; Ramagopalan et al., 2009; De Jager et al., 2009a; Maier et al., 2009b; Blanco-Kelly et al., 2010; Wang et al., 2010; Zuvich et al., 2011; Alcina et al., 2012).

The success of eQTL-based approaches is illustrated in recent studies that combine genotyping and gene expression datasets. For example, Göring et al. (2007) reported that, of around 20,000 autosomal gene transcripts, 1345 were regulated by nearby (cis) gene variants. With a false discovery rate of 5%, the median genotype-expression change was 24.6%. In a dataset combining very high density SNP genotyping and gene expression profiling of lymphoblast cell lines from 210 unrelated individuals, Veyrieras et al. (2008) found that, of 11,466 expressed genes, expression levels in 6.5% of these were highly associated with individual SNPs. The most significantly associated eQTL was an average of 7.5 kb from the transcript, and 99% of cis-eQTLs were found to lie between 110 kb upstream and 40 kb downstream of the transcription start site.

It is likely that eQTLs and splice QTLs will be cell subset specific. Dimas et al. (2009) identified eQTL in three cell types (fibroblasts, EBV-transformed B cells,

and T cells) in 75 newborns enrolled in a European Gencord project. Of 1007 unique eQTLs, only 8.5% were shared among all three cell types, 12% were shared between two of three cell types and 79.5% were cell-type specific. It is therefore necessary for cell subsets to be analyzed for gene expression profiles individually. The advantages for autoimmune diseases are that so much of the disease risk appears to be conferred by genes involved in leukocyte function, and a wide range of leukocytes can be accessed via peripheral blood using commercially available kits that facilitate subset purification from whole blood or buffy coat. We are currently identifying MS-associated eQTL in five peripheral blood leukocyte subsets: CD4 T cells, CD8 T cells, B cells NK cells, and monocytes. By combining this dataset with MSGC GWAS data ([International Multiple Sclerosis Genetics Consortium et al., 2011a](#)), we will be able to identify variants that are associated with differences in gene expression throughout the genome—whether in cis or trans. Some of these variants will also be associated with disease. These studies will dramatically increase our knowledge of each of these risk-associated haplotypes that contain eQTL: we will know what transcript it causes to be differentially expressed; we will know in what tissue that differential expression occurs; and we will know the direction of differential expression it confers, as well as the direction of change in expression that is associated with disease. With these four critical pieces of information we can generate animal models to test the validity of these candidate genes and therefore determine the molecular mechanisms of their actions.

CONCLUDING COMMENTS

In many regards, the true value of genomic studies of complex autoimmune traits are yet to be realized, and will require the identification of causal variants and their mechanisms of action. Nevertheless, work to date has strengthened our understanding of autoimmunity in many regards. We now know that some of the commonly used animal models have additional value in sharing susceptibility loci, and in some cases sharing molecular pathogenesis, with the human diseases. We now have a partial explanation for the coexistence of different autoimmune diseases within families, and in individuals, as several diseases have been found to share susceptibility alleles. And we now have a plethora of molecular clues suggesting disease aetiology, some raising intriguing questions—such as the opposite effects of many alleles on organ-specific autoimmune diseases versus the inflammatory bowel diseases. These molecular clues, and the availability of robust animal models, are likely to help dramatically improve our understanding of immune tolerance and autoimmunity over the next decade.

The biggest threat to survival of the human population is infection caused by microorganisms such as viruses, bacteria, and parasites. The major histocompatibility complex (MHC) on chromosome 6 plays a very important role in fighting these infections and comprises multiple genes encoding for molecules critical for mounting an immune response to invading pathogens. Human MHC complex is divided into three main regions, human leukocyte antigens (HLA) class I, II, and III. HLA class I and class II genes are mostly polymorphic genes in human genome. The high polymorphism in the MHC region can be attributed to strong selection pressure as the human population moved to different parts of the world, and encountered

new infections leading to diversity in MHC genes through mutation, gene duplication, or gene conversion. A population with diverse HLA class I and II alleles leads to herd resistance to infection and has a survival advantage.

MAJOR HISTOCOMPATIBILITY COMPLEX

Human MHC molecules are called HLA which are homologous to the H-2 of mice. The HLA complex is located on the short arm of chromosome 6 and is 3500 kilobases long. HLA class I molecules contain one heavy chain of 44 kilodaltons (kDa) and one non-MHC encoded

non-polymorphic $\beta 2$ microglobulin of 12 kDa. The heavy chain consists of three extracellular domains of 90 residues each. The polymorphic residues in class I molecules are located on $\alpha 1$ and $\alpha 2$ domains of the heavy chain. There are three class I genes designated HLA-A, HLA-B, and HLA-C which are expressed on all nucleated cells. Class I molecules can bind 8–10 amino acid-long peptides which have been processed endogenously.

HLA class II molecules are present as heterodimers on the cell surface consisting of an α chain (32–34 kDa) and a β chain (29–32 kDa), each with two extracellular domains of about 90 amino acids long ($\alpha 1$, $\alpha 2$, and $\beta 1$, $\beta 2$). The β chains of three class II genes, HLA-DR, DQ, and DP, are highly polymorphic while α chains are generally non-polymorphic. The class II molecules are expressed on antigen presenting cells (APCs) like B lymphocytes, macrophages, dendritic cells (DC), endothelial and other organ-specific APCs. In general, class II molecules can accommodate peptides up to 10–25 residues. In humans, DR, DQ, and DP are in linkage disequilibrium and are inherited en bloc as a haplotype. MHC genes are expressed co-dominantly in each individual. Crystal structures of the DR and DQ genes have shown that the MHC molecule has a single peptide binding cleft which can accommodate a variety of peptides which depends on the charge, stability, and binding affinity.

MHC and Autoimmunity

During evolution, HLA alleles offering an advantage during reproductive years have been selected and occur in populations with much higher frequency compared to other alleles. Abundance of HLA-DR2/DQ6, DR4/DQ8, and DR3/DQ2 haplotypes in various populations suggest the importance of these haplotypes in clearing infections and survival of the species. Although these haplotypes offered a survival advantage in terms of fighting infection, they can also generate an autoreactive response thus predisposing to a number of autoimmune diseases. Even though there are more than 450 DRB1 alleles and 75 DQB1 alleles with the possibility of generating thousands of haplotypes, only a few alleles of these three haplotypes are associated with most of the autoimmune diseases. DRB1 have the maximum allelic diversity, suggesting a rapidly evolving region due to positive or negative selective pressures. Thus nature leads to selection of alleles offering advantage over other alleles. Studies have suggested that HLA heterozygosity has an advantage over homozygosity in the generation of immune response. HLA diversity evolves via mutations, gene conversion, and genetic recombination. The most conserved haplotype, B8-DR3-DQ2, has been associated with autoimmunity, suggesting this haplotype provides an advantage over other haplotypes and is supported by a high

gene frequency of HLA-DR3 in centenarians. Most of the autoimmune diseases show association with HLA class II alleles except the HLA-B27-associated spondyloarthropathies.

The Mystery of HLA-B27 and Spondyloarthropathies

Ankylosing spondylitis (AS) is a joint disease which affects the spine, the sacroiliac joints, and shoulders. In 1973, Brewerton and his colleagues showed that the MHC gene HLA-B27 is linked to susceptibility to AS (Brewerton et al., 1973). While B27 was found in 5% of the general population, 95% of AS patients were HLA-B27 positive. This was the first MHC gene found to be associated with an autoimmune-type disease. Eventually, several other closely related diseases such as psoriatic arthritis, arthritis associated with inflammatory bowel disease, and reactive arthritis were also linked to HLA-B27, although at a much lower frequency (Allen et al., 1999a). Several enterobacteria were found to be implicated in the onset of the disease (Kvien et al., 1994). These diseases are now referred to as spondyloarthropathies. In order to understand the role of HLA-B27 in these diseases, Taugog and his colleagues developed a transgenic rat expressing human HLA-B27 gene from an AS patient (Hammer et al., 1990). Transgenic rats developed spontaneous symptoms characteristic of SPA, but the disease only developed in high gene copy number rats.

HLA-B27 Transgenic Mice

Mice expressing intact HLA-B27 on the cell surface developed normally, and showed no disease symptoms. Assuming the disease may require the human $\beta 2m$ gene, we initiated studies to replace mouse $\beta 2m$ with human $\beta 2m$. During this process, we noticed that mice lacking $\beta 2m$ altogether showed some symptoms of spondyloarthropathies (Khare et al., 1995). We found that these mice expressed about 10% of $\beta 2m$ free B27 heavy chains on their cell surface. Free heavy chains of class I molecules are rarely seen on the cell surface. This suggested that B27 may be a unique class I molecule capable of reaching the cell surface as free heavy chains. The frequency of symptoms increased after the mice were brought outside the pathogen-free barrier facility, suggesting environmental factors may play a role. Studies with B27⁺ CD4⁻ and CD8⁻ mice indicated that CD4 T cells were critical for the disease process. Computer simulation studies indicated that the pocket of a $\beta 2m$ free class I heavy chain may resemble a class II molecule with open ends which can load long exogenous peptides. Studies in Strominger's laboratory confirmed that some human B27 molecules were bound with 14–16 amino acid peptides

rather than 8–9 amino acid peptides normally found in most class I molecules (Madden et al., 1991). Transporter-associated proteins (TAP) interact with a unique class I conformation; whereas calnexin associates with multiple class I forms. Spontaneous inflammatory disease in HLA-B27 transgenic mice does not require TAP (Khare et al., 2001), and is independent of class II molecules, suggesting a direct role for B27 heavy chains and not B27-derived peptides (Khare et al., 1998).

On the basis of our studies with the HLA-B27 transgenic mice, we proposed the following hypothesis. HLA-B27 is a unique class I molecule that can be expressed on the cell surface as free heavy chains. They can load 14–16 amino acid-long exogenous bacterial peptides, and activate autoreactive CD4 T cells. Activated CD4 T cells migrate to target tissue and destroy cartilage causing various symptoms related to spondyloarthropathies.

HLA-B27 and AIDS

A major breakthrough came in the HLA-B27 field when it was identified as one of a very few HLA class I genes which protected HIV-infected individuals from progressing to full-blown disease (McMichael and Klenerman, 2002). The HLA-B27 molecules were able to bind and present multiple viral epitopes to generate a robust T cell response to clear infection (Streeck et al., 2007). The CD4 T cell level remained high and there was efficient B cell response also. Further proof came when it was shown that B27⁺ individuals were also protected against hepatitis C infections and endemic malaria (Mathieu et al., 2008).

Andrew McMichael and his group at the University of Cambridge became interested in the role of HLA-B27 in clearing viral infection. They initiated in-depth studies to understand how the B27 molecule is processed and loaded with peptides in human cells. When they tried to generate B27 tetramers for their studies, they noticed that B27 heavy chains were reaching the cell surface in the absence of β 2m and peptide. Further studies showed that these free chains were actually dimers of heavy chains (Allen et al., 1999b). This confirmed the findings on the HLA-B27 transgenic mice. The McMichael group expanded their studies to analyze the expression of HLA-B27 molecule in patients with spondyloarthropathies.

HLA-B27 and Peptide Binding

There are several critical residues in HLA-B27 molecules which may influence protection versus susceptibility against viral infection as well as autoimmunity. One such residue is at position 97 in the floor of the peptide binding pocket (McMichael and Jones, 2010). While most HLA class I molecules have arginine at this position, HLA-B27

has asparagine. Arginine is known to be a hindrance for peptide binding in the groove. HLA-B27 molecules in the thymus bind to multiple peptides, but there is a major difference in the affinity of the binding. While B27 bind very few peptides with high affinity, they bind many peptides with low affinity. Thus, fewer self-reactive T cells are deleted in the thymus, resulting in positive selection of autoreactive T cells. On the other hand, they may select virus specific T cells to broader fine specificity which could reduce virus options to escape by mutations, thus enhancing viral clearance.

Another key residue on the HLA-B27 molecule is at position 67 where B27 molecules have free cysteine (Bird et al., 2003). This residue enables the formation of dimers of the free heavy chains. The homodimer formation is dependent upon disulfide bonding through Cys67. Such bonding would require unwinding of the α 1 helix, enabling binding of longer peptides in a class II-like groove.

The HLA-B27 molecules have several other unique characteristics. The HLA-B27 molecules continue to be associated with calnexin after making a complex with β 2 microglobulin unlike other HLA molecules. However, they can be expressed on the cell surface in the absence of TAP and tapasin, which are involved in the loading of peptides into the class I molecule. We have previously shown that B27 mice in the context of the transporter-associated protein (TAP knockout) still get spontaneous disease, suggesting TAP may not be involved. Thus, HLA-B27 can be expressed on the cell surface in many different forms; as an intact molecule loaded with an endogenous peptide, or as β 2m free heavy chains, homodimers, or multimers either loaded with peptide or as empty molecules. CD4 T cells have been found to recognize HLA-B27 either as homodimers or heterodimers when they are devoid of peptide (Boyle and Hill Gaston, 2003). HLA-B27 reactive CD4⁺ T cells have been identified in HLA-B27⁺ AS patients.

HLA-B27 and Natural Killer Cells

We had shown a potential role of natural killer (NK) cells on HLA-B27-associated arthritis (Marietta et al., 2000). Introduction into T cells of NKB1, an allelic form of KIR3DL1, produces severe arthritis in HLA-B27 transgenic mice. Thus, interaction of free MHC heavy chains with MHC receptors could play a role in the development of arthritis in our HLA-B27 transgenic mice. Killer cell immunoglobulin-like receptors (KIR family) are expressed on NK cells, T cells, and NK T cells. KIR is polymorphic and demonstrates allele-specific recognition with a cognate KIR for HLA-B27 being the 3 domain, KIR3DL1. Our work with the mice was confirmed by Kollnberger and coworkers (Kollnberger et al., 2002)

who showed that HLA-B27 heavy chain homodimers and receptors for HLA-B27 homodimers are expressed on populations of peripheral blood, B and T lymphocytes, and synovial monocytes from patients with spondyloarthritis. Thus, interaction of HLA-B27 heavy chain with immunoreceptors on cells of the myelomonocytic cell lineage or lymphocytes might also be involved in the pathogenesis of spondyloarthritis.

HLA-B27 and Evolution

If HLA-B27 was a bad gene causing all of these diseases, it should have been eliminated during evolutionary time. On the contrary, HLA-B27 is one of the oldest MHC class I genes and has survived thousands of years. It is found on every continent, every geographical area, and in all ethnic and racial groups. It has one of the highest gene frequencies, and is very polymorphic with over 50 subtypes. These facts suggest that the HLA-B27 gene was positively selected during evolution and had to be a good gene.

The main function of MHC molecules is to clear infection. During thousands of years of evolution, HLA-B27 emerged as a class I molecule capable of presenting multiple epitopes of infectious agents to activate T cells to clear infection, as well as to generate cytotoxic T cells and help B cells to generate antibodies to clear infection. This could have happened by many different mechanisms. Key mutations in the peptide binding pocket could enable more promiscuous binding of multiple peptides for presentation to T cells. Mutations could have also enabled the B27 molecule to be expressed on the cell surface as free heavy chains capable of loading exogenous peptides and activating CD4 T cells. Thus, B27⁺ individuals would have survived many infectious episodes and bottlenecks, spread all over the world, and reproduced.

Unfortunately, HLA-B27 molecules can also generate adverse effects. The free chains of HLA-B27 are also expressed in the thymus where they can bind many self-peptides with low affinity and activate autoreactive CD4 T cells. These autoreactive CD4 T cells in the periphery can be activated by various mechanisms including molecular mimicry to cause autoimmunity.

In conclusion, the many forms of HLA-B27 can activate many different T cell populations. An intact B27 molecule would activate CD8 T cells. A free heavy chain or a homodimer loaded with an exogenous peptide will activate a CD4 T cell. B27 homodimers in complex with KIR molecules can activate NK cells. Finally, the β 2m free heavy chains may be able to directly interact and activate APCs such as B cells. Thus, the HLA-B27 molecule can generate a robust immune response against infectious agents to clear infections and maintain the health of the individual. On the other hand, aberrant

activation of an autoreactive CD4 T cell could result in autoimmune diseases.

HLA CLASS II ASSOCIATION WITH AUTOIMMUNE DISEASES

Susceptibility to the majority of autoimmune diseases is associated with the presence of certain HLA-DR and -DQ alleles (Table 27.1). Despite the presence of a high degree of polymorphism, only a few HLA class II alleles and their linked haplotypes are associated with autoimmune diseases. Although HLA class II genes are the strongest genetic factors associated with the development of autoimmune diseases, the exact role of these molecules in disease etiology is still being deciphered.

Predisposition

In the thymus, T cells are positively selected based on their ability to bind to self-MHC molecules expressed in the thymus; T cells binding to self-peptide–MHC molecules with moderate affinity are selected, while T cells binding to self-peptide–MHC complex with strong affinity or weak affinity are deleted (von Boehmer and Kisielow, 1990; Huang et al., 2004). Although effective, there is some leakiness as some T cells binding with weak

TABLE 27.1 Association of Various Autoimmune Diseases with HLA Class II Alleles and Haplotypes.

| Disease | Alleles | Haplotype |

affinity to the self-peptide–MHC complex escape the negative selection and circulate into the periphery. In most individuals these autoreactive T cells are kept in check through peripheral tolerance.

However, in some individuals these autoreactive T cells can be activated through an unknown mechanism and lead to the onset of autoimmune disease. Such a mechanism might explain the selection of a T cell repertoire that is protective or susceptible to autoreactivity. Elution of peptides from HLA class II molecules suggests that some of these peptides may indeed be derived from HLA molecules themselves (Chicz et al., 1994). Thus, HLA molecules not only function in the thymus by presenting other peptides but can also serve as a donor of self-peptides. This intricate relationship between MHC, self-peptides, and the T cell receptor (TCR) could determine the specificity of T cells in the periphery. Thus, the peripheral pool of T cells can recognize non-self-antigen to clear infection, recognize self-antigens to cause autoimmunity or can become tolerant/anergic. However, studies to resolve these issues in humans have been hampered by the lack of knowledge of “culprit” autoantigens as well as the difficulty in obtaining samples from affected organs. The other confounding problem has been the linkage disequilibrium of HLA class II alleles -DR and -DQ, making it difficult to interpret the association of a disease with a haplotype or specific allele. Despite this risk of autoimmunity in certain individuals, nature persisted with these HLA class II alleles due to the survival advantage associated with these genes. Thus, autoimmunity is a price we have to pay in order to control widespread infections and maintain the survival of the human population.

Onset

Among the individuals carrying the disease predisposing HLA allele/haplotype, only a small percentage develops autoimmune disease. This indicates that precipitation of disease requires a second hit in addition to genetic predisposition. Interestingly, besides genetic factors, most of the autoimmune diseases also show association with environmental factors. A number of environmental factors, both infectious as well as non-infectious, have been shown to play an important role in the onset of disease in genetically predisposed individuals (Klareskog et al., 2006). One mechanism could be molecular mimicry between infected agents and self molecules activating autoreactive T cells. Another mechanism by which pathogens can cause autoreactivity is when post-translational modification of proteins occurs to clear infections; it may inadvertently lead to the activation of self-reactive T cells.

ENVIRONMENTAL FACTORS

Infectious Agent

Among all the infectious agents associated with autoimmune diseases, such as rheumatoid arthritis (RA), multiple sclerosis (MS), and systemic lupus erythematosus (SLE), the strongest association had been reported with the presence of viruses, especially the Epstein–Barr virus (EBV) (Pender, 2003). The EBV is a ubiquitous virus found in populations all over the world. After the primary infection, the virus resides in memory B cells and secretes latent protein such as EBV nuclear antigen (EBNA). After an unknown period of latency, the virus reactivates and goes into a lytic phase infecting more cells. It has been hypothesized that EBV may cause autoimmunity by activation of autoreactive T cells either through molecular mimicry or bystander activation and the release of proinflammatory cytokines. There is strong evidence that EBV plays a central role in the etiology of autoimmune diseases including RA and MS (Alspaugh et al., 1981; Lunemann et al., 2008).

A pathophysiological link between EBV and RA was first described when 67% of patients with RA were shown to produce antibodies to EBNA (Alspaugh et al., 1981; Baboonian et al., 1989). Also, EBV-encoded protein gp110, a major replicative phase glycoprotein required for infection, shares sequence similarities with the QKRAA amino acid motif (the “shared epitope”) of HLA-DRB1*0401, suggesting molecular mimicry may be one way EBV could be involved in pathogenesis of RA. In addition, the presence of HLA-DR4 is associated with 10-fold high synovial EBV DNA loads compared to controls and low T cell response in RA patients. A clonal expansion of CD8⁺ EBV-specific T cells that are suggested to be dysfunctional has also been observed in RA patients. Patients with RA have higher numbers of circulating EBV-reactive B cells compared to controls (Tosato et al., 1984). Thus, a combination of impaired T cell response and presence of antibodies could lead to an immune complex disease.

The mechanism linking MS and EBV is not well understood but could involve a pathological role of antibodies to EBV antigens and activation of central nervous system (CNS) myelin-specific T cells by cross-recognition of EBV-specific T cells. Patients with MS have increased antibody reactivity against several EBNA domains, of which antibodies against EBNA-1 in HLA DRB1*1501 positive individuals were associated with a 24-fold increase in risk for MS (Sundstrom et al., 2009). Further, MS patients show a selective increase of CD4⁺ T cell response to the EBNA1, which also cross-reacted with myelin antigens (Lunemann et al., 2008). These reports indicate that EBNA1-specific antibodies and/or myelin cross-reactive CD4⁺ T cells in the presence of a

susceptible HLA-class II allele (HLA-DR β 1*1501) could potentially contribute to the development of MS. These reports suggest that molecular mimicry may be one way that EBV-derived protein could cause pathogenesis in autoimmune diseases.

PORPHYROMONAS GINGIVALIS AND RHEUMATOID ARTHRITIS

Porphyromonas gingivalis (*P. gingivalis*), a Gram-negative facultative anaerobe, is the major cause of an inflammatory condition of oral cavity called periodontitis (McGraw et al., 1999). Smoking has been shown to be the leading susceptibility factor for periodontitis (Klareskog et al., 2006; Lundberg et al., 2010). Further, an association between the presence of HLA-DR4 and periodontitis has been described indicating similarities with RA. *P. gingivalis* is present in more than 80% of RA patients. Recent epidemiology studies have shown an association between periodontal disease and RA (Farquharson et al., 2012). Antibodies to *P. gingivalis* are increased in RA patients and correlate with anti-citrullinated peptide antibodies (ACPAs). The potential role of *P. gingivalis* in RA pathogenesis has been suggested to be due to the presence of the bacterial peptidyl arginine deiminase (PAD) enzyme, even though there is no similarity with human PAD (Farquharson et al., 2012). These enzymes can deaminate an arginine residue to citrulline in antigens thus changing their binding affinity to HLA molecules. Further, more than 40% of RA patients are positive for antibodies to an immunodominant peptide, citrullinated alpha-enolase peptide 1, which bears sequence similarity and cross-reactivity with enolase from *P. gingivalis* (Lundberg et al., 2010). These studies suggest that molecular mimicry and immune response to a bacterial epitope may result in production of antibodies. Recent studies have shown that bacterial PAD enzyme can deaminate host fibrinogen peptides (Wegner et al., 2010), which may lead to the generation of new epitopes, so triggering an immune response in a genetically predisposed individual.

Smoking and Autoimmunity

Several retrospective and prospective studies have shown the association between cigarette smoking and susceptibility to a number of autoimmune diseases such as RA, MS, type 1 diabetes, thyroiditis, primary biliary cirrhosis, and Crohn's disease (Wingerchuk, 2012). This has led to the emergence of smoking as a risk factor linked to the onset and clinical development of these autoimmune diseases in genetically predisposed individuals. Although these studies show an association, there is no experimental proof of a direct link between smoking and autoimmune diseases, RA, and MS. Numerous studies have provided

evidence suggesting an association of smoking with development of RA. Smoking has been associated with extra-articular features of RA-like nodules and lung disease which is the third major reason for mortality in arthritis patients (Harel-Meir et al., 2007). An interaction between smoking and DRB1 alleles has been suggested to confer an increased risk of ACPA positive RA. An increase in the presence of citrulline-modified proteins observed in the lungs of smokers may be due to an increase in the PAD enzyme (Makrygiannakis et al., 2008). Although the mechanism of interaction between the RA susceptible class II alleles and environmental factors like smoking has not been elucidated, it is thought that RA onset may occur later in life (median age for RA onset is around 60 years) but the process of autoreactivity starts earlier. This is supported by the fact that autoantibodies in shared epitope positive individuals precede clinical disease, suggesting a role for smoking in triggering antibody production. A recent study using the multinational QUEST-RA database showed no significant differences in the clinical profile of RA patients who are smokers and non-smokers except for an increase in the presence of nodules in the smoker group (Naranjo et al., 2010). A study with a 3-year follow-up of patients with current smokers showed fewer swollen joints and no difference in radiologic damage, suggesting smoking may be contributing to disease by the production of autoantibodies (Harrison et al., 2001). Cigarette smoking is the most characterized environmental factor associated with pathogenesis of RA and suggests that the onset of RA may begin at a site other than joints.

Cigarette smoke can interact with other environmental factors such as EBV to increase the risk of MS, as smokers were twice as likely to have MS with high titers of anti-EBNA antibody compared to non-smokers (Simon et al., 2010). Smoking can increase risk of MS through a number of pathways such as (1) modulation of systemic immune response; (2) increasing the blood–brain barrier permeability; and (3) direct injury to CNS by neurotoxic chemicals present in smoke.

VITAMIN D IN AUTOIMMUNE DISEASES

Epidemiological studies have suggested that vitamin D deficiency is associated with a number of autoimmune diseases. Patients with autoimmune diseases such as RA, MS, T1D, as well as lupus have decreased serum levels of vitamin D3. In MS, there is both a strong north to south gradient as well as high altitude areas with low sunlight (decreased levels of vitamin D) that are associated with an increased disease incidence (Hogancamp et al., 1997; Kurtzke, 2005). African American patients are three times more likely to develop lupus as compared to Caucasian populations carrying a similar genotype. Together these studies point towards an important role of

vitamin D in predisposition to autoimmune diseases. Cells involved in immune response express vitamin D receptors. Since vitamin D shows a strong immunomodulatory effect, it is hypothesized that vitamin D suppresses autoimmune disease by inhibiting disease promoting proinflammatory response and maintaining immune tolerance (Wen and Baker, 2011). Induction of regulatory T cells and suppressor macrophages by vitamin D had been suggested to play an important role in maintaining homeostasis of the immune system.

Interaction between environmental and genetic factors in the etiology of autoimmune diseases can be explained by a “Causal Pie Model” (van der Mei et al., 2011), where MHC represents the major fixed slice, while other slices represent one or another individual component (genetic or environmental) and these can interact to cause disease. To develop an autoimmune disease such as MS or RA, a person must complete the pie, though different people or groups of people might have different slices in their pie. In RA patients an inverse relationship has been described between disease activity and levels of vitamin D metabolites (Patel et al., 2007). Further, an association between a polymorphism of the vitamin D receptor and onset of RA has been observed (Gomez-Vaquero et al., 2007). Vitamin D metabolites have been shown to inhibit the production of IL-17A and stimulate IL-4 production in early RA patients (Colin et al., 2010). Thus a deficiency of vitamin D may lead to proinflammatory conditions. Patients carrying susceptible genotypes may require one or more factors, such as smoking, infection, or deficiency in vitamin D, to precipitate RA.

Similarly, in a subset of MS patients carrying the HLA-DRB1*1501 allele, immune reactivity to EBV and smoking might complete the pie, leading to clinical disease. In other individuals vitamin D and smoking or EBV and vitamin D might complete the pie and cause precipitation of disease (Ascherio and Munger, 2007). EBV may cause MS through molecular mimicry as T/B cells against the EBV antigen have been shown to cross-react with myelin antigen, leading to a break in tolerance. Smoking can also increase immune reactivity to viruses like EBV, and T cells specific to EBV antigen can further activate myelin-specific T cells through molecular mimicry (Lunemann et al., 2008). These interactions might lead to MS-related immune dysregulation that involves activation of T cells, modulation of DC function, and blood–brain barrier permeability.

POST-TRANSLATIONAL MODIFICATIONS IN AUTOIMMUNITY

Post-translational modifications of proteins occur *in vivo* frequently. In most cases, this process enables the

clearance of infection and malignant cells. For example, modification of viral antigen could enable its binding to MHC molecules for activation of T cells. Similarly, malignant self-tissue could be modified to make them more antigenic. This process also occurs occasionally in normal proteins (Gyorgy et al., 2006; Greer and Shi, 2012). Unfortunately, post-translation modification of self antigen could activate autoreactive cells, for example post-translational modification of synovial or joint-related antigen could trigger an immune response which would activate autoreactive T cells in genetically predisposed individuals. There are many types of post-translational modifications (PTMs). Modifications that change an amino acid include phosphorylation, methylation, and glycosylation while enzymatic conversions include deimination and deamidation.

Deimination

The enzymatic process by which citrulline, a non-coded amino acid, is inserted in proteins is called deimination. PAD is the enzyme required for catalytic deimination of peptidyl arginine to citrulline, a process called citrullination, first described by Fearon (Fearon, 1939). Citrullination of proteins occurs under many conditions; however, an aberrant B cell response to citrullinated proteins is specific to RA. The presence of ACPAs has been shown to be specific to RA patients. RA is associated with the presence of DRB1*0401. Genome-wide association studies (GWAS) using genotyping for single nucleotide polymorphisms (SNPs) of RA patients have confirmed the association of DRB1 with RA (Wellcome Trust Case Control Consortium, 2007). Studies in some populations have shown association of RA with the PADI4 gene encoding for peptidyl arginine deiminase isotype 4 (Suzuki et al., 2003). The peptide binding region of *0401 has a positive charge, thus antigens with positive charged arginine cannot bind. Citrullination of arginine changes the charge to neutral, enabling the antigen to bind DRB1*0401 molecules for the generation of an immune response. This is supported by studies suggesting that ACPAs in RA sera strongly associate with the presence of DRB1-shared epitope alleles. In RA patients, the presence of ACPAs is used for clinical diagnosis in association with rheumatoid factor. Sera from RA patients have been shown to carry antibodies to citrullinated synovial proteins that include CII, fibrinogen, vimentin, and fibronectin. Citrullination of these proteins can potentially alter their antigenicity and function; and in genetically predisposed individuals this might lead to an autoreactive immune response.

Studies using DR4.IE transgenic mice have shown that citrullinated fibrinogen can induce arthritis although no significant difference was observed in T cell response

to citrullinated and native fibrinogen. In DR4⁺ RA patients, T cells reactive to citrullinated vimentin-derived peptides rather than native peptides have been described, suggesting a crucial role of citrullinated vimentin in RA pathogenesis. Thus post-translational conversion of peptidyl arginine to peptidyl citrulline by PAD enzymes appears to be an essential feature of many autoantigens in RA. Estrogen can increase production of the PAD enzymes required for citrullination of proteins (Senshu et al., 1989). A primary risk factor for the production of ACPAs in RA is the presence of the DRB1-shared epitope. Immunization with native CII-derived peptides that are non-responders in native form in DRB1*0401 mice followed by challenge *in vitro* with citrullinated peptide generated a higher response in female mice compared to males (Behrens et al., 2010). A higher antigen presentation has been shown by splenic cells and epithelial cells during proestrous when estrogen is high. One can speculate that the increased expression of the PAD enzyme during the estrous cycle could cause an increase in citrullination of peptides, not only in the uterus, but other tissues including synovial tissue. This could result in the citrullination of multiple synovial-specific autoantigens and their presentation by the DRB1*0401 molecule leading to activation of autoreactive CD4 T cells and autoimmunity. This could be one of the reasons for the higher incidence of autoimmune diseases in females.

Deamidation

Around 90% of proteins undergo some form of post-translational modifications, which increases the structural and functional diversity of the proteome. Post-translational modifications like deamidation have been shown to be associated with autoimmunity. Deamidation is a chemical reaction in which an amide functional group is removed from a protein leading to degradation of the protein because it damages the amide-containing side chains of the amino acids. Asparagine (Asn) and to a lesser extent glutamine (Gln) are prone to spontaneous deamidation changing them to aspartic/isoaspartic acid and glutamic acid, respectively. The rate at which Asn and Gln residues are deamidated is dependent on the neighboring residues in the peptide. The presence of glycine and serine as neighboring residues to Asn and Gln has a destabilizing effect, making them a target for deamidation.

In addition to spontaneous deamidation, enzymatic deamidation also occurs and requires transglutaminase (TG2). Transglutaminase is a calcium-dependent enzyme that is involved in deamidation of glutamine side chains. Enzymatic deamidation of glutamine converts it to glutamic acid. Tissue transglutaminase (tTg) is widely distributed and is ubiquitously present in the cytosol and the

extracellular space within many connective tissues and is involved in many functions. Deamidation by tTg is dependent on the presence of either a proline residue or a hydrophobic amino acid like the Phe C terminal of the target glutamine. In celiac disease patients, an immune response to a wheat-derived protein, gliadin, can generate an autoimmune response. Celiac disease is a good example of how modified proteins induce an immune response even though the initiating antigen may not involve a self-protein. T cells of patients with celiac disease recognize peptides of gliadin that are deamidated (Glu to Gln).

Celiac disease is associated with the presence of HLA-DQ2 in the majority of patients and the remaining patients are generally positive for DQ8. Deamidation of gliadin peptides changes the charge leading to better binding of peptides to DQ2 and DQ8 and generation of an immune response. Studies in celiac disease have shown that tissue transglutaminase enzymes can deamidate peptides of gliadin which are presented by DQ8 or DQ2 leading to gluten sensitivity.

HUMANIZED ANIMAL MODELS OF AUTOIMMUNITY

The advent of transgenic mice lacking endogenous class II molecules (A β 0) but expressing human HLA-DR and HLA-DQ genes has significantly advanced the understanding of the role of individual HLA class II molecules (Mangalam et al., 2008; Taneja and David, 2010). Introduction of HLA class II transgenes in A β 0 mice led to the expression of functional HLA class II molecules and reconstituted the CD4 T cell compartment, thus resulting in CD4 restricted immune response to various peptides. The HLA transgene in these mice is self and so they are tolerant to it. Experimental data from various laboratories have shown that the HLA class II molecules in these mice function in a way similar to that in humans. The first evidence came from *in vivo* and *in vitro* studies done with superantigens in HLA transgenic mice. Bacterial superantigens (SAg) have lower affinity for mouse MHC class II than for human MHC class II molecules. Because of this biological characteristic, SAg-induced toxicity is much lower in mouse models than it is in humans. When immunized with lower concentrations of SEB, HLA-DR3 transgenic mice respond vigorously, activate multiple T cells and secrete higher levels of proinflammatory cytokines than wild-type mice (DaSilva et al., 2002). The response to superantigens in transgenic mice can result in toxic shock and is dependent on the polymorphism of HLA class II alleles.

The second evidence comes from the peptide presentation by HLA class II molecules in transgenic mice. The HLA transgenic mice respond to similar epitopes as

observed in humans. In a comparison study, DR3.A β mice recognized only one epitope comprising aa 1–20 for heat shock protein (hsp) 65 of *Mycobacterium tuberculosis* as observed with human DR3-restricted T cells (Geluk et al., 1998). The response was specific in DR3 mice as DQ8 mice did not respond to this peptide. These studies suggest that processing and presentation of the antigens in the context of class II molecules is similar in transgenic mice and humans.

The third evidence that HLA transgenes in mice function similarly to humans comes from studies with experimental autoimmune myasthenia gravis (EAMG) in DR3 transgenic mice (Infante et al., 2003). The wild-type mice show a highly conserved TCR-BV gene usage and CDR3 sequences in response to acetylcholine receptor (AChR), an autoantigen for myasthenia gravis patients. However, DR3-restricted murine hybridomas generated from DR3 mice immunized with AChR expressed a diverse set of T cell receptor β chains, similar to that observed in humans. The TCRBV sequences from human MG patients were homologous to DR3-restricted murine clones, suggesting that human and mice can recognize similar epitopes and use similar CDR3 sequences for the recognition of the same peptide–MHC complex. Thus, transgenic mice can provide an important insight into peptide presentation by different class II alleles and the resulting pathogenesis.

Collagen-Induced Arthritis

Collagen-induced arthritis has been used as a model for inflammatory arthritis where immunization of susceptible strains of mice with type II collagen leads to the development of arthritis with features similar to those of human inflammatory arthritis. The first model of autoimmunity to determine the role of human class II molecules in arthritis was established by using DQA1*0301, DQB1*0302 (DQ8) transgenic mice. DQ8 occurs in linkage disequilibrium with DR4 and has been shown to be associated with RA in certain ethnic groups (Taneja et al., 1992). Collagen-induced arthritis, an animal model for RA, was studied *in vivo* in A β .DQ8 mice. Immunization of A β .DQ8 mice with heterologous type II collagen led to a pathogenic autoimmune CD4-mediated response leading to severe arthritis and antibodies to self-type II collagen (Nabozny et al., 1996). Both CD4 T cells and B cells are required for the development of arthritis in transgenic mice (Taneja et al., 2005, 2007b). This is the first model where arthritic mice produced rheumatoid factor (RF), one of the major features in patients with RA (Taneja et al., 2002). The scenario in the development of arthritis in transgenic mice can be compared to that of RA in human. Both require presentation of an arthritogenic epitope by HLA class II molecules to CD4 T cells, leading to proliferation of autoreactive cells and production of RF

by B cells, subsequently leading to joint pathology. Further, studies using CD4-deficient and CD8-deficient mice suggested that the disease was mediated by CD4⁺ T cells, while CD8⁺ T cells may be the regulatory cells as CD8-deficient mice transgenic for DQ8 develop high amounts of autoantibodies including RF and anti-nuclear antibodies (ANA) (Taneja et al., 2002). A similar phenomenon can be envisaged in RA where production of autoantibodies like RF and ANAs could be related to the functional status of CD8 T cells. On the other hand, mice expressing DQA1*0103, DQB1*0601 (DQ6) were resistant to developing CIA. The double transgenic mice expressing both DQ6 and DQ8 developed moderate CIA when compared with the severe arthritis observed in DQ8 transgenic mice (Bradley et al., 1998), much like RA patients bearing both susceptible and non-susceptible HLA haplotypes. These observations contributed to the concept that polymorphism in DQ may be a major contributing factor in human RA.

Predisposition to RA has been associated with the expression of some subtypes of HLA-DR4 in most human studies ever since the first association of DW4 and RA shown by Stastny (Stastny, 1978). However, most of the studies in different ethnic groups have observed only two alleles, DRB1*0401 and *0404, which occur with increased frequency in RA patients. Thus while DRB1*0401, 0404 are associated with predisposition, DRB1*0402 is associated with resistance or protection against RA. To determine the role of DR4 molecules in RA, DRB1*0401 mice were generated in complete MHC knockout mice (AE^{-/-}). DRB1*0401.AE^{-/-} mice develop arthritis which mimics human arthritis (Taneja et al., 2007a). AE^{-/-} mice have deletion of an 80 kb region of MHC class II such that none of the classical murine class II molecules are expressed. Human T cell is unique from mice in the expression of MHC class II molecules on their cell surface. Interestingly, similar to humans, T cells from AE^{-/-}.DR transgenic mice express HLA-DR molecules on their cell surface and can present peptide antigen. Thus presentation of an antigen in the context of HLA by an activated T cell might also contribute towards severity.

To simulate human haplotypes, double transgenic mice expressing autoimmune associated DQ and DR alleles were generated on the AE^{-/-} background. DR4\DQ8.AE^{-/-} mice developed arthritis similar to DQ8 but also showed gender differences. Gender differences in CIA were not observed in DQ8 mice suggesting modulation of DQ8-restricted disease by DR4 molecules. To understand the modulation by DR polymorphism, DRB1*0402 mice were studied (Taneja et al., 2008) for their influence on CIA. DRB1*0402 mice are not susceptible to arthritis, similar to humans. Mice expressing both susceptible and resistant DR4 subtypes, 0401/0402,

developed arthritis with lower incidence than *0401 mice (Taneja et al., 2003). Further, data in DR*0401/DQ8 mice suggested that APCs present DR-restricted peptides differentially, suggesting a role of hormones in influencing APCs (Behrens et al., 2010; Luckey et al., 2012). Based on the data in transgenic mice, it can be speculated that hormone-influenced PAD enzymes may lead to citrullination of antigens in females, thus enhancing presentation of certain antigens. The experimental and human data led us to hypothesize that DQ polymorphism may be responsible for susceptibility while DR may be involved in the modulation of disease. Thus both DQ and DR alleles as a haplotype influence the development of disease (Taneja et al., 1998). From the studies on DQ and DR transgenic mice, it can be extrapolated that gene complementation or interaction between DQ and DR molecules mediates susceptibility to RA in the human. Depending on the haplotypes carried by an individual, they could be susceptible to severe or mild disease. A homozygous haplotype for predisposing DQ and permissive DR will lead to severe disease. Also, heterozygous RA-susceptible haplotypes will result in very severe disease since there will be two predisposing DQ molecules. However, one predisposing and one protective haplotype should show less severity and low incidence.

Non-RA-Associated HLA Alleles Can Predispose to Autoimmunity

HLA-DQ6 alleles, DQB1*0601 and *0604, are not associated with susceptibility to develop arthritis. DQB1*0601 occurs in linkage with DQA1*0103 and DQB1*0604 with DQA1*0102. To understand if trans-heterodimers of two non-susceptible HLA alleles may have a role in rendering susceptibility to develop arthritis, we generated mice expressing DQB1*0601/DQA1*0103 (DQ6.1) and DQB1*0604/DQA1*0103 (DQ6.4). Immunization of transgenic mice leads to development of severe CIA in DQ6.4 but not DQ6.1 mice (Behrens et al., 2011). Further, data showed that DQ6.4 molecules could present CII-derived peptides similar to those presented by the CIA-susceptible DQ8 allele. These studies suggested that trans-heterodimer molecules between two DQB1 and DQA1 alleles may result in presentation of unique antigens and susceptibility to develop arthritis. Molecular modeling of the CII peptides showed that DQB1*0604/DQA1*0103 shares the p4 pocket with the arthritis-susceptible DQB1*0302 allele and further a critical role of p4 and p9 pockets is suggested with susceptibility to arthritis. This provides an explanation for the presence of non-susceptible alleles in some RA patients and a mechanism by which they can predispose to develop arthritis.

HLA-DR Transgenic Mice with EAE as an Animal Model of MS

MS, a chronic inflammatory disease of the CNS, shows strong linkage with the presence of HLA-DR2 haplotypes (DRB1*1501, DRB5*0101, DQA1*0102, and DQB1*0602) (Oksenberg et al., 1993). Besides DR2, MS has also been associated with HLA-DR3 and -DR4 haplotypes (Weinshenker et al., 1998; Coraddu et al., 2001). HLA DR3/DQ2 haplotypes have been shown to confer an increased risk for relapsing remitting MS in individuals (Weinshenker et al., 1998). The lack of a complete association to a particular HLA allele suggests that MS is a heterogeneous disease at the molecular level. MS is hypothesized to be mediated by autoreactive T cells against a variety of myelin antigens including myelin basic protein (MBP), proteolipid protein (PLP), and myelin oligodendrocytic glycoprotein (MOG).

Experimental autoimmune encephalomyelitis (EAE) has been used as an animal model of MS where immunization of susceptible strains of mice with autoantigens such as PLP, MBP, or MOG can lead to the development of inflammation and demyelination in the CNS, similar to MS pathology observed in patients (Mangalam et al., 2004; Rich et al., 2004). Induction of EAE with recombinant myelin oligodendrocyte glycoprotein (rMOG) in DR2 mice (DRB1*1501, DRB1*1502, and DRB1*1503) showed that all three strains developed EAE; however, the disease incidence and severity was higher in DRB1*1501 transgenic mice. Almost all of the T cell epitopes identified in HLA transgenic mice using overlapping epitopes of MBP, PLP, and MOG are similar to those identified among T cells isolated from peripheral blood mononuclear cells of MS patients (Kawamura et al., 2000; Khare et al., 2003). Administration of PLP91-110 peptide induced EAE in DR3 transgenic mice (Mangalam et al., 2009). Recently we have also observed that PLP178-197 peptide can induce EAE in HLA-DR4 (DRB1*0401) transgenic mice, while HLA-DR4 (DRB1*0402) transgenic mice were resistant to disease. The disease in transgenic mice was characterized by paralysis of limbs with mild demyelination while in humans demyelination is the major feature of MS. CD4⁺ T cells have been shown to infiltrate the CNS and are responsible for inflammation and demyelination in MS. It is speculated that class II molecules on T cells may present myelin antigen in CNS and exacerbate the disease. To replicate the human disease, DR3.AEo mice were utilized for EAE with PLP peptide (Mangalam et al., 2006). The DR3.AEo transgenic mice with EAE showed severe inflammation and demyelination in the meningeal, stratum, and brain stem regions, a hallmark for human MS. HLA class II expression was detected in the CNS, especially on microglial cells. These experiments suggest that

humanized HLA class II transgenic mice simulate human MS and are a good model to study the role of class II molecules in its pathogenesis.

Role of DQ Molecules in Predisposition to MS

To simulate the human haplotype, we generated double transgenic mice expressing HLA-DR2 and DQ8 (DR2/DQ8). When immunized with rMOG, 90% of mice developed disease accompanied with severe inflammatory and demyelinating lesions in the CNS as compared to DR2 single transgenic mice (Khare et al., 2005). Similarly, expression of DQ8 on disease-susceptible DR3 background (DR3/DQ8 double transgenic mice) led to the development of severe EAE upon immunization with PLP91-110 peptide (Mangalam et al., 2009). The disease in DR3/DQ8 double transgenic mice was characterized by earlier disease onset, higher clinical score, and increased inflammation and demyelination in CNS compared to single DR3 transgenic mice. Since HLA-DQ8 mice were resistant to EAE, our data suggested that DQ8 allele synergizes with disease susceptible HLA-DR allele(s) for a more severe disease phenotype suggesting its pathogenic role in disease etiology. We further determined that the increased susceptibility in DQ8/DR3 mice was due to an increased production of the proinflammatory cytokines IL-17 and GM-CSF. Higher IL-17 levels might lead to the activation and recruitment of more inflammatory cells inside the CNS, while GM-CSF has been shown to increase antigen presentation both in the periphery as well as the CNS.

In contrast HLA-DQB1*0601, observed frequently in Japanese and Asian populations, is known to be protective in MS (Amirzargar et al., 1998; Marrosu et al., 2001). DQB1*0601 transgenic mice were resistant to EAE on immunization with MOG, MBP, or PLP antigens. Expression of the HLA-DQB1*0601 allele in disease susceptible HLA-DR2 or -DR3 transgenic mice led to a decrease in disease incidence and severity suggesting a protective role of the allele in disease pathogenesis. Immunization of DR2/DQB1*0601 mice with rMOG led to lower disease incidence compared to DR2 single transgenic mice. Similar findings were also observed in DR3/DQ6 mice immunized with whole myelin or human PLP91-110 (Das et al., 2000). We have further characterized that the protective effect of the DQ6 molecule is due to high levels of IFN γ produced by DQ6-restricted T cells, which suppressed proliferation of encephalitogenic DR3-restricted T cells by inducing apoptosis. Our study suggests that DQ6 modifies the PLP91-110-specific T cell response in DR3 through anti-inflammatory effects of IFN γ .

From the EAE data generated using whole myelin (CNS extract), rMOG and PLP91-110, we have observed

that the presence of (1) the HLA-DR molecule is required for the development of disease; (2) HLA-DQ6 or DQ8 molecules alone are not sufficient for disease induction; (3) HLA-DQ8 on disease susceptible HLA-DR2 or HLA-DR3 transgenic mice increased the severity and incidence of disease; (4) DQ6 (DQB1*0601) molecules suppress disease incidence and severity on disease-susceptible HLA-DR2 or HLA-DR3 transgenic mice; (5) DQ6 or DQ8 on a disease-resistant background had no effect on disease induction as none of the HLA-DR2/DQ6, DR2/DQ8, or DR4/DQ8 double transgenic mice developed EAE on immunization with PLP91-110 peptide. These data would suggest that while the presence of certain DR gene(s) predisposes an individual to MS, polymorphism in DQ gene(s) might play a modulating role. This study also points out that MS is a heterogeneous disease and HLA association is specific for the various autoantigens involved.

Animal Model of Celiac Disease

We have used transgenic mice that express HLA-DQ8 to evaluate the response to gliadin (done in collaboration with Drs. Joseph Murray and Eric Marietta (Marietta et al., 2011)). Immunization of DQ8 mice with gluten led to a strong T cell response and IgG antibodies against gluten, but no enteropathy was observed. In order to introduce an autoimmune component to our mouse model of celiac disease, we back-crossed DQ8 transgenic mice to a non-obese diabetic (NOD) genetic background that was deficient in endogenous murine MHC II. This resulted in transgenic NOD mice that expressed human DQ8. With parenteral sensitization to gluten, these mice developed blistering upon the ears, reminiscent of dermatitis herpetiformis (DH), the skin manifestation that is found in 3–5% of patients with celiac disease (Marietta et al., 2004). This model had all the elements of DH, including IgA deposits at the dermal epidermal junction, infiltration of neutrophils into the dermis of the lesional tissue and, most importantly, resolution of the disease with a gluten-free diet and/or dapsone treatment. However, unlike the majority of DH patients, these mice did not develop enteropathy with gluten sensitization.

Using DQ8 mice, it was shown that T cell hybridomas generated to native peptides mounted a heteroclitic response against the deamidated peptide, suggesting a role of the class II molecule in amplifying the T cell response against dietary gluten. Thus an aberrant innate immune response to gliadin could activate tTg that would result in deamidated forms of gliadin-derived peptides. This could result in an enhanced T cell response to gliadin, causing damage and enteropathy. This heteroclitic response would also explain why most adult celiac patients have a strong T cell response against the deamidated forms of the specific gliadin-derived peptide.

Transgenic mice that express both HLA-DQ2 and DR3 (de [Kauwe et al., 2009](#); [Du Pre et al., 2011](#)), sensitization to gliadin resulted in a strong T cell response to gliadin, but no overt enteropathy. One group went further and generated a DQ2/DR3 mouse that expressed a gliadin-specific TCR that had been identified in the gliadin-sensitization studies (de [Kauwe et al., 2009](#)). These mice responded to deamidated gliadin peptide and generated the Th1 response present in CD patients but did not develop enteropathy, suggesting a second insult to mucosa may be required for development of enteropathy in humans. Absence of pathology in the presence of antigen-specific CD4 T cells may suggest other systemic factors may be involved in disease pathogenesis.

Animal Model for Type 1 Diabetes

Type 1 diabetes shows familial clustering and is linked to the presence of HLA-DQ8/DR4 and HLA-DQ2/DR3 haplotypes. Within the HLA-DQ8/DR4 haplotype, HLA-DQ8 is believed to be the predisposing class II molecule. Most knowledge about autoimmune diabetes comes from a special strain of NOD mice which develop spontaneous diabetes. Elegant genetic studies performed in these mice have mapped the development of disease to the presence of MHC class II molecule H2-A^{g7}. Interestingly, the H2-A^{g7} molecule shows strong structural and functional homology with the human HLA-DQ8 molecule, thus strengthening the major pathogenic role of DQ8 in human T1D. Although HLA-DQ8 transgenic mice do not develop spontaneous diabetes, they lost tolerance to self-GAD65 antigen, leading to activation of autoreactive T cells in the periphery and pancreas. These transgenic mice show insulinitis but do not progress to diabetes. As with DQ8 transgenic mice, the presence of a T1D predisposing MHC allele in certain individuals could result in the escape of autoreactive T cells against pancreatic antigens. However, the onset of disease might require a second hit in the pancreas. This second hit can come in the form of virus/bacterial infection, and/or overproduction of a cytokine, overexpression of an accessory molecule or other genetically-determined variations completing the causal pie and precipitation of disease in these individuals. To simulate such an insult in the pancreas, we generated HLA-DQ8 (disease-susceptible) and HLA-DQ6 (disease-resistant) transgenic mice expressing the costimulatory molecule CD80 (B7.1) in islet β cells under the rat insulin promoter (RIP) ([Wen et al., 2000](#)). HLA-DQ8/RIP/B7.1 mice developed spontaneous diabetes, while no disease was seen in DQ6/RIP/B7.1 transgenic mice. These studies further confirmed that while the HLA class II allele is the major predisposing gene for development of most if not all autoimmune diseases, other insults or signals are required for precipitation of the disease.

Further studies using double transgenic mice expressing DQ8 with HLA-DR3 or HLA-DR4 indicated that the HLA-DR molecule can modulate the diabetogenic effect of DQ8 ([Rajagopalan et al., 2003](#)), which in turn suggests that interaction between various MHC class II molecules in cis as well as trans plays an important role in predisposition, onset, as well as progression of the disease.

HLA CLASS II MOLECULES REGULATE INFECTION THROUGH MODULATION OF CYTOKINE NETWORKS

The MHC has evolved over millions of years to fight infection. Mediators such as cytokines and chemokines produced following antigen presentation play an important role in the clearance of pathogens. The association of a particular HLA class II haplotype with disease seems to depend on geographical locations as well as the ethnic composition of the populations. Evolutionarily DQ is a stable molecule with less polymorphism than observed in the DRB1 locus. The DQ8 molecule has not undergone many changes during evolution and occurs with only three known subtypes. This could be because DQ8 has the advantage of being able to bind and present multiple peptides. On the other hand, DR has many subtypes. For example, DRB1*04 has at least 50 subtypes; however, not all the subtypes are associated with susceptibility to autoimmune diseases. We speculate that DR4 polymorphism occurred to counteract the predisposition to autoimmunity imposed by the DQ8 molecule. Thus, multiple subtypes of DR4 lead to many possible DR4\DQ8 haplotypes. Only those with an advantage of presenting microbial antigens, clearing infections, and with the capacity to counter the autoimmune responses may eventually be selected. Therefore it is possible that HLA molecules were selected based on their ability to induce subsets of T cells for production of a particular cytokine that is responsible for controlling one set of microorganisms. Interferon gamma (IFN γ) is one of the signature cytokines of Th1 type of T cells and controls intracellular pathogens. At the same time interleukin (IL)-17, a signature cytokine of Th17 T cells, controls extracellular pathogens. Thus, one set of class II genes might have evolved to produce IL-17 for controlling the spread of extracellular pathogen, while others produce Th1/Th2 to control other pathogens. Using our transgenic mice we have observed that while transgenic mice expressing HLA-DQ8 induce more TH17 type of T cells, HLA-DQ6 transgenic mice induce more IFN γ producing CD4 T cells. This results in cytokine milieu that modulates disease. A scenario where interaction between HLA molecules and environmental factors leads to the onset of an autoimmune response and disease can be envisaged ([Figure 27.1](#)).

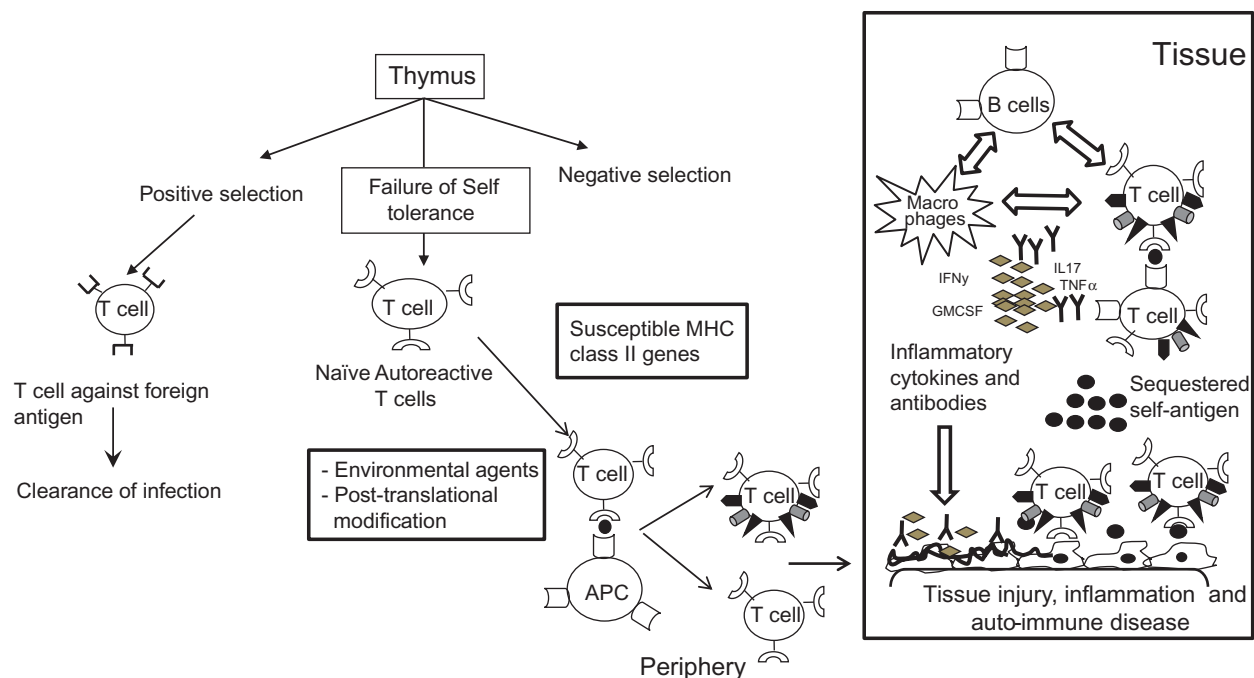

FIGURE 27.1 HLA molecules select T cell repertoire in the thymus by presenting peptides and also serving as donors of self-peptides. T cells are selected on the basis of their interaction with self-MHC molecules expressed in thymus. Thus, T cells reactive with self-peptide binding with high affinity to MHC are negatively selected in the thymus while those with weak interactions may escape negative selection. Such a mechanism may explain the selection of an autoreactive T cell repertoire. In the periphery, positively selected T cells can recognize non-self antigens and clear infection. The autoreactive T cells that have escaped can recognize viral peptide that mimic self antigen, or cryptic epitopes that are exposed during infection or post-translational modification causing activation of autoreactive T cells. These T cells can migrate to various organs, and depending on the host genotype and its interaction with the non-genetic factors, they can cause inflammation locally. The response can be exacerbated in the presence of self-peptides, that when presented by antigen presenting cells in the tissue leading to production of proinflammatory cytokines ensuing an autoimmune response.

CONCLUDING REMARKS

From various *in vivo* and *in vitro* studies, it has become clear that MHC and non-MHC genetic components are common elements for various autoimmune diseases, and in corresponding animal models. Thus polymorphism in MHC is an advantage for human survival, but autoimmunity is the price that the population must pay for combating infection effectively and for survival. In evolutionary terms, only those HLA genes which can generate strong immune responses to infections are selected. The constant mutations observed might be leading to the generation of new subtypes of an allele to circumvent autoimmunity. Haplotypes and not a single class II allele function in the selection of the T cell repertoire and susceptibility to disease.

| Rheumatoid Arthritis | 389 | References | 396 |

Alterations in genome architecture are associated with human diseases. In autoimmune diseases, however, although strong genetic bases have been found in genome-wide association studies, no unique genetic mechanism underlying immune tolerance breakdown was identified, and the significant genetic associations described are present only in a relatively small proportion of patients. As seen in other complex disorders, linkage studies and genome-wide profiling arrays have contributed to the identification of multiple genes that may exert a combinatorial effect in predisposing individuals to

develop the disease (Nylander and Hafler, 2012). The largely incomplete concordance rates of autoimmune diseases in monozygotic twins strongly support other complementary mechanisms involved in gene regulation ultimately causing overt autoimmunity (Zouali, 2009). It is therefore becoming increasingly evident that gene expression based on DNA sequence alterations or mutations is not sufficient to explain the variety of manifestations observed in disease states (Feil and Fraga, 2012), and that epigenetic deregulation contributes to the severity of these diseases.

EPIGENETIC MODIFICATIONS

Epigenetics can be defined by the heritable changes that occur in gene expression caused by mechanisms other than alterations in the underlying DNA sequence. These modifications are based on a set of molecular processes that can activate, reduce, or completely disable the activity of particular genes or entire genomic regions: methylation of cytosine residues in the DNA, remodeling of chromatin structure through covalent modification of histone proteins, and recruitment of chromatin-associated small RNA molecules that provide the sequence specificity to target transcriptional silencing. The combination of these different modifications, commonly referred to as the “epigenetic code,” adds a layer of complexity to the information present in the genetic code.

Several observations indicate that environmental changes can produce modifications in gene expression, suggesting that epigenetics can have a potential role in environmental/genetic interactions. First, when the diet *agouti* pregnant rodents were supplemented with foods rich in methyl donors, the offspring exhibited coat color changes, compared to mothers fed with a standard diet (Wolff et al., 1998). This observation was explained by an altered DNA methylation process that silenced the intracisternal A particle (IAP) retroviral insertional element, ultimately limiting the appearance of *agouti* alleles. A second remarkable example comes from Dutch individuals who were exposed to famine during intra-uterine life and childhood during the Second World War. Compared to non-exposed subjects, they had a well-conserved hypomethylation status of a region regulating the insulin-like growth factor 2 (IGF2) (Heijmans et al., 2008), providing an example of epigenetic imprinting.

DNA Methylation

In mammals, approximately 60% of CpG dinucleotides are methylated, and DNA methyltransferases (DNMTs) control DNA methylation of CpG residues and maintenance of methylation during cell differentiation (Bird, 2011). As a regulator of transcription, DNA methylation generally occurs on cytosines in cytosine–guanine (CG) dinucleotides located within the promoter, most often between 1 kb and 0.8 kb upstream of the transcription start site (Figure 28.1). It consists of the addition of a methyl group to the fifth carbon of cytosine residues, converting them to 5-methylcytosines, a reaction that involves DNMT1, DNMT3a, and DNMT3b, and a methyl group donor (S-adenosylmethionine). DNA methylation can be divided into two types: *de novo* introduction of methyl group by DNMT3a and DNMT3b; and maintenance methylation associated with the replication machinery of dividing cells and involving DNMT1. However, it

FIGURE 28.1 DNA Methylation. Methylation of DNA at 5-position of cytosine by DNA methyltransferases (DNMTs) that control DNA methylation of CpG residues and maintenance of methylation during cell differentiation.

has been reported that, in some CpG dense regions, DNMT1 is not sufficient to maintain the levels of methylated CpG during replication, and in such somatic cells, DNMT3a and DNMT3b play important roles in maintaining methylation. Altered CpG island methylation may change chromatin structure, modulating promoter–transcription factor interactions within the transcription machinery. Although DNA methylation was initially thought to be a stable modification with only passive removal of methyl groups possible, accumulating evidence suggests that DNA demethylation occurs actively, and appears to be key in a variety of cellular responses to environmental stimuli including hypoxia, hormonal signaling, and viral latency and reactivation. Furthermore, aberrant hypo- and hypermethylation may occur in specific genes within the same cell, as is the case in some neoplastic cells. Methylated CpG recruits transcriptional repressors, such as the methyl-binding proteins MBD and MeCP, and histone deacetylases (HDACs), which introduce positive charges in the histone tail, allowing tight binding to negatively charged nucleic acids and leading to the formation of closely compact nucleosomes that prevent transcription.

Histone Post-Translational Modifications

A variety of histone post-translational modifications (PTMs) that affect chromatin structure have been described, including acetylation, methylation, phosphorylation, ubiquitination, sumoylation, and adenosine diphosphate (ADP) ribosylation. They can be dynamically added or removed by a plethora of specific enzymes that can work to add or remove functional groups which are, in turn, recognized by nuclear factors. Together with the diverse nucleosome composition, these modifications can cause a change in the net charge of nucleosomes, and alter DNA–histone interactions, and affect chromatin structure. Additionally, individual histone PTMs, or specific combinations of them that form the “histone code,” can provide signals to other proteins able to influence chromatin structure, thereby regulating gene expression by the formation of transcriptionally active or repressed states (Li et al., 2007a; Berger, 2007).

Histones are highly conserved proteins that reside within nuclei of eukaryotic cells. They can be categorized into two main groups: core histones (H2A, H2B, H3, and H4), and linker histones (H1, H5). Two of each of the core histones assemble to form an octameric nucleosome core particle by wrapping approximately 147 base pairs of DNA around the protein spool in a 1.7 left-handed super-helical turn (Luger et al., 1997), thus providing DNA condensation and organization in the nucleus, and modulating DNA accessibility to the transcription machinery.

Specific amino acids of histone tails are targets for several PTM, including acetylation, phosphorylation, poly-ADP ribosylation, ubiquitination, and methylation. Likewise, each histone subtype can be modified by different chemical modifications at defined amino acids, leading to transcription modulation and, therefore, cell cycle regulation, development, and differentiation. Acetylation of histones in the nucleosome increases their net negative charge, thereby interrupting their interaction with DNA and leading to open chromatin with negatively charged DNA—a structure permissive for recruitment of transcriptional machinery to initiate gene transcription and expression.

Acetylation and Deacetylation

These processes are among the most important gene expression regulatory mechanisms (Strahl and Allis, 2000). They involve the conserved ϵ -amino group of lysine residues at the amino terminus of nucleosomal histones (Figure 28.2). Histone acetyltransferases (HATs) decrease the overall positive charge of histones, thereby decreasing their affinity for negatively charged DNA, and

providing a platform for the binding of transcription factors to the chromatin template. Thus, transfer of acetyl groups to lysine by HATs promotes gene expression. By contrast, removal of acetyl groups by HDACs is generally associated with gene repression (Thiagalingam et al., 2003).

According to size, subcellular expression, number of enzymatic domains, and structure, HDACs are divided into four classes. Class I HDACs (HDACs 1, 2, 3, and 8) are detected in the nucleus and ubiquitously expressed in different tissues and cell lines. Class II HDACs (HDACs 4, 5, 6, 7, 9, and 10) shuttle between the nucleus and cytoplasm, and are expressed in a tissue-specific manner. For example, human HDAC4 is more abundant in skeletal muscle, brain, heart, and ovary, but not detectable in liver, lung, spleen, and placenta. HDAC5 is expressed in mouse skeletal muscle, liver, and brain, but not in spleen (Brandl et al., 2009). Class III HDACs are structurally unrelated to class I and class II HDACs, but use a unique enzymatic mechanism of action that requires the cofactor NAD^+ for their activity. Finally, HDAC1 is the only member of class IV HDACs, and its classification is still under debate.

Histone Methylation

Another mechanism involves histone methylation and its effects depend on the position of the modified lysine residue within the histone tail and on the number of methyl groups added to such residues. For example, the presence of three methyl groups on lysine 4 of histone H3 (Me-H3K4) has been associated with transcriptional activation whereas the triple methylation of residues 9 or 27 determines repression (Kouzarides, 2007).

Arginine Methylation

Arginine can also be methylated/demethylated by specific enzymes (Chen et al., 1999). Methylation of arginine residue 3 on histone H4 (H4R3) and arginine 17 on histone H3 (H3R17) has been shown to induce gene activation. Remarkably, occupancy of coactivator-associated arginine methyltransferase-1 (CARM1), known to enhance transcriptional activation by nuclear receptors, together with histone H3-R17 methylation, and citrullination are regulated at the promoters of inflammatory genes in monocytes, thereby suggesting a novel role for histone arginine modifications in inflammatory diseases (Miao et al., 2006). Therefore, similar to histone lysine methylation, interest in histone arginine methylation is increasing. Based on current knowledge, the histone modification status of H3-R17 in cells can exist in at least three modes: arginine, methylated arginine, and citrullinated arginine. The biological meaning of the three modes or the “H3-R17 code” is slowly emerging, but needs more

FIGURE 28.2 Acetylation and Deacetylation of Lysine Residues in Histone Molecules. Histone acetylation is catalyzed by histone acetyltransferases (HATs). In general, histone acetylation is linked to transcriptional activation and associated with euchromatin. Histone deacetylases (HDACs) introduce positive charges in the histone tail, which bind tightly to negatively charged nucleic acids and lead to the formation of closely compact nucleosomes that prevent transcription.

investigation. It seems that H3-R17 methylation is associated with gene activation and that H3 arginine citrullination might be associated with repression of nuclear receptor and NF- κ B-regulated genes. This could suggest additional connections between arginine epigenetic markers and human diseases.

Ubiquitination

Ubiquitin is a 76 amino acid protein involved in specific protein labeling. Ubiquitinated proteins are committed to proteosomal degradation and, thus, ubiquitination controls the stability and intracellular localization of numerous proteins. Ultimately, it influences the status of histone methylation or acetylation and modulates gene expression, as in the case of the NF- κ B pathway.

MicroRNAs

Only recently has it been discovered that microRNA (miRNA) can regulate gene expression via messenger RNA (mRNA) degradation and translational repression (Bartel, 2004). miRNAs are a group of post-transcriptional regulators involved in many biological processes, including development, differentiation, proliferation, and apoptosis (Filipowicz et al., 2008). They are approximately 22-nt-long, non-coding RNAs that suppress translation by binding to complementary target mRNA species, causing the degradation of the target. miRNAs are genome-encoded and transcribed by RNA polymerase II, similar to ordinary protein-coding RNAs; and it is estimated that miRNA target <30% of the human transcriptome (Lewis et al., 2005). The role of miRNA in immunity is also beginning to be explored. For example, miR-146 was identified as a key player in innate immunity (Taganov et al., 2006), and miR-181a was found to modulate adaptive immunity, particularly T cell sensitivity and selection (Li et al., 2007c). Therefore, miRNAs are being investigated in autoimmune and chronic inflammatory conditions.

Epigenetic Stability

Maintenance of epigenetic marks during cellular division is important to maintain cell lineage commitment in progeny cells, and to shape a memory of transcriptional status. Several of the mechanisms discussed above are required for the transmission of epigenetic information through multiple cell divisions. These mechanisms also mediate the inheritance of epimutations (alterations to epigenetic marks that can be transmitted from parents to offspring via their germline), which can lead to changes in chromatin structure and transcription levels of genes in disease

conditions, such as cancer, imprinting disorders, and, potentially, autoimmune diseases.

Thus, even though DNA methylation shows dynamic changes during developmental stages, DNA methylation marks have been initially suggested to be relatively stable over time in adult individuals (Dolinoy et al., 2007). However, human and experimental studies revealed that DNA methylation can exhibit various temporal behaviors, ranging from a nearly absolute stability of the DNA sequence to the rapid variations typical of mRNA levels (Hoyo et al., 2009). Consistently, a recent study showed that DNA methylation markers in human blood DNA exhibit different degrees of short-term variability (Byun et al., 2012). Whether such variations can be extended to other cell types remains to be determined.

EPIGENETICS OF IMMUNE TOLERANCE TO SELF

In the B cell compartment, immune tolerance operates through several mechanisms (Zouali, 2007). Their epigenetic regulation has been discussed recently (see Zouali, 2013).

For T cells, central tolerance takes place in the thymus through negative selection, where developing thymocytes are deleted if they react too strongly to self-antigens presented by the major histocompatibility complex (MHC). However, since not all peripheral self-antigens are adequately presented in the thymus, central tolerance is incomplete, and self-reactive T cells escape negative selection and migrate to secondary lymphoid organs. In the periphery, autoreactive lymphocytes must be inactivated by deletion or by suppression by regulatory T cells (Tregs), and/or by cell-intrinsic programs that lead to a state of functional unresponsiveness, called anergy. Understanding the regulatory mechanisms that maintain or break T cell tolerance to self-antigens is required to prevent autoimmunity.

Epigenetic Regulators of Tolerant T Cells

Studies of histone acetylation *in vitro* and *ex vivo* suggested that immune tolerance is under epigenetic influences. A variety of HDAC inhibitors (HDACi), such as sodium butyrate or trichostatin A (TSA) and suberyolanilide hydroxamic acid (SAHA), induce anergy in Th1 cell cultures (Edens et al., 2006), as characterized by an inhibition of proliferation accompanied by a reduction of IL-2 production. The effect was attributed to chromatin remodeling at the IL-2 promoter, as well as to acetylation of transcription factors, such as NF- κ B (Matsuoka et al., 2007).

To identify genes and pathways critical for maintenance of unresponsiveness, an *in vivo* mouse model was

recently used to perform a microarray analysis of naïve (N), memory (M), and tolerant (T) T cells (Schietinger et al., 2012). The study revealed that T cells harbor a tolerance-specific gene signature markedly distinct from that of N and M cells, and 164 genes were identified as “tolerance-specific” gene sets representing uniquely over-expressed genes, including negative regulators of cell signaling and proliferation, transcription factors, and phosphatases. Genes modulating cell cycle, cell division, nucleosome assembly, mitosis, and DNA replication were also highly overrepresented and upregulated in T cells. Thus, T cells “remember” the tolerance program established during the initial encounter(s) with self-antigen in the periphery, raising the question of how such memory is encoded. The fact that transcripts of numerous genes regulating chromatin modification were enriched in T cells (e.g., *Jmjd3*, *Dnmt1*, *Hat1*, *Hdac2*, *Hdac3*, etc.) supports the view that epigenetic factors are involved. Consistently, genome-wide miRNA profiling revealed that N, M, and T had distinct miRNA expression patterns (Schietinger et al., 2012). Thus, these insights into the regulatory mechanisms that maintain or break self-tolerance may lead to new strategies for the treatment of autoimmunity.

Role of CpG DNA Methylation in Treg Development and Function

Foxp3 is a member of the forkhead/winged-helix family of transcription factors that acts as a “master” regulator for the development and suppressive function of Tregs. Its constitutive expression is necessary for the suppressive function of Tregs, and mutation or deficiency of *Foxp3* leads to development of autoimmune diseases. Genetic defects in *Foxp3* cause the *scurfy* phenotype in mice and IPEX syndrome (immune dysfunction, polyendocrinopathy, enteropathy, X-linked syndrome) in humans (Khattry et al., 2003). In the thymus, a subset of CD4⁺CD25⁺ T cells develops into Foxp3⁺CD4⁺ T cells, known as natural Tregs (nTregs). However, in peripheral lymphoid organs, TGF-β can induce naïve CD4⁺CD25⁻ T cells to develop into Foxp3⁺CD4⁺ T cells, known as adaptive or induced Tregs (iTregs). *In vitro* culture of peripheral naïve CD4⁺CD25⁻ T cells in the presence of TGF-β induces expression of Foxp3 and provides a method to generate Foxp3⁺ Tregs *ex vivo*. Importantly, nTregs and iTregs exhibit different functional characteristics (Tran et al., 2007), and nTregs are more stable than iTregs, a feature that may be related to the epigenetic regulation of Foxp3 (Polansky et al., 2008; Lal et al., 2009).

Early studies showed that differentiation of T helper cells is under epigenetic regulation through CpG methylation (Lee et al., 2001; Wilson et al., 2009). As regards

Tregs, different regulatory *cis*-elements are present in the *Foxp3* locus, upstream of the transcriptional start site (−600 to −1 bp) at the proximal promoter where the methylation status of the CpG residues plays an essential role in Foxp3 expression. Thus, 10–45% of the CpG sites in the *Foxp3* proximal promoter (−250 to +1) are methylated in naïve CD4⁺CD25⁻ T cells, whereas all are demethylated in nTregs (Kim and Leonard, 2007), and TGF-β induces demethylation of CpG at this site in CD4⁺CD25⁻ T cells. That methylation of the proximal promoter is an important regulator of Foxp3 expression is also supported by the observation that this region is ≈70% methylated in human CD4⁺CD25^{lo} cells compared with ≈5% in CD4⁺CD25^{hi} T cells (Janson et al., 2008). Further support comes from the fact that CpG residues in an intronic region (+4201 to +4500) are completely methylated in naïve CD4⁺CD25⁻ T cells and fully demethylated in mouse (Kim and Leonard, 2007; Polansky et al., 2008) and human nTregs (Baron et al., 2007). Also, an upstream enhancer (−5786 to −5558 bp) is methylated in naïve CD4⁺CD25⁻ T cells, activated CD4⁺ T cells, and iFoxp3⁺ Tregs, but is demethylated in nTregs (Lal et al., 2009). Together, these reports demonstrate that Foxp3 is regulated by complex mechanisms where many extracellular signals control transacting factors as well as chromatin remodeling through covalent modification of CpG DNA. Understanding these signals and their cumulative intracellular effect on Foxp3 *cis*-elements at different T cell developmental stages will be key for therapeutic manipulation of T cell responses.

Impacts of Histone Acetylation on Development and Function of Tregs

In addition to DNA methylation, Treg development and function are under influences of histone acetylation. For example, following T cell receptor (TCR) stimulation of murine T cells, class II HDACs are mainly expressed in Tregs (Tao et al., 2007b). On the other hand, HDACi enhance Foxp3 expression in both CD4⁺CD25⁻ and CD4⁺CD25⁺ T cells, suggesting that deacetylation directly regulates Foxp3 expression, and enhances Treg suppressive functions (Tao et al., 2007a,b; Lucas et al., 2009). Another class II histone deacetylase, HDAC9, interacts with Foxp3 and downregulates its acetylation. Treatment with the class I and II HDAC inhibitor TSA enhances Foxp3 acetylation and Treg function (Li et al., 2007b). In mice, administration of pan-HDACi increased *Foxp3* gene expression, as well as the production and suppressive function of Tregs *in vitro*. Additionally, HDAC9 proved particularly important in regulating Foxp3-dependent suppression, as demonstrated by *in vivo* data in

HDAC9 knockout mice (Tao et al., 2007a). At the molecular level, optimal functions of Treg cells required acetylation of several lysines in the forkhead domain of Foxp3 (Wang et al., 2009).

Epigenetic Modulation of Treg Stability

Several observations indicate that Foxp3⁺CD4⁺ Tregs encompass a heterogeneous population in mice (Komatsu et al., 2009) and humans (Miyara et al., 2009), and that their phenotype and functions are not as stable as initially thought (Zhou et al., 2009a; Lee et al., 2009). For example, a fraction of Foxp3⁺CD4⁺ nTregs adoptively transferred to lymphopenic mice converted into Foxp3⁻ T cells (Komatsu et al., 2009). Under inflammatory conditions, Foxp3⁺ Tregs lose Foxp3 expression and suppressive functions in an interleukin (IL)-6-dependent manner (Pasare and Medzhitov, 2003). The fact that different subsets of Tregs exhibit different levels of CpG DNA methylation at the Foxp3 locus suggests that Treg instability may be under epigenetic controls (Miyara et al., 2009). Thus, increased methylation of CpG at the *Foxp3* locus was linked with a lower Foxp3 expression, decreased Treg stability, and reduced suppressive Treg function (Lal et al., 2009; Miyara et al., 2009). Additionally, nTregs possess demethylated CpG at the *Foxp3* locus and show stable Foxp3 expression, whereas TGF- β -induced Tregs show methylated CpG, and do not maintain constitutive Foxp3 expression after restimulation in the absence of TGF- β . It is of further interest that HDACi can modulate Th cellular phenotypes. In one study, the HDAC inhibitor TSA could induce a profound negative effect on the emergence of IL-17-producing cells from Tregs (Koenen et al., 2008). Whereas sorted Tregs could be polarized from the Treg phenotype to Th17 cells in a defined cytokine milieu, this could be prevented by the presence of TSA (Koenen et al., 2008). Finally, while it is known that various cross-talks between (histone) methylation and acetylation exist, their impact on T cell polarization is being addressed. Investigators identified a highly conserved CpG island within a FoxP3 enhancer region that is methylated in peripheral CD4⁺ T cells, but not in nTreg (Lal et al., 2009). This region was histone H3 acetylated and bound by Sp1 and TGF-inducible early gene-1 (TIEG1). Removing this methylation in non-Tregs resulted in an increased and stable FoxP3 expression. This effect is similar to other reported modulations of FoxP3 expression via methylation (Polansky et al., 2008).

SYSTEMIC LUPUS ERYTHEMATOSUS

In lupus, there is strong evidence that the presence of one risk allele can influence that of other risk alleles across

different loci. With the recent identification of a number of gene–gene epistatic interactions (Hughes et al., 2012), it is becoming clear that epigenetic factors play a key role in systemic lupus erythematosus (SLE) pathogenesis. Likewise, interactions between environmental and genetic factors have been proposed to explain why certain individuals develop the disease while others do not, and to account for the discordance rates for the disease in monozygotic (MZ) twins (Zouali, 2005, 2011; Gourley and Miller, 2007).

DNA Methylation

This epigenetic modification has emerged as an important contributing factor in lupus. Patients exhibit global T cell hypomethylation (Richardson et al., 1990), and the changes correlate with increased disease activity (Deng et al., 2001). T cell DNA hypomethylation has been implicated in the development of drug-induced lupus by hydralazine and procainamide, and in the pathogenesis of lupus-prone MRL-*lpr* mice (Yung et al., 1997). Interruption of the extracellular signal-regulated kinase (ERK) signaling pathway in T cells and the subsequent suppression of the maintenance DNA methyltransferase DNMT1 induces anti-dsDNA antibody production and a lupus-like gene expression profile in mice (Sawalha et al., 2008).

The *CD40LG* gene, located on the X chromosome, is hypomethylated in T cells from healthy men, while healthy women have one methylated and one hypomethylated allele (Lu et al., 2007). Treatment of CD4⁺ T cells with the DNA methylation inhibitor 5-azacytidine demethylated *CD40LG* and doubled its expression in normal healthy women, but not men (Lu et al., 2007; Zhou et al., 2009b). These findings suggest that hypomethylation of the normally inactivated and silenced X chromosome might be related to the higher prevalence of lupus in women. Indeed, men with Klinefelter's syndrome (47, XXY) have a similar risk of developing lupus as normal women (46, XX) and ~14 times higher risk to develop lupus compared to normal men (46, XY). This gene–dose effect may be achieved by hypomethylation of the X chromosome, making more than one X chromosome available for transcription (Scofield et al., 2008).

Other abnormally methylated genes include the ITGAL (CD11a), which is important for cell–cell adhesion (Lu et al., 2002), TNFSF7 (CD70), which is required for T cell proliferation, clonal expansion and promotion of effector T cell formation (Oelke et al., 2004), and CD40L, which stimulates IgG overproduction (Lu et al., 2007). Other factors, such as the gene encoding perforin 1 (PRF1) (Kaplan et al., 2004), which contributes to autoreactive killing of macrophages and release of apoptotic material, CD3 ζ chain, CTLA4, IL-2, IL-4, IL-10, and interferon (IFN)- γ (Richardson et al., 1992; Mishra et al., 2001; Lee et al., 2002; Kaplan et al., 2004; Januchowski

and Jagodzinski, 2005; Lu et al., 2005; Thomas et al., 2005; Schmidl et al., 2009). In resting SLE B cells, the E1B promoter of the CD5 gene was reportedly hypomethylated (Lu et al., 2002). These data show that DNA methylation and chromatin structure can influence the expression of SLE-related genes. In mice, demethylating drugs can trigger overexpression of these same molecules and induce both autoreactive T cells and a lupus-like syndrome (Yung et al., 1997).

The observation that several susceptibility genes (*STAT4* or *MECP2*) bear connections with DNA methylation and the existence of polymorphisms in genes that can influence DNA methylation prompted further investigation of epigenetic changes in lupus. Initial candidate gene studies revealed several pathways in which aberrant gene expression due to DNA demethylation was linked with SLE development (Huck and Zouali, 1996). They have demonstrated that abnormal hypomethylation of CD4⁺ T cell DNA can contribute to the pathogenesis of lupus-like diseases (Ballestar et al., 2006), and this phenomenon is associated with reduced expression and activity of DNMT1 in patient CD4⁺ T cell samples (Dubroff and Reid, 1980; Deng et al., 2001; Balada et al., 2008; Lei et al., 2009). In a genome-wide DNA methylation study, 236 hypomethylated and 105 hypermethylated CG sites were identified among 27,578 CG sites located within the promoter regions of 14,495 genes in lupus CD4⁺ T cells, as compared to normal controls (Jeffries et al., 2011). Among the hypermethylated genes identified, several genes are overrepresented in gene ontologies of metabolic pathways and responses to micronutrients, suggesting a link between environmental factors and epigenetic modifications. The data also suggest that DNA methylation changes in specific loci correlate with lupus disease activity.

Because lupus peripheral blood mononuclear cells (PBMCs) express high levels of IL-10 mRNA and protein, and since the serum levels of the potent B cell stimulator IL-10 correlate with disease activity and severity, it has been hypothesized that the Th2 cytokines IL-10 and IL-13 may be upregulated in SLE due to an aberrant DNA methylation of their promoter regions in CD4⁺ T cells, thereby contributing to the activation of the humoral immune arm and triggering lupus disease activity. In one study, methylation of C/G pairs within the IL-10 and IL-13 promoters was found to be significantly reduced in T cells from SLE CD4⁺ T cells, as compared with healthy control samples, and the methylation status was inversely correlated with the levels of IL-10 and IL-13 transcripts and proteins, as well as with disease severity (Zhao et al., 2010a). Furthermore, treatment of healthy CD4⁺ T cells with the methylation inhibitor 5-azacytidine triggered IL-10 and IL-13 expression to levels similar to those observed in SLE CD4⁺ T cells, suggesting an important role of DNA methylation in

regulating the expression of Th2 cytokines in SLE. These findings may provide a basis for the design of a new therapy aimed at reversing the epigenetic alternations of gene expression in SLE patients.

DNA Methylation Control by miRNA

In a study of 23 SLE patients and 10 healthy controls, seven miRNAs (miR-196a, miR-17-5p, miR-409-3p, miR-141, miR-383, miR-112, and miR-184) were downregulated and nine miRNAs (miR-189, miR-61, miR-78, miR-21, miR-142-3p, miR-342, miR299-3p, miR-198, and miR-298) were upregulated in patients, as compared with healthy controls (Dai et al., 2007). In further studies using pilot expression profiling, underexpression of miR146a was identified in PBMCs from SLE patients (Tang et al., 2009), and miR-146a was found to negatively regulate type I IFN induction by TLR-7 signaling. The strong association between miR-146a levels and clinical disease activity suggested that it may serve as a new disease biomarker, and that miRNA could serve as therapeutic targets for SLE treatment (Tang et al., 2009). In another study, miR-125a was found to be reduced, and the expression of its predicted target gene, KLF13 (encoding a transcription factor that regulates the expression of the chemokine (C-C motif) ligand 5 (CCL5) in T lymphocytes was increased (Zhao et al., 2010b). Additionally, miR-125a negatively regulated RANTES expression by targeting KLF13 in activated T cells.

In SLE, as well as in the anti-phospholipid syndrome (APS), there is an increased tissue factor (TF) expression in monocytes and endothelial cells. The fact that in several web databases and algorithm target predictions miR-19b and miR-20a were reported to target TF expression, led to a study that tested whether miRNA levels may influence TF levels in patients. In APS, the levels of these two miRNAs were decreased in comparison with monocytes from healthy controls. In monocytes from SLE, miR-20a levels were also lower than those from healthy subjects (Teruel et al., 2011). In addition, the reduced expression of miR-19b and miR-20a was inversely correlated with TF cell surface expression.

In line with these findings, one investigation disclosed that among the 11 microRNA that showed increased or decreased expression in SLE CD4⁺ T cells, miR-126 was significantly overexpressed, and its upregulation was inversely correlated with DNMT1 protein levels (Zhao et al., 2011). miR-126 reportedly could directly inhibit DNMT1 translation by interacting with its 3'-UTR, leading to a significant reduction in DNMT1 protein levels. This observation suggests that overexpression of miR-126 can cause demethylation and upregulation of genes encoding LFA-1 (CD11a) and CD70, two receptors that have been linked to disease activity. Importantly,

knocking down miR-126 in SLE CD4⁺ T cells reduced their autoimmune activity and their stimulatory effect on IgG production in co-cultured B cells (Zhao et al., 2011).

Recent investigations suggest that, in SLE, miRNAs can regulate DNA methylation by targeting the DNA methylation machinery. In one study, miR-21 and miR-148a were found to be upregulated in CD4⁺ T cells in both patients with lupus and MRL-*lpr* mice (Pan et al., 2010). Moreover, both miRNAs downregulated DNMT1 protein levels, thus resulting in hypomethylation of CD4⁺ T cells. Whereas miR-21 indirectly downregulated DNMT1 by targeting its upstream regulator (Ras guanyl-releasing protein 1), miR-148a directly downregulated DNMT1 by targeting the protein-coding region of its transcript, leading to a depression of autoimmune-associated methylation-sensitive genes in CD4⁺ T cells, such as CD70 and LFA-1 (CD11a). An alleviation of hypomethylation could also be induced in CD4⁺ T cells from lupus patients by transfection with miR-21 and miR-148a inhibitors (Pan et al., 2010).

Histone Acetylation

In addition to hypermethylation, global H3 and H4 hypoacetylation characterize CD4⁺ T cells from SLE patients (Hu et al., 2008). Moreover, a recent study found significant clusters of aberrantly expressed genes in SLE, including those coding for chemokines, which are strongly associated with altered H4 acetylation (Zhang et al., 2010).

Environmental Epigenetics in SLE

Direct comparison of identical twins represents a unique approach to test environmental epigenetics, because DNA sequence differences, including single-nucleotide polymorphisms, which would be abundant in singleton-based studies, cannot interfere. Not surprisingly, twin studies demonstrated the existence of genome-wide epigenetic differences that potentially could explain phenotypic differences (Fraga et al., 2005; Kaminsky et al., 2009). They demonstrated how epigenetic differences between MZ twins become more pronounced with age, supporting the notion that “epigenetic drift” plays a role in divergence of MZ phenotypes (Fraga et al., 2005). More recently, a collection of identical twins discordant for SLE and two other related systemic autoimmune diseases (rheumatoid arthritis and dermatomyositis) was used to perform a high-throughput analysis of DNA methylation changes (Javierre et al., 2010). Only SLE samples exhibited significant changes in the DNA methylation status at both the global and sequence-specific levels in comparison with their healthy, discordant twins and compared with unrelated matched normal controls. Comparison of SLE twins

with their corresponding healthy twins showed a decrease in global 5-methylcytosine content and a change in DNA methylation status of the CpG-rich region of the ribosomal DNA repeat, which contains the transcribed 18S and 28S genes. The study also yielded a list of epigenetically deregulated DNA sequences in SLE. Importantly, gene ontology analysis revealed enrichment in categories associated with immune function, and individual analysis confirmed the relevance of DNA methylation changes in genes to SLE pathogenesis, supporting the notion that epigenetic alterations may be critical in the clinical manifestations (Javierre et al., 2010). The results reinforce the notion that, for a particular genetic background, environmental factors can modulate SLE onset. However, it remains unclear whether environmental factors caused the epigenetic changes observed, or whether environmental factors cause lupus by some unknown mechanisms, possibly associated with inflammatory and immune responses that give rise to epigenetic changes.

Epigenetic Disruption of B Cell Tolerance in SLE

In the B cell compartment, self-tolerance operates by several processes, including deletion, anergy, and receptor editing, a powerful mechanism that allows autoreactive B cells to revise their receptors and to escape apoptotic death (Radic and Zouali, 1996). Several studies found that receptor editing is impaired in SLE and rheumatoid arthritis, and that this abnormality could account for the ineffective silencing of B cells that have acquired autoreactive receptors (Bensimon et al., 1994; Suzuki et al., 1996; Samuels et al., 2005; Yurasov et al., 2005; Faber et al., 2006; Zouali, 2008). Further insight into the molecular basis of inefficient editing as a potential cause of autoimmunity comes from studies based on different approaches. One line of evidence comes from studies on drug-induced lupus. This autoimmune disease can be induced by more than 40 medications, such as the anti-hypertensive drug hydralazine (Zouali, 2011). Interestingly, aromatic amines and hydralazine derivatives can be found in a wide variety of compounds used in agriculture and industry, and commercial applications. Hydralazine itself also occurs in tobacco and tobacco smoke, and a lupus-like syndrome has been reported in individuals who have been in contact with these agents (Reidenberg et al., 1993). To test the hypothesis that drugs that alter DNA methylation and trigger a lupus-like syndrome can disrupt the mechanisms that maintain B cell tolerance, the effects of hydralazine on receptor editing were investigated in mice harboring human transgenic immunoglobulins. The studies revealed that, by disrupting the ERK signaling pathway, hydralazine reduces receptor

editing in B lymphocytes and contributes to the generation of pathogenic autoreactivity (Mazari et al., 2007). The data also support the view that epigenetic alterations contribute to exacerbated activation or deregulation of the mechanisms that maintain tolerance to self-antigens in patients with lupus. Future studies will determine whether other drugs and xenobiotics that trigger autoimmunity in humans also can act through similar mechanisms.

RHEUMATOID ARTHRITIS

Like several other chronic immune-mediated diseases, the pathology of rheumatoid arthritis (RA) involves excessive production of inflammatory mediators, and large quantities of cytokines and chemokines are detectable in the synovial fluid. Another hallmark of RA is the hyperplasia of the synovium, with increased cell density and infiltration of inflammatory cells. The aggressive and invasive behavior of RA synovial fibroblasts (RASFs) and their increased resistance to apoptosis account for the fact that they are also referred to as cells with a “tumor-like phenotype” (Fassbender et al., 1992). Together with cell–cell contacts, inflammatory mediators can activate stromal fibroblast-like synoviocytes (FLS), leading to production of enzymes that degrade cartilage and bone. While there is no genetic background for these alterations, several studies suggest that epigenetic modifications could contribute to the characteristic changes of RASFs.

Acetylation Marks

Hyperacetylation and hypoacetylation are postulated to tightly regulate production of inflammatory cytokines at multiple levels, including regulation of transcription factor access to gene promoters, post-transcriptional mRNA processing, and protein secretion. In RA, analysis of human monocytes revealed that HDACi are potent anti-inflammatory agents (Leoni et al., 2002), and there are indications that decreased expression of HDACs in synovial tissue may contribute to RA pathogenesis (Huber et al., 2007a). Nuclear extracts of RA synovial tissue samples showed lower HDAC activity than those of osteoarthritis (OA) tissue samples (Huber et al., 2007a). More recently, RA PBMCs were found to exhibit increased HDAC activity compared to PBMCs from healthy individuals, and the increase was unaltered after 12 weeks of etanercept therapy (Gillespie et al., 2012).

TSA treatment of synovial macrophages reduced the level of IL-6 production and the reduction correlated with enhanced mRNA degradation in RA macrophages and RASFs (Grabiec et al., 2010). Consistently, TSA was a potent inhibitor of TNF- α and IL-6 production in both RA and healthy PBMCs (Gillespie et al., 2012). By contrast, another HDACi (MI192) inhibited TNF- α

production at high concentrations and dose dependently inhibited IL-6 in RA PBMCs, but not in healthy PBMCs. More recently, HDACi were found to reduce RA FLS IL-6 production induced by cytokines and TLR ligands (Grabiec et al., 2012), providing a mechanistic evidence by which HDACi might suppress inflammatory cytokine production and supporting the view that HDACi may represent a novel therapeutic approach for RA.

In murine models of RA, nonselective HDAC inhibitors have been used with positive results, including reduced proinflammatory cytokine expression, joint destruction, and disease severity (Lin et al., 2007). However, further characterization of HDAC inhibitors is needed to better establish their role in the management of RA, and changes in RA acetylation patterns have to be firmly determined before molecular therapeutic targeting becomes feasible.

Genomic DNA Hypomethylation and the Activated Phenotype of RASFs

In RA, converging observations support the hypothesis that progressive loss of methylation marks may give rise to the activated phenotype of RASFs. For example, methylation of CpG islands in the promoter region of the Death receptor 3 (DR3) of RASFs result in a higher resistance to apoptosis (Takami et al., 2006). More recently, hypomethylated nuclei were reportedly present in the synovial tissue of RA patients, and RASFs retained their demethylation profile *in vitro* (Karouzakis et al., 2009). In further experiments, it was demonstrated that chronic treatment of normal synovial fibroblasts with the DNMT inhibitor 5-AZA (5-aza-2'-deoxycytidine) changes the cellular profile into an RASF-like phenotype.

Overall, the data support the hypothesis that genomic hypomethylation could account for the activated phenotype of RASFs, in particular with respect to their destructive potential. This hypomethylation could also explain the increased expression of multiple receptors, adhesion molecules, and matrix-degrading enzymes, which play a role in RA. It remains unclear whether the epigenetic modifications of RASFs can contribute to RA chronicity, and can be responsible, at least in part, for the fact that current therapies do not work in all patients.

Defective DNA methylation was also described in other lineages, such as lymphocytes (Schwab and Illges, 2001), potentially leading to the emergence of autoreactive T and/or B cell clones in RA, as it does in lupus. The CD21 and IL-6 promoters are also demethylated in RA PBMC and synovial fluid cells (Nile et al., 2008). However, further analysis of isolated lymphocytes is necessary to confirm whether deregulated IL-6 expression occurs in these cells as a consequence of epigenetic

changes. Nevertheless, altered methylation of the IL-6 gene in RA reinforces the notion that epigenetic pathways are affected.

miRNA and the Destructive Potential of RASFs

Accumulating evidence implicates an important role of miRNAs in the regulation of immune responses and the development of autoimmunity, and recent observations suggest that altered expression and function of miRNAs may also be involved in RA pathogenesis. In one study, treatment of RASFs with TNF- α , IL-1 β , lipopolysaccharide, or poly(I-C) led to an upregulation of miR-155 and miR-146, and these two miRNAs were constitutively more highly expressed in RASFs than in synovial fibroblasts of OA patients (Stanczyk et al., 2008). Peripheral blood monocytes of RA patients also displayed higher levels of miR-155. Furthermore, enforced expression of miR-155 repressed the levels of matrix metalloproteinase-3 (MMP-3), and reduced the induction of MMP-3 and MMP-1 by TLR ligands and cytokines (Stanczyk et al., 2008). The repressive effect of miR-155 on MMPs may suggest that miR-155 plays a role in the modulation of the destructive behavior of RASFs (Stanczyk et al., 2008). This conclusion is supported by another study showing an enhanced expression of miR-146 in RA synovial tissue (Nakasa et al., 2008). In that study, the expression levels of miR-146 in RASFs were increased upon stimulation with TNF- α and IL-1 β . Consistently, investigation of 33 RA patients revealed that synovial fluid and peripheral blood CD4⁺ T cells exhibit upregulation of miR-146a and downregulation of miR-363 and miR-498 (Li et al., 2010). Moreover, the levels of miR-146a expression were positively correlated with those of TNF- α . In addition, miR-146a overexpression was found to suppress T cell apoptosis, suggesting a role for miR-146a in RA pathogenesis (Li et al., 2010).

Further evidence for the involvement of miR-146a in inflammation and cytokine production comes from the observation that the expression of miR-146a was associated with that of IL-17 in the PBMC and synovium of RA patients, and that the increased expression of both molecules correlated with disease activity (Niimoto et al., 2010). A parallel survey further demonstrated that a polymorphism in the 3'-UTR of IL-1 receptor-associated kinase (IRAK1), a target gene of miR-146a, is associated with RA susceptibility (Chatzikyriakidou et al., 2010). Since overexpression of miR-146a was found to significantly deregulate the function of Th1 cells, and because miR-146a treatment *in vitro* could induce protein expression of key proinflammatory cytokines (Guo et al., 2010), the results support the hypothesis that miR-146a may be

directly involved in the pathogenesis of RA and, possibly, other inflammatory diseases. Thus, in reports from different research groups, miR-146a and miR-155 have been consistently found to be upregulated in RASFs, PBMCs, synovial fluid, PBMC-derived CD4⁺ T cells, and Th17 cells from patients with RA when compared with healthy controls or OA patients (Pauley et al., 2008; Stanczyk et al., 2008; Li et al., 2010).

Aberrant SUMOylation

In addition to DNA and histone modifications, post-translational processes can have direct or indirect effects on epigenetic events. Thus, ubiquitin and a related family of proteins, the small ubiquitin-like modifiers (SUMOs), have been shown to impact the potential of RASFs to react to Fas-induced apoptosis. In RA, SUMO is overexpressed in synovial tissue and synovial fibroblasts (Meinecke et al., 2007). However, despite the availability of chemical modulators of ubiquitination and SUMOylation, a better understanding of the molecular mechanisms that underlie these modifications must be achieved before clinical applications can be considered.

SYSTEMIC SCLEROSIS

There is increasing evidence that histone modifications of certain genes might play a role in the pathogenesis of systemic sclerosis (SSc). In one study, hypermethylation of CpG islands and deacetylation in the FLI-1 promoter region in SSc fibroblasts and skin biopsy specimens were found to be associated with the increased production of type I collagen (Wang et al., 2006). Remarkably, there was a direct influence of Dnmt3a on the degree of histone modification, and a reduced Dnmt3a expression resulted in an enhanced histone acetylation, further underlining the repressive nature of Dnmt3a on acetylation of core histones. Nevertheless, the beneficial therapeutic use of HDACi has been shown in an animal model of SSc. Knockdown of HDAC7 in skin fibroblasts and treatment of bleomycin-induced skin fibrosis in mice with TSA remarkably reduced the accumulation of extracellular matrix proteins and fibrosis (Huber et al., 2007b).

SJÖGREN'S SYNDROME

In this disease, studies have focused on analyzing DNA methylation alterations in mechanotransduction, a mechanism that allows the conversion of mechanical stimuli into chemical activity. By translating mechanical forces and deformations into biochemical signals, mechanotransduction enables cells to sense their physical three-dimensional environment. In turn, these signals can adjust

cellular and extracellular structures. Experimental evidence suggests that a physical continuum directly connects the extracellular matrix (ECM) to the cellular nucleus (Herrmann et al., 2007). An example of a mechanotransduction-mediated mechanism is the production of lactotransferrin by glandular cells: high levels of lactotransferrin mRNA have been detected in a cell fraction enriched in epithelial cells from salivary glands of patients with Sjögren's syndrome (SS), together with an altered distribution of $\alpha\beta34$ integrin and an acinar cell shape (Perez et al., 2009). Increased transcription of the lactotransferrin gene suggests a role of mechanotransduction-signaling pathways in SS etiopathogenesis. The role of epigenetic processes in the development of glandular damage was investigated through hemidesmosome (HD) organization-mediated mechanisms. HDs are protein complexes that mediate epithelial cell adhesion to the ECM and are composed of an $\alpha\beta34$ integrin dimer that binds to laminin, plectin, and other proteins (bullous pemphigoid antigens BP180 and BP230). Suggestive of epigenetic control, reduced levels of BP230 mRNA were found in epithelial cells of patients with SS in comparison with controls and, in contrast, an accumulation of BP230 on the basal surface of acini was documented (Gonzalez et al., 2011). The reduced levels of BP230 mRNA could be related to an increased methylation index of CpG islands. In addition, differential methylation changes of the BP230 gene promoter may explain the up- and downregulations detected in patients with SS. It is of related interest that CD70 expression was elevated, and the changes correlated with a decrease in TNFSF7 promoter methylation in SS CD4⁺ T cells compared to controls (Yin et al., 2010). As for SLE, demethylation of the CD70 promoter regulatory elements could contribute to CD70 overexpression in SS CD4⁺ T cells and, thereby, to autoreactivity.

Studies of miRNAs in SS pathogenesis have centered on analyzing miRNAs from salivary exosomes. Thus, miRNA profiling of salivary glands of healthy controls and patients with SS who were classified according to a high or a low focus score revealed patterns that could distinguish control subjects and the two SS groups (Alevizos et al., 2011). In particular, expression of two miRNAs (768-3p and 574) was inversely correlated with the focus score, and downregulation of the mir-17-92 cluster was observed in half of the SS patients with a high focus score (a "focus" refers to a cluster in a labial salivary gland biopsy of at least 50 lymphocytes, based on survey of at least four lobules). Here, it is remarkable that previous studies had associated downregulation of the mir-17-92 cluster with an accumulation in pro-B cells and a marked reduction of pre-B cells, which have been associated with lymphoproliferative and autoimmune diseases (Mendell, 2008; Xiao et al., 2008). However, larger studies are

required to validate the usefulness of miRNAs in salivary glands as diagnostic markers in SS.

ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODIES-ASSOCIATED VASCULITIS

Activation of neutrophils represents a hallmark of antineutrophil cytoplasmic autoantibodies (ANCA)-associated vasculitis. It results in an increased adherence and transmigration to the vascular endothelium, where neutrophils produce reactive oxygen species and release granule constituents, including proteolytic enzymes (Kallenberg et al., 2006). To account for this activation, it has been proposed that the major neutrophil granule protein ANCA autoantigens—proteinase 3 (PR3) and myeloperoxidase (MPO)—are aberrantly expressed in mature neutrophils of ANCA patients (Ohlsson et al., 2005). In contrast, silencing mechanisms would maintain normal expression of PR3 and MPO in mature neutrophils of healthy controls. Support to this view comes from recent observations showing that aberrant expression of proteolytic enzymes in ANCA disease patients could result from active gene transcription, suggesting a failure in normal gene silencing (Ciavatta et al., 2010). Specifically, at the *PR3* and *MPO* loci, levels of H3K27me₃, a mark of transcriptionally silent chromatin, were reduced in neutrophils of ANCA patients relative to those of healthy controls. A potential additional silencing mechanism may be DNA methylation, because a CpG island in *MPO* was found to be unmethylated in patients, and there was a significant increase in methylated DNA at this CpG island in healthy controls (Ciavatta et al., 2010). Overall, the evidence suggests that transcriptional regulation of *PR3* and *MPO* may involve an epigenetic process in normal neutrophils that is perturbed in neutrophils of ANCA-associated patients.

TYPE 1 DIABETES

Whereas type 2 diabetes is associated with a relative lack of insulin, most commonly due to failure of the β cells to compensate for insulin resistance caused by obesity, type 1 diabetes (T1D) is associated with absolute insulin deficiency due to selective destruction of β cells. Affecting more than 30 million people worldwide, T1D is a complex autoimmune disease caused by a combination of genetic and non-genetic factors, leading to immune destruction of insulin-secreting islet cells. A role for non-genetic factors is supported by the recent rise in T1D prevalence, and by studies of twin cohorts (Leslie and Delli Castelli, 2004). Thus, even though MZ twins are genetically identical, only ~50% of twins of T1D-affected co-twins will develop the disease (Redondo

et al., 2001; Hyttinen et al., 2003; Leslie and Delli Castelli, 2004). This MZ twin pair discordance for childhood-onset T1D implicates roles for genetic and non-genetic factors in the etiology of this complex autoimmune disease, including viral infections, dietary factors, or vitamin D deficiency (Knip et al., 2005).

DNA Methylation Profiling

To determine whether epigenetic variation can underlie some of the non-genetic components of T1D etiology, an epigenome-wide association study was devised (Rakyan et al., 2011). To rule out genetic differences and to establish the temporal origins of T1D-associated epigenetic variation, the study combined T1D-discordant MZ twins with longitudinally sampled pre-T1D singletons. Genome-wide DNA methylation profiling led to the identification of 132 different CpG sites at which the direction of the intra-MZ pair DNA methylation difference significantly correlated with the diabetic state, i.e., T1D-associated methylation variable positions (T1D-MVPs). Since these T1D-MVPs were found in MZ twins, they cannot be due to genetic differences. Additional experiments revealed that some of these T1D-MVPs are found in individuals before T1D diagnosis, suggesting that they arise very early in the process that leads to overt T1D and that they are not simply due to post-disease associated factors (i.e., medication or long-term metabolic changes). However, the origin of these T1D-MVPs remains unclear. First, given that stochastic epigenetic variation in humans is more common than previously appreciated, as demonstrated by genome-scale analysis of DNA methylation profiles in 114 MZ and 80 dizygotic (DZ) twins (Kaminsky et al., 2009), these T1D-MVPs could be of early life stochastic origin. Second, since disease-relevant environmental factors can operate in early life to influence disease risk (Knip et al., 2010), the T1D-MVPs could have been induced environmentally in MZ twins who were exposed to similar, but not identical, environments. Analysis of individuals before they present with autoantibodies should establish whether T1D-MVPs are valuable disease biomarkers, capable of augmenting the predictive power of autoantibodies and genetic variants.

Chromatin Remodeling and Histone Acetylation

HDAC inhibition is known to modify innate and adaptive immune responses. In monocytes isolated from patients with T1D or T2D, histone H3 was hyperacetylated in the promoters of TNF- α and the inflammatory-associated enzyme cyclooxygenase (COX)-2 (Miao et al., 2004), suggesting a potential importance of HATs and HDACs

in the expression of proinflammatory genes (Miao et al., 2004).

A more recent study was based on the view that environmental factors can trigger epigenetic changes, and that variations in histone PTMs at the promoter/enhancer regions of T1D susceptible genes may be associated with T1D (Miao et al., 2012). Likewise, histone PTM variations at known T1D susceptible genes were evaluated in blood cells from T1D patients versus healthy non-diabetic controls, and key histone PTMs were profiled. Marked variations in H3K9 acetylation (H3K9Ac) levels were observed at the upstream regions of *HLA-DRB1* and *HLA-DQB1* in T1D monocytes relative to controls (Miao et al., 2012). Additional experiments demonstrated increased expression of *HLA-DRB1* and *HLA-DQB1* in response to IFN- γ and TNF- α treatment that were accompanied by changes in H3K9Ac at the same promoter regions. These results suggest that the H3K9Ac status of *HLA-DRB1* and *HLA-DQB1*, two genes highly associated with T1D, may be relevant to their regulation and transcriptional response toward external stimuli. Thus, the promoter/enhancer architecture and chromatin status of key susceptible loci could be important determinants in their functional association to T1D susceptibility. In summary, the findings point to inappropriate chromatin remodeling and histone acetylation as important pathogenetic factors in diabetes.

Histone Deacetylase Inhibitors in Preclinical Studies

In *in vitro* experiments, increased histone acetylation can be induced by high glucose concentrations and HDACi in monocytes from diabetics (Miao et al., 2004). Similarly, production of the inflammatory cytokines IL-1 γ and TNF- α was induced by high glucose concentrations through activation of NF- κ B (Shanmugam et al., 2003), suggesting that hyperacetylation is a consequence of hyperglycemia or other metabolic aberrancies of diabetes, rather than a cause. Such studies suggest that acetylation favors insulin expression and that HDAC activity decreases insulin expression. In support of this view, TSA and sodium butyrate (NaB) increase histone H4 acetylation and enhance insulin expression at low glucose levels (3 mmol/L), supporting a repressive role of HDACs on pre-/pro-insulin transcription (Mosley and Ozcan, 2003). Of note, TSA and NaB do not potentiate acetylation of H4 after exposure to high concentrations (30 mmol/L) of glucose (Mosley and Ozcan, 2003). A stimulatory effect of sodium valproate (VPA) on insulin release has also been reported in human islets incubated in low glucose concentrations (2.8 mmol/L). In contrast, accumulated insulin release from rat islets incubated in 11 mmol/L

glucose was unaffected by SAHA and the HDAC inhibitor ITF2357, but was slightly inhibited by TSA (Lundh et al., 2010).

Overall, converging observations indicate that there is evidence of genetic association between diabetes and HDACs, and that HDACs are involved in several biological pathways relevant for the etiology and pathogenesis of T1D, but also T2D. The observations that HDACi can promote β cell development, proliferation, differentiation and function, prevent β cell inflammatory damage, improve insulin resistance, and positively affect late diabetic microvascular complications provide a strong rationale for continuing preclinical studies, with the aim of testing the clinical utility of HDACi in diabetes. On the basis of the preclinical evidence, inhibition of various HDACs represents a promising novel therapeutic principle to correct the insulin-resistant state. However, further studies are needed to clarify the differential importance of various HDAC subtypes and, thereby, different HDACi, and to optimize the concentrations of HDACi to be used. The use of more specific HDACi, along with careful titration studies, should provide even more encouraging preclinical results. Lastly, the enigma of how HDAC inhibition, an apparently nonspecific treatment, can exert therapeutic benefits in so many diverse disorders needs to be unraveled.

MULTIPLE SCLEROSIS

In this chronic, inflammatory, and demyelinating neurological disease of the central nervous system, the precise mode of inheritance is not established. Approximately 15–20% of the patients have one or more affected relatives, and first-, second- and third-degree relatives are more likely to develop the disease than the general population (Sadovnick et al., 1988). If genetic information were the sole determinant for multiple sclerosis (MS) susceptibility, one would expect that MZ twins, who are genetically identical, should display the same risk of developing the disease. By contrast, in MS the concordance rate for MZ twins is only 20–30% (Willer et al., 2003; Hansen et al., 2005), implying a multi-factorial etiology, with interactions among genetic, environmental, and stochastic factors (Dyment et al., 1997).

Generation of Neo-Epitopes

Following episodes of neuroinflammation in MS, myelin is lost in multifocal loci of demyelination, called “plaques,” that are often characterized by the appearance of new myelin at the lesion edge. Pathological studies of post-mortem tissue obtained from MS brains revealed that the composition of myelin in the normal appearing white matter is different from that of non-MS brains

(Moscarello et al., 1994). The coexistence of multiple cell populations in the normal appearing white matter, and the observation that HDAC is necessary for the definition of an epigenetic signature of oligodendrocytes in developing rodents (He et al., 2007), led to the proposal that, as a result of a deregulated “epigenetic identity,” disease progression may result from the generation of neo-epitopes.

Further evidence that epigenetic deregulation could lead to the emergence of immunogenic forms of myelin basic protein (MBP) comes from studies of PAD2, a peptidylarginine deiminase that catalyzes the conversion of the guanidino group of arginine to citrulline in MBP. PAD2 levels are elevated in MS and in a transgenic animal model of the disease (Mastronardi et al., 2007). While in normal brains only a very small proportion of MBP is citrullinated, in chronic MS, citrullinated MBP comprises approximately 40% of the total MBP (Moscarello et al., 1994). The observation that there was over 90% citrullination of MBP in a rare acute Marburg’s form of MS suggested a relationship between the amount of citrullinated MBP and MS severity. The conversion of the majority of arginines into citrullines resulted in a visible apparent mass change of MBP, and in a net reduction of its positive charge, thereby affecting the interactions of MBP with other myelin components and leading to an aberrant localization of the citrullinated form of MBP in human brain white matter biopsies (Wood et al., 1996). Altogether, citrullination of MBP caused by epigenetic deregulation of PAD2 could lead to the release of modified and/or highly immunogenic forms of MBP, which may affect disease progression (Tranquill et al., 2000; Mastronardi et al., 2007; Musse and Harauz, 2007). In one scenario, citrullination could increase the generation of immunodominant peptides, due to increased auto-cleavage of the protein. Alternatively, citrullination could disrupt the physico-chemical properties of MBP and thereby affect its localization within the myelin membrane. Finally, the importance of sex hormones in MS suggests that sex steroids could epigenetically modulate PAD2 gene expression by affecting chromatin components and transcriptional complexes (Kaminsky et al., 2006).

DNA Hypomethylation

DNA isolated from the white matter of MS brains contained only about one-third of the amount of methyl cytosine found in DNA from normal subjects (Mastronardi et al., 2007). This decreased methylation of cytosines in CpG islands was not the result of decreased DNMT activity, but rather the result of a two-fold higher DNMT activity (Mastronardi et al., 2007). Importantly, it was specific for MS because DNAs from the thymus of the same MS patients and patients with Alzheimer’s,

Parkinson's, and Huntington's diseases were normally methylated, and the DNMT activity was unaffected (Mastronardi et al., 2007). An important target of this hypomethylation in MS brains is the activation of the PAD2 (peptidylarginine deiminase) locus. Its promoter has 74% GC content, and sequence analysis revealed that this region is hypomethylated in MS brains compared to controls (Mastronardi et al., 2007). Together with the findings of increased DNA demethylase, the data suggest that specific genes are reactivated in MS brains, due to epigenetic modulation.

Deregulation of Acetylation Homeostasis

HATs and HDACs fine-tune cellular acetylation, targeting not only histones, but also a variety of proteins with key roles in cell metabolism, signaling, and death. Several observations indicate that, within neural cells, aberrant regulation of acetylation homeostasis may represent a common pathogenetic mechanism underlying neurodegeneration in neurological diseases (Sweet et al., 2012). In an animal model of MS—experimental autoimmune encephalomyelitis (EAE) in SJL mice—the HDACi sodium phenylbutyrate (SPB) and its metabolite sodium phenylacetate (SPA) almost completely abrogated the development of adoptive transfer of EAE (Dasgupta et al., 2003). Similarly, SPA suppressed neurological impairment in MBP-primed T cell recipient mice. Both SPA pretreatment of donor EAE mice *in vivo* or MBP-primed T cells *in vitro* were able to reduce adoptive EAE symptoms and neuropathology in recipient mice (Dasgupta et al., 2003). In C57BL/6 mice immunized with the myelin oligodendrocyte glycoprotein peptide MOG35–55, injection of TSA reduced neurological impairment (Camelo et al., 2005). In that study, increased histone acetylation levels in the spinal cord of TSA-treated EAE mice correlated with reduced levels of caspase-3 and -9. In addition, TSA treatment reduced transcripts for IL-2 receptor, IL-8 receptor, IL-12, and the costimulatory molecule CD28 in the spleen of EAE mice, and proliferation to MOG35–55 as well as to nonspecific T cell activators (Camelo et al., 2005). The findings indicate that TSA treatment during EAE severely affects development of the autoimmune response.

Other studies demonstrated that immunological functions of dendritic cells (DCs), Th1, Th17, and Treg, as well as glial cells, are affected profoundly by HDACi. For example, exposure of *in vitro*-generated human DCs to the HDAC inhibitors valproic acid or entinostat (MS-275) impaired cell differentiation and immunogenicity (Nencioni et al., 2007). Likewise, DC production of proinflammatory cytokines (IL-6, IL-12, TNF- α) was reduced by the two HDACi. Consistently, two other HDAC inhibitors (SAHA and ITF2357) reportedly

suppressed IL-6, IL-12, and TNF- α expression by mouse bone marrow-derived DCs challenged with different activators (Reddy et al., 2008). The two HDACi also impaired costimulatory molecule expression by DCs as well as their T cell stimulatory capacity. In addition to the HDACi-dependent DC suppression, which might be relevant to MS therapy during different disease phases, different HDACi are able to impair Th1 and Th17 actions. Thus, the HDAC inhibitors TSA and SAHA could reduce the amount of IL-12 and IL-23 (two key cytokines necessary for DC-dependent polarization of T cells toward Th1 and Th17 cells) produced by human DCs *in vitro* or mouse DCs *in vivo* (Bosisio et al., 2008).

Further underscoring the therapeutic relevance of HDACi to MS therapy, several lines of evidence indicate that HDACs negatively regulate Treg generation and function. Whereas Treg transfer affords protection from EAE in rodents (Kohm et al., 2002), reduced numbers and functional deficiency of Treg have been reported in MS patients (Zhang et al., 2004). In further studies, TSA was found to assist proliferation of Treg as well as their suppressive function on effector T cells *in vivo* (Tao et al., 2007a). These effects are due to inhibition of HDAC9-dependent Foxp3 transcription factor deacetylation. Additional evidence indicates that the functional enhancement is also prompted in freshly isolated and expanded human Treg by several HDACi, and the promotion of Treg functions by HDACi seems to be due to increased expression of the negative immune regulator CTLA-4, also called CD152 (Akimova et al., 2010).

Overall, inhibitors of HDACs might exert protection from the autoimmune response to the nervous system via both immunosuppressive effects and promotion of neuronal survival. The preclinical evidence suggests that pharmacological inhibition of HDACs is a promising therapeutic strategy for the treatment of neurological disorders, including MS. However, based on preclinical data, the drugs also might exert detrimental effects that may contribute to MS pathogenesis. For example, HDACi can impair remyelination in cuprizone-treated mice, which may reduce the therapeutic potential of these compounds in MS in light of the emerging role of drug-induced remyelination in protection from EAE (Taveggia et al., 2010). It is also worth noting that the various HDACi used in preclinical studies are pan-HDAC inhibitors with off-target effects (Kazantsev and Thompson, 2008). It is therefore hoped that isoform-selective HDACi will be available shortly.

EPIGENETIC THERAPY

The use of drugs to correct epigenetic defects, referred to as epigenetic therapy, is a new and rapidly developing

area of pharmacology. Compared to genetic defects, which are permanent, epigenetic defects are more easily reversible with pharmacological intervention. Therefore, epigenetic therapy promises to offer agents capable of controlling and, possibly, preventing various diseases (Egger et al., 2004). This offers the possibility of using epigenetic drugs to reverse patterns of epigenetic alterations and to relieve particular conditions. Epigenetic drugs can be divided into two major groups: DNMT and HDAC inhibitors.

Targeting DNA Methylation

The prototypic inhibitor 5-azacytidine was developed as a cytotoxic agent and subsequently has been discovered to possess potent DNMT inhibitor activity. Since the drug is converted into nucleotide triphosphates and is incorporated in place of cytosines into replicating DNA, it is more active in the S-phase of cells. Because it binds both RNA and DNA, it both interrupts mRNA translation and inhibits methylation by trapping DNMTs. The disadvantages of azanucleosides (instability in aqueous solutions and toxicity) might be overcome by the use of other analogues, such as zebularine, procainamide (used to treat cardiac arrhythmia), 5-fluoro-2'-deoxycytidine, and hydralazine (used to treat hypertension). Several natural products derived from tea and sponges, such as epigallocatechin-3-gallate, also show DNMT inhibitory activity (Fang et al., 2003). Clinical trials that target DNMT1 are under way in tumors (<http://clinicaltrials.gov>).

In autoimmune diseases, inhibiting DNA methylation would not be appropriate because the changes identified to date are hypomethylation, not hypermethylation. Furthermore, DNA demethylating agents such as hydralazine have been shown to subvert B lymphocyte tolerance and to contribute to the generation of pathogenic auto-reactivity (Mazari et al., 2007). Likewise, agents should be designed to specifically increase methylation. Nevertheless gene—gene-specific hypermethylation cannot be ruled out (Ballestar et al., 2006).

Histone Deacetylase Inhibitors

HDAC and HAT enzymes play an important role in regulating gene transcription through chromatin remodeling, which comprises histone protein—DNA complexes that tightly package to form chromosomes. HATs promote the transcriptionally active “decondensed” chromatin state by catalyzing the addition of acetyl groups onto the N-terminal tails of histone lysine residues, causing spatial distortion and allowing transcription factor and RNA polymerase complex recruitment. On the other hand, HDACs catalyze the removal of acetyl groups from lysine

tails and restore the transcriptionally inactive “condensed” state.

HDACi show promising anti-inflammatory properties, as demonstrated in an increasing number of animal and cellular models of inflammatory diseases (Halili et al., 2009). As indicated by their name, the molecular function of HDACs was thought to be restricted to histone deacetylation, but recent advances in phylogenetic analysis suggested that HDACs regulate the activity of a wide range of nonhistone proteins; and 3600 acetylation sites (of which only 61 were on histones) were found on 1750 proteins, including cytoplasmic proteins. Thus, the impact of acetylation in terms of post-translational regulation is comparable to that of phosphorylation. A growing number of HDACi are being developed for the treatment of an expanding range of conditions, from cancer to neurodegenerative and other inflammatory diseases.

To date, HDACi, such as SAHA and TSA, have proved to be useful for relieving lupus disease in mice (Ballestar et al., 2006). The effects of TSA on human T cells are predominantly immunosuppressive and reminiscent of the signaling aberrations that have been described in patients with SLE (Hasler and Zouali, 2001; Zouali and Sarmay, 2004). Inhibition of HDACs has also been shown to alleviate renal disease in an SLE mouse model (Mishra et al., 2003; Reilly et al., 2004). In juvenile idiopathic arthritis, HDAC inhibition provides beneficial effects (Vojinovic et al., 2011). In studies of experimental diabetes, acetylation is recognized to regulate NF- κ B, the master transcription factor in inflammation, whose activation is critical in IL-1 β -induced β cell death. As a result, HDAC inhibition exerts protective effects on β cells exposed to toxicity-mediating cytokines.

Studies of chemically induced experimental colitis that mimics human ulcerative colitis also show a similar trend. For example, inhibition of HDAC in trinitrobenzene- and oxazolone-induced colitis resulted in amelioration (Glauben et al., 2006, 2008). HDACi of different classes (the hydroxamic acids SAHA and ITF2357, as well as the short-chain fatty acid valproic acid) suppressed the inflammatory parameters in acute dextran sulfate sodium-induced colitis, and ameliorated weight loss, bleeding, and colon shortening (Glauben et al., 2008). These macroscopic data were paralleled by a reduction of proinflammatory cytokines at the site of inflammation in colon cultures and by a reduced histological inflammation score (Glauben et al., 2006).

However, despite encouraging preclinical observations, epigenetic therapy may have limitations. Because of lack of specificity, DNMT and HDACi may activate oncogenes, potentially resulting in accelerated tumor progression. Additionally, once corrected, epigenetic states may revert to the original state because of the reversible nature of DNA methylation patterns.

Epigenetic Generation of Tregs

Whereas a variety of methods can be used to generate Tregs, the stability of Foxp3 expression in Tregs is important for their therapeutic use (Roncarolo and Battaglia, 2007). However, the conversion of antigen-specific Tregs into effector T cells will have detrimental effects and limit clinical applicability. It is therefore possible that epigenetic regulation may be an efficient therapeutic strategy to generate stable, suppressive Tregs. *In vivo* injection of HDAC9, a member of the class II HDACi, increases Treg numbers and function in mice (Tao et al., 2007a) and rhesus monkeys (Johnson et al., 2008). Remarkably, pan-HDACi, but not class I-specific HDACi, increased the function of Foxp3⁺ Tregs, and prevented and reduced established colitis in mice. These pan-HDACi-mediated effects were associated with increased numbers of Foxp3⁺ Tregs within the lamina propria. As regards DNMT inhibitors, they induce strong Foxp3 expression, but are associated with cell toxicity as well as induction of Th1 and Th2 cytokines, which limits their use (Lal et al., 2009).

In humans, an epigenetic approach was followed to generate enhanced Foxp3⁺-suppressive Tregs that could be used in cell therapy (Lal et al., 2009). Human Foxp3⁺CD4⁺ T cells are very heterogeneous, based on CD25, CD62L, CD45RA, HLA-DR, and ICOS expression, but can be divided into three different subsets of Foxp3⁺CD4⁺ T cells in the peripheral blood (Miyara et al., 2009). CD45RA⁺Foxp3^{lo} resting Tregs and CD45RA⁻Foxp3^{hi}-activated Tregs show completely demethylated CpG at the proximal promoter (−256 to −16 bp) and more than 85% demethylation of the intronic region promoter (+3824 to +3937 bp), and are suppressive (Miyara et al., 2009). However, CD45RA⁻Foxp3^{lo} Tregs show less than 50% demethylation at the intronic region, secrete cytokines such as IL-2 and IFN- γ , and do not show suppressive functions (Miyara et al., 2009). These findings suggest that epigenetic mechanisms may help design better approaches to generate suppressive human Tregs.

FUTURE PROSPECTS

The above hypothesis-driven studies are being complemented by resource-generating activities. Thus, the International Human Epigenome Consortium (<http://www.epigenome.org>) coordinates a number of epigenomic projects in Europe, the USA, Canada, and South Korea. It aims to analyze at least 1000 epigenomes within 7 to 10 years, and at producing histone modification maps, DNA methylation maps, transcription start site maps, and catalogues of small RNAs and non-coding RNAs. The consortium also plans to compare epigenome

maps of model organisms relevant to human health and disease, and to encompass a variety of human cell and tissue types from a variety of disease states, including autoimmune diseases. This could lead to the discovery and validation of epigenetic markers for diagnostic use and for the development of novel and more individualized medical treatments.
