antibodies against the 30 kDa protein, Boulassel et al. (2001a) reported also the presence of antibodies against a 42 kDa protein identified as beta-actin and against a 68 kDa protein identified as HSP70 by some authors (Billings et al., 1998; Bloch et al., 1999) but not by others (Yeom et al., 2003). The Western blot test for HSP70 has a very low sensitivity (García-Berrocal et al., 2002b); however, its positivity seems to correlate with steroid responsiveness in subjects with IMIED (Hirose et al., 1999). The 58 kDa inner ear protein recognized by the sera of some patients with SNHL has been identified as cochlin, a molecule highly expressed in the cochlea (Boulassel et al., 2001b). Mutation at the “coagulation factor C homology gene” (COCH gene) encoding for cochlin causes progressive DFNA9 hearing loss and vestibular disorder (Roberston et al., 2006). Increased expression of cochlin and decreased expression of its associated basement membrane proteins have been found also in Ménière's disease (Calzada et al., 2012b).

Another protein, highly expressed in the inner ear tissues, such as hair cells, supporting cells, and spiral ligament of stria vascularis, is beta-tubulin. Antibodies against the 55 kDa protein beta-tubulin have been identified in 59% of patients with autoimmune SNHL and Ménière's disease (Zhou et al., 2011a).

Cochlin, β -tectorin, and β -tubulin have been used to induce SNHL in animal models (see below). A 68–72 kDa

inner ear membrane glycoprotein called choline transporter-like protein 2 (CTL2) has been identified as a target of autoantibodies in patients with autoimmune hearing loss. Moreover, the presence of these antibodies seems to be correlated with response to corticosteroids (Kommareddi et al., 2009). Table 56.1 summarizes the putative autoantigens believed or proved to be involved in the pathogenesis of IMIED.

We can conclude that sera of patients with SNHL recognize a large array of proteins of variable molecular weight, only a few of which have been identified so far. However, there is no direct proof that any of the antibodies directed against such autoantigens may be immunopathogenic and cochleopathic in IMIED. Indeed the majority of them could not induce SNHL in immunized animals (see below).

The first evidence for an implication of autoreactive T cells was reported by McCabe and McCormick (1984), who observed leukocyte migration inhibition by T cells exposed to inner ear extracts. Lorenz et al. (2002) reported an increased number of inner ear-specific IFN- γ producing T cells in the peripheral blood of patients with SNHL believed to be of autoimmune origin. This finding indicated that proinflammatory T cells specific for as yet unknown inner ear antigens may play a role in the development and progression of inner ear autoimmunity.

GENETIC SUSCEPTIBILITY

As IMIED and Ménière's disease can be of autoimmune origin, interactions between genetic factors and environmental factors play a pivotal role in the pathogenesis of the disease.

Variability in acute immune response genes could determine susceptibility and prognosis of SNHL.

Functional allelic variants of genes encoding for the proinflammatory cytokines tumor necrosis factor alpha (TNF-alpha), interferon gamma, and macrophage migration inhibitory factor have not been found associated with disease susceptibility or hearing loss progression in patients with Ménière's disease (Gásquez et al., 2012).

Since increased permeability of blood vessels, as shown by MRI, suggests inflammation of the inner ear, different genes involved in inflammatory pathways have been analyzed; polymorphisms of the gene encoding for IL-6 (Hiramatsu et al., 2012) and for IL-1 β (Um et al., 2013) have been found associated with risk of sudden SNHL. Moreover, IL-1 β seems to be overexpressed and aberrantly regulated in patients with autoimmune inner ear disease who are non-responders to steroid therapy (Pathak et al., 2011). Finally, SNHL has been observed in autoinflammatory syndromes such as Muckle–Wells syndrome, whose hallmark is IL-1 β dysregulation (Kuemmerle-Deschmer et al., 2013). Therefore IL-1 β blockade may be an alternative method to restore hearing in patients who do not respond to steroid therapy.

Oxidative stress seems to be related to the pathology of inner ear; however, polymorphisms of genes involved in oxidative stress have not been found associated with the risk of SNHL or Ménière's disease (Teranishi et al., 2012).

Aquaporins are water channel proteins that play a pivotal role in the regulation of perilymph and endolymph volume; two of the eight aquaporin subtypes seems to be involved in impaired fluid regulation present in Ménière's disease and in Sjögren's syndrome (Eckhard et al., 2012).

Finally, the study of coagulation has identified risk factors such as hyperhomocysteinemia and polymorphism of the MTHFR gene associated with SNHL (Massimo et al., 2012), whereas decrease of plasminogen activator inhibitor-1 (PAI-1) levels due to gene polymorphism may be associated with reduced risk of sudden SNHL in the Italian population (Cho et al., 2012).

ANIMAL MODELS

A major barrier in understanding the pathophysiology of IMIED derives from the paucity of available inner ear tissue. This problem underlines the importance of animal models of this disorder, which may provide insights into pathogenesis, diagnosis, and treatment of IMIED.

A recent animal model of autoimmune inner ear disease has been obtained in Sprague-Dawley rats by combination with a high dose of pertussis toxin: cellular infiltration, missing hair cells, degeneration of the spiral ganglion cells, endolymphatic hydrops, and autoantibodies directed to inner ear-specific antigens were all noted after immunization (Kong et al., 2011).

Immunization with the better characterized putative autoantigens, such as collagen type II, HSP70, and myelin P0, has failed to elicit hearing loss (Harris et al., 1986; Billings et al., 1998; Boulassel et al., 2001c). Attempts to develop animal models of IMIED have been made by immunizing guinea pigs with either isologous or bovine inner ear homogenates (Harris, 1987; Gong et al., 2002); this model was hampered by the vast array of immunologically active components involved, making it impossible to identify the specific self-antigens involved in disease initiation and progression. The use of fractions of inner ear proteins has partially addressed this problem (Tomiyama, 2002), which will be solved by the availability of recombinant antigens (Billings, 2004). Gloddek et al. (1999) induced SNHL in naïve Lewis rats following passive transfer of activated T cells specific for bovine inner ear extract, demonstrating the role of T cells in the initiation and pathogenesis of SNHL. A confirmation of the importance of T cells was recently provided by Solares et al. (2004), who showed that SWXJ mice immunized with peptides derived from two proteins of the inner ear, cochlin and β -tectorin, had significant hearing loss. Two selected peptides elicited a CD4⁺ T cell response of the Th1-like phenotype. Moreover the passive transfer of peptide-activated CD4⁺ T cells into naïve SWXJ recipient induced leukocytic infiltration of inner ear and hearing loss. However, it is not clear whether cochlin and β -tectorin are implicated in IMIED in humans and how accurately this model reflects events occurring in the spontaneous disease (Billings, 2004). Zhou et al. (2011a) have shown that immunization of Balb/c mice with β -tubulin is able to cause lesions in the cochlear hair cells and cochlear damage of the spiral ganglion, mediated by CD4⁺ T cells producing IFN- γ . Hearing loss was induced by the passive transfer of CD4⁺ T cells specific for β -tubulin to naïve mice and this is accompanied by a decreased frequency and impaired suppressive function of regulatory T cells. In this murine model of autoimmune hearing loss, systemic infusion of adipose tissue-derived mesenchymal stem cells significantly improved hearing function and protected hair cells by decreasing proliferation of antigen-specific Th1/Th17 cells and by inducing generation of antigen-specific Treg cells (Zhou et al., 2011b). Moreover, the severity of β -tubulin-induced experimental autoimmune hearing loss is exacerbated by IL-10 deficiency (Zhou et al., 2012).

Interestingly, oral administration of β -tubulin in female C57BL/6 mice induced decreased hearing loss and

inner ear damage through induction of oral tolerance by increasing Th2-type cytokines (Cai et al., 2009).

The administration of monoclonal antibodies directed either against the guinea pig inner ear supporting cell antigen (KHRI-3 antibody) (Nair et al., 1995) or against type II collagen fragment CB11 peptide-induced SNHL with loss of hair cells, inflammatory cell migration, and endolymphatic hydrops (Matsuoka et al., 2002) suggests that antibodies also play a critical role in autoimmunity of the inner ear.

IL-1 β has been observed highly expressed in an animal model of autoimmune inner ear disease; in this model, LPS was required in addition to Ag re-exposure to initiate cochlear IL-1 β expression, leukocyte ingress into the cochlea, and hearing loss (Pathak et al., 2011).

TREATMENT

Since IMIED may result in severe deafness and vestibular dysfunction, patients must be treated aggressively and immediately after the onset of the symptoms. The mainstay of therapy is high-dose corticosteroids (1 mg/kg/day) (Chen et al., 2003) continued for at least 2 weeks and then for another 2 weeks in the case of improvement. The steroid is then tapered in a period variable between 2 and 3 months and in some cases maintained at low dosage for a long period (e.g., methylprednisolone 4 mg/day). Different steroid administration schemes, including intratympanic dexamethasone and 6-methylprednisolone injections, have been used with good results (Garcia-Berrocal et al., 2006; Alexander et al., 2009; Lim et al., 2012; Gallo et al., 2013). In the case of deterioration of symptoms or of a not significant improvement during the first 2 weeks of treatment, other immunosuppressive agents (Buniel et al., 2009) are added such as cyclophosphamide (CYP), 2 mg/kg/day, or methotrexate (MTX), 7.5–20 mg/wk. Because of the well-known side effects of CYP, clinicians prefer the use of MTX; however, despite the preliminarily favorable responses (Kilpatrick et al., 2000; Matteson et al., 2001; Rahman et al., 2001; Matteson et al., 2003), the unique controlled trial published so far does not support the efficacy of long-term MTX in maintaining the improvement achieved with glucocorticoid therapy (Harris et al., 2003). Since MTX is slow acting, its effect may start too late in a disease that rapidly leads to hearing loss. In 1989 McCabe reported the promising results obtained with the CYP–prednisolone combination therapy. We have used oral methylprednisolone and CYP pulse therapy in two particularly rapid and severe cases; this therapy blocked and reversed the hearing loss.

The results obtained with steroids and aggressive immunosuppression are variable (Broughton et al., 2004; Loveman et al., 2004; Ruckenstein, 2004) depending on

the characteristics of the patients included, on the severity of the hearing loss at the beginning of the treatment, and on how early the therapy is started. Also proinflammatory cytokines and cytokines receptors polymorphisms may affect the steroid responsiveness (Vambutas et al., 2009).

Biological agents can play a role in the management of patients with IMIED (reviewed by Lobo et al., 2012): most studies achieved a hearing improvement or stabilization in more than 70% of patients treated. The biological agents used include anti-TNF-alpha inhibitors (etanercept, infliximab, adalimumab), anti-IL-1 antagonist (anakinra), and anti-CD20 surface antigen (rituximab). Infliximab has been also delivered locally through transtympanic administration (Van Wijk et al., 2006) and has been used in the treatment of Cogan's syndrome (Beccastrini et al., 2010).

There are reports on the utility of plasmapheresis (Luetje and Berliner, 1997), therapeutic apheresis of LDL (Bosch, 2003), and fibrinogen (Suzuki et al., 2003). Suckfull and the Hearing Loss Study Group (2002) reported the beneficial effects of a single fibrinogen/LDL apheresis compared to conventional infusion treatment and prednisolone for 10 days. In controlled studies the use of antiviral therapy with valacyclovir (Tucci et al., 2002) and acyclovir (Uri et al., 2003; Westerlaken et al., 2003) in addition to steroids was no more beneficial than steroids alone. Finally, there are recent reports on the utility of low molecular weight heparins (Yue et al., 2003; Mora et al., 2004) and antioxidants (Joachims et al., 2003) in addition to the usual therapy and the efficacy of intravenous infusion of tissue plasminogen activator (Mora et al., 2003) alone.

In the case of permanent severe bilateral hearing loss, auditory function may be partially replaced with a cochlear implant, an electrical prosthesis with electrodes inserted into the cochlea through mastoidectomy (Cohen et al., 1993). Cochlear implantation has been successfully used in patients with SNHL (Gaylor et al., 2013), with IMIED, and with Cogan's syndrome (Aftab et al., 2010; Wang et al., 2010; Malik et al., 2012). Of the 17 patients with Cogan's syndrome we are following at the moment, nine (age 7–30) have undergone multichannel cochlear implant, resulting in a great improvement to their quality of life, without any complication.

Cochlear implantation has been applied with benefit in children 12 months of age or younger (Holman et al., 2013). Bilateral cochlear implantation seems to be more beneficial than unilateral implantation (van Schoonhoven et al., 2013).

Hematopoietic stem cell transplantation led to improvement in sensorineural hearing in patients with mucopolysaccharidosis (Da Costa et al., 2012). The recent emergence of stem cell technology has the potential to open new approaches for hair cell regeneration (Okano and Kelley, 2012).

CONCLUDING REMARKS AND FUTURE PERSPECTIVES

It is now evident that the inner ear is not an “immunologically privileged” site and may mount an immune response against both foreign and self-antigens. The association of IMIED with systemic autoimmune diseases provides evidence that autoimmunity can damage the inner ear, but it does not address organ-specific disease (Mijovic et al., 2013). Antibodies directed against different inner ear antigens have been identified in some patients; however, they are neither diagnostic nor correlate with disease state. In the future the major goals for research in this field will be: (1) the identification of pathogenetically relevant autoantigen(s); (2) the development of a highly specific diagnostic test; and (3) gaining better knowledge of the immunopathological mechanisms in an organ as inaccessible as the inner ear and allied to the above, defining the best timing and treatment for the disease.

INTRODUCTION

A new understanding of neuronal autoimmunity has evolved rapidly over the last few decades. Historically, multisystem autoimmune disorders, notably systemic lupus erythematosus (SLE, lupus) and sarcoidosis, have been long recognized to affect the central nervous system (CNS). Autoimmunity to specific neuronal antigens was the first-described involvement of the peripheral nervous system (PNS) with the recognition in myasthenia gravis of pathogenic autoantibodies to the acetylcholine receptor (AChR). Subsequently numerous autoantibodies to intracellular CNS and PNS antigens, starting with ANNA-1 (Hu), were associated with neurological syndromes, often in the setting of an extraneural malignancy. These “paraneoplastic” syndromes can affect the brain, brainstem, spinal cord, cerebellum, nerve roots, and

peripheral nerves. Although the syndromes appear to reflect damage to neurons expressing the antigens, the symptoms bear little relationship to the actual functions of these antigens. It was proposed initially that these “onconeurological” antibodies were directly pathogenic, but more likely they mark a cell-lethal T cell response. Next, and starting with autoantibodies to the voltage-gated potassium channel (VGKC) complex, a series of antibodies to various neurotransmitter receptors, synaptic proteins, and cell adhesion molecules were described. Here, the autoantibodies likely do have direct effects on the target antigens, and the symptoms so induced resemble those caused by genetic or pharmacologic disruption of the cognate receptor. Notably, the discovery of aquaporin-4 (AQP4) antibodies has provided a plausible mechanism for neuromyelitis optica (NMO) and

related disorders. The particular focus of this chapter is on autoimmune disorders associated with encephalitis or myelitis, subdivided into three groups: (1) systemic diseases with CNS manifestations, (2) CNS diseases with antibodies to synaptic and cell-surface proteins, and (3) CNS diseases with antibodies to intracellular antigens.

NEUROLOGICAL SYNDROMES OF AUTOIMMUNE CAUSATION

Autoimmunity affecting the CNS may result in diverse clinical syndromes, including encephalitis, psychiatric symptoms, acquired epilepsy, cerebellitis, stiff person syndrome, and myelitis. Before surveying the implicated disorders, these clinical presentations should be considered.

The diagnosis of autoimmune CNS disorders requires clinical history and neurological examination to define the syndrome, neuro-imaging and laboratory testing to exclude other causes, and specific serological testing to confirm an autoimmune basis. Since these autoimmune syndromes are often treatable, their recognition is important. We can list the clinical presentations as follows.

Cerebral Syndromes

Autoimmune encephalitis which most often develops sub-acute, over weeks or months, with memory loss, confusion, unusual behaviors including hallucinations or delusions, and fluctuating levels of consciousness.

Psychiatric disorders which may be prominent early, as in encephalitis with disruption of critical receptors, NMDAR and AMPAR, thus resembling schizophrenia or new onset psychosis.

Epilepsy wherein onset of seizures or unusual movements or features of autonomic disorder should prompt consideration of autoimmune encephalitis.

Ataxia

Ataxia due to cerebellitis which may occur as an isolated syndrome or as part of a more general encephalitis wherein patients typically have ataxia of limb, trunk, and/or ocular movements with nystagmus, diplopia, vertigo, and nausea.

In these presentations, an infectious cause such as herpes simplex virus encephalitis will be suspected and excluded after CSF analysis and other specific testing. Also, patients will be assessed for inflammatory/autoimmune conditions (SLE, sarcoidosis), fulminant multiple sclerosis and paraneoplastic causes, including cancer screening and testing for paraneoplastic autoantibodies. While many cases of encephalitis lack any specific clues to an autoimmune etiology, there are findings that do suggest a specific diagnosis. Thus, NMDA receptor autoantibodies are associated with a distinct clinical syndrome described

below, and autoantibodies to the VGKC complex mark patients with coexisting neuromyotonia, thymoma, and/or myasthenia gravis. Autoantibodies to Tr (or more precisely DNER) or rarely to mGluR1 are found in some patients with cerebellitis in the setting of Hodgkin's lymphoma. If specific clues are lacking, testing for autoantibodies to a panel of candidate antigens is appropriate.

Spinal Myelitis

Spinal myelitis affects the long tracts of the spinal cord resulting in numbness and weakness of the extremities. Damage to spinal cord gray matter also results in flaccid paralysis and/or depressed tendon reflexes at affected levels. Due to the longer fiber tracts between brain and lower spinal cord, symptoms affecting the lower extremities, bowel, and bladder are the most prominent. Sensory loss is characterized by a spinal sensory level, or differential effects on the sensory pathways for pain/temperature and vibration/proprioception, which may run along different sides of the cord and be unequally disrupted. Rapidly progressive disorders may initially present as "spinal shock" with suppressed reflexes, whereas in sub-acute progressive cases, or the chronic state, hyper-reflexia and upper motor neuron signs become prominent.

Stiff Person Syndrome

Stiff person syndrome presents as stiffness of the limbs and/or trunk. Patients lack sensory deficits, abnormal reflexes, or upper motor neuron signs, so that Parkinson's disease or a related disorder is suspected. An autoimmune basis is confirmed by positive serological tests and/or improvement with immunotherapy. While a specific autoantibody syndrome cannot be distinguished with certainty, particular findings suggest specific diagnoses. Thus, stiffness with acquired hyperekplexia (an extremely exaggerated startle response) has been associated with autoantibodies to the glycine receptor, and stiff person syndrome in the setting of gynecologic cancers with autoantibodies to amphiphysin.

SYSTEMIC IMMUNOPATHIC DISORDERS WITH ENCEPHALITIS AND MYELITIS

Various of the multisystem/vasculitic diseases have a well-described involvement of the CNS but, striking as the features may be, there is no consistently demonstrable CNS-specific mechanism of neuronal damage.

Systemic Lupus Erythematosus

SLE may have diverse neuropsychiatric expressions, including cerebrovascular events, stroke, transient ischemic attack

(TIA), encephalitis, movement disorders most commonly chorea, headache, seizures, anxiety, and/or psychosis (see Chapter 32). The American College of Rheumatology (1999) proposed criteria for 19 distinct neuropsychiatric symptoms associated with SLE with 12 involving the CNS. The large retrospective analysis of Chiewthanakul et al. (2012) showed that 13% of patients with SLE were affected by these CNS disorders, most often seizures, vascular events, and/or psychosis: their mortality rate was 18.8%. In patients with neuropsychiatric features attributed to SLE, these were the presenting signs in some 40% (Padovan et al., 2012). A standardized set of measurements for neuropsychiatric impairment associated with SLE has been proposed for clinical trials (Mikdashi et al., 2007). In SLE, many of the neurological syndromes have a high frequency in the general population (e.g., headache) or have other risk factors (e.g., hypertension for stroke), making it unclear whether or not SLE is causally involved. However, several studies have associated antiphospholipid antibodies with neurovascular complications (Sanna et al., 2003; Mikdashi and Handwerger, 2004; Govoni et al., 2012).

Some 1–2% of patients with SLE are affected by transverse myelitis (Provenzale et al., 1994); these were more likely to be African American, and to have an elevated CSF IgG index and erythrocyte sedimentation rate (Schulz et al., 2011). Birnbaum and colleagues distinguished two subgroups with myelitis: those with primarily long-tract signs (spasticity, hyper-reflexia) and those with flaccid paralysis (indicating gray matter damage) (Birnbaum et al., 2009). The former group was more likely to meet criteria for neuromyelitis optica, and the second group had a worse outcome (Birnbaum et al., 2009). Episodes of transverse myelitis are accompanied by other signs of active SLE in only half of the cases, and in 25% of patients with SLE-associated myelitis there were no prior systemic signs of SLE (Espinosa et al., 2010). Patients typically have sensory, motor, and urinary dysfunction (Espinosa et al., 2010). MR imaging shows T2 hyperintense lesions of the cervical or mid-lower thoracic spinal cord in some patients with less extensive disease and in almost all with lesions involving more than four cord segments (Kovacs et al., 2000; Espinosa et al., 2010). Therapy with steroids, cyclophosphamide, rituximab, mycophenolate mofetil and other agents has given mixed results (Mok et al., 1998, 2006; Kovacs et al., 2000; Birnbaum et al., 2009). Two case series showed statistically non-significant associations between early immunotherapy and better outcomes (Harisdangkul et al., 1995; Lu et al., 2008). A minority of patients recover completely. Recurrences are common (Provenzale et al., 1994).

Several immune mechanisms have been proposed to cause CNS disorders associated with lupus. Thrombosis

and infarction, such as may be associated with the prothrombotic state (e.g., aPL antibodies), may result in stroke or venous sinus thrombosis (Sanna et al., 2003; Mikdashi and Handwerger, 2004; Govoni et al., 2012). More rarely, vasculitis may be implicated. Inflammatory cytokines have been proposed to affect cognition and injure neurons. Antineuronal antibodies are more common in SLE patients with CNS disease than those without CNS manifestations (Kang et al., 2008; Cojocaru et al., 2010). Specific antibodies to several different neuronal antigens have also been reported (Iizuka et al., 2010). However, it has not been established whether any of these antibodies are pathogenic. Antibodies whose pathogenesis is more likely (e.g., NMDAR or AMPAR) may also be found in lupus patients

Sarcoidosis

Sarcoidosis is not formally enumerable as an autoimmune disease, although this possibility has been raised from time to time. Neural tissues are affected in 5–13% of patients, including peripheral nerves, cranial nerves, meninges, brain (including hypothalamus), and/or spinal cord (Lacomis, 2011). In about half of the cases, the neurological symptoms were the initial presentation (Chapelon et al., 1990; Zajicek et al., 1999; Joseph and Scolding, 2009). Cranial nerve involvement of the optic, facial, or multiple cranial nerves was the most common manifestation (Zajicek et al., 1999; Joseph and Scolding, 2009; Pawate et al., 2009). Meningitis particularly affecting the basilar meninges may occur with or without associated cranial neuropathies (Gullapalli and Phillips, 2002). The definitive demonstration of non-caseating granulomas in the affected areas of the nervous system is available only in a minority of cases. More often, a diagnosis of probable neurosarcoidosis is made based upon accessory evidence (Zajicek et al., 1999). Treatment with corticosteroids is usual and some patients do improve (Lower et al., 1997; Joseph and Scolding, 2009; Lacomis, 2011). Patients refractory to initial therapy have received numerous other immunosuppressive medications, including azathioprine, cyclophosphamide, and methotrexate (Lower et al., 1997; Scott et al., 2007), or even cranial irradiation (Chapelon et al., 1990; Agbogu et al., 1995) but optimal regimens are not yet established. The actual immunological nature of the sarcoid process remains obscure.

Sjögren's Syndrome

Sjögren's syndrome is an autoimmune inflammatory disease affecting salivary and lacrimal glands. Approximately 25% of patients have features of PNS or CNS involvement, most typically sensory neuropathy, sensory neuronopathy, or mononeuritis multiplex (Sene et al., 2011). However, the

true percentage of neurologically affected patients is controversial, in part due to the wide diversity of manifestations (Soliotis et al., 2004) such as encephalitis, cerebellitis, aseptic meningitis, brainstem syndromes, migraines, seizures, and psychiatric symptoms. Alexander et al. (Alexander, 1993; Alexander et al., 1986, 1994) demonstrated intrathecal antibody synthesis in patients with encephalopathic Sjögren's syndrome and suggested vasculopathy as a pathogenic mechanism, and reported an association between the presence in serum of anti-Ro (SS-A) and more severe CNS disease. More recently, Estiasari et al. found that one-third of patients with Sjögren's syndrome, particularly those with spinal cord lesions or optic neuritis, had antibodies to AQP4 (Estiasari et al., 2012). Given the important prognostic therapeutic and mechanistic implications of these antibodies (see following section on NMO), a patient with Sjögren's syndrome and CNS symptoms should be tested for anti-AQP4. The pathophysiology of anti-AQP4-negative patients with Sjögren's syndrome and CNS symptoms is unclear and may involve other as yet undiscovered autoimmune reactivities.

Behçet's Disease

Behçet's disease is a multisystem inflammatory vasculitic disorder characterized by oral aphthae, genital ulcerations, and uveitis. The typical patient is male, aged 30–40 years, with recurrent attacks of inflammation affecting the eye, oral and genital mucosa, the gastrointestinal (GI) tract, large vessels, or CNS (Sakane et al., 1999). The disease is most common in a region extending from Turkey to East Asia (Nishiyama et al., 1999; Siva and Saip, 2009). Some 50% of patients experience neurological disorder, almost always involving the CNS (Akman-Demir et al., 1999; Borhani Haghighi et al., 2005). Involvement of pyramidal motor pathways is common, particularly in the brainstem, and other presentations included sensory deficits, cerebellar ataxia, and/or cranial nerve or brainstem abnormalities. Most patients have discrete attacks, most commonly including hemiparesis, and a half have behavioral changes. Indirect effects on the CNS from venous sinus thrombosis or the superior vena cava syndrome may occur (Siva and Saip, 2009), possibly as part of a thrombophilia affecting other tissues (Yazici et al., 2007). Pathological studies have revealed perivascular lymphocytic infiltrates, especially in the basal ganglia, midbrain, and thalamus (Borhani Haghighi et al., 2007), whereas others report perivascular neutrophilic infiltrates (Arai et al., 2006). Brain perfusion MRI showed prolonged mean transit time for cerebral blood flow and decreased relative cerebral blood flow in patients with neuro-Behçet's disease and Behçet's disease without neurological symptoms (Alkan et al., 2012), suggesting that sub-clinical CNS involvement may be common,

and that distinction between patients with and without CNS symptoms is simply a matter of degree.

DISEASES WITH AUTOANTIBODIES TO CELL-SURFACE CHANNELS, RECEPTORS

Neuromyelitis Optica (NMO; Devic's disease)

NMO has been the subject of the transformative discovery of autoimmunity affecting a water channel, aquaporin-4 (AQP4). Long considered a variant of multiple sclerosis, NMO is characterized by episodes of often bilateral optic neuritis, spinal cord lesions often longitudinally extensive and very disabling, and a relative paucity of brain lesions. The identification in NMO of an initially characteristic pattern for an autoantibody response, subsequently defined as specific anti-AQP4 antibodies, has revolutionized our understanding of this disorder (Lennon et al., 2004): as many as 77% of patients with a clinical diagnosis of NMO have AQP4 antibodies (Waters et al., 2012). In addition to lesions of the optic nerves and spinal cord, half of the patients show brain lesions on MRI (Nagaishi et al., 2011) particularly frequently in children (Pena et al., 2011), and such may be the presenting feature in children or adults (Kim et al., 2011).

Detection of AQP4 antibodies has important clinical implications including presence during an initial clinical event suggesting a risk of further attacks (Weinschenker et al., 2006). The severe disability caused by NMO should prompt potent therapies immediately upon diagnosis (Sato et al., 2012). Notably, interferon- β therapy, successfully used to treat MS, appears to worsen rather than benefit NMO (Kim et al., 2012); also, in a single case report, there was worsening in a patient given the drug fingolimod used orally in MS (Min et al., 2012). But other "suppressive" therapies such as the anti-IL-6 monoclonal antibody tocilizumab (Araki et al., 2013) and azathioprine (Costanzi et al., 2011) do appear to be effective in NMO. Finally, studies on anti-idiotypic antibodies directed against patients' AQP4 antibodies might provide a highly specific therapy for NMO (Tradtrantip et al., 2012). A recent open-label study of eculizumab, a monoclonal antibody that inhibits the complement protein C5, showed promising results for stopping attacks and improving disability in patients with active NMO (Pittock et al., 2013).

AQP4 proteins are water channels expressed in astrocytes and other cells, and organize into large molecular aggregates called orthogonal arrays of particles (Jung et al., 1994; Rossi et al., 2012). AQP4 channels are important for regulating brain water balance, astrocyte migration, glial scar formation, and responses to brain edema and injury (Verkman et al., 2006). AQP4 antibodies target

extracellular (surface) epitopes, predominantly in the C-loop, and these surface epitopes may be formed by the interactions of AQP4 subunits in functional tetramers (Iorio and Lennon, 2012). AQP4 antibodies are thought to cause internalization of AQP4 channels, along with the closely associated glutamate transporter EAAT2, disrupting both water and glutamate homeostasis for astrocytes (Hinson et al., 2008). AQP4 exists as two major isoforms, M23 and M1, that have identical extracellular domains but are affected differently by patients' antibodies (Crane et al., 2009; Hinson et al., 2012). The M1 isoform is internalized but the M23 isoform is found in the large orthogonal arrays that resist internalization, and more effectively activate complement. Antibodies disrupt the ability of both types of channel to conduct water, but complement fixation may be important for determining the severity of clinical attacks; sera from patients experiencing severe attacks is more effective at fixing complement on AQP4-expressing cells than sera from patients with milder attacks and a similar anti-AQP4 level (Hinson et al., 2009). The strongest evidence that AQP4 antibodies are directly pathogenic comes from animal experiments in which IgG from affected humans is directly injected into the brain of rodents. The IgG, particularly along with complement, reproduced the characteristic pathology of neuromyelitis optica (Brady et al., 2009; Saadoun et al., 2010) and this pathology was abrogated in aquaporin-4-null mice, confirming that AQP4-specific antibodies are critical for the disease. The promising effects of the C5 complement inhibitor eculizumab on patients' attacks provides a powerful argument that complement activation is important for pathogenesis in humans (Pittock et al., 2013).

It is unknown what triggers development of AQP4 antibodies and NMO. Patients generally do not have unusual mutations or polymorphisms of AQP4 (Matiello et al., 2011). Some with NMO have coexisting myasthenia gravis (Jarius et al., 2012; Leite et al., 2012) and, in one series, 19% had co-morbid Sjögren's syndrome and 13% co-morbid thyroid disease, suggesting predisposition in NMO to form multiple autoantibodies (Nagaishi et al., 2011). Reported pedigrees of multiple affected family members suggest a complex genetic susceptibility to formation of AQP4 antibodies (Matiello et al., 2010).

Testing for NMO antibody reactivity initially involved indirect immunofluorescence against a composite substrate of mouse tissues, specifically at the blood-brain barrier, to detect a characteristic pattern of reactivity (Lennon et al., 2004). A recent study comparing the multiple methods available now found ELISA and detecting IgG binding to transfected cells (by flow cytometry or visual observation with fluorescent antibodies) to be most sensitive and specific (Waters et al., 2012). The recent identification of antibodies to the Kir4.1 inwardly-rectifying potassium channel in a subset of patients with

MS hints that other specific autoantibody-associated syndromes might account for other subsets currently diagnosed with MS (Srivastava et al., 2012).

Encephalitis with Antibodies to N-methyl-D-aspartate Receptor (NMDAR)

NMDAR targets an ionotropic, excitatory glutamate receptor that has a relatively high permeability to calcium, and hence is important for triggering calcium-dependent synaptic plasticity. NMDARs are structurally and functionally diverse tetramers comprised of many combinations of the eight GluN1 isoforms, the four GluN2 isoforms, and the two GluN3 isoforms (Paoletti, 2011). Antibodies to the GluN1 (NR1) subunit were initially reported in young women with encephalitis and ovarian teratoma, some of whom responded to tumor therapy and/or immunotherapy (Dalmau et al., 2007). Subsequently, hundreds of cases have been reported, so expanding and further clarifying the associated disorder (Dalmau et al., 2011). Some patients have an initial prodrome resembling a viral illness, and the onset of disease, whether behavioral or psychiatric, includes hallucinations, delusions, agitation, inappropriate (violent or hypersexual) behaviors, and/or decreased speech. Memory loss is nearly universal, although often overlooked in the setting of dramatic psychotic features resembling those seen initially in schizophrenia. Patients then develop seizures, decreased responsiveness, and/or autonomic instability. Writhing movements of the face, tongue, and extremities may occur. A catatonic or comatose state develops, and central respiratory failure may require mechanical ventilation. With treatment, patients usually become more responsive, but may pass through the "psychotic" stage of the illness again before recovering more fully. The resemblance of symptoms to effects of pharmacologic NMDAR blockade has been noted (Dalmau et al., 2011). Anti-NMDAR encephalitis affects children, and symptoms may differ from those in adults: behavioral change is a common presenting sign and language disruption, sleep disruption, seizures, and abnormal movements are common at diagnosis (Florange et al., 2009).

Based on the rapid accrual of cases, anti-NMDAR is probably the most common type of CNS synaptic autoantibody (Dalmau et al., 2011). Some 80% of patients are female and 59% have ovarian teratomas (Dalmau et al., 2008). Neuronal tissues within these teratomas express NMDAR, and patients' antibodies are found bound to these receptors, indicating that the teratomas trigger the immune response; in patients without teratomas the source of the response is unknown, but some of the patients appear predisposed to forming autoantibodies. While peak age incidence appears to be between 13 and 30, all ages may be affected, including infants and the elderly (Dalmau et al., 2011). Although clinical trials to

define the optimal treatment have not been done, treatment of the tumor and/or with immunotherapy is associated with better outcomes. Treatment with corticosteroids and IVIg is usually followed, failing a good response, by second line treatment with cyclophosphamide and/or rituximab. Approximately 75% of patients have a substantial recovery (Dalmay et al., 2011).

NMDAR antibodies appear to be directly pathogenic. IgG from patients causes cross-linking and internalization of synaptic NMDARs, resulting in decreased NMDAR-mediated synaptic currents (Dalmay et al., 2008; Hughes et al., 2010). This rapid functional disruption of NMDAR-mediated neurotransmission would account for patients' symptoms by disruption of NMDAR-dependent synaptic circuits (Moscatto et al., 2010). Notably, affected neurons are able to restore their synapses and function after removal of the antibodies. Consistent with this, autopsy studies have shown widespread antibody binding to CNS neurons but not significant neuronal death (Tuzun et al., 2009).

Testing for anti-NMDAR consists in screening with indirect immunofluorescence for IgG reactivity to cultured cells expressing the NR1 subunit of the receptor.

Anti-AMPA

The extracellular domains of the GluR1 and GluR2 subunits of the 2-amino-3-(5-methyl-3-oxo-1,2-oxazol-4-yl) propanoic acid receptor, (AMPA) is the reactant for autoantibodies (anti-AMPA) that have been reported in patients with encephalitis (Lai et al., 2009). AMPA is the other main ionotropic glutamate receptor, along with NMDAR, used in the human brain for rapid excitatory synaptic transmission; it is critical for learning and memory (Lee and Kirkwood, 2011). Patients with anti-AMPA may present with either encephalitis or psychiatric symptoms, and the patients may have tumors of the lung, breast, or thymus (Bataller et al., 2010; Graus et al., 2010). Anti-AMPA antibodies have effects similar to those of anti-NMDAR in causing antibody-mediated capping and internalization of the receptor, and disruption of AMPA-mediated synaptic transmission (Lai et al., 2009).

Testing for anti-AMPA is by screening with indirect immunofluorescence for IgG reactivity to cultured cells expressing the GluR1 and GluR2 subunits of the receptor.

Anti-GABA-B-R

The γ -amino-butyric acid receptor B is a metabotropic GABA receptor that can exert both pre- and post-synaptic inhibitory effects. In particular, autoantibodies to the extracellular domain of the B1 subunit are found in patients with encephalitis, especially encephalitis with severe seizures or status epilepticus (Lancaster et al., 2010). The receptors consist of two subunits, a B1 subunit

important for GABA binding, and a B2 subunit important for effecting inhibition (Bettler et al., 2004). Small cell lung cancer is found in about half of the patients; in fact, GABA-B-R may be the most common type of synaptic autoantibody in patients with this tumor type (Boronat et al., 2011). The clinical improvement of some patients with tumor- and/or immune-therapy supports a functional effect of the antibodies.

Testing for anti-GABA-B-R is carried out by screening with indirect immunofluorescence for IgG reactivity to cultured cells expressing the GABA-B1 subunit of the receptor.

Group 1 Metabotropic Glutamate Receptors (mGluR1, mGluR5)

These receptors are closely homologous (85% by amino acid structure) but serve distinct functions: mGluR1 is critical for rapid synaptic transmission in the cerebellum, whereas mGluR5 is more important for synaptic plasticity in the hippocampus, for learning, and for memory (Ichise et al., 2000; Faas et al., 2002). Autoantibodies to mGluR1 have been reported in four patients with cerebellitis, two having Hodgkin's lymphoma (HL) (Sillevis Smitt et al., 2000; Coesmans et al., 2003; Marignier et al., 2010; Lancaster et al., 2011a). These antibodies have demonstratively functional effects on neurons. Interestingly, neoplastic HL cells are not thought to express mGluR1, but may rather trigger the disease by causing dysregulation of the immune system. mGluR1 antibodies may be directly pathogenic, since injection of mGluR1 antibodies near the cerebellum of rodents induces reversible ataxia, and mGluR1 antibodies partially attenuated long-term depression (LTD) in cerebellar slices (Coesmans et al., 2003).

Antibodies to mGluR5 have been found in two patients with Ophelia syndrome, a form of encephalitis associated with Hodgkin's lymphoma that improves rapidly with tumor treatment (Lancaster et al., 2011a). Despite the close homology between these two antigens, the autoimmune syndromes are clinically and immunologically distinct—and the antibodies do not cross-react. These two rare disorders raise the distinct possibility that there are other synaptic proteins and receptors that are autoantigenic causes of presently uncharacterized syndromes.

Testing for mGluR1 and mGluR5 antibodies is done by screening with indirect immunofluorescence for IgG reactivity to cultured cells expressing the respective receptors.

Glycine Receptor (GlyR)

GlyR is the major inhibitory ionotropic receptor in the brainstem and spinal cord, and consists of five units (α 1–4, β) (Hernandes and Troncone, 2009). Pharmacologic inhibition of the GlyR with strychnine results in painful and debilitating muscle spasms, and

pathologically exaggerated startle responses, but preserved consciousness. Genetic mutations of GlyR are found in patients with hereditary hyperekplexia (human startle disease) (Harvey et al., 2008). Autoantibodies to the $\alpha 1$ subunit of the GlyR were first reported in a patient with progressive encephalitis with myoclonus and rigidity (PERM), a disorder characterized by muscle spasms, stiffness, and exaggerated startle responses (Hutchinson et al., 2008); subsequently, similar patients were identified (Mas et al., 2011; Piotrowicz et al., 2011). Thereafter a series of patients with stiff person syndrome and its variants associated with anti-GlyR antibodies, to the $\alpha 1$ subunit and other subunits as well, has been reported (McKeon, 2012). This disorder is not known to be cancer associated, and sometimes responds to immunotherapy. The resemblance of the autoimmune syndrome to effects of pharmacological and genetic disruption of the receptor suggests a functional effect of the antibodies. Testing for these glycine receptor antibodies is performed by screening with indirect immunofluorescence for IgG reactivity to cultured cells expressing the receptor subunits.

Voltage-Gated Potassium Channel Complex (VGKC)

The VGKC contained Kv1.1/Kv1.2, “Kv1,” and regulates, voltage-gated potassium channels, and thus the excitability of neurons, shaping action potential discharge and synaptic transmission, and controlling axonal excitability (Robbins and Tempel, 2012). Kv1 channels are homo- or hetero meric tetramers of α subunits, along with four associated β subunits, allowing for functional diversity. Antibodies to the VGKC complex were first detected in patients with Isaacs’ syndrome, an autoimmune disorder of acquired peripheral nerve hyperexcitability (Hart et al., 1997). Patients with Isaacs’ syndrome have the subacute onset of muscle twitching, cramps, and stiffness, sometimes accompanied by hyperhidrosis, and electrodiagnostic testing showed abnormal spontaneous action potential discharges originating from peripheral nerve axons (Isaacs, 1961, 1967). Some patients were found to have thymomas and some responded to plasmapheresis, suggesting an antibody-mediated pathogenesis (Sinha et al., 1991; Shillito et al., 1995). Due to the resemblance of Isaacs’ syndrome to poisoning with the Kv1 toxin α -dendrotoxin, it seemed plausible that patients might have autoantibodies to the VGKC complex. A test for VGKC complex antibodies was therefore designed based on the ability of patients’ IgG to immunoprecipitate Kv1 channels labeled with ^{125}I - α -dendrotoxin. Over the last 15 years hundreds of patients have been reported with these antibodies (Apiwattanakul et al., 2010; Irani et al., 2010). These patients may have peripheral nerve

hyperexcitability, encephalitis, or both encephalitis and peripheral nerve hyperexcitability (Morvan’s syndrome) (Tan et al., 2008). Several other less common clinical accompaniments, such as unexplained epilepsy and pain syndromes, have also been reported.

While the autoantibodies were initially thought to directly target Kv1 subunits (Kleopa et al., 2006), recent work has shown that other members of the VGKC complex are actually the primary autoantigens, such as leucine-rich glioma-inactivated 1 (LGI1) and contactin-associated protein-like 2 (Caspr2) (Irani et al., 2010; Lai et al., 2010). A small fraction of those with anti-VGKC may have autoantibodies that directly target Kv1 subunits. Another small group of patients have antibodies reactive with contactin-2 but, since many also have antibodies to LGI1 or Caspr2, the clinical significance of this finding is uncertain (Irani et al., 2010). It should be noted that in a considerable fraction of cases with antibodies to the VGKC complex, particularly those with solely peripheral nervous system manifestations, the target autoantigens are unknown. Since the ^{125}I - α -dendrotoxin assay detects most, but not all, patients with LGI1 and Caspr2 antibodies, it is often used as a screening test. Specific detection of LGI1 or Caspr2 antibodies is done with indirect immunofluorescence of sera or CSF against cells transfected to express the proteins.

LGI1

This is a secreted protein that binds to pre- and post-synaptic proteins at CNS synapses (Fukata et al., 2010). LGI1 interacts with presynaptic Kv1 channels via the transmembrane protein ADAM23, and also with post-synaptic AMPA receptors via the transmembrane protein ADAM22 (Fukata et al., 2006; Sagane et al., 2008). Genetic mutations of LGI1 in humans account for a relatively common form of inherited epilepsy known as autosomal dominant lateral temporal lobe epilepsy or autosomal dominant partial epilepsy with auditory features (Gu et al., 2002; Kalachikov et al., 2002; Morante-Redolat et al., 2002). Animals with genetic deletion of LGI1 die of intractable seizures about 10–14 days after birth (Yu et al., 2010). Patients with anti-LGI1 have encephalitis without peripheral nerve manifestations, consistent with the CNS expression pattern of LGI1 (Irani et al., 2010; Lai et al., 2010). Some patients may have prominent myoclonus and cognitive impairment, and there may be an initial clinical suspicion of Creutzfeldt–Jakob disease (Geschwind et al., 2008). Most patients improve with treatment and outcomes are relatively good. There are no strong associations with cancer in these patients. It is unknown how antibodies to LGI1 cause disease. LGI1 associates with Kv1 channels, explaining the positive ^{125}I - α -dendrotoxin assay results, but it also associates with other synaptic proteins such as

AMPA receptors. Therefore, while anti-LGI1 may well disrupt the VGKC complex, other equally plausible mechanisms are proposed (Lancaster and Dalmau, 2012).

Caspr2

Caspr2 is a transmembrane protein expressed on CNS and PNS axons (Poliak et al., 1999). Caspr2 is critical for concentrating Kv1 potassium channels at the juxtaparanodes of myelinated axons, although the precise mechanism by which this is accomplished is unknown (Traka et al., 2003; Horresh et al., 2010). Genetic mutations in the human gene encoding Caspr2, *CNTNAP2*, have been associated with epilepsy, autism and other intellectual disabilities, and defective neuronal migration (Verkerk et al., 2003; Arking et al., 2008; Gregor et al., 2011; Penagarikano et al., 2011; Whalley et al., 2011). Patients with anti-Caspr2 may have encephalitis or peripheral nerve hyperexcitability or both (Irani et al., 2010; Lancaster et al., 2011b). The symptoms may occur in either order, potentially months or years apart. Some patients with anti-Caspr2 have thymoma and/or myasthenia gravis, but most do not have any tumor. Outcomes are relatively good; most patients improve with immunotherapy although relapses occur.

PCA-Tr

Autoantibodies to PCA-Tr (Tr antibodies) are associated with paraneoplastic cerebellar degeneration (PCD) in the setting of Hodgkin's lymphoma (HL), or more rarely non-Hodgkin's lymphoma (Bernal et al., 2003). Anti-PCA-Tr are probably rarer than either Yo or Hu antibodies among patients with PCD (see below), but are more common than mGluR1 antibodies (Shams'ili et al., 2003). Anti-PCD-Tr react with cerebellar Purkinje cells, and were initially defined by their fine granular staining of these neurons (Graus et al., 1997). Recent work has shown the Delta/notch-like epidermal growth factor-related receptor (DNER) to be the actual autoantigen (de Graaff et al., 2012), but the precise mechanisms of pathogenesis are unknown. Since the antibodies react with surface epitopes of the DNER on living neurons, an antibody-mediated mechanism is possible. However, pathological studies from these patients typically show a permanent loss of cerebellar neurons and patients often respond poorly to immunotherapy (Bernal et al., 2003). These findings suggest cytotoxic effects of either the antibodies or a coexisting T cell-mediated response.

While testing for anti-Tr initially involved recognizing a pattern of reactivity with cerebellar neurons, screening with indirect immunofluorescence for IgG reactivity to cultured cells expressing the DNER is more specific for this disorder.

CNS DISEASES WITH AUTOANTIBODIES TO INTRACELLULAR ANTIGENS

GAD65

The 65 kd isoform of glutamic carboxylase (GAD) is the autoantigen for prevalent autoantibodies associated with stiff person syndrome (SPS) and cerebellar ataxia, and, more rarely, other syndromes such as encephalitis and epilepsy (Meinck et al., 2001; Pittock et al., 2006). Anti-GAD65 is characteristically associated with type 1 diabetes (Baekkeskov et al., 1990). Along with the GAD67 isoform (which is not intrinsically autoantigenic), GAD65 is one of two enzyme isoforms of the GAD enzyme that neurons use to synthesize GABA. GAD65 is concentrated in presynaptic terminals and is important for maintaining GABA-ergic transmissions during sustained neuronal activity (Soghomonian and Martin, 1998; Tian et al., 1999; Fenalti et al., 2007). Anti-GAD65 B cell and T cell immune responses predominantly target the COOH terminal of the enzyme (Fenalti et al., 2008), and the target epitopes differ in patients with SPS from those in patients with type 1 diabetes (Ali et al., 2011).

Anti-GAD65 are very weakly associated with thymoma, but most patients do not have any malignancy (Vernino and Lennon, 2004; McKeon et al., 2012, 2013) and anti-GAD65 are frequently found in patients with other neuronal autoantibodies, perhaps explaining some of the diversity of symptoms in these patients (Pittock et al., 2005; Lai et al., 2009; Lancaster et al., 2010). Anti-GAD65 interfere with GABA synthesis in tissue extracts and affect GABA-ergic transmission when applied to tissue slices (Dinkel et al., 1998; Ishida et al., 1999, 2008), and also are reported to cause abnormal spontaneous electrical discharges in spinal motor neurons (Manto et al., 2007, 2011). It is not clear whether these antibody-mediated effects *in vitro* are relevant *in vivo*.

The presence of anti-GAD65 may signify a T cell-mediated pathophysiological mechanism. Immunization of mice with GAD65 produced T cells that react to GAD65 (Burton et al., 2008, 2010), and such mice developed encephalomyelitis; retrogenic transfer of these T cells to naïve mice also produced encephalomyelitis. Transfer to mice that lacked B cells produced identical findings, substantiating a T cell-mediated effect. While mice with intact B cells developed anti-GAD65, these did not influence the encephalomyelitis.

Amphiphysin I

Amphiphysin I is a reactant for autoantibodies found in patients with stiff-person syndrome, encephalitis and certain other syndromes. Some 90% of patients with anti-amphiphysin I have breast cancer, although

adenocarcinoma has also been reported (Dropcho, 1996). Compared to patients with stiff person syndrome and anti-GAD65 antibodies, those with anti-amphiphysin I tend to be older and female, have prominent cervical stiffness, are responsive to benzodiazepine therapy, and show abnormal spontaneous activity on EMG (Murinson and Guarnaccia, 2008). Amphiphysins are proteins of the BAR superfamily required for regulating membrane curvature, particularly of clathrin-coated synaptic vesicles (Zhang and Zelhof, 2002; Wu et al., 2009). Amphiphysin I is strongly expressed in brain, and genetic deletion of amphiphysin I in mice results in seizures and cognitive deficits, findings that may be influenced by indirect effects on amphiphysin II in this animal model (Di Paolo et al., 2002). Anti-amphiphysin I are reported to cause direct effects on neurons. Transferred patient antibodies, or selectively purified patient-derived antibodies to amphiphysin I, cause stiffness in mice (Sommer et al., 2005; Geis et al., 2009, 2010), but these studies were from samples from only two patients and, in the case of non-purified antibodies, could be confounded by other coexisting autoantibodies. A post-mortem study of a patient who died of brainstem encephalitis associated with anti-amphiphysin I showed an intense CD8⁺ predominant T lymphocytic infiltrate, along with neuronal loss, and perivascular lymphocytic cuffs in affected brainstem areas (Wessig et al., 2003). Pathological studies of another patient also showed CD8⁺ T cell infiltrates in the brainstem, spinal cord, and dorsal root ganglia (Pittock et al., 2005). Thus a T cell-dependent disease process is likely.

Neuronal Nuclear Antigens (NNA)

Autoantibodies to NNA (ANNA 1-3) have acquired a dual terminology. In the earlier days of autoimmunity, antigens for newly discovered autoantibodies were identified by the initial letters of the donor patient's surname (e.g., Sm for the lupus autoantigen from patient Smith), and hence the derivation of the neuronal nuclear antigens *Hu* and *Ri*. Autoantibodies to neuronal nuclear antigens ANNA-1 and ANNA-2 correspond to anti-Hu and anti-Ri, respectively. These autoantibody reactivities are observed mostly in paraneoplastic diseases.

ANNA-1/anti-Hu

These are associated with subacute neuropathy, cerebellitis, encephalitis, and autonomic dysfunction (Dalmau et al., 1992; Lucchinetti et al., 1998; Graus et al., 2001), with many of the patients having small-cell lung cancer. Mortality is high (20% three-year survival) due to the serious underlying malignancy and poor responses of the neurological symptoms to treatment. react with HuD (embryonic lethal abnormal vision-like 4, ELAVL4) and

three related RNA-binding proteins, HuC, Hel-N1, and Hel-N2 (Dalmau et al., 1990; Szabo et al., 1991; King and Dropcho, 1996). HuD is expressed in neurons and neuroendocrine tumor cells, and is important for cell-cycle regulation and neuronal development (Okano and Darnell, 1997; Hubers et al., 2011). Several lines of evidence suggest that ANNA-1/anti-Hu are not directly pathogenic, being found in many patients with malignancy but without neurological symptoms (Darnell and Posner, 2003), failing when injected into animals to recapitulate neurological symptoms (Sillevis Smitt et al., 1995), and failing to induce any CNS disorder using antibodies to Hu raised by immunization of rodents (Sillevis Smitt et al., 1996; Carpentier et al., 1998). Pathological studies point more to T cell responses to neurons as the disease mechanism (Wanschitz et al., 1997; Plonquet et al., 2002; Rousseau et al., 2005).

ANNA-2 (anti-Ri)

These are associated with cerebellar degeneration, opsoclonus–myoclonus, encephalitis, myelitis, or other CNS disorders. Patients have small-cell lung cancer or breast cancer (Pittock et al., 2003; Shams'ili et al., 2003) and ANNA-2, like ANNA-1, may be found in cancer patients without neurological symptoms (Drlicek et al., 1997). ANNA-2/anti-Ri react with Nova-1, an RNA-binding protein expressed by various subcortical neurons (Buckanovich et al., 1993). While ANNA-2 block the binding of Nova-1 to RNA *in vitro*, it is unknown how relevant this might be *in vivo* (Buckanovich and Darnell, 1997).

ANNA-3

These are associated with diverse neurological phenotypes including neuropathy, myelopathy, ataxia, and brain stem and limbic encephalopathy, and are detected in patients with lung cancer (Chan et al., 2001). The autoantigen is an unidentified and functionally unknown 170 kDa protein expressed by nuclei of Purkinje and granular neurons, enteric neurons, and small-cell lung cancer cells.

Ma1/Ma2 (Ma and Ta)

These autoantigens are reactants for the closely related Ma and Ta antibodies; Ma antibodies target the onconeural proteins PNMA-1 (paraneoplastic Ma antigen-1; the Ma1 response) and PNMA-2 (paraneoplastic Ma antigen-2; the Ma2 response); also, anti-Ta react with PNMA-2 (Graus et al., 2004). Patients with anti-Ma most often have limbic encephalitis, but cerebellitis, brainstem encephalitis, and polyneuropathy have also been described (Rosenfeld et al., 2001; Hoffmann et al., 2008). Anti-Ma1 are strongly associated with cancer, but many different tumor types have been reported, and response to

therapy is poor. Anti-Ma2 are usually detected in young men with germ cell tumors, among whom outcome is more favorable (Dalmau et al., 2004).

There are four known PNMA proteins and these are expressed by brain, testes, and other tissues (Schuller et al., 2005). PNMA-1 is a pro-apoptotic protein in developing brain, and increased PNMA-1 expression has been proposed to contribute to neurodegenerative diseases (Chen and D’Mello, 2010). In a rat model of PNMA-1 immunity, immunization with PNMA-1 elicited specific CD4⁺ T cells and an antibody response to PNMA-1, and transfer of T cells to naïve rats resulted in a CNS inflammatory response but no neurological symptoms (Pellkofer et al., 2004); thus a PNMA-1 antibody response was generated but not associated with neurological findings. These studies suggest that a T cell rather than a direct antibody response may be more relevant, and that a strong immune tolerance to PNMA proteins must be overcome for disease to occur.

Purkinje Cell Antigen-1 (PCA-1; Yo)

This is the reactant for anti-Purkinje cell antibodies (APSA, anti-Yo) that are associated with paraneoplastic cerebellar degeneration (PCD) in women. Patients typically have limb and truncal ataxia, nystagmus, and dysarthria, resulting in significant disability within a few months of diagnosis. Less often they have rigidity, spasticity, cognitive impairment, or emotional dysregulation. Almost all patients are eventually diagnosed with breast or gynecological cancer (Peterson et al., 1992). These tumors often respond to treatment, but the neurological symptoms less so (Rojas et al., 2000).

Anti-PCA-1 were initially defined by their reactivity with the cytoplasm of Purkinje cells (Greenlee and Brashear, 1983). The minor and major target antigens are two unrelated proteins of 34 kDa and 62 kDa, cerebellar degeneration related-34 (CDR34; CDR1; OMIM 302650), and cerebellar degeneration related-62 (CDR62; CDR2; OMIM 117340), respectively (Fathallah-Shaykh et al., 1991; Dropcho, 1996). CDR1 is a neuroectodermal protein, strongly expressed in Purkinje cells, with a unique tandem hexapeptide repeat structure and unknown function (Furneaux et al., 1989; Chen et al., 1990). CDR2 has a leucine zipper motif and may be involved in cell-cycle regulation, mitosis, and transcriptional regulation (Okano et al., 1999; O’Donovan et al., 2010). Tumor tissues express the target antigens (Peterson et al., 1992), and CDR2-selective T cells kill tumor cells *in vitro* (Santomasso et al., 2007), but the immune response seems ineffective for control of tumors *in vivo* (Rojas et al., 2000; Mathew et al., 2006). CDR2 is expressed in all ovarian tumors and normal ovary, with no apparent differences in expression of CDR2 in cancer patients with or without anti-PCA-1 (Totland et al., 2011). Post-mortem studies have

shown T cell infiltration of the cerebellum with extensive loss of Purkinje cells, but no deposits of IgG or complement, or B cell infiltrates (Giometto et al., 1997; Storstein et al., 2009). Despite the lack of B cell infiltrates, there is evidence of intrathecal antibody synthesis, which is important for establishing CNS antibody titers (Peterson et al., 1992; Stich and Rauer, 2007). T cell infiltrates have also been described in tumors of patients with anti-PCA-1. Interestingly, patients with PCA-1 antibodies and related disorders may have lower levels of regulatory T lymphocytes, suggestive of T cell dysregulation (Tani et al., 2008). Two reports have described cytotoxic T cell responses to CDR2 in patients with anti-PCA-1 (Albert et al., 1998, 2000), but others find that most patients do not have such cytotoxic T lymphocyte responses (Sutton et al., 2004), leaving it unclear what antigen in brain is actually targeted. When DNA immunization was used to induce CDR2 reactive T cells and antibodies in mice, the T cells killed antigen-expressing cells *in vitro*, but the animals remained asymptomatic (Sakai et al., 2001). A direct toxic effect of the antibodies has been proposed. Anti-PCA-1 are taken up by cerebellar neurons in slice culture and induce cell death, in contrast to normal IgG which does enter the Purkinje cell cytoplasm but is cleared without toxicity (Greenlee et al., 2010). Similarly, anti-PCA-1 injected into guinea pigs intraventricularly, or intraperitoneally with blood–brain barrier disruption into rats, are taken up by Purkinje cells, but have not been shown to cause neuronal death *in vivo* (Graus et al., 1991; Greenlee et al., 1995).

PCA-2

PCA-2 is an antigen for autoantibodies that are strongly associated with lung cancer, and with neurological presentations that include encephalitis, cerebellitis, neuropathy, and Lambert–Eaton myasthenic syndrome (Vernino and Lennon, 2000). Anti-PCA-2 are defined by a characteristic pattern of Purkinje cell staining, involving the soma and dendrites. The antigen is an unidentified 280 kDa protein. Anti-PCA-2 are frequently encountered together with other co-morbid antibodies, and it is unknown how the antibodies relate to the pathophysiology of the disorders (Lennon et al., 2004).

CONCLUSIONS AND FUTURE PROSPECTS

The field of autoimmune CNS disorders is rapidly evolving and touches on many aspects of neurology and neuroscience. The autoimmune disorders targeting synaptic proteins provide interesting insights into the effects of disrupting key neurotransmitter receptors in the adult nervous system. Vague descriptive diagnoses of unclear pathophysiology, such as encephalitis lethargica, are gradually being replaced by disorders defined by specific autoantibodies, such as anti-NMDAR encephalitis. Recognition of these disorders may lead to the search for

specific tumors, and should prompt tumor and/or immunotherapy since, with appropriate treatment, even profoundly ill patients can recover. With some of these disorders, the autoantibodies are directly pathogenic and in others they mark a specific T cell response. The antibody tests are generally very helpful for confirming a specific diagnosis, but in some patients with multiple autoantibodies, it can be difficult to determine which immune response is causing disease. Thus, future research should focus not just on detection of the various autoantibodies, but also on the pathophysiology of the accompanying disorders, and on mechanisms for clearly differentiating incidental findings from pathological responses. This should lead to more informative diagnostic testing, precisely targeted therapies, and better outcomes. For immunology in general, it seems not too much to expect that insights from these strange paraneoplastic disorders will enlighten us on maintenance of self-tolerance and evasion of autoimmunity.

ACKNOWLEDGMENTS

I would like to thank my mentors, Dr. Josep Dalmau, Dr. Steven S. Scherer, and Dr. Rita Balice-Gordon. I am grateful to Dr. Vanda Lennon, who suggested I write this chapter. I also thank the National Institutes of Health (NIH), National Organization for Rare Disorders (NORD), and the Dana Foundation for their generous support.

ABBREVIATIONS

| | |
|------------------------|---|
| AMPAR | 2-amino-3-(5-methyl-3-oxo-1,2-oxazol-4-yl) propanoic acid receptor |
| ANNA-1 (-2, -3) | autoantibodies to neuronal nuclear antigens -1 (-2, -3) |
| AQP4 | aquaporin-4 |
| Caspr2 | contactin-associated protein-like 2 |
| DNER | delta/notch-like epidermal growth factor-related receptor |
| GABA-B-R | γ -amino-butyric acid receptor B |
| Kv1 | voltage-gated potassium channels containing Kv1.1 and/or Kv1.2 subunits |
| LGII | leucine-rich, glioma inactivated 1 |
| NMDAR | N-methyl-d-aspartate receptor |
| PCA | Purkinje cell antibodies |
| SPS | stiff person syndrome |
| VGCC | voltage-gated calcium channel |
| VGKC | voltage-gated potassium channel |

| Ion Channel Antibodies | 843 | References | 848 |

INTRODUCTION

The term paraneoplastic describes syndromes caused by cancer, but not as a direct result of invasion or infiltration of the target organ or tissue by the primary tumor or its metastases. Paraneoplastic syndromes have several different causes, only some of which are fully understood (Table 58.1). An autoimmune reaction to the tumor that secondarily affects the nervous system is one mechanism, and that is the focus of this chapter. A more comprehensive review can be found in a recently published monograph (Darnell and Posner, 2011).

Paraneoplastic disorders can affect any part of the nervous system (Box 58.1). The syndrome may cause destruction of a single cell type, such as the Purkinje cell of the cerebellum (paraneoplastic cerebellar degeneration, PCD), a single area of the nervous system such as the medial

temporal lobes (limbic encephalopathy, LE), or multiple areas of the nervous system simultaneously (carcinomatous encephalomyeloradiculopathy). In some instances, the disorder targets a specific receptor such as the NMDA receptor on the cell surface of hippocampal neurons causing limbic encephalitis, or the presynaptic voltage-gated calcium channel causing the Lambert–Eaton myasthenic syndrome (LEMS).

Paraneoplastic neurologic syndromes can be categorized as classical or non-classical (Box 58.1). Classical syndromes are those so commonly associated with cancer that they demand a rigorous evaluation for an underlying neoplasm. Non-classical syndromes can also be associated with malignancy, but are more likely to occur in patients without cancer. Despite this distinction, classical paraneoplastic syndromes are sometimes found in patients without cancer. In a

TABLE 58.1 Pathogenesis of Paraneoplastic Syndromes

| Pathogenesis | Example(s) | Neurologic Symptoms |
|--|-------------------------------|--|
| Ectopic secretion of ectopic substance(s) by the tumor | ACTH ADH | Cushing syndrome (myopathy, psychosis) SIADH (seizures) |
| Destruction of non-nervous system organs | Liver Bone (hypercalcemia) | Hepatic encephalopathy Muscle weakness, delirium |
| Immunosuppression | Sepsis, meningitis | Seizures, headache |
| Exosome secretion | Hypercoagulability | Stroke |
| Anorexia | Vitamin deficiency | Wernicke encephalopathy |
| Cytokine secretion | Interleukin-6 | Cachexia, weakness |
| Immune response to tumor | PCD, LE | Refer to text below |

ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone; SIADH, syndrome of inappropriate antidiuretic hormone secretion; PCD, paraneoplastic cerebellar degeneration; LE, limbic encephalopathy.

few instances, an identifiable cancer has regressed or even disappeared with the emergence of a paraneoplastic syndrome (Byrne et al., 1997).

PATHOGENESIS

Although the syndromes discussed in this chapter are considered to be the result of an immune response to a cancer, the exact pathogenesis is not yet fully understood. The most straightforward explanation is that an antigen normally restricted to the nervous system (or sometimes the testes, also an immunologically privileged site) is ectopically expressed in a tumor. The antigen present in the tumor is structurally identical to that found in the nervous system, but is recognized by the immune system as “foreign” (Schreiber and Rowley, 2008). The antigen expressed by the tumor triggers an immune response and the result is two-fold. Structures in the nervous system containing the antigen are damaged or destroyed causing neurological signs and symptoms. The same immune response may slow the growth of the tumor or sometimes even cause regression. For this reason, in up to three-quarters of patients, the

FIGURE 58.1 Five years after he developed an anti-Hu limbic encephalitis, this man underwent a temporal lobe resection for the treatment of intractable seizures. The surgery was successful. The surgical material was assayed for the presence of IgG within the brain. (A) Section of the lateral temporal cortex. There is no evidence of IgG within the brain, but there is ample staining within small blood vessels. (B) Section of the parahippocampus. IgG is seen decorating the brain parenchyma as well as most neurons, sparing the glia. The neurons do not appear to be degenerating. Photos courtesy of Dr. Mark Rosenblum.

neurologic signs appear when the tumor is small or even undetectable.

In a few paraneoplastic syndromes such as LEMS, well-characterized animal models implicate B cells (antibodies) as the major culprit. The same is probably true for anti-NMDA receptor encephalopathy (Dalmat et al., 2011) and stiff person syndrome, for which there is also an animal model (Hansen et al., 2013). However, the underlying mechanism for most syndromes, particularly those involving the brain, remains to be elucidated. The primary question is whether those syndromes are mediated by T cells (the majority opinion), B cells, or both. T cells are thought to play a major role when the antigen triggering the paraneoplastic syndrome is intracellular, whereas B cells may be more important when the antigen is on the surface and accessible to antibodies. In some reports, IgG has been detected in the brains and even within the affected neurons of patients with paraneoplastic syndromes (Graus et al., 2004) (Figure 58.1). However, others have been skeptical.

DIAGNOSIS

The diagnosis of a paraneoplastic syndrome can only be unequivocally established if an antibody is detected in the serum of a patient, and it is then found to react with both the affected portion of the nervous system and the cells of a neoplasm identified in the same patient. In the absence of this type of clear-cut evidence, one may refer to a set of diagnostic criteria that has been established to assist the clinician (Graus et al., 2004) (Box 58.2).

Box 58.2 Diagnostic Criteria for Paraneoplastic Neurologic Syndromes

Definite paraneoplastic neurologic syndromes

1. A classical syndrome and cancer that develops within 5 years of the diagnosis of the neurological disorder
2. A nonclassical syndrome that resolves or significantly improves after cancer treatment without concomitant immunotherapy, provided that the syndrome is not susceptible to spontaneous remission
3. A nonclassical syndrome with onconeural antibodies (well characterized or not) and cancer that develops within 5 years of diagnosis of the neurological disorder
4. A neurological syndrome (classical or not) with well-characterized onconeural antibodies (anti-Hu, Yo, CV2, Ri, Ma-2, or amphiphysin), and no cancer

Possible paraneoplastic neurologic syndromes

1. A classical syndrome, no onconeural antibodies, no cancer but at high risk to have an underlying cancer
2. A neurological syndrome (classical or not) with partially characterized onconeural antibodies and no cancer
3. A nonclassical syndrome, no onconeural antibodies, and cancer present within 2 years of diagnosis

From Graus et al. (2004), with permission.

Characteristics which should lead the clinician to suspect a paraneoplastic syndrome in a patient with neurologic signs and symptoms include the following:

1. Most paraneoplastic syndromes begin quickly and follow a subacute course, progressing over several days to weeks or months and then stabilizing. Occasionally a

- patient develops a severe neurologic disability overnight.
- Most paraneoplastic syndromes cause severe neurologic disability. Mild sensory symptoms and nonspecific imbalance are likely due to other causes. Many cancer patients present with minor neurologic symptomatology which may or may not be paraneoplastic (Erlington et al., 1991).
 - In patients with a paraneoplastic syndrome involving the central nervous system (CNS), cerebrospinal fluid (CSF) often reveals a lymphocytic pleocytosis (typically 20–100). Protein concentration may be increased, with elevated gamma globulin and oligoclonal bands. The latter may represent paraneoplastic antibody IgG (Stich and Rauer, 2007). The inflammatory infiltrate, if present, typically disappears after several weeks.
 - As indicated in Box 58.1, almost any constellation of neurologic symptoms can occur in patients with a paraneoplastic syndrome. However, one should be most suspicious in patients who present with a clinical syndrome affecting a specific portion of the nervous system such as the cerebellar Purkinje cell, the dorsal root ganglion, or the cholinergic synapse. Widespread nervous system damage, e.g., encephalomyelitis, is less specific.
 - A physical examination with careful attention to lymph nodes, breasts, prostate, and testes may reveal signs of an underlying malignancy that was previously unsuspected.

ANTIBODIES

Measurement of paraneoplastic antibodies in the serum is the most important diagnostic test. In addition to its value in establishing the diagnosis of a paraneoplastic syndrome, the antibody identified may reveal the likely underlying tumor. However, it is important to remember that not all paraneoplastic syndromes are antibody positive. For example, opsoclonus–myoclonus syndrome associated with neuroblastoma is clearly the result of an autoimmune process, yet a specific antibody has never been identified in the serum of affected children (Bolognani et al., 2007). Conversely, not all patients with serum antibodies have a paraneoplastic syndrome. This is illustrated by LEMS and myasthenia gravis in which the same antibodies (voltage-gated calcium channel and acetylcholine receptor, respectively) are found in patients with and without an underlying malignancy. In addition, low titers of paraneoplastic antibodies may be found in patients with cancer but without neurological symptoms (Tanner et al., 2008). Table 58.2 lists many of the serum antibodies found in paraneoplastic syndromes and the

malignancies with which they are typically associated. More common syndromes are discussed in the text that follows.

It is usually not necessary to measure paraneoplastic antibodies in the CSF. However, there are instances in which CSF testing is positive while serum levels are very low or undetectable (Tora et al., 1997; Graus et al., 2001; Fornaro et al., 2007). Higher activity of antibody in the CSF relative to serum indicates intrathecal antibody synthesis (Graus et al., 1997; Lucchinetti et al., 1998; Jarius et al., 2008a,b).

Paraneoplastic antibodies can be divided into two large groups (Stich et al., 2009). Group 1 consists of intracellular antigens, either cytoplasmic or nuclear, while Group 2 is composed of antibodies directed against antigens on the surface of the neuron or at its synapses. This classification also effectively divides the antibodies based upon likelihood of treatment response and probable pathogenesis. In Group 2, the antibodies are probably causal and these disorders typically respond to treatment. For disorders resulting from Group 1 antibodies, in which pathogenesis may be T cell mediated, treatment response is usually poor.

Some have further subdivided these broad groups (Budde-Steffen et al., 1988). Group 1A consists of antigens that are usually paraneoplastic; Group 1B consists of intracellular antigens that are cancer specific, but not specific to a paraneoplastic syndrome; Group 1C is composed of intracellular antigens associated with autoimmune disorders of the nervous system that are only sometimes paraneoplastic. Group 2A consists of surface antigens associated with autoimmune CNS syndromes which are only sometimes paraneoplastic and Group 2B is composed of surface antigens associated with paraneoplastic disorders.

Of note, the nomenclature of paraneoplastic antibodies has varied over time. Prior to formal identification, the Memorial Sloan-Kettering group named the antibodies after the first two letters of the last name of the index patient (e.g., Anti-Yo). However, the Mayo Clinic group named the same antibodies after the clinical syndrome (e.g., PCD1—anti-paraneoplastic cerebellar degeneration 1). Once characterized, the name changed to that of the antigen (e.g., VGCC—anti-voltage-gated calcium channel).

Nuclear/Nucleolar Antibodies

Anti-Hu (ANNA1)

The anti-Hu antibody reacts with the nuclei and, to a lesser extent, the cytoplasm of all neurons in both the central and peripheral nervous systems (Figure 58.2A). This antibody identifies a family of proteins of approximately 37 kDa, of

TABLE 58.2 Selected Paraneoplastic Antibodies and the Cancers and Neurologic Syndromes with which they are Associated

| Antibody | Cancer | Neurologic disorder |
|-------------------------|------------------------------------|---|
| Anti-Hu (-1*) | SCLC, neuroblastoma, prostate | PEM, PSN, autonomic dysfunction |
| Anti-Yo (PCA-1*) | Ovary, breast, lung | PCD |
| Anti-Ri (ANNA-2*) | Breast, gynecologic, lung, bladder | Ataxia/opsoclonus, brainstem encephalitis |
| Anti-CRMP5 (anti-CV2*) | SCLC, thymoma | PEM, PCD, chorea, optic/sensory neuropathy |
| Anti-Ma2 | Testis | Limbic, brainstem (diencephalic) encephalitis |
| Anti-amphiphysin | Breast, SCLC | SPS |
| Anti-Sox (AGNA-1*) | SCLC | LEMS |
| Anti-Tr (PCA-Tr*) | Hodgkin | PCD |

*Nomenclature used at the Mayo Clinic laboratory (based upon immunohistochemistry staining patterns).

CAR, cancer-associated retinopathy; LE, limbic encephalopathy; LEMS, Lambert–Eaton myasthenic syndrome; MAR, melanoma-associated retinopathy; MG, myasthenia gravis; PCD, paraneoplastic cerebellar degeneration; PEM, paraneoplastic encephalomyelitis; PERM, progressive encephalomyelitis, rigidity and myoclonus; PSN, paraneoplastic sensory neuropathy; SPS, stiff person syndrome.

which the most relevant in paraneoplastic syndromes is a neuron-specific protein designated HuD. The exact function of the Hu protein has not been definitively established. They bind to AU-rich elements of several different mRNAs *in vitro* and are believed to be important in the development and maintenance of neurons (Bolognani et al., 2007; Tanner et al., 2008; Perrone-Bizzozero and Bird, 2013). Electron microscopic studies have identified the protein at the site of nuclear pores, within layers of the Golgi apparatus and within the mitochondria (Fornaro et al., 2007). The antigen also has been reported to be expressed on the surface

membranes of small cell lung cancer (SCLC) and neuroblastoma cells in tissue culture (Tora et al., 1997).

Although the antibody is associated with a wide variety of neurological symptoms (Lucchinetti et al., 1998; Graus et al., 2001), the two most common findings are subacute sensory neuropathy and limbic encephalitis. The most frequently associated malignancy is SCLC. The antigen is expressed in all SCLC tumors and in many other neuroendocrine tumors. Once the symptoms have become relatively severe, the prognosis for neurologic recovery is poor despite treatment. However, low titer antibodies are

FIGURE 58.2 Several paraneoplastic antibodies reacted with sections of cerebellum. (A) Anti-Hu antibody. There is intense staining of the nuclei of all of the cells in the Purkinje, molecular and granule cell layer. All neurons in both central and peripheral nervous system react the same. (B) Anti-Ri antibody. The reaction predominantly with the nuclei of neurons is the same as with anti-Hu. The difference is that the anti-Ri antibody does not react with neurons in the peripheral nervous system. (C) Anti-Yo antibody. The reaction is with the cytoplasmic Purkinje cells. Other cells in the cerebellum are spared. (D) Anti-Tr antibody. The Purkinje cell reaction is similar but reaction product is also seen in the molecular layer, presumably in Purkinje cell dendrites.

identified in approximately 20% of SCLC patients without a paraneoplastic syndrome, and when present suggest a better prognosis for the tumor (Graus et al., 1997a).

Anti-Ri (ANNA2)

The anti-Ri antibody is structurally similar to the anti-Hu antibody and reacts with the nuclei of all neurons in the CNS; however, unlike anti-Hu, it does not affect neurons in the peripheral nervous system (Figure 58.2B). The antibody is detectable in both serum and CSF, with higher titers in the CSF (Jarius et al., 2008a,b). In one patient, an increase in the antibody level preceded relapse of the underlying malignancy (Stich et al., 2009), suggesting that quantification of antibody levels may be useful in predicting relapse of cancer.

Western blot against cortical neurons identifies bands at 55 and 80 kDa (Budde-Steffen et al., 1988). The Ri antigens are RNA-binding proteins (Lewis et al., 1999) that identify two genes, Nova-1 and Nova-2 (neuro-oncological ventral antigen). The Nova-1 protein is highly expressed in the ventral portion of the brainstem and spinal cord, while Nova-2 is expressed predominantly in the neocortex. Both genes regulate alternative splicing of RNAs encoding synaptic proteins (Licatalosi et al., 2008) and appear to be particularly involved in regulating synaptic proteins, including the regulation of splicing of the inhibitory glycine receptor (Ratti et al., 2008); such inhibition could lead to uncontrollable eye movements.

In one patient, autopsy revealed deposits of IgG in the cytoplasm and the nuclei of neurons throughout the brain, most impressively in the brainstem. Likewise, Western blot

FIGURE 58.3 Anti-Ma 2 antibody. The primary reaction is in nucleoli of neurons. The remainder of the nucleus is spared.

analysis revealed the presence of anti-Ri IgG in the brain, with its distribution most prominent in the brainstem. There was little in the cerebellum, perhaps because there were no detectable Purkinje cells (Hormigo et al., 1994).

The characteristic findings of the anti-Ri syndrome are opsoclonus–myoclonus and truncal ataxia (Hormigo et al., 1994). Other manifestations of brainstem encephalitis, including dystonia and laryngospasm (Pittock et al., 2010), may also occur. The antibody is associated with a variety of cancers, of which breast cancer and SCLC are the most common (Pittock et al., 2010). Opsoclonus–myoclonus often responds to immunosuppressive treatment or may resolve spontaneously (Pittock et al., 2003). Other neurologic symptoms, including cognitive difficulties, have been less responsive.

Anti-Ma

Anti-Ma antibodies react with all neurons of the central and peripheral nervous system, including sympathetic and dorsal root ganglia and the myenteric plexus. They react mainly with the nuclei and nucleoli of neurons, predominantly the nucleoli, and to a lesser degree with the cytoplasm (Figure 58.3). The antibodies do not react with other tissues with the notable exception of testicular germ cells, especially spermatocytes and early spermatids which react with Ma1 but not Ma2.

Western blot using either nervous system or testicular tissue identifies an antigen of approximately 40 kDa (Rosenfeld et al., 2001). The Ma proteins are a family of highly homologous proteins that contain several potential phosphorylation sites for protein kinase C, casein kinase II, and cyclic AMP-dependent protein kinase. The first three genes are the most important in paraneoplastic Ma2 encephalitis (Rosenfeld et al., 2001; Schuller et al., 2005).

The typical anti-Ma2 (anti-Ta) patient is a young man not known to have cancer who develops limbic

encephalopathy, diencephalic symptoms, brainstem encephalitis, or a combination of these. A report of 38 patients identified 34 with isolated or combined limbic, diencephalic, or brainstem dysfunction (Dalmau et al., 2004). Other neurologic findings in this or other reports include narcolepsy with low hypocretin1 CSF levels (Overeem et al., 2004), gaze palsy (Compta et al., 2007), and parkinsonism (Adams et al., 2011).

Anti-Ma2 is typically associated with testicular cancer, but occurs in other tumors including lymphoma (Kraemer and Berlit, 2007). The tumor may be occult; in some cases, despite a complete clinical work-up, pathology following orchiectomy will reveal microscopic tumor (Landolfi, 2003).

Treatment of neurological symptoms appears to be effective in some anti-Ma2-positive patients. Of 33 patients in one series, 11 improved following treatment of the underlying tumor, immunotherapy (usually intravenous immunoglobulin, IVIg), or both (Dalmau et al., 2004). Seven others stabilized, while nine deteriorated despite treatment. Six patients received neither tumor nor immunological therapy and all deteriorated.

Cytoplasmic Antibodies

Anti-Yo (PCA1)

The anti-Yo antibody reacts predominantly with Purkinje cells of the cerebellum (Figure 58.2C) and with some neurons in the deep cerebellar nuclei. The reaction is cytoplasmic, sparing the nucleus. On immunoelectron microscopy, the antibodies are found to bind clusters of ribosomes, granular endoplasmic reticulum, and the *trans* face of the vesicles of the Golgi complex in Purkinje cells, suggesting that at least one of the autoantigens may be a glycoprotein specific to cerebellar tissue (Rodriguez et al., 1988).

On Western blot against extracts of Purkinje cells, the antibody identifies two groups of antigens, the first 62 kDa and the second 34 kDa (Cunningham et al., 1986). The major antigen, CDR2, encodes a leucine zipper motif, suggesting that the protein might interact with other proteins that also express that motif (Sakai et al., 2002). Serum from patients blocks the interaction between c-Myc and CDR2 *in vitro* (Okano et al., 1999), effectively preventing downregulation of c-Myc activity by CDR2. The failure of downregulation may allow c-Myc transport to the nucleus promoting dysregulated cell signaling and apoptosis.

Although CDR2 mRNA is expressed in all tissues, significant amounts of the protein are detectable only in the brain and testes (Corradi et al., 1997). In brain tissue, the mRNA is confined primarily to neurons in the cerebellum and brainstem, and in the retina and olfactory

bulb. However, the protein is widely expressed in gynecologic tumors, most of which do not elicit an immune response (Darnell et al., 2000).

Most patients with paraneoplastic syndromes resulting from anti-Yo antibodies have ovarian or gynecologic cancers and the most common manifestation is paraneoplastic cerebellar degeneration (see below). The neurologic symptoms only occasionally respond to treatment (Keime-Guibert et al., 2000; Phuphanich and Brock, 2007).

Anti-Tr

The anti-Tr antibody reacts exclusively with cytoplasm of Purkinje cells, in a pattern less granular than that of the anti-Yo antibody. It further differs from anti-Yo in that it diffusely stains the molecular layer of the cerebellum in a manner that originally suggested reaction with dendritic spines of Purkinje cells (Graus et al., 1997b, 1998) (Figure 58.2D). A recent report has identified the antigen as a delta/notch-like epidermal growth factor-related receptor (de Graaf et al., 2012). The antigen may mediate neuron–glia interactions through notch signaling. Experimental animals lacking the antigen exhibit motor incoordination.

The anti-Tr antibody is almost always associated with paraneoplastic cerebellar degeneration. It is typically associated with Hodgkin disease or other lymphomas. Anti-Tr-positive patients have been reported to improve after successful treatment of the underlying tumor (Geromin et al., 2006) and/or immunosuppressive treatment (Taniguchi et al., 2006).

Anti-CRMP5 (Anti-CV2)

This antibody, originally named anti-CV2, was later found by Yu and colleagues from Dr. Lennon's laboratory (Yu et al., 2001) to react with a protein which is a member of the collapsing response mediator family and was thus renamed anti-CRMP5. It reacts with the cytoplasm of glial cells and, to a lesser extent, with neurons in cerebral cortex, cerebellum, and optic nerve. A staining pattern resembling amphiphysin (see below) is found in the cerebellar cortex (Yu et al., 2001). The antibody also reacts with enteric neurons, but not with Purkinje cell cytoplasm, smooth muscle, kidney, or gut (Yu et al., 2001). Oligoclonal bands in the CSF are specific for the CRMP5 antigen (Stich and Rauer, 2007).

Immunofluorescence and Western blotting techniques identify the antibody less frequently than does immunoprecipitation (only one of 10 SCLC patients positive by competitive radioimmunoassay and five of nine thymoma patients). The titer is generally lower than in those patients with paraneoplastic syndromes (Monstad et al., 2008).

Collapsin response mediator protein 5 is a member of a family of five developmentally regulated neuronal phosphoproteins that are highly expressed during brain development. The protein is located predominantly in the dendrites of neurons, including cortical pyramidal neurons, hippocampal CA1 pyramidal cells and Purkinje cells. In tissue culture, the protein is equally distributed throughout cell bodies, axons, and dendrites. Oligodendroglia also express the protein in cell bodies and processes in both adult brain and primary cultures (Bretin et al., 2005). The CRMP proteins are involved in apoptosis and proliferation, as well as migration and differentiation in the developing brain (Charrier et al., 2003). Their function in the adult brain is less clear.

The antibody may be associated with a wide variety of neurologic disorders affecting cranial nerves and both the central and peripheral (Antoine et al., 2001) nervous system. Findings that strongly suggest the presence of the anti-CRMP5 antibody include optic neuropathy with or without uveitis (Antoine et al., 1993; Vernino et al., 2002), chorea (Vernino et al., 2002), and sometimes an associated obsessive compulsive behavioral disorder (Muehlschlegel et al., 2005). SCLC and thymoma are the most common tumors (Yu et al., 2001). Treatment of the underlying tumor and/or immunosuppressive therapy leads to resolution of the neurologic disorder in some cases.

Synaptic/Cell Surface Antibodies

Anti-Amphiphysin

Serum and CSF of patients with anti-amphiphysin antibodies react with the neuropil of brain (Folli et al., 1993) and spinal cord, and also react diffusely with the cytoplasm of large hippocampal neurons (Dropcho, 1996). There is somewhat less intense staining of Purkinje cell cytoplasm, often concentrated at the periphery of the perikarya, suggesting reaction with synaptic terminals.

Western blot against brain extracts or breast cancer tissue of patients harboring the antibody identified bands at 128 kDa (De Camilli et al., 1993) and 108 kDa (Floyd et al., 1998). One laboratory reported that, in 38% of patients, the antibody coexists with other paraneoplastic antibodies, particularly CRMP-5 and voltage-gated calcium channel antibodies (Pittock et al., 2004).

The antigen identified in the serum of patients with anti-amphiphysin antibodies is amphiphysin I, a 128 kDa protein highly concentrated in nerve terminals where it appears to be involved in synaptic vesicle recycling (Murthy and De, 2003; Dawson et al., 2006; Nguyen-Huu et al., 2006).

The paraneoplastic syndrome most strongly associated with antibodies against amphiphysin is the stiff person syndrome, and it is usually found in patients with breast cancer

(Nguyen-Huu et al., 2006). Immunotherapy with IVIg or rituximab is sometimes effective (Baker et al., 2005) in treating the neurological disorder. Baclofen, administered orally or intrathecally, or propofol may be effective in relieving some of the stiffness (Hattan et al., 2008).

Anti-Glutamic Acid Decarboxylase

The anti-glutamic acid decarboxylase (anti-GAD65) antibody recognizes cerebellar neurons, reacting with the cytoplasm of Purkinje cells and nerve terminals in both molecular and granular cell layers (Solimena et al., 1990). The antibody also reacts with nerve terminals throughout the neuraxis, but when applied to hippocampal neurons, appears to have a different labeling pattern depending on the underlying neurologic disease (Vianello et al., 2006). Although antibodies are present in most patients with type 1 diabetes (Taplin and Barker, 2008), titers are considerably higher in patients with antibody-associated neurologic disorders (Honnorat et al., 2001).

On Western blot, the antibody usually recognizes the 65 kDa isoform of GAD, the enzyme that catalyzes the conversion of glutamic acid to gamma-aminobutyric acid, but not the similar 67 isoform (Fenalti and Rowley, 2008). A radioimmunoassay is sensitive and specific (Vianello et al., 2005). In patients with antibody-associated CNS disorders, the specific activity of antibody is higher in the CSF than in the serum, indicating intrathecal synthesis (Rakocevic et al., 2004).

SPS associated with anti-GAD antibodies is found primarily in patients without cancer, and in many with diabetes. It is also reported in association with several neurologic disorders, either alone or in combination, most of which are non-paraneoplastic (Saiz et al., 2008).

In cases of paraneoplastic SPS, the patient may also present with myasthenia gravis or encephalomyelitis (Saiz et al., 2008). Several tumors have been associated with SPS, including Hodgkin disease, renal cell carcinoma, multiple myeloma, and colon cancer. The disorder often responds to immunosuppression, as does its non-neoplastic counterpart.

Anti-N-Methyl-D-Aspartate Receptor

The anti-N-methyl-D-aspartate receptor (anti-NMDAR) antibody is present on the surface of hippocampal neurons and their processes (Florance et al., 2009). It specifically reacts with the NR1 subunit of the NMDA receptor. The antibody is present at relatively higher titer in the CSF than in the serum indicating intrathecal synthesis, and there appears to be a correlation between the CSF titer and the severity of clinical symptomatology (Dalmau et al., 2008). The NMDA receptor is one of three ion channel glutamate receptors at the post-synaptic excitatory synapse. The other

two NMDA receptors are the AMPA receptor (alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid) and the kainite receptor (Kalia et al., 2008).

The paraneoplastic syndrome is typically characterized by an encephalitis with clinical abnormalities referable to the medial temporal lobe (limbic encephalitis), the hypothalamus (sleepiness, weight gain), and the brainstem (respiratory failure), and may progress to coma (Dalmau et al., 2008). A neoplasm is not always present, but when identified is most often an ovarian teratoma. Many patients recover after treatment of the underlying tumor and with immunosuppressive therapy (Dalmau et al., 2008).

Ion Channel Antibodies

Several ion channel antibodies have been associated with autoimmune disorders, only some of which are paraneoplastic (Vincent, 2010). These antibodies include anti-acetylcholine receptor (anti-AChR) and muscle-specific kinase (anti-MuSK) antibodies in myasthenia gravis, P/Q type voltage-gated calcium channel (anti-VGCC) antibodies in LEMS and paraneoplastic cerebellar degeneration, $\alpha 3$ nicotinic muscle-specific kinase acetylcholine receptor (anti- $\alpha 3$ AChR) antibodies in autonomic neuropathy, and voltage-gated potassium channel (anti-VGKC) antibodies in limbic encephalitis and myotonia. Only the last two are discussed here.

Anti-Ganglionic Neuronal Acetylcholine Receptor

Nicotinic acetylcholine receptors are ligand-gated cation channels that are present throughout the nervous system (Vernino et al., 2008). Immunizations with the antigen can induce the clinical syndrome in experimental animals (Lennon et al., 2003).

The primary clinical manifestation in patients with antibodies to this ligand-gated channel is a subacutely-developing autonomic neuropathy (Altermatt et al., 1991; Wang et al., 2007; Vernino et al., 2008). Neurologic abnormalities may also include peripheral neuropathy, myasthenia gravis, and CNS dysfunction. Those with high titers were more likely to have dysautonomia (McKeon et al., 2009).

The disorder is not paraneoplastic in all cases of antibody-positive autonomic neuropathy (Vincent et al., 2006). In a recent study of 155 patients, 30 of 78 tested for cancer were found have a malignancy. Neoplasm was more likely in those with high or medium titers versus low but positive titers (McKeon et al., 2009). The most commonly associated cancers are SCLC or thymoma.

Anti-Voltage-Gated Potassium Channel

Although the term voltage-gated potassium channel antibodies is now entrenched in the literature, the measurements actually encompass at least two different antibodies linked to the potassium channel. These antibodies, called LGI1 and CASPR2, are associated with limbic encephalitis and neuromyotonia, respectively (Vincent, 2009). LGI1 is not actually an ion channel protein, but instead is a secreted protein.

Most patients with the antibody do not have cancer, but, when it is present, SCLC and thymoma are the most commonly found types. A report of positive voltage-gated potassium channel antibodies should prompt additional analysis to differentiate between LGI1 and CASPR2. The former is associated with limbic encephalitis and the latter with neuromyotonia or Morvan syndrome (Abou-Zeid et al., 2012). Patients often respond to immunotherapy (Buckley et al., 2001).

TREATMENT

There are two components to the treatment of a paraneoplastic syndrome. The first and foremost is to identify and treat an underlying malignancy. Effective treatment of the tumor often prevents progression of the neurologic syndrome and sometimes reverses it, probably by removing the inciting antigen. It is important to note that suppression of the immune response does not appear to worsen the outcome of the tumor (Keime-Guibert et al., 1999).

The second approach is immunosuppression, which may include plasmapheresis, IVIg, immunosuppressive drugs such as corticosteroids, cyclophosphamide, cyclosporin or tacrolimus, or immunosuppressive antibodies, e.g., rituximab (Table 58.3) (Viaccoz and Honnarat, 2013).

Because many chemotherapeutic agents are also immunosuppressive, treatment of the tumor may achieve both effects. However, several of the neurologic syndromes are so devastating that concomitant immunosuppression and tumor treatment is warranted. Table 58.3 summarizes treatment recommendations and the likelihood of success for various clinical syndromes. The earlier tumor treatment and/or immunosuppressive therapy is begun, the more likely the patient is to stabilize or improve (Sillevis et al., 2002).

CLINICAL SYNDROMES

The list of paraneoplastic syndromes is provided in Box 58.1. Following are brief descriptions of some key clinical syndromes. References to less common neurologic disorders are not described due to space limitations but can be

found in a recently published monograph (Darnell and Posner, 2011).

Paraneoplastic Cerebellar Degeneration

Paraneoplastic cerebellar degeneration (PCD) is the most common paraneoplastic disorder of the CNS. In the Euronetwork database (Giometto et al., 2010), PCD represented one-quarter of all paraneoplastic disorders and one-half of all CNS paraneoplastic syndromes. PCD usually occurs in isolation but may also occur as one manifestation of paraneoplastic encephalomyelitis (see below).

The clinical syndrome is so distinct that one must always search for an underlying malignancy when it is encountered. Patients with PCD present with relatively rapid onset (sometimes overnight) of signs of cerebellar dysfunction and including nausea and vomiting, vertigo, diplopia, incoordination, imbalance, and dysarthria. A viral-like syndrome with dizziness, nausea, and vomiting precedes cerebellar signs by a few days in some cases. Symptoms typically worsen progressively over the course of days to weeks only to stabilize in several weeks to a few months, often (but not always) with severe disability. Extra-cerebellar neurologic symptoms including cognitive dysfunction and extensor plantar responses, and evidence of peripheral neuropathy is present in some patients but it is usually mild (Peterson et al., 1992).

Imaging is typically normal at onset, although a rare patient will show evidence of inflammation (contrast enhancement) in cerebellar folia. With time, cerebellar atrophy becomes apparent. CSF usually shows a lymphocytic pleocytosis (10–50 cells) early in the illness, with elevated protein and immunoglobulin concentration and oligoclonal bands. Lymphocytes generally normalize over time but protein abnormalities remain.

The three most common antibodies are anti-Yo (gynecologic and breast cancers), anti-Hu (SCLC), and anti-Tr (Hodgkin disease). CSF antibody titers are usually higher than in serum, and in anti-Tr may be detectable only in the CSF (Bernal et al., 2003). Mimics of PCD are few, and include post-infectious cerebellitis, Miller–Fischer syndrome, and HIV infection. Other disorders, including alcoholism, vitamin deficiency, metastases, celiac disease, and spongiform encephalopathy, are rarely so abrupt in onset or involve so much of the cerebellum simultaneously.

The pathogenesis of the Purkinje cell destruction is not established. Cerebellar slice cultures bind the antibody and cause Purkinje cell death (Greenlee et al., 2010).

It is essential that treatment begin as early as possible in an effort to avoid further destruction of remaining Purkinje cells (Greenlee, 2013). Treatment usually will not reverse the illness, but may help to stabilize it. A few case reports describe a favorable response to immunosuppressive therapy (Counsell et al., 1994; Esposito et al., 2008).

TABLE 58.3 Approach to Treatment of Neurologic Paraneoplastic Syndromes

| Syndrome | Treatment |
|---|--|
| Syndromes that usually respond to treatment* | |
| Lambert–Eaton myasthenic syndrome | IVIg, plasma exchange, 2,3-diaminopyridine, immunosuppression** |
| Myasthenia gravis | IVIg, plasma exchange, immunosuppression, acetylcholinesterase inhibitors |
| Dermatomyositis | IVIg, immunosuppression |
| Opsoclonus–myoclonus (pediatric) | IVIg, corticosteroids, ACTH, rituximab |
| Neuropathy associated with osteosclerotic myeloma | Radiation, chemotherapy |
| Anti-NMDAR encephalitis | First line: corticosteroids, IVIg, plasma exchange Second line: cyclophosphamide, rituximab |
| Anti-LGI1 encephalitis | Corticosteroids, IVIg, plasma exchange |
| Anti-cell surface antigens other than NMDAR and LGI1 (AMPA receptor, GABA(B) receptor, CASPR2) | Corticosteroids, IVIg, plasma exchange, cyclophosphamide |
| Syndromes that may respond to treatment | |
| Stiff person syndrome | IVIg, steroids, diazepam, baclofen |
| Neuromyotonia | IVIg, plasma exchange, phenytoin, carbamazepine |
| Guillain–Barré (in Hodgkin lymphoma) | IVIg, plasma exchange |
| Vasculitis of nerve and muscle | Corticosteroids, cyclophosphamide |
| Limbic encephalitis | IVIg, corticosteroids |
| Opsoclonus–myoclonus (adults) | Corticosteroids, cyclophosphamide, protein A column, clonazepam, thiamine |
| Anti-MAG-associated peripheral neuropathy (Waldenstrom macroglobulinemia) | IVIg, plasma exchange, chlorambucil, cyclophosphamide, fludarabine, rituximab |
| Acute necrotizing myopathy | Immunosuppression |
| Syndromes that usually do not respond to treatment | |
| Encephalomyelitis | |
| Sensory neuronopathy | |
| Autonomic dysfunction | |
| Cerebellar degeneration | |
| Cancer- and melanoma-associated retinopathy | |
| *In all cases, initial treatment should focus on identifying and treating the underlying tumor. | |
| **Immunosuppression includes corticosteroids, azathioprine. | |
| IVIg = intravenous immunoglobulin. | |

Paraneoplastic Encephalomyelitis

Paraneoplastic encephalomyelitis (PEM) is an inflammatory disorder that includes limbic encephalitis, brainstem encephalitis, myelitis, dorsal root ganglionitis (sensory neuronopathy), and autonomic neuropathy. One or all of these areas may be involved. The disorder was diagnosed in 5.6% of 979 patients in the Euronetwork database (Giometto et al., 2010). The full-blown syndrome is usually caused by SCLC associated with the anti-Hu antibody.

Paraneoplastic Limbic Encephalitis

Paraneoplastic limbic encephalitis (LE) is the most common paraneoplastic syndrome affecting the cerebral hemispheres. It was identified in 10% of patients in the

Euronetwork database (Giometto et al., 2010). Patients with LE typically present with short-term memory loss, behavioral changes, and/or seizures. Symptoms may begin with changes in mood and personality over days to weeks, progressing relatively rapidly, with development of potentially severe memory deficits. In some cases, patients present with short-term memory loss but otherwise preserved cognitive function, the so-called Ophelia syndrome (Carr, 1982). When the disorder is associated with anti-NMDAR antibodies, florid psychiatric symptoms are especially common at onset. When associated with other antibodies, LE more commonly presents with short-term memory loss and otherwise normal cognitive function, with or without complex partial seizures.

Although LE can be associated with a variety of antibodies (Table 58.2), the most prominent are anti-Hu,

anti-LGI1 (previously anti-VGKC), and anti-NMDAR. Almost all anti-Hu patients have SCLC and respond relatively poorly to treatment. In contrast, only about 15% of patients with anti-LGI1-associated LE have cancer. Many of these patients respond to immunosuppressive treatment regardless of etiology.

Many patients with anti-NMDAR antibodies demonstrate a characteristic EEG pattern called extreme delta brush (Rosenfeld et al., 2012). There is also a fronto-temporo-parieto-occipital gradient of glucose metabolism that correlates with disease activity (Rosenfeld et al., 2012). These patients may also develop brainstem encephalitis with respiratory dysfunction and coma. Anti-NMDAR antibody patients are typically young women with ovarian teratomas (non-malignant). Most of these patients respond to treatment, sometimes even after weeks of coma.

Brainstem Encephalitis

Brainstem encephalitis can cause a multitude of symptoms and signs including movement disorders, deafness, gaze palsies, respiratory dysfunction, and even coma. The only relatively common symptom of brainstem dysfunction that occurs in isolation is opsoclonus, with or without myoclonus and with or without ataxia. Opsoclonus is characterized by involuntary, arrhythmic, multidirectional, high amplitude conjugate saccades occurring in all directions and without an inter-saccadic interval. Myoclonus and/or ataxia may also be present.

When opsoclonus occurs in children, approximately 40% of cases are paraneoplastic, usually caused by neuroblastoma (Singhi et al., 2013). However, only about 3% of patients with neuroblastoma have opsoclonus. When the syndrome occurs, it usually portends a good prognosis with regard to the neuroblastoma. While neurologic symptoms do respond to immunosuppression, patients are often left with other evidence of brain damage (Gorman, 2010).

A number of antibodies have been identified in the childhood syndrome but none, with the possible exception of a recently described cell surface antibody (Blaes et al., 2008), appears to be clearly related to the paraneoplastic disorder. In adults, the paraneoplastic disorder, which represents about 20% of adult cases of opsoclonus, is associated with a number of well-characterized paraneoplastic antibodies including anti-Hu and anti-Ri. Causal tumors include SCLC as well as breast and gynecological cancers.

The symptoms sometimes resolve spontaneously and have been reported to respond to immunosuppression including removal of antibodies via protein A column (Cher et al., 1995). Although included here as a brainstem symptom, the actual site of pathology is unknown. Pathologic study of the brainstem in affected patients failed to show specific abnormalities.

Myelitis

Acute or subacute inflammatory transverse myelitis may occur in isolation or be associated with the encephalomyelitis syndrome. In the vast majority of patients, transverse myelitis is not paraneoplastic. When it is, it is usually associated with the anti-Hu syndrome. Clinical findings that mimic amyotrophic lateral sclerosis may be the presenting symptom, followed by signs of more widespread encephalomyelitis. Other transverse myelopathies that are sometimes paraneoplastic include necrotizing myelopathy, demyelinating myelopathy, and neuromyelitis optica, the last disorder only rarely associated with cancer.

Subacute Sensory Neuronopathy

This disorder is as common as PCD, having been identified in 24% of 979 patients with paraneoplastic syndromes in the Euronetwork database (Giometto et al., 2010). Unlike most other sensory neuropathies, it has a rapid onset and is characterized by sensory loss and paresthesias. While symptoms can begin distally in all four extremities (as is typical of many neuropathies), in subacute sensory neuronopathy patients may present with symptoms beginning in other areas such as the trunk or the neck, or sensory changes may occur in the hands before the feet. Symptoms are often, but not always, asymmetric. Sensation to all modalities is affected—e.g., pain, temperature, vibration, proprioception—and most patients become very ataxic as a result of the proprioceptive deficit. Deep tendon reflexes are usually lost. Motor function is generally spared.

The most common cancer is SCLC and the most common antibody is anti-Hu. Treatment may stabilize or improve symptoms; patients usually do not fully recover and many progress despite treatment.

Autonomic Neuropathy

Autonomic neuropathy may present as a prominent or a minor deficit in patients with encephalomyelitis. It may also occur in isolation. A variety of symptoms of autonomic dysfunction may occur, including orthostatic hypotension, impotence, incontinence, pupillary abnormalities, anhydrosis, xerostomia, or xerophthalmia; however, the most significant distressing symptom is constipation/pseudoobstruction, which may be the presenting or sole complaint in patients with SCLC and anti-Hu antibody syndrome. Autonomic neuropathy is also associated with the anti-ganglionic neuronal acetylcholine receptor antibody (Vernino et al., 1998), which is only sometimes paraneoplastic.

Vision Loss

Paraneoplastic syndromes can cause vision loss by affecting either the retina or the optic nerve or both (Cornblath, 2004; Thirkill, 2005; Shildkrot et al., 2011; Braithwaite et al., 2012). The retinal disorder can affect photoreceptors—rods, cones or both—or can cause retinal vasculitis. Paraneoplastic visual disorders may occur as an isolated phenomenon or as part of a widespread encephalomyelopathy.

Retinopathy

Paraneoplastic photoreceptor degeneration has two causes: cancer-associated retinopathy (CAR), which usually occurs in association with SCLC and gynecological tumors, and melanoma-associated retinopathy (MAR). Visual symptoms—which include episodic visual obscurations, night blindness, light-induced glare, photosensitivity, and impaired color vision—precede the diagnosis of cancer (Shildkrot et al., 2011). Symptoms progress to painless vision loss. Visual testing demonstrates peripheral and ring scotomata, and loss of acuity. Fundoscopic examination may reveal arteriolar narrowing and abnormal mottling of the retinal pigment epithelium. The electroretinogram is abnormal. CSF is typically normal, although elevated immunoglobulin levels have been reported. Inflammatory cells are sometimes seen in the vitreous by slit-lamp examination.

Pathologically, a loss of photoreceptors and ganglion cells with inflammatory infiltrates and macrophages is usually noted. MAR is usually less severe than CAR, typically occurs in patients already known to have melanoma, and is generally associated with better vision. Symptoms include night blindness, photopsias, and visual glare (Dhingra et al., 2011).

Several autoantibodies have been identified in patients with CAR. The most common is recoverin (Shildkrot et al., 2011), a 23 kDa protein that modulates dark and light adaptation through calcium-dependent regulation of rhodopsin phosphorylation in photoreceptor cells. Recoverin antibodies can cross the blood–brain barrier gaining access to photoreceptor cells within the aqueous humor (Ohguro et al., 2002). Similar to CAR, a number of antibodies have been detected in the serum of patients with MAR (Lu et al., 2009) and, as in CAR, treatment is usually ineffective.

Optic Neuropathy

Paraneoplastic optic neuropathy occurring in the absence of other neurological symptoms is extremely uncommon (Ko et al., 2008). Cross and colleagues described 16 patients with optic neuritis (five of whom also had retinitis), all of whom harbored antibodies to CRMP5 (Cross et al., 2003). The patients had subacute vision loss. Optic discs were

swollen and visual field defects were present. All patients had other neurological symptoms including cognitive changes, ataxia, sensory neuropathy, and myelopathy. Some patients had symptoms resembling those of neuromyelitis optica (Cree, 2008). SCLC was the most commonly associated malignancy.

Stiff Person Syndrome

Originally termed the stiff man syndrome, this disorder affects more women than men. It is characterized by muscle stiffness and rigidity that is usually painful (Rakocevic and Floeter, 2012; Ciccoto et al., 2013). The paraspinal and abdominal muscles are almost always involved, and those of the lower extremity are usually affected as well.

Sustained muscle contraction results in abnormal posture, such as an exaggerated lumbar lordosis. In addition to chronic contractions, severe muscle spasms may be precipitated by voluntary movements, unexpected environmental stimuli, and emotional upset. Muscles are firm on palpation and may be difficult to move passively. The EMG is characterized by sustained continuous motor unit activity that disappears during sleep and general anesthesia.

The non-paraneoplastic disorder is associated with diabetes and anti-GAD65 antibodies (Pittock et al., 2006). Paraneoplastic SPS is associated with antibodies against amphiphysin (Pittock et al., 2005), anti-GAD antibodies, anti-Ri antibodies, gephyrin, and glycine receptor alpha-1 subunit antibody (McKeon et al., 2013). GABA_A receptor has also been reported in isolated cases. The common tumors include breast cancer, SCLC, Hodgkin disease, and colon cancer. Although the pathogenesis of the disorder is not fully understood (Rakocevic and Floeter, 2012), the disorder may be antibody mediated; injection of either anti-GAD65 (Hansen et al., 2013) or anti-amphiphysin antibodies (Geis et al., 2009) into experimental animals reproduces the syndrome.

Benzodiazepines and baclofen may relieve symptoms. Treatment of the underlying tumor and immunosuppression with corticosteroids, IVIg, or repeated plasmapheresis (Casa-Fages et al., 2012) are sometimes effective.

Lambert–Eaton Myasthenic Syndrome

Lambert–Eaton myasthenic syndrome (LEMS) is the most common of the classical paraneoplastic syndromes. The likelihood of cancer (usually SCLC) in the presence of LEMS is relatively high, at approximately 40–60%. However, the chance that a patient with SCLC will develop LEMS remains low, at less than 6% (Seute et al., 2004).

Patients typically present with progressive proximal weakness and fatigue (Wirtz et al., 2002). Early in the disease course they may complain of difficulty in walking up stairs, in rising from a chair without using hands to push off, or in opening windows. Weakness may fluctuate, which can lead to an inconsistent and confusing clinical presentation. Patients may complain of cramping with exercise. Cranial nerve involvement is less common than in myasthenia gravis, especially at onset of the condition. Autonomic symptoms are common early in the course and may include erectile dysfunction in men or xerostomia and/or metallic taste in either sex. Orthostatic hypotension is less common but may also occur.

Exam typically reveals proximal weakness (hip and shoulder girdles) and diminished or absent deep tendon reflexes. In some patients, strength and reflexes will transiently improve after brief exercise, followed shortly thereafter by increased weakness and recurrence of hyporeflexia or areflexia. All patients, whether paraneoplastic or not, harbor serum anti-VGCC antibodies.

The most important initial step is treatment of the underlying malignancy (usually SCLC), which may ameliorate symptoms from LEMS as well. However, if symptoms are severe one can administer concomitant immunosuppressive therapy such as plasma exchange, IVIg, oral agents (e.g., corticosteroids, azathioprine), or possibly rituximab. For patients who remain symptomatic, consideration may be given to medications that increase the availability of acetylcholine at the neuromuscular junction.

Celiac disease (also termed gluten sensitive enteropathy) has autoimmune features of which the highly disease-specific antibodies to the enzyme transglutaminase 2 (TG2), a.k.a. tissue transglutaminase, are particularly striking. The disease is precipitated in genetically susceptible individuals by the ingestion of cereal gluten proteins of wheat, barley, and rye. Some historical findings which have led to our current understanding of the pathogenesis of celiac disease are listed in [Box 59.1](#). If the critical role of gluten was not known in celiac disease, this disorder would not have been related to food hypersensitivity, but rather been considered a bona fide autoimmune disease with tissue-specific destruction of enterocytes in the small bowel—not very different from the destruction of islet cells in the pancreas in type 1 diabetes. The combination of the knowledge of the disease-driving antigen, the easy access to the target organ by gastroduodenoscopy, and an unusually clear HLA association has led to a detailed understanding of pathogenic mechanisms.

Thus, among the chronic inflammatory disorders with autoimmune components, celiac disease stands out as a particularly good model. Insight into the pathogenesis of this disorder is relevant for diseases for which the genetic and environmental components are poorly characterized.

CLINICAL, PATHOLOGIC AND EPIDEMIOLOGIC FEATURES

Clinical Features and Associated Disorders

Celiac disease may present in early childhood soon after the introduction of gluten-containing food. A dramatic and even fatal clinical picture with diarrhea, anorexia, failure to thrive, abdominal distension, and growth retardation was once regarded as typical. This is now rare, and most children and adults present with a milder, pauci- or mono-symptomatic disease (Mäki et al., 1988). Many of the symptoms associated with the milder disease form, like chronic

BOX 59.1 Important Historical Achievements in the Study of Celiac Disease Pathogenesis

- First description of a condition resembling celiac disease by Aretheus from Cappadocia (second century AD)
- First precise description of the disorder (Gee, 1888)
- Suggestion that banana diet can cure the disease (Haas, 1932)
- Wheat gluten identified as a causative agent (Dicke, 1950)
- Villous atrophy and crypt hyperplasia found to be pathognomonic for the disease (Paulley, 1954)
- Celiac disease of childhood and adult nontropical sprue share the same pathogenesis (Rubin et al., 1960)
- Familial clustering of biopsy proven celiac disease (MacDonald et al., 1965)
- First diagnostic criteria of pediatric celiac disease from ESPGAN (Meeuwisse, 1970)
- Celiac disease found to be an HLA-associated disorder (Falchuk et al., 1972; Stokes et al., 1972)
- Existence of autoantibodies to reticulin detected (Alp and Wright, 1971; Seah et al., 1971)
- Cell-mediated immunity to gliadin in coeliac disease intestinal biopsy specimens (Ferguson et al., 1975)
- HLA-DQ2 heterodimer (DQA1*05/DQB1*02) identified as the primary HLA susceptibility factor (Sollid et al., 1989)
- Isolation of gliadin-specific, HLA-DQ2-restricted T cells from intestinal biopsies (Lundin et al. 1993)
- Celiac disease autoantigen identified as transglutaminase 2 (Dieterich et al., 1997)
- Role of TG2 for making gluten peptides more immunogenic by deamidation recognized (Molberg et al., 1998; van de Wal et al., 1998a)

fatigue, joint pain, and neuropsychological problems, do not directly point to a small intestinal disorder (Murray, 1999; Fasano and Catassi, 2001; Farrell and Kelly, 2002). Neither do complications like osteoporosis, reduced fertility, peripheral neuropathy, epilepsy with cerebral calcifications or dermatitis herpetiformis (Ciacci et al., 1995; Collin and Reunala, 2003; Hadjivassiliou et al., 2003; Sanders et al., 2003). The coexistence of autoimmune diseases is striking; in particular there is an overrepresentation of type 1 diabetes (Green et al., 1962; Koletzko et al., 1988; Cronin et al., 1997), Sjögren's syndrome (Collin et al., 1994), autoimmune thyroid disorders (Collin et al., 1994; Counsell et al., 1994), connective tissue disease (Collin et al., 1994), and IgA deficiency (Mawhinney and Tomkin, 1971; Cataldo et al., 1997; Wang et al., 2011). Like many autoimmune disorders, pediatric and adult celiac disease show a gender bias with a female to male ratio of approximately 2:1 (Ciacci et al., 1995; Ivarsson et al., 2003b).

Recently there has been much interest in the clinical entity of “non-celiac gluten sensitivity.” Such patients may have symptoms resembling celiac disease, but the enteropathy, serology, and HLA association typical of celiac disease are lacking as are clear diagnostic criteria (Ludvigsson et al., 2012).

Pathology of the Intestinal Lesion

The intestinal lesion in celiac disease can be classified into three dynamically connected stages as suggested by Marsh; the infiltrative, the hyperplastic, and the destructive lesion (Marsh, 1992) (Figure 59.1). In the infiltrative lesion (Marsh 1) the mucosal architecture is normal, but there is an increased infiltration of intraepithelial lymphocytes (IEL) in the villous epithelium. The hyperplastic lesion (Marsh 2) is similar to the infiltrate lesion, but in addition has enlarged

hyperplastic crypts. The last stage is the destructive lesion which can be subgrouped into partial, subtotal, or total villous atrophy (Marsh 3 A–C) (Oberhuber et al., 1999). The latter corresponds to the classic flat lesion, which in addition to the increased IEL, is characterized by swelling and infiltration of plasma cells, CD4⁺ αβ T cells, macrophages/dendritic cells, mast cells, and neutrophils in the lamina propria (Figure 59.2).

Epidemiology

Celiac disease has a world wide distribution, but is primarily a disease of Caucasians. The prevalence in Europe and USA is around 1:130–1:300 (Catassi et al., 1996; Fasano et al., 2003). There are unexplained differences in prevalence between European countries with adult prevalence figures ranging from 2.4% in Finland to 0.3% in Germany (Mustalahti et al., 2010). More than half the cases are now diagnosed in adult life, and the disease can be diagnosed even after the age of 60 years. Many patients may have had undetected celiac disease in childhood, whereas in others, the disease has started later. The natural history and the timing for conversion to seropositivity and/or mucosal inflammation are not fully understood. Studies from Finland suggest that some children may have transient positive serology that normalizes without dietary manipulation (Mäki et al., 2003; Simell et al., 2007). These rare events suggest that at least some aspects of celiac disease may be transient.

Between 1985 and 1995 there was an epidemic of celiac disease in Sweden among children below 2 years with a three-fold increase in incidence (Ivarsson et al., 2000). The sharp rise and subsequent abrupt decrease in incidence was likely related to changes in infant feeding habits, including the amount of gluten given, the age at introduction of gluten to the diet, and whether

FIGURE 59.1 Schematic representation of the stages of the intestinal lesion in celiac disease according to Marsh. The stages are dynamically related. The normal stage is Marsh type 0. In Marsh type 1 there are increased numbers of intraepithelial lymphocytes (IELs). Marsh type 2 has increased numbers of IELs and enlarged, hyperplastic crypts. Marsh type 3 has, in addition to increased numbers of IELs and crypt hyperplasia, also partial to complete blunting of the villous structures. The numbers of leukocytes in the lamina propria, such as plasma cells and T cells, are increased in the full blown celiac disease lesion, but their presence is not included as parameters for the Marsh staging. *Courtesy of A.-C.R. Beitnes and Jorunn Stammaes.*

FIGURE 59.2 The celiac lesion is characterized by increased infiltration of T cells and plasma cells. Immunohistochemical staining of T cells (CD3, green), plasma cells (CD138, red) and epithelial cells (cytokeratin, blue) in biopsy sections of (A) a patient with untreated celiac disease and (B) a normal subject. *Courtesy of A.-C.R. Beitnes.*

breastfeeding was ongoing or not when gluten was introduced. Notably, breastfeeding reduced the risk of early celiac disease (Ivarsson et al., 2002). Later follow-up at the age of 12 years has shown an astonishingly high prevalence of 3% for celiac disease in these children (Myleus et al., 2009). The increase is not, however, confined to these high-risk cohorts and celiac disease has become far more prevalent in Sweden.

AUTOIMMUNE FEATURES

Autoantibodies

Untreated celiac disease patients (on a regular diet) usually have increased levels of antibodies against gluten,

other food antigens, and autoantigens. Initially, autoantibodies in celiac disease were detected as anti-reticulin antibodies by staining of various rat tissue (Alp and Wright, 1971; Seah et al., 1971). Later IgA anti-endomysium antibodies (EMA) either as detected by staining of monkey esophagus (Chorzelski et al., 1984) or human umbilical cord (Ladinser et al., 1994) were recognized. The main antigen recognized by anti-reticulin antibodies and EMA was identified as the enzyme transglutaminase 2 (TG2) (Dieterich et al., 1997), although antibodies to calreticulin and actin are also found (Clemente et al., 2000; Sanchez et al., 2000). The antibodies to TG2 are both of the IgA and IgG isotypes, but the IgA antibodies are most closely linked with celiac disease (Rostom et al., 2005).

Anti-TG2 antibodies only occur in individuals who are HLA-DQ2 or HLA-DQ8 (Bjorck et al., 2010). Moreover, the production of the IgA anti-TG2 antibodies is entirely dependent on dietary gluten exposure (Dieterich et al., 1998; Sulkanen et al., 1998). These two observations indicate that gluten-reactive T cells are implicated in the generation of these antibodies. A model has been proposed where gluten-reactive T cells provide help to TG2-specific B cells by means of hapten carrier-like gluten–TG2 complexes (Sollid et al., 1997) (Figure 59.3c). This model can explain why the serum TG2 antibodies in celiac disease disappear when the patients are put on a gluten-free diet. When the gluten goes, so does the T cell help needed for the B cells to switch isotype and differentiate to plasma cells (Sollid et al., 1997).

Production of anti-TG2 antibodies is vigorous in the active celiac lesion, and on average 10% of the plasma cells in the lesion produce anti-TG2 antibodies (Di Niro et al., 2012). IgA is the dominating isotype, and such cells

are absent in celiac patients on a gluten-free diet (Di Niro et al., 2012). The TG2 antibodies have a unique repertoire with overusage of VH5-51 (Marzari et al., 2001; Di Niro et al., 2012), and they have few mutations despite being part of a chronic inflammatory response (Di Niro et al., 2012). The somatic mutations, though they are modest, speak of T cell involvement in the antibody response as the displacement mutations dominate silent mutations (Di Niro et al., 2012; Marzari et al., 2001) and as reversion of some selected antibodies to germline sequence lead to reduction in antibody affinity (Di Niro et al., 2012).

It is uncertain whether autoantibodies play a role in the pathogenesis. High incidence of celiac disease in IgA deficiency (Wang et al., 2011) argues that IgA antibodies *per se* play a minor pathogenic role. The involvement of the humoral immune system does not need to be at the level of soluble antibodies, but could at the level of B cells. If TG2-specific B cells are indeed able to present gluten peptides to gluten-specific T cells, this would be an extremely effective amplification step in the anti-gluten T cell response.

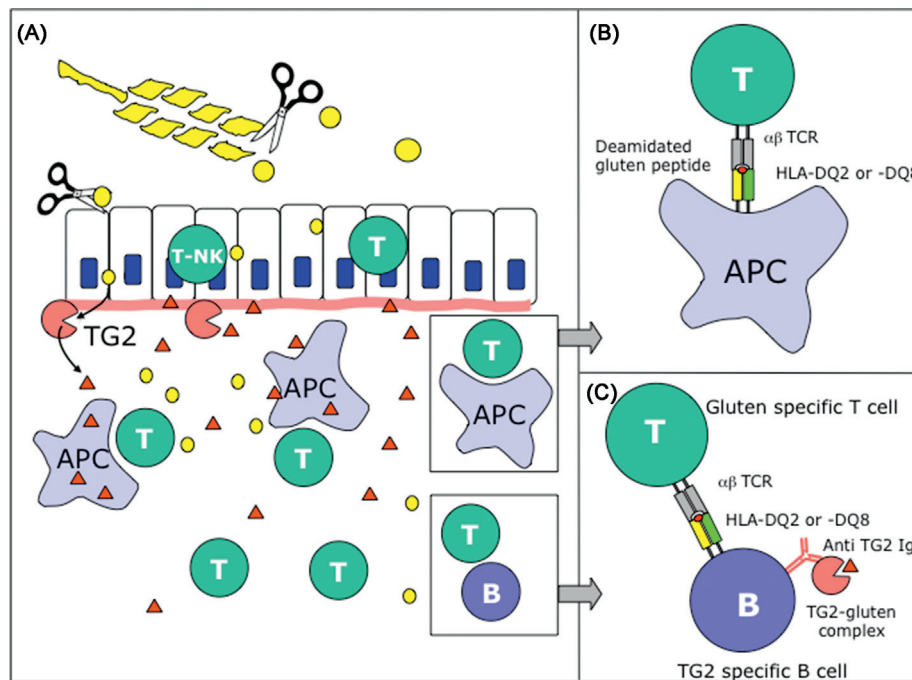

FIGURE 59.3 The celiac small intestinal lesion. (A) Depiction of the intestinal mucosa with emphasis on the factors taking part in the development and control of celiac disease. The parts of the gluten proteins that are resistant to processing by luminal and brush border enzymes will survive digestion, and can be transported across the epithelial barrier as polypeptides. Gluten peptides are deamidated by transglutaminase 2 (TG2), which, in the intestinal mucosa, is mainly located extracellularly in the subepithelial region, but is also found in the brush border. TG2 may also be expressed by antigen-presenting cells (APCs [i.c.]) like macrophages and dendritic cells. $CD4^+$ T cells in the lamina propria recognize predominantly deamidated gluten peptides, presented by HLA-DQ2 or -DQ8 molecules on the cell surface of the APC. (B) HLA-DQ2 and -DQ8 molecules have preference for binding peptides with negatively charged amino acids (DQ2 in positions P4, P6, and P7; DQ8 in positions P1 and P9) and thereby bind gluten peptides deamidated by TG2 with increased affinities. (C) Model of how gluten-reactive T cells control the formation of antibodies to TG2 by intramolecular help. TG2 and gluten can form complexes. Such complexes of gluten and TG2 bound by surface immunoglobulin of TG2-specific B cells (anti TG2 Ig) will be endocytosed, and deamidated gluten peptides can be released for binding to DQ2 or DQ8 molecules. After transport to the cell surface of the HLA molecules with bound peptides, gluten-reactive T cells can recognize the deamidated gluten peptides and thereby provide T cell help to the TG2-specific B cells.

Involvement of TG2-specific B cells in the pathogenesis of celiac disease could then explain why anti-TG2-specific antibodies are such precise predictors of disease.

The autoantibodies may well be implicated in the extraintestinal manifestations of celiac disease. In dermatitis herpetiformis, which could be considered as celiac disease with additional skin lesions, IgA autoantibodies are prime suspects. These patients, in addition to anti-TG2 antibodies, have antibodies that target transglutaminase 3 (TG3), and the IgA anti-TG3 antibodies are more closely associated with the disease than the IgA anti-TG2 antibodies (Sardy et al., 2002). TG3 is closely related to TG2 and is also able to modify gluten peptides, but is paradoxically not expressed in the dermal papillae where the granular IgA deposits in dermatitis herpetiformis are located.

Autoreactive Intraepithelial Lymphocytes (IELs)

Untreated celiac disease is characterized by an increased density of proliferating $\text{TCR}\alpha\beta^+$ $\text{CD8}^+\text{CD4}^-$ and $\text{TCR}\gamma\delta^+$ $\text{CD8}^-\text{CD4}^-$ cells in the villous epithelium. In contrast to the $\text{TCR}\alpha\beta^+$ CD8^+ IELs that return to normal when gluten is removed from the diet, the $\text{TCR}\gamma\delta^+$ IELs remain at an elevated level (Kutlu et al., 1993). This may suggest that these two types of T cells play different roles in the pathogenesis process. Many of the IELs co-express innate (NK cell) receptors recognizing non-classical HLA molecules like MIC molecules and HLA-E. In celiac disease there is a decrease in IELs expressing the inhibitory receptor CD94-NKG2A (Meresse et al., 2006) and an increase of IELs expressing the activating receptors NKG2D (Hüe et al., 2004; Meresse et al., 2004) and CD94/NKG2C (Meresse et al., 2006) (Figure 59.3A). These activated IELs can kill enterocytes by use of the NK cell receptors possibly without involvement of the T cell receptor (Hüe et al., 2004; Meresse et al., 2004).

GENETIC FEATURES

A high prevalence (10%) among first-degree relatives of celiac disease patients indicates that susceptibility to develop celiac disease is strongly influenced by inherited factors (Ellis, 1981). Familial clustering is stronger in celiac disease than in most other chronic inflammatory diseases with a multifactorial etiology (Risch, 1987). The strong genetic influence in celiac disease is further supported by a high concordance rate (~75%) in monozygotic twins (Greco et al., 2002). Both HLA and non-HLA genes contribute to the genetic predisposition.

HLA Genes

The strongest HLA association in celiac disease is the presence of a variant of HLA-DQ2 which is often termed HLA-DQ2.5 (Figure 59.4). Usually 90% or more of the celiac disease patients carry this HLA molecule. The DQ2.5 molecule is found in individuals who carry the DR3-DQ2 haplotype encoded by DQA1 and DQB1 alleles (DQA1*05:01 and DQB1*02:01) which are located on the same chromosome (*cis* position). Alternatively it can be expressed by individuals who are DQ5DQ7/DR7DQ2 heterozygous and then the alleles (DQA1*05:05 and DQB1*02:02) are located on opposite chromosomes (*trans* position). About half of the remaining celiac patients carry HLA-DQ8 encoded by the DQA1*03 and DQB1*03:02 alleles. The rest of the patients are DQ2.2 or DQ7.5 (Karell et al., 2003); thus they carry either the α -chain or the β -chain of the DQ2.5 molecule. DQ2.5 and DQ8 have population frequencies each around 20–25% in most Caucasian populations so the majority of the individuals with these HLA types do not develop celiac disease. Because of the strong HLA association in celiac disease, HLA can be considered a necessary but not sufficient genetic factor for disease development.

Non-HLA Genes

Genome-wide association studies (GWAS) have greatly advanced the knowledge of non-HLA genes in celiac disease. So far 39 loci outside of HLA have been identified to harbor one or more genes predisposing to or protecting against celiac disease (Trynka et al., 2011). Individually, these non-HLA genes contribute little to genetic risk. It has been estimated that with a population prevalence of 1% and a heritability of 50%, the 39 non-HLA loci account for 14% of the genetic variance whereas HLA in comparison accounts for 40% (Trynka et al., 2011). Evidence suggests the existence of many additional non-HLA genes with even smaller effect than those identified to date. However, these genes would make little contribution to the overall genetic risk, and it is unclear what should account for the remaining half of the heritability. Unprecise heritability estimates and complex gene–gene interactions have been suggested to be relevant factors.

Most of the 39 non-HLA loci contain genes with immunological functioning. Many of these genes are associated with the functioning of T cells. Thus the pathogenesis model established by studies of immune cells of celiac disease patients is confirmed by the findings of the GWAS. Most celiac disease-associated risk variants in the 39 non-HLA loci are not located in protein coding regions but rather in regions implicated in gene regulation. This suggests that differences in gene expression play an important factor in the pathogenesis of celiac disease. Finally, celiac

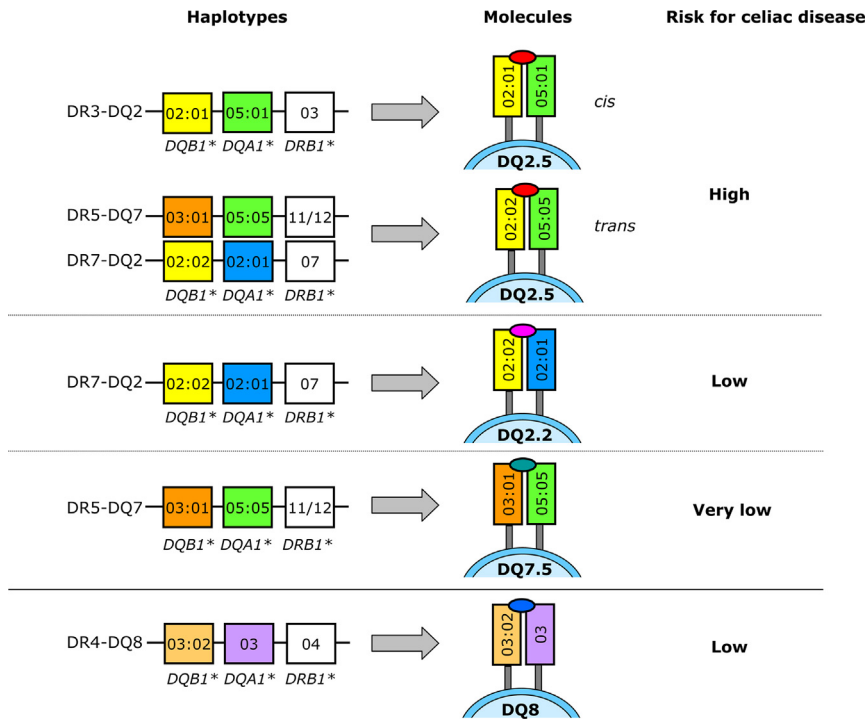

FIGURE 59.4 HLA association in celiac disease. The majority of celiac disease patients carry the HLA-DQ2.5 molecule, which can be encoded in *cis* or in *trans* positions. Most of the remaining patients express HLA-DQ8 whereas the rest of the celiac disease patients express HLA-DQ2.2 or HLA-DQ7.5. The polypeptides encoded by DQA1*05:01 and DQA1*05:05 differ by one residue in the leader peptide, whereas those encoded by DQB1*02:01 and DQB1*02:02 differ by one residue in the membrane proximal domain. It is unlikely that these substitutions have functional consequences.

disease and other immune-mediated diseases, in particular type 1 diabetes (Smyth et al., 2008), share risk gene variants speaking of sharing of critical pathways in the development of the various diseases. New therapeutics for treatment of autoimmune diseases, including biologicals, may thus find a rational basis for testing in celiac disease as well.

ENVIRONMENTAL INFLUENCES

Gluten Proteins

Gluten is the cohesive mass that remains when dough is washed to remove starch. Gluten was originally used to denote wheat proteins only, but is now increasingly used as a term for proline- and glutamine-rich proteins of wheat, barley, rye, and also oat. In wheat, gluten consists of the gliadin and glutenin subcomponents. The gliadin proteins can be subdivided into α -, γ -, and ω -gliadins, while the glutenin proteins can be subdivided into high molecular weight (HMW) and low molecular weight (LMW) subunits (Shewry et al., 2003). The number of unique gluten proteins in common bread wheat is huge due to a hexaploid genome, multiple encoding loci, and allelic variation. Thus, in a single wheat variety there are several hundred different gluten proteins, many of which only differ by a few amino acids. The high content of proline residues makes the gluten proteins particularly resistant to gastrointestinal digestion (Shan et al., 2002). This has important implications for their immunogenicity for T cells.

The gluten proteins of barley are termed hordeins, those of rye, secalins, and those of oat, avenins. Clinical observations suggest that the gluten proteins of barley and rye are also toxic for celiac disease patients (Farrell and Kelly, 2002), and T cell epitopes of barley and rye have been defined (see below). In general, feeding studies have indicated that oat is safe for celiac disease patients (Janatuinen et al., 1995, 2002; Hoffenberg et al., 2000). Rare cases of oat-intolerant celiac patients exist (Lundin et al., 2003; Arentz-Hansen et al., 2004). The lesions of these rare patients harbor T cells specific for oat avenin peptides that closely resemble gliadin T cell epitopes, but which are present in low amounts (Arentz-Hansen et al., 2004).

Other Environmental Factors

Infections may play a role in the development of celiac disease. Some of the best evidence comes from studies in Sweden. In children below the age of 2 years, a positive correlation was found between celiac disease risk and being born during the summer, and children born in the summer are first exposed to dietary gluten during the winter when infections are more prevalent (Ivarsson et al., 2003a). Moreover, in the same population case-control studies indicated that celiac subjects experience three or more infection episodes, more frequently than referents.

IN VIVO AND IN VITRO MODELS

Animal Models

With the possible exception of gluten-sensitive conditions in macaques (Bethune et al., 2008) and in horses (van der Kolk et al., 2012), there exists no good animal model for celiac disease. Several attempts have been made to establish a mouse model, so far with limited success. Gluten-sensitive enteropathy could not be induced in mice made transgenic for HLA-DQ2.5 (Chen et al., 2002, 2003) or HLA-DQ8 (Black et al., 2002). Not even HLA-DQ2.5 transgenic mice made transgenic also for T cell receptors specific for celiac disease-relevant gluten epitopes developed enteropathy (de Kauwe et al., 2009; Du Pre et al., 2011). Notably, dermatitis herpetiformis like skin lesions occurred in a fraction of HLA-DQ8 transgenic mice on a NOD background after systemic immunization with gluten, but without enteropathy (Marietta et al., 2004). Oral tolerance to dietary antigens is strong in rodents, and this could be one of the reasons why gluten-sensitive enteropathy does not develop in these models. Studying immune responses to dietary antigens, it was demonstrated that mice made transgenic for IL-15 and given retinoic acid lost oral tolerance to gliadin and developed gliadin-specific T cells producing IFN- γ (DePaolo et al., 2011). However, also these mice lacked enteropathy suggesting yet other factors are required for the formation of full blown celiac disease.

Organ Culture Assays

Culturing of small intestinal biopsies *ex vivo* has frequently been used to dissect pathogenic events in celiac disease. This assay for instance has been used to examine innate effects of gluten (Maiuri et al., 2003), and to show that gluten challenge induces a stress response with upregulation of IL-15, MICA, and heat shock proteins (Hüe et al., 2004). Although the *ex vivo* culture system has been very important in clarifying the pathogenic mechanisms of celiac disease (Lindfors et al., 2012), the result should be carefully interpreted. One of the problems with the *ex vivo* organ culture system may relate to uneven distribution of inflammatory cells in the mucosa (our unpublished results).

PATHOGENIC MECHANISMS

The strong HLA association in celiac disease and the overrepresentation of non-HLA susceptibility genes related to T cell function strongly suggests that T cells are important in the pathogenesis of celiac disease.

Gluten-reactive CD4⁺ T Cells

CD4⁺ T cells specific for gluten proteins can be isolated from the small intestinal biopsies of the majority of celiac disease patients (Lundin et al., 1993; van de Wal et al., 1998b), but not from biopsies obtained from disease controls (Molberg et al., 1997). In contrast, patients and many control subjects have gliadin-reactive T cells in their peripheral blood. These T cells use many different HLA molecules for presentation (DR, DQ, and DP) (Gjertsen et al., 1994), and their reactivity is not enhanced by deamidation of the gliadin (Molberg et al., 1998). This implies that many individuals can be immunologically sensitized to gluten without having small intestinal pathology. The gluten-specific T cells derived from the intestinal celiac lesions display a remarkable feature as they are invariably restricted by the disease-associated HLA-DQ molecules (Lundin et al., 1993, 1994) (Figure 59.3B). Most gluten proteins appear to be recognized by such DQ2.5 and DQ8 restricted T cells, although with variable frequency (Lundin et al., 1997; Sjöström et al., 1998; van de Wal et al., 1999; Anderson et al., 2000; Arentz-Hansen et al., 2000, 2002; Vader et al., 2002b; Molberg et al., 2003). The intestinal T cell responses to gluten are thus characterized by heterogeneity and many T cell epitopes exist (Sollid et al., 2012) (Figure 59.5). T cells responsive to the same epitopes are usually not detectable in the peripheral blood, but they can be detected in this compartment in patients in remission after a short-term oral gluten challenge either by ELISPOT (Anderson et al., 2000) or by HLA tetramer staining (Ráki et al., 2007; Brottveit et al., 2011). DQ2 tetramers are recombinantly made DQ2.5 molecules with tethered gluten epitopes that are multimerized (Quarsten et al., 2001), and which hence have sufficient avidity to stain antigen-specific T cells. Also celiac patients who are DQ2.2 but not DQ2.5 or DQ8 have gluten-reactive T cells in the intestinal lesions (Bodd et al., 2012).

Role of Transglutaminase 2

The role of the TG2 enzyme in the pathogenesis of celiac disease is not completely understood, but it clearly encompasses more than simply being the target of the autoantibodies in the disease. There are elevated levels of active TG2 in tissue homogenates made from biopsies of untreated celiac disease patients (Bruce et al., 1985) and the gluten proteins are excellent substrates for TG2. Most importantly, however, the T cells within the celiac lesions predominantly recognize gluten peptides modified by TG2 (Molberg et al., 1998; van de Wal et al., 1998a).

TG2 catalyzes a post-translational transamidation or deamidation of specific glutamine residues within its substrate proteins (Folk, 1983; Lorand and Graham, 2003).

FIGURE 59.5 T cell epitopes of gluten recognized by CD4⁺ T cells of celiac disease patients. Epitopes presented by HLA-DQ2.5 are shown in (A) and epitopes presented by HLA-DQ8 are shown in (B). The 9-mer core regions of the epitopes are given with one letter amino acid codes in the register with which they bind to the HLA molecules. T cell receptors recognizing the epitopes often are sensitive to residues outside the 9-mer core region. Glutamate residues (E) formed by TG2-mediated deamidation, which are important for recognition by T cells, are shown in red. Additional glutamine residues (Q) also targeted by TG2 are underlined. Of note is the abundance of proline (P) residues within the epitopes. Further information about epitopes and epitope nomenclature can be found in *Sollid et al. (2012)*.

In the transamidation reaction, the glutamine becomes cross-linked to a protein-bound lysine or a polyamine, whereas the deamidation reaction results in conversion of the glutamine to glutamic acid. The enzyme displays regional selectivity for glutamine residues in gliadin peptides, and QXP is a particularly good target sequence (Fleckenstein et al., 2002; Piper et al., 2002; Vader et al., 2002a). There is now strong evidence that the enzyme is involved in the selection of DQ2.5 restricted T cell epitopes (see later).

Gluten Antigen Presentation by Disease-associated DQ Molecules

HLA class II molecules bind antigenic peptides in a groove in their membrane distal part. In this groove there are pockets which accommodate side chains of amino acids of the peptide, so-called anchor residues. In HLA class II peptides anchor residues are found at positions P1, P4, P6, P7, and P9. Both DQ2.5 and DQ8, which are associated with celiac disease, have a fairly unique preference for binding peptides with multiple negatively charged residues. DQ2.5 has a preference for negatively charged anchor residues at positions P4, P6, and P7 (Kim et al., 2004; Tollefsen et al., 2006), whereas DQ8 has preference for negatively charged anchor residues at positions P1 and P9 (Tollefsen et al., 2006; Henderson et al., 2007) (Figure 59.6). The HLA association in celiac disease can thus be explained by a superior ability of the disease-associated HLA-DQ molecules to bind the biased repertoire of proline-rich gluten peptides that have

survived gastrointestinal digestion and which have been deamidated by TG2.

There is a hierarchy among the gluten T cell epitopes both in terms of how many T cells of a single patient respond to each, and in terms of the responder frequency among different patients (Marti et al., 2005; Tye-Din et al., 2010). The same epitopes dominate in each of these settings, likely reflecting variation in immunogenicity between the epitopes. In α -gliadin of wheat there are two immunodominant epitopes (i.e., DQ2.5-glia- α 1a/b and DQ2.5-gli- α 2) (Arentz-Hansen et al., 2000). In some α -gliadin proteins these epitopes are expressed in, altogether, six copies within a 33-mer fragment. This potent antigen is resistant to degradation by gastric, pancreatic, and intestinal brush border membrane proteases (Shan et al., 2002). Other immunodominant epitopes are the DQ2.5-glia- ω 2 which comes from ω -gliadin of wheat, and a shared 9 amino acid sequence found in wheat, rye, and barley (termed DQ2.5.glia- ω 1, DQ2.5-hor-1, and DQ2-sec-1) (Tye-Din et al., 2010). A similar hierarchy probably exists for HLA-DQ8 restricted epitopes. Celiac disease patients who express DQ2.2 but not DQ2.5 or DQ8, do not have T cells that respond to the common DQ2.5 restricted epitopes but often respond to an immunodominant DQ2.2 restricted epitope (DQ2.2-glut-L1) (Bodd et al., 2012). The common DQ2.5 restricted epitopes bind stably to DQ2.5 but unstably to DQ2.2 (Fallang et al., 2009), and interestingly the immunodominant DQ2.2 epitope binds stably to DQ2.2 (Bodd et al., 2012).

Stable binding of a gluten peptide to the HLA molecule thus seems to be important for a successful T cell

FIGURE 59.6 Three-dimensional structures of the binding sites of HLA-DQ2.5 (A) and HLA-DQ8 (B) complexed with deamidated gliadin peptide epitopes (carbon = yellow, nitrogen = blue, oxygen = red; amino acid residues in positions P1 to P9 are labeled). The electrostatic potential surface of the HLA molecules is shown as red (=negative) and blue (=positive). HLA-DQ2.5 (PDB 1S9V) (Kim et al., 2004) is complexed with the DQ2.5-glia- α 1a epitope, and HLA-DQ8 (PDB 2NNA) (Henderson et al., 2007) is complexed with the DQ8-glia- α 1 epitope. Courtesy of K. Hotta.

priming, possibly because the peptide in complex with the HLA molecule has to be transported on the surface of antigen-presenting cells from the mucosa to the mesenteric lymph node where the priming most likely takes place (Fallang et al., 2009). Notably, deamidation of gluten peptides decreases the off-rate for binding to DQ2.5 (Xia et al., 2005), and one effect of demidation could be that more gluten–DQ complexes reach the lymph node resulting in productive priming.

Only few sequences in the huge gluten proteome give rise to T cell epitopes. This suggests that there are strong guidance factors in the selection of T cell epitopes. Three factors have been identified as being particularly important: protease resistance, MHC binding, and TG2

efficiency. The clustering of epitopes to regions of gluten proteins which have a high content of proline residues and which are proteolytically stable is evidence that proteolytic stability is important. Antigen concentration is important for T cell stimulation, and fragments that are resistant to breakdown will survive at higher concentrations. The selection by MHC would relate to selection of peptides with the correct binding motif as well as selection of peptides that form stable HLA complexes. The observation that HLA-DQ2.5 and HLA-DQ8 in general select discrete epitopes in gluten epitopes underscores the effect of the former factor (Tollefsen et al., 2006). Finally, TG2 specificity appears to be important. There is a correlation between how frequently T cell epitopes are

recognized by celiac disease patients and their propensity to be targeted as substrates for TG2 (Dorum et al., 2009). Moreover, using TG2 to select its best substrates from a proteolytic digest of gluten consisting of several thousand different peptides, the majority of about 30 peptides selected contained celiac disease-related T cell epitopes (Dorum et al., 2010). This suggests that TG2 specificity is a major force in T cell epitope selection.

Mucosal Antigen-presenting Cells

Several types of HLA-DQ positive cells can serve as antigen presenting cells in the small intestinal mucosa (Raki et al., 2006; Beitnes et al., 2011). There are CD163⁺CD11c⁻ macrophages and CD11c⁺ dendritic cells which express either CD163 or CD103 and CD1c. The CD163⁺CD11c⁺ dendritic cells likely derive from circulating monocytes as they co-express CD14 and CCR2. The CD11c⁺ dendritic cells expressing CD103⁺ or CD1c⁺ do not express CD163 or CD14, suggesting the existence of separate functional lineages. In the active celiac disease lesion there is an increase of CD163⁺CD11c⁺ dendritic cells, whereas CD163⁺CD11c⁻ macrophages and CD103⁺ and CD1c⁺ dendritic cells are all decreased (Beitnes et al., 2011). Based on studies in mice (Schulz et al., 2009) it is tempting to speculate that the CD11c⁺CD103⁺ dendritic cells function to transport antigen to mesenteric lymph nodes for presentation to naïve or central memory cells T cells whereas the CD163⁺CD11c⁻ macrophages and CD163⁺CD11c⁺ dendritic cells serve to present antigen locally to effector T cells.

Effector Mechanisms Leading to Mucosal Alterations

Despite the lack of detailed knowledge of effector mechanisms involved in creation of the celiac lesion, evidence suggests that inflammatory cytokines, particularly interferon- γ , are involved. Messenger RNA for IFN- γ is abundant in biopsies taken from untreated patients and is rapidly induced when biopsies from treated patients are challenged *ex vivo* with gluten (Nilsen et al., 1998). IFN- γ is also produced by the intestinal, gluten-specific CD4⁺ T cells (Nilsen et al., 1995), and by IELs (Forsberg et al., 2002; Olausson et al., 2002).

IL-15 is another important cytokine in celiac disease. In active celiac disease there is increased expression of IL-15, both in the lamina propria (Maiuri et al., 2000) and in the epithelium (Mention et al., 2003). Enterocyte bound IL-15 can activate and expand IELs (Mention et al., 2003), and can induce epithelial Fas expression promoting apoptosis of epithelial cells (Maiuri et al., 2000). The expression of IL-15 increases following *in vitro* gluten challenge of celiac biopsies, and certain gluten peptides appear to cause innate immune activation and IL-15 production (Maiuri et al.,

2003). IL-15 is a key factor for reprogramming IELs in celiac disease, where the IELs downregulate inhibitory and upregulate activating NK cell receptors (Meresse et al., 2006) (Figure 59.3A). Activated IELs can kill stressed enterocytes, and this seems to be a crucial step in creating the celiac lesion (Jabri and Sollid, 2009).

Taken together, currently available data places the activation of CD4⁺ T cells recognizing gluten peptides presented by HLA-DQ2 or HLA-DQ8 molecules as the central key gateway for the control of celiac disease development. The activation of naïve T cells probably takes place in mesenteric lymph nodes, and effector cells then seed to the lamina propria in the small intestine where they are reactivated upon challenge with gluten. This model would explain the dominant genetic role of HLA. The products of the other predisposing genes likely feed into the processes that lead to T cell activation or tissue destruction, but as the non-HLA susceptibility genes each has small effects this indicates a lack of critical checkpoints or redundancy in pathways.

AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

The diagnosis of celiac disease in adults requires demonstration of enteropathy corresponding to Marsh 3 (Kagnoff, 2006; Ludvigsson et al., 2012). Serology is supportive of the diagnosis. Moreover, it is clear that even less pronounced enteropathy can be compatible with celiac disease, and there is a need for both a combined approach and revision of guidelines (Kurppa et al., 2009). New European guidelines for children were recently published (Husby et al., 2012), but are not yet generally implemented. These guidelines state that the diagnosis in some cases can be made without assessment of intestinal histology by using a combination of strongly positive serology, HLA typing, and clinical criteria.

Serology

More than 95% of untreated celiac disease patients (at least in selected patient cohorts) have high titers of serum IgA antibodies reactive with TG2 (Dieterich et al., 1998; Sulkanen et al., 1998). Most tests are ELISA based with human recombinant TG2 as antigen. In the recent European guidelines for pediatric celiac disease (Husby et al., 2012), the EMA test is included in the diagnostic algorithm as this test was judged to outperform the anti-TG2 ELISA for prediction of celiac disease (Giersiepen et al., 2012). This may relate to the fact that the celiac anti-TG2 antibodies are reactive with conformational epitopes and that the TG2 antigen in some commercial kits is suboptimally folded. If so, one may expect that anti-TG2 ELISA kits will replace the EMA

test when the TG2 antigen is produced carefully and the test is performed in an optimal way. IgG anti-TG2 antibodies can be useful for evaluation in patients with selective IgA deficiency, but should otherwise not be tested for (Collin, 1999; Murray, 1999).

Patients with untreated celiac disease also have increased levels of IgA and IgG anti-gluten antibodies. Monitoring of such antibodies, in particular anti-gliadin antibodies, was for many years used in the clinical workup of celiac disease. However, the IgA EMA and anti-TG2 tests gradually took over in clinical practice due to better performance. Some of the anti-gluten antibodies are directed against deamidated epitopes (Osman et al., 2000), and tests based on reactivity to deamidated gliadin peptides perform at the level of anti-TG2 tests (Lewis and Scott, 2010). A problem is that the performance of serological tests is less impressive in clinical practice, at least for adults, when the tests are used in unselected, “everyday” patients as compared to the majority of publications where the proportion of serology-positive celiac disease has been high (Leffler and Schuppan, 2010).

Some celiac disease patients present with negative serology (Dahele et al., 2001; Kaukinen et al., 2002), and an intestinal biopsy should therefore always be taken when there is high clinical suspicion of celiac disease (Farrell and Kelly, 2002). Notably, false-positive anti-TG2 tests do also occur, particularly in patients with inflammatory bowel disease (Dahele et al., 2001; Carroccio et al., 2002).

Staining of Immune Complexes

In patients with active celiac disease there are deposits of IgA in the small intestine corresponding to the distribution of fibronectin bound extracellular TG2, typically as a band beneath the epithelium (Korponay-Szabo et al., 2004). Such deposits of specific IgA complexed with TG2 can be found in the intestinal mucosa even in those patients where serum autoantibodies are undetectable (Salmi et al., 2006b). In IgA deficient patients, these deposits are made up of IgM (Borrelli et al., 2010). Case reports have described autoantibody deposits years before any intestinal damage was observed, and the production of TG2-specific autoantibodies is therefore considered an early marker for developing celiac disease (Salmi et al., 2006a). Because detection of IgA deposits can only be done with frozen tissue sections, this method has not reached widespread usage.

TREATMENT AND OUTCOME

Current Treatment and Outcome

The current treatment of celiac disease is a life-long gluten exclusion diet. The disease is largely a benign disorder, and particularly so in patients detected by screening

(West et al., 2003). Although celiac patients overall have an increased relative risk for non-Hodgkin’s lymphoma of the gastrointestinal tract, the absolute risk is low and lower than previously anticipated (Askling et al., 2002; Catassi et al., 2002). In an Italian study it was found that the overall mortality rate in celiac disease was two times greater than in the controls (Corrao et al., 2001). This increased mortality was accounted for by increased death rates in the first 3 years after diagnosis. The gluten-free diet has been considered to be protective against development of malignancy, but this notion was not supported by a study from the United States (Green et al., 2003). Persistent mucosal inflammation (compatible with either lack of compliance or other autoimmune phenomena) is of particular concern (Ludvigsson et al., 2009).

The most frequent reason for absent or incomplete clinical improvement is poor diet compliance (Ciacci et al., 2002), but it is clear that some patients have refractory disease that does not respond to an adequate diet. A majority of the patients with refractory celiac disease have monoclonal expansions of intraepithelial lymphocytes that can progress to become overt enteropathy-associated T cell lymphoma (Cellier et al., 2000). The management of severe complications in this condition is difficult and has yet to be based on recommendations obtained by multi-center trials (Rubio-Tapia and Murray, 2010).

Novel Therapeutic Options

Many patients cope with the gluten-free diet easily. Others find that the dietary restrictions are laborious and negatively impact their quality of life. Better alternatives are thus called for. It is hence promising that the insight into the molecular mechanisms involved in the intestinal T cell reactivity to gluten has uncovered novel targets for therapy. Several avenues are being pursued for the development of new therapies. One possibility, which is basically an extension of today’s treatment with a gluten-free diet, is to produce cereals with bread-making properties that are devoid of T cell epitopes, either by breeding programs or transgenic technology (Gil-Humanes et al., 2010). Another possibility is enzyme supplementation with the aim either to destroy T cell epitopes directly or to facilitate their gastrointestinal proteolysis (Hausch et al., 2002; Gass et al., 2007; Mitea et al., 2008). Prolyl endopeptidases are particularly attractive enzymes as they will target the proline-rich regions of gluten that harbor the T cell epitopes. TG2 is a target for intervention because of the critical role it plays in generating gluten T cell epitopes, and a series of TG2 inhibitors have been developed (Badarau et al., 2011) that potentially may be useful in therapy of celiac disease. A potential problem with this approach may be

that TG2 inhibitors can have unacceptable side effects, as TG2 is involved in many different physiological processes (Lorand and Graham, 2003). TG2 inhibitors may also not be specific for TG2, but may affect the function of other transglutaminases. Another strategy would be to aim directly at the gluten-reactive T cells. This can possibly be achieved by peptide vaccination or by deletion of antigen-specific T cells. Yet another possible target would be to block presentation of gluten peptides by DQ2 and DQ8, and thereby activation of gluten-reactive T cells. The challenge with this approach will be to find an efficient way to target and block the binding sites of DQ molecules, which are continuously synthesized by antigen-presenting cells. Whatever new therapeutic modality is introduced in celiac disease, it will have to prove as good as or better than the current gluten-free diet regime, with regard to its long-term safety and outcome. This fact must be taken into consideration when devising new treatments.

CONCLUDING REMARKS—FUTURE PROSPECTS

Considerable progress has been made in recent years on the understanding of the molecular basis for celiac disease, but several new questions have emerged. Many of these relate to the autoimmune aspects of the disease. Is celiac disease an autoimmune disorder? To what extent are the autoimmune components of celiac disease involved in disease development? What is the key event transforming the mucosal immune system from gluten tolerant to gluten intolerant? How relevant are the findings of T cell recognition of post-translationally modified peptides and autoantibody formation driven by an exogenous food antigen for other autoimmune disorders? Can it be that other autoimmune disorders are driven by immune responses to foreign, not yet identified, antigens? Finally, in the coming years it will be interesting to see if any of the novel therapies being developed become real alternatives to the gluten-free diet.

INTRODUCTION

Inflammatory bowel disease (IBD) is divided into two distinct but related entities: Crohn's disease (CD) and ulcerative colitis (UC). While the two diseases share some features, there are important clinical differences between them and thus they will be presented separately for part of this discussion. It should also be noted that the etiology and pathophysiology of IBD is not yet clearly established; furthermore, the degree to which these diseases are truly autoimmune in nature is unclear.

HISTORY

Numerous case reports exist from the 19th century describing inflammatory diseases of the small and large

intestine that may have represented CD (Baron, 2000). Ileocecal inflammation as seen in CD is also characteristic of intestinal tuberculosis, which was the most commonly recognized disease of the small intestine at that time. As microscopy evolved, case series have emerged of patients with inflammation and strictures of the ileocecal region that were determined to be neither tuberculous nor malignant. These strongly suggest that CD, as we presently know it, existed at least as far back as the 19th century.

The seminal work describing CD was a paper from the Mount Sinai Hospital in New York by Burrill B. Crohn, Leon Ginzburg, and Gordon D. Oppenheimer (1932) entitled "Regional Ileitis: A Pathologic and Clinical Entity." The authors described a series of 14 patients operated upon by Dr. A.A. Berg with granulomatous inflammation of the terminal ileum. The title of the paper reflected Crohn's belief that the disease affected only the ileum (Wells, 1952) despite evidence presented by Ginzburg and Oppenheimer (1932) and others of cases affecting the small and large intestine. Interestingly, the

[†] With their deepest regret, the Editors note the death of Dr Lloyd Mayer during the composition of this text. The Editors' Preface contains a tribute to his many valued achievements and contributions. The corresponding author is Vera Denmark.

disease came to be known as Crohn's only because the authors agreed to list their names alphabetically and because the surgeon Berg humbly declined to be included as an author (Baron, 2000).

Early work on UC was also complicated by difficulty in distinguishing it from infectious colitides such as bacillary dysentery. Credit for the discovery of UC as a distinct entity has been given to Samuel Wilks (1859) who termed it "idiopathic colitis." The term "ulcerative colitis" was first used by Hale-White (1888), although in retrospect these patients may not have had UC but rather irritable bowel syndrome (Baron, 2000). Further work was facilitated by the introduction of the electric sigmoidoscope; studies by Sir William Hurst (1909) and also Lockhart-Mummery (1907) helped to clarify the appearance of the colon in UC.

EPIDEMIOLOGY AND ENVIRONMENTAL FACTORS

The highest of rates of IBD are found in northern Europe, the United Kingdom, and North America (Loftus, 2004). However, it is increasingly recognized that IBD can occur in persons from other areas such as Africa, Latin America, and Asia. Extrapolation of incidence and prevalence rates for North America as presented by Loftus (2004) and suggests the following: approximately 780,000 persons in the USA and Canada have UC and 630,000 have CD. Between 7000 and 46,000 new diagnoses of UC are made yearly and between 10,000 and 47,000 new diagnoses of CD are made. Similarly to multiple sclerosis, IBD does appear to be more frequently found in the northern latitudes (Blanchard et al., 2001; Sonnenberg et al., 1991).

IBD may present at any age; however, it is most commonly diagnosed in the second or third decade of life. There does not seem to be a major gender preference in IBD. Other than genetic risk factors, which will be addressed in a separate section, several environmental risk factors have been hypothesized to predict the development or course of IBD. Cigarette smoking is an important risk factor with divergent effects on CD and UC. Numerous studies have confirmed that smoking is associated with a higher risk of developing CD (Calkins, 1989), an earlier need for surgery for CD (Sands et al., 2003), and earlier relapse after surgery (Timmer et al., 1998). Conversely, cigarette smokers are less likely to develop UC (Calkins, 1989) or to require colectomy for UC (Boyko et al., 1988). In numerous case-control studies as well as a meta-analysis by Koutroubakis et al. (2002), appendectomy for appendicitis has been shown to protect against a subsequent diagnosis of UC. The pathophysiologic effects of smoking and appendectomy are as of yet unclear. Numerous other environmental factors have been studied,

TABLE 60.1 Major Categories in the Differential Diagnosis of IBD

| Category | Examples |
|--------------|--|
| Infectious | Bacterial (<i>Salmonella</i> , <i>Shigella</i> , <i>E. coli</i> , <i>Yersinia</i> , <i>Clostridium difficile</i> , <i>Campylobacter</i>) |
| | Viral (<i>Cytomegalovirus</i>) |
| | Mycobacterial (<i>M. tuberculosis</i> , <i>M. avium-intracellulare</i>) |
| | Parasitic (<i>Entamoeba histolytica</i> , <i>Strongyloides</i> , <i>Giardia</i>) |
| Vascular | Vasculitis (polyarteritis nodosa, Henoch-Schönlein purpura) |
| | Radiation-induced enteritis |
| | Ischemia |
| Oncologic | Lymphoma, adenocarcinoma, carcinoid, metastatic disease |
| Inflammatory | Microscopic colitis, diverticular colitis, diversion colitis, celiac disease |
| Functional | Irritable bowel syndrome |
| Drug-induced | Non-steroidal anti-inflammatory drugs |

including breast feeding, diet, measles vaccination, oral contraceptives, and various infectious agents. However, none of these has been conclusively shown to affect the development or course of IBD (see Table 60.1).

CLINICAL AND PATHOLOGIC FEATURES

Disease Presentation

Crohn's Disease

A hallmark of CD is its ability to involve any part of the gastrointestinal tract from mouth to anus. Multiple sites of disease can be affected in the same individual. The inflammation in CD, as distinct from UC, is discontinuous; diseased bowel is separated by areas of healthy bowel (so-called "skip lesions"). The location of CD in the bowel usually falls into one of three patterns: isolated small bowel disease, combined small and large bowel disease, and isolated colitis. The most commonly affected segment of bowel is the terminal ileum, which is diseased in two-thirds of patients (Munkholm and Binder, 2004). Colonic involvement in CD typically does not involve the rectum, which is always involved in UC. A small percentage of patients have disease of the jejunum or esophagus only.

CD can also be divided into three types of disease behavior: pure inflammatory, stricturing, or fistulizing. These behavior types are not mutually exclusive; however,

the combination of disease behavior and location can nonetheless often dictate clinical presentation. For example, a common presentation of CD is inflammatory disease of the terminal ileum with symptoms of pain, diarrhea, and weight loss. When inflammatory disease involves the colon, a more UC-type syndrome ensues with diarrhea and occasional rectal bleeding. Stricturing disease can be more subtle in development, with a long time course of relatively normal bowel function before symptoms of pain, bloating, and eventually obstruction ensue.

The ability of CD to cause fistulae reflects its transmural nature. UC involves only the mucosal layer of the GI tract while CD can involve all layers from mucosa to serosa. When inflammation is severe enough to extend from mucosa to serosa, fistulae result such that the contents of the intestinal tract spill out into an adjacent space. The perianal region is the most common site of fistula development in CD. About 20% of patients with CD will have perianal fistulas (Schwartz et al., 2002) which present clinically with perianal abscesses that may spontaneously drain. Fistulas can also arise in the bowel and invade other parts of bowel, bladder, vagina, or psoas muscles causing abscesses or frank drainage of stool.

Ulcerative Colitis

UC affects only the colon. As a result, its presentation is more consistent than that of CD. UC usually presents with symptoms of diarrhea and rectal bleeding. Abdominal pain and constitutional symptoms (fever, weight loss) are less frequent than in CD, except in severe UC flares. The amount of colon that is involved in UC can vary from the entire colon (pan-colitis) to just the most distal part (left-sided colitis or proctitis). As a rule, the more proximal colon will only be affected when the more distal area is as well. Thus the endoscopic findings of isolated right-sided colitis (in combination with other features such as rectal sparing) argue strongly for a diagnosis of CD as opposed to UC. Isolated proctitis can present as tenesmus or rectal bleeding in the absence of diarrhea given the normal proximal colon. Infrequently, pan-colitis can progress to toxic megacolon, a massively dilated colon with accompanying fever and tachycardia; immediate surgery is indicated for this condition.

Pathology

Microscopy of specimens from endoscopic mucosal biopsies or surgical resections can help ascertain the diagnosis of IBD and frequently distinguish between UC and CD. Common features of IBD include ulceration, acute and chronic inflammatory infiltrate, crypt abscesses, and crypt distortion. Though suggestive of IBD, these changes can sometimes be seen in other conditions such as infectious

colitis. The findings of transmural inflammation (usually possible only in surgical specimens) or of non-caseating granulomas suggest a diagnosis of CD as opposed to UC. Unfortunately, granulomas may be identified in as few as 15% of endoscopic biopsies (Okada et al., 1991) and thus the absence of granulomas does not rule out CD. The cellular infiltrate in the Crohn's mucosa is one of activated lymphocytes (mostly T cells) and macrophages. In UC, neutrophils and mast cells predominate although activated lymphocytes and macrophages are present as well.

GENETICS

Several factors point to a genetic contribution to the etiology of IBD. Rates of IBD are considerably higher in certain ethnic groups such as Ashkenazi Jews as compared with others living in the same geographic area. Relatives of patients with IBD also have a higher rate of developing the disease. For monozygotic twins, the concordance rate is about 40–60% for CD and about 5–20% for UC (Subhani et al., 1998; Orholm et al., 2000; Halfvarson et al., 2003). This suggests that CD may have more of a genetic basis, but clearly since both rates are much less than 100% the environment and possibly the microbiome must play a role as well. Five to 15% of patients with IBD will have an affected first-degree relative, and the subtype (CD vs. UC) will be the same in 75–80% of cases (Binder, 1998). This corresponds to about a 15-fold increased risk of disease if one has a first-degree relative with IBD (Satsangi et al., 1994; Peeters et al., 1996).

Genome-wide association studies have identified 99 non-overlapping susceptibility loci for CD, including 28 that are shared between CD and UC (Anderson et al., 2011). Approximately 50% of IBD susceptibility loci have also been associated with other autoimmune diseases. Analysis of genetic loci implicated in IBD underscore the importance of several pathways that are involved in the maintenance of gut homeostasis: epithelial restitution and barrier function, regulation of innate and adaptive immunity, microbial defense, and autophagy. Each of these pathways will be discussed in the subsequent section. A few of the major IBD susceptibility loci will be reviewed here.

NOD2 (*CARD15*) (see Table 60.2) was the first CD susceptibility gene identified, emphasizing the importance of defects in innate immunity in the pathogenesis of CD (Hugot et al., 2001; Ogura et al., 2001a; Hampe et al., 2001). It is present in 8–25% of CD patients and is encountered in the greatest percentage of the patients as compared to other mutations. *NOD2* is an intracellular receptor for muramyl dipeptide, a motif present in bacterial cell walls. It appears to modulate signaling through Toll-like receptor pathways, thereby activating NF- κ B. *NOD2* may also trigger autophagy after detecting

TABLE 60.2 Genomic Regions Associated with Inflammatory Bowel Disease in Genome-wide Association Studies of Patients of European Descent

| Predominantly Associated with CD | Predominantly Associated with UC | Significant Associations with CD and UC |
|----------------------------------|---|---|
| NOD2 (16q12) | MHC region (6p21) | Factors in IL-23 pathway (12q13, 5q33, 19p13) |
| ATG16L1 (2q37) | FCGR2A (1q23, Fc fragment receptor) | 1q32 (region includes IL-10) |
| IRGM (5q33.1) | Loci that affect epithelial defenses (7q22) | Gene deserts (5p13, 9q32) |
| 5q31 | 12q14 | 9q34 (region includes <i>CARD9</i>) |
| 9q32 | 20q13 | Transcription factors (10q22, 10q24, 15q22) |
| 10q21 | | |
| 18p11 | | |
| 22q13 | | |
| 12q12 | | |

intracellular bacteria (Zaki et al., 2010). Interestingly, *NOD2* variants associated with CD result in loss of function of the *NOD2* protein. This is puzzling as increased, rather than reduced, inflammatory activity is observed in CD patients. This loss of function of a key component of innate immunity may be overcompensated for by the adaptive immunity arm, which may drive the inappropriate inflammatory response observed in CD patients. This theory remains to be proven, however.

CARD9 is an IBD-implicated adaptor protein which integrates signals from many innate immune receptors that recognize microbial motifs (Ogura et al., 2001b). *CARD9* is required for the development of an appropriate intestinal immune response in the steady state and in the colitis setting. *CARD9* knockout (KO) mice exhibit defective expression of IL-17A and IL-22 in the recovery phase following DSS-induced injury (Sokol et al., 2006). In addition, KO mice show a decrease proportion of Th1, Th17, and innate lymphoid cells (ILCs). Thus, *CARD9* is notably involved in Th17 and IL-22 responses that are required to eradicate some intestinal pathogens and to recover after intestinal inflammation.

The IL-23/IL-12 pathway has been extensively studied in respect of IBD as it determines differentiation of naïve T cells into effector Th1 cells (driven by IL-12) or Th17 cells (driven by IL-23). Variants in the IL-23 receptor gene (IL-23R) on chromosome 1p31 were found to be associated with CD susceptibility (Duerr et al., 2006). This association was also confirmed in UC (Tremelling et al., 2007). Other components of the Th17 pathway have been associated with CD, including signal transducers STAT2 and JAK3, the chemokine receptor CCR6 and costimulatory molecule ICOS-L, highlighting the

important role the Th17 pathway plays in the pathogenesis of CD (Barrett et al., 2008). Interestingly, *NOD2* and *IL-23R* were not found to be associated with IBD in Japan (Yamazaki et al., 2007).

Genetic analyses have revealed a role for autophagy in innate immunity and IBD, implicating two genes, *ATG16L1* and *IRGM*, in IBD pathogenesis (Hampe et al., 2007; McCarroll et al., 2008). Autophagy is involved in the degradation and recycling of cytosolic contents and organelles, as well as in the removal of intracellular microbes. *ATG16L1* is essential for all forms of autophagy and the coding mutation T300A is associated with increased risk of CD. Epithelial cells and dendritic cells containing CD-associated *ATG16L1* and *NOD2* variants show defects in antibacterial autophagy (Cooney et al., 2010; Travassos et al., 2010). These results suggest that genetic polymorphisms may affect both pathways concomitantly and underscore a close relationship between *NOD2*, *ATG16L1*, and autophagy.

IBD represents a complex genetic disorder in which each gene mutation contributes to the disease. However, other than *NOD2*, the other 98 genes identified in the genome-wide association studies contribute only 1% or less to the risk of developing IBD. Many healthy controls carry the same genetic mutations but do not have the disease. Thus, predicting the development of IBD remains a challenge.

IMMUNOPATHOGENESIS

Inflammatory bowel disease (IBD) is a chronic disease of the intestinal tract, which results from a complex interplay between genetic factors and environmental triggers.

It is believed that aberrant innate immune responses to commensal flora play an important role in IBD pathogenesis. Patients with IBD develop strong immune responses to common bacterial antigens that do not trigger an immune response in a normal host (Dahan et al., 2007). Controlling inflammatory responses to commonly encountered antigens presents a challenge to the mucosal immune system of patients with IBD. The basal state of mucosal immune suppression observed in healthy people is important to prevent a pathologic response to the constant presence of commensal flora and dietary antigens. While the immunologic tone of a mucosa-associated lymphoid tissue (MALT) in a normal host is that of hyporesponsiveness or suppression, the immunologic tone of the MALT in an IBD patient is that of activation. The mechanisms responsible for the healthy tone of hyporesponsiveness in a normal host involve complex interactions between the intestinal epithelial cell (IEC) of the GI tract and the underlying T lymphocyte in the lamina propria. We will discuss each of the three major players in the pathogenesis of IBD (the epithelial barrier, the innate and adaptive immune responses, and the host–microbial interactions) separately.

Epithelial Barrier and Innate Immunity

The first line of defense against luminal pathogens is a layer of mucus produced by specialized cells within the epithelial lining called goblet cells. Mice deficient in the main component of goblet cell mucus, Muc2, develop spontaneous colitis (Heazlewood et al., 2008). Patients with IBD frequently have a compromised mucus layer and increased mucolytic bacteria. In addition to the mucus layer, another layer of protection is provided by Paneth cells that are located in the crypts of the small intestine. Paneth cells are the primary source of antimicrobial peptides. Interestingly, patients with CD carrying the *ATG16L1* (T300A) mutation have Paneth cell granule abnormalities (Cadwell et al., 2008). This defect in Paneth cell biology may define a subset of patients with CD.

Intestinal epithelial cells (IECs) perform both barrier and signal-transduction functions. The structure of tight junctions is crucial for the integrity of the epithelial layer. Genetic studies have shown that truncated forms of the adherens junction protein E-cadherin (encoded by *CDH1*, a CD susceptibility gene) are associated with CD. Intestinal biopsies from patients with these CD alleles show inappropriate protein localization and cytosolic accumulation.

We now know that the epithelial cell not only serves as a physical barrier between the intestinal lumen and the underlying lymphoid tissue, but is also involved in the regulation of innate and adaptive immune responses (Dahan et al., 2007). IECs produce intestinal alkaline

phosphatase, which can mediate lipopolysaccharide detoxification. IECs can also attenuate neutrophil transmigration by generating resolving-E1 through the action of cyclooxygenase-2 (Campbell et al., 2010). IECs can also modulate adaptive immune responses by functioning as nonprofessional antigen-presenting cells to the T lymphocytes in the lamina propria (Campbell et al., 2002). Epithelial antigen processing occurs in a highly polarized fashion, with apical antigens being sorted and presented exclusively basolaterally. Studies from the Mayer lab have identified a regulatory/suppressor CD8⁺ T cell population, CD8⁺CD28⁻CD103⁺, which undergoes oligoclonal expansion in the lamina propria of the gut after interacting with an MHC class I-like complex on the basolateral surface of an epithelial cell (Allez et al., 2002). This suppressor T cell population is absent or markedly reduced in the lamina propria of IBD patients (Brimnes et al., 2005). A lack of activation of this regulatory lymphocyte population may contribute to the uncontrolled inflammation seen in IBD.

Adaptive Immunity

Professional and nonprofessional antigen-presenting cells (APCs), such as dendritic cells, macrophages, and intestinal epithelial cells, communicate with lamina propria lymphocytes through a broad array of cytokines. Cytokines have been demonstrated to play a central role in fostering gut inflammation in CD. Inflammatory responses in UC are driven by a complex of activated T cells, while inflammation in CD is driven by an interplay between Th1 and Th17 responses, creating a constantly evolving cytokine milieu (Kamada et al., 2010; Strober et al., 2010). The conventional Th1 response is characterized by an increased production of IL-12 and IFN- γ . This response is followed by a Th17 response, characterized by an increase in IL-23 and IL-17. Indeed, increased IL-17 production occurs in the lamina propria of CD patients and IFN- γ levels correlate with disease severity (Strober et al., 2010). In addition, CD patients harbor increased numbers of circulating IL-17 and IFN- γ producing memory cells. IL-17 and IFN- γ , the major players in the CD inflammatory response, induce production of “downstream” cytokines, such as TNF- α , IL-6 and IL-1 β that play important roles in the mediation of inflammation and tissue destruction. A unique IL-17⁺ FoxP3⁺ T cell population has recently been identified in the lamina propria of CD patients but not in patients with UC or healthy controls (Hovhannisyan et al., 2011). This CD4⁺ population shares phenotypic characteristics of both Th17 and Treg cells and shows potent suppressor activity *in vitro*. Thus, the specific microenvironmental cues likely determine cellular commitment to either lineage and affect the balance between regulation and inflammation.

Another example of the diverse effects environmental cues have on cellular/cytokine behavior is illustrated by a newly discovered cytokine IL-22, a member of the IL-10 family. IL-22 has recently been found to be upregulated in the inflamed mucosa of CD patients (Brand et al., 2006). Although IL-22 has been shown to promote epithelial barrier function by inducing epithelial cell differentiation, co-secretion of IL-22 with proinflammatory cytokines such as TNF- α , IFN- γ , and IL-17 results in a dramatic increase in an inflammatory immune reaction (Eyerich et al., 2010). Thus, IL-22 can be a pro- as well as an anti-inflammatory cytokine depending on the microenvironment.

Host–Microbial Interactions

Accumulating evidence suggests that luminal flora is a requisite factor in the development of IBD. The animal models have served to underscore the role of the luminal flora. In virtually every model identified to date (over 50 described), the animals fail to develop disease when reared in a germ-free environment (Podolsky, 1997) (see Table 60.3). When normal flora is added, disease ensues rapidly. Microbial signals also shape innate and adaptive immune responses. Germ-free animals have underdeveloped Peyer's patches, as well as fewer lamina propria CD4⁺ cells, underscoring the role microbiota plays in generating mature adaptive immune responses.

Studies of luminal bacterial composition in patients with IBD have revealed a decrease in beneficial bacteria such as the bifidobacteria *Lactobacilli* and *Firmicutes* and an increase in putative pathogenic bacteria such as *Bacteroides* and *E. coli* (Swidsinski et al., 2002; Sokol et al., 2006). This dysbiosis may promote inflammation by altering the balance between protective and harmful intestinal bacteria. Recently, adherent-invasive *E. coli* (AIEC) has been shown to adhere to IECs in the ileal mucosa in CD patients but not to ileal mucosa of normal controls, implicating AIEC as a potential inflammatory trigger in CD patients (Barnich et al., 2007). It is still unclear, however, whether the abundance of AIEC in the

terminal ileum of CD patients is the cause of inflammation or a consequence of the disease. CEACAM6, a surface epithelial glycoprotein, has been shown to be the receptor for AIEC. CEACAM6 is expressed to a greater extent in ileal IECs of CD patients as compared to normal controls. Therefore, it is unclear whether the presence of AIEC in the terminal ileum of CD patients stimulates CEACAM6 expression and facilitates its own cell adhesion or whether the abnormal ileal expression of CEACAM6 during inflammation in CD mediates binding of pathogenic *E. coli*.

In summary, IBD appears to occur in the setting of host genetic susceptibility due to impaired function in host defense against intestinal bacteria, induced by polymorphisms in innate effector systems, such as NOD2 and autophagy pathways.

BIOMARKERS

Numerous fecal and serological biomarkers have been proposed to be used for the purpose of identifying patients with IBD, differentiating between active and quiescent disease, predicting disease course and monitoring response to therapy. Here we will briefly describe the major biomarkers used in clinical practice.

Fecal Markers

The two fecal markers most commonly utilized are calprotectin and lactoferrin. Calprotectin is a calcium- and zinc-binding protein that represents 60% of cytosolic proteins in granulocytes. Lactoferrin is an iron-binding protein found in neutrophil granules and is secreted by mucosal membranes. Both markers are indirect measures of the neutrophil infiltrate in the bowel mucosa (Kane et al., 2003; Vermeire et al., 2006). Based on a recent meta-analysis, the estimate sensitivity and specificity values for the two fecal markers for the identification of patients with IBD, compared to those without, are 82–89% and 81%, respectively ((Lewis, 2011). Concentrations of fecal calprotectin and lactoferrin have

^aIndirect immunofluorescence after DNase.

^bIgG or IgA ASCA.

respectively been correlated with histologic and endoscopic disease activity in patients with UC and CD. Fecal markers correlated better with colonic than with ileal disease (Sipponen et al., 2008). The sensitivities of these tests to detect any active mucosal disease ranged from 70 to 100%, while specificities ranged from 44 to 100%, depending on the cut-off points used (Lewis, 2011). Despite the high predictive value of fecal tests, a combination of clinical symptoms and elevated serum CRP values was superior to fecal tests in predicting endoscopic disease activity (Solem et al., 2005). Of note, fecal calprotectin is increased in other infectious and inflammatory conditions, such as infectious and ischemic colitis and non-IBD inflammatory disorders.

Serologic Markers

C-reactive protein (CRP) is one of many acute phase reactants that increase in the serum of patients with active IBD. CRP is elevated in close to 100% of patients with active CD and only in about 50% of patients with active UC (Poullis et al., 2002). Erythrocyte sedimentation rate (ESR) has also been found in some studies to correlate with CD activity but it is used less widely than CRP in CD because ESR levels do not change as quickly with disease activity. However, in UC the ESR is more of a reliable marker.

A number of circulating antibodies directed against self-antigens as well as microbial components have been found in sera of IBD patients. These biomarkers have been used in attempts to help differentiate between CD and UC in 10% of patients with IBD-type unclassified, in whom the exact diagnosis is difficult to make. Antibodies associated with CD are anti-*Saccharomyces cerevisiae* antibodies (ASCA), anti-*Escherichia coli* outer membrane porin (OmpC), anti-*Pseudomonas fluorescens*-associated sequence (I2), and anti-flagellin (CBir1). On the other hand, patients with UC have higher titers of perinuclear antineutrophil cytoplasmic antibodies (pANCA) than CD patients. These tests are specific but not sensitive in identifying patients with IBD; thus, close to 50% of patients with IBD may have normal titers of these circulating antibodies (Reese et al., 2006). Additional anti-microbial antibodies have been described (such as anti-glycan antibodies) and these appear to be directed towards fungi.

In addition to being used for diagnostic purposes, combinations of seromarkers have been used to predict disease behavior over time, such as the development of fistulizing and penetrating complications and the need for surgery. Studies by Mow et al. and Dubinsky et al. have demonstrated that ASCA, OmpC, and I2 were each associated with features of complicated disease and that the number of positive tests for antibodies and the concentrations of antibodies were associated with complications

such as stenosis, penetrating disease, and the need for small bowel surgery (Mow et al., 2004; Dubinsky et al., 2006, 2008). It is still unclear, however, whether early aggressive intervention in patients with markers of a worse prognosis will change long-term outcomes.

TREATMENT

Medical

The medical treatment of IBD involves a growing armamentarium of medications, as a fundamental knowledge of disease pathogenesis expands. Many of these drugs are used for both UC and CD. Clinical trials are hampered by a consistent finding of placebo response rates of about 30%. The various classes of medications will be presented here, with specific mention of their use in CD and UC.

Aminosalicylates

The first aminosalicylate used in IBD was sulfasalazine, which consists of 5-aminosalicylic acid (5-ASA) bound to the antibiotic sulfapyridine via an azo-bond. This bond is split by enzymes present in colonic bacteria. It is the free 5-ASA that is released into the colon to exert the therapeutic effect. 5-ASA has multiple anti-inflammatory properties including inhibition of production of IL-1 (Mahida et al., 1991), interference with binding of TNF (Shanahan et al., 1990), and as a free radical scavenger (Ahnfelt-Ronne et al., 1990). These effects appear to be mediated in part by inhibition of activation of NF- κ B (Bantel et al., 2000). The most commonly used aminosalicylate in the treatment of IBD today is mesalamine. Various mesalamine preparations exist including coated drugs designed to delay release until the terminal ileum or colon is reached, and topical enemas or suppositories for treatment of the distal colon and rectum.

The aminosalicylates are effective first-line agents in the induction and the maintenance of remission in moderately active ulcerative colitis. There is no convincing evidence of the superiority of any one preparation over another (Mahadevan and Sandborn, 2004). Evidence for the effectiveness of aminosalicylates in the treatment of active CD is not as strong as for UC. Sulfasalazine may be effective in the treatment of active colonic disease whereas controlled-release mesalamine is preferred for treatment of ileal disease. Studies of mesalamine for maintenance of remission show little if any benefit (Sandborn, 2004).

Glucocorticoids

Corticosteroids are used extensively in the treatment of IBD. Glucocorticoids are steroid hormones that bind to cytosolic receptors and are then translocated to the

nucleus where they affect transcription of various genes. This leads to inhibition of various proinflammatory mediators such as cytokines, leukotrienes, adhesion molecules, and nitric oxide synthase (Sands, 2002). Most patients with active UC or CD will respond to a course of oral glucocorticoids, although occasionally the intravenous route is required for severe disease. In many patients, however, tapering the drug will lead to a flare; this phenomenon is termed steroid dependence. The well-known side effects of chronic steroid use are common and troublesome; these include diabetes, bone loss, acne, moon facies, and adrenal suppression. Attempts to limit these side effects have resulted in other formulations such as topical foam and enemas which can be effective for left-sided colonic disease. Budesonide is an oral glucocorticoid that undergoes extensive first-pass metabolism in the liver. As a result, high topical levels are achieved in the GI tract with only about 10% systemic absorption and thus fewer steroid side effects (Edsbacker et al. 1999). Budesonide has been shown to have some efficacy as a treatment for mild to moderately active CD (Greenberg et al., 1994; Tremaine et al., 2002).

Thiopurines

The thiopurines include azathioprine and 6-mercaptopurine (6-MP). Azathioprine is metabolized to 6-MP, which can eventually be converted into a number of metabolites including 6-thioguanine nucleotides (6-TG). The exact mechanism of action of the thiopurines is unknown, but studies have shown that their therapeutic effect is either due to blocking of the TcR signaling pathway, which leads to T cell apoptosis, or 6-TG inhibition of purine synthesis. The beneficial effect of thiopurines is generally not seen until 3–6 months of use. The ideal use of thiopurines is as a so-called “steroid-sparing” agent: to allow for the discontinuation of steroids in the patient who requires chronic or frequent use. Clinical studies have confirmed the utility of thiopurines as steroid-sparing agents effective in inducing and maintaining remission in CD and UC (Present et al., 1980; George et al., 1996). The side effects of thiopurines are far less than those of glucocorticoids but include leukopenia, pancreatitis, and hepatitis. The leukopenia is a result of 6-MP metabolism to 6-TG, whereas the hepatitis is associated with the accumulation of the 6-MMP metabolite. Interestingly, genetic variations in the enzyme thiopurine methyltransferase increase the risk of leukopenia by increasing 6-TG levels.

Cyclosporine

Cyclosporine is a fungal product that functions as an inhibitor of calcineurin, a cytoplasmic enzyme required for activation of T cells (Mahadevan and Sandborn, 2004).

Intravenous cyclosporine is an effective treatment for severe steroid-refractory UC (Lichtiger et al., 1994). The utility of cyclosporine is limited by significant side effects including hypertension, seizures, and nephrotoxicity.

Methotrexate

Methotrexate is a folate analogue that inhibits dihydrofolate reductase. Its anti-inflammatory effect is due to a reduction in various proinflammatory cytokines, an induction of lymphocyte apoptosis, and perhaps an increase in extracellular adenosine (Mahadevan and Sandborn, 2004). Intramuscular methotrexate is effective in inducing and maintaining remission in patients with CD (Feagan et al., 1995; Arora et al., 1999). Side effects of methotrexate at doses used for CD include rare hepatotoxicity, pneumonitis, and rash.

Anti-TNF Antibody Therapies

Infliximab (Remicade) was the first anti-TNF agent to be approved for use in IBD. It is a chimeric monoclonal antibody against TNF- α administered as an i.v. infusion. Neutralization of soluble TNF seems not to be the primary mechanism since the soluble TNF-receptor etanercept is not effective in CD (Sandborn et al., 2001). It appears that binding of infliximab to membrane-bound TNF on inflammatory cells leads to T cell apoptosis, thereby reducing the effector cell pool (Lugering et al., 2001; Van den Brande et al., 2003).

Infliximab has initially been shown to induce and maintain remission in patients with moderate to severe luminal (non-fistulizing) CD (Targan et al., 1997). Since the initial studies showing efficacy of infliximab in luminal CD, it has also been found to be effective for healing of perianal fistulas due to CD (Present et al., 1999), as well as for the induction and maintenance of remission in fistulizing CD (Sands et al., 2004). Subsequent studies have demonstrated efficacy of infliximab as induction and maintenance therapy in UC (Rutgeerts et al., 2005). Antibodies to infliximab (ATIs) are of concern in that they appear to increase the risk of infusion reactions and limit effectiveness (Baert et al., 2003). Increasing the dose given at each infusion, shortening the interval between infusions, and dosing infliximab based on trough levels are strategies that are currently being explored in patients who lose response to infliximab over time.

Adalimumab (Humira), a fully human anti-TNF monoclonal antibody administered subcutaneously, has also been shown to induce and maintain remission in patients with moderate to severe CD (Colombel et al., 2007). In addition, adalimumab demonstrated fistula healing and improved quality of life in patients with CD who failed prior infliximab therapy (Lichtiger et al., 2010).

Certolizumab pegol (Cimzia), a polyethylene glycolated Fab' fragment of humanized anti-TNF monoclonal antibody administered subcutaneously, has been found to be effective in inducing and maintaining remission in CD patients who have lost response to infliximab (Sandborn et al., 2010). However, in patients with moderate to severe CD who were naïve to anti-TNF agents certolizumab pegol was not found to be effective at inducing remission (Sandborn et al., 2011). In a subgroup analysis, CD patients with elevated CRP levels (> 5 mg/L at entry) had remission rates at week 6 that were significantly higher than placebo.

Inhibitors of Leukocyte Infiltration

A new approach to biologic therapy has been the development of inhibitors of various elements in the leukocyte infiltration process. The main targets of these new agents are the integrins $\alpha 4\beta 1$ and $\alpha 4\beta 7$, which interact with VCAM-1 and MAdCAM-1, respectively, to mediate interactions between leukocytes and endothelial cells. Here we will focus on the monoclonal antibodies natalizumab and MLN0002, which target $\alpha 4$ and $\alpha 4\beta$, respectively.

Natalizumab (Tysabri) is a humanized monoclonal antibody against $\alpha 4$ integrin. Natalizumab has recently been approved for use in CD after being found to be superior to placebo in inducing remission in patients with elevated CRP levels (Targan et al., 2007). The limiting factor in the use of this agent is a high rate of JC virus reactivation, which results in progressive multifocal leukoencephalopathy (PML). It is estimated that one in 1000 patients treated with natalizumab will develop PML (Yousry et al., 2006). It is recommended that patients be tested for JC virus seropositivity prior to undergoing therapy with natalizumab, as it is the seropositive patients that develop JC virus reactivation in the setting of immune suppression.

Another antibody against $\alpha 4\beta 7$ integrin, MLN0002, demonstrated a dose-dependent beneficial effect on clinical remission in patients with active CD in a phase 2 randomized, double-blind, placebo-controlled trial (Feagan et al., 2008). In addition, MLN0002 was demonstrated to be more efficacious than placebo in inducing clinical and endoscopic remission at 6 weeks in patients with active UC (Feagan et al., 2005). More studies are needed to examine long-term efficacy of anti- $\alpha 4\beta 7$ integrin in patients with CD and UC.

New Biologic Therapies

New biologic therapies aim to reduce pathogenic T cell activation and its effects by inhibiting the actions of proinflammatory cytokines, blocking T cell co-stimulation and inducing T cell apoptosis. Monoclonal antibodies

against the following proinflammatory cytokine targets have been developed: α -chain (CD25) of the IL-2 receptor, IFN- γ , IL-6, IL-6 receptor, IL-13, IL-17, IL-18, and IL-22. Unfortunately, antibodies against both IL-2R and IFN- γ failed to show benefit over placebo in inducing remission in patients with UC and CD, respectively (Van Assche et al., 2006; Reinisch et al., 2010). Of interest, the monoclonal antibody against IL-17 was tested in a phase II trial in CD patients. Not only did the patients not respond to anti-IL-17 but their condition worsened. The other monoclonal antibodies against proinflammatory cytokines are entering phase I trials.

Visilizumab is a monoclonal antibody against the CD3 chain of the T cell antigen receptor. CD3 is expressed on all T cells and its blockade leads to T cell apoptosis. Visilizumab was tested in severe, steroid-resistant UC in phase I/II trials. All patients reported significant adverse events, such as abdominal abscesses, atrial fibrillation, cytokine release syndrome, CMV, and herpes zoster reactivation (Baumgart et al., 2010). Visilizumab was not shown to be efficacious in the management of IBD in larger trials.

Stimulators of the innate immune system have been tested in CD. Granulocyte–monocyte colony-stimulating factor (GM-CSF), sargramostim, underwent an open-label trial and was found to produce a clinical response in patients with moderate to severe CD (Dieckgraefe and Korzenik, 2002). However, follow-up trials did not meet their primary therapeutic end points (Egea et al., 2010).

Surgical

Around 70–80% of CD patients and 30–40% of UC patients will require surgery at some point in their lives (Larson and Pemberton, 2004). Indications for surgery in UC include toxic megacolon, severe disease not responding to maximal medical therapy, medication side effects, dysplasia or cancer, severe hemorrhage, and intractable extraintestinal manifestations. In almost all cases, complete removal of the entire colon and rectum (total proctocolectomy) is required to eliminate the risk of recurrent or residual disease as well as subsequent cancer.

Indications for surgery in CD are similar to those for UC but include the complications of stricturing or fistulizing disease such as obstruction and abscess. The most common operation performed for ileal disease is the ileocolic resection, in which the terminal ileum and cecum are resected and an anastomosis is performed between ileum and ascending colon. For the treatment of strictures in patients with multiple prior resections or with multiple skip lesions, a stricturoplasty can be performed in which

the stricture is widened without resection. For colitis, in which the rectum is usually spared, a subtotal colectomy with ileorectal or ileosigmoid anastomosis can usually be performed with good functional results. If there is rectal involvement or perianal disease, a total proctocolectomy with permanent ileostomy is usually required.

FUTURE PROSPECTS

During the last 15 years there have been great advances in the understanding of processes involved in the pathogenesis of both types of IBD, Crohn's disease and ulcerative colitis. These were earlier thought to be based on adaptive autoimmune responses but newer concepts have arisen. These recently elucidated pathways have in turn led to the development of new therapies for IBD. A major challenge now is to determine which inflammatory pathways predominate in which subgroups of patients. Studies are needed to determine how the products of the numerous IBD susceptibility genes modify immune responses and, ultimately, responses to different therapeutic agents. Combined analysis of clinical phenotypes, genotypes and peripheral and mucosal cytokine profiles will be called for, to predict responses to different therapies including biological agents. Current studies indicate that starting biologic therapy early in the course of the disease, and targeting patients with the more aggressive disease phenotype, improves long-term disease control. However, better pathogenesis-driven markers are needed for risk-stratification of patients into aggressive and non-aggressive phenotypes. Studies on families with multiple affected family members may help identify genetic loci predisposing to aggressive disease type. The identification of the dominant inflammatory pathway(s) prior to, or at the time of, diagnosis would allow for individualized tailoring of therapeutic options. In addition, new serologic and mucosal markers likely will identify post-operative patients (especially with CD) at a high risk for disease recurrence, sparing low-risk patients of exposure to biologic therapies and affording high-risk patients the best available post-operative prophylaxis. Better understanding of the genetics and immune pathways involved in the pathogenesis of the IBDs will move clinical practice closer towards individualized therapy.

Autoimmune hepatitis (AIH) is an inflammatory liver disease, affecting mainly females, characterized by elevated transaminase and immunoglobulin G (IgG) levels, interface hepatitis on histology, and positive autoantibodies, whose profile allows its distinction into two types. The etiology of AIH is said to be unknown but, as for complex diseases in general, it results from interplay of multiple predisposing causes, genetic and environmental. The outcome is immune reactivity against host liver antigens. AIH responds to immunosuppressive treatment, which should be instituted as soon as the diagnosis is made, as untreated disease progresses to liver failure.

Historically, a chronic hepatitis with a female preponderance associated with high serum proteins was noted as early as the 1940s (Meyer zum Büschenfelde, 2003). A fuller description of AIH was given by the Swedish physician Jan Gösta Waldeström at the German Society for Digestive and Metabolic Disorders meeting in September 1950 (Waldenstrom, 1950). He described six patients, five female, with “hepatitis sui generis,” characterized by a marked elevation of gamma globulins, in whom administration of ACTH to investigate the nature of amenorrhea resulted in a striking subjective improvement and a dramatic fall in the erythrocyte sedimentation rate.

Waldeström concluded that these “patients may benefit from ACTH treatment.” This early report defines key characteristics of AIH: female preponderance, hyperglobulinemia, and response to corticosteroid drugs. It was suspected that a persisting virus in the liver was to blame. In 1951, confirming Waldeström’s observation, Henry George Kunkel in New York noted that some patients had additional clinical features such as fever and joint involvement (Kunkel et al., 1951). In 1954 the Italian physician Leoni reported the lupus erythematosus (LE) cell phenomenon (“fenomeno LE”) in the ascites fluid of a patient with cirrhosis (Leoni, 1954), and in 1955 Joske and King (Joske and King, 1955) in Melbourne, Australia, described LE cells in the blood of two patients with hypergammaglobulinemic active chronic hepatitis. In a landmark article in 1956 (Mackay et al., 1956), Mackay and co-workers reported five additional hypergammaglobulinemic chronic hepatitis patients recruited in the same unit, and, in view of the presence of LE cells, proposed the term of “lupoid hepatitis” to define this condition. A decade later, when it became clear that liver disease is rare in typical systemic lupus erythematosus (SLE) and that LE cells reflect the presence of anti-nuclear antibody, Mackay suggested the alternative name of “autoimmune hepatitis” (Mackay

et al., 1965). This term, however, was universally accepted only in the 1990s, after several different labels (mostly “chronic active hepatitis”) had been given to this condition over the years. In addition to seropositivity for anti-nuclear antibodies (ANA), reports from the early 1960s showed that anti-smooth muscle antibodies (SMA) are also markers of what is known today as AIH type 1 (Meyer zum Büschenfelde, 2003). Thirty years after the first description of “lupoid hepatitis,” AIH type 2, characterized by the presence in the serum of anti-liver kidney microsomal type 1 and/or anti-liver cytosol type 1 antibodies, was described (Homberg et al., 1987; Martini et al., 1988).

Awareness over the years that the clinical and pathological picture of chronic hepatitis may be due to causes other than AIH, such as persistent infection with the hepatotropic viruses B and C, alcohol abuse, and non-alcoholic steatohepatitis, prompted the establishment in the 1990s of an expert panel with the brief of defining criteria for the diagnosis of AIH (International Autoimmune Hepatitis Group, IAIHG (Johnson and McFarlane, 1993)).

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Clinical Features

The diagnosis of AIH is based on a combination of clinical, biochemical, immunological, and histological features and the exclusion of other known causes of liver disease. Liver biopsy is needed to confirm the diagnosis and to evaluate the severity of liver damage (Krawitt, 2006; Manns et al., 2010a), as transaminase and IgG levels do not reflect the degree of tissue inflammatory changes or indicate the presence or absence of cirrhosis. Conditions that may share serological and histological features with AIH, such as viral hepatitis B and C, Wilson disease, non-alcoholic steatohepatitis, and drug-induced liver disease, must be excluded by accurate clinical history and appropriate investigations.

Three-quarters of patients with AIH are female. AIH type 1 affects all ages with two peaks, one in childhood/adolescence, and the other in adulthood around the age of 40 years. Only 20% of patients are diagnosed after the age of 60 years (Krawitt, 2006; Manns et al., 2010a). AIH type 2 affects mainly children and young adults, being rare, though not absent, in older individuals. In pediatrics, AIH type 2 represents one-third of all cases and has a clinical course similar to AIH type 1, though anti-LKM1-positive children present at a younger age, more often with an acute onset, including fulminant hepatitis, and have associated IgA deficiency (Gregorio et al., 1997; Oettinger et al., 2005).

Forty to 60% of adult patients with AIH type 1 have a chronic disease course with non-specific symptoms such

as fatigue, nausea, abdominal pain, and arthralgia (Czaja et al., 1983; Al-Chalabi et al., 2008). AIH may be diagnosed after the incidental finding of abnormal liver function tests during routine investigations.

About one-third of adult patients present acutely with jaundice, arthralgia, anorexia, and fatigue, symptoms indistinguishable from those of an acute hepatitis due to other causes (Crapper et al., 1986; Amontree et al., 1989). Acute hepatic episodes alternating with spontaneous clinical and biochemical improvement are not uncommon, being a relapsing pattern that often leads to a dangerous delay in diagnosis and treatment. Occasionally the first symptoms of AIH are complications of portal hypertension, e.g., gastrointestinal bleeding or hypersplenism, without previous knowledge of liver disease. The acute presentation is more commonly observed in children and young adults than in older patients. At times AIH, particularly AIH type 2, presents as fulminant hepatic failure (Gregorio et al., 1997). Because of the variability of its presenting features, AIH should be suspected and excluded in all patients with symptoms and signs of prolonged, relapsing, or severe liver disease, so that the appropriate treatment can be instituted promptly.

At least one-third of patients with AIH already have cirrhosis at the time of diagnosis, irrespective of the mode of presentation (Roberts et al., 1996; Gregorio et al., 1997), indicating that the disease process is longstanding. Also patients presenting acutely have often advanced fibrosis or cirrhosis on liver biopsy.

About 40% of patients with AIH have a family history of autoimmune disorders, and associated autoimmune features (e.g., thyroiditis, inflammatory bowel disease, type 1 diabetes, arthritis, hemocytopenias, vitiligo) are present at diagnosis or develop during follow-up in some 20% of patients (Gregorio et al., 1997; Mieli-Vergani and Vergani, 2011).

In children and young adults, a form of sclerosing cholangitis, known as autoimmune sclerosing cholangitis (ASC), and characterized by ANA and SMA positivity, high levels of IgG, and interface hepatitis, is as prevalent as AIH type 1 (Gregorio et al., 2001). Alkaline phosphatase and gamma glutamyl transpeptidase levels, which are usually elevated in cholestatic disease, are often normal or only mildly increased in the early disease stages of ASC and a cholangiography is needed to make the diagnosis. In the absence of bile duct imaging, these patients are diagnosed and treated as AIH type 1. The presence of sclerosing cholangitis may be discovered during follow-up, after the appearance of an overt cholestatic biochemical profile. In childhood, ASC affects equally males and females (Gregorio et al., 2001). If treatment is started early, the parenchymal liver damage in ASC responds well to the same immunosuppressive treatment used for AIH, with good medium- to long-term survival. However,

TABLE 61.1 International Autoimmune Hepatitis Group Revised Diagnostic Scoring System

| Parameter | Feature | Score |
|---|----------------------------------|-------|
| Sex | Female | +2 |
| ALP: AST (or ALT) ratio | >3 | -2 |
| | 1.5–3 | 0 |
| | <1.5 | +2 |
| Serum globulins or IgG (times above normal) | >2.0 | +3 |
| | 1.5–2.0 | +2 |
| | 1.0–1.5 | +1 |
| | <1.0 | 0 |
| ANA, SMA or anti-LKM1 titers | >1:80 | +3 |
| | 1:80 | +2 |
| | 1:40 | +1 |
| | <1:40 | 0 |
| AMA | Positive | -4 |
| Viral markers of active infection | Positive | -3 |
| | Negative | +3 |
| Hepatotoxic drug history | Yes | -4 |
| | No | +2 |
| Average alcohol | <25 g/day | +2 |
| | >60 g/day | -2 |
| Histological features | Interface hepatitis | +3 |
| | Plasma cells | +1 |
| | Rosettes | +1 |
| | None of the above | -5 |
| | Biliary changes ^a | -3 |
| | Atypical changes ^b | -3 |
| Immune diseases | Thyroiditis, colitis, other | +2 |
| HLA | DR3 or DR4 | +1 |
| Seropositivity for other autoantibodies | Anti-SLA/LP, actin, ASGPR, pANNA | +2 |
| Response to therapy | Remission | +2 |
| | Relapse | +3 |

^aIncluding granulomatous cholangitis, concentric periductal fibrosis, ductopenia, marginal bile duct proliferation and cholangiolitis.

^bAny other prominent feature suggesting a different etiology.

Pre-treatment score >15: definite AIH; 10–15: probable AIH.

Post-treatment score >17: definite AIH; 12–17: probable AIH.

ALP, alkaline phosphatase; AST, aspartate aminotransferase; ALT, alanine aminotransferase; IgG, immunoglobulin G; ANA, anti-nuclear antibody; SMA, anti-smooth muscle antibody; anti-LKM1, anti-liver kidney microsomal type 1 antibodies; AMA, anti-mitochondrial antibodies; SLA/LP, soluble liver antigen/liver pancreas; ASGPR, asialoglycoprotein receptor; pANNA, peripheral anti-nuclear neutrophil antibody; HLA, human leukocyte antigen.

Adapted from Alvarez et al. (1999a).

the bile duct disease progresses in about 50% of patients despite treatment (Gregorio et al., 2001).

In the absence of a single diagnostic test for AIH, the IAIHG has devised a diagnostic system for comparative and research purposes, which includes several positive and negative scores, the sum of which gives a value indicative of probable or definite AIH (Johnson and McFarlane, 1993; Alvarez et al., 1999a) (Table 61.1). A simplified IAIHG scoring system published more recently is better suited to clinical application (Hennes et al., 2008b) (Table 61.2). However, neither the original nor the simplified scoring system is perfect, particularly for the juvenile

TABLE 61.2 Simplified Criteria for the Diagnosis of Autoimmune Hepatitis

| Variable | Cut-off | Points |
|--------------------------------|-----------------------------------|----------------|
| ANA or SMA | ≥1:40 | 1 |
| ANA or SMA or anti-LKM1 or SLA | ≥1:80 | 2 ^a |
| IgG | ≥1:40 | 1 |
| | Positive | 1 |
| | >upper limit of normal | 2 |
| | >1.10 times upper limit of normal | 2 |
| Liver histology | Compatible with AIH | 1 |
| | Typical of AIH | 2 |
| Absence of viral hepatitis | Yes | 2 |

^aAdditional points for all autoantibodies cannot exceed a maximum of 2. Score ≥6: probable AIH; ≥7: definite AIH.

ANA, anti-nuclear antibody; SMA, anti-smooth muscle antibody; anti-LKM1, anti-liver kidney microsomal antibody type 1; SLA, soluble liver antigen; IgG, immunoglobulin G; AIH, autoimmune hepatitis.

form of the disease, in which diagnostically relevant autoantibodies often have titers lower than the cut-off value considered positive in adults. In addition, neither system can distinguish between AIH and ASC.

Pathologic Features

The typical histological feature of AIH is interface hepatitis, which is, however, not exclusive to this condition (Czaja and Carpenter, 1997). Interface hepatitis is characterized by a dense inflammatory infiltrate composed of lymphocytes and plasma cells, which crosses the limiting plate and invades the surrounding parenchyma (Figure 61.1). Hepatocytes surrounded by inflammatory cells become swollen and undergo pyknotic necrosis, representing apoptosis (Searle et al., 1987). We emphasize this feature because not only was the liver the site wherein apoptosis was first recognized nearly a century ago but also, in some other autoimmune diseases, disordered apoptosis can yield potentially immunogenic particles—apoptopes (Leo et al., 2009). Though plasma cells are characteristically abundant at the interface and within the lobule, their presence in low number does not exclude the diagnosis of AIH. When AIH presents acutely, and during episodes of relapse, a common histological finding is panlobular hepatitis with bridging necrosis and, if the disease takes a fulminant course, massive necrosis and multilobular collapse.

Though sampling variation may occur in needle biopsy specimens, particularly in cirrhotic livers, the severity of the histological appearance is usually of prognostic value. Inflammatory changes surrounding the bile ducts are present in a small proportion of adult patients with AIH, but

FIGURE 61.1 Interface hepatitis. when conspicuous they suggest an overlap with sclerosing cholangitis (Gregorio et al., 2001).

Epidemiologic Features

AIH occurs worldwide, but its prevalence remains to be established. Most information on prevalence had been obtained for AIH type 1 before the introduction of the IAIHG diagnostic scoring system (Johnson and McFarlane, 1993; Alvarez et al., 1999a), therefore without standard criteria for patient inclusion. Prevalences reported in early papers range from 1.9 cases/100,000 in Norway (Boberg et al., 1998) and 1/200,000 in the US general population (Manns et al., 1998), to 20/100,000 in females over 14 years of age referred to a tertiary center in Spain (Primo et al., 2004). A more recent study from a UK secondary referral center reported an AIH annual incidence of 3.5/100,000 (Whalley et al., 2007). Two studies using standardized criteria for the diagnosis of AIH published in 2002 and 2010 report a point prevalence of 24.5/100,000 in New Zealand (Ngu et al., 2010) and of 34.5/100,000 in Alaskan natives (Hurlburt et al., 2002). In Asia, AIH was widely considered less frequent than in Western countries, with a reported incidence in Japan ranging between 0.08 and 0.15 cases/100,000/year (Nishioka and McFarlane, 1998). A better awareness of its clinical characteristics has led to an increased frequency in the diagnosis of AIH in China, where this condition was hitherto considered very rare (Qiu et al., 2011). It is likely, however, that all these

epidemiological figures are underestimates, since AIH may remain undiagnosed for several years and present eventually with decompensated liver disease attributed to “cryptogenic” cirrhosis.

The prevalence of AIH type 2, which affects mainly children and young adults, is unknown, also because the diagnosis is often overlooked. Intriguingly AIH type 2 has been reported more frequently in Europe than in the USA (Czaja and Freese, 2002), possibly because of the lack of testing for anti-LKM1 antibodies in the latter, due to the unsubstantiated belief that AIH type 2 is rare and therefore that testing for anti-LKM1 antibodies is not cost-effective (Duchini et al., 2000).

At the King’s College Hospital tertiary pediatric hepatology referral center there has been a seven-fold increase in incidence of AIH over the last decade, perhaps a result in part of increased awareness of the disease. AIH represents approximately 10% of some 500 new referrals per year, two-thirds of the cases being AIH type 1 and one-third AIH type 2.

AUTOIMMUNE FEATURES

AIH has several characteristics of an organ-specific autoimmune disease: it affects mainly females, it is accompanied by serological features of autoimmunity (organ and non-organ-specific autoantibodies; high levels of IgG), it is associated with human leukocyte antigen (HLA) allo-types predisposing to autoimmunity, it has a strong

connectivity with other autoimmune disorders, and it responds satisfactorily to immunosuppressive treatment.

AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

Key to the diagnosis of AIH is positivity for circulating autoantibodies (Johnson and McFarlane, 1993; Alvarez et al., 1999a; Vergani et al., 2004; Hennes et al., 2008b). Their detection by indirect immunofluorescence (Figures 61.2–61.5) on a rodent substrate not only assists in the diagnosis but also allows differentiation into two forms of AIH. ANA and SMA characterize AIH type 1, while anti-LKM1 and anti-LC1 define AIH type 2. The two autoantibody profiles rarely occur simultaneously (Vergani et al., 2004). As interpretation of the immunofluorescence patterns can be difficult, guidelines have been provided by the IAIHG regarding methodology and interpretation of liver autoimmune serology (Vergani et al., 2004). A major advantage of testing for autoantibodies by indirect immunofluorescence on a freshly prepared rodent substrate that includes kidney, liver, and stomach is that it allows the concurrent detection of several autoreactivities relevant to AIH. These include ANA, SMA, anti-LKM1, and anti-LC1, as well as anti-mitochondrial antibody (AMA), the serological hallmark of primary biliary cirrhosis (PBC), the presence of which weighs against the diagnosis of AIH (Johnson and McFarlane, 1993; Alvarez

et al., 1999a; Vergani et al., 2004; Hennes et al., 2008b). Autoantibodies are considered positive when present at a dilution of 1:40 or more in adults, while in children, who are rarely positive for autoantibodies in health, positivity at a dilution $\geq 1:20$ for ANA and SMA or $\geq 1:10$ for anti-LKM1 is clinically significant (Mieli-Vergani et al., 2009). Both in adults and in children autoantibodies may be present at a low titer or even be negative at disease onset, to become detectable during follow-up (Gregorio et al., 2001). If AIH is suspected, it is advisable to repeat autoantibody testing and to ask the laboratory to report any level of positivity.

ANA is detectable on all rodent tissues and in AIH usually has a homogeneous pattern (Figure 61.2). For a clearer and easier definition of the pattern, HEp2 cells that have prominent nuclei are used (Figure 61.2), though these cells, derived from a laryngeal carcinoma, should be used with caution for screening purposes, because of a high proportion of low titer positivity within the normal population (Tan et al., 1997). There are no ANA molecular targets specific for AIH. A varied profile of ANA reactivities reminiscent of that found in SLE (e.g., to nuclear chromatin, histones, centromere, double-stranded DNA and single-stranded DNA, and ribonucleoproteins) (Peakman et al., 1989; Burlingame et al., 1993; Czaja et al., 1994; Strassburg et al., 1996a; Bogdanos et al., 2008, 2009) has been reported in AIH, but at least a third of AIH patients positive for ANA do not react with known nuclear targets (Bogdanos et al., 2008, 2009).

FIGURE 61.2 Antinuclear antibodies. Immunofluorescence pattern of antinuclear autoantibodies on rodent liver (main image) and HEp2 cells (inset), which, because of their large nuclei, allow pattern recognition. The homogeneous pattern (inset left) is the most common in autoimmune hepatitis; the speckled pattern (inset right) is much rarer. HEp2 cells should not be used for sample screening because of a high frequency of false-positive results. H = homogeneous; Sp = speckled.

FIGURE 61.3 Anti-smooth muscle antibodies. Immunofluorescence pattern of smooth muscle autoantibodies (SMA) on rodent kidney. SMA stains the smooth muscle of arterial vessels (V), glomeruli (G), and tubules (T). *Courtesy of Dr. Luigi Muratori.*

Immunofluorescence remains therefore the gold standard for ANA testing, as recently surmised by the American College of Rheumatology ANA Task Force (Meroni and Schur, 2010), but is not universally practiced. There is an impression, albeit poorly documented, that higher levels of autoantibody and/or multiple autoantibodies are a pointer to a diagnosis of AIH, as pertains in type 1 diabetes.

The immunofluorescent staining of SMA is detected in the arterial walls of rodent kidney, liver, and stomach. In the kidney, SMA can have three patterns: V (vessels), G (glomeruli), and T (tubules) (Bottazzo et al., 1976) (Figure 61.3). The V pattern is present also in non-autoimmune inflammatory liver disease, in autoimmune diseases not affecting the liver, and in viral infections, but the VG and VGT patterns are indicative of AIH. The VGT pattern corresponds to the “F actin” or microfilament (MF) pattern observed using cultured fibroblasts as substrate. Neither the VGT nor the anti-MF patterns are, however, entirely specific for the diagnosis of AIH type 1. The molecular target of the microfilament reactivity observed in AIH type 1 remains to be identified. Though “anti-actin” reactivity is strongly associated with AIH type 1,

some 20% of SMA-positive AIH type 1 patients do not have the F-actin/VGT pattern. The absence, therefore, of anti-actin SMA does not exclude the diagnosis of AIH (Muratori et al., 2002).

The anti-LKM1 pattern is characterized by bright staining of the hepatocyte cytoplasm and of the P3 portion of the renal tubules (Figure 61.4). Anti-LKM1 is frequently confused with AMA, as both autoantibodies stain liver and kidney, though AMA, in contrast to anti-LKM1, also stains gastric parietal cells. The identification of the molecular targets of anti-LKM1, cytochrome P4502D6 (CYP2D6), and of AMA, enzymes of the 2-oxo-acid dehydrogenase complexes, has allowed the establishment of immuno-assays using recombinant or purified antigens (Vergani et al., 2004), which can be used to resolve doubtful cases. In the context of AIH, there can be positivity for AMA in a small subset of patients (3–5%) in whom there are overlapping features with PBC (Montano-Loza et al., 2008; O’Brien et al., 2008). Additional LKM reactivities have been described. Anti-LKM2 antibodies, which target cytochrome P4502C9, are of historical interest only because of their association

FIGURE 61.4 Anti-liver kidney microsomal type 1 antibodies. Immunofluorescence pattern of anti-liver kidney microsomal type 1 (LKM1) autoantibodies on liver (A) and kidney (B) rodent sections; anti-LKM1 stains the cytoplasm of hepatocytes and proximal renal tubules.

with ticrynafen-induced hepatitis, a uricosuric diuretic withdrawn from clinical use in 1980 because of its severe hepatotoxicity. Anti-LKM3 antibodies are specific for members of the uridine glucuronosyltransferase (UGT) family 1 and give an immunofluorescence pattern similar to anti-LKM1. Although anti-LKM3 are most commonly detected in patients with hepatitis delta, they have also been reported in approximately 10% of patients with AIH type 2 (Strassburg et al., 1996b).

Anti-LC1 (Figure 61.5), which is an additional marker for AIH type 2, can be present on its own, but frequently occurs in association with anti-LKM1, and targets formimino-transferase cyclodeaminase (FTCD) (Lapierre et al., 1999). Anti-FTCD antibody can be detected by commercial ELISA (Vergani et al., 2004).

Other autoantibodies less commonly tested, but of diagnostic importance, include anti-soluble liver antigen (anti-SLA) and anti-perinuclear neutrophil cytoplasm (pANCA) antibodies.

Anti-SLA is highly specific for the diagnosis of AIH, usually type 1 (Baeres et al., 2002). Its presence identifies patients with more severe disease and worse outcome (Czaja et al., 2002; Ma et al., 2002). Anti-SLA was thought to identify a third type of AIH in which tests for conventional autoantibodies were negative (Manns et al., 1987). However, early reports predated the publication of the IAIHG recommendations and used a cut-off point for conventional autoantibody levels higher than that currently used for the diagnosis of AIH. Several patients considered to have AIH type 3 were positive for conventional autoantibodies. At variance with standard diagnostic autoantibodies, anti-SLA is not detectable by immunofluorescence. The molecular target of anti-SLA is Sep (O-phosphoserine) tRNA:Sec (selenocysteine) tRNA synthase (SEPSECS) (Costa et al., 2000; Wies et al., 2000; Palioura et al., 2009). Cloning of this reactant has led to the availability of molecularly-based diagnostic assays for anti-SLA, but their full evaluation is still under way.

In AIH type 1, akin to primary sclerosing cholangitis and inflammatory bowel disease, pANCA are frequently detected, but they are atypical, since they react with peripheral nuclear membrane components (perinuclear anti-nuclear neutrophil antibodies, pANNA) (Bogdanos et al., 2009). In curious contrast to AIH type 1, pANNA are virtually absent in AIH type 2 (Vergani et al., 2004).

Anti-asialoglycoprotein receptor antibodies (ASGPR) were identified in 1984 during an attempt to detect putative autoantigenic targets located on the hepatocyte membrane. ASGPR is the main constituent of the crude liver cell extract known as liver-specific protein (LSP) and is the only liver-specific autoantigen discovered so far (Bogdanos et al., 2009). Some 50–90% of patients with AIH type 1 or 2 are anti-ASGPR/anti-LSP seropositive (Gregorio et al., 2001); anti-ASGPR is found in

combination with ANA, SMA, and anti-LKM1 and its level correlates with disease activity. However, the detection of anti-ASGPR requires either purified or recombinant antigen, and the development of reliable molecular assays has been difficult; therefore their applicability to clinical practice is limited. Moreover, since these autoantibodies have also been detected in patients with viral hepatitis, drug-induced hepatitis, and PBC, they are not disease specific (Bogdanos et al., 2009).

GENETIC FEATURES

AIH is a “complex trait” disease, i.e., a condition not inherited in a Mendelian autosomal dominant, autosomal recessive, or sex-linked fashion (Donaldson, 2002, 2004). The mode of inheritance of a complex trait disorder involves one or more genes, operating alone or in concert, to increase or reduce the risk of the trait, and interacting with environmental factors.

Several genes have been reported to confer susceptibility to AIH, and influence clinical manifestations, response to treatment, and prognosis. Most are located within the human leukocyte antigen (HLA) region (the human major histocompatibility complex [MHC]), the gene products of which are involved in the presentation of antigenic peptides to T cells and the initiation of adaptive immune responses. The strongest associations lie within the HLA-DRB1 locus, with alleles encoding the HLA-DR3 (*DRB1*0301*) and DR4 (*DRB1*0401*) molecules conferring susceptibility to AIH type 1 in European and North American populations (Donaldson, 2002, 2004). These associations are sufficiently strong to score positively for the diagnosis of AIH according to the revised diagnostic IAIHG system (Hennes et al., 2008b). Links have been reported between possession of these alleles and clinical manifestations, response to treatment, and prognosis. Thus, among white Northern Europeans, *DRB1*0301* is more common in patients who deteriorate despite corticosteroid treatment (Donaldson, 2002, 2004). The residues within the cleft of the HLA class II molecules specifically linked to the pathogenesis of AIH reported from various countries differ, suggesting that the antigenic peptides recognized by T cell-mediated immune responses in AIH may derive from different exogenous triggers and that they are embraced by geographically/ethnically distinct HLA molecules (Donaldson, 2002, 2004). These HLA associations may be the molecular footprints of the prevailing triggers that precipitate AIH in different environments. In this context, it is of interest that in South America possession of the HLA *DRB1*1301* allele, which predisposes to pediatric AIH type 1 in that population, is also associated with persistent infection with the endemic hepatitis A virus (Fainboim et al., 2001).

Susceptibility to, and severity of, AIH type 2 has been linked to alleles encoding the *DRB1*0301* and

DRB1*0701 molecules in the United Kingdom and Brazil. Allelic variation within HLA-DRB1 has been linked to differences in the autoantibody seropositivity profiles of AIH type 2 patients (Djilali-Saiah et al., 2006).

There are also reports of susceptibility to AIH linked to polymorphisms in genes located outside the MHC; the cytotoxic T lymphocyte antigen-4 (CTLA-4) (Agarwal et al., 2000), the tumor necrosis factor alpha (TNF- α) gene promoter (Cookson et al., 1999), and Fas (Agarwal et al., 2007) are notable examples.

A form of AIH serologically resembling AIH type 2 affects some 20% of patients with autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) (see Chapter 43). APECED is a monogenic autosomal recessive disorder caused by homozygous mutations in the *AIRE1* gene and characterized by a variety of organ-specific autoimmune diseases, the most common of which are hypoparathyroidism and primary adrenocortical failure, accompanied by chronic mucocutaneous candidiasis (Simmonds and Gough, 2004; Liston et al., 2005). Interestingly there are neutralizing autoantibodies to type 1 interferons, perhaps accounting for the associated immune deficiencies (see Chapter 76). APECED has a high level of variability in symptoms, especially between populations. Carriers of a single *AIRE1* mutation (heterozygotes) do not develop APECED. However, although the inheritance pattern of APECED indicates a strictly recessive disorder, there are anecdotal data of mutations in a single copy of *AIRE1* being associated with human autoimmunity of a less severe form than classically defined APECED (Simmonds and Gough, 2004; Liston et al., 2005).

The role of the *AIRE1* heterozygote state in the development of type 2 AIH remains to be established, though heterozygous *AIRE1* mutations have been reported in three children with severe AIH type 2 and extrahepatic autoimmune manifestations (Lankisch et al., 2005).

ANIMAL MODELS

Research on the pathogenesis of AIH has been hampered by the lack of animal models reproducing faithfully the human condition. Findings in animal models of AIH have been recently reviewed by Hardtke-Wolenski et al. (2012). Most animal models of AIH, though informative regarding single steps leading to liver inflammation and damage, do not mimic the chronic relapsing course of the human disease. In fact, they demonstrate the difficulty in breaking tolerance towards liver antigens, and the involvement of regulatory mechanisms in maintaining it.

A widely studied model of experimental hepatitis is that induced by concanavalin A (Tiegs et al., 1992). Though this model does not reflect accurately the pathological entity of AIH in humans, it has provided evidence

that liver damage mainly occurs within a Th1 scenario, with the involvement of activated CD4 T cells and release of the proinflammatory cytokines interferon gamma and tumor necrosis factor alpha against a specific genetic background. Interleukin-4, a cytokine with mainly regulatory activity, is also required for the establishment of concanavalin A-induced hepatitis. This finding and those of Takeda and collaborators, who have shown that NKT cells, which secrete both interleukin-4 (IL-4) and interferon gamma, are critical to the development of concanavalin A-induced hepatitis in C57/B6 mice, suggest that both adaptive and innate immunity are involved (Takeda et al., 2000).

The ideal model for AIH should have a well-defined initiating event followed by chronic inflammation leading to fibrosis. More recently, researchers have focused on animal models of AIH type 2, since in this condition the autoantigens are well defined. The model produced by the group of Alvarez (Lapierre et al., 2004) is based on immunizing every 2 weeks for three times C57BL/6 female mice with a plasmid containing the antigenic region of human CYP2D6, the target of anti-LKM1, and FTCD, the target of anti-LC1, together with the murine end terminal region of cytotoxic T lymphocyte antigen 4 (CTLA-4). The latter was added to facilitate antigen uptake by antigen-presenting cells. In a parallel set of experiments a plasmid containing the DNA encoding IL-12, a Th1 skewing proinflammatory cytokine, was also used. When autoantigens and IL-12 were used to break tolerance, antigen-specific autoantibodies were produced, a relatively modest elevation of transaminase levels at 4 and 7 months was observed, and a portal and periportal inflammatory infiltrate composed of CD4 and CD8 T cells and, to a lesser extent, B cells was demonstrated 8–10 months after the third immunization. When the same immunization protocol was used in different mouse strains, either a mild hepatitis or no inflammatory changes were observed, indicating the importance of a specific genetic background. Recently, these authors have shown, in the same animal model, that adoptive transfer of *ex vivo* expanded Tregs expressing the chemokine receptor CXCR3 targets efficiently the inflamed liver, restores peripheral tolerance to FTCD, and induces disease remission (Lapierre et al., 2013). Using FTCD as immunogen in an adenovirus shuttle vector, Hardtke-Wolenski et al. have described a model of AIH evolving to portal and lobular fibrosis, in which the genetic predisposition afforded by the NOD background was key to the development of the disease (Hardtke-Wolenski et al., 2013).

Another model of AIH type 2 uses CYP2D6 transgenic mice and aims at breaking tolerance with an adenovirus-CYP2D6 vector (Holdener et al., 2008). While focal hepatocyte necrosis was seen both in mice treated with the Adenovirus-CYP2D6 vector and in

control mice treated with Adenovirus alone, only the former developed chronic histological changes, including fibrosis, reminiscent of AIH. The hepatic lesion was associated with a specific immune response to an immunodominant region of CYP2D6 and a cytotoxic T cell response to Adenovirus-CYP2D6 vector-infected target cells.

A complex and somewhat artificial strategy, involving neonatal thymectomy to prevent Treg development and egress from the thymus, was used in PD-1 deficient mice to produce a fulminant hepatitis characterized by spontaneous and severe CD4 and CD8 T cell liver infiltration, lobular necrosis, and elevated titers of ANA. Also in this model, adoptive transfer of Tregs was able to reverse progression to fatal hepatitis, providing support for a protective role of this cell population in AIH (Kido et al., 2008).

Though these experimental approaches provide useful information on some of the possible pathogenic mechanisms leading to AIH type 2, a model more closely representative of type 1 AIH in humans is still missing.

PATHOLOGIC EFFECTOR MECHANISMS

In patients with increased genetic susceptibility to AIH, immune responses to liver autoantigens could be triggered by molecular mimicry. Cross-reactivity is an inherent property of the cells of the adaptive immune system (Vergani et al., 2002), derived from the need of T and B lymphocytes to recognize a potentially infinite number of non-self antigens without any prior information as to their structure. This implies that these cells, rather than responding to single antigen specificities, are able to cross-reactively respond to a number of antigens, thus expanding the antigenic specificities of the immune system to a level that reflects the antigenic diversity of the external environment.

This inherent potential for cross-reactivity, while allowing efficient responses to a vast array of pathogens, also provides the immune system with the potential to cross-react with self, leading to autoimmunity. This concept has been termed “molecular mimicry,” where immune responses to external pathogens become directed towards structurally similar self components.

The strongest support to this model is in the context of AIH type 2, where T lymphocytes that target a key epitope of CYP2D6 also react with self-mimicking exogenous sequences present on the hepatitis C virus and members of the herpes virus family, cytomegalovirus, Epstein–Barr virus, and herpes simplex virus (Vergani et al., 2002). It is conceivable that, in genetically predisposed individuals, T cells targeting the self-epitope may be primed and expanded through exposure to the self-mimicking exogenous sequences with consequent initiation and perpetuation of liver autoimmunity.

This potential scenario is supported by a case report describing a 10-year-old girl who acquired HCV infection following a liver transplant for end-stage liver disease caused by alpha1-anti-trypsin deficiency. Two weeks after HCV infection, IgM anti-LKM1 autoantibodies appeared, followed by IgG anti-LKM1 antibodies, suggestive of HCV as the initiator of a primary anti-LKM1/anti-CYP2D6 autoimmune response (Mackie et al., 1994); 10 years later, the patient developed florid AIH type 2, which responded satisfactorily to immunosuppressive treatment, but by this time there was no trace of the previous HCV infection (Bogdanos et al., 2004).

Putative mechanisms of autoimmune liver damage are depicted in Figure 61.6. The immune response in AIH is believed to be initiated by the presentation of self-antigenic peptides (as yet unknown) to the T cell receptor (TCR) of uncommitted naïve CD4⁺ T-helper (Th0) lymphocytes. Self-antigenic peptides are processed and presented by professional antigen-presenting cells (APCs), including dendritic cells (DCs), macrophages, and B lymphocytes. The liver is home to several specialized APC populations, including liver sinusoidal endothelial cells (LSECs), Kupffer cells, and DCs, where antigen presentation to both CD4 and CD8 effector T cells can occur *in situ*, perhaps averting the need for trafficking to the regional lymphoid tissues (Crispe, 2011; Ebrahimkhani et al., 2011).

During antigen presentation, in the presence of appropriate costimulatory signals, CD4⁺ Th0 cells become activated and undergo differentiation into distinct T-helper cell subsets, depending on the cytokine milieu to which they are exposed. In the presence of IL-12 or IL-4, Th0 lymphocytes differentiate into Th1 or Th2 cells respectively, while predominance of IL-1beta and IL-6 favors differentiation into Th17 cells. Differentiation into Th1 cells leads to the production of IL-2 and IFN-gamma and the concomitant activation of CD8 T lymphocytes that produce IFN-gamma and TNF-alpha and exert cytotoxicity upon recognition of an antigen/MHC class I complex (Ichiki et al., 2005). Exposure of hepatocytes to IFN-gamma results in the upregulation of MHC class I and in the aberrant expression of MHC class II molecules, which leads to further T cell activation and to the perpetuation of liver damage (Lobo-Yeo et al., 1990; Senaldi et al., 1991). IFN-gamma also favors monocyte differentiation, promotes macrophage and immature DC activation (Delneste et al., 2003), and contributes to enhanced natural killer (NK) cell killing (Schroder et al., 2004).

Differentiation of Th0 into Th2 cells leads to the secretion of IL-10, IL-4, and IL-13, cytokines essential for B cell maturation into plasma cells and consequently to the production of autoantibodies, which can participate in mechanisms of damage such as antibody-mediated cellular cytotoxicity and complement activation (Longhi et al., 2010). Of note,

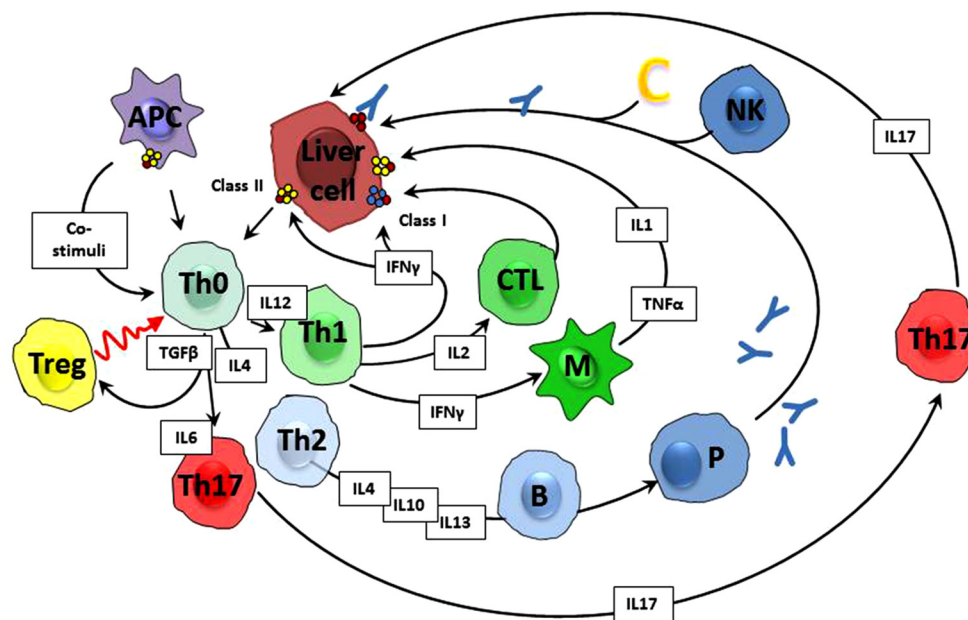

FIGURE 61.6 Autoimmune attack to the hepatocyte. An autoantigen is presented to uncommitted T-helper (Th0) lymphocytes within the HLA class II molecule of an antigen-presenting cell (APC) either in the regional lymph nodes or within the liver itself. Activated Th0 cells differentiate into Th1 or Th2 cells in the presence of interleukin (IL)-2 or IL-4, respectively, and according to the nature of the antigen. This triggers a series of immune reactions determined by the cytokines they produce. Th1 cells secrete IL-2 and interferon (IFN)- γ , which are cytokines that stimulate cytotoxic T lymphocytes (CTL), enhance expression of class I HLA molecules, induce expression of class II HLA molecules on the liver cells, and activate macrophages. Macrophages (M) release IL-1 and tumor necrosis factor (TNF). Th2 cells secrete mainly IL-4, IL-10, and IL-13, and stimulate autoantibody production by B lymphocytes. Regulatory T cells (Tregs) are derived from Th0 in the presence of transforming growth factor (TGF)- β . In the presence of defective Treg, hepatocyte destruction ensues from the engagement of damaging effector mechanisms, including CTL, cytokines released by Th1 and by activated macrophages, complement activation, or adhesion of natural killer (NK) cells to autoantibody-coated hepatocytes through their Fc receptors. Th17 cells produce the inflammatory cytokine IL-17 and derive from Th0 cells in the presence of TGF- β and IL-6. They are the focus of current investigations.

the titers of several autoantibodies, including anti-liver-specific protein and its components, correlate with indices of disease severity (Jensen et al., 1978; McFarlane et al., 1986). Moreover, in AIH type 2, the target of the disease-defining antibody anti-LKM1, CYP2D6 is present not only in the endoplasmic reticulum, but also is expressed on the membrane of hepatocytes and therefore readily accessible to the immune attack (Muratori et al., 2000).

Th17 cells contribute to autoimmunity by producing the proinflammatory cytokines IL-17, IL-22, and TNF- α , and inducing hepatocytes to secrete IL-6 (Zhao et al., 2011a), which further enhances Th17 activation. The role of Th17 cells, which has been documented in PBC (Harada et al., 2009), is currently under investigation in AIH, where an elevated level of Th17 cells has been reported in both blood and liver (Zhao et al., 2011a).

Gamma/delta T cells, which account for a low proportion of circulating lymphocytes, are relatively abundant in the liver (Wen et al., 1992) and might contribute to the pathogenesis of AIH, as they are elevated during active disease phases. Moreover, in AIH, gamma/delta T cells produce high levels of granzyme B and IFN- γ the expression of which correlates with

biochemical indices of liver damage, suggesting a direct involvement of this cell population in hepatic injury (Ferri et al., 2010).

A deficiency of immunoregulation, enabling the autoimmune response to develop, has been repeatedly reported in AIH. Thus, earlier, patients with AIH had low levels of circulating CD8⁺ T cells and impaired T cell suppressor function which segregated with disease-predisposing HLA alleles B8/DR3 and was correctable by therapeutic doses of corticosteroids (Nouri-Aria et al., 1982). Furthermore, there was a defect in a subpopulation of T cells controlling the immune response to liver-specific membrane antigens (Vento et al., 1984). More recent evidence based on the now “genuine” Treg cells confirms an impairment of immunoregulatory function in AIH. Among recently defined T cell subsets with potential immunosuppressive function, CD4 cells constitutively expressing the IL-2 receptor alpha chain (CD25) (T-regulatory cells, Tregs) have emerged as the dominant subset. These cells, representing 5–10% of all peripheral CD4 cells in health, control innate and adaptive immune responses by limiting the proliferation and effector function of autoreactive T cells (Sakaguchi, 2000). Their mechanism of action involves

mainly a direct contact with the target cells, and to a lesser extent the release of immunoregulatory cytokines, such as IL-10 and tissue growth factor beta 1.

In addition to CD25, which is also present on T cells undergoing activation, Tregs express a number of additional markers such as the glucocorticoid-induced tumor necrosis factor receptor, CD62L, CTLA4, and the fork-head/winged helix transcription factor FOXP3, whose expression has been associated with the acquisition of regulatory properties. Treg impairment is linked with various human autoimmune diseases including AIH (Sakaguchi et al., 2010). In patients with AIH type 1 and type 2, Tregs are defective in number compared to normal controls and this reduction is disease stage related, being more evident at diagnosis and during relapses than during drug-induced remission (Longhi et al., 2005; Longhi et al., 2010; Ferri et al., 2010). The percentage of Tregs inversely correlated with markers of disease severity, such as anti-SLA and anti-LKM1 autoantibody titers, suggesting that reductions in regulatory T cells favor manifestations of autoimmune liver disease. Moreover, Tregs from AIH patients at diagnosis are impaired in their ability to control the proliferation of CD4 and CD8 effector cells compared to Tregs isolated from AIH patients at remission or from healthy subjects (Longhi et al., 2005; Ferri et al., 2010). Though most published literature indicates a numerical and functional Treg defect in AIH, these findings were disputed in a recent paper which used a different methodological approach (Peiseler et al., 2012; reply Longhi et al., 2012).

The immunoregulatory defects described above have been complemented recently by findings that effector CD4 T cells in AIH are less susceptible to restraints exerted by Tregs. This defect is linked to reduced expression of the receptor molecule Tim-3 (inhibitory receptor T-cell-immunoglobulin-and-mucindomain-containing-molecule-3, which upon ligation of galectin-9 expressed by Tregs, induces effector cell death) (Liberal et al., 2012a). Thus data so far point to failure in homeostatic mechanisms in which Th17 cells override Tregs.

If loss of immunoregulation were central to the pathogenesis of autoimmune liver disease, treatment should concentrate on restoring the ability of Tregs to expand, with consequent increase in their number and function. However, we must be mindful that further confirmatory data are needed, and that the studies in AIH type 1 are being performed in the “vacuum” of lack of any knowledge of the provocative liver autoantigen.

TREATMENT AND OUTCOME

The aim of treatment in AIH is to attain an early complete remission to prevent disease progression and to maintain the remission long term using the lowest

possible dose of medication. In all types of presentation apart from a fulminant onset with encephalopathy, AIH responds well to immunosuppressive treatment whatever the degree of liver impairment with a reported remission rate of $\approx 80\%$ (Krawitt, 2006).

Standard Treatment

Since the late 1960s a combination of predniso(lo)ne and azathioprine has remained the basis of treatment for AIH (Mackay, 1968; Cook et al., 1971; Soloway et al., 1972; Murray-Lyon et al., 1973). The earlier unfounded suggestion of waiting for 6 months before starting immunosuppression has long been abandoned, since it is now clear that treatment should be started as soon as possible to avoid disease progression (Manns et al., 2010a).

The American Association for the Study of Liver Diseases (AASLD) practice guidelines, published in 2010, recommend for adult patients either an initial dose of 30 mg predniso(lo)ne combined with 1–2 mg of azathioprine daily, or monotherapy with prednis(lo)ne at a starting dose of 40–60 mg daily (Manns et al., 2010a). For children, a dose of 1–2 mg/kg predniso(lo)ne up to a daily dose of 60 mg is recommended in combination with azathioprine (1–2 mg/kg) or its parent drug 6-mercaptopurine (6MP) (1.5 mg/kg) (Mieli-Vergani et al., 2009). As azathioprine can be hepatotoxic, particularly in the presence of frank icterus, jaundiced patients should be treated with high-dose prednisolone first and azathioprine should be added later when partial disease control is achieved and jaundice has subsided.

The most common corticosteroid side effect affecting most patients after prolonged administration is Cushingoid changes, and recurrent cutaneous warts are also frequent. Less common but severe side effects include osteoporosis, vertebral collapse, diabetes, cataract, hypertension, and psychosis. But only $\approx 13\%$ of treated patients develop side effects that necessitate dose reduction or premature drug withdrawal, this being usually for cosmetic changes or obesity, osteopenia with vertebral collapse, and brittle diabetes (Czaja and Freese, 2002). Indeed the impression exists that corticosteroids are tolerated relatively well in AIH. Adverse effects of azathioprine (cholestatic hepatitis, veno-occlusive disease, pancreatitis, nausea and vomiting, rash, bone marrow suppression) affect less than 10% of patients and usually subside upon drug withdrawal (Manns et al., 2010a). Determination of thiopurine methyltransferase activity is only warranted when there is pre-treatment or intra-treatment cytopenia, or the need for higher than conventional doses of azathioprine to maintain remission (Czaja, 2008), as only patients with near-zero erythrocyte concentrations of the enzyme are at risk of developing

myelosuppression during treatment (Lennard et al., 1989; Ben Ari et al., 1995).

Criteria for complete remission are the disappearance of clinical symptoms, normalization of transaminase and IgG levels in adults and children, and, in addition, abrogation or reduction to a very low titer of the autoantibodies in children (Mieli-Vergani et al., 2009). Histological resolution of inflammation lags well behind biochemical improvement (Sogo et al., 2006; Ustundag et al., 2008; Manns et al., 2010a). Response to immunosuppressive treatment in AIH is usually so swift that a lack of response should prompt investigation of other causes of liver disease.

Relapse is characterized by an increased level in serum of transaminase enzymes, and is common, occurring in 40–80% of patients usually during attempts to withdraw treatment or because of non-adherence, and requires a temporary increase in the steroid dose (Gregorio et al., 1997; Czaja and Freese, 2002; Krawitt, 2006; Manns et al., 2010a). Non-adherence is particularly common in young adults and adolescents (Kerkar et al., 2006) and should not be mistaken for inefficacy of the drugs. Most patients, including those with cirrhosis (Manns et al., 2010a), attain complete remission on the above treatment schedules. In the presence of severe steroid side effects, remission can be maintained with azathioprine alone at a dose of up to 2 mg/kg daily (Johnson et al., 1995; Czaja, 2008). Treatment with both steroids and azathioprine can be safely continued during pregnancy (Heneghan et al., 2001; Candia et al., 2005; Terrabuio et al., 2009). Though azathioprine is classified as a category D drug by the FDA, it has no reported teratogenic effects in humans. If concerns remain about its use, women can be switched to steroid monotherapy.

For adult patients who are asymptomatic, paucisymptomatic, or are identified incidentally, the benefit of therapy should be weighed against the adverse effects of corticosteroids, particularly in postmenopausal women or elderly patients, with the histological severity of inflammation and liver damage being the best guide. In contrast, children, despite being rarely symptomatic, should start treatment promptly, even if the diagnosis is made incidentally, as they have a more aggressive and rapidly progressive disease (Czaja et al., 2005).

Long-term immunosuppressive treatment could be associated with the development of malignancies since extrahepatic cancers, including non-Hodgkin lymphoma and skin cancer, are reported to be more frequent in patients with AIH than in age-matched and sex-matched normal populations (Wang et al., 1989; Werner et al., 2009). The risk of developing primary hepatocellular carcinoma (HCC) in AIH is associated with the presence of cirrhosis, akin to other chronic liver diseases (Yeoman et al., 2008; Wong et al., 2011); hence the AASLD

Autoimmune Hepatitis Guidelines recommend active surveillance for HCC (Manns et al., 2010a).

Alternative Treatments

Cyclosporine and tacrolimus, calcineurin inhibitors, have been used as steroid-sparing agents in an attempt to induce remission while avoiding high-dose steroid adverse effects (Van Thiel et al., 1995; Alvarez et al., 1999b; Debray et al., 1999; Cuarterolo et al., 2006), but whether the use of these toxic and expensive drugs confers any advantage over standard treatment remains to be evaluated in controlled studies.

A large European trial investigating the effect of a combination of budesonide and azathioprine in AIH reported remission in a higher proportion of non-cirrhotic patients with less adverse effects than medium-dose standard prednisone and azathioprine (Manns et al., 2010b). This study compared the effect of budesonide at a dose of 3 mg three times daily, decreased upon response, with prednisone 40 mg once daily reduced per protocol, irrespective of response. Six months after starting treatment, remission was observed in 60% of the budesonide group but in only 39% of the prednisone group. When pediatric patients were considered separately, no difference in response was observed between the budesonide and prednisone groups at 6 months (16% versus 15%) and 12 months (50% versus 42%) (Woynarowski et al., 2013). Of note, the remission rate in the prednisone arm of this study is considerably less than that reported both in adults and children ($\approx 80\%$) when a higher starting dose of prednisone is used and tapered according to biochemical response (Kanzler et al., 2001; Gregorio et al., 1997). A limitation of budesonide, moreover, is that it is ineffective in patients with cirrhosis, who represent at least one-third of all AIH cases (Roberts et al., 1996; Gregorio et al., 1997). Despite limitations, this trial does show budesonide to be a valid alternative in patients at selected risk of adverse effects from prednisone.

Difficult-to-treat cases are reported to respond to mycophenolate mofetil at a dose of 20 mg/kg twice daily in association with prednisone (Richardson et al., 2000; Devlin et al., 2004; Aw et al., 2009) although this experience is not unanimous (Hennes et al., 2008a). In adults, mycophenolate mofetil appears to be effective in patients intolerant of, but not in those unresponsive to, azathioprine (Hennes et al., 2008a). For patients who do not respond to, or are intolerant to, mycophenolate mofetil (headache, diarrhea, nausea, dizziness, hair loss, and neutropenia), a calcineurin inhibitor in combination with prednisone is suggested (Manns et al., 2010a). In patients particularly difficult to treat, the use of rituximab (Barth and Clawson, 2010) and infliximab (Weiler-Normann et al., 2009; Weiler-Normann et al., 2013) has been

recently reported, but with variable outcomes. An important risk of these biological treatments is the occurrence of severe infections.

Duration of Treatment

No optimal length of treatment has been established. Most authors recommend at least 3 years of continuous therapy (Manns et al., 2010a). Treatment should cease only when a follow-up liver biopsy shows resolution of inflammation. Cessation should proceed with caution during or immediately before puberty, when relapses are more frequent, possibly because of poor adherence to treatment during adolescence (Kerkar et al., 2006).

During withdrawal close monitoring is needed as relapse may be severe and even fatal. Successful stopping of immunosuppression should be followed up long term, as relapses can occur even several years later (Manns et al., 2010a). Some 20% of patients with juvenile type 1 AIH can stop treatment successfully and permanently, but treatment cessation is achieved only rarely for patients with type 2 AIH (Gregorio et al., 1997). Levels of autoantibody and IgG (Gregorio et al., 2002; Luth et al., 2008) are important markers of disease activity and are useful to monitor response to treatment. Most AIH patients who respond to immunosuppressive treatment have an excellent outcome and lead a normal life on low-dose medication.

Liver Transplantation

Liver transplantation is the treatment of choice for patients who present with fulminant hepatic failure (grade II–IV encephalopathy), or who progress to end-stage liver disease despite immunosuppression (≈ 10 – 20% of patients). Recurrence of AIH, characterized by high transaminase levels, positive autoantibodies, interface hepatitis, and/or steroid dependence, occurs in $\approx 20\%$ of patients receiving transplant (Milkiewicz et al., 1999; Duclos-Vallee et al., 2003) and can happen even years after transplantation. Prednisolone treatment long term and at a dose higher than that generally used after liver transplantation for other conditions is recommended to avoid recurrence. Besides recurrent AIH, there is a form of graft dysfunction characterized by chronic liver damage with interface hepatitis, high transaminase and IgG levels, and positive tests for autoantibodies that occurs in ≈ 6 – 10% of patients receiving transplants for non-autoimmune disorders. It has been named “de novo AIH” (Kerkar et al., 1998; Liberal et al., 2012b). This condition does not respond satisfactorily to anti-rejection regimens but only to the addition of standard treatment for AIH (Liberal et al., 2012b) or, in resistant cases, rapamycin (Kerkar et al., 2005); an early diagnosis is needed to avoid graft loss.

Future Treatment Approaches

As loss of immunoregulation appears central to the pathogenesis of AIH, so treatment should concentrate on restoring the ability of Tregs to expand in number, with consequent increase in their function. The immunotherapeutic use of autologous $CD4^+CD25^+$ Tregs derived from patients, however, is hindered by their limited ability to proliferate and by their propensity to apoptosis (Akbar et al., 2003), which usually precludes cell numbers adequate for treatment. The partial Treg restoration in patients during remission (Longhi et al., 2004, 2005) indicates that Tregs in AIH, although impaired, can expand and regain function. Following *in vitro* exposure to polyclonal T cell stimulation, Tregs can be expanded not only in healthy individuals, but also in patients with AIH (Longhi et al., 2008). While maintaining the phenotypic features of original $CD4^+CD25^+$ T cells, expanded Tregs express increased FOXP3 and display augmented suppressor function.

Studies in mice show that Tregs with autoantigen specificity suppress immune effectors more efficiently than do their non-antigen-specific counterparts (Tarbell et al., 2004; Albert et al., 2005). In this regard, type 2 AIH is an excellent model for specific reconstitution of self-tolerance since not only is the key autoantigen, CYP2D6, known, but also the specific autoepitope regions (CYP2D6_{217–260} and CYP2D6_{305–348}), targeted by B cells, CD4 cells, and CD8 T cells (Kerkar et al., 2003; Ma et al., 2006; Longhi et al., 2007). Antigen-specific Tregs have been obtained from patients with type 2 AIH and exert a more powerful immunosuppressive effect than polyclonally expanded Tregs (Longhi et al., 2011). The most efficient suppression of autoreactive T cells was achieved after Tregs were exposed to CYP2D6 peptides co-cultured with semi-mature dendritic cells loaded with the same peptide. Thus adoptive transfer of autologous CYP2D6-specific Tregs could become an effective and even curative therapy for type 2 AIH, as suggested also in an animal model of type 2 AIH (Lapierre et al., 2013). In type 1 AIH, immune intervention based on SLA might be a possibility, since at least 50% of patients have autoantibodies to this autoantigen. An even higher proportion of patients with type 1 AIH have cellular immune reactivity to HLA DRB1*0301 (Meda et al., 2007) or HLA DRB1*0401 (Zhao et al., 2011b)-restricted SLA epitopes. SLA-specific Tregs could, therefore, be considered for antigen-specific immune intervention in type 1 AIH as well.

Another possible therapeutic approach is exploitation of the Treg response to low doses of IL-2, since Saadoun et al. (2011) report encouraging results in the treatment of hepatitis C virus-associated vasculitis that was refractory to conventional antiviral therapy and anti-CD20 monoclonal

antibody, using repeated courses of low-dose IL-2, which led to an increase in Treg numbers and also clinical improvement.

CONCLUDING REMARKS—FUTURE PROSPECTS

AIH requires consideration in the differential diagnosis of any instance in serum of increase in liver enzyme levels. Several pathogenic aspects of AIH have been elucidated, including predisposing genetic factors and (to a degree) disease-specific humoral and cellular immune responses. Prompt immunosuppressive treatment provides a good outcome with a mostly symptom-free long-term survival.

Even so, type 1 (but not type 2) AIH is one of those autoimmune diseases for which clear knowledge on initiation, immunopathogenic mechanisms, and effector processes remains quite lacking. The necessary better understanding of each of these aspects could facilitate our tasks for the future which include establishment of novel treatments aimed specifically at arresting liver autoaggression or, ideally, at reinstating failed tolerance to liver autoantigens, thereby abrogating our hitherto long reliance on non-specific immunosuppression with all of its discomforts and hazards.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

History

Biliary cirrhosis, although possibly secondary, was first reported in the work of the Italian pathologist Giovanni Battista Morgagni in 1761. The first report of non-obstructive biliary cirrhosis was by Addison and Gull in 1851. The term primary biliary cirrhosis (PBC) became accepted in medical literature following the report of Ahrens et al. (Ahrens et al., 1950). The first long-term study of PBC cases observed that the patients presented with pruritus as well as jaundice and features of end-stage liver disease (Sherlock, 1959), but there have been significant changes in the clinical presentation at diagnosis since then. In 1965 was recognized the association between serum antimitochondrial antibody (AMA) and PBC from the immunofluorescence pattern given by serum with reactivity against antigens present in cytoplasmic organelles: such reactivity was found almost

exclusively in affected individuals (Walker et al., 1965). Some 20 years later gene cloning revealed the identity of the autoantigen as an enzyme of the pyruvate dehydrogenase complex (PDC) located on the inner mitochondrial membrane (Gershwin et al., 1987). This led to more sensitive assays for AMA testing, although indirect immunofluorescence remains the method of routine testing in most clinical centers.

Diagnosis

The diagnosis of PBC is based on three criteria: increased serum alkaline phosphatase levels indicating cholestasis for longer than 6 months, a positive test for AMA in serum by indirect immunofluorescence (IIF) at a titer of or >1:40, and a compatible liver histology (Selmi et al., 2011). Patients who lack AMA presence but otherwise present signs of PBC are specified as “AMA-negative PBC” as they follow a natural history similar to AMA-positive patients (Selmi et al., 2008a).

Pathology

Liver biopsy remains critical for histological staging, but it is currently uncertain whether it is still needed for the diagnosis of PBC when the other two diagnostic criteria are met. It should be done when the diagnosis is suspected but AMA testing is negative and/or alkaline phosphatase levels are normal, and when it is required to stage the disease, both at presentation and in the follow-up (Heathcote, 2000). Sampling error should always be considered and if one biopsy appears to have variable staging the highest stage should be accepted (Ludwig, 2000). Histological classification (Ludwig et al., 1978) identifies four stages of PBC. Stage I shows portal-tract inflammation with predominantly lymphoplasmacytic infiltrates, loss of septal and interlobular bile ducts (diameter <100 μm), and non-caseating granulomas in absence of features of sarcoidosis or tuberculosis. Stage II shows a periportal inflammatory infiltrate, cholangitis, granulomas, and proliferation of ductules. Stage III shows septal or bridging fibrosis, ductopenia (over half of the interlobular bile ducts have vanished) and copper deposition in periportal and paraseptal hepatocytes. Stage IV is frank cirrhosis. The non-caseating epithelioid granulomas in PBC, as seen too in sarcoidosis, remain a mysterious feature since these are not a histological characteristic of any other autoimmune disease. Granulomas encountered in unselected liver biopsies are mostly attributable to PBC, but their pathogenic significance (if any) remains unknown (You et al., 2012).

Clinical Features

Unlike in the past, in the majority of cases (20–60%) the diagnosis of PBC is now made in the absence of symptoms that indicate a liver condition or cholestasis. This is due to the increased awareness of the disease and the availability of more sensitive and non-invasive tests, such as those for AMA detection. Interestingly, however, symptomless patients are commonly older than the symptomatic ones, possibly indicating a difference in the progression of PBC in these two groups (Howel et al., 2000). During extended clinical follow-up, most apparently normal AMA-positive patients will eventually develop PBC (Metcalf et al., 1997). In the last cirrhotic stage of PBC features of advanced liver disease, such as portal hypertension, jaundice, ascites, porto-systemic encephalopathy, and upper digestive bleeding, are predominant as with liver cirrhosis from any cause.

Fatigue is the most common symptom, affecting 70% of patients, but prevalence rates vary across cohorts. The fatigue is sufficient to cause severe distress and disability. The severity of fatigue is independent of the severity of liver disease or other symptoms and of psychiatric factors. The

cause of fatigue is unknown, and numerous pathological and neurophysiological mechanisms have been unconvincingly proposed including daytime somnolence, autonomic dysfunction, and cognitive impairment (Hollingsworth et al., 2008, 2009; Newton et al., 2011; Pearce et al., 2011; Hale et al., 2012). Pruritus is the second most common symptom of PBC; long-term observations showed that most patients experience pruritus, especially at advanced stages. It can anticipate jaundice by months or years. Pruritus is usually diffuse, typically worsens at night and following contact with certain fabrics (wool), or in a warm climate. Recent studies point towards lysophosphatidic acid (LPA), a potent neuronal activator, as a pruritogen in cholestasis pruritus (Kremer et al., 2011). Specific treatments are awaited. Cholestyramine (4 g before and after the first meal) improves pruritus. The only other pharmaceutical therapies are short cycles of rifampin or opiate antagonists. Intractable pruritus can require liver transplantation. Portal hypertension develops in over 50% of untreated patients over a 4-year follow-up and may manifest at upper digestive endoscopy before other signs of liver cirrhosis appear.

Metabolic bone disease in PBC is secondary to reduced bone deposition. Therapy includes oral calcium supplementation, weight-bearing activity, and vitamin D replacement if a deficiency is present; bisphosphonates appear to be safe but benefits are inconclusive (Rudic et al., 2011). Dyslipidemia is present in up to 85% of patients with PBC and may precede the diagnosis with elevations of both serum cholesterol and serum triglyceride levels but these do not correlate with the risk of cardiovascular events or atherosclerosis as measured by intima-media thickness of carotid arteries (Longo et al., 2002).

Coexistence with other autoimmune diseases occurs with PBC in 70% of patients (Table 62.1) with comorbidities including keratoconjunctivitis sicca, Raynaud's phenomenon, and limited cutaneous systemic sclerosis (lcSS). Systemic lupus erythematosus (lupus) was highlighted as a frequently self-reported coexistence in one large cohort of patients with PBC but this was unconfirmed in other studies and could be an overestimation attributable to autoantibody misinterpretation.

Hepatocellular carcinoma (HCC) is a risk in PBC as for other chronic cirrhotic liver conditions, and should be monitored for using ultrasonography (and CT in selected cases), particularly when orthotopic liver transplantation (OLT) is being considered (Cavazza et al., 2009). There is no association with cholangiocarcinoma in contrast to primary sclerosing cholangitis (PSC) (see Chapter 63) or with breast carcinoma as previously suspected.

Epidemiology and Natural History

PBC epidemiology is mainly descriptive. Published studies have major methodological flaws such as non-uniform

TABLE 62.1 Prevalence of Disorders Associated with PBC Derived from Clinical Studies. Other associations Suggested by Limited Case Reports are Not Indicated Herein

| | Prevalence in PBC | Reference |
|--|-------------------|---------------------------|
| Keratoconjunctivitis sicca | 75% | Tsianos et al. (1990) |
| Renal tubular acidosis ^a | 50% | Pares et al. (1981) |
| Reduced alveolar diffusion capacity ^a | 39% | Costa et al. (1995) |
| Raynaud's phenomenon | 32% | Marasini et al. (2001) |
| Hashimoto's disease | 11% | Elta et al. (1983) |
| Celiac disease | 6% | Kingham and Parker (1998) |
| Systemic sclerosis | 12% | Marasini et al. (2001) |

^aUsually of limited clinical significance.

case definition; even so in most cases such definition is more solid compared to other similar autoimmune or chronic inflammatory diseases, notably PSC. Indeed, ideal population-based studies have not been performed to establish the true prevalence of PBC, as a noninvasive highly sensitive marker is not currently available. The most specific candidate marker is AMA, but this is negative in 5–10% of patients as discussed below, and the absence of disease registers precludes the recognition of all cases. Tables 62.2 and 62.3 cite PBC and AMA epidemiology in available studies. PBC is considered to be most prevalent among northern European and northern American populations, as shown in Table 62.2. The highest prevalence rate reported is 402 cases/million, but a true prevalence is undetermined as case finding methods overlook asymptomatic subjects marked only by abnormal tests of liver function and a positive test for AMA and, moreover, depend on physician awareness. Further, incidence rates appear to be increasing over time, perhaps real or secondary to more sensitive AMA laboratory tests and availability of better administrative datasets. Evidence suggests an unexplained seasonal and time clustering of newly diagnosed cases (McNally et al., 2009, 2011). There is a striking female predominance, about 10:1 (Table 62.2); yet, notably, the sex ratio among all AMA-positive samples in large serum collections is significantly lower, only 2–3:1. This suggests that a discrimination bias may apply also in this case, similar to what has been proposed for disease prevalence (Podda et al., 2013) (Table 62.3), or that “femaleness” may continue to influence progression after initial seroconversion. The characteristic female predominance in PBC could result from sex hormones acting on the immune system, the number of pregnancies, or sex chromosome abnormalities, as explained later.

Risk factors for PBC have been hypothesized from both epidemiological studies and a susceptible genetic background. In epidemiological surveys, history of recurrent urinary tract infections, co-morbidity like other autoimmune diseases, and lifestyle factors, such as smoking and a high-fat diet, are the most consistent findings, while less notable associations were reported for frequent use of hair dye or nail polish, and a higher family income (Prince et al., 2010) (Box 62.1). This latter factor is of interest as PBC is mainly asymptomatic and a higher social status may lead to better healthcare and an earlier recognition of the disease, and in women a more frequent use of cosmetics.

PBC progresses at a variable pace over time. One final note is related to the proposed ethnic and racial factors that may contribute to the cause of PBC. There is a variable prevalence, with subjects of African American descent being underrepresented among collected cases when compared to other chronic liver diseases or to the general population, and these show a more aggressive disease progression (Peters et al., 2007). Whether this could be related to genetics or to environmental factors, possibly insufficient vitamin D, remains to be determined.

Some patients have a stable disease without symptoms for decades and others rapidly advance towards end-stage liver disease. We can identify three periods: (1) an asymptomatic stage lasting even for decades in which the diagnosis is usually incidental; (2) a phase with non-specific symptoms and mild jaundice, with a shorter duration; and (3) a rapidly progressing pre-terminal stage with frank jaundice and complications of liver cirrhosis. The presence of symptoms at the time of diagnosis constitutes a major factor limiting survival (Pares and Rodes, 2003). Nevertheless, a shorter survival of presymptomatic patients was reported possibly secondary to a higher prevalence of non-hepatic causes

of death compared to deaths related to PBC ([Prince et al., 2004](#)). Multivariate analysis among symptomatic patients has indicated several factors that can negatively influence the outcome in PBC including clinical features (older age, ascites, edema, hepatic encephalopathy), analytical features (hyperbilirubinemia, hypoalbuminemia),

and histological features (fibrosis or cirrhosis) ([Pares and Rodes, 2003](#)). The prognostic model based on the Mayo risk score is widely used for survival estimations ([Grambsch et al., 1989](#)) while PBC-specific ANA may also identify patients with a worse outcome, as discussed later.

BOX 62.1 Proposed Risk Factors and their Association with PBC**Significant Associations**

- Female sex
- Family history for PBC
- Non-PBC autoimmune disease (particularly autoimmune thyroiditis, Sjögren's syndrome, lupus)
- Pregnancies
- Former smoking habit
- History of recurrent vaginal or urinary tract infection
- Previous tonsillectomy
- Frequent use of hair dye
- Frequent use of nail polish
- Unlikely associations
- Previous surgery (particularly appendectomy, uterine surgery)
- Previous hepatitis A infection
- Use of contraceptive pill

No Association

- Dietary fat intake
- Childhood diseases
- Breast cancer

Treatment

Ursodeoxycholic acid (UDCA) is the only therapy that has received US Food and Drug Administration approval (Serfaty and Poupon, 2012). UDCA accounts for 4% of the bile acid pool in human bile and is more hydrophilic compared to other bile acids. UDCA action depends on (1) modification of the bile-acid pool, (2) reduction in proinflammatory cytokines, and (3) decreases in degrees of apoptosis and levels of vasoactive mediators (Poupon, 2012). Doses ranging from 13 to 20 mg/kg of UDCA lead to optimum bile enrichment, and long-term survival with UDCA therapy is higher than predictions based on mathematical models of survival for PBC. However, a meta-analysis of published trials indicated that UDCA influences biochemical factors and histology without improving survival, at least according to the Cochrane data base (Rudic et al., 2012). But, notably, a complete biochemical response to UDCA with normalization of serum liver tests in the absence of cirrhosis was achieved in some 40% of treated patients (Leuschner et al., 2000), and recent data suggested that a response at 12 months does predict a different outcome in patients receiving an adequate UDCA dose (Zhang et al., 2013).

The use of immunosuppressive/immunomodulatory drugs including azathioprine, cyclosporine, penicillamine, and colchicine is not recommended unless combined with UDCA in the autoimmune hepatitis–PBC overlap syndromes, while methotrexate with UDCA may prove

beneficial in a subgroup of patients despite some safety concerns (Leung et al., 2011). Data on the effects of corticosteroids and fibrates in PBC are inconclusive particularly at early stages and their long-term use is not recommended pending longer clinical trials (Poupon, 2011) or unless autoimmune hepatitis features coexist (Tanaka et al., 2011a). Recent data on the use of B cell depletion for PBC suggest that this approach may help in UDCA non-responders (Tsuda et al., 2012), thus raising interesting questions on the role of B cells in PBC pathogenesis.

OLT is considered the *extrema ratio* treatment for end-stage PBC: interestingly, the effects of UDCA are making it less frequently needed (Singal et al., 2013). Post-OLT survival rates are excellent with either living or cadaver donors (Kashyap et al., 2010; Kaneko et al., 2012). A re-transplantation is needed in fewer than 10% of patients despite high recurrence rates of disease, possibly influenced by the use of specific immunosuppressive post-OLT regimens (Ilyas et al., 2011). The use of UDCA in patients receiving transplants is safe and needed when disease recurs since one would expect a similar natural history with AMA appearance and subsequent histological stages. PBC frequently recurs after OLT and data suggest incidence rates of 21–37% and 43% at 10 and 15 years, respectively, when histology is assessed (Carbone and Neuberger, 2011).

AUTOIMMUNE FEATURES

An autoimmune pathogenesis for PBC appears indisputable according to different lines of evidence, notably high levels/counts of serum autoantibodies and autoreactive T cells directed at overlapping epitopes on the mitochondrial constituent pyruvate dehydrogenase complex (Folci et al., 2012), and/or reactivity to nuclear autoantigens (ANA) of very particular specificities. Detectable AMA in serum exist in some 90% of affected individuals, but AMA negative cases are clinically similar, and AMA titers do not correlate with disease staging or grading (Selmi et al., 2008b). If ANA positivity were taken into account, then nearly all cases of PBC could show seropositivity. Autoreactive T cells were equally detectable in the peripheral blood of AMA positive and negative PBC cases and virtually all patients with PBC, and recognize the same overlapping epitopes within the PDC-E2 autoantigens as do AMA (Selmi et al., 2011b). There is no direct proof for a pathogenic role of serum AMA in the bile duct injury observed in PBC but, as is well known, this applies to many other of the disease-specific autoantibodies with the exception of damaging anti-double-stranded DNA (dsDNA) antibody in lupus nephritis. Finally there is no established benefit from immunosuppressants in PBC but we should also note that

long-term treatment is required and thus adequate clinical trials are poorly feasible.

AMA are directed against components of the 2-oxoacid dehydrogenase complexes (2-OADCs), a family of functionally related enzymes within the mitochondrial respiratory chain. Recognized autoantigens include particularly the E2 subunit of the pyruvate dehydrogenase complex (PDC), the E3 binding protein (E3BP) of PDC, and the E2 subunit of the 2-oxoglutarate dehydrogenase complex (OGDC-E2) and the branched-chain 2-oxo acid dehydrogenase complex (BCOADC-E2). In particular, these autoantigens include closely-related conformational epitopes, notably the inner lipoylated domains of all three complexes. The lipoic acid cofactor has been suggested as contributing to epitope recognition (Bruggraber et al., 2003), but results on this have been conflicting.

Antinuclear antibodies (ANA) are detectable in PBC sera by indirect immunofluorescence (IIF), and three patterns are described, i.e., “nuclear rim,” “multiple nuclear dots” (MND), and anti-centromere. The nuclear rim pattern depends on the recognition of proteins gp210 and nucleoporin 62 within the nuclear pore complex and on the MND pattern on the Sp100 and promyelocytic leukemia (PML) proteins, and the anti-centromere pattern is seen in cases of lcSS. Interestingly, the presence of serum reactivity against proteins from the nuclear pore complex (gp210, p62) in PBC was found to be associated with a more severe disease in longitudinal studies (Wesierska-Gadek et al., 2006; Nakamura et al., 2007). The nuclear body protein Sp100 and PML, giving the MND pattern, have been shown to be complexed with small ubiquitin-like molecules (SUMO) for cell transport regulation, and SUMO are in turn independent antigens specific for ANA-positive PBC (Janka et al., 2005). The anti-centromere antibodies (ACA) in patients with PBC and limited cutaneous systemic sclerosis possibly signify a more benign PBC phenotype (Rigamonti et al., 2006).

Cumulatively, serum ANAs are detected in 30–50% of patients with PBC but, as for AMA, their pathogenic role is undetermined. The IIF staining patterns of these PBC-related ANAs do not in any way point to a coexisting SLE. The T cell response in PBC is characterized by a multilineage reactivity to PDC-E2 epitopes with participation of Th1 CD4⁺ T cells and CD8⁺ T cells: the latter are considered as the true effectors by reason of their prevalence at sites of bile duct injury (Shimoda et al., 2008b) and capacity to transfer biliary disease in animal models (Yang et al., 2008; Kawata et al., 2013). Most recently, a detailed phenotype of the CD8⁺ T cell subpopulations in PBC was derived using peripheral blood, demonstrating a higher frequency of effector memory CD8 T cells (CD45RO^{high} CD57⁺ CD8^{high}) and the gut homing integrin $\alpha 4\beta 7$ (Tsuda et al., 2011). Such CD8^{high} effector memory T cells accumulate within the portal

areas of PBC liver samples, respond to the peptide epitope of PDC-E2 associated with HLA class I, and thus contribute to the destruction of intrahepatic bile ducts; this in turn may further costimulate an overall T cell response (Kamihira et al., 2005). Likely participants are also autoreactive CD4⁺ T cells of phenotype Th1 that respond to PDC-E2 163-176 in a “universal” fashion, regardless of serum AMA positivity (Shimoda et al., 2008a). These results can be aligned with the striking observation in PBC of a 100–150-fold increase in the precursor frequency of PDC-E2-specific T cells in the hilar lymph nodes and liver compared with counts in peripheral blood (Shimoda et al., 1998). The Th17 and T regulatory profiles also have been investigated in PBC, as in other autoimmune conditions. There is an elevation of levels in blood of Th17-related cytokines and the number of Th17 cells in peripheral blood of patients with PBC (Rong et al., 2009), and in liver of PBC animal models (Lan et al., 2009), and numbers of T regulatory cells (FoxP3 expression) are significantly reduced in PBC (Rong et al., 2009). This is similar to autoimmune hepatitis where Tregs are quantitatively reduced (Longhi et al., 2012) and possibly functionally impaired, although the latter observation has not been confirmed and its relevance needs to be determined (Fenoglio et al., 2012).

GENETIC FEATURES

Familial PBC: Twins and Relatives

The concordance for PBC among monozygotic (MZ) twins is 63%, among the highest reported among autoimmune diseases (Bogdanos et al., 2012), and significantly higher than concordance for dizygotic twins (Selmi et al., 2004). Nevertheless, phenotype differences are found also in twin pairs concordant for PBC including significant differences in disease progression and severity. Further, the frequency of PBC is higher among relatives of affected individuals and the term “familial PBC” has been coined to indicate families that have more than one case. Variable rates of familial PBC are seen in different geographical areas, possibly due to different methods of case ascertainment but also perhaps to differences in local environmental provocation. As with disease prevalence estimates, family studies have significant limits, since the reported methodology was substantially based on case-note review, with criteria for case ascertainment neither uniform nor clearly illustrated, no attempt made to calculate the size of the patient pedigree, and no control group available for comparison of the population prevalence rate. In general, data indicate that 1–6% of PBC cases have at least one other family member with the disease (Table 62.4), and a higher prevalence is ascertained for serum AMA (Lazaridis et al., 2007). Of note, serum AMA in first-

TABLE 62.4 Prevalence of Familial Cases of PBC

| Affected Families | First-Degree Relatives | Author, Year |
|-------------------|------------------------|---------------------------|
| 17 (4.3%) | – | Bach and Schaffner (1994) |
| 6 (3.8%) | 8 (1.1%) | Brind et al. (1995) |
| 10 (6.4%) | 5 (3.2%) | Floreani et al. (1997) |
| 8 (5.1%) | 8 (5.0%) | Jones et al. (1999) |
| 8 (3.6%) | 8 (5.1%) | Tsuji et al. (1999) |
| 17 (4.3%) | 57 (5.5%) | |
| 57 (5.5%) | 8 (3.6%) | Corpechot et al. (2010) |

degree relatives supports the role of genetic factors in loss of tolerance towards mitochondrial antigens. Earlier studies based on indirect immunofluorescence for AMA reported familial prevalence rates for AMA between 4.9 and 7.4% (Feizi et al., 1972; Galbraith et al., 1974), but recent data for first-degree relatives using recombinant mitochondrial autoantigens gave an overall 13.1% prevalence, with higher rates, as expected, in siblings (Lazaridis et al., 2007) that had been largely excluded from previous studies. In conclusion, the occurrence of PBC among first-degree relatives of patients—“familial PBC”—is common and these have a 50–100-fold higher risk to develop PBC (Selmi et al., 2008a), particularly so for mothers, sisters, and daughters (Lazaridis et al., 2007). Cumulatively, the sibling relative risk, that is the risk for having PBC of a subject with a sibling affected by the disease, is 10.5, among the highest for autoimmune diseases.

HLA Association

An HLA association with one or another class 2 DR alleles is such a characteristic of human autoimmune diseases that we are surprised by the weakness and regional-ity of such an association for PBC; this has not been satisfactorily explained (Invernizzi, 2011). The susceptibility (DR8) and protective (DR11) associations have now been confirmed in different populations and fine mapping has most recently proposed a better definition of the associated loci (Invernizzi et al., 2012), following GWAS data (Hirschfield and Invernizzi, 2011) and pathway-based analyses (Kar et al., 2013).

Genome-wide Association Studies (GWAS)

GWAS studies can provide substantial information about gene polymorphisms and disease association provided that adequately large and well-characterized samples of patients and, more importantly, controls are included (see Chapter 26). Recent studies have disclosed consistent

associations but the candidate polymorphisms were found only in a fraction of patients, thus limiting the clinical use of the data. Patients from Canada and the USA (Hirschfield et al., 2009) or Italy (Liu X et al., 2010) were included in the earlier studies that reported associations with the gene loci for IL12A, IL12RB2, and STAT4 while a combined analysis of both cohorts confirmed these associations and identified new susceptibility loci at SPIB, IRF5-TNPO3, and a chromosome 17 region containing IKZF3-ZPBP2-GSDMB-ORMDL3 with unclear functional significance (Hirschfield and Invernizzi, 2011). A GWAS on patients from Japan disclosed similar associations (Tanaka et al., 2011b). Among candidate genes, IL12A and IL12RB2 are pivotal in the immune responses against certain infectious diseases (Filipe-Santos et al., 2006), so that the PBC genetic association discerned by GWAS could be responsible of an impaired response to infection and determine an augmented risk to generate autoimmune responses (Selmi and Gershwin, 2009) and ultimately indicate new biotherapeutic approaches (Yeilding et al., 2011). Further studies have identified additional linked loci (Mells et al., 2011; Hirschfield et al., 2012), and a pathway analysis supports an association with the tumor necrosis factor/stress-related signaling system (Kar et al., 2013). We may expect that next generation sequencing will provide new clues to genetic susceptibility to PBC.

Epigenetic Effects

Epigenetic effects are emerging as a promising field of research for autoimmune disease pathogenesis (see Chapter 28) but so far data for PBC are limited to just one study in monozygotic twins supporting the role of X chromosome gene methylation (Mitchell et al., 2011). We foresee that the genome-wide approach on specific cell subpopulations will in the coming years provide new data on the methylome and histone code associated with PBC, particularly in the unique model of monozygotic twin pairs.

Fetal Microchimerism

Similarly to other autoimmune diseases that are prevalent in women following their reproductive years (Selmi et al., 2012a,b,c), an effect of fetal microchimerism has been a suggested contributor to PBC, according to small amounts of fetal (paternal) DNA being found in the maternal liver (Stevens et al., 2004). This is an intriguing hypothesis wherein microchimerism due to replicating fetus-derived lymphocytes induces a condition analogous to chronic graft-versus-host disease (Nelson, 2003). However, the data are cumulatively unconvincing (Tanaka et al., 1999).

Genes on the X Chromosome

There are genes on the X chromosome, including but not limited to the gene for FoxP3, that are critical to the maintenance of physiological sex hormone levels and, more importantly, of immune responsiveness (see Chapter 24, Selmi, 2012b). This is well represented in clinical practice by autoimmune features in women with a constitutional X monosomy, i.e., Turner syndrome (Lleo et al., 2012a). An age-dependent enhanced monosomy X in peripheral blood leukocytes of women with PBC was reported (Invernizzi et al., 2004) indicative of a polygenic model for PBC with an X-linked major locus of susceptibility in which genes escaping inactivation are major candidates (Mitchell et al., 2011). These data, of note, have been recapitulated in other autoimmune diseases with an advanced age onset, such as systemic sclerosis (scleroderma) and autoimmune thyroid disease (Invernizzi et al., 2005), but not in younger women with systemic lupus erythematosus (Invernizzi et al., 2007). Finally, one fascinating observation is the enhanced loss of the Y chromosome in men with PBC (Lleo et al., 2013).

ENVIRONMENTAL PROVOCATION OF PBC

The paucity in PBC of strong genetic associations and the less than complete concordance in MZ twins suggest that environmental influences must contribute to autoimmunity in PBC (Liang et al., 2011). As other evidence there is a latitudinal gradient for PBC prevalence, coined geoepidemiology, quite similar to that pertaining for other autoimmune diseases. The epidemiology data report the highest incidence of PBC in northern European countries, namely northern England and Scandinavia, and northern American regions, i.e., in one Minnesota county. However, these data may be biased by different and usually better methodologies for diagnosis (Selmi, 2012a,c).

Infections

The ability of infectious agents, particularly bacteria, to induce autoimmune responses in the human setting is well accepted, noting the association between streptococcal infections and rheumatic carditis. Molecular mimicry is the most widely studied explanation. In the case of PBC, evidence points to *Escherichia coli* according to reports of an increased prevalence of urinary tract infections, *Chlamydia pneumoniae* infections despite some conflicting results, and occurrence of *Novosphingobium aromaticivorans* infection (Selmi et al., 2003). Whether the proposed associations are based merely on cross-reactivity noting the high similarity of PDC-E2 across species (yeast and some bacteria) remains to be determined (Ortega-Hernandez et al., 2010). In the case of *N. aromaticivorans*, data from infected mice support a more direct pathogenic role (Mattner et al., 2008).

Xenobiotics

These are foreign (non-self) compounds that may either alter or form complexes with defined self proteins, so inducing a change in the molecular structure of the native protein sufficient to induce an immune response to the complexed self protein (Selmi et al., 2010). Such an immune response may then result in the cross-recognition of the self form, thereby perpetuating the immune response and leading on to chronic autoimmunity (Selmi et al., 2011b). Results from experiments in animals and serological data in humans support this hypothesis as a cause of PBC (Leung et al., 2012), and data include the induction of PBC-like liver lesions in experimental models and the study in humans of serum reactivity against specific compounds included in cosmetic products (Leung et al., 2007; Wakabayashi et al., 2009; Chen et al., 2013). This latter association appears fascinating in the context of the female predisposition to PBC and the role of other PBC risk factors. A provocative effect for a number of specific environmental compounds has been proposed for various other autoimmune conditions (see Chapter 21), and are shown in Table 62.5. Whatever the case, it is difficult to escape the conclusion that the “etiology” of PBC (and most other autoimmune diseases) depends on unfortunate combinations of multiple genetic and environmental risk factors each individually conferring a relatively low risk but cumulatively “spilling over” to create an autoimmune phenotype.

EXPERIMENTAL ANIMAL MODELS

Obviously the availability of a valid animal model would be extremely helpful in elucidating the multi-factorial causation and relentless progression of human PBC. Several models,

TABLE 62.5 The Role of Xenobiotics in Autoimmune Disease

| Compound | Associated Autoimmune Condition |
|---------------------------|---|
| Mercury | Immune complex formation Glomerulonephritis |
| Iodine | Autoimmune thyroiditis |

| Halothane | Autoimmune hepatitis |
| Canavanine | SLE-like syndromes |
| 6-Bromohexanoate | PBC |

For a complete discussion please refer to the recent NIEHS workshop results (Germolec et al., 2012; Selmi et al., 2012a,b,c).

mostly murine, were proposed in earlier years, albeit with some limitations. However, from 2006, novel and informative experimental models of PBC have been developed. These are subdivisible into spontaneously occurring models based on germline genetic modifications, and induced models based on immunization with xenobiotics structurally similar to PDC-E2 (Tsuneyama et al., 2012). These models are listed and compared in Table 62.6. The spontaneous models include (1) NOD.c3c4 congenic mice, (2) dominant negative TGF- β receptor II mice, (3) IL-2a (CD25)^{-/-} mice, (4) Ae2_{a,b}^{-/-} mice, and (5) scurfy mice. The induced xenobiotic-immunized models are represented by (1) 6-bromohexanoate-immunized guinea pigs, and (2) 2-octanoic acid-immunized mice. Of note, all models share the occurrence of high-titer serum AMA (and sometimes other autoantibodies as well) and exhibit hepatocellular and cholangiocellular injury inflicted by the infiltrating lymphocytes, and express a similar proinflammatory cytokine profile. Some of these models have already been used to investigate the impact of pathway-specific treatments, as in the case of B cell depletion (Dhirapong et al., 2011) or IL-12 (Lleo et al., 2012b). In this case, the deletion of the gene encoding for one IL-12 subunit led to an amelioration of the PBC-like pathology in the TGF- β R2II model (Yoshida et al., 2009). Nevertheless, the nature of the liver pathology is frequently unclear as some models manifest features uncommon in human PBC, i.e., peritonitis in the 2-octanoic acid-induced model or inflammatory bowel disease in the

CD25^{-/-} model; also the models fail to recapitulate the female sex imbalance characteristic of human PBC.

Several obstacles still militate against the development of a consistent and reliable animal model for PBC, one being a long latency between the appearance of AMA and the occurrence of liver pathology as pertains also in humans, and may well be reflective of autoimmune disease in general. However, it is a drawback given the short life expectancy of the experimental mice. On the positive side the models developed so far have provided very useful lessons in (1) showing the tightness of the nexus between AMA reactivity and biliary epithelial cell pathology, (2) indicating that deficiency in the Treg compartment is highly complicit in the genesis of human PBC, (3) identifying target-specific pathways that might be utilized to modulate the disease, and (4) maintaining confidence in the participation of environment (xenobiotic agents) in pathogenesis.

PATHOLOGIC EFFECTOR MECHANISMS

The striking tissue specificity of the pathology observed in PBC has been the focus of different lines of research. An earlier thesis was that anti-PDC-E2 antisera reacted not only with PDC-E2 in mitochondria but additionally with material located at the apical end of the biliary epithelial cell (BEC) in close apposition to the cell surface (Van de Water et al., 1993). Similarly postulated was an

TABLE 62.6 PBC Animal Models Proposed since 2006

| | NOD.c3c4 mice (Irie et al., 2006) | dnTGF-βRII mice (Oertelt et al., 2006) | IL-2 R α ^{-/-} mice (Wakabayashi et al., 2006) | Scurfy mice (Zhang et al., 2009) | Ae2 _{a,b} ^{-/-} mice (Salas et al., 2008) | 6-BH-immunized guinea pigs (Leung et al., 2007) | 2-OA-immunized mice (Wakabayashi et al., 2008) |
|---------------------------|-----------------------------------|--|--|----------------------------------|---|---|--|
| AMA | 50–6% | 100% | 100% | 10% | 40–80% | 100% | 100% |

| Granuloma | + | + | +/- | - | | + | + |
| Proinflammatory cytokines | + | + | + | + | + | + | + |
| Collateral observations | Biliary dilatation | Moderate colitis | Severe colitis Severe hemolytic anemia | Short lifespan | Late onset | Late onset | peritonitis |

In all cases the main AMA target is PDC-E2.
Modified from Tsuneyama et al. (2012).

aberrant expression in PBC of a molecule that shared epitopes with PDC-E2 and was located exclusively in the BECs targeted by the immune system (Joplin et al., 1997). If this material were to be derived from PDC-E2, there could be sequence variants common in PBC patients that lead to an altered turnover of the molecule, and high accumulation of PDC-E2 specifically in BECs. Moreover, chemicals (xenobiotics) metabolized by the liver could significantly modify PDC-E2, so leading to the production of such variants (Leung et al., 2012). It is noteworthy that the material is found in association with IgA and the polymeric Ig receptor (Migliaccio et al., 1998; Fukushima et al., 2002) on the cell membranes of cholangiocytes. However, interest in this line of research has waned.

A more contemporary theory seeks to explain PBC tissue specificity by unique features of apoptosis affecting the cholangiocyte. Thus during apoptosis PDC-E2 remains intact and maintains its immunogenicity, due to a cell-specific lack of glutathionylation within BECs, and the postulate is that intact PDC-E2 in apoptotic fragments could be taken up by local antigen-presenting cells and transferred to regional (portal) lymph nodes for priming of cognate T cells, thus initiating the PBC cascade (Leo and Invernizzi, 2013). As direct evidence of this, Leo and colleagues demonstrated that PDC-E2 is found in the blebs of human intrahepatic bile duct cells undergoing apoptosis and this effect was not observed in other epithelial cell lines (Leo et al., 2009). Although the biliary epithelium represents only a small proportion of all liver cells, these cells contribute to the induction of immune activity against microbes and foreign antigens as

they express HLA and adhesion molecules. Thus cholangiocytes may be implicated in the failure of immune tolerance by impairment of a correct clearance process of apoptotic cells by specific local phagocytes, and cell lysates can release intracellular molecules initiating the autoimmune reaction when taken up by local macrophages. Similar ideas have been invoked by others in different contexts, with the immunogenic apoptosis-derived material being specified as an “apotope” (Leo et al., 2008; Reed et al., 2008; Rudic et al., 2011). Additional items, as recently suggested (Rong et al., 2009; Fenoglio et al., 2012), include alterations in the balance of Th17 cells and Tregs (Fenoglio et al., 2012), and activity of NK and NKT cells (Shimoda et al., 2012). B cell/antibody effects have received relatively little attention as pathogenic effectors, but we draw attention to the sometimes prominent presence of plasma cells among the periductular lymphoid infiltrates in human PBC, and the ameliorative effects in PBC of the anti-CD20 monoclonal rituximab (Tsuda et al., 2012). All in all, PBC well illustrates the multiplicity of contributors to the autoimmune-orchestrated response against intrahepatic cholangiocytes.

AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

The significance of serum autoantibodies in PBC pathogenesis was the subject of a previous paragraph but we discuss here the appropriate clinical use of the available diagnostic tests. Serum AMA remains the most widely

utilized test when PBC is suspected and indirect immunofluorescence is the routine test for their detection. Notably, there is significantly lower operator variability than for serum ANA patterns. However, increasingly, less labor-intensive methods such as commercially available ELISAs and immunoblots are being used, at least for preliminary screens, and comparative tests are becoming available (Liu X et al., 2010; Bizzaro et al., 2012). Although “traditionalists” prefer to use indirect immunofluorescence primarily, they would call on second-level tests (Western blot and ELISA) to confirm the immunofluorescence results, and particularly to detect AMA in a suspected case of PBC with a negative test by IIF. Because of the higher sensitivity of the ELISA test, the number of AMA-negative PBC patients has been decreasing (Liu X et al., 2010; Bizzaro et al., 2012). On the contrary, Western blot (which detects autoantibodies to the E2 subunit of all three of the 2-OADC enzymes) represents the most specific method for AMA detection. The introduction of a triple hybrid recombinant mitochondrial preparation for Western blot and ELISA has increased the sensitivity and the specificity of the diagnostic tests with reduction in the proportion of AMA-negative PBC (Moteki et al., 1996). The presence of AMA in as many as 73% of IIF-negative patients was identified using a recombinant mitochondrial preparation in an ELISA format (Miyakawa et al., 2001), and the use of a multiplex platform further increased the sensitivity of detection methods (Oertelt et al., 2007). However, and of particular note, head-to-head comparisons of the available tests have not been performed in a rigorous fashion using histology as the gold standard, meaning that we do not really know the rate of “falsely positive” tests for PBC by any test format. Some may hold that a positive test always heralds “incipient” PBC but we cannot be sure of this.

As previously discussed, 30–50% of PBC sera are also ANA positive, and possibly even more among those AMA negative by IIF. It is a pity that the historically embedded term “ANA” has been retained for these because this term is so tightly linked in practitioners’ minds with lupus. In fact PBC-associated ANA has nothing to do with lupus, particularly since the homogeneous pattern characteristic of lupus is virtually absent in PBC, while one or another of the other three “PBC-related” ANA patterns by IIF are common. One of these, anti-centromere, specifies the unique syndrome of mixed PBC-limited cutaneous systemic sclerosis. Other PBC-specific ANA antigens include those that give by IIF the multiple nuclear dot pattern (Sp100/PML), or rim pattern (gp210/p62) for which serological kits are commercially available and their detection may prove helpful in AMA-negative cases suspect for PBC (Liu X et al., 2010). Among less specific serum markers, variable proportions of PBC sera manifest positivity

for rheumatoid factor, smooth muscle antibody, anti-thyroglobulin antibody, and anti-ribonucleoprotein antibody, but definitive data on the significance of these other autoantibodies in PBC are not available despite observations that anti-RNP antibody-positive subjects frequently manifest PBC (Takada et al., 2008). One serum antibody that warrants further investigation is that directed at Ro52/TRIM21 which is observed, albeit not specifically, in a proportion of PBC cases (Chou et al., 1995; Takada et al., 2007). So, in conclusion, it is not too much to say that with the present availability of serological tests for ANA and AMA based on recombinant antigens, PBC is the most amenable among all of autoimmune diseases to expect an accurate laboratory serological diagnosis.

CONCLUDING REMARKS—FUTURE PROSPECTS

PBC is indeed a characteristic disease within the ambit of autoimmunity and amply fulfills the defining features for autoimmune disorders, including the association with highly epitope-specific autoantibodies and autoreactive T cells. Yet there are some unusual features, notably (1) the insensitivity of PBC to conventional immunosuppressive drugs but responsiveness to UDCA which is not a first-line therapy for any other autoimmune disease, (2) the relative weakness of the genetic associations, including HLA, and (3) the histological non-caseating granulomas among the cellular infiltrates in the liver. However, regarding genetics, informative immune models in animals, mainly inbred mice, indicate that genetically-based immune derangements are critical to pathogenesis, notwithstanding disappointing data from GWAS so far. The extreme female predisposition to the disease is puzzling but may be just the top end of the general female predisposition to autoimmunity. Also, the pathogenetic pathways to the characteristic terminal cholangiolitic damage are not clear, although immunohistological evidence in human PBC points to CD8⁺ T cell cytotoxicity. From where might come the solution to the riddle of autoimmunity in PBC? One opinion is that this might come from the study of very large numbers of PBC cases and their families, and more searching GWAS with even larger cohorts of cases categorized according to location and disease features, along with the implementation of next generation deep sequencing that could at least unravel the complex genetic basis of PBC. Or it could come from the development in the laboratory of novel experimental models that are more directly representative than those hitherto of human PBC. Or it could even come from some serendipitous result obtained by an astute researcher whose primary investigational enquiries bore no direct relationship to PBC.

EPIDEMIOLOGY AND RISK FACTORS

Epidemiologic Features

Adult primary sclerosing cholangitis (PSC) affects mainly patients in their third to fourth decade of life with a male-to-female ratio of 2:1 (Lee and Kaplan, 1995). Although an uncommon disease, the diagnosis of PSC is increasing over time (Molodecky et al., 2011). Population-based cohorts suggest the incidence rate of PSC in North American populations is 1 per 100,000 inhabitants (Bambha et al., 2003; Kaplan et al., 2007). The prevalence of PSC in North America and Europe is reported to be between six and 16 cases per 100,000 individuals (Bambha et al., 2003; Berdal et al., 1998; Lindkvist et al., 2010). Contemporary data suggests PSC is less common

in Southern Europe and Asian populations (Escorsell et al., 1994; Ang et al., 2002).

Risk Factors

Risk factors for PSC are poorly understood. Inflammatory bowel disease (IBD) is the primary risk factor and condition associated with PSC. Among patients with PSC, up to 86% will have concurrent IBD, typically ulcerative colitis (UC) (Chapman et al., 2010). In contrast only 4% of patients with UC will have PSC (Olsson et al., 1991; Chapman et al., 2010). Even after controlling for UC, smoking may be protective of PSC whereas male gender and a family history of PSC appear to be associated with the disease (Mitchell et al., 2002; Bergquist et al., 2005; Molodecky et al., 2011).

NATURAL HISTORY, CLINICAL FEATURES, AND PSC-IBD

Natural History and Clinical Features

Classic PSC is associated with progressive stricturing and dilation of the extra and/or intrahepatic bile ducts. Approximately 50% of patients with PSC are asymptomatic at the time of diagnosis and the condition is detected based on the presence of abnormal liver tests (Broome et al., 1996). Following a diagnosis of asymptomatic PSC, nearly 25% will develop clinical symptoms after 5 years and the majority of patients will have some clinical or objective evidence of progression 6 years after the diagnosis (Porayko et al., 1990; Broome et al., 1996). Patients who present with asymptomatic disease have a better long-term prognosis compared to those who are symptomatic at the time of diagnosis (Broome et al., 1996). However, asymptomatic patients have a worse survival compared to the general population (Porayko et al., 1990).

Over time biliary strictures can lead to the development of symptoms, progressive cholestasis, and cirrhosis. When symptoms do develop, patients may present with fatigue, abdominal pain, jaundice, or fever. It is unusual for decompensated liver failure to be the initial manifestation (Broome et al., 1996). Refractory pruritus, metabolic bone disease, IBD, complications from portal hypertension and cholangitis (occurring in 10–45% of patients) add to the morbidity and can impact the quality of life of affected individuals (Chapman et al., 1980; Lee and Kaplan, 2002). Dominant strictures (stenosis ≤ 1.5 mm in common bile duct or ≤ 1.0 mm in hepatic duct) have been reported in up to 50% of PSC patients (Stiehl et al., 2002; Chapman et al., 2010). Among those with a dominant stricture 10–30% will be symptomatic (Kaya et al., 2001; Stiehl et al., 2002). It is important to note that both colorectal cancer and cholangiocarcinoma (CCA) can be present at the time of diagnosis in many patients regardless of the presence of symptoms (see below) (Razumilava et al., 2011).

Various studies have reported median a time of 9–18 years to the development of death or liver transplantation (LT) for all patients with PSC (Broome et al., 1996; Porayko et al., 1990; Ponsioen et al., 2002). Among population-based studies, the survival for PSC patients is estimated to be 65% after 10 years (Bambha et al., 2003). Prognostic models such as the revised Mayo PSC Risk score are not recommended for routine use in individual patients (Chapman et al., 2010).

PSC-IBD

The most common co-morbid condition associated with PSC is IBD, particularly UC. IBD can be diagnosed at

any point in the disease course, even after LT (Verdonk et al., 2006). Similarly, PSC can develop after a colectomy for UC (Chapman et al., 1980). Approximately 86% will have features consistent with UC whereas 13% of PSC patients have features more typical of Crohn's disease (Chapman et al., 2010). PSC-IBD may represent a unique phenotype. For example, the colonic involvement with PSC-IBD is more extensive, yet with minimal endoscopic inflammation despite a greater degree of histologic inflammation (Loftus et al., 2005; Jorgensen et al., 2012a). Some have reported an increased presence of backwash ileitis and rectal sparing compared to UC alone (Loftus et al., 2005). PSC-IBD patients are associated with an increased risk of colorectal neoplasia compared to those with IBD alone (Soetikno et al., 2002). Following proctocolectomy, PSC-IBD patients are at an increased risk of pouchitis and parastomal varices (Penna et al., 1996; Soetikno et al., 2002). Interestingly, recent studies have suggested patients with more severe colitis tend to have less severe liver disease, and vice versa (Marelli et al., 2011; Navaneethan et al., 2012). Because of the prevalence of IBD in PSC, patients with a new diagnosis of PSC should immediately undergo a colonoscopy with surveillance biopsies to screen for IBD and malignancy, regardless of symptoms (Chapman et al., 2010).

DIAGNOSIS

Biochemical Features

For many patients, an elevated alkaline phosphatase level may be the only laboratory abnormality. Fluctuations in alkaline phosphatase can occur throughout the disease course and improvement in alkaline phosphatase has been associated with improved outcomes (Stanich et al., 2011). Elevations in aminotransaminases less than 3–4 times the upper limit of normal can also be observed. Bilirubin can be increased particularly in the presence of a severe stricturing disease. Abnormalities in hepatic synthetic function are rare unless cirrhosis is present (Chapman et al., 2010). Liver enzyme abnormalities such as an isolated alkaline phosphatase in someone with IBD should immediately raise the suspicion for PSC.

A variety of autoantibodies can be detected in the sera of patients with PSC (see below) (Chapman et al., 2010). However, autoantibodies are non-specific and do not play a role in the diagnostic evaluation of patients with typical PSC. In retrospective studies, elevated IgG4 levels have been described in 9–12% of patients with a previous diagnosis of PSC. The distinction of IgG4-associated cholangitis and PSC with elevated IgG4 levels can be challenging (Mendes et al., 2006; Bjornsson et al., 2011). In contrast to classic PSC, IgG4-associated cholangitis is associated with steroid responsive biliary strictures and a

lymphoplasmacytic infiltrate on biopsy. Because a subset of patients with biochemical and cholangiographic features of PSC may have IgG4, it is recommended that a serum IgG4 be measured in all cases of suspected PSC (Chapman et al., 2010). Importantly, CCA in PSC patients can be associated with an elevated IgG4. Although an elevated IgG4 greater than four times the upper limit of normal has been reported to have a high specificity for IgG4-associated cholangitis, it is still important to carefully exclude malignancy in patients with elevations in IgG4 (Oseini et al., 2011).

Cholangiography

Cholangiography plays a central role in the diagnosis and management of patients with PSC. After laboratory testing raises the possibility of PSC, cholangiography can help secure the diagnosis without the need for additional testing. Cholangiography can reveal typical multifocal strictures with dilatations in the intrahepatic and/or extrahepatic bile ducts in patients with typical PSC (Figure 63.1). Compared to endoscopic retrograde cholangiography (ERC), magnetic resonance cholangiography (MRC) is less invasive, avoids radiation, and is a cost-effective method to diagnose PSC (Talwalkar et al., 2004; Kaltenthaler et al., 2004). ERC is an essential therapeutic tool for the management of biliary strictures and for characterizing biliary lesions suspicious for CCA.

Histology

The histologic findings in classic PSC are often nonspecific. Rarely are the pathognomonic “onion skin” lesions present (Figure 63.2). The Batts–Ludwig grading system has historically divided the pathologic features of classic PSC based on the presence or absence of bile ducts and degree of fibrosis into four stages (Ludwig et al., 1986). A liver biopsy is rarely needed and should be reserved for suspected small duct PSC, or primary sclerosing cholangitis–autoimmune hepatitis (PSC-AIH) overlap.

PSC SUBTYPES AND PEDIATRIC PSC

There are several key PSC subtypes which appear to have different features compared to classic large duct PSC. Recognition of these phenotypic differences is important as these subtypes often have an improved prognosis and the treatment may differ when compared to large duct PSC.

Small Duct PSC

Small duct PSC should be suspected among individuals with elevations in alkaline phosphatase and a normal

FIGURE 63.1 Cholangiogram of an adult patient with primary sclerosing cholangitis showing severe widespread strictures and dilatations of the intra- and extrahepatic bile ducts.

FIGURE 63.2 “Onionskin” fibrosis around a damaged bile duct. This is the characteristic lesion of sclerosing cholangitis, but is rarely seen in percutaneous liver biopsies.

cholangiogram. A liver biopsy is required to secure the diagnosis and the histologic features are similar to classic PSC. Among IBD patients with evidence of chronic cholestasis despite a normal cholangiogram, nearly 6%

will have small duct PSC (Angulo et al., 2002). The prevalence of IBD in small duct PSC is similar to typical large duct PSC (Bjornsson et al., 2008). Classic features of large duct PSC will eventually develop in 12–23% of patients with small duct PSC over 7–10 years (Bjornsson et al., 2002, 2008). Therefore, it is unclear if some small duct PSC patients represent an early form of classic PSC. Although both small duct and classic PSC can have similar symptoms, patients with small duct PSC rarely develop CCA and have an improved prognosis compared to those with classic PSC (Bjornsson et al., 2008).

PSC-AIH

PSC-AIH overlap syndrome is characterized by cholangiographic features of typical PSC with histologic and laboratory evidence suggestive of AIH. The frequency of PSC-AIH is unclear, but has been reported to occur in 1–17% of patients with PSC (Chapman et al., 2010). This wide variability may be related to differences in case ascertainment, varying diagnostic criteria, and center location. PSC-AIH tends to be diagnosed in younger patients compared to classic PSC but the coexistence of IBD is comparable between the two disorders (Abdalian et al., 2008; Trivedi and Hirschfield, 2012). Patients with PSC-AIH have a worse prognosis compared to those with AIH alone or other overlap syndromes yet their survival is improved compared to patients with classic PSC (Floreani et al., 2005; Al-Chalabi et al., 2008).

There are no standard diagnostic criteria for PSC-AIH. It should be suspected in patients diagnosed with AIH who have concurrent IBD, or are refractory to immunosuppression. Conversely, PSC-AIH should be suspected among those diagnosed with PSC if serum transaminases are elevated (particularly if greater than five times the upper limit of normal). High titers of antinuclear antibody (ANA), antismooth muscle antibodies (ASMA), or IgG may also raise the suspicion of concurrent AIH, but such tests are not diagnostic since these antibodies can be found in those with PSC alone (Trivedi and Hirschfield, 2012). Although the simplified international autoimmune hepatitis group criteria can aid in the diagnosis of AIH, it is not recommended this be applied to diagnose subgroups. Instead, individual patients should be categorized based on the dominant disease entity. Supportive histologic findings include lymphoplasmacytic portal-based infiltrates and interface hepatitis (Trivedi and Hirschfield, 2012). Unlike classic PSC, immunosuppression may have a role in the treatment of patients with PSC-AIH (Chapman et al., 2010).

FIGURE 63.3 Portal tract inflammatory cell infiltrate in a case of juvenile sclerosing cholangitis positive for anti-nuclear and anti-smooth muscle antibodies. Plasma cells and lymphocytes cross the limiting plate invading the parenchyma (interface hepatitis). The arrow points to a damaged bile duct.

Pediatric PSC

Pediatric PSC is less common than classic adult PSC with an incidence rate of 0.2 per 100,000 person-years (Ghazale et al., 2008). Most cases occur in pre-teen years. However, it should be noted that inherited conditions such as cystic fibrosis and immunologic defects may present in a manner similar to PSC in childhood.

It is unresolved whether pediatric PSC represents a distinct pathologic entity or an earlier form of classic PSC. However, adult and pediatric PSC share several features. For example, both are often associated with IBD, are more common in males, and have similar cholangiographic features (Ibrahim and Lindor, 2011). Similarly to adults, the median transplant-free survival in children is 13 years and pediatric PSC is associated with a worse survival compared to age and gender-matched controls in the general population (Feldstein et al., 2003). In contrast to adult PSC, pediatric patients with PSC are more likely to be symptomatic upon presentation (81% in one retrospective study) and have higher elevations in serum aminotransferases and gamma glutamyltranspeptidase levels (Floreani et al., 1999; Miloh et al., 2009). Furthermore, pediatric PSC patients are more likely to have AIH overlap features which include elevated ANA, SMA, and IgG titers along with interface hepatitis (Figure 63.3). In one center the frequency of pediatric PSC-AIH was 25% and small duct PSC occurred in 34% of pediatric patients (Miloh et al., 2009). Therefore, histology may play a more important role in the diagnostic evaluation in pediatric patients. Finally, dominant strictures and malignancy such as CCA are rare in childhood PSC (Chapman et al., 2010).

PSC-ASSOCIATED MALIGNANCIES

Colorectal Neoplasia

Patients with PSC-UC are four times more likely to develop colorectal neoplasia than patients with UC alone (Soetikno et al., 2002). The risk is also elevated in PSC patients with concurrent Crohn's disease (Lindstrom et al., 2011). Colorectal neoplasia is often present shortly after the conditions are diagnosed (Thackeray et al., 2011). Consequently once PSC-IBD is diagnosed, a colonoscopy with surveillance biopsies for flat neoplasia should be undertaken to evaluate for cancer or dysplasia. Surveillance colonoscopy with biopsies should continue annually. The risk of colorectal neoplasia does not dissipate after LT and surveillance should be continued in post-transplant patients (Chapman et al., 2010). Indications for colectomy include cancer, high grade dysplasia, and unresectable low grade dysplasia that have been confirmed by two expert pathologists. Several studies have suggested that ursodeoxycholic acid (UDCA) may reduce the risk of colorectal neoplasia in PSC-IBD patients (Tung et al., 2001; Pardi et al., 2003). However, studies have been inconsistent and some studies suggest UDCA may increase the risk of colorectal neoplasia (Wolf et al., 2005; Eaton et al., 2011; Jorgensen et al., 2012b; Lindstrom et al., 2012). Therefore, routine use of UDCA to prevent colorectal neoplasia is not recommended at this time (Chapman et al., 2010).

Cholangiocarcinoma (CCA)

CCA is one of the most feared complications related to PSC. The lifetime risk is up to 10% with an annual risk of 1–2% (Bergquist et al., 2002). Similar to colorectal neoplasia, CCA is frequently detected within the first 3 years after the diagnosis of PSC (Bergquist et al., 2002). The diagnosis is often challenging. The development of CCA should be suspected with worsening cholestasis or the development of dominant strictures. Distinguishing between dominant strictures and CCA is difficult, in part because CCA is a desmoplastic malignancy making tissue sampling challenging. Consequently, traditional cytology has a low sensitivity. Fluorescence *in situ* hybridization (FISH) utilizes centromeric probes against specific chromosomes and is able to detect the abnormal loss or gain of chromosomes. Polysomy in PSC patients is 46% sensitive and 88% specific for CCA and patients with recurrent polysomy are more likely to develop CCA compared to those without recurrent polysomy (75% versus 18% after 3 years) (Bangarulingam et al., 2010; Barr Fritcher et al., 2011). Therefore, patients with polysomy who otherwise do not have CCA should be monitored closely.

Treatment options for CCA are limited and the 5-year survival rates remain 10% or less (Rosen and

Nagorney, 1991). In a highly selective group of patients with unresectable hilar CCA less than 3 cm may be candidates for an intensive multimodal approach that culminates with an LT. There appear to be good long-term outcomes following LT for this indication (Darwish Murad et al., 2012).

Gallbladder Neoplasia

PSC patients commonly have cholelithiasis and are at a higher risk for gallbladder neoplasia. Although the exact prevalence of gallbladder neoplasia in PSC is unclear, when gallbladder polyps are detected (particularly if greater than 8 mm) they are often malignant. For example, in one series 14% of PSC patients had gallbladder lesions detected and 57% were malignant (Buckles et al., 2002). Current guidelines suggest an annual ultrasound to detect gallbladder lesions in PSC patients and if a gallbladder polyp is detected they should undergo a cholecystectomy (Chapman et al., 2010). However, the natural history of gallbladder polyps less than 8 mm is less clear and the risks and benefits of undergoing a cholecystectomy for small polyps should be discussed with each patient (Eaton et al., 2012).

Hepatocellular Carcinoma

Cirrhosis is an important risk factor for hepatocellular carcinoma and the prevalence of this malignancy in PSC associated with cirrhosis is 2% (Harnois et al., 1997). Therefore, screening every 6 months with an ultrasound is recommended once cirrhosis is detected (Bruix and Sherman, 2011).

GENETICS

Patients with a first degree relative with PSC are at a higher risk for developing the condition, which suggests a genetic predisposition for the development of the disease. The strongest genetic risk factors to date have been localized to the human leukocyte antigen (HLA) complex. Haplotypes that have been associated with PSC include HLA-DRB1*1501-DQB1*0602, HLA-DRB1*1301-DQB1*0603, and HLA-A1-B8-DRB1*0301-DQB1*0201 (Farrant et al., 1992; Mehal et al., 1994; Olerup et al., 1995; Spurkland et al., 1999). Genome-wide association studies have also revealed strong associations with PSC near HLA-B at chromosome 6p21 (Karlsen et al., 2010). HLA DR4 may be a marker for rapid disease progression (Mehal et al., 1994). In contrast, DRB1*04, DQB1*302, DRB1*0701 DQB10303, and MICA*002 have been shown to be protective from PSC (Norris et al., 2001; Donaldson and Norris, 2002).

Genome-wide association studies have also revealed potential non-HLA associations. To date, many of the non-HLA associations appear to play an immunoregulatory role. Examples include GPC5/GPC6 region on chromosome 13q21 (function unknown but may regulate inflammatory cytokines in cholangiocytes), GPBAR1 on chromosome 2q35 (may represent a bile acid suppressor), MST1 on chromosome 3p21 (encodes a protein that inhibits lipopolysaccharide induced nuclear factor $\kappa\beta$ signaling), and BCL2L11 (encodes Bcl-2 interacting protein which maintains tolerance through induction of apoptosis of autoreactive T cells) (Karlsen et al., 2010; Melum et al., 2011).

ANIMAL MODELS

Overview

Currently, there is no single animal model for PSC. This may be related to the uncertainty regarding the pathophysiology of PSC and the multifactorial processes that are involved in the development of this condition. Consequently, multiple models may be necessary to study the various facets of PSC.

Summary of PSC Models

Key models for PSC currently fall into the following broad categories: (1) creation of cholangitis secondary to infectious organisms (example, *Cryptosporidium parvum*); (2) creation of cholangitis via chemicals (example, lithocholic acid); (3) bacteria or cell wall components inducing hepatobiliary injury (example, small intestinal bacterial overgrowth); (4) apoptosis in cholestatic liver disease (example, death receptor 5 and TNF-related apoptosis inducing ligand deficient mice); (5) knockout mice (example, *Mdr2*^{-/-}); (6) experimental biliary obstruction (example, bile duct ligation in mice); and (7) models of biliary and endothelial cell injury (example, graft versus host disease models in mice) (Takeda et al., 2008; Pollheimer et al., 2011).

POTENTIAL PATHOGENIC MECHANISMS

Overview

The inciting etiology of PSC and the precise pathogenic mechanism remain elusive. Several hypotheses and indirect lines of evidence are outlined below. It likely involves one or more environmental triggers in a genetically susceptible individual which probably leads to a series of events resulting in the activation of the innate immune system, lymphocyte homing, cholangiocyte immune-mediated damage, and progressive fibrosis.

Bacterial Translocation, Pathogen-associated Molecular Patterns, and Innate Immune Response

Translocation of bacteria across a permeable, inflamed bowel with subsequent immune activation which leads to biliary inflammation has been suggested as a potential mechanism. Although bacterial overgrowth and introducing bacterial antigens into the portal circulation have been shown to result in cholangitis in animal models, it appears that in humans portal venous bacteremia in UC patients is uncommon (Palmer et al., 1980; Lichtman and Sartor, 1991; Yamada et al., 1994; O'mahony and Vierling 2006; Pollheimer et al., 2011). Intestinal flora express the protein FtsZ, which is cross-reactive with p-ANCA (Terjung et al., 2010). This raises the possibility of an inappropriate immune response towards intestinal bacteria (Terjung and Spengler, 2009). The role of the microbiome in the development and progression of PSC is unknown and further studies are needed.

Biliary epithelial cells are normally exposed to pathogen-associated molecular patterns such as lipopolysaccharides. Lipopolysaccharide exposure to colonic and biliary epithelial cells has been shown to disrupt tight junctions through a Toll-like receptor 4 (TLR-4)-dependent mechanism (Sheth et al., 2007; Guo et al., 2013). Disruption of critical paracellular barriers could expose cholangiocytes to a variety of factors, such as bile acids (see below) that could promote injury. Indeed animal models suggest that disruption in bile duct tight junctions is a key step in the development of sclerosing cholangitis (Fickert et al., 2004). Despite this exposure, the innate immune system appears relatively downregulated in normal individuals (Medvedev et al., 2006; Mueller et al., 2011). In contrast, PSC patients exhibit features of innate system upregulation when exposed to such endotoxins. Interferon- γ (IFN- γ) and tumor necrosis factor- α (TNF- α) likely mediate a TLR4-mediated endotoxin incorporation in biliary cells and a diminished ability to deactivate the TLR4 signaling cascade. TNF- α inhibition partly restored the protective innate immune tolerance in one *in vitro* study (Mueller et al., 2011). Cholangiocytes from PSC liver explants have an increased expression of TLRs, nucleotide-binding domains, MyD88/IRAK complex formation, TNF- α , IFN- γ , and interleukin-8 (IL-8). Upregulation of TLR, IL-8, and TNF- α is more pronounced in late stage PSC (Mueller et al., 2011). Therefore, based on this observation, the innate immune system hyperresponsiveness observed in *in vitro* studies may bolster the inflammatory response as the disease progresses rather than act as an inciting event. In contrast, others have suggested that the innate immune system could play a key early role in the development of PSC. This hypothesis involves pathogen-associated molecular patterns activating macrophages, NK

cells, and dendritic cells through pattern recognition receptors including TLRs which ultimately leads to NK and lymphocyte activation (Aron and Bowlus, 2009).

Adhesion Molecules, Lymphocyte Homing, and the Liver–Gut Axis

A variety of adhesion molecules such as intercellular adhesion molecules (ICAM), mucosal addressin cellular adhesion molecule 1 (MAdCAM-1), and vascular adhesion molecule-1 (VCAM-1) are upregulated in PSC patients. Increased expression of chemokines such as CCL25, CCL28, CXCL12, and CXCL16 has been described in PSC. Activation of $\alpha 4\beta 7$ integrins is achieved through this increase in CCL25 and CCL28 which enables lymphocytes to bind to MAdCAM-1 (located in gut and liver). CCL28 also activates $\alpha 4\beta 1$ integrins to enhance adhesion to VCAM-1 (primarily expressed in the portal and sinusoidal endothelial cells of the liver). It has been postulated that once lymphocytes enter the portal tract, CXCL12 and CXCL16 aid in lymphocyte binding to the bile duct epithelium (Borchers et al., 2009).

Some have proposed that lymphocyte homing between the so-called liver–gut axis may play an important role in the pathogenesis of PSC (Grant et al., 2002). Chemokines and specific adhesion molecules, particularly those shared by the gut and liver, may mediate immune cell trafficking and binding. For example, vascular adhesion protein 1 (VAP-1) is found in liver endothelial cells and in mucosal vessels. The chronic inflammation observed in patients with IBD upregulates VAP-1 in the gut venules. This activation of VAP-1 has been shown to increase the expression of MAdCAM-1—primarily expressed in the gut—in hepatic vessels. This may result in the recruitment of effector lymphocytes to the liver (Liaskou et al., 2011). In addition, $\alpha 4\beta 7^+ \text{CCR}9^+ \text{CD}8^+$ T cells found in the liver in PSC are primed by dendritic cells in the gut rather than antigen-presenting cells in the liver (Eksteen et al., 2009). Subclinical inflammation in patients without a diagnosis of IBD being sufficient to trigger cross-talk between immune cells from liver and the gastrointestinal tract as a potential explanation why a subset of PSC patients do not have IBD, is unclear. Nonetheless the above observations suggest a possible role for lymphocyte trafficking along the liver–gut axis in PSC patients.

Antibodies, Memory, and Regulatory T cells

PSC patients have a variety of nonspecific autoantibodies. In addition to atypical p-ANCA which cross-reacts with a ubiquitous protein in intestinal bacteria (see above), nearly two-thirds of PSC patients have autoantibodies against cholangiocytes (Xu et al., 2002). These autoantibodies may cause cholangiocytes to express CD44 and

increase IL-6 production which could potentially lead to the recruitment of memory T cells via CD44 and upregulation of the innate immune system via ERK1/2 transcription factor signaling and upregulation of TLRS (Xu et al., 2002; Karrar et al., 2007). T cells in the liver and bile ducts of PSC patients may have oligoclonal restriction (Broome et al., 1997; Probert et al., 1997). Furthermore, the proportion of $\gamma\delta^+$ T cells in the liver and peripheral circulation is increased in PSC patients. The peripheral $\gamma\delta^+$ T cells co-express CD45RO and IL-2 receptors which suggests they have an activated memory phenotype (Wen et al., 1992; Martins et al., 1996). $\text{CD}4^+ \text{CD}25^+$ T regulatory cells are believed to play an important role in autoimmune diseases. Indeed, patients with PSC-UC appear to have a higher peripheral proportion of $\text{CD}4^+ \text{CD}25^+$ T cells when compared to UC patients without PSC (Kekilli et al., 2013). The significance of this observation remains unclear but warrants further study.

Transporter Defects and Bile Acids

Normally, bile acids and biliary phospholipids are transported into bile via the canalicular phospholipid flippase (multidrug resistance gene 2 [Mdr2]/Abcb4) and the bile salt export pump (Bsep/Abcb11) to form mixed micelles which protect cholangiocytes from bile acid toxicity (Trauner and Boyer, 2003). Disruption of the Mdr2 gene in mice results in an impairment of biliary phospholipid secretion and an increased concentration of bile acids that ultimately cause bile duct injury (Fickert et al., 2004; Lammert et al., 2004). In addition, the human MDR3 (analogue to rodent Mdr2) has been associated with a variety of cholestatic syndromes (Trauner et al., 2007). For example, MDR3 mutations have been associated with pediatric small duct PSC (Jacquemin et al., 2001; Chapman et al., 2010). Patients with cystic fibrosis can have cholangiographic features similar to those seen in PSC patients. Indeed, there have been mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene described in PSC patients (Sheth et al., 2003). The precise role of MDR3 and CFTR is unclear but a central role in the pathophysiology of PSC in the majority of patients seems unlikely.

Lithocholic acid (LCA) is a hydrophobic secondary bile acid that is primarily formed in the intestine by bacterial metabolism of chenodeoxycholic acid. LCA-fed mice developed bile duct crystals with bile infarcts and a destructive cholangitis that was followed by myofibroblast proliferation. One of the proposed mechanisms behind these findings involved alteration of cholangiocyte tight junctions leading to permeable bile ducts (Fickert et al., 2006). In another animal model, bile was able to reflux into the portal tracts in the presence of altered bile duct tight junctions and basal membrane

integrity. This resulted in an inflammatory response with an influx of CD4 and CD8-positive T cells and overexpression of TNF- α , IL-1 β , IL-6, and transforming growth factor β 1 (TGF- β 1). This proinflammatory infiltrate resulted in activation of myofibroblasts, which lead to periductal fibrosis (Fickert et al., 2004).

Autoimmune Features

A variety of other autoantibodies have been described in PSC patients including ANA, SMA, antimitochondrial antibodies, and antineutrophil cytoplasmic antibodies (Hov et al., 2008). Sera from nearly two-thirds of patients with PSC have circulating autoantibodies against amino acid sequences shared in common by colon and biliary epithelial cells (Mandal et al., 1994) and anti-biliary epithelial cell antibodies (Xu et al., 2002). The significance of this observation on the pathogenesis of PSC and the relationship between PSC and IBD is unclear. Other autoantibodies include anti-endothelial cell antibody (35%) (Gur et al., 1995), anticardiolipin antibody (4–66%) (Angulo et al., 2000), antithyroperoxidase (7–16%) (Angulo et al., 2000), antithyroglobulin (4%) (Gur et al., 1995), and rheumatoid factor (15%) (Angulo et al., 2000). An increased level of circulating immune complexes and activation of the classical complement pathway has been described (Bodenheimer et al., 1983; Senaldi et al., 1989). No autoantibody to date is specific enough to play a role in the diagnosis of classic PSC. Nonetheless the presence of autoantibodies coupled with the genetic association with HLA haplotypes, influx of lymphocytes, particularly T lymphocytes with an increase in circulating memory T cells plus the strong association with PSC and other immune-mediated conditions, are several of the key indirect lines of evidence that suggest PSC is mediated by an autoimmune phenomenon. In contrast, the lack of a proven response to immunosuppression and male predominance are features which suggest PSC is not a classic autoimmune disorder.

TREATMENT

Medical Therapy

To date, there are no proven effective therapies for PSC. The use of immunosuppressive agents has not demonstrated benefit for the treatment of classic PSC. Of the numerous agents examined, UDCA has been investigated the most extensively. One of the first randomized studies utilizing UDCA showed improvement in liver biochemistries and histology (Beuers et al., 1992). Subsequent studies did not show differences in liver-related endpoints between the placebo and UDCA treatment group. Another study which utilized 17–23 mg/kg/day of UDCA was not

associated with improved survival; however, it may have been underpowered (Olsson et al., 2005). A North American randomized control trial found high-dose UDCA (28–30 mg/kg/day) was associated with worse outcomes and another study showed an increased risk of colorectal neoplasia in the high-dose group (Lindor et al., 2009; Eaton et al., 2011). The American Association for the Study of Liver Disease advises against the use of UDCA for PSC while the European Association for the Study of Liver Disease neither approves nor advises against the use of UDCA (Chapman et al., 2009, 2010). Treatment for patients with PSC-AIH, as for patients with AIH alone, can be initiated using corticosteroids and other immunosuppressive agents (Chapman et al., 2010).

Therapeutic Endoscopy

New or worsening symptoms of cholestasis in PSC patients should alert the clinician to the possible development of a dominant stricture or CCA. Cholangitis may also be a manifestation of progressive disease. Endoscopic therapy, either dilation or stenting, via ERC plays a key role in the management of symptomatic biliary strictures and can provide patients with long-term symptomatic relief. Retrospective data suggest expansion of strictures with dilation (compared to dilation plus stenting) is associated with fewer complications (Kaya et al., 2001). However, biliary stent placement may be necessary in cases where dilation is unable to maintain patency of the bile duct lumen. Upper endoscopy plays a key role in the surveillance, diagnosis, and treatment of gastroesophageal varices in patients with cirrhosis.

Liver Transplantation

Currently, liver transplantation (LT) is the most effective therapy for PSC. Indications for deceased donor transplant are similar to other LT indications and priority is determined based on the model for end stage liver disease (MELD) score. As mentioned above, a select group of patients with CCA and PSC may be eligible for LT. Patients with other disease-related complications of PSC such as recurrent cholangitis and intractable pruritus may be eligible to undergo living related donor LT despite a low MELD score. Outcomes following LT for PSC are excellent with reported 5-year survival rates exceeding 80% (Graziadei et al., 1999).

Recurrent PSC can develop in 25% of cases following a LT (Chapman et al., 2010). The diagnosis is typically established based on elevated liver tests and classic features on cholangiography. A liver biopsy can provide a supportive role in the diagnosis. Other conditions that can mimic recurrent PSC such as hepatic artery thrombosis, CMV infection, non-anastomotic biliary strictures, and

ABO incompatible mismatch LT should be excluded (Fosby et al., 2012). There is no effective therapy for recurrent PSC and some patients may undergo a repeat LT.

CONCLUDING REMARKS

PSC remains a rare but important cause of cholestatic liver disease. Although the pathophysiology is poorly understood, there are key direct and indirect lines of evidence which suggest PSC is an immune-mediated disorder that develops in susceptible individuals. Clarifying the pathophysiology through a variety of methods such as genome-wide association studies should help shed light on the underlying pathophysiology, important PSC disease modifiers, and open the door to novel therapeutic targets. Contemporary management of PSC depends on establishing the diagnosis, early recognition, and treatment of PSC-associated malignancies and other co-morbid conditions, and transplantation for select individuals. Future therapies may employ novel bile acids or target lymphocyte migration and adhesion, or progression of fibrosis.

HISTORICAL BACKGROUND

In 1961, Sarles et al. first reported a specific type of pancreatitis as chronic inflammatory sclerosis of the pancreas that showed hyperglobulinemia and histologically marked lymphocytic infiltration (Sarles et al., 1961). In 1978, Nakano et al. reported the first case that had been successfully treated with corticosteroids (Nakano et al., 1978). In 1991, Kawaguchi designated this condition as a lymphoplasmacytic sclerosing pancreatitis (LPSP) based on a detailed pathological study (Kawaguchi et al., 1991). In 1992, Toki et al. reported chronic pancreatitis showing

diffuse irregular narrowing of the entire main pancreatic duct (Toki et al., 1992). Yoshida and Toki et al. summarized the clinical features and designated this condition as autoimmune pancreatitis based on clinical findings of hypergammaglobulinemia, positive tests for autoantibodies and lymphoplasmacytic infiltration in the pancreas, and a favorable response to corticosteroid treatment (Yoshida et al., 1995). Since then, many patients have been diagnosed based on these characteristic clinical findings, and a number of reports on single cases or small series of cases have been published. In 2001, Hamano et al. reported that patients with autoimmune pancreatitis

frequently and specifically have high serum IgG4 concentrations that correlate well with disease activity, suggesting that this disease is a discrete clinical entity different from ordinary chronic pancreatitis (Hamano et al., 2001). In 2002, Hamano et al. first reported abundant IgG4-bearing plasma cell infiltration in the pancreas and extra-pancreatic sites of disease, and this remains as a histological hallmark of autoimmune pancreatitis and IgG4-related disease (Hamano et al., 2002). In 2002 and 2006, the Japanese Pancreas Society and the Research Committee of Intractable Diseases of the Pancreas proposed Japanese diagnostic criteria for autoimmune pancreatitis (Steinberg et al., 2003; Okazaki et al., 2006). Subsequently, diagnostic criteria for autoimmune pancreatitis were proposed in other countries, and the International Consensus Diagnostic Criteria (ICDC) for Autoimmune Pancreatitis was published in 2011 (Shimosegawa et al., 2011). The ICDC allow diagnosis of autoimmune pancreatitis based on the international standards and differentiate this condition from pancreatic cancer and other types of pancreatitis.

Notably, there has been reported another type of autoimmune pancreatitis that is based pathologically on granulocyte infiltration into the pancreatic duct epithelium. These pathological findings were termed “idiopathic duct-centric chronic pancreatitis” (IDCP) (Notohara et al., 2003) or “autoimmune pancreatitis with granulocytic epithelial lesions” (AIP with GEL) (Zamboni et al., 2004). Recently, the LPSP form of autoimmune pancreatitis which was closely associated with IgG4 was designated as type 1 autoimmune pancreatitis, whereas the IDCP/AIP with GEL form was designated as type 2 (Sugumar et al., 2009). Although the IDCP/AIP with GEL form of autoimmune pancreatitis seems to be prevalent in Western countries, the clinical features, including the autoimmune nature, remain obscure. Accordingly, this article focuses on the LPSP form of autoimmune pancreatitis.

AUTOIMMUNE PANCREATITIS – CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGICAL FEATURES

Clinical Features

Symptoms

We analyzed the clinical findings in 98 patients with autoimmune pancreatitis that fulfilled the diagnostic criteria proposed by the ICDC. The summarized clinical features based on our results and published reports are as follows. The male-to-female ratio was 75:23 (male 77%), and the median age of occurrence was 63 years (range 38–85), suggesting that this disease shows an elderly male preponderance. Few patients complained of severe attacks of pancreatitis, but many (80%) had mild to moderate

epigastralgia or discomfort, thus different from those of classical acute pancreatitis. A striking feature was obstructive jaundice in 70%, caused by the stenosis or obstruction of the intra-pancreatic common bile duct (Yoshida et al., 1995; Horiuchi et al., 1998, 2001; Kawa et al., 2011a). Diabetes mellitus (DM) was often observed, and the majority were thought to have type 2 DM. Some patients improved after steroid therapy (Tanaka et al., 2000).

Laboratory Tests

Laboratory tests showed several abnormal findings related to the obstructive jaundice such as elevated serum levels of bilirubin, biliary enzymes, and transaminases in 70–80% of patients. The tumor-associated antigen, CA19-9, showed elevated levels in 50% of patients, probably due to cholestasis rather than a malignant process. Serum elevations of pancreatic enzyme were mild or moderate, and were found in 60% of patients. Serum elevations of γ -globulin and IgG were found in 60% and 70%, respectively. Positive rates for antinuclear antibody were 40%, and those of other antibodies were 10–30%. Decreased exocrine and endocrine function by the bentiromide test and HbA1c were found in 66% and 51%, respectively (Horiuchi et al., 1998, 2001; Kawa et al., 2011a).

Ultrasound and Radioimage Findings

Abdominal ultrasonography (US) showed characteristic sonolucent swelling, a so-called sausage-like appearance, and dilatation of the common bile duct. Computed tomography (CT) with contrast material revealed swelling and delayed enhancement of parenchyma, resulting in a peripheral low-density area and a capsule-like rim (Figure 64.1). Endoscopic retrograde cholangiopancreatography (ERCP) showed a characteristic pancreatogram of diffuse but irregular narrowing (Figure 64.2). Cholangiography showed severe narrowing of the lower bile duct, which was caused by swelling of the head of the pancreas. However, intraductal ultrasonography (IDUS) showed that thickening of the bile duct wall also contributed to narrowing of the bile duct. In some cases, bile duct changes extended to extra-pancreatic regions such as the intrahepatic bile duct system and resembled primary sclerosing cholangitis (PSC) (Figure 64.3). Gallium-67 scintigraphy and fluorine-18 fluorodeoxyglucose positron emission tomography (FDG-PET) showed characteristic pancreatic and extra-pancreatic accumulation during the active stage of the disease (Saegusa et al., 2003; Ozaki et al., 2007).

Misdiagnosis of Pancreatic Cancer

Patients with autoimmune pancreatitis sometimes receive the erroneous diagnosis of pancreatic cancer because of the preponderance of the disease in the elderly together with

FIGURE 64.1 Contrast-enhanced computed tomography (CT) image of autoimmune pancreatitis, showing swelling and delayed enhancement of parenchymal tissue. The result is a peripheral low-density area and a capsule-like rim.

FIGURE 64.2 Endoscopic retrograde cholangiopancreatography (ERCP) showing the characteristic pancreatogram of diffuse irregular narrowing seen in autoimmune pancreatitis.

obstructive jaundice, serum elevations of CA19-9, and irregular narrowing or obstruction of the pancreatic duct. Pathological analysis after pancreaticoduodenectomy (Whipple resection), performed because of a diagnosis of pancreatic cancer, disclosed results representative of autoimmune pancreatitis (lymphoplasmacytic sclerosing pancreatitis: LPSP) in 2.2% of patients (Hardacre et al., 2003). Because of similar pathological findings, this disease has also been diagnosed as pancreatic lymphoma (Horiuchi et al., 1996).

Extra-pancreatic Lesions

Autoimmune pancreatitis is characterized by extra-pancreatic lesions (Figure 64.4) (Hamano et al., 2006; Fujinaga et al.,

FIGURE 64.3 Endoscopic retrograde cholangiopancreatography (ERCP) showing the characteristic intrahepatic bile duct changes in autoimmune pancreatitis that are similar to those in primary sclerosing cholangitis (PSC).

2009) such as swelling of the lacrimal and salivary glands (Figure 64.5) (Kamisawa et al., 2003a; Yamamoto et al., 2005a), sclerosing cholangitis (Figure 64.3) (Erkelens et al., 1999; Nakazawa et al., 2001; Horiuchi et al., 2001), retroperitoneal fibrosis (Hamano et al., 2002), interstitial lung disease (Taniguchi et al., 2004), hilar lymphadenopathy (Saegusa et al., 2003), lung nodules (Zen et al., 2005), tubulointerstitial nephritis (Takeda et al., 2004; Saeki et al., 2010), liver disease or IgG4-hepatopathy (Umemura et al., 2007a), hypophysitis (van der Vliet et al., 2004), gastric ulcer (Shinji et al., 2004), hypothyroidism (Komatsu et al., 2005), and prostatitis (Yoshimura et al., 2006). These extra-pancreatic lesions share common clinical and pathological features, i.e., favorable response to corticosteroid therapy and IgG4-bearing plasma cell infiltration, suggesting the presence of systemic disease, i.e., IgG4-related disease (Kamisawa et al., 2003b; Kawa and Sugai, 2011b; Umehara et al., 2012a,b). Autoimmune pancreatitis is now recognized as the pancreatic manifestation of IgG4-related disease.

Pathological Features

On gross examination, the involved pancreas appears glistening white, is firm or hard, and may be enlarged or show mass lesions. The lesion may be limited to one portion of the pancreas, most often the head, or may involve the body, tail, or entire organ. Lymphoplasmacytic infiltration and fibrosis are characteristic microscopic features of the pancreatic lesions, and in some cases result in the formation of

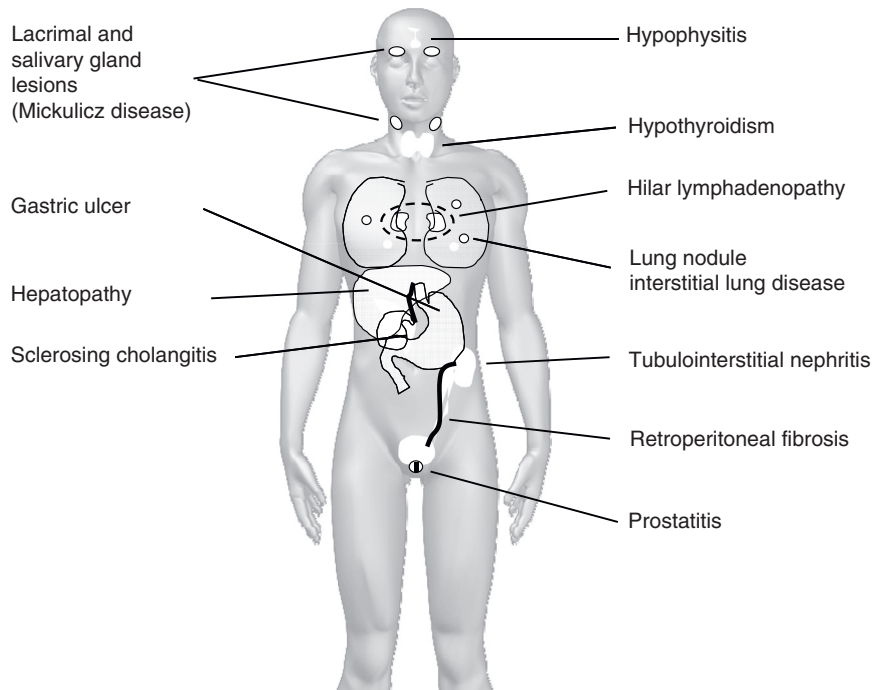

FIGURE 64.4 Extra-pancreatic lesions associated with autoimmune pancreatitis. These lesions are comprehensively termed IgG4-related disease.

FIGURE 64.5 Magnetic resonance imaging (MRI) showing swelling of salivary glands (arrows) complicated with autoimmune pancreatitis.

lymphoid follicles. Immunostaining has demonstrated that T cells predominate over B cells among the infiltrating lymphocytes. The infiltrating plasma cells characteristically bear IgG4 (Hamano et al., 2002) (Figure 64.6). The cell infiltration is prominent around the pancreatic duct,

resulting in stenosis or obstruction of the duct, stasis of the pancreatic secretions, and damage to the pancreatic lobules. Obliterating phlebitis is another characteristic feature, which shows a marked cellular infiltration of the venous wall and venous thrombosis (Kawaguchi et al., 1991). The histological features observed in the extra-pancreatic lesions such as in the salivary glands (Kamisawa et al., 2003a) or retroperitoneal fibrosis (Hamano et al., 2002) resemble those seen in the pancreas.

Epidemiologic Features

A nationwide survey in Japan by the Research Committee of Intractable Diseases of the Pancreas showed a prevalence of 0.82/100,000 inhabitants, corresponding roughly to 2% of all patients with chronic pancreatitis (Nishimori et al., 2007; Shimosegawa and Kanno, 2009). Due to diagnostic criteria proposals, the number of patients in Japan and other countries has increased (Hart et al., 2012). However, autoimmune pancreatitis is a relatively rare disorder, and its exact prevalence remains unknown.

Autoimmune Features

Positive rates for antinuclear antibody were 40%, and those of other antibodies were 10–30%. We found no patients with positive test for SS-A/Ro or SS-B/La antibodies, or anti-mitochondrial antibodies that represent disease-specific antibodies for the diagnosis of Sjögren's syndrome or primary biliary cirrhosis (PBC), respectively. These findings suggest that the autoantibodies found in

FIGURE 64.6 IgG4 immunostaining of pancreatic tissue with autoimmune pancreatitis, showing abundant infiltration of IgG4-bearing plasma cells.

this disease are not pathogenic, and that patients have a tendency to produce various autoantibodies that are neither disease specific nor of primary relevance. However, the occasional coexistence of pancreatitis with salivary gland lesions and cholangitis suggests shared target antigens. Carbonic anhydrase II (CA II) and lactoferrin are distributed in the cells of several exocrine organs, including the pancreas, salivary glands, and biliary duct. In this context, CA II or lactoferrin have been proposed as a candidate target antigen, but the presence of autoantibodies for these antigens is not sufficiently specific or sensitive (Kino-Ohsaki et al., 1996).

Protein electrophoresis of patients' sera showed a polyclonal band in the rapidly migrating fraction of γ -globulins. Later, immunoelectrophoresis confirmed that this polyclonal band was caused by a high serum concentration of IgG4. We confirmed that serum IgG4 elevation could be found in 90% of patients with autoimmune pancreatitis, but in very few patients with other conditions including pancreatic cancer, chronic pancreatitis, and Sjögren's syndrome, suggesting that IgG4 is a sensitive and specific marker for this disease. In addition, levels of IgG4 correlate well with disease activity (Hamano et al., 2001).

Genetic Features

Autoimmune diseases are multifactorial, and pathogenesis involves a complex interplay of multiple genetic and environmental factors. Several genes, including human leukocyte antigen (*HLA*), Fc receptor-like 3 (*FCRL3*), and cytotoxic T lymphocyte antigen (*CTLA4*), contribute to autoimmune diseases. HLA serotypes DR4 and DQ4 are the markers most frequently associated with autoimmune pancreatitis among the major histocompatibility complex

(MHC) class I and class II molecules. Among the DR4 and DQ4 subtypes, the frequencies of *DRB1*0405* and *DQB1*0401* are significantly higher in autoimmune pancreatitis patients than in normal subjects or in patients with chronic pancreatitis. In the Japanese population, *DRB1*0405* is known to be in strong linkage disequilibrium with *DQB1*0401*, resulting in the *DRB1*0405-DQB1*0401* haplotype. This haplotype is specifically associated with susceptibility to autoimmune pancreatitis and may play a functional role in antigen presentation and induction of an autoimmune response (Kawa et al., 2002). *HLA-DR*0405* transgenic mice experience a high prevalence of autoimmune pancreatitis after sublethal irradiation and adoptive transfer of $CD90^+$ T cells. *HLA-DR*0405* transgenic mice can also develop unprovoked autoimmune pancreatitis, whereas *HLA-DR*0401*, *HLA-DQ8*, and *HLA-DR*0405/DQ8* transgenic controls all remained normal, even after irradiation and adoptive transfer of $CD90^+$ T cells. Since *HLA-DR*0405* expression fails to protect mice from autoimmune pancreatitis, this allele appears to be an important risk factor for autoimmune pancreatitis in the *HLA-DRB1*0405/DQB1*0401* haplotype (Freitag et al., 2010). In a case-control study using microsatellite markers distributed throughout the HLA region, we mapped autoimmune pancreatitis susceptibility to two regions of the telomeric region of HLA adjacent to the C3-2-11 marker and to HLA DRB1-DQB1. The region adjacent to C3-2-11 contains the ATP-binding cassette sub-family F (*ABCF1*) gene, which is regulated by $TNF-\alpha$, a major cytokine that participates in inflammatory and autoimmune reactions (Ota et al., 2007).

Although autoimmune pancreatitis responds well to corticosteroid therapy, relapse is not uncommon during maintenance therapy or after the cessation of corticosteroids. A previous study found that DQ β 1 mutations with

substitutions in aspartic acid at residue 57 were significantly associated with relapses of autoimmune pancreatitis (Park et al., 2008).

Polymorphisms in the *FCRL* genes alter the binding affinity of nuclear factor κ B and regulate *FCRL3* expression. An analysis of genotype frequencies for *FCRL3-110* polymorphisms revealed a significant association between the -110A/A genotype and autoimmune pancreatitis, and serum IgG4 concentrations were significantly and positively correlated with the number of susceptibility alleles (Umemura et al., 2006).

The *CTLA4* (or *CD152*) gene product is an inhibitory receptor expressed on the surface of activated memory T cells and CD4⁺CD25⁺ regulatory T cells (Tregs); this receptor largely acts as a negative regulator of T cell responses. The *CTLA4* +49A/G single nucleotide polymorphism (SNP) has been associated with susceptibility to autoimmune diseases. We found that the frequency of the +6230G/G genotype was significantly higher in Japanese patients with autoimmune pancreatitis than in those without the disease, and that the +49A/A and +6230A/A genotypes were associated with an enhanced risk of autoimmune pancreatitis relapse (Umemura et al., 2008). The *CTLA-4* 49A polymorphism and the -318C/+49A/CT60G haplotype have also been associated with autoimmune pancreatitis in a Chinese population (Chang et al., 2007).

An association analysis involving 400 microsatellite markers with an average spacing of 10.8 cM in the genome revealed the association of autoimmune pancreatitis with seven SNPs within the 20-kb region around the potassium voltage-gated channel, shaker-related subfamily, member 3 gene (*KCNA3*). Further analysis of *KCNA3* by SNP genotyping revealed four SNPs that were significantly associated with autoimmune pancreatitis susceptibility (Ota et al., 2011). Notably, *KCNA3* is involved in immunomodulation of autoreactive effector T cell- and memory T cell-mediated autoimmune diseases.

ANIMAL MODELS

Putative animal models of autoimmune pancreatitis have been developed by immunizing thymectomized neonatal mice with carbonic anhydrase (CA II) and lactoferrin and transferring immunized spleen cells to nude mice (Uchida et al., 2002). In that study, inflammation was present in the pancreas of the immunized thymectomized neonatal mice and in all mice that received whole spleen cells or CD4⁺ cells. CA II- or lactoferrin-immunized mice develop apoptotic duct cells or acinar cells, respectively. Taken together, these observations suggest that an immunological response to CA II or lactoferrin is involved in pathogenesis of these pancreatitis models in which the effector cells are Th1-type CD4⁺ T cells. Adoptive transfer of amylase-

specific CD4⁺ T cells in rats also results in pancreatitis characterized by mononuclear cell infiltrates and destruction of lobular tissue (Davidson et al., 2005). Another animal model for autoimmune pancreatitis was developed by exposing C57BL/6 mice to heat-killed *Escherichia coli*, which results in marked cellular infiltration with fibrosis in the exocrine pancreas and salivary gland. Antibodies for CA II and lactoferrin, as well as antinuclear antibody, occur in the sera of mice inoculated with heat-killed *E. coli* (Haruta et al., 2010). These findings suggest that silently infiltrating microorganisms such as avirulent bacteria can engage pathogen-associated molecular patterns (PAMPs) and thereby activate the innate immune systems so as to elicit a host immune response to the target antigen by molecular mimicry, and at the same time result in the establishment of autoimmune pancreatitis (Oldstone, 1998; Haruta et al., 2010).

PATHOLOGICAL MECHANISMS

An aberrant immune response to microbial antigens may underlie the immunopathogenesis of autoimmune pancreatitis. Antigens derived from intestinal microflora may activate the host's innate immune system via pattern recognition receptors such as the Toll-like receptors (TLRs) and nucleotide-binding oligomerization (NOD)-like receptors (NLRs). Peripheral blood mononuclear cells, presumably B cells, from patients with autoimmune pancreatitis show enhanced production of IgG4 upon stimulation with NLR and TLR ligands, which is associated with release of B cell-activating factor (BAFF) (Yamanishi et al., 2011; Watanabe et al., 2011). Since the systemic IgG4 response is one of the most important immunological features of autoimmune pancreatitis, abnormal innate immune responses via NLRs and TLRs may underlie the immunopathogenesis of IgG4-related autoimmune pancreatitis (Watanabe et al., 2011).

Helicobacter pylori infection may also trigger autoimmune pancreatitis, possibly as a result of molecular mimicry. There is substantial homology between human CA II and *H. pylori* alpha-carbonic anhydrase; the homologous segments contain the binding motif of the HLA molecule *DRB1*04:05*, which is closely associated with autoimmune pancreatitis (Kawa et al., 2002). These data led to the hypothesis that the *DRB1*0405*-restricted peptide of CA II is presented in genetically predisposed subjects, and reactive T cells injure pancreatic tissue via interaction with the CA II of pancreatic ductal cells (Guarneri et al., 2005). To identify pathogenetically relevant autoantigen targets, a random peptide library derived from pooled IgGs obtained from patients with autoimmune pancreatitis was screened. Selected peptides exhibited homology with an amino acid sequence from the plasminogen-binding protein (PBP) of *H. pylori* and

with ubiquitin-protein ligase E3 component n-recognin 2 (UBR2), an enzyme that is highly expressed in acinar cells of the pancreas. Antibodies against the PBP peptide were detected at high levels in patients with autoimmune pancreatitis but were barely detectable in patients with pancreatic cancer. It seems likely that UBR2 from pancreatic acinar cells may be targeted by an autoantibody against PBP of *H. pylori* in patients with autoimmune pancreatitis (Frulloni et al., 2009).

Since the serum IgG4 and IgG4-type immune complexes are closely associated with disease activity, they may play a major role in the pathogenesis of autoimmune pancreatitis. However, the exact role(s) of IgG4 remains unclear, and may be either beneficial or harmful. To date, the pathological effects of IgG4 and IgG4-type immune complexes have been reported in limited settings, such as in groups of patients with pemphigus or idiopathic membranous nephropathy. Pemphigus vulgaris and pemphigus foliaceus are autoimmune skin diseases that are characterized by the presence of IgG4-type autoantibodies against the cell adhesion molecules desmoglein-3 and desmoglein-1 (see Chapter 65). The IgG4-type anti-desmoglein antibodies may cause the skin lesions characteristic of acantholysis. Idiopathic membranous nephropathy has been characterized by IgG4-subclass glomerular deposits, and IgG4-type antibodies against phospholipase A₂ receptor (PLA₂R) were found in a majority of patients. PLA₂R is present in podocytes in normal human glomeruli and in immune deposits in these patients, indicating that PLA₂R is a major target antigen in this disease (Beck et al., 2009). In autoimmune pancreatitis, IgG4-type autoantibodies may elicit an inflammatory response after interacting with an undefined target antigen.

Recent studies have shown that IgG4 has two outstanding characteristics: Fab-arm exchange (van der Neut Kofschoten et al., 2007) and rheumatoid factor-like activity (Figure 64.7) (Kawa et al., 2008). These properties may enable IgG4 to contribute to the defense against disease progression. Specifically, dynamic Fab-arm exchange in the IgG4 molecule results in bispecific activity, loss of monospecific cross-linking activity, and loss of the ability to form immune complexes, resulting in anti-inflammatory effects (van der Neut Kofschoten et al., 2007). IgG4 has also been reported to bind IgG or exert rheumatoid factor activity; however, IgG4 Fc, but not IgG4 Fab, binds to IgG Fc, indicating that IgG4 binding to IgG Fc occurs via an Fc–Fc interaction, not via rheumatoid activity *per se* (Figure 64.7). The role of the IgG4 Fc–IgG Fc interaction is unclear, but its rheumatoid factor-like activity may promote the formation of large circulating immune complexes that are easily eliminated from the circulation (Kawa et al., 2008).

Previous investigations have addressed the effector cells in autoimmune pancreatitis (Okazaki et al., 2011;

FIGURE 64.7 Rheumatoid factor-like activity of IgG4. IgG4 Fc, but not IgG4 Fab, binds to IgG Fc, indicating that IgG4 binding to IgG Fc is via an Fc–Fc interaction (A), not via rheumatoid activity *per se* (B) (Kawa et al., 2008).

Zen et al., 2011). In peripheral blood or pancreatic tissue, activated CD4⁺ or CD8⁺ T cells bearing HLA-DR molecules are aggregated mainly around the pancreatic duct, which expresses HLA-DR molecules (Okazaki et al., 2000). CD4⁺ T cells are subdivided into Th1 and Th2 cells based on cytokine production profiles (see Chapter 6). In some cases, CD4⁺ Th1 cells predominate over Th2 cells, suggesting that Th1 cytokines are essential for the induction and maintenance of autoimmune pancreatitis, with Th2 cytokines involved in disease progression (Okazaki and Chiba, 2002). However, there is evidence that a Th2-predominant immune response is predominant in autoimmune pancreatitis (Zen et al., 2007). Thus an immunopathological study using histological specimens to assess cytokine production *in situ* revealed higher expression levels of Th2 cytokines such as IL-4, IL-5, and IL-13, and quantitative real-time PCR revealed significantly higher ratios of IL-4/IFN- γ , IL-5/IFN- γ , and IL-13/IFN- γ (Zen et al., 2007).

TGF- β secreted from naïve Th0 cells can induce CD4⁺ CD25⁺ Tregs, which have potent inhibitory function via the transcription factor forkhead box P3 (Foxp3). In peripheral blood, numbers of Tregs were significantly increased in patients with autoimmune pancreatitis, and this increase was correlated with increased serum concentrations of IgG4. In contrast, naïve Tregs are significantly decreased in patients with autoimmune pancreatitis. These observations suggest that increased numbers of Tregs may influence IgG4 production and reflect disease progression, whereas decreased numbers of naïve Tregs may be involved in the pathogenesis of autoimmune pancreatitis (Miyoshi et al., 2008). The ratio of Foxp3-positive cells to infiltrated mononuclear cells (Foxp3/Mono) in patients with autoimmune pancreatitis is

significantly higher than in patients with alcoholic chronic pancreatitis, and the Foxp3/Mono and IgG4/Mono ratios have a positive correlation with each other (Kusuda et al., 2011). In the periphery, two functionally different subsets of effector Tregs, inducible costimulatory molecule (ICOS)⁺ or ICOS⁻ effector Tregs, actively produce the suppressive cytokines IL-10 and TGF- β , respectively. Levels of ICOS⁺ Tregs and IL-10⁺ Tregs are significantly higher in patients with autoimmune pancreatitis, suggesting that ICOS⁺ Tregs may influence IgG4 production via IL-10 in this disease (Kusuda et al., 2011). Further, fibrosis may be regulated by TGF- β , which is secreted by ICOS⁻ Tregs.

Taking these observations into account, the following pathogenesis pathway was proposed for autoimmune pancreatitis. An initial response to self-antigens, such as lactoferrin, CA II, or the PBP peptide of *H. pylori*, may be induced by decreased levels of naïve Tregs and followed by a Th1-type immune response that releases proinflammatory cytokines (IFN- γ , IL-1 β , IL-2, TNF- α). Next, Th2-type immune responses that produce IgG, IgG4, and autoantibodies are involved in the pathophysiology of progression. IgG4 and fibrosis may be regulated by increased levels of IL-10 and TGF- β , respectively, which are secreted from inducible memory Tregs (Okazaki et al., 2011).

IMMUNOLOGICAL MARKERS IN DIAGNOSIS

In patients with autoimmune pancreatitis, the positive rates for various immunological markers are as follows: increased γ -globulin, 60%; increased IgG, 70%; any of the autoantibodies noted above, 80%; and increased IgG4, 90%. Serum IgG4 elevation is seldom observed in patients who have conditions other than autoimmune pancreatitis, suggesting that IgG4 is the most sensitive and specific immunological marker for diagnosis (Hamano et al., 2001). Interestingly, decreased IgA and IgM concentrations were detected in patients with increased IgG4 levels (Taguchi et al., 2009). Serum concentrations of the complement proteins C3 and C4 were reduced in 36% of patients, suggesting that the complement activation system may contribute to the pathogenesis of autoimmune pancreatitis (Muraki et al., 2006). The serum immune complex value, as determined by the monoclonal rheumatoid factor method, also reflects disease activity (Kawa et al., 2009). Although autoantibodies to CA II and lactoferrin have been reported to be useful markers, their diagnostic value for autoimmune pancreatitis has not been fully accepted due to insufficient sensitivity and specificity (Kino-Ohsaki et al., 1996; Okazaki and Chiba, 2002).

TREATMENT AND OUTCOME

Steroid treatment should be standard therapy for patients with autoimmune pancreatitis (Ito et al., 2007; Okazaki et al., 2009). Pancreatic tissue obtained by needle biopsy after corticosteroid therapy showed marked histological improvements (Song et al., 2005; Ko et al., 2010). Most patients with obstructive jaundice, diffuse enlargement of the pancreas, associated extra-pancreatic involvement, and abdominal pain are good candidates for steroid therapy, although spontaneous remission has been observed in patients with low disease activity (Kamisawa et al., 2009). In general, patients are started on 30–40 mg, or 0.6 mg/kg, per day of prednisolone for 2–4 weeks with careful assessment of clinical findings and laboratory and imaging results. Thereafter, the dosage is reduced and maintained (Ito et al., 2007; Kamisawa et al., 2009; Okazaki et al., 2009). Some patients with high disease activity may thus continue maintenance therapy for 3 years. Studies of long-term outcomes of autoimmune pancreatitis show recurrence and pancreatic stone formation, indicating that autoimmune pancreatitis has the potential to be a progressive disease with pancreatic lithiasis (Takayama et al., 2004; Kawa et al., 2009). Narrowing of the pancreatic ducts was a risk factor for pancreatic stone formation; this presumably leads to pancreatic juice stasis and stone development (Maruyama et al., 2012), and possibly transforms this condition into classical chronic pancreatitis (Maruyama et al., 2013).

IgG4-related DISEASE

Definition

IgG4-related disease includes systemic syndromes characterized by tumefactive lesions, a high serum IgG4 concentration, abundant lymphoplasmacytic infiltration with a large number of IgG4-positive plasma cells, a favorable response to corticosteroid treatment, and various associated diseases. The major characteristic is autoimmune pancreatitis. The concept of IgG4-related disease was developed for disorders that include extra-pancreatic lesions related to autoimmune pancreatitis and have the common features of lymphoplasmacytic infiltration with IgG4-bearing plasma cells and a favorable response to corticosteroids (Kawa et al., 2011a; Zen et al., 2011). In IgG4-related disease, lesions may exist in almost any organ including the central nervous system, eye and salivary glands, respiratory system, hepato-biliary-pancreatic system, retroperitoneum, aorta, renal system, genitourinary system, and endocrine system (Figure 64.4). In addition, other previously recognized conditions are now considered as IgG4-related disease, including multifocal idiopathic fibrosclerosis, Mikulicz's disease, Küttner's

tumor, Ormond's disease, and idiopathic hypertrophic pachymeningitis (Stone et al., 2012).

Historical Background

In 1967, Comings reported on multifocal idiopathic fibrosclerosis (MIF), a systemic disease with retroperitoneal fibrosis, mediastinal fibrosis, sclerosing cholangitis, Riedel's thyroiditis, and sicca complex (Comings et al., 1967). Later, pancreatic lesions were added as a component of MIF by Clark and Levy (Clark et al., 1988; Levey and Mathai, 1998). In 1991, Kawaguchi described the histology of autoimmune pancreatitis as lymphoplasmacytic sclerosing pancreatitis (LPSP), and suggested that LPSP be categorized with MIF (Kawaguchi et al., 1991). The disease distribution of MIF seemed similar to that of the extra-pancreatic lesions of autoimmune pancreatitis (Kamisawa et al., 2003a) or IgG4-related disease; as a result, MIF is now considered under the IgG4-related disease category. In 2001, Hamano reported the close association between autoimmune pancreatitis and a high serum IgG4 concentration (Hamano et al., 2001). In 2002, Hamano also reported IgG4-bearing plasma cell infiltration as a histological hallmark of autoimmune pancreatitis and extra-pancreatic lesions (Hamano et al., 2002). Various styles of nomenclature associated with IgG4 were then proposed, including: IgG4-related autoimmune disease (Kamisawa et al., 2003b), IgG4-related plasmacytic disease (Yamamoto et al., 2006), hyper-IgG4 disease (Neild et al., 2006), and IgG4-positive multi-organ lymphoproliferative syndrome (Masaki et al., 2008). In 2010, Japanese researchers agreed on the nomenclature of "IgG4-related disease" (Umehara et al., 2012a,b), which was accepted worldwide at the first international symposium for IgG4-related disease (Stone et al., 2012).

Epidemiology

The prevalence and distribution of the disorders included within the IgG4-related disease category are unclear because most are recognized as complications of autoimmune pancreatitis (Figure 64.4) or Mikulicz's disease. Based on images, a radiologist reported the following prevalence of extra-pancreatic lesions in autoimmune pancreatitis: lacrimal and salivary gland lesions, 48%; lung lesions, 54%; biliary tract lesions, 78%; renal lesions, 14%; retroperitoneal fibrosis, 20%; and prostate lesions, 10% (Fujinaga et al., 2009). Correspondingly a gastroenterologist showed the prevalence based on clinical findings was: lacrimal and salivary gland lesions, 39%; thyroid lesions, 22%; hilar lymphadenopathy, 80%; biliary tract lesions, 74%; and retroperitoneal fibrosis, 13% (Hamano et al., 2006). Finally, based on pathological findings, the prevalence of the location of IgG4-related

disease was reported as: head and neck, 20%; thoracic, 14%; hepatic and pancreatobiliary (HPB), 24%; retroperitoneal, 11%; and systemic, 31% (Zen et al., 2010).

Clinical Features of IgG4-related Disease

IgG4-related disease appears as single or multiple organ lesions. In multiple organ lesions, each lesion appears simultaneously or metachronously with the other lesions. In general, multiple organ lesions represent a highly active state with a high serum IgG4 concentration (Hamano et al., 2006). Disease activity may differ in each IgG4-related disease: for example, lacrimal and salivary gland lesions usually represent a higher state of activity, whereas retroperitoneal fibrosis represents a lower state (Hamano et al., 2006). IgG4-related disease can be erroneously diagnosed as an inherent disease of the affected organ, especially when autoimmune pancreatitis or Mikulicz's disease is not present. Intensive differentiation with histological evidence is needed, especially when IgG4-related disease mimics malignant conditions. IgG4-related disease may be divided into definite and probable entities, with the latter lacking supporting evidence such as characteristic histological findings or sufficient case numbers.

Definite IgG4-related Diseases

IgG4-related Lacrimal and Salivary Gland Lesions

IgG4-related lacrimal and salivary gland lesions include Mikulicz's disease or Küttner's tumor and show symmetrical swelling of lacrimal and salivary glands (Figure 64.5). These lesions have been observed in ≈ 14 –39% of patients with autoimmune pancreatitis and were sometimes misdiagnosed as Sjögren's syndrome (Kamisawa et al., 2003a; Yamamoto et al., 2005a, b, 2006). Compared with Sjögren's syndrome, IgG4-related lacrimal and salivary gland lesions show milder exocrine dysfunction, are negative for anti-SS-A/Ro and SS-B/La autoantibodies, and have an excess of submandibular gland lesions (Yamamoto et al., 2005b).

IgG4-related Lung Disease

There are a variety of IgG4-related respiratory lesions, which may result in interstitial pneumonia (Taniguchi et al., 2004), inflammatory pseudotumor (Zen et al., 2005), hilar or mediastinal lymphadenopathy (Saegusa et al., 2003), and bronchial wall thickening (Ito et al., 2009). Interstitial pneumonia has been observed in ≈ 8 –13% of patients with autoimmune pancreatitis. Clinical findings include dry cough, high serum Krebs

von den Lungen-6 (KL-6) concentrations, and a ground glass appearance in the middle and lower lung fields and honeycombing in the lower lung field in CT imaging (Kobayashi et al., 2007). An inflammatory pseudotumor presents as nodular lesions in a chest X-ray or CT, which correspond to a plasma cell granuloma, and this is frequently misdiagnosed as a lung tumor (Zen et al., 2005). CT, gallium scintigraphy, and FDG-PET revealed hilar and mediastinal lymphadenopathy in $\approx 60\text{--}70\%$ of patients with autoimmune pancreatitis (Saegusa et al., 2003). CT showed bronchial wall thickening, which results in central airway stenosis. Central airway stenosis and hilar lymphadenopathy should be differentiated from sarcoidosis, and the absence of raised serum levels of angiotensin-converting enzyme (ACE) and histological examination may help differentiate between these conditions (Ito et al., 2009).

IgG4-related Sclerosing Cholangitis

IgG4-related sclerosing cholangitis has been observed in $\approx 60\text{--}70\%$ of patients with autoimmune pancreatitis, and is found in any part of the biliary system (Erkelens et al., 1999; Horiuchi et al., 2001; Nakazawa et al., 2001). Lower bile duct lesions should be differentiated from pancreatic cancer, and intrahepatic or hilar lesions from primary sclerosing cholangitis (PSC) and biliary malignancies (Figure 64.3). PSC is usually observed in young and middle-aged patients and may accompany inflammatory bowel disease (Nakazawa et al., 2005). On cholangiography, the characteristics of PSC include a band-like stricture, beaded or pruned tree appearance, and diverticulum-like outpouchings. In contrast, cholangiography of IgG4-related sclerosing cholangitis showed evidence of lower bile duct stenosis and relatively long strictures from the hilar to intrahepatic biliary systems with distal duct dilatation (Figure 64.3) (Nakazawa et al., 2004).

IgG4-related Liver Disease

IgG4-related liver disease consists of a variety of histological changes, including portal inflammation, interface hepatitis, large bile-duct obstructive features, portal sclerosis, lobular hepatitis, and canalicular cholestasis, which are collectively designated as IgG4 hepatopathy (Umemura et al., 2007a). Some of these lesions mimic those observed in autoimmune hepatitis (AIH) and have a similar clinical presentation; therefore, they fulfill the diagnostic criteria of AIH (Umemura et al., 2007b).

IgG4-related Kidney Disease

Most IgG4-related kidney disease involves the uriniferous tubules, with few being glomerular; in addition, there is

tubulointerstitial nephritis with hypocomplementemia and deposits of immune complexes and C3 in tubular basement membranes (Takeda et al., 2004; Saeki et al., 2010). CT shows renal cortical lesions with decreased enhancement that appear as small peripheral cortical nodules and round or wedge-shaped lesions (Takahashi et al., 2007; Fujinaga et al., 2009).

IgG4-related Retroperitoneal Fibrosis

Retroperitoneal fibrosis, observed in about 10–20% of patients with autoimmune pancreatitis, may affect the urinary system or aorta (Hamano et al., 2002; Fujinaga et al., 2009). CT or MRI shows soft tissue density or masses around the aorta and ureters (Fujinaga et al., 2009). Patients with peri-ureteral lesions sometimes complain of lumbago or back pain due to hydronephrosis, which may result in renal atrophy and renal failure (Hamano et al., 2002). Thickening of the aortic wall or aneurysms are sometimes observed, which gave rise to the concept of IgG4-related periaortitis (Ito et al., 2008).

Possible IgG4-related Diseases

IgG4-related Hypophysitis

IgG4-related hypophysitis presents with compressive optic neuropathy, panhypopituitarism, pituitary hypothyroidism, adrenocortical insufficiency, and syndrome of inappropriate secretion of antidiuretic hormone (SIADH) (van der Vliet and Perenboom, 2004; Taniguchi et al., 2006; Tanabe et al., 2006; Shimatsu et al., 2009). MRI analysis revealed pituitary gland and pituitary stalk swelling that produced a high signal on T1-weighted images and early enhancement on dynamic studies, findings which disappeared after corticosteroid treatment (Taniguchi et al., 2006; Tanabe et al., 2006; Shimatsu et al., 2009).

IgG4-related Hypertrophic Pachymeningitis

Hypertrophic pachymeningitis is a rare fibroinflammatory lesion, which causes thickening of the dura in the cranium and/or spinal canal and presents as radiculomyelopathy, headache, or cranial nerve palsies depending on the site of involvement. Hypertrophic pachymeningitis was considered a member of MIF and histological findings showed IgG4-positive plasma cell infiltration in the dura, suggesting a close association with IgG4-related disease (Chan et al., 2009; Riku et al., 2009).

IgG4-related Thyroid Disease

Hypothyroidism has been reported as a complication of autoimmune pancreatitis (Komatsu et al., 2005). Patients with Hashimoto's thyroiditis were classified as having

TABLE 64.1 Comprehensive Clinical Diagnostic Criteria for IgG4-related Disease, 2011

1. Clinical examination showing characteristic diffuse/localized swelling or masses in single or multiple organs.
2. Hematological examination shows elevated serum IgG4 concentrations (135 mg/dl).
3. Histopathologic examination shows:
 - a. Marked lymphocyte and plasmacyte infiltration and fibrosis.
 - b. Infiltration of IgG4⁺ plasma cells: ratio of IgG4⁺/IgG⁺ cells >40% and >10 IgG4⁺ plasma cells/HPF.

Definite: (1) + (2) + (3); Probable: (1) + (3); Possible: (1) + (2)

However, it is important to differentiate IgG4-RD from malignant tumors of each organ (e.g., cancer, lymphoma) and similar diseases (e.g., Sjögren's syndrome, primary sclerosing cholangitis, Castleman's disease, secondary retroperitoneal fibrosis, Wegener's granulomatosis, sarcoidosis, Churg–Strauss syndrome) by additional histopathological examination.

Even when patients cannot be diagnosed using the CCD criteria, they may be diagnosed using organ-specific diagnostic criteria for IgG4-RD.

IgG4 thyroiditis and non-IgG4 thyroiditis, based on immunostaining of IgG4 (Li et al., 2009). IgG4-related disease is also significantly associated with hypothyroidism that favorably responds to corticosteroid therapy, suggesting the existence of an IgG4-related thyroid disease or an IgG4-related thyroiditis (Watanabe et al., 2013).

Gastrointestinal Disease

Gastric ulcers may be associated with autoimmune pancreatitis and they occur independently from NSAID medication or *Helicobacter pylori* infection (Shinji et al., 2004). Swelling of the main duodenal papilla is observed in ≈40–65% of patients with autoimmune pancreatitis that responds well to corticosteroid therapy (Unno et al., 2002; Kubota et al., 2007). Similarly to pancreatic lesions, significant numbers of IgG4-positive plasma cells have been detected in these lesions, suggesting that tissue assays may provide an alternative to pancreatic tissue biopsy (Kubota et al., 2007).

Prostate Disease

Some patients with autoimmune pancreatitis have experienced an improvement in symptoms associated with prostatitis, polyuria, dysuria, and nocturia, after corticosteroid therapy, suggesting the existence of an IgG4-related prostatitis (Yoshimura et al., 2006). Patients present with a symmetrical, non-tender, swollen prostate, and imaging has shown severe inflammatory lesions, mainly in the central and transition zones (Uehara et al., 2008).

Pathological Features

The pathological findings of each type of IgG4-related disease share common features that are also seen in autoimmune pancreatitis; however, there are subtle variations among some organs or organ-specific features (Zen et al., 2010). Unique pathological features include dense fibrosis in lacrimal gland lesions, numerous lymph follicles in

lacrimal and salivary gland lesions, and obliterative arteritis in lung lesions (Zen et al., 2010). Obliterative phlebitis is scarcely found in lacrimal gland lesions. Semiquantitative analysis of IgG4-bearing plasma cells may help to distinguish IgG4-related disease from other conditions (Deshpande et al., 2006; Dhall et al., 2010). The ratio of IgG4-bearing plasma cells to IgG-bearing plasma cells further assists in confirming the diagnosis of IgG4-related disease, with a ratio higher than 50% being very suggestive of this diagnosis. The closest histopathological mimics of IgG4-related disease are lymphomas, and clonality studies are necessary to differentiate these two conditions (Stone et al., 2012).

Autoimmune Features, Genetic Features, Animal Models, and Pathological Mechanisms

These are as described in the section on autoimmune pancreatitis.

Diagnosis

Diagnostic criteria have been proposed for some of the IgG4-related diseases, such as autoimmune pancreatitis (Kawa et al., 2011a; Shimosegawa et al., 2011), Mikulicz's disease (Masaki et al., 2010), and IgG4-related kidney disease (Kawano et al., 2011). Japanese researchers proposed comprehensive diagnostic criteria for IgG4-related disease in 2011, based on morphological, serological, and pathological findings (Table 64.1) (Umehara et al., 2012b).

Treatment

When vital organs are involved and serious organ dysfunction or failure may occur, aggressive treatment is needed. However, not all forms of IgG4-related disease require immediate treatment and simple observation is justified in some cases. The correlation between the

extent of disease and the need for treatment is imperfect, and the establishment of guidelines for the treatment of each IgG4-related disease is desirable (Stone et al., 2012). Glucocorticoids are typically the first line treatment as described in the autoimmune pancreatitis section.

CONCLUDING REMARKS: FUTURE PROSPECTS

Autoimmune pancreatitis and IgG4-related diseases provide a new disease concept which consists of a distinctive disease profile characterized by high serum IgG4 concentrations and IgG4-bearing plasma cell infiltration. In the future, researchers need to clarify the following: (1) the pathogenesis and role of elevated serum IgG4; (2) the detailed characteristics and the global prevalence of IgG4-related disease; and (3) the long-term outcome with respect to structure and function and predisposition to malignancy.

Autoimmune pancreatitis has received particular attention in Japan, from where the early reports on this disease were mainly published. However, there are now reports from Europe, the United States, and East Asia (Hart et al., 2012). Affected patients in other countries may have been overlooked, or categorized as having other diseases (Kim et al., 2004). The use of the ICDC criteria will enable the correct diagnosis based on internationally recognized standards. A growing awareness of autoimmune pancreatitis and IgG4-related disease will result in an increase in diagnoses as well as more international studies in the future.

INTRODUCTION

Autoimmune bullous diseases are rare disorders affecting skin and mucous membranes. These diseases are mediated by pathogenic autoantibodies against keratinocyte adhesion molecules (Diaz and Giudice, 2000). In the epidermis, neighboring keratinocytes adhere to each other through organelles known as desmosomes, whereas dermal–epidermal junction adhesion is mediated by hemidesmosomes. The majority of antigens recognized by these autoantibodies are desmosomal and hemidesmosomal

transmembrane glycoproteins involved in epidermal cell–cell and epidermal–dermal adherence.

The desmosome contains two parallel intracellular plaques, which are located just beneath the cell membranes of neighboring cells (Figure 65.1). Transmembrane glycoproteins emerge from the desmosomal plaques and meet in the narrow extracellular space shared by the two cells, constituting the desmosomal core. The desmosomal plaques are composed of plakin family proteins and serve as insertion sites of intracellular keratins, whereas the core is composed of transmembrane calcium-dependent cell

adhesion molecules known as desmosomal cadherins. The desmosomal cadherins include desmogleins (Dsg1–4) and desmocollins (Dsc1–3) (Getsios et al., 2004), the isoforms of which vary in expression throughout the epidermis and in different squamous epithelial tissues. For example, in the skin Dsg1 is expressed throughout the epidermis with predominance in the upper layers of this tissue, whereas Dsg3 is expressed mainly in the suprabasal layers of the epidermis.

The hemidesmosomes, located on the dermal pole of the epidermal basal cells, also contain an intracellular plaque and a core structure (Figure 65.1). The extracellular space, termed the lamina lucida (corresponding to the desmosomal core), separates these cells from the underlying lamina densa (composed of collagen IV) (Diaz and Giudice, 2000). The sub-lamina densa region contains other matrix molecules and the anchoring fibrils (collagen VII). The hemidesmosomal plaque, linked to the keratin network, contains the intracellular proteins BP230 and plectin. The lamina lucida contains the ectodomains of transmembrane proteins BP180, $\alpha 6\beta 4$ integrin, and laminin 5.

The pemphigus group includes diseases that are characterized by autoantibodies against desmosomal cadherins (Dsg and Dsc) (Beutner and Jordon, 1964; Anhalt and Diaz, 2001), and intraepidermal cell–cell detachment known as acantholysis (Civate, 1943). This group comprises the two classical forms of pemphigus: pemphigus vulgaris (PV) and pemphigus foliaceus (PF). PV is characterized by suprabasilar acantholysis and anti-Dsg3 IgG autoantibodies, whereas PF is characterized by subcorneal acantholysis and anti-Dsg1 IgG autoantibodies. Other infrequent forms of pemphigus include paraneoplastic pemphigus (PNP), drug-induced pemphigus, and IgA pemphigus (Table 65.1).

The pemphigoid group and other rare subepidermal autoimmune blistering diseases (Table 65.1) are characterized by separation of the epidermis from the dermis. Bullous pemphigoid (BP), the most common autoimmune bullous disease seen in the elderly (Lever, 1965), is characterized by subepidermal blisters and autoantibodies against the hemidesmosomal BP180 and BP230 antigens (Stanley et al., 1981; Mutasim et al., 1985; Labib et al., 1986). Other subepidermal blistering diseases such as cicatricial pemphigoid (CP), herpes gestationis (HG), and linear IgA dermatosis (LAD) exhibit distinctive clinical, histological, and immunologic features, yet share a humoral autoimmune response to BP180 and occasionally other antigens. The remainder of the acquired subepidermal blistering diseases show autoantibody responses to structural molecules of the dermal extracellular matrix. They include epidermolysis bullosa acquisita (EBA) with a target antigen of collagen VII and dermatitis herpetiformis (DH) with a target antigen of epidermal transglutaminase.

While the autoantibody response in most of these autoimmune skin diseases belongs to the IgG class, there are exceptions (IgE and IgM in endemic PF, IgE in BP, and IgA in IgA pemphigus, LAD, and DH).

In this chapter we shall review the current clinical, histological, and immunological features of the most common forms of autoimmune bullous diseases (PV, PF, and BP) (Figure 65.2), and briefly discuss other infrequent forms of pemphigus and other subepidermal autoimmune bullous diseases.

PEMPHIGUS VULGARIS

Clinical, Pathologic, and Epidemiologic Features

Pemphigus vulgaris (PV) is the most severe and common form of pemphigus (Lever, 1965). The disease usually begins with painful ulcerations or erosions of the oral mucosa (mucosal PV), which may last for several months. This process is gradually followed by involvement of the skin (mucocutaneous PV) where the disease produces flaccid blisters and erosions. Other squamous epithelial tissues (e.g., nasal, esophageal, larynx, pharynx, conjunctival, vaginal, and rectal) may also be involved.

Histologically, the lesions of PV show intra-epidermal separation just above the basal cell layer of the epidermis with acantholysis, or rounding up of individual cells (Figure 65.2, left panel). The basal cells remain attached to the dermis but laterally detached from each other producing the histological sign known as “row of tombstones” (Civate, 1943). Inflammatory infiltration is usually mild and composed of lymphocytes and eosinophils in the superficial dermis.

The incidence of PV ranges from one to five new cases per million persons per year, with a mean age of onset of 50 to 60 years of age (Chams-Davatchi et al., 2005). Although found in all ethnic and racial groups, the disease is more prevalent in patients harboring certain HLA class II alleles (see Genetic Features, below).

Autoimmune Features

Autoantibodies

The serum of PV patients contains IgG autoantibodies that stain the epidermal intercellular spaces (ICS) by indirect immunofluorescence (IF) producing titers that roughly correlate with disease activity (Beutner and Jordon, 1964). Direct IF of perilesional skin reveals IgG bound to keratinocyte cell surfaces. These autoantibodies are predominantly of the IgG4 subclass (Jones et al., 1988). Noteworthy, non-pathogenic anti-Dsg3 autoantibodies have been detected in first-degree relatives of PV

FIGURE 65.1 Diagrammatic representation of the desmosome and the hemidesmosome.

TABLE 65.1 Autoimmune Blistering Diseases of the Skin

| Diseases | Cleavage Site | Skin Organelle | Autoantigens | Pathogenic Autoantibodies |
|---------------------------------|------------------------------------|--------------------------|--|------------------------------|
| Pemphigus vulgaris | Suprabasilar acantholysis | Desmosome | Desmoglein 3 | Passive transfer |
| Pemphigus foliaceus | Subcorneal acantholysis | Desmosome | Desmoglein 1 | Passive transfer |
| Paraneoplastic pemphigus | Suprabasilar acantholysis | Desmosome, hemidesmosome | Desmoglein 3, desmoglein 1 and plakin family | Passive transfer (Dsg3) |
| Drug-induced pemphigus | Subcorneal acantholysis (commonly) | Desmosome | Desmoglein 1 | ? |
| IgA pemphigus | Subcorneal/intraepidermal pustules | Desmosome | Desmocollin 1 | ? |
| Bullous pemphigoid | Subepidermal | Hemidesmosome | BP180 and BP230 | Passive transfer (BP180) |
| Herpes gestationis | Subepidermal | Hemidesmosome | BP180 | Passive transfer |
| Cicatricial pemphigoid | Subepidermal | Hemidesmosome | BP180, laminin 5, $\alpha6\beta4$ integrin | Passive transfer (laminin 5) |
| Linear IgA dermatosis | Subepidermal | Hemidesmosome | BP180 fragments | ? |
| Epidermolysis bullosa acquisita | Subepidermal | Anchoring fibrils | Type VII collagen | Passive transfer |

patients, which are mainly IgG1 subclass (Bhol et al., 1995; Kricheli et al., 2000).

The target antigen recognized by PV autoantibodies is desmoglein 3 (Dsg3), a 130-kDa desmosomal core

glycoprotein (Amagai et al., 1991). While patients with limited mucosal lesions have autoantibodies to Dsg3 exclusively, patients who develop skin lesions may possess autoantibodies against Dsg1 as well (Ding et al., 1997). It is

FIGURE 65.2 Clinical, histologic, and immunofluorescent features of pemphigus vulgaris, pemphigus foliaceus, and bullous pemphigoid human disease. The clinical (A), histological (B), and immunofluorescent (C) features of pemphigus vulgaris (PV, left panel), pemphigus foliaceus (PF, middle panel), and bullous pemphigoid (BP, right panel) are shown.

well established that about 50% of PV patients show autoantibodies against Dsg3 and Dsg1.

Dsg1 and Dsg3 belong to the cadherin superfamily of calcium-dependent cell adhesion molecules and share high sequence homology (Getsios et al., 2004). The ectodomain of these glycoproteins is composed of four cadherin repeats (EC1–4) and a variable extracellular anchor (EC5). The six putative calcium-binding motifs of the ectodomain are believed to be involved in maintaining the conformation and adhesive function of Dsg3. A putative adhesion site (RAL) is located on the EC1 domain. The ectodomain of Dsg3 has been expressed in the baculovirus system and employed to adsorb pathogenic autoantibodies from PV serum. The Dsg3 affinity-purified autoantibodies are sufficient to induce suprabasilar acantholysis when passively transferred to neonatal mice (Amagai et al., 1992; Ding et al., 1999). These pathogenic autoantibodies recognize conformational and calcium-dependent epitopes located on the EC1 domain of Dsg3 (Sekiguchi et al., 2001), which is believed to be involved in the adhesion function of the molecule.

T Cell Activation

Like most other antibodies, induction of anti-Dsg3 autoantibodies is T cell dependent. Indeed, *in vitro* anti-Dsg3

antibody production by autoreactive B cells is abolished upon depletion of CD4⁺ T cells (Nishifuji et al., 2000). Other investigators have successfully derived T cell clones from PV patients that proliferated when stimulated with various Dsg3 peptides (Wucherpfennig et al., 1995; Lin et al., 1997; Veldman et al., 2004). Most of the T cell epitopes identified are located in the first three ectodomains of Dsg3. The HLA restrictions and cytokine profiles of the T cell clones have been characterized. The reactivity of one of these T cell clones with the Dsg3 peptide (residues 190–204) is restricted to PV-associated DRB1*0402 allele and associated with high levels of Th2 cytokines (Wucherpfennig et al., 1995). Similarly, CD4⁺ T cells from PV patients responsive to three polypeptides (residues 145–192, 240–303, and 570–614) were also restricted to HLA-DR and exhibit a Th2-like cytokine profile (Lin et al., 1997). These studies suggest that Th2 cells are relevant in the induction of Dsg3-specific autoantibodies. Not only autoreactive Th2 cells, but also Th1 cells are found in PV patients (Veldman et al., 2004). Both Th1 and Th2 cells may be involved in the production of PV autoantibodies, since the ratio of Dsg3-specific Th1/Th2 cells in PV patients correlated well with the serum autoantibody titers of the patients. In addition, recent studies have shown that an imbalance of Dsg3-specific type 1 regulatory T cells and Th2 cells may be

critical for the loss of tolerance against Dsg3 in PV (Veldman et al., 2009).

Interestingly, Dsg3-specific T cells are not only detected in PV patients, but are also detected in healthy individuals who carry PV susceptible HLA alleles (Veldman et al., 2004). However, in contrast to PV patients, Dsg3-responsive T cell clones from the healthy donors exhibit exclusively Th1 (IFN-1) cytokine profiles.

Recent studies have shown that Dsg3-specific CD4⁺ T cells can induce pemphigus vulgaris in mice, further underscoring the importance of T cells in initiation of disease (Takahashi et al., 2011).

Genetic Features

HLA alleles may play important roles in the development and progression of PV (Sinha et al., 1988; Delgado et al., 1997). Two haplotypes, HLA-DR4 and HLA-DR6, are strongly associated with PV in different ethnic groups (Todd et al., 1988). In the non-Jewish population, DRB1*0402 and DQB1*0503 are the two candidate alleles most likely associated with disease susceptibility, whereas in the Ashkenazi Jewish population DRB1*0402 seems to be singularly associated with PV (Lee et al., 2006).

In Vivo and in Vitro Models

Autoantibody Passive Transfer Model

As described in previous sections, neonatal mice have been used as targets for passive transfer experiments of PV IgG (Anhalt et al., 1982). The small size of the animals and the lack of hair allow the use of smaller amounts of IgG and the lesions are easily visible on the hairless skin. PV IgG transferred to neonatal mice reproduces the clinical, histological, and immunological features of human disease within the first 24 hours post injection (Figure 65.3, left panel). The disease induced in these animals is dose dependent and also correlates with the titers of PV autoantibodies detected in the sera of the injected mice.

Active Immunization Model

The efforts to induce PV phenotype in adult mice by conventional active immunization with human Dsg3 have been largely unsuccessful. While the immunized animals produce anti-Dsg3 antibodies that were able to induce skin blisters when passively transferred into neonatal mice, the animals themselves do not develop disease (Fan et al., 1999). Amagai et al. have developed an active mouse model of PV using a novel strategy to overcome the barrier of self-tolerance (Amagai et al., 2000). They immunized Dsg3 knockout mice (Koch et al., 1997) with human Dsg3, and adoptively transferred the splenocytes from these immunized animals to immunodeficient

Rag-2^{-/-} mice which express Dsg3 in their epidermis. The recipient mice produced anti-Dsg3 antibodies and show suprabasilar acantholysis histologically. Some of the animals developed spontaneous crusted erosions on the skin around the snout.

Pathologic Effector Mechanisms

Pathogenic Role of Autoantibodies

Several studies have demonstrated the correlation of PV autoantibody titers and disease extent and activity. *In vitro* studies also showed that PV IgG can induce acantholysis in skin organ cultures and cell detachment in primary epidermal cell cultures. The *in vivo* passive transfer studies demonstrating that PV IgG is able to faithfully reproduce the disease in neonatal mice finally attributed a pathogenic role for PV autoantibodies (Figure 65.3, left panel) (Anhalt et al., 1982). These pioneer studies were extended to demonstrate that PV autoantibodies are able to induce disease by passive transfer in a process that is independent of activation of complement or plasminogen activator (Anhalt et al., 1986; Mascaro et al., 1997; Mahoney et al., 1999).

Another area of intensive research is addressing the molecular mechanisms of acantholysis, i.e., how PV autoantibodies trigger cell detachment. Recent studies have shown that PV autoantibodies bind Dsg3 on the keratinocyte cell surfaces forming clusters that are internalized and fused with lysosomes (Calkins et al., 2006). It has been proposed that PV IgG may alter the assembly/disassembly of desmosomes by impairing the dynamics of the soluble and insoluble pools of Dsg3, which in turn may lead to acantholysis (Jennings et al., 2011). The epidermis of mice passively transferred with PV IgG shows binding of these autoantibodies to the epidermal ICS, and initiation of the cell detachment process begins in the space between desmosomes. This process was followed by desmosome splitting and complete cell detachment (Takahashi et al., 1985). Similar findings were reported in an active mouse model for PV (Shimizu et al., 2004), and thus lead to the appealing hypothesis that autoantibodies to non-desmosomal cadherins, i.e., E-cadherin, may play a role in pemphigus acantholysis.

A longstanding theory for autoantibody-mediated pathogenesis is the steric hindrance theory, in which binding of the autoantibodies to Dsg3 directly impairs the adhesive ability of the molecules thereby causing cell separation (Diaz and Marcelo, 1978). However, substantial evidence is accumulating in support of a complementary hypothesis in which binding of PV autoantibodies to Dsg3 leads to activation of intracellular signaling pathways that ultimately lead to acantholysis. Several signaling pathways have been shown to be activated upon

FIGURE 65.3 Clinical, histologic, and immunofluorescent features of the murine models of pemphigus vulgaris, pemphigus foliaceus, and bullous pemphigoid. The clinical (A), histological (B), and immunofluorescent (C) features of pemphigus vulgaris (PV, left panel), pemphigus foliaceus (PF, middle panel), and bullous pemphigoid (BP, right panel) murine models are shown. The animals passively transferred with human IgG (and IgG4) develop skin lesions (A), which histologically (B) are similar to the human disease. The human autoantibodies are detected bound to lesional skin (C) and circulating in the mouse serum.

autoantibody binding to Dsg3 including p38MAPK/HSP27, Rho family GTPase, c-myc, protein kinase C, and phospholipase C (Caldelari et al., 2001; Kitajima, 2003; Sharma et al., 2007; Berkowitz et al., 2008). Furthermore, modulation of these pathways can prevent autoantibody-induced acantholysis.

Autoantibodies as Potential Immunologic Markers

As PV autoantibodies are the direct effectors of keratinocyte dissociation and blister formation, anti-Dsg3 and anti-Dsg1 autoantibodies are not merely immunologic markers of PV, but are critical for the diagnosis.

PEMPHIGUS FOLIACEUS

Clinical, Pathologic, and Epidemiologic Features

Unlike PV, PF affects skin only and the disease is manifested by superficial blisters and erosions which may lead to crusting and formation of keratotic plaques (Figure 65.2, middle panel). The skin lesions initially

involve the central areas of the face, scalp, the mid chest, and the upper back. From these areas the disease may spread to involve the entire body, producing an exfoliative erythroderma. Histological examination of these lesions reveals subcorneal vesicles and acantholysis, predominantly in the upper layers of the stratum spinosum (Lever, 1965).

The classic form of PF is non-endemic and seen sporadically in different parts of the world with an incidence of less than one case per million persons per year. A second form of PF is endemic and was originally described in certain states of Brazil with the name of fogo selvagem (FS) and with a prevalence of 1–3% (Diaz et al., 1989). Endemic forms of PF have also been reported in Colombia and Tunisia. Epidemiological studies suggest environmental triggers for FS development (Aoki et al., 2004).

Autoimmune Features

Autoantibodies

Similarly to PV, PF patients are characterized by anti-epidermal ICS autoantibodies, predominantly of the IgG4

subclass (Rock et al., 1989). These autoantibodies are detected bound to diseased epidermis and circulating in the serum of the patients, with titers that roughly correlate with disease extent and activity.

Dsg1, expressed mostly in the superficial layers of the epidermis, is the target antigen of PF autoantibodies. Affinity-purified anti-Dsg1 antibodies from PF serum are able to induce disease in neonatal mice (Amagai et al., 1995). The majority of PF autoantibodies recognize conformational and calcium-dependent epitopes residing in the NH₂-terminal amino acid 1-161 of Dsg1 (Sekiguchi et al., 2001). In the pre-clinical stage of FS, during disease remission, and in some normal individuals exhibiting no skin disease, the anti-Dsg1 autoantibodies recognize the EC5 domain only. On the contrary, FS anti-Dsg1 autoantibodies from patients showing active disease or during disease relapses recognize the EC1/EC2 domains (Li et al., 2003). Although the majority of PF/FS autoantibodies are of IgG4 subclass, it appears that epitope specificity, rather than the subclass of IgG, is the driver of the pathogenicity of the autoantibodies (Li et al., 2002). Considering these findings we hypothesize that an environmental agent(s) cross-reacts with the EC5 domain of Dsg1 and triggers an initial nonpathogenic anti-EC5 autoimmune response (Diaz et al., 2004). In genetically predisposed individuals, the autoimmune response may undergo intramolecular epitope spreading toward pathogenic epitopes on the EC1/EC2 domains of Dsg1, which leads to disease onset.

T Cell Activation

It has been demonstrated that CD4⁺ T cell lines and clones derived from peripheral blood of FS patients show a proliferative response when incubated with the Dsg1 ectodomain (Lin et al., 2000a). The stimulation of these CD4⁺ T cells is HLA-DR restricted. Moreover, these cells secrete Th2-like cytokines.

Genetic Features

HLA alleles strongly associated with FS are DRB1*0404, *1406, *1402 (relative risk = 14) and *0102 (relative risk = 7.3) (Moraes et al., 1997). A common epitope of LLEQRRAA, the residues 67–74 of the third hypervariable region of the DRB1 molecule, is shared by these susceptibility alleles. Similarly, a strong association of DRB1*0102 and DRB1*0404 is also found in non-endemic PF patients in France (Loiseau et al., 2000). Interestingly, two susceptible alleles in PV, DRB1*1401 and DQB1*0503, have been also reported with high frequencies in Italian and Japanese PF patients (Lombardi et al., 1999; Miyagawa et al., 1999).

In Vivo and In Vitro Models

The classic animal model of PF was developed by passively transferring IgG from patients into neonatal mice (Roscoe et al., 1985). The animals develop skin blisters, which show the typical histological features of the human disease, i.e., subcorneal vesicles (Figure 65.3, middle panel). The extent of the disease correlates well with the indirect IF titers of human autoantibodies detected in the mouse. These animals develop classic ultrastructural subcorneal acantholysis (Futamura et al., 1989). The disease is induced as a complement-independent process and by monovalent PF IgG fragments as well (Espana et al., 1997). Despite the availability of recombinant human and murine Dsg1, the studies on inducing disease by active immunization have been unsuccessful.

Pathologic Effector Mechanisms

The IgG4 autoantibodies are pathogenic as demonstrated by passive transfer studies (Figure 65.3, middle panel) (Rock et al., 1989). Activation of the complement cascade and plasminogen activator is not required for the induction of acantholysis by these autoantibodies in the mouse model (Espana et al., 1997; Mahoney et al., 1999).

Autoantibodies as Potential Immunologic Markers

The importance of anti-Dsg1 autoantibodies as markers of disease has been illustrated in the FS population, where IgG4 anti-Dsg1 autoantibodies serve as a novel classifier/predictor that identifies FS patients with high sensitivity and specificity (92% and 97%, respectively). In an FS prone population with an incidence of 3%, detection of IgG4 anti-Dsg1 autoantibodies has a positive predictive value of 49% and a negative predictive value of 99.7% (Qaqish et al., 2009).

Environmental Factors involved in Fogo Selvagem

A remarkable characteristic of FS is its epidemiology. Several independent lines of evidence indicate that FS is precipitated by exposure to an environmental factor(s) (Aoki et al., 2004). Anti-Dsg1 autoantibodies are detected in 55% of normal individuals living in an area exhibiting a high prevalence (3.4%) of FS (Warren et al., 2000). Remarkably, anti-Dsg1 autoantibodies are also detected in FS patients from one to several years before the clinical onset of disease (Qaqish et al., 2009). These antibodies are a mixture of IgG1 and IgG4 subclasses and recognize the EC5 domain of Dsg1 (Li et al., 2003; Warren et al., 2003).

A case–control epidemiological study points to hematophagous insects as a prime etiological agent of FS (Aoki et al., 2004). For example, anti-Dsg1 EC5 antibodies have been detected in the sera of patients with onchocerciasis, leishmaniasis, and Chagas disease, though the patients exhibit no skin lesions of FS (Diaz et al., 2004). It is known that hematophagous vectors (black flies, sand flies, and kissing bugs, respectively) are involved in the transmission of the respective tropical diseases. It is postulated that the saliva of these vectors may contain proteins that contain specific epitopes that cross-react with Dsg1, thus inducing a non-pathogenic anti-EC5 domain autoantibody response. Detection of anti-Dsg1 autoantibodies of the IgM and IgE classes provides further support of an environmental trigger (Diaz et al., 2008; Qian et al., 2011).

OTHER TYPES OF PEMPHIGUS

Paraneoplastic Pemphigus

Paraneoplastic pemphigus (PNP) is a severe mucocutaneous disease that runs a usually lethal course in patients with underlying lymphoproliferative malignancy, i.e., non-Hodgkin's lymphoma, chronic lymphocytic leukemia, and Castleman's diseases (Anhalt et al., 1990, 2004). Patients exhibit severe stomatitis and skin lesions that may be vesiculobullous in some patients or show erythema multiforme or lichen planus features in other patients. In approximately 30% of the patients there is a bronchiolitis obliterans syndrome with severe respiratory insufficiency.

Histological examination of the skin lesions reveals keratinocyte necrosis, basal cell vacuolization, and suprabasilar acantholysis. Direct IF shows deposition of IgG and C3 in the epidermal intercellular spaces (as in pemphigus) and along the basement membrane zone (BMZ). The unique and characteristic immunological finding in PNP patients is the polyclonal autoantibody response against structural antigens of the desmosome and hemidesmosome. The antigens that have been characterized besides Dsg3 and Dsg1 are members of the plak family of proteins that includes desmoplakin I and II, BP230, envoplakin, periplakin, and plectin. Removal of anti-Dsg3 autoantibodies from PNP sera abrogates the pathogenicity of the IgG fraction (Amagai et al., 1998). Affinity-purified anti-Dsg3 antibodies and monoclonal anti-Dsg3 antibodies derived from PNP patients (Saleh et al., 2012) are able to induce skin lesions in neonatal mice. Autoantibody-mediated disease may explain only part of the complex epithelial injury found in these patients. Other mechanisms of tissue injury that have been proposed are those of T cell-mediated cytotoxicity.

It has been proposed that the autoantibody response in PNP is primarily directed against tumor antigens that cross-react with epithelial structural proteins. Additionally the tumor may produce cytokines that modulate the autoimmune response. Interestingly, Wang et al. (2004) have demonstrated that tumor B cells are able to produce anti-epidermal antibodies. In those patients that receive rituximab, the B cell-mediated aspect of the disease, and, therefore, autoantibody detection, wanes. In these cases, the T cell-mediated aspect predominates and the disease takes on a distinct lichenoid pattern with absent or low PNP autoantibodies (Cummins et al., 2007).

The diagnosis of PNP is made clinically, histologically, and immunologically. By indirect IF, the serum of PNP patients typically stains rat bladder epithelium, which produces negative results when stained with the serum of PV or PF. Immunoprecipitation techniques using radiolabeled keratinocyte extracts reveal reactivity with the plak proteins.

Drug-induced Pemphigus

Certain drugs, particularly thiol-containing drugs, such as penicillamine and captopril, may induce clinical and histological features of PF, and less commonly PV. The majority of drug-induced pemphigus patients exhibit circulating autoantibodies to the epidermal ICS and epidermal-bound IgG. In cases of drug-induced PF, the autoantibodies recognize Dsg1. Some of these drugs have been shown to cause acantholysis *in vitro* directly. Drug-induced pemphigus may be transient and usually resolves upon withdrawal of the medication, although in rare cases the disease may run a chronic course. The mechanisms involved in the induction of the autoimmune response by drugs in pemphigus remain obscure (Brenner and Goldberg, 2011).

IgA Pemphigus

This variant of pemphigus is unique because of its clinical and histological phenotype. Clinically, the patients show superficial clusters of small vesicles and pustules, in some cases producing annular patterns. The Nikolsky sign is positive and the great majority of patients show no mucosal lesions. The histological features show, in addition to the acantholysis, an intense neutrophilic infiltrate in the epidermis. This infiltrate may be subcorneal (subcorneal pustular dermatosis type or SPD type) or located in the mid-epidermis (intraepidermal neutrophilic type or IEN type). The immunological hallmark of this form of pemphigus is the presence of IgA class autoantibodies directed to the epidermal ICS (like PV or PF). The antigen recognized in the SPD type has been shown to be another desmosomal cadherin, desmocollin 1, whereas for the IEN type, the target antigen appears to

be a non-desmosomal cell surface protein (Hashimoto, 2001). The pathogenic role of these IgA autoantibodies has not been demonstrated. Further, the intense neutrophilic infiltrate of the epidermis and a rapid response of the disease to dapsone (a neutrophilic-targeted drug) might indicate a unique IgA-mediated pathway of tissue damage (Tsuruta et al., 2011).

BULLOUS PEMPFIGOID

Clinical, Pathologic, and Epidemiologic Features

Bullous pemphigoid (BP) is the most common autoimmune bullous disease affecting the skin primarily (Lever, 1965). The incidence of disease is 7–14 cases per million per year in France, Germany, and Scotland (Bernard et al., 1995; Zillikens et al., 1995; Gudi et al., 2005). Recent studies suggest that the incidence may be as high as 43 cases per million per year in the United Kingdom (Langan et al., 2008). BP occurs most frequently in the elderly (60 to 80 years of age) and affects men and women equally. The skin lesions usually begin as urticarial plaques or erythematous papules, which evolve into large, tense bullae filled with clear fluid (Figure 65.2, right panel). Histological examination of these lesions shows detachment of the epidermis from the dermis, producing subepidermal blisters. The upper dermis exhibits an inflammatory infiltrate including eosinophils, neutrophils, lymphocytes, and monocytes/macrophages. The predominant inflammatory cells in early lesions are usually eosinophils and eosinophilic spongiosis may be present. Histological evidence of mast cell degranulation has also been reported.

Autoimmune Features

Autoantibodies

BP patients have circulating and tissue-bound IgG autoantibodies described by Jordon et al. (Jordon et al., 1967), which are directed against two hemidesmosomal proteins (Mutasim et al., 1985) known as the BP230 (BPAG1) and the BP180 (BPAG2, type XVII collagen) antigens (Jordon et al., 1967; Stanley et al., 1981; Labib et al., 1986). The autoantibodies in BP sera are predominantly of IgG1 and IgG4 subclasses (Laffitte et al., 2001). In addition to IgG autoantibodies, IgE autoantibodies to BP180 are found in the majority of untreated BP patients (Dimson et al., 2003). Only antibodies to BP180 have been demonstrated to be pathogenic in neonatal mice (Figure 65.3, right panel) (Liu et al., 1993).

The BP230 antigen is an intracellular hemidesmosomal plaque protein belonging to the plakin family

(Tanaka et al., 1991), whereas the BP180 antigen is a hemidesmosomal transmembrane protein belonging to the collagen family (Giudice et al., 1992). The BP180 protein shows a type II orientation, with its amino-terminal region toward the intracellular hemidesmosomal plaque and its carboxy-terminal half projecting into the extracellular milieu of the BMZ. The anti-BP180 autoantibodies from BP patients recognize multiple epitopes that cluster within the noncollagen 16A (NC16A) domain of the BP180 ectodomain (Giudice et al., 1993). It has been reported recently that the serum levels of autoantibodies to BP180 NC16A in patients are directly correlated to disease severity (Haase et al., 1998; Tsuji-Abe et al., 2005).

Intra- and intermolecular epitope spreading has also been reported in BP and may shape the course of individual disease (Di Zenzo et al., 2011).

T Cell Activation

It has been recently reported that BP180-specific autoreactive T cells recognize epitopes located predominantly on the NC16A domain of the molecule (Budinger et al., 1998; Lin et al., 2000b). These T lymphocytes express CD4 memory T cell surface markers and exhibit a Th1/Th2 mixed cytokine profile.

Genetic Features

Earlier HLA studies involving American, Japanese, and British BP patients showed no significant association between the disease and HLA-A, B, C, and DR loci, while a marked increase in the HLA-DR5 allele was found in BP patients from France. Recent studies have demonstrated that HLA-DQB1*0301 is associated with Caucasian BP (Delgado et al., 1996), whereas DRB1*0403, 0406 or DRB1*1101 has high frequency in Japanese BP (Okazaki et al., 2000).

In Vivo and In Vitro Models

Early studies on passive transfer of human BP IgG containing anti-BP180 and anti-BP230 autoantibodies to neonatal mice were unsuccessful. It was found later that the murine BP180 protein did not react with human anti-BP180 antibodies largely due to differences at the amino acid level of the NC16A domain of the molecule. This problem was overcome by raising rabbit antibodies against a segment of murine BP180 homologous to the human epitope. It was demonstrated that these anti-BP180 antibodies were pathogenic if passively transferred into neonatal mice. The animals recapitulate the key clinical and histological features of the human disease (Figure 65.3, right panel) (Liu et al., 1993).

In contrast to PV and PF mouse models, the subepidermal blistering in mice induced by anti-BP180 antibodies depends on complement activation and a subsequent cascade of inflammatory events including mast cell degranulation and neutrophil infiltration. Proteolytic enzymes released from recruited neutrophils are the final effector molecules that cause the epidermal–dermal separation seen in skin lesions (Liu, 2004).

To directly test the pathogenicity of anti-BP180 IgG autoantibodies from BP patients, humanized BP180 mice were generated which harbor the human BP180 or NC16A domain in place of the murine protein (Nishie et al., 2007; Liu et al., 2008). Injection of anti-BP180 IgG into these humanized mice leads to subepidermal blister formation in a process dependent on complement, mast cells, and neutrophils (Nishie et al., 2007; Liu et al., 2008).

IgE purified from BP patient sera was also shown to be pathogenic upon passive transfer into athymic nude mice with human skin grafts. The human skin grafts developed urticarial plaques and subepidermal splitting at higher doses (Fairley et al., 2007).

Pathologic Effector Mechanisms

As opposed to the pemphigus group where the autoantibodies directly induce blister formation, bullous pemphigoid is the result of autoantibody deposition leading to a complex inflammatory cascade. In addition to autoantibody deposition at the basement membrane zone, inflammatory cells are present in the upper dermis and bullous cavity, including both intact and degranulating eosinophils, neutrophils, and mast cells (Wintroub et al., 1978; Dvorak et al., 1982; Czech et al., 1993; Borrego et al., 1996). Proteinases including plasmin, MMP-9, collagenase, and elastase are present in blister fluid and lead to blister formation by their ability to degrade BP180 and other extracellular matrix proteins (Ujiiie et al., 2011).

Autoantibodies as Potential Immunologic Markers

Detection of anti-BP180 autoantibodies by DIF, indirect IF, and/or ELISA is critical for the diagnosis of BP. However, a recent study of 337 patients with various non-BP dermatologic disorders suggests that 4% of individuals without BP show a low positive level of anti-BP180 by ELISA. The relevance of anti-BP180 autoantibodies in these patients is unclear (Wieland et al., 2010).

OTHER SUBEPIDERMAL BULLOUS DISEASES

Herpes Gestationis (Pemphigoid Gestationis)

Herpes gestationis (HG), also known as pemphigoid gestationis (PG), is a variant of BP affecting pregnant women primarily. The incidence is about one in 50,000 pregnancies. The disease usually develops during the second or third trimester of pregnancy or in the immediate postpartum period. HG has rarely been associated with underlying trophoblastic tumors. Similarly to BP, HG patients develop subepidermal blisters and linear deposition of C3 at the BMZ (Provost and Tomasi, 1973). The sera of these patients are usually negative by conventional indirect IF assays but become positive when complement fixation to the skin is assayed (HG factor) (Provost and Tomasi, 1973). The HG factor was found to be a complement fixing autoantibody against the BP180 antigen (Jordon et al., 1976; Katz et al., 1976; Morrison et al., 1988; Giudice et al., 1993). This autoantibody is predominantly IgG1 and recognizes the same epitope (within the BP180 NC16A domain) as do BP autoantibodies. BP180-specific T cells also recognize the BP180 NC16A and express a CD4⁺ Th1 memory phenotype (Lin et al., 1999). Like BP, HG is also associated with DQB1*0301. The mechanism of autoimmunity in HG and the role of pregnancy are not fully understood.

Cicatricial Pemphigoid

Cicatricial pemphigoid (CP), also known as mucous membrane pemphigoid, is a group of heterogeneous diseases characterized by subepithelial blistering involving mucous membranes exclusively (Korman and Cooper, 2000). The oral and ocular surfaces are most commonly involved, while skin lesions occur only in one-third of CP patients. A striking clinical feature of CP is that healing of the lesions leads to scarring and dysfunction of the affected organs. For example, ocular involvement may cause blindness due to corneal scarring and fibrosis. Direct IF reveals linear deposition of IgG, IgA, or C3 along the epithelial BMZ (Egan et al., 2003). CP is also associated with DQB1*0301 (Delgado et al., 1996).

The majority of CP patients show circulating IgG autoantibodies against BP180 antigen (Balding et al., 1996). Some of these CP autoantibodies recognize the C-terminal domain of BP180, which is different from BP. A subset of CP patients exhibits circulating autoantibodies against laminin 5 (epiligrin), also known as epiligrin (Domloge-Hultsch et al., 1994; Egan et al., 1999). Experimentally, it was shown that anti-laminin 5 antibodies are able to induce subepidermal blisters in neonatal

mice (Lazarova et al., 1996). There appears to be a relationship of anti-laminin 5 with underlying malignancy (Egan et al., 2003). Many patients with ocular involvement have autoantibodies against $\alpha 6\beta 4$ integrin (Tyagi et al., 1996). The pathogenic role of the various autoantibodies found in CP and their link to scarring remain to be elucidated.

Linear IgA Disease

Linear IgA disease (LAD) is a subepidermal blistering disorder characterized by pruritic lesions and linear deposition of IgA autoantibodies at the BMZ (Nemzer et al., 2000). Mucosal membrane involvement is common (60–80%). LAD can be subdivided into adult-onset, childhood-onset, and drug-induced LAD (Zone et al., 2004). The histology of lesional and perilesional skin reveals subepidermal vesicles with neutrophilic infiltration along the BMZ and in the superficial dermis.

IgA autoantibodies in LAD serum react with multiple antigenic peptides derived from the BP180 ectodomain. The most common antigenic peptides for the major type of LAD (lamina lucida type), detected by immunoblotting using epidermal extracts, are the 97-kDa protein (LABD97) and the 120-kDa antigens (LAD-1), which are considered to be the proteolytic fragments of the BP180 polypeptide (Zone et al., 2004). These findings suggest that the majority of LAD autoantibodies recognize epitopes on LABD97 and LAD-1, which are different from those bound by BP autoantibodies on the intact BP180 molecule.

Epidermolysis Bullosa Acquisita

Epidermolysis bullosa acquisita (EBA) is an acquired subepithelial blistering disease of the skin and mucous membranes mediated by IgG autoantibodies against type VII collagen (O'Toole and Woodley, 2000). Lesions occur predominantly on areas of trauma and often heal with scarring, like CP. Subepidermal blisters are formed as a result of detachment of the epidermis at the level of the sublamina densa area as demonstrated by ultrastructural studies (Figure 65.1). EBA is associated with HLA-DR2 (Gammon et al., 1988).

The target antigen of EBA is type VII collagen (C-VII), which is confined to anchoring fibrils of the sublamina densa region of the skin. EBA autoantibodies react with four major epitopes within the amino-terminal non-collagenous NC1 domain of C-VII. It is hypothesized that binding of these autoantibodies may interfere with dimer formation of the C-VII molecule or may impair the association of C-VII with its ligands, laminin 5 and fibronectin. It has also been suggested that complement activation by

the autoantibodies induces inflammation and blistering. Rabbit anti-human type VII collagen NC1 domain IgG induced EBA-like lesions in adult hairless mice and nude mice bearing human skin grafts (Chen et al., (2004)). Furthermore, rabbit antibodies specific to a murine portion of type VII collagen induced subepidermal blistering when passively transferred into adult mice, thereby reproducing the clinical, histological, and immunopathological features of human disease in a complement-dependent fashion (Sitaru et al., 2005).

Dermatitis Herpetiformis

Dermatitis herpetiformis (DH) is an IgA-mediated skin blistering disease characterized by intensive pruritic erythematous papules and vesicles symmetrically distributed over extensor surfaces (Bagheri and Hall, 2000). The skin rash is gluten dependent and responsive to gluten-free diet. Skin biopsies from DH lesions show a characteristic neutrophilic infiltration in the upper dermis involving the dermal papillae. Perilesional and normal skin in DH show a granular deposition of IgA along the BMZ. Recently it has been shown that DH patients possess in their sera IgA autoantibodies that recognize epidermal transglutaminase (Sardy et al., 2002). It is unknown if these anti-transglutaminase autoantibodies are pathogenic or an epiphenomenon, but the autoantibodies can be used as a sensitive serologic marker for DH. A remarkable feature of DH is its high association with celiac disease (CD), another IgA-mediated gluten-sensitive (GSE) disorder involving the small intestine. Patients with DH and GSE share an increased expression of the HLA-A1, HLA-B8, HLA-DR3, and HLA-DQA1*0505 and DQB1*02 genes (Sollid, 2000) and a humoral response to transglutaminases. Both diseases are exacerbated by the intake of gluten-containing food. The mechanisms of gluten-induced autoimmunity and the relationship of the IgA autoantibody response to transglutaminase in DH remain unclear.

TREATMENT OF AUTOIMMUNE BULLOUS DISEASES

The aim of the therapy in all autoimmune blistering diseases of the skin is to abrogate the pathogenic autoantibodies and to decrease the tissue inflammatory response triggered by some of these antibodies. Elimination of pathogenic autoantibodies from the patient is accomplished by immunosuppression or plasmapheresis. The inflammatory response in the skin may be modulated by using topical or systemic steroids or drugs that are known to impair the effector function of neutrophils such as dapsone. It is understood that systemic steroids may modulate

the production of antibody and also benefit the local inflammatory response in the skin.

Systemic corticosteroids are the first line of therapy for patients with all clinical forms of pemphigus and pemphigoid. Doses of prednisone in the range of 1.0 mg/kg q.a.m. are used initially. If patients continue to develop new lesions, the dose of prednisone can be increased incrementally to 2.0 mg/kg; however, in our practice we rarely exceed a total prednisone dose of 100 mg q.d. The use of azathioprine, cyclophosphamide, methotrexate, or mycophenolate mofetil, as adjunctive therapy, is beneficial in controlling the disease of these patients. The use of these drugs enhances the chances of inducing a prolonged remission of the disease. They are excellent steroid sparing agents. The patients must be fully evaluated clinically and tested to reveal hematological, renal, and liver function parameters. The doses and side effects for any of these drugs are described in detail in dermatological textbooks. The mortality rate for patients with pemphigus has been reduced to less than 10%; however, these patients are prone to develop severe complications of the therapy, e.g., osteoporosis, diabetes, hypertension, and obesity.

It is well documented that some patients are “resistant” to all these therapeutic modalities. These rare patients may benefit from the use of plasmapheresis or parenteral infusions of human immunoglobulin. Recently, therapy with anti-CD20 humanized monoclonal antibodies has been shown to induce clinical and serological remissions in severe cases of pemphigus.

Dapsone is the drug of choice in dermatitis herpetiformis (DH); it exerts its anti-inflammatory effects by direct action on the neutrophil by interfering with the myeloperoxidase–hydrogen peroxide–halide-mediated cytotoxic system in neutrophils. Dapsone can cause hemolysis and methemoglobinemia; therefore, it is mandatory to assay the levels of the enzyme glucose 6-phosphate dehydrogenase (G6PD) prior to beginning dapsone as G6PD deficient patients may experience severe hemolysis. There are other side effects of dapsone such as hepatitis and thrombocytopenia that may need to be monitored. Not only patients with DH, but also those with LAD, IgA pemphigus show a remarkable clinical response to dapsone. These diseases may be kept in remission with small doses of dapsone. Additionally, CP and certain cases of BP might respond favorably to dapsone as well.

The therapy for patients with EBA is limited since most of the drugs used to control other autoimmune blistering diseases do not change the course of the disease in most patients. The use of systemic steroids, immunosuppressive drugs, or dapsone may be individualized in each patient. Removal of underlying malignancy, steroids, immunosuppressive drugs, and supportive therapy has

been attempted in PNP patients. The prognosis of these patients, however, is poor.

CONCLUDING REMARKS

The autoimmune blistering disorders represent classic antibody-mediated organ-specific autoimmune diseases that can serve as models for understanding the development and pathogenesis of antibody-mediated autoimmune disease in general. New treatments continue to emerge based on our current understanding of disease pathogenesis. Furthermore, unique disease responses to some of these treatments have led investigators back to the bench to further explore the immunologic aberrations present in these patients.

ALOPECIA AREATA

Clinical, Pathologic, and Epidemiologic Features

Alopecia areata (AA) is perhaps the most common autoimmune disease, affecting 5.3 million Americans including males and females across all ethnic groups (Petukhova et al., 2011), with a lifetime risk of 1.7% (Safavi et al., 1995). The most common presentation of AA is reversible loss of one or a few patches of hair called transient alopecia areata (TAA). More extensive persistent hair loss is classified as patchy persistent alopecia areata (PPAA) (Figure 66.1). Loss of all hair of the scalp is called alopecia totalis (AT), and loss of all scalp and body hair is termed alopecia universalis

(AU). Loss of hair localized to the retroauricular area and occipital areas is called ophiasis, and has a poor prognosis. Onset early in life, severe and long-lasting course (Chu et al., 2011), extensive disease, and associated nail dystrophy (pits, ridges, or trachonychia), also indicate poor prognosis.

In AA a mononuclear cell inflammatory infiltrate attacks the hair follicle (HF) bulb, the factory which produces the hair shaft. T cell cytokines and cytotoxic T cells produce cytotoxic damage (Whiting, 2003) and disrupt the normal function of the HF. This leads to production of thin, fragile hairs, which easily break off or detach from the follicle and fall out. Since the hairs which fall out in AA are in actively growing anagen follicles, AA is classified as a form of anagen effluvium.

FIGURE 66.1 Patchy persistent, extensive alopecia areata.

Alopecia areata is commonly associated with atopy, especially in severe forms, where the incidence of atopy may be 50% or more (Barahmani et al., 2009). AA is highly associated with other autoimmune diseases, the most common being hypothyroidism, especially autoimmune thyroiditis (Goh et al., 2006). Because the immune damage is localized to the hair bulb, the stem cell populations are preserved and normal cycling HF can be regenerated, and regrowth of the hair can occur even years after total hair loss.

Autoimmune Features

There are multiple observations supporting the concept that AA is an autoimmune disease:

1. AA HFs are surrounded by an immune infiltrate of activated T helper(h) cells, cytotoxic T cells and natural killer (NK) cells, and a Th1-type cytokine profile (Petukhova et al., 2011).
2. The target of the immune response in AA appears to be the pigmented anagen HF. Anagen is the growing phase of the hair cycle. Neither resting HFs (telogen phase) nor white hair-containing follicles are affected in AA.
3. Autoantibodies are common both in human AA and in the C3H/HeJ mouse model of AA, and their specificities are quite different from the antibody specificities in human vitiligo (Cui et al., 1992; Tobin et al., 1997) where melanocytes are the targets. Antibodies in the C3H/HeJ mouse and in human AA appear to react to

proteins of 40–46 kDa, possibly HF-specific keratins (Tobin et al., 1997). Other candidate targets are trichohyalin, an HF keratin-associated protein, and keratin 16 (Tobin, 2003; Leung et al., 2010). Attempts to identify antibodies specific for HF melanocytes have not been successful.

4. Autoreactive T cells and NK cells are necessary for hair loss in AA, as demonstrated in a xenograft model in which hair-bearing skin from AA patients is grafted onto the severe combined immunodeficiency (SCID) mouse. This is followed by injection into the graft of leukocytes from the AA patient stimulated *in vitro* with various melanocyte antigens (Gilhar et al., 1998). In this model CD4⁺ and CD8⁺ T lymphocytes transferred the disease after they were primed *in vitro* by the melanocyte antigens gp100, MART-1, or tyrosinase (Gilhar et al., 2001). In a recent update of this model, leukocytes from AA patients are first stimulated with IL-2 (not melanocyte antigens), producing hair loss dependent on NK cells, CD8⁺NG2D⁺, and CD8⁺CD56⁺ cells (Gilhar et al., 2012, 2013).
5. CD8⁺ T cells are necessary for local HF cytotoxicity, while CD4⁺CD25⁺ T cells can transfer the disease systemically in the C3H/HeJ mouse (McElwee et al., 2005).
6. The adhesion pair Cadm-1/CRTAM-1 appears to be necessary to mediate CD8⁺ T cell cytotoxicity in AA. Cadm-1 is expressed by epidermal cells and mediates heterotypic adhesion to lymphocytes expressing the class 1-restricted T cell-associated molecule (CRTAM). Overexpression of Cadm-1 in a mouse model of alopecia

increased the progression of alopecia (Giangreco et al., 2012).

- It has been hypothesized that low expression of class I and II MHC molecules in the HF, together with local expression of potent immunosuppressants, maintains a state of immune privilege of HF, in which the cytotoxic immune attack on the HF is suppressed (Ito et al., 2008). Several reports indicated that AA occurs because of the breakdown in this immune privilege in the follicle (Paus et al., 2003; Ito et al., 2008; Kang et al., 2010). According to this hypothesis, proinflammatory signals such as interferon (IFN)- γ and substance P cause upregulation of class I MHC molecules and allow the presentation of previously sequestered HF antigens to preexisting autoreactive CD8⁺ T cells. Costimulatory signals from CD4⁺ T cells and mast cells also facilitate the attack of lymphocytic infiltrates on the HF (Gilhar et al., 2012).

Genetic Features

As the approaches to studying the genetics of AA have broadened from observed heritability in first-degree relatives, twin studies, and family-based linkage studies (Martinez-Mir et al., 2007), to genome-wide association studies or deep sequencing of key areas of the genome, it has been increasingly clear that genetic control of innate and acquired immunity is the most powerful factor in determining the susceptibility to all variants of AA, from patchy disease to alopecia universalis. The two GWAS studies performed in AA to date (Petukhova et al., 2010; Jagielska et al., 2012) provided compelling evidence for the implication of numerous individual genes, most of them with immune function, and have established the major determinants of autoimmunity in AA (Table 66.1) (Petukhova et al., 2010).

In Vivo and In Vitro Models

Since AA is a complex immune process attacking the human anagen HF, and since the exact targets of autoimmune damage are not known, *in vitro* experiments based on single cell populations have not been very useful. However, both naturally occurring and engineered animal models have been extremely useful in defining disease mechanisms in AA, in identifying potential drug targets, and more recently, in testing new drugs for future use in human experimentation.

The C3H/HeJ mouse has been an indispensable tool in defining the immunoregulatory AA genes (Sundberg et al., 2004). As in humans, the alopecia developed in these mice is strongly IFN- γ and IL-2 dependent (Freyschmidt-Paul et al., 2005) and is characterized by a diffuse inflammatory hair loss, which closely mimics in terms of histology, gene

TABLE 66.1 Alopecia Areata Major Susceptibility Genes with Role in Innate or Acquired Immunity

| Mechanism | Genes |
|-------------------------------|--|
| Innate Immunity | |
| NK cell activation | NKG2D ligands: <i>ULBP6</i> , <i>ULBP3</i> , <i>MICA</i> |
| Cytokine | <i>IL-2</i> , <i>IL-21</i> , <i>IL2RA</i> |
| Acquired Immunity | |
| Antigen presentation | <i>HLA-DRA</i> , <i>HLA-DQA1</i> , <i>HLA-DQA2</i> , <i>HLA-DQB2</i> , <i>HLA-DOB9</i> |
| T cell proliferation | <i>CTLA4</i> , <i>ICOS</i> , <i>IL-21</i> , <i>IL-2</i> , <i>IL2RA</i> , <i>IKZF4</i> , <i>BTNL2</i> |

| Premature graying | <i>STX17</i> |
| With supposed immune function | <i>KIAA0350/CLEC16A</i> |

expression, and response to treatment, the human disease AA. The AA phenotype could be adoptively transferred to a whole colony of other syngeneic C3H/HeJ mice by transplanting involved alopecic skin, providing the ability to synchronize AA development in large cohorts of mice, and an exciting basic and clinical research platform (Sun et al., 2008). Newer engineered mouse models promise to validate T cell and NK cell roles in AA pathogenesis (Alli et al., 2012; Gilhar et al., 2012).

The xenograft mouse model using hairy skin from AA patients and autologous PBMC sensitized *in vitro* has already been described in a review by Gilhar et al. (Gilhar et al., 1998). This model has been instrumental in showing that melanocyte-specific CD4⁺, CD8⁺, and NK cells are effectors of hair loss in AA.

Pathologic Effector Mechanisms

At the recent AA Research Summit “From Basepairs to Bedside: Innovations in the Immunology and Clinical Science of Alopecia Areata,” Raphael Clynes and Angela Christiano presented their recent investigations on the inflammatory cascade in AA. As summarized in Table 66.2, the effector cascade in AA encompasses danger signals, NK/innate immune first responders, APC/Sentinel presentation of HF antigens and adaptive responses dependent on the interplay of multiple T and B cell populations, and a complex cytokine network (Petukhova et al., 2011). Their studies on gene expression in AA lesions show that 16 of the top 20 signals are IFN- γ response genes.

TABLE 66.2 Inflammatory Response Underlying Alopecia Areata

| Type of Response | Cells and Signaling Molecules |
|-----------------------|---|
| Innate/NKG2D response | Alarms: hair follicle TNF- α , IL-15, IFN- γ , MICA, UBLP-3, UBLP-6, Rae-1 First responders: DETC, NK, NKT, γ /8T |
| APC/Sentinel | Cellular sentinels: Langerhans cells, dermal dendritic cells, dermal macrophage, mast cells Determinants: HLA, TAP, IFN- γ |
| Adaptive immunity | Immune cells: CD4 ⁺ T cells, CD8 ⁺ T cells, Tregs, B cells, CTLA4, iCOS, IL-2, IL-2R, IL-21 Cytokine network: IL-2, IL-6, IL-17, IL-21, IFN- γ , IFN- α Downstream signaling pathways: Jak 1/2, Syk |

Autoantibodies as Potential Immunologic Markers

To date, no widely accepted or validated antibody markers in AA have been identified. Research is under way to use validated techniques to identify and quantitate autoantibodies in AA.

autoimmune diseases are being developed: anti-CTLA4, anti-Jak {1/2}, anti-Syk, anti-IL-15, anti-NKG2D (Colonna et al., 2010; Petukhova et al., 2011).

It is unknown whether it is necessary to purposefully reactivate affected HF in AA.

Future research programs will determine the effectiveness of direct HF stimuli to reactivate hair growth in AA.

Concluding Remarks— Future Prospects

It is widely accepted that current treatments for AA are inadequate. As stated in a recent Cochrane review, “There is no good trial evidence that any treatments provide long-term benefit to patients with alopecia areata, Totalis and universalis” (Delamere et al., 2008). Initial studies of biologics that are highly effective in psoriasis were stunningly unsuccessful in AA. The National Alopecia Areata Foundation (NAAF) has organized a program to develop and test new treatments in AA. This includes an intensive effort to design and validate a uniform clinical research platform for testing effectiveness of new treatments. Multiple new approaches using drugs effective in other

VITILIGO

Clinical, Pathologic, and Epidemiologic Features

Vitiligo is the most common acquired type of leukoderma, causing significant social and psychological difficulties in people with darker skin phototypes. The hallmark of the disease is the white patch with well-defined borders, affecting the skin and mucous membranes (Birlea et al., 2012). Based on the lesions’ distribution, extension and number, the disease is divided into non-segmental vitiligo (NSV), segmental vitiligo (SV), mixed, and unclassified (Taieb et al., 2013) (Table 66.3). In general,

TABLE 66.3 Classification of Vitiligo

| Types and Subtypes of Disease | Features |
|----------------------------------|--|
| 1. Non-segmental vitiligo (NSV) | |
| 1.1. Generalized/vulgaris | Presents as multiple scattered lesions over the body |
| 1.2. Acrofacial | Begins typically on the fingers and feet and around facial orifices |
| 1.3. Universalis | Depigmentation over the whole body |
| 2. Segmental vitiligo (SV) | |
| 2.1. Uni/pluri-segmental | Follows a dermatomal distribution; stops at the midline; most common type in childhood |
| 2.2. Focal | |
| 2.3. Mucosal | One/few macules in one site. Lesions on multiple sites |
| 3. Mixed | NSV + SV |
| 4. Unclassified | |
| 4.1. Focal | At onset; an earlier stage of generalized type |
| 4.2. Multifocal asymmetrical NSV | Becomes generalized/mixed over time |
| 4.3. Mucosal | Lesions on one site |

Modified from Taieb et al., 2012

NSV is characterized by symmetrical depigmentation (Figure 66.2) with earlier onset and progression over time. SV is characterized by a unilateral distribution that may be dermatomal, rapid in onset, and with involvement of both epidermal and hair follicle (HF) melanocytes (Taieb et al., 2013). Vitiligo often occurs in a photodistribution, and commonly affects body folds and periorificial areas. The most common triggers include sunburn, physical trauma, repeated rubbing of the skin (so-called Koebner phenomenon), psychological stress, and pregnancy. The clinical course of vitiligo is unpredictable; in general, NSV is gradually progressive, while most SV cases rapidly stabilize.

In atypical cases of vitiligo, pathologic exam of lesional skin is necessary to confirm the diagnosis. It shows an epidermal basal layer completely devoid of melanocytes in the center of the lesions (Le Poole et al., 1993a); cells expressing melanocyte markers are sometimes observed at the margins of lesions. In early vitiligo or in episodes of progression, the dermis at the margin of lesions may contain sparse perivascular and perifollicular infiltrates, consistent with cell-mediated immune processes destroying melanocytes *in situ* (Kim et al., 2008).

Vitiligo affects all races and geographic areas with a frequency of 0.3–0.5% (Birlea et al., 2012). Generalized vitiligo (GV), the most common subtype, occurs with equal frequency in males and females and may manifest at any time in life, with the average age of onset of 24 years (Spritz, 2010).

FIGURE 66.2 Generalized symmetric vitiligo of the anterior forearms with perifollicular repigmentation process (brown dots).

Autoimmune Features

Several clinical and experimental observations support the autoimmune basis of vitiligo:

1. In GV subjects of white European ancestry there is a 15–25% incidence of at least one additional concomitant autoimmune disease, particularly autoimmune thyroid disease, pernicious anemia, rheumatoid arthritis, psoriasis, type 1 diabetes, Addison's disease, or systemic lupus erythematosus. These diseases also occur at increased frequencies in first-degree relatives of patients with GV (Spritz, 2010), indicating a heritable autoimmune diathesis in vitiligo. In contrast with GV, in SV the occurrence of other autoimmune diseases is uncommon (el-Mofty and el-Mofty, 1980; Koga and Tango, 1988; Park et al., 1988).
2. Circulating anti-melanocyte antibodies (anti-tyrosinase, anti-tyrosinase-related protein-1, anti-dopachrome tautomerase) have been described in GV. Vitiligo antibodies were initially described by immunoprecipitation studies using melanoma cell extracts; they were most commonly directed against antigens with molecular weights of 35, 40–45, 75, 90, and 150 kDa; the antigens of 35 and 90 kDa were preferentially expressed on melanocytes (Cui et al., 1992). Antigens of 45, 65, and 110 kDa have been identified in immunoblotting studies with melanocyte extracts (Hann et al., 1996b; Park et al., 1996), while vitiligo-associated antibodies have been demonstrated to recognize melanoma cell proteins of 68, 70, 88, 90, 110, and 165 kDa (Hann et al., 1996a; Rocha et al., 2002). Other vitiligo-associated antibody targets have been reported (lamin A, MCHR-1, PM-17, SOX-9, SOX-10, tyrosine hydroxylase).
3. The presence of circulating skin-homing cytotoxic T cells (T_c) (Ogg et al., 1998) and infiltrates containing activated cytotoxic T cells and macrophages was described at the margins of active vitiligo lesions (Gross et al., 1987; Badri et al., 1993a, Le Poole et al., 1993b, 1996). The T_c were shown to target melanocyte-specific antigens [including Melan-A (MART-1), gp100 (Pmel17) and tyrosinase] (Ogg et al., 1998; Lang et al., 2001; Palermo et al., 2001) and to express high levels of the skin-homing receptor cutaneous lymphocyte-associated antigen (CLA). The frequency of T_c correlated with both the extent and activity of the disease (Lang et al., 2001). In progressive disease, the CD4/CD8 ratio was reported decreased among skin-infiltrating T cells, which exhibited a predominant Th1 cytokine secretion profile (Wankowicz-Kalinska et al., 2003). It is accepted that skin-homing, autoreactive, melanocyte-specific T cells cause melanocyte destruction in vitiligo, and that regulatory cells ineffectively restrain autoreactive T cells in GV (Klarquist et al., 2010).

4. Recent evidence suggests that immune responses may also contribute to the pathogenesis of SV, in which the melanocyte loss, which remains more localized, seems to be related to a lymphocytic infiltrate of interferon- γ -producing CD8⁺ and of some CD4⁺ T cells found at the lesional margin of early stages, similar to those observed in GV (van Geel et al., 2011).
5. An immune mechanism in vitiligo was also implied by experimental observations in occupational vitiligo (Manga et al., 2006). So-called chemical leukoderma can initially occur on upper extremities of subjects coming in contact with cleaning solutions containing phenolic compounds (like 4-tertiary butyl phenol). It was hypothesized that these agents are directly toxic to melanocytes, in the context of a possible genetic susceptibility of patients' melanocytes to chemical injuries, which can lead to melanocyte death, release of intracellular proteins, and subsequent autoimmunity.
6. Vitiligo-like depigmentation occurring during interleukin-2 immunotherapy for malignant melanoma was proposed to follow an autoimmune mechanism. Since some melanoma-associated antigens (such as MART-1, gp100, and tyrosinase) are shared by normal melanocytes and melanoma, the onset of vitiligo suggests that the cytotoxic T cells activated by IL-2 (Feliciani et al., 1996; Verheyen et al., 2001) can also attack normal tissue (Phan et al., 2001), producing vitiligo-like depigmentation.
7. Lymphocyte-mediated destruction of melanocytes can occur in other non-vitiligo scenarios: (a) intratumor depigmentation during melanoma regression; (b) leukoderma acquisitum centrifugum around melanoma and nevi (the latter defining the "halo nevi" phenomenon), and (c) vitiligo-like depigmentation, observed at distant sites from primary melanoma (Birlea et al., 2012).
8. Immunosuppressive drugs may induce repigmentation in vitiligo. As such, topical calcineurin inhibitors (tacrolimus or pimecrolimus) are first-line therapy in vitiligo and exert an immunosuppressive effect on T cells, by blocking the action of the cytokine gene-activating cofactor calcineurin (Homey et al., 1998; Boone et al., 2007; Hartmann et al., 2008; Kemp et al., 2011). Topical corticosteroids have anti-inflammatory and immunosuppressive effects and are recommended typically in children and adults with SV or NSV of recent onset (Abu Tahir et al., 2010; Gawkrödger et al., 2010). Systemic corticosteroids, which represent a second-line alternative, can halt the progression of the rapid-spreading vitiligo. Unfortunately, well-established depigmented vitiligo lesions often do not repigment in response to immunosuppressives or corticosteroids. In these

circumstances, was ultraviolet light-based therapies are necessary to trigger repigmentation (Figure 66.2), through a regenerative process involving hair follicle melanocyte precursors (Birlea et al., 2012).

Genetic Features

Epidemiologic studies showed that 15–20% of vitiligo patients have one or more affected first-degree relatives, although most vitiligo cases occur sporadically. A single-locus Mendelian pattern of transmission was not supported for vitiligo. Most reports favored a polygenic, multifactorial model involving multiple genes and also environmental risk factors, features that define a "complex trait" (Spritz, 2011). In addition to the genetic factors, a considerable effect of non-genetic, environmental triggers has been implicated by the observation of a low concordance rate of 23% in monozygotic twins (Alkhateeb et al., 2003). Different earlier approaches, like candidate gene association studies (Birlea et al., 2011) or genome-wide linkage studies (Spritz, 2011), tested the involvement of susceptibility genes in vitiligo pathogenesis, some of which could not be confirmed to date. More successful in gene identification were the genome-wide association studies applied more recently; they have produced a rich yield of validated GV susceptibility genes that encode components of biological pathways reaching from immune cells to the melanocyte (Birlea et al., 2010, 2013; Jin et al., 2010a,b, 2012a; Quan et al., 2010). Among the most informative signals in Caucasians (Jin et al., 2010a) were those within MHC class I single nucleotide polymorphisms (SNP) rs12206499 which tags the HLA-A*02a marker that was associated with a favorable response to melanoma therapy. Also significant, and within the *TYR* gene locus, was the R402Q polymorphism which is associated with susceptibility to malignant melanoma (Spritz, 2011). Currently, the corresponding underlying causal variants for the two above-mentioned signals have already been identified by next generation resequencing (Jin et al., 2012b).

In Vivo and *In Vitro* Models

Several animal models of naturally occurring vitiligo (the Smyth line chicken, the gray horse, the vitiligo mouse, and the Sinclair pig) were identified and described (Boissy and Lamoreux, 1988). Of these, the Smyth line chicken continues to be studied extensively because it recapitulates the entire spectrum of clinical and biological manifestations of the human disease (mainly an inherent defect in the melanocytes in feathers and ocular tissue, and an associated autoimmune response that eliminates

pigment cells). Recently, a new spontaneous mouse model for autoimmune vitiligo was created by introducing a human T cell receptor to human tyrosinase (h3T) into mice, combined with transgenic expression of the associated human HLA-A*0201 molecule (Mehrotra et al., 2012; Mosenson et al., 2013). The ensuing h3TA2 mice develop rapid, symmetrical, and progressive depigmentation of the pelage during adolescence.

Research in vitiligo using *in vitro* models has greatly advanced over the past two decades, providing a range of methodological options to study discrete mechanistic questions, as cited by Dell'anna et al. (2012):

1. Histological, immunofluorescence, and molecular techniques to test the destruction of melanocyte in vitiligo, and the migration of melanocytes to the interfollicular epidermis during vitiligo repigmentation.
2. Monolayer cell culture studies from vitiligo skin to characterize the response of vitiligo melanocytes to various pharmacological agents, and to study melanocyte differential susceptibility to noxious stimuli (UVB, cumene, hydrogen peroxide, and tert-butyl-phenol).
3. Three-dimensional skin models, like reconstructed epidermis with keratinocytes and melanocytes on dead de-epidermized dermis (DDD) offer the possibility of reproducing the epidermal melanin unit.
4. Analysis of peripheral blood mononuclear cells (PBMC) in vitiligo consists in characterization of the immunological status of such cells, their ability to recognize specific melanocyte antigens, their cytotoxic effects to melanocytes or melanoma cell lines, and their redox status and responses to DNA damage.
5. Computer simulation models where structural and functional features can be reproduced to define better the sequence of events that possibly lead to functional defects.
6. Fluorescence-based assays, like microscopy and flow cytometry, represent easy methods to study some functional parameters and cell morphology.

Pathogenetic Mechanism

One of the most important factors in vitiligo pathogenesis is the unique nature of the human melanocyte as a target of cytotoxic damage. Melanocytes are factories for melanin, a heterogeneous protein product that absorbs light over a broad range of wavelengths. The melanization apparatus is enclosed in the melanosome, an organelle that separates the toxic intermediates of melanization from the cytoplasm of melanocytes. These melanocytes are transferred to surrounding keratinocytes to produce an intact pigment network. Melanocytes are terminally differentiated cells of neuroendocrine lineage. They have limited regenerative capacity and are highly resistant to

apoptotic cell death because of high expression of Bcl-2, Bcl-X, and Mcl-1 (Bowen et al., 2003). As discussed in the “Autoimmune features” section, melanocyte-specific Tc can cause the progressive depigmentation seen in vitiligo (van den Boorn et al., 2009). Moreover, vitiligo-associated antibodies are able to destroy melanocytes and melanoma cells *in vitro* and *in vivo* by complement-mediated damage and antibody-dependent cellular cytotoxicity (Fishman et al., 1993; Gilhar et al., 1995; Norris et al., 1998a; Gottumukkala et al., 2006). However, the current opinion is that these autoantibodies reflect a humoral response secondary to melanocyte destruction, rather than a primary cause of GV (Kemp, 2007). There is also extensive evidence that other mechanisms participate in the development and progression of disease, and in the induction of autoimmunity (Le Poole et al., 1993a; Norris et al., 1994). *In vitro* studies have connected cellular oxidative stress (Schallreuter et al., 1991, 2001, 2005; Dell'anna and Picardo, 2006) with the immune response in vitiligo: stressed melanocytes were found to mediate dendritic cell activation with the consequent dendritic cell effector functions playing a role in the destruction of melanocytes (Kroll et al., 2005). These experimental observations suggest that, like other autoimmune diseases, intrinsic damage to melanocytes could be the initiating event in vitiligo, followed by a secondary immune response by Tc lymphocytes which exacerbates the destruction of melanocytes (Le Poole and Luiten, 2008; Hariharan et al., 2010; van den Boorn et al., 2011).

The observation that depigmented lesions develop at a site previously exposed to a physical trauma (Le Poole and Luiten, 2008) suggests that immune response follows melanocyte damage. Cryptic epitopes of several vitiligo-associated intracellular melanocyte autoantigens such as tyrosinase and gp100 could be released during apoptosis and lead to T cell activation (Namazi, 2007; Westerhof and d'Ischia, 2007; Kemp et al., 2011). Antibodies could then be produced following the stimulation of B lymphocytes by activated helper T cells (Namazi, 2007); activated Tc could directly attack melanocytes that express antigenic peptides on their surface in the context of MHC class I molecules (Le Poole et al., 1993b; Hedley et al., 1998; Kemp et al., 2011). The selective destruction of melanocytes in vitiligo might occur because they are intrinsically more sensitive to immune-mediated injury than other skin cells (Norris et al., 1988b).

Autoantibodies as Potential Immunologic Markers

The use of melanocyte antibodies as markers of vitiligo activity is a controversial subject. While a recent study reported no correlation between the presence of

antibodies and recent disease activity or different clinical parameters (e.g., age, gender, extension, and duration of vitiligo) (Kroon et al., 2012), other reports found the incidence and/or level of melanocyte antibodies linked to the activity and extent of vitiligo (Naughton et al., 1986; Aronson and Hashimoto, 1987; Harning et al., 1991; Yu et al., 1993; Kemp et al., 2011).

Following treatment with systemic steroids, a reduction in anti-melanocyte antibody levels and in antibody-mediated anti-melanocyte cytotoxicity has been reported (Hann et al., 1993; Takei et al., 1984). After therapy with psoralen and ultraviolet radiation (PUVA), decreased expression of vitiligo-associated melanocyte antigens was noted, leading to a blocking of antibody-dependent cell-mediated cytotoxicity against melanocytes (Kao and Yu, 1992; Viac et al., 1997). The presence or levels of anti-melanocyte antibodies have not yet been effectively developed as diagnostic tools or markers of disease activity.

Concluding Remarks—Future Prospects

Vitiligo has been observed and treated since antiquity, but it still remains an enigmatic disorder in which combined genetic and non-genetic factors can cause the autoimmune-mediated destruction of melanocytes from epidermis, but often sparing HF melanocytes. Treatment in vitiligo must consider two distinct aspects: (1) limitation of the immune process which halts the progression of depigmentation and (2) stimulation of repigmentation of vitiligo lesions by mobilizing the stem cell populations to proliferate, migrate, and differentiate to regenerate the interfollicular melanocytes. Effective treatment of vitiligo involves topical medications and phototherapy to both suppress the immune response and to activate melanocyte regeneration from HF reservoirs of pluripotent stem cells (Birlea et al., 2012). New research initiatives are focusing on the repopulation of affected interfollicular epidermis with melanocyte precursors from the bulge region of the HF. This process is a classic example of regenerative medicine, based on stem cell activation. The key to improving therapeutic approaches for vitiligo is targeted stimulation of the principal repigmentation genes/proteins or designing new compounds which are potent and selective inducers of melanocyte activation, migration, and differentiation.

PSORIASIS

Clinical, Pathologic, and Epidemiologic Features

Psoriasis is a common, chronic, immune-mediated inflammatory skin disease with polygenic inheritance, characterized by erythematous scaly plaques that can

range from a few scattered lesions to involvement of the entire body surface. Psoriasis may progressively worsen with age, or wax and wane in severity (Stern et al., 2004; Gelfand et al., 2005; Kurd and Gelfand, 2009; Parisi et al., 2013). The disease prevalence is 2–4% of the population in Western countries (Parisi et al., 2013), ranging from 0.91% (United States) (Robinson et al., 2006) to 8.5% (Norway) (Bø et al., 2008). Psoriasis can present at any age (see Table 66.4); type I psoriasis presents in younger patients and has a poor prognosis, while type II psoriasis presents in elderly patients and is easier to control. When psoriasis has extensive distribution, especially involving the groin and hands or feet, it produces significant morbidity and a decrease in the quality of life (Nestle et al., 2009). The prototypic lesion is plaque psoriasis, characterized by raised, well-demarcated, erythematous, oval plaques with adherent silvery-white, dry scales (Figure 66.3). The histopathology of psoriasis characteristically shows a thickened epidermis with an expanded proliferative compartment, premature maturation of keratinocytes and incomplete cornification with retention of nuclei in the stratum corneum (parakeratosis) (Nestle et al., 2009). The dermal inflammatory infiltrate consists mainly of dendritic cells, macrophages, and T cells, while the epidermis contains neutrophils and some T cells. Erythema in lesions is due to increased numbers of tortuous capillaries in the rete ridges, covered by a very thin epidermis (Nestle et al., 2009). Psoriasis may be triggered by trauma or injury (Koebner's phenomenon), infections (Leung et al., 1995, 1998), xerosis, and reactions to various drugs (Gudjonsson and Elder, 2008). Psoriatic arthritis presents as distal interphalangeal disease, axial arthritis, or symmetrical arthritis (Winchester, 2008) (see Chapter 38). Nail involvement may be present, particularly associated with arthritis. The various types and presentations of psoriasis are outlined in Table 66.4 (Langley et al., 2005) and guttate and pustular psoriasis are presented in Figures 66.4 and 66.5.

Autoimmune Features

It is now generally accepted that psoriatic lesions are caused by abnormal reactivity of specific T cells in the skin. It is also accepted that alterations in the epidermal barrier, in innate immune defenses, and in processing of inflammatory signals may all contribute to the triggering of nonspecific innate immune mechanisms. The effector mechanisms in the epidermis include increased production of IL-23 and Th1- and Th17-type cytokines (Gudjonsson and Johnston, 2009).

The concept of an autoimmune basis for psoriasis notwithstanding the presence of a dysregulated immune

TABLE 66.4 Classification of Psoriasis

| Types and Subtypes of Disease | Features |
|--|---|
| 1. Plaque psoriasis/vulgaris type | <ul style="list-style-type: none"> – sharply circumscribed, round-oval, or nummular (coin-sized) plaques – plaques occur on elbows, knee, trunk, back – most common type, occurring in 85–90% of patients |
| 2. Guttate psoriasis | <ul style="list-style-type: none"> – small, 2–10 mm diameter; acute onset, centripetal distribution – lesions occur shortly after an acute streptococcal infection of the pharynx or tonsils – common in children; occasionally in adults |
| 3. Flexural (inverse) psoriasis | <ul style="list-style-type: none"> – affects the flexures (inframammary, perineal, and axillary) – lesions devoid of scale appear as red, shiny, well demarcated plaques – differential diagnosis: candidal intertrigo, dermatophyte infections |
| 4. Erythroderma | <ul style="list-style-type: none"> – total or subtotal involvement of the body skin – may impair the thermoregulatory capacity of the skin, leading to hypothermia, high output cardiac failure, and metabolic changes |
| a. chronic plaque psoriasis | <ul style="list-style-type: none"> a. lesions gradually progress as plaques and become confluent and extensive |
| b. unstable psoriasis | <ul style="list-style-type: none"> b. precipitated by infection, tar, drugs, withdrawal of corticosteroids; becomes rapidly extensive |
| 5. Generalized pustular psoriasis (von Zumbusch) | <ul style="list-style-type: none"> – monomorphic, sterile pustules, which may coalesce to form sheets – active, unstable disease; sometimes requires hospital admission – precipitated by withdrawal of systemic or potent topical corticosteroids and by infections |
| 6. Palmoplantar pustulosis | <ul style="list-style-type: none"> – sterile, yellow pustules on erythematous-squamous background – frequently with nail involvement – prevalent in women, in the 4th–6th decade, and in smokers |
| 7. Psoriatic nail disease | <ul style="list-style-type: none"> – small pits, onycholysis, “oil spots” thickening, dystrophy, discoloration, subungual hyperkeratosis |

**FIGURE 66.3** Typical plaque of psoriasis.**FIGURE 66.4** Guttate psoriasis of the trunk.

system (Nestle et al., 2009) is supported by the following:

1. Increased numbers of immune cells (mainly dendritic and T cells) within the lesions, and the appearance of oligoclonal T cells in lesions over time.
2. Oligoclonal T cell activation in psoriatic lesions (Lin et al., 2001).
3. Efficacy of T cell-targeted treatments (cyclosporine, efalizumab, alefacept) (Lowes et al., 2007), drugs that inhibit Th1 and Th17 cells and their cytokines

(ustekinumab), or therapies that are thought to target the adaptive immune system rather than modify keratinocyte function (corticosteroids, UVB) (Schwarz, 2008; Bergboer et al., 2012).

4. Genetic associations that are largely immunologic (discussed below).
5. Xenograft animal models (Bergboer et al., 2012) that have focused on the functional role of T cells and cytokines (Nestle et al., 2009).
6. The observation that bone marrow transplantation into psoriasis patients may cure the disease, and that psoriasis can be transferred from a psoriatic transplant donor to the recipient (Nestle et al., 2009).

However, as yet there is no convincing evidence identifying the specificity of autoreactive T cell clones in psoriasis. Although it has been proposed that CD4⁺ T cell activation initiates psoriasis and CD8⁺ intraepidermal T cells cause lesion persistence, there is no evidence that these cells are activated by self-antigens (Lin et al., 2001). Many of the triggers for psoriasis are not antigen specific (Leung et al., 1993, 1998), and several of the most effective treatments such as anti-tumor necrosis factor (TNF) biologics may affect both innate and acquired immunity as well as inflammation in general.

FIGURE 66.5 Pustular psoriasis of the neck and upper chest.

Genetic Features

The importance of a hereditary component in the pathogenesis of psoriasis has been established through population-based studies (Gudjonsson and Elder, 2008). They indicate that the incidence of psoriasis is greater among first-degree and second-degree relatives of patients than among the general population (Nestle et al., 2009). Twin studies showed a concordance rate of 35–72% in monozygotic twins and 12–23% in dizygotic twins (Bowcock and Krueger, 2005). About 71% of the patients with childhood psoriasis report a positive family history (Morris et al., 2001). In the past decades, several linkage studies and genome-wide association studies (Bergboer et al., 2012) identified susceptibility loci for psoriasis. Genome-wide linkage analysis has identified at least nine chromosomal loci with statistically significant linkage to psoriasis (called PSORS1 through PSORS9) (Nestle et al., 2009). Genomic signatures in psoriatic lesions point to dendritic cells as a key cell type, and IFN- γ and TNF- α as key cytokines; this reinforces the concept that cells and mediators of the immune system have essential roles in susceptibility to and maintenance of psoriasis (Nestle et al., 2009). The psoriasis genome-wide association signals confirmed (Bergboer et al., 2012) are listed in Table 66.5.

In Vivo and In Vitro Models

In Vivo Models

Spontaneous Mouse Models

A number of spontaneous mouse mutations give rise to psoriasisiform inflammatory and scaly phenotypes (Sundberg and King, 1996; Raychaudhuri et al., 2001), which usually represent only a limited set of psoriatic features (Gudjonsson et al., 2007; Nestle et al., 2009).

Genetically Engineered Mouse Models

Transgenic mice have been generated that overexpress adhesion molecules, cytokines, transcription factors, and inflammatory mediators in both keratinocytes and immunocytes to define the important cell types in psoriasis disease initiation. Epidermal overexpression of molecules

TABLE 66.5 Top Psoriasis Signals with Immune Function

| Putative Biological Pathway | Gene/Locus |
|-----------------------------|--|
| Adaptive immunity | IL23R, ERAP1, IL-12B, TNF, TRAG3IP2, IL-4, IL-13, IL-23A, ZNF313/RNF114, HLA-C |
| Barrier skin function | LCERB, LCE3C, CDSN, DEFB, GJB2 |
| Innate immunity | IF1H1, REL, TNIP1, TNFAIP3, IL-28RA, NFKBIA, FBXL19, NOS2, TYK2 |

under the control of promoters in the epidermis (e.g., keratin (K)5, K14, and K10, or involucrin) induce the development of a psoriasis-like disease in several mouse models. The K5-STAT3C mouse develops a psoriasis-like disease, with keratinocyte hyperplasia, loss of stratum granulosum, and parakeratosis.

Knockout or hypomorphic mice, in which the genetic element has been removed or attenuated, respectively, have also been used to study a given mediator in psoriasis. Mice develop a condition that resembles psoriatic skin disease after *ITGB2*, *ITGAE*, *IL1RN*, and *IRF2* genes are knocked out (Wagner et al., 2010).

Transplantation Models (Nestle et al., 2009; Gudjonsson et al., 2007)

Psoriasis-like findings were observed in Prkdc^{scid} mice receiving CD4⁺-CD45-RBhi T cells from donors who were MHC matched, but mismatched for minor histocompatibility antigens (Schön et al., 1997). Humanized xenotransplantation models most closely resemble psoriasis. Their advantage is that both human skin and immune cell infiltrate are transplanted and can be studied directly.

In Vitro Models

Because of the complex nature of psoriasis, *in vivo* models are the preferred platform for investigation of most aspects of disease. However, *in vitro* studies have been useful in isolating infiltrating lymphocytes from lesional areas, in studying selected functions in psoriatic keratinocytes, and showing the effects of de-epidermized psoriatic dermis on the disease process.

Pathogenic Mechanism

The mechanism of evolution of a psoriatic lesion from initiation to persistence of disease has been thoroughly studied (Nestle et al., 2009).

1. Initial triggers (e.g., physical trauma or bacterial products) start a cascade of events that include the formation of DNA–LL-37 complexes, activation of plasmacytoid dendritic cells, and secretion of the cytokine IFN- α (both found increased in early psoriatic lesions). Clinical observation points to an important role of IFN- α as an inducer of psoriasis (Funk et al., 1991).
2. Psoriatic keratinocytes are a rich source of antimicrobial peptides, including LL-37, β -defensins, and psoriasin. In addition, keratinocytes are responsive to key dendritic cell-derived and T cell-derived cytokines, including interferons, TNF, IL-17, and IL-20, and in turn will

produce proinflammatory cytokines including IL-1, IL-6, and TNF- α .

3. Myeloid dermal dendritic cells are increased in psoriatic lesions and induce proliferation of T cells and production of Th1 cytokines. Activated myeloid dendritic cells migrate into draining lymph nodes and stimulate differentiation of naïve T cells into effector cells, Th17 or type 17 cytotoxic T cells (Tc)17, Th1 or Tc1 (Nestle et al., 1994). They have proinflammatory effects, producing TNF- α and nitric oxide synthase (NOS) (Lowes et al., 2005).
4. Effector cells recirculate and slow down in skin capillaries in the presence of selectin- and integrin-guided receptor–ligand interactions. Immune cells expressing the chemokine receptors CCR6, CCR4, and CXCR3 emigrate into skin tissue along these chemokine gradients. Key processes during disease maintenance are the presentation of putative autoantigens to T cells and the release of IL-23 by dermal dendritic cells, the production of proinflammatory mediators such as TNF- α and nitric oxide (NO) by TNF- α and inducible NOS-producing dendritic cells, and the production of IL-17 and IL-22 by Th17 and Tc17 cells, and of IFN- γ and TNF- α by Th1 and Tc1 cells. These mediators act on keratinocytes, leading to the activation, proliferation, and production of antimicrobial peptides (e.g., LL-37, cathelicidin, and β -defensins), chemokines (e.g., CXCL1, CXCL9 through CXCL11, and CCL20), and S100 proteins by keratinocytes. Dendritic and T cells form perivascular clusters in the presence of CCL19 produced by macrophages. An essential event is the migration of T cells from the dermis into the epidermis, controlled through the interaction of α 1 β 1 integrin (very late antigen 1 [VLA-1]) on T cells with collagen IV at the basement membrane.
5. Natural killer (NK) T cells contribute to the disease process.
6. Feedback loops involving keratinocytes, fibroblasts, and endothelial cells contribute to tissue reorganization with endothelial cell activation and proliferation and deposition of extracellular matrix. Neutrophils in the epidermis are attracted by chemokines, including CXCL8 and CXCL1.
7. Studies have indicated a defect in the overall suppressive activity of T regulatory (Treg) cells (Sugiyama et al., 2005), with decreased contra-regulation of the proinflammatory state (Nestle et al., 2009).

Autoantibodies as Potential Immunologic Markers

Autoantibodies to keratin-associated intermediate filaments (Shigenobu et al., 1989), to U1 and U2 small

nuclear ribonucleoproteins (Reeves et al., 1986), to calpastatin (Matsushita et al., 2005), and to other epidermal proteins have been described in psoriasis, but none has proven reliable as a biomarker of disease activity, or has been accepted as a participant in disease pathogenesis.

Concluding Remarks—Future Prospects

Psoriasis is a common inflammatory skin disease of undetermined etiology in which an autoimmune basis is suspected, but is far from established. There is no cure, although multiple treatments can produce worthwhile disease remissions (UV light phototherapy, methotrexate, biologicals); all of the treatments that induce remissions decrease the population of activated T cells within the lesions. This heterogeneous, cutaneous, inflammatory disorder is histopathologically characterized by prominent epidermal hyperplasia and a distinct inflammatory infiltrate. Crosstalk between immunocytes and keratinocytes, which results in the production of cytokines, chemokines, and growth factors, is thought to mediate the disease. Given that psoriasis is only observed in humans, numerous genetic approaches to model psoriasis in mice have been undertaken (Wagner et al., 2010). Existing and new mouse models are needed in order to dissect this complex disease and to provide novel insights into the molecular mechanisms and pathways that incite the disease initiating events, and also those which are responsible for recurrences following successful treatment. Biological therapies are already giving promising results but, owing to the heterogeneity of psoriasis, optimal treatments are unlikely to be restricted to individual targets. Combination treatments intended to reduce the immune activation and angiogenesis and to restore differentiation of keratinocytes in a disease stage-dependent manner will be beneficial.

CHRONIC URTICARIA

Clinical, Pathologic, and Epidemiologic Features

Chronic urticaria (CU) is a relatively common type of urticaria, defined as hives lasting longer than 6 weeks (Kaplan, 2004). It affects around 0.1% of the population including both adults and children (Schocket, 2006), with a higher predilection in women than in men (2:1), and with significant adverse effects on quality of life (Schocket, 2006). CU is currently divided into three subcategories (Greaves and Tan, 2007): (1) urticarial vasculitis (leukocytoclastic vasculitis of the small vessels with hives duration of more than 24 hours which can accompany autoimmune rheumatic diseases, inflammatory bowel disease, viral hepatitis, and paraproteinemia); (2)

physical urticarias (with several subtypes, e.g., solar, cold, aquagenic, delayed pressure, vibratory, cholinergic, and dermographism); and (3) chronic autoimmune urticaria (which is caused by anti-Fc ϵ RI antibodies, and less often by anti-IgE antibodies).

Chronic spontaneous urticaria (with more than 6 weeks' duration of symptoms) is a subtype of urticaria in which there is no identifiable cause (Zuberbier, 2012).

The characteristic clinical lesion of both acute urticaria and CU is the hive; hives present as pruritic, erythematous, blanching, circumscribed macular or raised lesions, involving the superficial layers of the skin (Joint Task Force on Practice, 2000). Up to 40% of CU patients have associated angioedema (swelling of the deeper structures) (Kaplan, 2004). Generally an individual CU lesion does not persist in the same location for greater than 24 hours (Joint Task Force on Practice, 2000). Untreated CU should virtually always be associated with pruritus. In the absence of pruritus the clinician should consider alternative diagnoses. A thorough history is critical to identifying known causes of urticaria.

CU is diagnosed clinically. The patient history is critical in making the diagnosis, identifying a potential trigger, and ruling out other diseases. For both acute and chronic urticaria, important specific points of history include physical triggers, recent changes in medications, recent travel, infections (including parasitic), history of atopy, and a complete review of systems. Additional dermatologic conditions should be considered in the differential diagnosis: erythema annulare centrifugum, erythema chronicum migrans, and erythema multiforme.

The principal histologic finding in CU is dermal edema. There is variable cellular infiltrate around vessels, with predominance of neutrophils and eosinophils in early lesions and of lymphocytes accompanied by neutrophils and eosinophils in advanced lesions (Lee et al., 2002).

Autoimmune Features

The presence of autoimmunity in a significant proportion of CU patients was initially suggested by demonstration of skin reactivity to the injection of the patient's own serum, the so-called autologous serum skin test (ASST) (Grattan et al., 1986, 1990). Later, it was shown that the serum and purified IgG of a subset of patients with chronic idiopathic urticaria releases histamine from basophils and dermal mast cells when incubated with leukocytes prepared from peripheral blood from two healthy human donors. This release could be inhibited by preincubation with recombinant Fc ϵ R1 α , the α -chain of the high-affinity IgE receptor. In a small proportion of patients (5%), the histamine-releasing factor was inhibited not by the α -chain of Fc ϵ R1 but by IgE itself (Hide et al., 1993; Niimi et al., 1996).

CU has been shown to be associated with an autoimmune mechanism in 30–50% of idiopathic urticaria cases. In addition, other concomitant autoimmune disorders including autoimmune thyroid disorders, rheumatoid arthritis, type 1 diabetes mellitus, celiac disease, Sjögren's syndrome, and systemic lupus erythematosus were significantly more prevalent in patients with CU when compared to the general population (Confino-Cohen et al., 2012). Moreover, in the same population, CU patients showed a higher prevalence of other serologic markers of autoimmunity, notably rheumatoid factor and antinuclear antibodies, as compared with non-CU controls (Confino-Cohen et al., 2012). The association of CU with thyroid autoimmunity was described earlier (Leznoff et al., 1983), followed by the observation that suppression of thyroid activity results in CU remission (Schocket, 2006).

The presence of an inflammatory perivascular infiltrate in many CU patients also supports the immune basis of this disease. This infiltrate is predominantly composed of T lymphocytes, specifically CD4⁺, T helper cells, and a small number of CD8⁺ cytotoxic T cells (Mekori et al., 1983).

Genetic Features

Autoimmune CU is a complex multifactorial disease with probably genetic and environmental components. CU clusters in families, being more frequent among the first-degree relatives of affected individuals than in the general population (Asero, 2002). There is a paucity of literature on proposed genetic susceptibilities, mainly consisting of small candidate genes studies, of which results are still unconfirmed. These studies targeted protein tyrosine phosphatase-22 (*PTPN22*) (Brzoza et al., 2012), formyl peptide receptor like 1 (*FPRL1*) (Yang et al., 2010), HLA-DRB1, and HLA-DQB1 (Chen et al., 2005).

In Vivo and In Vitro Models

While it is understood that autoimmune mechanisms are responsible for a subset of CU, no single test is diagnostic, and therefore all require clinical correlation. Biopsy and histologic evaluation is only valuable to confirm features consistent with urticaria when the diagnosis is in doubt, or when alternative diagnoses are being strongly considered. While there is evidence suggesting the presence of IgG directed against both the IgE receptor α subunit and the Fc region of IgE (Sabroe and Greaves, 2006), there remains significant debate as to the clinical utility of the available testing modalities. One of the earliest tests performed on patients with CU is the ASST. This involves intradermal injection of autologous serum on the volar surface of an unaffected arm along with positive and negative controls (typically saline and histamine).

The test is read 30 minutes later and is considered positive if the wheal at the serum site is 1.5 mm greater than that of the wheal at the negative control. The sensitivity was calculated at 65–81% and specificity 71–78% (Sabroe et al., 1999). Other authors have shown unacceptably high false-positive reactions in healthy controls with the autologous serum skin test as high as 56% (Taskapan et al., 2008).

Other testing modalities including basophil activation and commercial assays for detecting anti-Fc ϵ R1 α antibodies (sometimes referred to as the CU index) are available although there remains much debate regarding their clinical utility. More recently an assay focusing on a unique connective tissue mast cell line has been proposed (Posthumus et al., 2012).

Animal models for contact urticaria were previously described; however, a suitable model for CU has not been reported so far.

Pathologic Effector Mechanisms

Histamine-releasing IgG autoantibodies directed against both the IgE receptor α subunit and the Fc region of IgE remain the basis of the autoimmune subset within CU (Hide et al., 1993; Niimi et al., 1996; Kaplan 2004; Mlynek et al., 2008). It was also suggested that the sera from patients with CU containing Fc ϵ R1 α antibody release mediators and tumor necrosis factor (TNF)- α by activating human foreskin mast cells (Lee et al., 2002). Mast cells are considered to be the primary effector cells in CU, by releasing a variety of inflammatory mediators such as leukotrienes, tryptase, prostaglandins, histamine, interleukin (IL)-1, IL-6, IL-8, and TNF- α (Lee et al., 2002), which regulate the emigration of leukocytes; these mediators induce a sequential upregulation of endothelial adhesion molecules [P-selectin, E-selectin, intercellular adhesion molecules 1 (ICAM-1)], and vascular cell adhesion molecule-1 (VCAM-1) (Lee et al., 2002), which facilitate the binding of the activated leukocytes to endothelial cells, and then transmigrate into tissues. Recent literature has suggested alternative mast cell activating factors relate to the coagulation cascade. Activation of the classical complement pathway and formation of C5a are important for dermal mast cell activation and for neutrophil and eosinophil chemoattraction (Greaves and Tan, 2007). Autologous sera from some patients with CU retain the ability to induce a wheal-and-flare reaction when injected intracutaneously even after depletion of IgG (Mlynek et al., 2008). Other studies have demonstrated that thrombin causes edema development by both direct endothelial and indirect inflammatory mediator mechanisms (Asero et al., 2006, 2007a,b). This effect is reduced by antihistamines and completely absent if mast cell granules are eliminated. One recent study showed

high serum levels of the Th17 cell profile of cytokines including IL-17, IL-23, and TNF- α among chronic spontaneous urticaria patients (Atwa et al., 2013). Other recent work has focused on a possible hormonal component given that CU is twice as prevalent in women. To date there is no evidence to suggest a hormonal mechanism.

Autoantibodies as Potential Immunologic Markers

Numerous attempts to develop immunoassays that measure serum levels of IgG and anti-Fc ϵ RI or anti-IgE antibodies in urticaria, although successful, have shown low specificity and poor correlation with *in vitro* serum histamine release and disease activity (Greaves and Tan, 2007).

Concluding Remarks—Future Prospects

Regardless of the mechanism, first-line treatment for CU remains H1 antihistamines. Second-line treatments include addition of an H2 antihistamine, or of a leukotriene modifier (Tilles, 2005). Using oral glucocorticoids is a common practice for refractory symptoms. In light of the likely adverse effects with long-term use, most clinicians recommend using them for short periods (usually 3–7 days) at the minimally effective dose to control symptoms. Third-line treatments include immunomodulators, but evidence for efficacy with these agents is largely based on clinical experience and small-scale studies. Management guidelines also recommend dapsone as the next line of therapy. In patients with anemia, sulfasalazine is used as an alternative. In patients with only modest impairment in quality of life, use of hydroxychloroquine was suggested given its slow onset of action (Reeves, 2004). Alternative immunomodulators used for refractory cases include other calcineurin inhibitors (Trojan and Khan, 2012), mycophenolate mofetil (Zimmerman et al., 2012), immunoglobulin (Asero, 2000), TNF inhibitors, colchicine (Pho et al., 2011), methotrexate (Gach et al., 2001; Perez et al., 2010; Sagi et al., 2011), and cyclophosphamide (Bernstein et al., 2002; Asero, 2005). Phototherapy has also been shown to be effective and is a treatment option for patients desiring to avoid systemic medications (Berroeta et al., 2004; Engin et al., 2008; Aydogan et al., 2012). More recently, omalizumab, a human monoclonal antibody against the high-affinity IgE receptor Fc ϵ RI, has been shown to be effective, although cost remains a limiting factor (Maurer et al., 2013).

Although CU is a relatively common condition, identifying the precise trigger in individual patients is usually not possible. Better testing for antigen specificities is a high priority to correct this important issue and is essential for the best treatment outcomes. Blocking mast cell degranulation or blocking the effects of released mast cell mediators is often an inadequate approach to treatment.

The addition of immunosuppressive drugs and specific anti-IgE biologics has enhanced the effectiveness of treatment for recalcitrant CU patients. Nevertheless, better tools for immunologic characterization of the autoimmune mechanism in individual patients, better drugs for mast cell stabilization, and better drugs to block the autoimmune mechanisms of CU are all important to enhance the effectiveness of treating these patients.

INTRODUCTION

Autoimmune diseases as a whole are a diverse class of over 80 diseases that affect different organs and tissue types. Because of this diversity, we tend to study them as individual diseases rather than as a whole. This is comparable to cancer, which is also a diverse group of diseases that are studied individually such a colon or lung cancer. This view was changed quite radically by Hanahan and Weinberg in their proposed Hallmarks of Cancer (Hanahan and Weinberg, 2000). They proposed that all cancer types (organ, species) could be characterized by a small number of acquired characteristics. This approach might also be applied to autoimmune diseases, leading to a “small number of underlying principles.”

ARE THERE HALLMARKS OF AUTOIMMUNE DISEASE?

By definition, a *hallmark* is a distinguishing characteristic, trait, or feature. What are the enabling characteristics or hallmarks that drive the inception of autoimmune disease? In this chapter, we propose a holistic view of common traits among autoimmune diseases of the kidney. Diseases considered in this discussion include anti-glomerular basement membrane (anti-GBM) disease, systemic lupus erythematosus (SLE) nephritis,

and anti-neutrophil-cytoplasmic-autoantibody (ANCA) pauci-immune small vessel vasculitis. IgA nephropathy will not be included, although it is now considered to be immune mediated, as the diseases listed above provide ample support for the point of discussion in this chapter. A brief description of the three diseases discussed is given in the following section.

Autoantibodies and Their Antigens

Anti-GBM disease is the only kidney disease in which it is definitely known that antibodies develop against a native renal antigen, the $\alpha 3$ helix of collagen IV. Rapidly progressive glomerulonephritis in GBM disease is mediated by autoantibodies binding to the non-collagenous NC1 domain of $\alpha 3$ (IV) collagen in the glomerular basement membrane (Borza and Hudson, 2003). The epitope is made up of nine discontinuous amino acids in the C-terminal non-collagenous domain of the $\alpha 3$ helix (abbreviated $\alpha 3$ (IV)NC1) (Hellmark et al., 1999; Gunnarsson et al., 2000). Anti-GBM antibodies bind to the renal and alveolar basement membranes, inducing complement fixation and leukocyte recruitment and activation. Anti-IgG stains show intense diffuse linear staining of the glomerular basement membrane in all patients.

Numerous human and animal studies support the hypothesis that lupus nephritis is an immune complex

disease. The diversity of the autoantibody repertoire associated with SLE is well recognized. Lupus nephritis can occur in any SLE patient with any autoantibody profile; however, specific antibodies or antibody repertoires are associated with a higher incidence of kidney disease (Lefkowitz and Gilkeson, 1996; Lefkowitz et al., 1996). The strongest association identified thus far is with circulating antibodies directed against RNA complexes or anti-Sm antibodies with or without concurrent anti-U₁RNP, which predicts development of nephritis in approximately 50% of SLE patients. Other circulating antibodies associated with nephritis include anti-C1q-CLR, anti-heparan sulfate, and anti-endothelial cell antibodies (D'Cruz et al., 1991; Coremans et al., 1995; Ravirajan et al., 2001). Autoantibodies frequently found deposited within kidneys of lupus patients include anti-C1q-CLR, anti-SSA, anti-Sm, anti-SSB, antihistone, and antichromatin antibodies (Mannik et al., 2003). Immunoglobulin deposition can occur in subepithelial or subendothelial spaces and typically contains predominantly IgG and complement with variable levels of IgM and IgA (reviewed in Couser, 1990). For example, anti-dsDNA and anti-histone antibodies in particular are thought to be more nephritogenic than other autoantibodies due to overall charge and due to their potential to cross-react with native GBM antigens (Foster et al., 1993; Xie et al., 2003; Cortes-Hernandez et al., 2004). Although serum autoantibody titers generally correlate with presence and severity of nephritis, some patients with high titers do not develop kidney disease while others with low titers may have severe nephritis (Chien et al., 2001; Horvath et al., 2001; Reveille, 2004; Linnik et al., 2005). This inconsistency is reflected in findings that, in some cases, the antigen specificity of antibodies eluted from a lupus nephritis kidney are different from those detected in the serum (Mannik et al., 2003), alluding to the importance of the properties of the immune complexes, such as antigen specificity and charge, for binding within the kidney (Vogt et al., 1990; Suenaga and Abdou, 1993; Woitas and Morioka, 1996).

ANCA occur in more than 80% of patients with pauci-immune small vessel vasculitis. These antibodies are specific for neutrophil and monocyte granule proteins, with a given patient typically having antibody reactivity to a single antigen (Charles et al., 1992). The major neutrophil granule protein targets of ANCA are proteinase-3 (PR3, a serine protease) and myeloperoxidase (MPO, a lysosomal enzyme that produces hypochlorous acid). Indirect immunofluorescence staining of neutrophils using sera from ANCA patients results in cytoplasmic fluorescence. PR3-ANCA produce a cytoplasmic staining pattern (C-ANCA pattern), whereas MPO-ANCA produce a perinuclear cytoplasmic staining pattern (P-ANCA) (Jennette and Falk, 1990).

ANCA are IgG, mostly of the IgG1 subclass, with lesser amounts of IgG3 and IgG4 (Segelmark and Wieslander, 1993). There is no single epitope on either PR3 or MPO that is uniformly recognized by ANCA from different patients; additionally a single ANCA patient can have antibodies against multiple epitopes of a single protein target (Bini et al., 1992; Russell et al., 2001; Rarok et al., 2003; Pfister et al., 2004; Selga et al., 2004; Farrag et al., 2007). ANCA binding to their specific antigens in combination with Fc region binding to an Fc receptor results in neutrophil and monocyte activation with induction of the respiratory burst, degranulation, and release of cellular inflammatory products into the microenvironment (Falk et al., 1990b; Keogan et al., 1992; Savage et al., 1992; Mulder et al., 1994; Porges et al., 1994; Johnson et al., 1997). Interaction of these leukocytes and their products with the endothelium causes inflammatory injury and vasculitis (Falk and Jennette, 1988; Gross et al., 1993; De'Oliviera et al., 1995). Rapidly progressive glomerulonephritis secondary to vasculitis is one of the most common clinical manifestations (Castillo et al., 1993). Renal involvement is found in approximately 90% of patients with microscopic polyangiitis (MPA), 80% of patients with granulomatous polyangiitis (GPA), 45% of patients with the Churg–Strauss syndrome and, by definition, 100% of patients with renal-limited small vessel ANCA vasculitis (Falk and Jennette, 1988; Jennette and Falk, 1997a,b).

HALLMARKS OF AUTOIMMUNE DISEASES OF THE KIDNEY

Not everyone who develops self-reactive autoantibodies develops autoimmune disease. Autoimmune disease is a multistep process with a succession of genetic and epigenetic changes, culminating in susceptibility to disease. Collectively, these changes dictate physiologic changes whereby novel capabilities are acquired. How many traits must an individual acquire before onset of disease? Moreover, what are these traits or hallmarks leading to disease? The following sections address these questions. After review of existing information, we propose six traits or hallmarks that are highly likely to be common to, and contribute to, disease onset (Figure 67.1).

Autoreactive T and B Cells Evade Deletion

Both basic and translational research efforts are expanding our understanding of how humeral immune cell regulation may be subverted or disrupted to such an extent so as to trigger and perpetuate autoimmune disease. For example, anti-GBM disease is devastating if unrecognized or when treatment is delayed, typically resulting

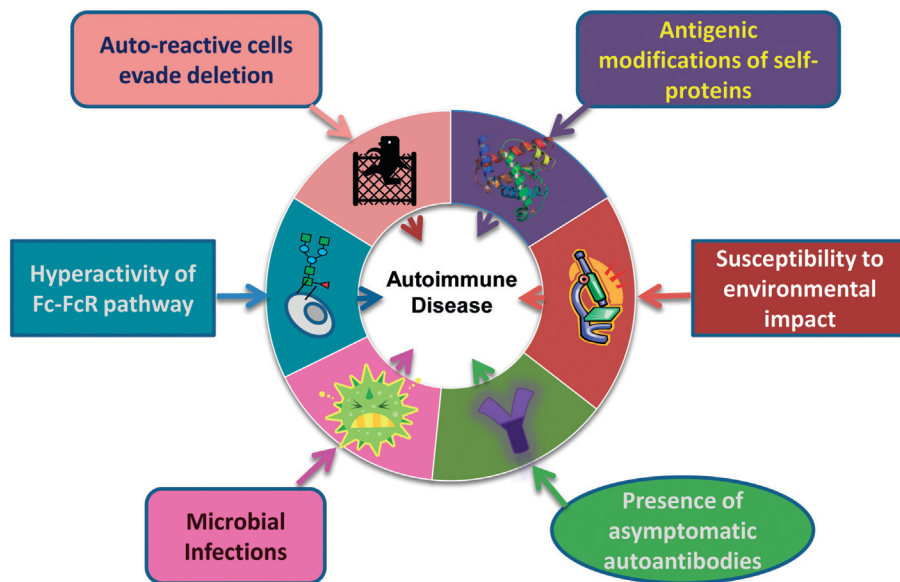

FIGURE 67.1 Hallmarks of autoimmune diseases of the kidney.

in irreversible renal failure and the risk of pulmonary hemorrhage but, unlike ANCA vasculitis and lupus nephritis, the risk of relapse following treatment for anti-GBM disease is generally very low (Savige et al., 1991). Recent evidence indicates that this is attributable to the development of protective regulatory T cell subsets (adaptive Tregs) (Ooi et al., 2011; Peto and Salama, 2011). The opposite appears to occur in relapsing diseases SLE and ANCA vasculitis, where regulatory T cells not only fail to develop but may be dysfunctional at the onset (Marinaki et al., 2005; Yoshimura et al., 2010). Tregs are central to maintaining order in the immune system. Without regulation, “effector T cells are free to cause destruction,” leading to injury for the host (Walters et al., 2009). In autoimmune disease, an acquired trait common among diseases is an increased level of effector T cells that are resistant to Treg suppression. The phenomenon of repression-resistant effector T cells has “prompted a shift in focus from how Tregs rule to how their jurisdiction can be overturned” (Walker, 2009). For example, a deficiency in $\alpha 3(\text{IV})$ NC1-specific $\text{CD4}^+\text{CD25}^+$ Tregs in anti-GBM disease is attributed to unrestrained expansion of autoreactive T lymphocytes that cause disease (Salama et al., 2003; Robertson et al., 2005). Similarly, persistent or aberrant T cell activation was identified as an initiating defect in SLE; abnormal CD40L expression on lymphocytes and decreased $\text{CD4}^+\text{CD25}^+$ Treg activity have both been implicated (Desai-Mehta et al., 1996; Powrie and Maloy, 2003). In ANCA disease effector T cells appeared to be activated above normal levels, with exaggerated skewing of cytokine profiles in response to

antigenic stimulation (Gross et al., 1998). In addition, a newly described $\text{CD4}^+\text{CD25}^{\text{intermediate}}$ effector cell population is linked with ANCA disease and lupus nephritis (Free et al., 2013). This unusual effector T cell subset (1) comprises the majority of the peripheral CD4^+ T population, (2) is antigen-experience, (3) produces proinflammatory cytokines, and (4) is resistant to Treg suppression (Figure 67.2) (Free et al., 2013). In these same individuals, Treg frequency was increased not decreased, counterintuitive in light of the expanded effector cell population. Functionality studies showed that the suppressive capability of Tregs was disrupted due to expression of a FoxP3 splice variant in which exon 2, an essential domain for Treg function, was spliced out (Figure 67.3). A hint that this phenotype may be an acquired trait of susceptibility lies in the fact that patients in disease remission continue to express the splice variant, raising the question of its existence before disease onset. Investigations in other autoimmune diseases may prove expression of the FoxP3 splice variant to be a predisposing trait, or hallmark, of autoimmune diseases.

If the amalgamation of experimental data and clinical observations persuades us of the central importance of autoantibodies in the pathogenesis of glomerular injury for anti-GBM, lupus nephritis, and ANCA-vasculitis, then it also signals a fundamental need to unravel the identity of the key autoreactive B cells. Perturbations of B cell populations exist in the peripheral blood of patients with SLE and ANCA vasculitis, in particular a subset of $\text{CD19}^{\text{HI}}\text{CD27}^+$ memory B cells that may be linked to autoantibody production (Culton et al., 2007).

FIGURE 67.2 Altered effector T cell dynamics in disease. Representative flow cytometric analysis of CD3⁺ CD4⁺ lymphocytes, when stratified by CD127 versus CD25 reactivity, identified a CD25^{int} T cell population.

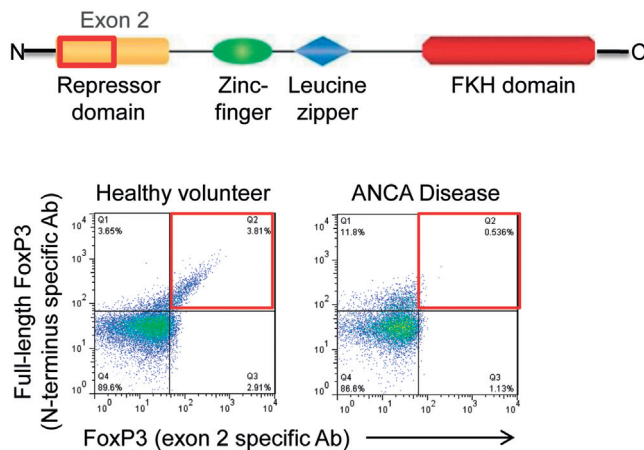

FIGURE 67.3 Regulatory CD4⁺ T cells are dysfunctional due to FoxP3 splice variant. Exon 2-deficient FoxP3 splice variant predominates in AAV. Schematic highlights the repressor domain of FoxP3 protein coded by exon 2. Representative flow cytometric analysis of CD4⁺ T cells plotting reactivity to antibody recognizing exon 2 on the X-axis versus reactivity to an antibody recognizing the full-length N-terminus of FoxP3. Dual positive cells were detected in healthy individuals but were absent in patients.

CD19 is a B cell receptor (BCR) co-receptor that enhances BCR signal transduction to activate CD21 binding, the receptor for complement component C3d(g) (Walters et al., 2009). Complexes of antigen and C3d(g) are 10,000 times more potent in B cell activation than antigen alone (Lee et al., 2005b). Concomitant with CD19^{hi} B cells is a decrease in CD5 expression, which functions as a negative regulator of the B cell receptor (Bunch et al., 2013).

Pre-existence of Asymptomatic “Normal” Autoantibodies

Does pre-existence of self-reactive autoantibodies predispose an individual to autoimmune disease? Are they a hallmark of autoimmune disease? Anti-GBM autoantibodies were detected in sera of ostensibly healthy individuals months to years before onset of anti-GBM disease (Olson et al., 2011). Similarly, circulating autoantibodies were found in healthy individuals who eventually develop SLE (Arbuckle et al., 2003), and natural autoantibodies against MPO and PR3 were detected in healthy individuals (Cui et al., 2010). The presence of serologically-detectable autoantibodies years prior to disease onset compels one to consider whether the presence of these autoantibodies predispose individuals to develop disease. The clinical utility of testing for autoantibodies is apparent but even robust associations between specific immunoglobulins and particular autoimmune diseases or patterns of organ involvement do not guarantee a causal link. An epitope specificity study of “normal” autoantibodies provides a, somewhat incriminating, clue (Roth et al., 2013). The study aims were to (1) determine if differences in ANCA epitope specificity would explain why, in some cases, conventional serologic assays do not correlate well with disease activity, especially in MPO-ANCA, (2) explore why naturally occurring anti-MPO autoantibodies can exist in disease-free individuals, and (3) address the question of why ANCA are not detected in patients with ANCA-negative disease. Using a highly sensitive excision/mass spectrometry approach, data indicated that autoantibodies from healthy individuals had different epitopes than

FIGURE 67.4 Visualization of anti-MPO autoantibodies binding sites on the crystal structure of MPO showed epitopes of asymptomatic or “natural” autoantibodies (green) are spatially adjacent to epitopes exclusive to active disease (blue). Amino acids predicted to be required for autoantibody binding are highlighted in red.

autoantibodies from diseased patients. However, visualization of amino acid sequences of epitopes on the three-dimensional crystal structure of MPO (pdb 3f9) revealed an interesting adjacency of “natural” epitopes to epitopes exclusive to active disease (Figure 67.4). This suggests the possibility that an asymptomatic or “natural” autoantibody response to MPO may precede the onset of autoimmune disease, and that epitope spreading to epitopes exclusive to active disease may be one step of a cascade that initiates disease onset. Epitope spreading has been hypothesized to drive the pathogenesis of autoimmune diseases, where autoreactive lymphocytes react with determinants distinct from the initial, disease-inducing epitope as a result of chronic tissue damage (Vanderlugt and Miller, 1996). Lastly, another consideration would be that antigen binding by asymptomatic autoantibodies may structurally distort the conformation of the antigen exposing cryptic epitopes leading to production of pathogenic autoantibodies.

MPO-ANCA, reactive with a sole linear sequence on MPO, are now known to be present in sera from patients with what has been historically labeled, “ANCA-negative disease” (Figure 67.5) (Roth et al., 2013). Why had these autoantibodies gone undetected by routine clinical tests? Detection required prior purification of IgG from sera (Roth et al., 2013). When screening for autoantibodies specific for this epitope, it was found that assays using sera were negative due to the presence of a proteolytic fragment of an abundant protein in sera, a fragment of ceruloplasmin, which obscured antibody binding. The broader issue raised by these data is that management of many autoantibody-mediated diseases relies on tests that explore antibody reactivity to the whole molecule rather than target epitopes, and utilize sera where critical epitope recognition is marked and correlates well with disease activity.

Hyperactivity of Fc–FcR Pathway

All antibodies are glycosylated at conserved positions in their constant regions. At least 36 structurally unique oligosaccharide chains may be attached at each Asn-297

residue in both of the C_H2 domains of the Fc region. More than 50% of Fc oligosaccharides are accounted for by three main glycans: G0, G1, and G2 (designated according to the numbers of terminal Gal) (Figure 67.6). Reduction in galactosylation is routinely measured by comparing the relative abundances of glycoforms G0, G1, and G2 using mass spectrometry. The structure of the attached carbohydrates can affect antibody activity. Hyposialylation and hypoglycosylation of total IgG-Fc from serum was reported for PR3-ANCA disease, as indicated by elevated levels of G0 truncated *N*-glycans lacking the terminal galactose (Holland et al., 2002, 2006). This deficit results in a positive amplification of the Fc/cReceptor signaling and has been linked with active PR3-ANCA disease (Espy et al., 2011). Further, IgG glycan hydrolysis attenuates ANCA-mediated glomerulonephritis (van Timmeren et al., (2010)). Changes in the glycan structures of some glycoproteins have been observed in SLE and rheumatoid arthritis (Tomana et al., 1988). A deficiency of α -mannosidase II, which is associated with branching in *N*-glycans, has been found to induce SLE-like glomerular nephritis in a mouse model (Hashii et al., 2009).

Effects of altered glycoforms of the Fc are intertwined with Fc receptor polymorphisms, which are also known to contribute to autoimmune disease (reviewed in Bournazos et al., 2009). The genes with the strongest association with development of lupus nephritis are Fc receptor polymorphisms thought to increase susceptibility and affect its rate of progression by altering or inhibiting clearance of immune complexes, or by inappropriately activating leukocytes, which bind deposited complexes (Salmon and Roman, 2001; Yun et al., 2001; Zuniga et al., 2001).

Antigenic Alterations of “Self” Proteins

What causes the autoimmune response to begin and what causes it to worsen into autoimmune disease? In the case of anti-GBM disease, mounting evidence indicates it is initiated by exposure of epitopes normally sequestered or buried, as conceptualized in the Cryptic Epitope Theory

FIGURE 67.5 ANCA-negative small vessel vasculitis develops a restricted autoantibody response against a linear epitope on MPO (aa447-459), shown in red.

FIGURE 67.6 Antibody glycosylation deficit autoimmune diseases. At least 36 structurally unique oligosaccharide chains may be attached at each Asn-297 residue in both of the C_H2 domains of the Fc region. More than 50% of Fc oligosaccharides are accounted for by three main glycans: G0, G1, and G2 (designated according to the numbers of terminal Gal). The sugar moiety functions as a molecular switch to enhance either the proinflammatory or anti-inflammatory activity of IgG.

(Lanzavecchia, 1995). Epitopes reactive with anti-GBM autoantibodies are cryptic (sequestered) within the NC1 hexamers of the $\alpha3\alpha4\alpha5(IV)$ collagen network. Disruption in the hexamer structure, through some unknown mechanism, causes disassociation of the endogenous hexamer structure of the α -3 chain of type IV collagen and exposure of a pathogenic epitope (Borza et al., 2005). A pathogenic autoantibody may be available for months to years prior to disease but the target epitope had been concealed. Do naturally occurring autoantibodies contribute to disruption, or is it due to post-translational changes, proteolytic cleavage by exogenous environmental factors, or is it a combination of events? As discussed above, it is conceivable that asymptomatic autoantibodies reactive to one part of a target antigen could pry open or disrupt autoantigen conformation.

Apoptosis has been implicated in the onset of autoimmune disease whereby an accumulation of autoantigens on

the surface of apoptotic cells coupled with a defect in clearance of apoptotic material helps to drive systemic autoimmune diseases (Rosen and Casciola-Rosen, 1999). Proximal defects in the classical complement pathway, leading to aberrant clearance of apoptotic cells, are well understood as potential initiators of autoimmune disease, in particular SLE (Prokunina et al., 2002). The autoantigens of SLE are exposed on dead and dying cells and released from injured tissues. Large quantities of antigen become available, so large numbers of small immune complexes are produced continuously and are deposited in the walls of small blood vessels in the renal glomerulus, in glomerular basement membrane in joints, and in other organs. Inefficient clearance of apoptotic cells may also have a role in ANCA vasculitis; macrophages that have engulfed apoptotic neutrophils appear to be diverted away from a non-phlogistic phenotype and this may contribute to the failure of effective healing (Ohlsson et al., 2012).

Additionally, the presence of ANCA accelerates neutrophil apoptosis without promoting concomitant externalization of phosphatidylserine which likely impairs neutrophil clearance and promotes secondary necrosis, amplifying tissue damage.

Proteins processed with modifications in glycosylation, phosphorylation, or proteolysis, etc., have differences in structure resulting in new epitopes or “neoantigenic determinants.” New antigenic determinants may give rise to specific autoantibodies and/or autoreactive T cells that now attack cells/tissues that bear the self-antigen. ANCA disease research suggests that the molecular architecture of PR3 and MPO, which are aberrantly transcribed in mature neutrophils, may be compromised producing neoantigenic determinants (Yang et al., 2004). How do cells transport these proteins? Are they secreted, or does the cell see them as misfolded proteins and shuttle them to lysosomes? Neutrophils have the ability to function as antigen-presenting cells (Cao et al., 2011). Peripheral neutrophils from patients homozygous for *DRB1*1501* expressed surface of *DRB1*15* protein, in response to TNF- α exposure, that bound amino acids sequences of sense-PR3, purportedly an antigenic epitope in an experimental setting. Neutrophils expressing modified proteins in the periphery of patients could deliver proteins for MHC class II presentation through the process of autophagy. Autophagy is now emerging as a spotlight in trafficking events that activate adaptive immunity due, in part, to promoting MHC class II presentation of peptides from intracellular source proteins (Dengjel et al., 2005). This may explain why HLA genes are highly linked with susceptible genetic background for autoimmune diseases (Lyons et al., 2012). Analysis of the MHC class II ligandome shows that 20 to 30% of self-class II epitopes are derived from cytosolic and nuclear proteins (Dengjel et al., 2005; Fissolo et al., 2009; Nedic et al., 2009). The *HLA-DB1*15* alleles were identified as a risk factor for PR3-ANCA disease in African Americans with an odds ratio of 73.3 ($p = 2.3 \times 10^{-9}$) (Cao et al., 2011). Patients with anti-GBM disease carry the *HLA-DRB1*1501* or *HLA-DRB1*04* alleles in approximately 80% of cases, as compared to only 20% of people in the general population (Phelps and Rees, 1999).

Susceptibility to Environmental Impacts

There are numerous articles implicating aging, chronic stress, hormones, even sunlight as “triggers” for the development of autoimmune disease. Epigenetics is receiving unprecedented attention as evidence mounts that autoimmune diseases arise from a combination of genetic susceptibility and environmental factors. Epigenetic mechanisms link external stimuli and gene expression. Perturbation of epigenetic regulation of gene transcription was discovered as a manifestation of ANCA disease (Ciavatta et al., 2010).

The result was increased expression of the known autoantigens PR3 and MPO, raising questions of increased antigen availability as a pathogenic factor (Yang et al., 2004; Ciavatta et al., 2010). These observations, among others, depict the neutrophil, not as a terminally differentiated, transcriptionally silent cell, but as a cell poised to respond to external stimuli. Probing deeper, it was found that silencing was deficient in patients due, at least in part, to inadequate levels of RUNX3, a transcriptional repressor with binding sites within both the PR3 and MPO genes. An article by Ben Harden in *Science News* reads, “All Roads Lead to RUNX: Several Autoimmune Diseases Share One Bad Actor.” A central role for RUNX proteins in the development of autoimmunity was first described in 2003 (Alarcon-Riquelme, 2003). Normally, RUNX3 mediates histone methylation by carrying the H3K27 methyltransferase, EXH2, to the RUNX3-specific DNA binding sites.

Another “sensor” and “transmitter” of environmental signals, protein tyrosine phosphatase-N22 (PTPN22), is linked to increased susceptibility to autoimmune disease (Bottini et al., 2004; Begovich et al., 2004, 2005; Kyogoku et al., 2004; Behrens et al., 2005; Canton et al., 2005; Carlton et al., 2005; Criswell et al., 2005; Jagiello et al., 2005; Ladner et al., 2005; Lee et al., 2005a; Burkhardt et al., 2006; Carr et al., 2009; Fiorillo et al., 2010; Martorana et al., 2012). In this case the genetic polymorphism responsible conferred a gain-of-function phenotype. This gain-of-function allele strongly correlates with numerous autoimmune diseases including SLE and ANCA disease.

Environmental factors known to impact ANCA and SLE diseases, at both disease onset and relapse, include aging (Hogan et al., 2005, 2007), seasonal changes (Falk et al., 1990a), and silica exposure (Hogan et al., 2001). The Mitochondrial–Lysosomal Axis Theory suggests that oxidized proteins, generated by reactive oxygen species (ROS), coupled with their inefficient breakdown by lysosomes, leads to generation of antigenic protein–protein cross-links (Kannan, 2005). Hydrocarbon and cigarette smoke exposures have been associated with anti-GBM disease, particularly in patients with significant pulmonary hemorrhage (Stevenson et al., 1995). Similarly, lithotripsy, MPO-ANCA, and other causes of “renal trauma” have occasionally been reported to be associated with development of anti-GBM disease (Xenocostas et al., 1999).

Microbial Infections

Scientific evidence has linked autoimmune disorders with infection for well over a century. What is the connection? Epidemiologic studies and case reports have suggested an association between anti-GBM disease and microbial infections. The first description of two patients with

influenza-like clinical signs, and sporadic reports of an association between these two diseases, can still be found (Salama et al., 2001). One study raised the possibility that a single T cell epitope mimicry by microbial Ag may be sufficient to induce the anti-GBM disease (Arends et al., 2006). The fact that 20 to 60% of patients report a prodromal upper respiratory tract infection increases suspicion of involvement of infection or toxin-triggered events (Perez et al., 1974). The most consistent microbial trigger in ANCA disease appears to be *Staphylococcus aureus*, which produces a superantigen response that may play a role in some patients (Stegeman et al., 1994; Mayet et al., 1999; Hellmich et al., 2001; Tadema et al., 2011).

Microbes carry proteins molecularly similar to “host” proteins. The Theory of Molecular Mimicry posits that a bacterial or viral protein is sufficiently similar, in either sequence and/or structure, to a host protein to cause a breakdown of immune tolerance to the host protein (Albert and Inman, 1999). Sequence similarities between foreign and self-peptides are sufficient to result in the cross-activation of autoreactive T or B cells by pathogen-derived proteins (Fujinami et al., 1983; Levin et al., 2002; Kohm et al., 2003). For example, GBM disease was induced in a rat model with microbial peptides that mimicked a previously identified T cell epitope that could induce the disease (Arends et al., 2006). Molecular mimicry has been implicated as a mechanism for initiation of ANCA by a group who found that patients had anti-LAMP-2 autoantibodies that cross-reacted with Fim-H, a bacterial adhesion protein (Kain et al., 2008).

Generally listed alongside molecular mimicry as a possible mechanism of autoimmunity caused by viral infection is the Direct Bystander Effect Theory which posits that an infection leading to inflammatory tissue damage and necrosis of cells uncovers epitopes of autoantigens that reactivate resting autoreactive T cells (Horwitz et al., 1998). This leads to the discussion of the recently discovered neutrophil extracellular traps (NETs), also called TRAPS. NETs are thought to be formed through a novel cell death program. Upon activation, neutrophils release granule proteins and chromatin that together form extracellular fibers that bind Gram-positive and -negative bacteria. Thus, NETs appear to be a form of innate response that binds microorganisms, prevents them from spreading, and ensures a high local concentration of antimicrobial agents to degrade virulence factors and kill bacteria. PR3 was shown to be present in these NETS (Brinkmann et al., 2004; Fuchs et al., 2007; Bosch, 2009).

While these examples of molecular mimicry in autoimmune disease are compelling, they do not satisfy the question of why there aren't more examples given the plethora of microbial and viral sequences similar to human proteins. Alternative ideas for how infectious agents induce autoimmune disease continue to build on

the Theory of Autoantigen Complementarity (Pendergraft et al., 2004). This theory is in line with a hypothesis published in 1983 of how a viral infection leads to autoimmune disease (Figure 67.7) (Plotz, 1983). The host-cell receptor is envisioned as an internal image of the virus. The variable region of the primary antibody against the viral protein is similar in shape to the host receptor. The anti-idiotypic antibody against the variable region of the primary antibody consequently has a shape similar to the viral protein thus producing an internal image cascade. The anti-idiotypic antibody which now carries the internal image of the viral protein can bind to the host receptor and act as an autoantibody. The process of internal image binding to a protein opposite in shape is termed “complementarity.” Proteins complementary to the autoantigen PR3 are carried by many different microbes and viruses. Among these microbes are Ross River virus, *Staphylococcus aureus*, and *Entamoeba histolytica*, all of which have been previously linked with ANCA disease (Davies et al., 1982; Pudifin et al., 1994; Stegeman et al., 1994). Pertinent to this finding, the onset of ANCA disease is commonly associated with a flu-like illness (Falk et al., 1990a). Alternatively patients may be producing complementary PR3 protein themselves. Investigations of ANCA patients' leukocytes reveal the presence of PR3 antisense RNA in approximately one-half of the patients tested (Pendergraft et al., 2004). The question remains whether these antisense transcripts are, or can be translated into, a protein product to produce the complementary protein. Translation of an antisense transcript has been reported (Van Den Eynde et al., 1999). It may be that aberrantly expressed antisense transcripts are a component of a range of human diseases (Lavorgna et al., 2004).

In support, it has been suggested that molecular complementarity contributes to the pathogenesis of other, non-renal autoimmune diseases as well. Evidence already exists for molecular complementarity in patients with Sjögren's syndrome and SLE (Papamattheou et al., 2004). Anti-idiotypic antibodies were detected in patients' sera using peptides complementary to the autoantigen B cell epitopes, and mice immunized with either the B cell epitope peptide or its complement developed antibodies against both immunogens (Routsias et al., 2003; Papamattheou et al., 2004).

In conclusion, after producing over 20,000 papers on autoimmune disease of the kidney, we are yet to understand when and how autoimmune disease develops. These hallmarks of the disease provide a comprehensive and cohesive foundation for the field that will influence biomedical researchers in their quest for new treatments. We suggest that a holistic approach may provide clarity of mechanism and help to understand how and what treatments would be efficacious for treatment of disease.

FIGURE 67.7 Hypothesis of how a viral infection leads to autoimmune disease. The host-cell receptor is envisioned as an internal image of the virus. The inciting antigen is not the autoantigen, but a viral protein complementary in shape to the host's cell surface protein. This complementary protein elicits an antibody response, which in turn elicits an anti-antibody, referred to as an anti-idiotypic response. The anti-antibody then reacts with the host's cell surface protein, now becoming an autoantigen. This process relies upon the activation of the immune system's idiotypic network.

SUMMARY

This chapter enumerates six tentative hallmarks that represent common denominators of autoantibody-mediated autoimmune disease of the kidney. These hallmarks are autoreactive cells to achieve the capability to evade deletion, the presence of asymptomatic autoantibodies, hyperactivity of the Fc–FcR pathway, enhanced susceptibility to environmental factors, antigenic modifications of self-proteins, and microbial infections.

FUTURE DIRECTIONS

A major challenge is to dissect the interconnectedness between the candidate hallmarks and their relative contributions to disease with the final goal of identifying pharmaceutical targets to develop new treatment approaches with minimal side effects.

INTRODUCTION

Experimental studies predict a frequent occurrence of human gonadal autoimmunity. In spontaneous autoimmune model targeting multiple organs, the testis and ovary are the dominant targets. Sperm autoimmunity commonly occurs after vasectomy, and autoimmune orchitis can be induced by testis antigens without adjuvant; thus male meiotic germ cell antigens are highly immunogenic to the autologous host. Autoimmune disease of the testis (orchitis) occurs spontaneously in essentially all animal species examined. Despite these observations, human gonadal disease with proven autoimmune etiology has yet to be identified and characterized. The slow progress in clinical research is in part explained by the success of assisted reproduction techniques that

partly overcome the adverse effects of antisperm antibodies. Nonetheless, the experimental studies have yielded exceptional information on the fundamental mechanisms of tolerance and autoimmunity. They include: the discovery and functional analysis of the CD4⁺CD25⁺ Foxp3⁺ regulatory T cells (Treg) and of the autoimmune response (AIRE) gene, molecular mimicry as a basis of autoreactive T cell response, and the epitope spreading phenomenon in autoantibody production. In addition, they provide guidelines for translational research into human gonadal autoimmunity, and for better understanding of chronic inflammatory conditions of the gonads associated with subfertility and infertility. In this chapter, we will present the experimental autoimmune models, followed by a description of existing data supporting an autoimmune basis in human testicular and ovarian diseases.

EXPERIMENTAL AUTOIMMUNE DISEASE OF THE TESTIS

Classical experimental autoimmune orchitis (EAO) is induced by immunization with testis antigen in adjuvant. In addition, autoimmune orchitis occurs spontaneously after manipulation of the immune system or following vasectomy, without Ag immunization. Studies on the spontaneous orchitis models have addressed the genetic and cellular mechanisms that terminate tolerance, leading to spontaneous autoimmune disease. Studies on the classical EAO model clarified the local immune mechanisms by which the protection of the testis is compromised, leading to autoimmune tissue injury.

Autoimmune Orchitis in the Dark Mink

Inbreeding of mink for a dark fur, co-selected male infertility in this seasonal breeder (Tung et al., 1981), but also affects mink with other fur colors (Pelletier, 1986). There are two histopathologic patterns: one has massive granulomatous inflammation, and the other extensive germ cell loss with little inflammation. In the latter, antibodies to sperm acrosome form an immune complex, with IgG and complement C3 depositing in the basement membrane outside the Sertoli cell barrier (SCB). Interestingly, there is an association of autoimmune orchitis with abnormal hypothalamic-pituitary-testicular function since correction of the hormonal defect prevented testis pathology (Tung et al., 1984). A study by Pelletier et al. (2009) has critically analyzed the spermatogenic cycle in this seasonal breeder and provided evidence that defects in the regulatory clearance mechanisms favor the breakdown of self-tolerance during spontaneous autoimmune orchitis in mink.

Autoimmune Orchitis in Rats Expressing Transgenic Human HLA B27 and Human β 2 Microglobulin

Lewis rats with transgenic human HLA B27/ β 2m spontaneously develop spondyloarthritis and rheumatoid arthritis that mimic human disease (Taurog, 2009). Unexpectedly, severe autoimmune orchitis occurs in the transgenic rats several months before the onset of joint disease (Taurog et al., 2012). Inflammation first appears in the ductus efferentes at 3 weeks when the first wave of apoptotic testicular germ cells begins to transit the ductus efferentes to reach the epididymis. B27/ β 2m transgene expression somehow reduces male germ cell specific tolerance. When autoreactive T cells respond to their cognate

peptides in this vulnerable region of male reproductive tract, they trigger persistent granulomatous inflammation. Interestingly, it takes another 3 months before the inflammation shifts to the testis and ultimately eliminates sperm production. Importantly, bilateral surgical excision of the orchitic testes prevents arthritis development and documents for the first time a causal link between two organ-specific autoimmune diseases (Taurog et al., 2012). The new model will provide an excellent opportunity to investigate molecular mimicry, and the finding supports the hypothesis of persistent innate cell activation as a factor in rheumatoid arthritis (Noss and Brenner, 2008). Although autoimmune orchitis has not been reported in men with spondyloarthritis, recent study detected sperm abnormalities in these patients (Villiger et al., 2010). Notably, lower urinary tract infections may be associated with this male-dominant human spondyloarthritis.

Post-vasectomy Autoimmune Orchitis in Mice with Treg Depletion and Post-vasectomy Tolerance to Testis Antigens

Vasectomy is a major global contraceptive method adopted by over 0.5 million men in the USA alone. Autoimmune orchitis with immune complex deposition occurs in vasectomized rabbits, guinea pigs, monkeys, and others (Bigazzi, 1981). Although vasectomized men develop sperm antibody, well-characterized autoimmune orchitis has not been documented. A recent study on the early autoimmune response to vasectomy discovered that the Treg response critically controls the response to sperm antigens that influence long-term outcome. Post-vasectomy autoimmune orchitis does not occur in the susceptible A/J or (B6xA/J) F1 mice unless Treg are partially (60%) depleted, whereas in the genetically resistant C57BL/6 mice, 98% Treg depletion is required. Unexpectedly, vasectomy alone does not lead to autoimmune orchitis at least within 10 weeks. Instead, sperm antigen-specific tolerance is the outcome. When subsequently immunized with tissue antigens in adjuvant, the vasectomized mice resist experimental autoimmune orchitis but not experimental autoimmune encephalomyelitis induction, indicating that vasectomized mice developed sperm-specific tolerance (Wheeler et al., 2011). Thus, sperm antigens released from the post-vasectomy epididymal granuloma induce tolerance or autoimmunity depending on the balance of effector Treg and effector T cell responses. The long-term immune sequel of vasectomy is likely determined by the genetic control of this dual response, including the individual's Treg capacity.

Autoimmune Orchitis Associated with Viral Infection

Infection may be followed by an autoimmune response that prolongs inflammation and tissue damage. Orchitis occurs in rabbits with infection of myxoma virus (Fountain et al., 1997) and Sendai virus closely related to mumps virus (Melaine et al., 2003). In mice unilaterally infected with *Listeria monocytogenes*, the contralateral testis develops orchitis without detectable microorganisms, providing evidence for an autoimmune component of infectious orchitis (Mukasa et al., 1995). Indeed, CD4⁺ T cells from infected donors transfer orchitis to uninfected recipients. In this study, $\gamma\delta$ T cells are found to regulate $\alpha\beta$ pathogenic T cells by cytokines, notably IL-10 and TGF- β (Mukasa et al., 1998).

Autoimmune Orchitis in Day 3 Thymectomized (d3tx) Mice

D3tx B6AF1 mice produce sperm-specific and oocyte-specific autoantibodies (autoAb). The testis and epididymis, and the ovary, are three of the five organs that develop autoimmune disease. A more detailed description of the d3tx autoimmune model is presented in the section on autoimmune oophoritis.

Classical Experimental Autoimmune Orchitis Induced by Immunization with Testis Antigen in Adjuvant

Historical Aspect

EAO, the first “tissue antigen/adjuvant” autoimmune model, was described by Voisin et al. (1951) and by Freund et al. (1953). Attempts to transfer disease by serum antibody to normal guinea pig failed but the study clarified regional differences in different spermatogenic compartments, and supported the physiological findings in the normal testis (Tung et al., 1971a; Johnson, 1973). Lymphocytes retrieved from immunized guinea pig induced EAO when they were injected directly into the testis, but not intravenously (Tung et al., 1971b). The finding supports the notion that normal recipients are resistant to Ab transfer of autoimmune disease, and T cells need to express tissue homing receptor to enter target organs. Further progress in the EAO mechanism has come from mouse and rat models. In general, EAO induction requires co-injection of testis antigen in complete Freund’s adjuvant (CFA) and/or pertussis toxin (Kohno et al., 1983; Doncel et al., 1989); however, murine EAO can also be induced by subcutaneous injections of viable testicular cells without adjuvant (Sakamoto et al., 1985; Itoh et al., 1991, 2005). A detailed description of the

protocols for testicular autoimmune disease was described by Tung et al. (1994).

Testicular Immunoprivilege (Local Regulation)

Head et al. (1983) discovered the prolonged survival of an allogeneic organ engrafted in the testicular interstitium, and called attention to the testis as an immunoprivileged organ (reviewed by Fijak et al., 2011a and Li et al., 2012). Since then, many soluble and cell-based immunosuppressive factors have been discovered in the testis interstitium, largely based on *in vitro* studies. The testis resident macrophages, peritubular cells, Leydig cells, and Sertoli cells have documented immunoregulatory properties (Meinhardt and Hedger, 2011). Testosterone has an immunosuppressive role and may directly enhance Treg function (Fijak et al., 2011b). These interstitial regulatory mechanisms can reduce local inflammation and prevent the efferent arm of immune response to self or microbial antigens, and are likely to operate in an antigen-independent manner. Recent *in vivo* studies emphasize the critical regulatory functions of the Sertoli cells. Co-implantation with Sertoli cells led to prolonged survival of functioning allogeneic pancreatic islets in diabetic mice (Selawry and Cameron, 1993; Mital et al., 2010). Mechanistically, the Sertoli cell expresses the Tyro-3 family receptors (Tyro 3, Ax1, and Mer) (Lu et al., 1999) that normally regulate the innate cellular response to Toll-like receptor stimulation (Rothlin et al., 2007). Major defect in spermatogenesis occurs in mice with triple genetic deletion of the TAM receptors (Lu et al., 1999). The Sertoli cells produce TGF- β ; and through a cell-to-cell immunomodulatory action, they can inhibit CD8⁺ T cell proliferation via B7-H1, and increase Tregs (Dal Secco et al., 2008). In addition, Sertoli cell-specific androgen receptor deletion led to breakdown of the SCB, which normally separates the antigenic and immunogenic meiotic germ cells from the interstitial space. There is reduced expression of claudin 3, a component of the SCB, and the emergence of interstitial inflammation and sperm antibody response (Meng et al., 2011).

Immature or tolerogenic testis dendritic cells (DCs) or macrophages in the testis may also control the inductive phase of an autoimmune response to meiotic germ cell antigens. But the current dogma, that these antigens are completely sequestered by the SCB, would deem this scenario unlikely. However, it should be emphasized that the truism of the dogma has never been tested experimentally. In addition, study on vasectomy and spontaneous orchitis models support Treg-dependent systemic tolerance to testis antigen, and this would require continuous priming of Tregs by germ cell antigens (Setiady et al., 2006). It is therefore very likely that at least some of the meiotic germ cell antigens are not sequestered.

Testicular Antigens

Orchitogenic antigens are localized in male meiotic germ cells including the spermatozoa. Their identity and immunogenicity are only partially known (reviewed by Frayne and Hall, 1999 and Tung et al., 2000). Some orchitogenic antigens are not testis specific, and they react with sera from rats with EAO, and their identity is revealed by a proteomics approach. These include heat shock protein 70, disulfide isomerase ER-60 and heterogeneous nuclear ribonucleoprotein H1 (Fijak et al., 2005). Recently, a murine orchitogenic antigen has been identified as the glycosylated murine zonadhesin (Wheeler et al., 2011). Zonadhesin is expressed on the outer acrosomal membrane of spermatids and sperm. It binds to the zona pellucida and prevents interspecies sperm–oocyte interaction (Hardy and Garbers, 1994; Tardif et al., 2010).

Mechanisms of Disease Initiation

T Cell and Autoantibody

CD4⁺ T cells are pivotal in EAO pathogenesis. Polyclonal or monoclonal murine CD4⁺ T cells adoptively transfer severe EAO (Tung et al., 1987; Yule and Tung, 1993). In rat EAO, an increase in the testicular IL-17 and IL-23 was detected, suggesting the involvement of Th17 subsets (Jacobo et al., 2011a). Variations in the number and cytokine profile (Th1 and Th17) of CD8⁺ T cells are also identified in EAO testis, in the chronic stage of the disease (Jacobo et al., 2009, 2011a). Tregs are distributed as clusters in subcapsular seminiferous tubules of rats with classical EAO (Jacobo et al., 2009). Tregs isolated from regional lymph nodes (LN) are more potent suppressors of polyclonal T cell response than the Tregs from other LN *in vitro* (Jacobo et al., 2010). However, Tregs fail to effectively suppress ongoing inflammation *in vivo*. This may be caused by T cell imbalance induced by cytokines in the inflamed testis, leading to effector T cell resistance to suppression or to reduction of the Treg suppressive function (Jacobo et al., 2011b).

Autoantibody participation in EAO is supported by immune complex detection in the tubular basement membrane in murine EAO and in the spontaneous autoimmune orchitis. Immune complexes are characterized by granular deposition of immunoglobulin (Ig) G and complement C3 (Figure 68.1D). Although antibody *per se* does not transfer EAO to normal recipients, antibody can synergize with effector T cells to induce severe EAO (Wheeler et al., 2011). The detection of immune complexes in frozen sections of human testis biopsies would provide more definitive evidences for an ongoing autoimmune process. See the oophoritis section for further discussion on autoantibody action.

Mechanism of Testis Inflammation

When orchitogenic T cells are adoptively transferred to normal recipients, they initially target the straight tubules and the ductus efferentes, and subsequently spread to the seminiferous tubules (Tung et al., 1987). In contrast, EAO induced by active immunization is initiated equally between the region of the rete testis and seminiferous tubules. After migration from blood vessels into testis interstitium, the macrophages, DCs, and T cells form multiple cell clusters around the seminiferous tubule. In many species, with the exception of rat EAO, the cells invade the SCB and enter the seminiferous tubules. It is important to understand how T cells enter the testis, damage the SCB, and injure the seminiferous tubules. Recent studies in the rat support the following scenario in active EAO induction. Chemokines and cytokines upregulate adhesion molecules on the endothelial cell (EC), and support T cell attachment to EC, and extravasation into the interstitial space. Contact between the activated form of CD44 on lymphocytes and its major ligand hyaluronic acid expressed on EC is required (Guazzone et al., 2005). Chemokines (which include CCL2/MCP-1, CCL3/MIP-1 α , and CCL4/MIP-1 β) expressed by testicular cells convert the leukocyte rolling into cell arrest. In addition, the higher percentage of leukocytes expressing CD49d integrin and the increased expression of CD106/VCAM ligand in endothelial cells mediate the step of firm adhesion. Finally, inflammatory cell transmigration occurs via the interaction of CD106 and CD31/PECAM-1 (Guazzone et al., 2009, 2012).

Interstitial macrophages and DCs play a critical role in testis inflammation. They express high levels of MHC class II, CD80, and CD86 and increase in number in the testicular interstitium of rats with EAO (Rival et al., 2008). They produce proinflammatory cytokines (mainly TNF- α , IL-6, and IFN- γ) (Suescun et al., 2003; Rival et al., 2006) and nitric oxide (Jarazo-Dietrich et al., 2012). In EAO of the B27/ β 2m transgenic rats, there is distinct distribution between the testis M1 and M2 macrophages; and the M1 macrophages dominantly target the seminiferous tubules (Taurog et al., 2012). Importantly, *in vivo* depletion of macrophages and DCs in rat EAO by clodronate-containing liposomes significantly reduces EAO incidence and severity suggesting that they are derived from circulating monocytes (Rival et al., 2008). Proinflammatory cytokines and nitric oxide alter the integrity and function of Sertoli adherens and tight junctions facilitating germ cell sloughing (Lee and Cheng, 2003; Pérez et al., 2011, 2012). Finally, germ cell apoptosis involves the TNF- α /TNFR1, IL-6/IL-6R, and FasL/Fas systems (Suescun et al., 2003; Theas et al., 2003, 2008; Rival et al., 2006). Death receptor and mitochondrial apoptotic pathways are involved

FIGURE 68.1 Comparing the immunopathology shared between autoimmune orchitis in mice and human orchitis with unexplained infertility. Frames A, C, and D illustrate immunopathology of autoimmune orchitis in mice. (A) A typical monocytic inflammatory cell cluster that “cups” the perimeter of seminiferous tubule. Although the inflammatory cells remain external to the SCB, the adjacent Sertoli cells and germ cells inside the tubule have disappeared ($\times 100$, hematoxylin and eosin). (C) Dendritic cells in the cell cluster (red fluorescence: CD11c) detected by immunofluorescence on frozen section, adjacent to a split myoid cell layer (green fluorescence: alpha actin) ($\times 400$). Not shown are co-localized T cells and macrophages in the cell cluster. (D) Direct immunofluorescence detection of testicular immune complexes on a frozen section of mouse testis with EAO. Immune complexes appear as peri-tubular IgG granules (green fluorescence). Frame B represents an immunoperoxidase study of the testis biopsy from a patient with unexplained infertility. CD3⁺ T cells form a peritubular “cup” that resembles the murine EAO shown in frame A. Note some T cells are inside the hypospermatogenic seminiferous tubule in B ($\times 400$, anti-CD3). Tung, K., Meinhardt, A., Schuppe, H.C., Bergmann, M. and Kliesch, S., personal observation.

(Theas et al., 2006). Excessive male germ cell antigens released into the interstitium during EAO further stimulate T cell response in the testicular draining LN (TLN). The TLN-specific DCs from these rats are more mature and express more IL-12p35 mRNA than do DCs from non-draining LN (Guazzone et al., 2011). Loss of SCB integrity is important in EAO pathogenesis, as documented by the finding in Sertoli cell-specific deletion of androgen receptor, reported by Meng et al. (2011).

CLINICAL AUTOIMMUNE DISEASE OF THE TESTIS

Idiopathic Male Infertility

The advent of the immunobead assay allows for objective semi-quantitation of anti-sperm antibody (ASA) of different Ig classes against antigens present in different surface domains of viable spermatozoa (Marshburn and Kutteh, 1994). ASA are found in 3–12% of men with

infertility, compared to 0–2% of the general male population (reviewed by Turek and Lipshultz, 1994). In principle, ASA may cause infertility by interfering with sperm transport and other fertilization events. ASA from infertile patients and animals can affect many steps of fertilization *in vitro*, such as sperm motility, cervical mucus penetration, acrosome reaction, zona binding, zona penetration, oolema binding, and pronucleus formation in the fertilized oocyte (reviewed by Tung et al., 2002). The detection of ASA of IgA and IgG isotypes to sperm head in the local genital secretion is strongly associated with male infertility (reviewed by Marshburn and Kutteh, 1994). Deciphering the nature of the cognate sperm antigens will add insight into ASA-mediated human infertility (Frayne and Hall, 1999) because ASA is also a component of autoimmune response that causes autoimmune orchitis and gonadal failure.

The diagnosis of human autoimmune orchitis depends on immunopathologic evaluation of testis biopsies; however, testis biopsy is rarely performed. The

common finding of reduction in spermatogenesis is not diagnostic of an autoimmune process. More important are the findings of orchitis and immune complexes. Two types of human orchitis with possible autoimmune basis are reported. The first is granulomatous orchitis of non-infectious origin. Clinically, patients present mild scrotal pain or swelling, or a hard scrotal mass. Histologically, the seminiferous tubules are replaced by granulomatous inflammation consisting of T cells, macrophages, and multinucleated giant cells (Figure 68.2). These findings mimic the changes in rat EAO (Doncel et al., 1989; Taurog et al., 2012). The second and more common type of orchitis contains multiple foci of monocytic inflammation (Suominen and Söderström 1982; Chan and Schlegel, 2002a,b) (Figure 68.1B), and resembles the finding in early lesions found in EAO of mice and guinea pig. T cell and macrophage clusters are located at the boundary of seminiferous tubules and penetrate them through disrupted SCB (Figure 68.1A, C) (Kohno et al., 1983; Schuppe et al., 2008). A recent study detected IL-17, IL-21, and IL-23 among the inflammatory cells, and suggests involvement of the proinflammatory Th17 pathway in human orchitis (Duan et al., 2011). Finally, in addition to chronic inflammation of unknown etiology associated with infertility, infectious orchitis can mimic autoimmune orchitis, and similar lymphocyte infiltrations are found in testicular biopsies in patients with other diseases including cryptorchid testes and testicular cancer *in situ* (Nistal et al., 2002; Jahnukainen et al., 1995).

Even more helpful in autoimmune orchitis diagnosis is the detection of testis immune complexes. Technically, the most accurate and convincing method of tissue immune complex detection is immunofluorescence on frozen testis sections. They are readily detected by this approach in many types of experimental autoimmune orchitis (Tung, 1978; Tung et al., 1981; Bigazzi, 1981; Lustig et al., 1987, 2000). Surprisingly, a systematic study of human testis biopsy with this approach has not been reported. However, earlier light and electron microscope studies show deposits or electron dense material in the tubular basement membrane that reacts with antibody to human IgG and complement C3 (Salomon et al., 1982; Lehmann et al., 1987).

Infertility and ASA Coexist with Other Autoimmune Diseases

The major evidence for an autoimmune basis of human autoimmune orchitis comes from patients with the autoimmune polyglandular syndrome (APS) (see Chapter 43 for details). APS-1 is a rare autosomal recessive disease caused by AIRE gene mutation (Kisand and Peterson,

2011). About 30% of male patients develop testis failure with autoantibody to steroidogenic enzymes and other antigens expressed in the Leydig cells (Maclaren et al., 2001).

Vasectomy, Sperm Granuloma, and Cystic Fibrosis

Patients with vasectomy commonly produce ASA, detectable several months after surgery. Post-vasectomy ASA may be a cause of infertility in men with vasovasostomy and adequate sperm count (Lee et al., 2009). Focal orchitis has also been reported in the testes of vasectomized men (McDonald, 1997), and by epidemiological analysis (Goldacre et al., 2007). However, a systematic immunopathologic analysis of the human testes and epididymis in vasectomized subjects is still lacking. Epididymal sperm granuloma commonly occurs in vasectomized mice (>80%), and also occurs in men, but the incidence in human is unknown without histopathologic data. Finally, ASA response also occurs in patients with congenital absence of the vas deferens and seminal vesicles associated with cystic fibrosis (D’Cruz et al., 1991).

Orchitis Associated with Virus Infections

Virus infection of the testis may cause orchitis by disrupting local immune privilege besides a direct viral cytopathological effect. The best-known orchitogenic viruses are mumps virus and HIV. The symptoms of mumps in prepubertal boys are limited to parotitis; however, 5–37% of male adults with mumps infection also develop orchitis (Erpenbach, 1991). Lymphocytic infiltration followed by oligozoospermia with tubular atrophy and fibrosis contribute to transient or permanent subfertility or infertility. Mumps virus does not appear to induce germ cell transformation, and may not be directly spermatogenotoxic. However, mumps virus replicates in Leydig cells *in vitro*, inhibits testosterone secretion and induces production of the chemokine CXCL10 that recruits leukocytes to the testis (Le Goffic et al., 2002; Mouchel et al., 2002). ASA is reported in AIDS patients who develop orchitis, hypogonadism, oligozoospermia, or azoospermia. The reduced testosterone levels in AIDS may result from a reduction of Leydig cell number or function. Proinflammatory cytokines may also alter the hypothalamic-pituitary-gonadal regulation of Leydig cell function (reviewed by Dejuq and Jégou, 2001), and affect SCB integrity (Xia et al., 2009). Sexual transmission of acquired immunodeficiency disease by HIV-infected macrophages from inflamed testis has been proposed but not further investigated.

FIGURE 68.2 Immunopathology of human granulomatous orchitis. (A) Seminiferous tubules, devoid of germ cells, are filled with monocytic inflammatory cells with associated peritubular and interstitial fibrosis ($\times 200$), and multi-nucleated giant cells ($\times 400$, insert) (hematoxylin and eosin). (B) Immunoperoxidase stain showing massive infiltration of $CD3^+$ T cells in the interstitial space and inside the seminiferous tubular lumen devoid of germ cells ($\times 100$, CD3 stain). *Tung, K., Meinhardt, A., Schuppe, H.C., Bergmann, M. and Kliesch, S., personal observation.*

EXPERIMENTAL AUTOIMMUNE DISEASE OF THE OVARY

Spontaneous Autoimmune Ovarian Disease (AOD) in AIRE Null Mice

Mice with AIRE deficiency resemble humans with the APS1 syndrome including a high incidence of spontaneous AOD (Kuroda et al., 2005; Cheng et al., 2007). AIRE regulates the transcription of many tissue-specific antigens that are ectopically expressed in thymic medullary epithelial cells. These antigens, presented by epithelial cells or DC, participate in central tolerance by either deleting autoreactive effector T cells, or by promoting development of antigen-specific natural Treg (Anderson et al., 2002; Derbinski et al., 2005). In AIRE null mice, the lack of thymic expression of ovarian antigens allows the emergence of pathogenic effector T and B cell responses against the autoantigens and AOD development. The ovarian disease in AIRE null mice is associated with lymphocytic infiltration in both ovarian follicles and the interstitial space. Severe AOD causes loss of oocytes and ovarian atrophy. The autoantibody in AIRE null mice in the AOD background reacts with the oocyte antigen NALP5/MATER (Cheng and Nelson, 2011). The similarity between AIRE null mice and the d3tx mice raises the intriguing possibility that the two diseases share common mechanisms.

AOD in Day 3 Thymectomized (d3tx) Mice

Autoimmune disease in d3tx B6AF1 mice most commonly targets the ovary (Figure 68.3), lacrimal gland, prostate, and epididymis (Nishizuka and Sakakura, 1969). The d3tx disease was once thought to be due to depletion of Tregs of late ontogeny. However, this notion has been challenged by several independent studies (Dujardin et al., 2004; Ang et al., 2007; Samy et al., 2008). Notably, normal day 3-old mice were found to have functional Tregs; and their depletion greatly enhanced disease frequency and severity. Monteiro et al. (2008) further reported enhanced effector T cells in alymphopenic environment due to imbalance in Tregs and effectors, possible modified thymic T cell repertoire, and lymphopenia. Although the d3tx disease is not due entirely to Treg depletion, the process is effectively inhibited by early infusion of exogenous CD4 Tregs from normal donors (Nishizuka and Sakakura, 1969). Indeed, this is the key experiment that ultimately led to the discovery of $CD25^+$ $Foxp3^+$ Tregs (Sakaguchi et al., 1995; Fontenot et al., 2003; Hori et al., 2003). In d3tx mice, effector T cells spontaneously respond to endogenous ovarian antigens in the ovarian draining LN (Alard et al., 2001). Disease suppression achieved by exogenous Tregs occurs in the ovarian draining LN where abundant antigen-specific donor Tregs accumulate (Samy et al., 2005). Subsequently, antigen-specific polyclonal Tregs in normal mice were also found

FIGURE 68.3 Immunopathology of autoimmune oophoritis in d3tx mice. (A) Atrophic ovary with absence of ovarian follicles and minimal oophoritis in severe and late AOD ($\times 50$, hematoxylin and eosin). (B) Inflammatory mononuclear cells surrounding and infiltrating ovarian follicles and surrounding interstitial atretic follicle; note leukocytes inside the oocyte space ($\times 200$). Wheeler, K. and Tung, K., personal observation.

to accumulate in regional LN of the internal organs; and they exert Ag-specific and Ag-dependent protection of the antigens in the draining organs (Samy et al., 2005, 2006, 2008; Setiady et al., 2006; Wheeler et al., 2009). Importantly, the repertoires of Treg antigen receptors present in individual LN are unique (Hsieh et al., 2012).

AOD in Neonatal Mice by Maternal Antibody to Murine ZP3

AOD is induced in neonatal mice (neonatal AOD or nAOD) by passive transfer of maternal antibody specific for a ZP3 B cell epitope 335-342 (Setiady et al., 2003, 2004). Although ZP3 antibody readily forms immune complex in the zona pellucida of both neonatal and adult ovaries, AOD occurs only in the neonatal but not adult mice. The immune complexes are targeted by activated $Fc\gamma RIII^+$ NK cells, which are critical for nAOD induction. The increased susceptibility of newborns to nAOD is not explained by ovarian ontogenetic differences (Setiady et al., 2003). In fact, the activating $Fc\gamma RIII$ -positive antigen-presenting cells located in both neonatal and adult ovaries can process ZP3 antigens, and stimulate a *de novo* pathogenic T cell response that can adoptively transfer nAOD to naïve recipients. The unique neonatal NK cells are required for both induction and effector functions of the autoreactive T cell response in adoptive transfer of nAOD (Setiady et al., 2003, 2004).

Classical Experimental Autoimmune Oophoritis

AOD was first induced in rabbit by immunization with pig zona pellucida in complete Freund adjuvant (CFA)

(Wood et al., 1981), and this was soon confirmed by AOD induction in dogs (Mahi-Brown et al., 1982). Extensive mechanistic study of AOD began after the disease was induced in mice immunized with a 13-mer murine ZP3 peptide (pZP3) (Rhim et al., 1992). The pZP3 contains both T cell and a native B cell epitopes. AOD can be induced by immunization with microbial and tissue peptides that mimic the pZP3. This T cell epitope molecular mimicry depends on very limited partial sharing of residues critical for induction of the ZP3 specific T cell response (Luo et al., 1993; Garza and Tung, 1995). Th1 subset is the major pathogenic T cell, and AOD is dependent on both CD28 and CD40 costimulatory pathways (Griggs et al., 1996). pZP3-specific Th2 cells also elicit AOD with dominant eosinophilic inflammation, and this can be transferred by T cell clones that produce IL-4 and IL-5 but not $IFN-\gamma$ (Lou et al., 2000; Agersborg et al., 2001). While most human ovarian autoimmune inflammation is monocytic, some are dominantly eosinophilic (Lewis, 1993). The enteric nematode (the rodent pinworm) strongly promotes a Th2 autoimmune response to pZP3, particularly in the neonatal period. Without adjuvant, pZP3 plus pinworm infection elicits strong Th2 response and eosinophilic AOD in neonatal mice. Moreover, this imprints long-term Th2 memory for pZP3, and mice develop rapid and intense Th2-mediated autoimmune response upon secondary challenge (Agersborg et al., 2001).

The pZP3-AOD model revealed unexpected mechanisms of autoAb induction and autoAb actions in tissue inflammation. Surprisingly, mice with ongoing pZP3-specific T cell response rapidly developed antibodies to antigenic determinants outside the pZP3 (Lou et al., 1996; Bagavant et al., 1999). Thus, when immunized with a truncated pZP3 lacking its native B cell epitope, mice develop ZP3 antibodies that recognize distant native B cell epitopes of ZP3, and the antibodies do not

cross-react with the truncated pZP3. This amplified antibody response is driven by endogenous ovarian antigen as it is abrogated in mice with ovarian ablation. Thus autoreactive B cells to ovarian antigens are not tolerized but are normally “primed” by endogenous antigens. This discovery preceded the study on diversification of lupus autoantibody, and provided the first definitive evidence that endogenous antigens can drive diversified autoantibody response (Lou and Tung, 1993). Second, although ZP antibodies do not cause adult AOD, they influence the distribution of AOD induced by CD4⁺ T cells. Atretic follicles in the ovarian interstitial space are the prime targets for pathogenic T cells, and T cell-mediated interstitial oophoritis is compatible with normal ovarian function (Bagavant et al., 1999). However, in the presence of ZP antibody, which binds to the oocytes in normal follicles, the T cell-mediated inflammation is “retargeted” to those ovarian follicles, leading to ovarian atrophy and infertility (Lou et al., 2000). The results from the experimental testis and ovarian models have provided insight into the pathogenetic role of autoAb in organ-specific autoimmunity. Although autoAb do not induce autoimmune disease when transferred to normal mice, they do so in “modified” recipients. This includes: (1) neonatal mice with unusual NK cell function and (2) recipients with ongoing T cell response, either by redirecting the T cells to new a new target within the organ, or by enhancing T cell mediated injury as in post-vasectomy orchitis.

CLINICAL AUTOIMMUNE DISEASE OF THE OVARY

Premature ovarian insufficiency (POI) occurs in 1% of women before the age of 40 years, with amenorrhea, sex steroid deficiency, and elevated levels of gonadotropins (Conway, 2002; Rees and Purdie, 2006; Rebar, 2006; La Marca et al., 2010). POI has known genetic, developmental and environmental causes, but many POI cases are idiopathic. Kim et al. (1995) and Hoek et al. (1997) summarized the arguments for autoimmunity as a basis for idiopathic POI: circulating autoantibodies against ovarian targets, association with other autoimmune diseases, ovarian function recovery after immunosuppressive therapy, and ovarian lymphocytic infiltration.

Human autoimmune ovarian disease is best documented in POI patients with adrenal autoimmunity; they, in fact, produce antibody to antigens shared by the two organs (Hoek et al., 1997; Bakalov et al., 2005). Two to 10% of the POI cases show this association (LaBarbera et al., 1988; Betterle et al., 1993; Kim et al., 1997; Bakalov et al., 2002), which can manifest as part of the autoimmune polyglandular syndrome type 1

(APS-1) or type 2 (APS-2). APS-1 of early childhood is characterized by mucocutaneous candidiasis, hypoparathyroidism, and adrenal insufficiency, and the incidence of POI is found in 60% of APS-1 patients. APS-1 patients have mutations in the AIRE gene on chromosome 21 (Nagamine et al., 1997; The Finnish-German APECED Consortium, 1997). Although the prevalent paradigm that explains autoimmunity in APS patients is the incomplete deletion of autoreactive T cells, Kriegel et al. (2004) demonstrated that patients with this disease exhibit a defective Treg function. Antibodies against antigenic enzymes common to ovary and adrenal gland include: cytochrome P450 side-chain cleavage enzyme (P450SCC), 17- α hydroxylase/17, 20-lyase (CYP17A1), and 21-hydroxylase (CYP21). Indirect immunofluorescence on frozen adrenal gland sections, and CYP21 antibody detection by radioimmunoassays are sensitive diagnostic tests (Falorni et al., 2002a,b; Dal Pra et al., 2003). The theca cells of preantral and antral follicles are the main targets in some POI cases.

POI also occurs as an independent autoimmune ovarian disease, which can result in unsuccessful IVF—embryo transfer therapy. Recent studies have identified cognate antigenic peptides recognized by the serum antibodies from POI patients, including alpha actinin 4, heat shock 70 protein 5, and actin beta (Mande et al., 2011). Although they are not ovary specific, mice immunized with the peptides develop loss of ovarian structure and partial fertility reduction (Mande et al., 2012). In general, POI patients have a higher risk in autoimmune disease (Hoek et al., 1997); and some POI patients produce autoAb to antigens other than those of the steroidogenic cells (Hoek et al., 1997). The most common association is thyroid autoimmunity at 20% (Hoek et al., 1997; Kim et al., 1997); less common are autoimmune gastritis with parietal cell antibodies (4%), myasthenia gravis with acetylcholine receptor antibodies (2%), and/or insulin-dependent diabetes (2%) (Hoek et al., 1997; Kim et al., 1997).

Histopathologically, the ovaries from POI patients may show complete or partial loss of ovarian follicles (Hoek et al., 1997). Oophoritis is represented by infiltration of monocytes, lymphocytes (mainly effector CD4⁺ T cells), macrophages, and plasma cells in the theca layer of large, antral follicles, while earlier stage follicles are consistently free of lymphocytic infiltration (Bakalov et al., 2005; La Marca et al., 2010). There is upregulation of class II MHC antigen expression in granulosa cells and an increase in the number of CD8⁺ T cells and NK cells (Hill et al., 1990; Giglio et al., 1994; Wu et al., 2004). Because the primordial follicles are unaffected in POI, fertility may be partially conserved in autoimmune oophoritis, but may progress to severe POI and infertility (Gloor and Hurlimann, 1984; Bannatyne et al., 1990).

CONCLUDING REMARKS

EAO and AOD research has provided new approaches to investigate human gonadal autoimmunity and chronic inflammation of the gonads associated with subfertility and infertility. We have described the experimental autoimmune diseases that occur in animals with perturbed immune regulation, in this chapter. They include: d3tx, Treg depletion/vasectomy, AIRE deficiency, and transgenic HLA B27/β2m expression. In all instances, the testis and the ovary are among the few organs affected. Moreover, the major regulatory elements that have been perturbed are Treg and AIRE. We propose that the gonads, and their unique functions, demand exceptional protection from autoimmune destruction, and this requires the Treg. We also hypothesize that a unique Treg function may in fact be the protection of the continuum of physiological events in reproduction, which include gamete production, gamete transfer, embryo implantation, and maintenance of the pregnancy itself (Trowsdale and Betz, 2006; Mold et al., 2008; Guerin et al., 2009; Kahn and Baltimore, 2010; Samstein et al., 2012), to assure successful procreation.

ACKNOWLEDGMENTS

We wish to thank the following graduate students and postdoctoral fellows for their contribution to the chapter: Sallie Agersborg, Harini Bagavant, Kristina Garza, Vanesa Guazzone, Patricia Jacobo, Sabrina Jarazo-Dietrich, Yahuan Lou, Cecilia Pérez, Claudia Rival, Eileen Samy, Yulius Setiady, Hedy Smith, Cristian Sobarzo, María Theas, Karen Wheeler, and Terecita Yule.

CLINICAL, PATHOLOGICAL, AND EPIDEMIOLOGIC FEATURES

The clinical profile of rheumatic fever (RF) was first described by Cheadle in 1889 and the manifestation of the disease follows defined criteria established by Jones in 1944, which were updated in 1992 and remain useful today (Dajani et al., 1993). Briefly, the disease follows an untreated *S. pyogenes* infection in children and teenagers that present some genetic factors that predispose to the diverse clinical manifestations. The diagnosis is made on a clinical basis. The major manifestations include polyarthritis, carditis, chorea, subcutaneous nodules, and erythema marginatum. The minor manifestations are fever, arthralgia (clinical) and prolonged PR interval, increased erythrocyte sedimentation rate, and presence of C-reactive protein.

Polyarthritis and carditis are the most frequent manifestations of the disease and occur in around 70% of children. Arthritis is one of the earliest and most common

features of the disease, present in 60–80% of patients. It usually affects the peripheral large joints; small joints and the axial skeleton are rarely involved. Knees, ankles, elbows, and wrists are most frequently affected. The arthritis is usually migratory and very painful. Carditis is the most serious manifestation of the disease, occurring a few weeks after the infection, and usually present as a pancarditis. Endocarditis is the most severe sequel and frequently leads to chronic rheumatic heart disease (RHD). Mitral and aortic regurgitation are the most common events caused by valvulitis. Sydenham's chorea is less common (30–40%), characterized by involuntary movements, especially of the face and limbs, muscular weakness, and disturbances of speech, gait, and voluntary movements. It is usually a delayed manifestation, and often the sole manifestation of acute rheumatic fever. Other manifestations such as subcutaneous nodules and erythema marginatum can also occur during RF episodes and are characterized by nodules on the surface of joints and skin lesions, respectively (Mota et al., 2009).

Streptococcus pyogenes, or group A streptococcus, was identified in 1941 by Rebecca Lancefield through serology based on its cell wall polysaccharide that is composed of carbohydrates such as N-acetyl β -D-glucosamine linked to a polymeric rhamnose backbone. Group A streptococci contain M, T, and R surface proteins and lipoteichoic acid (LTA), involved in bacterial adherence to throat epithelial cells. The M protein, which extends from the cell wall, is composed of two polypeptide chains with approximately 450 amino acid residues, in an alpha-helical coiled-coil configuration. The amino-terminal (N-terminal) portion is composed of two regions, A and B, which present variable numbers of amino acid residues. The A region shows high polymorphism and defines the different M types, currently more than 225 according to CDC (Centers for Disease Control and Prevention, <http://www.cdc.gov/ncidod/biotech/strep/strepblast.htm>). The C-terminal portion (regions C and D) is highly conserved (Smeesters et al., 2010).

The incidence of ARF in some developing countries exceeds 50 per 100,000 children. The worldwide incidence of RHD is of at least 15.6 million cases and the major cause of around 233,000 deaths/year. However, since these estimates are based on conservative assumptions, the actual disease burden is probably substantially higher. The incidence of ARF can vary from 0.7 to 508 per 100,000 children per year in different populations from several countries (Carapetis et al., 2005). In Brazil, according to the WHO epidemiological model and data from IBGE (Brazilian Institute of Geography and Statistics), the number of streptococcal pharyngitis infections is around 10 million cases, which could lead to 30,000 new cases of RF, of which around 15,000 could develop to cardiac lesions (Barbosa et al., 2009).

AUTOIMMUNE FEATURES

RHD is the most serious complication of RF and depends on several host factors that mediate a heart tissue-driven autoimmune response triggered by a defensive immune response against *S. pyogenes*.

Genetic predisposition is one of the leading factors contributing to the development of autoimmunity. In the last 5 years, using molecular biology tools, several new single nucleotide polymorphisms of genes involved with the activation of both innate and adaptive immune responses were associated with the development of RF/RHD (see Genetic Features).

The first genetic associations described in the 1980s focused on HLA class II alleles coded by HLA-DRB1 and DQB1 genes. The HLA class II molecules are expressed in the surface of antigen-presenting cells (APCs), e.g., macrophages, dendritic cells, and B lymphocytes, and trigger

activation of the immune system. In the case of RF/RHD, T cell populations activated upon specific self antigen stimulation will trigger autoimmune reactions. The production of several inflammatory cytokines will perpetuate the heart-tissue damage. These observations are corroborated by the fact that during the acute phase of disease, Aschoff bodies, a granulomatous lesion containing macrophages, Anitschkow cells, multinucleated cells, and polymorphonuclear leukocytes develop in the myocardium and/or endocardium of RHD patients. Inflammatory cytokines such as IL-1, TNF-alpha, and IL-2 have been found, depending on the developmental phase of the Aschoff bodies (Fraser et al., 1997) and as mentioned above, probably initiate the inflammatory process leading to heart tissue rheumatic lesions.

More recently, other molecules were described involved with the inflammatory process like integrins and chemokines and cytokines such as IFN-gamma, IL-23, and IL-17 that play a role in the recruitment of both T and B lymphocytes leading to the autoimmune reactions observed in rheumatic heart lesions (reviewed by Guilherme et al., 2011). T and B lymphocytes react against self antigens through molecular mimicry, first in the periphery and later in the heart tissue. The mechanisms of T cell receptor degeneracy and epitope spreading amplifies the autoimmune reactions (see Pathologic Effector Mechanisms). All these steps are represented in Figure 69.1.

GENETIC FEATURES

RF and RHD occur in 1 to 5% of untreated children with genetic predisposition. The disease is associated with several genes, some of which are related to the innate or adaptive immune response or both (Table 69.1).

In order to facilitate the comprehension of the role of implicated genes known up to now, we describe the associated genes/alleles based on their role.

Innate Immune Response

MBL2 Gene

MBL (mannan-binding lectin) is an acute phase inflammatory protein and functions as a soluble pathogen recognition receptor. It binds to a wide variety of sugars on the surface of pathogens and plays a major role in innate immunity due to its ability to opsonize pathogens, enhancing their phagocytosis and activating the complement cascade via the lectin pathway (Jack et al., 2001). Different variants of the promoter and exon 1 regions of the *MBL2* gene, which encodes mannan-binding lectin, have been reported in patients with RF/RHD. Interestingly, the A allele that codes for high production of MBL was associated with development of mitral

FIGURE 69.1 Acute phase rheumatic lesions (A and B) and cultured intralesional T lymphocytes (C).

stenosis (MS) and most of these patients presented high serum levels of MBL (Messias-Reason et al., 2006). In contrast, RHD patients with aortic regurgitation (AR) presented the O allele that codes for low production of MBL, and the patients presented low serum levels of MBL (Ramasawmy et al., 2008).

TLR-2 Gene

Toll-like receptors (TLRs) are sensors of foreign microbial products, which initiate host defense responses in multicellular organisms. A polymorphism of TLR-2 at codon 753 generally leads to the replacement of arginine with glutamine. The genotype 753Arg/Gln was more frequent in a Turkish ARF cohort when compared to controls (Berdeli et al., 2005).

Ficolin Gene

Ficolins trigger the innate immune response by either binding collectin cellular receptors or initiating the complement lectin pathway (Meassias-Reason et al., 2009). In Brazilian chronic RHD patients, with prolonged time of infection or repeated streptococcal infections, the haplotype G/G/A (-986/-602/-4) was found to be more frequent

than in controls, and was also correlated with low expression levels of this protein.

Fc γ RIIA Gene

This protein plays a role in the clearance of immune complexes by macrophages, neutrophils, and platelets (Hirsch et al., 1996). ARF patients presented histidine (H) in the codon 131, which typically encodes for argenin (A); consequently RF/RHD patients present a protein with low binding capacity to the immune complex, favoring the inflammatory response.

Adaptive Immune Response

The HLA (human leukocytes antigens) system is located in the short arm of the human chromosome 6 and codes for diverse proteins; it is considered the most polymorphic system, composed of several genes with several alleles. The class I proteins are present in all nucleated cells; however, the class II are expressed only in specialized cells of the immune system (B lymphocytes, activated T lymphocytes, monocytes/macrophages, and dendritic cells). These proteins are involved with antigen recognition and presentation of self and foreign (microbes) antigens.

TABLE 69.1 Genetic Polymorphism Associated with Development of RF/RHD

| Immune response | Gene | Chromosome localization | Polymorphism | Allele/Genotype/Haplotype associated with disease | Clinical picture | Population studied | References | |

MHC: major histocompatibility complex; TNF- α : tumor necrosis factor alpha; TGF- β : transforming growth factor beta; IL-1RA: IL-1 receptor antagonist; MBL: mannan binding lectin; TLR-2: Toll-like receptor 2; FCN-2: ficolin 2; FC γ RIIA: IgG Fc receptor; CTLA-4: cytotoxic T cell lymphocyte antigen 4; ARF: acute rheumatic fever; RHD: rheumatic heart disease; AR: aortic regurgitation; MS: mitral stenosis; MVD: mitral valve disease; MVL: multivalvular lesions.

Major Histocompatibility Complex (MHC): *DRB1, DRB3, DQB1, DQA1* Genes

Several HLA class II alleles have been described in association with RF/RHD. Patarroyo et al. (1979) described an alloantigen on the surface of B cells, designated 883, probably related to the HLA class II molecules, which was present in a high frequency in RF patients. Later, a monoclonal antibody (D8/17 MoAb) was produced against B cells from RF patients bearing the 883 alloantigen. Studies performed by Zabriskie et al. (1985) showed an increased frequency of this alloantigen in RF patients.

The susceptibility of developing RF/RHD was first associated with alleles of HLA class II genes (*DRB1, DRB3, DQB, and DQA*), which are located on human chromosome 6 (Table 69.1). Briefly, HLA-DR7 was the allele most consistently associated with RF (Guilherme et al., 1991; Ozkan et al., 1993; Weidebach et al., 1994; Guedez et al., 1999; Visanteiner et al., 2000; Stanevicha et al., 2003). In addition, the association of DR7 with different DQ-B or DQ-A alleles seems to be related to the development of multiple valvular lesions (MVL) or mitral valve regurgitation (MVR) in RHD patients (Guedez et al., 1999; Stanevicha et al., 2003). HLA-DR53 coded by the *DRB3* gene is another HLA class II molecule in linkage disequilibrium with HLA-DR4, DR7, and DR9. This allele was strongly associated with RF/RHD in two studies with Mulatto Brazilian patients (Guilherme et al., 1991; Weidebach et al., 1994), but not in Brazilian Caucasian patients (Visanteiner et al., 2000). Although DR53 has not been described in previous studies, DR4 and DR9 were associated with RF in American Caucasian and Arabian patients (Ayoub, 1984; Rajapkase et al., 1987), whereas in Egyptian and Latvian patients, DR7 was associated with the disease (Guedez et al., 1999; Stanevicha et al., 2003) (Table 69.1). In Japanese RHD patients, susceptibility to mitral stenosis seems to be in part controlled by the HLA-DQA gene or by genes in close disequilibrium linkage with HLA-DQA*0104 and DQB1*05031 (Koyanagi et al., 1996). HLA-DQA*0501 DQB*0301 with DRB1*1601 (DR2) were associated with RHD in a Mexican Mestizo population (Hernandez-Pacheco et al., 2003a).

The molecular mechanism by which MHC class II molecules confer susceptibility to autoimmune diseases is not clear. However, since the role of HLA molecules is to present antigens to the T cell receptor, it is probable that the associated alleles facilitate the presentation of some streptococcal peptides that will later trigger autoimmune reactions mediated by molecular mimicry mechanisms.

CTLA-4 Gene

This gene is an essential inhibitor of T cell responses. It is a strong candidate susceptibility gene in autoimmunity

and several studies suggest disease-associated polymorphisms (reviewed by Gough et al., 2005).

Both Innate and Adaptive Immune Response

More recently, with new technologies that have allowed the description of gene variability by single nucleotide polymorphisms (SNPs), other associations have been established that could clarify some reactions related to both the innate and the adaptive immune response leading to the autoimmune reactions in RF/RHD.

- *TNF- α* gene, also located in the chromosome 6, between HLA class I and II genes, codes for a proinflammatory cytokine that plays a role during the *S. pyogenes* infection and later in the inflammatory process in the valves. Polymorphisms at -308 G/A and -238 G/A were associated with the susceptibility of RHD patients from several countries (Hernandez-Pacheco et al., 2003b; Sallakci et al., 2005; Berdeli et al., 2006; Ramasawmy et al., 2007).
- *IL-10* gene is responsible for the production of IL-10, an anti-inflammatory cytokine. The genotype -1082 G/A, misrepresented in RHD patients, is apparently associated with the development of multivalvular lesions (MVL) and with the severity of RHD (Settin et al., 2007).
- *TGF- β 1* is a gene that controls the proliferation and differentiation of cells. The polymorphisms of both the SNPs 869 T and -509 T alleles were considered as possible risk factors for the development of valvular RHD lesions in Egyptian and Taiwanese RHD patients (Chou et al., 2004; Kamal et al., 2010).
- *IL-1Ra* gene, for which the most frequent alleles are 1 and 2, encodes the antagonist of IL-1 α and IL-1 β , which are inflammatory cytokines. Two studies in Brazilian and Egyptian RHD patients with severe carditis showed low frequencies of allele 1, suggesting lack of inflammatory control (Settin et al., 2007; Azevedo et al., 2010).

IN VIVO AND IN VITRO MODELS

In Vivo Model of Myocarditis and Valvulitis

Humans are unique hosts for *S. pyogenes* infections. However, several studies have been performed to determine a suitable animal model and numerous different species (mice, rats, hamsters, rabbits, and primates) have been tested for the development of autoimmune reactions that resemble those observed in RF/RHD patients (Unny and Middlebrooks, 1983), all with little success.

In the last decade, a model that appears to be useful for the study of RF/RHD has been developed with Lewis

rats. These rats have already been used to induce experimental autoimmune myocarditis and to study the pathogenesis of RF/RHD (Li et al., 2004)

Immunization of Lewis rats with recombinant M6 protein induced focal myocarditis, myocyte necrosis, and valvular heart lesions in three out of six animals. The disease in these animals included verruca-like nodules and the presence of Anitschkow cells, which are large macrophages (also known as caterpillar cells), in mitral valves. Lymph node cells from these animals showed a proliferative response against cardiac myosin, but not skeletal myosin or actin. A CD4⁺ T cell line responsive to both the M protein and cardiac myosin was also obtained. Taken together, these results confirmed the cross-reactivity between the M protein and cardiac myosin triggered by molecular mimicry, as observed in humans, possibly causing a break in tolerance and consequently leading to autoimmunity (Quin et al., 2001).

In another study done by the same group, Lewis rats were immunized with a pool of synthetic peptides from the conserved region of the M5 protein. Mononuclear spleen cells from these animals were able to proliferate in response to peptides from both the C-terminal region of M5 protein and the N-terminal region of a heterologous protein (M1) and myosin. These rats developed focal infiltration of mononuclear cells predominantly in the aortic valve, although no evidence of Aschoff bodies, the hallmark of RF lesions, or Anitschkow cells was observed (Lymbury et al., 2003).

Another study immunized Lewis rats with recombinant M5 or synthetic peptides from the B- and C-regions of GAS M5 (Gorton et al., 2009). Sera and T cells from these animals recognized a peptide (M5-B.6) from the B-repeat of the N-terminal portion of M5 protein and induced heart lesions (Gorton et al., 2010), confirming the previous results. The immunized rats (five out of seven) developed mononuclear cell infiltration in the myocardial or valvular tissue. Histopathological analysis of valve lesions showed the presence of both CD4⁺ T cells and CD68⁺ macrophages (Gorton et al., 2010), consistent with human studies (Guilherme et al., 1995).

Altogether, these studies indicated that the Lewis rats could be a model of autoimmune valvulitis.

***In Vitro* Model of Rheumatic Heart Disease Autoimmune Reactions**

The major sequels of rheumatic fever are heart tissue lesions that lead to chronic rheumatic heart disease, which is characterized by permanent valvular lesions. The heart disease starts by pericarditis, followed by myocarditis episodes in which the healing process results in varied degrees of valvular damage (Mota et al., 2009).

By isolating infiltrating T lymphocytes from damaged valvular tissue, we could establish the mechanism by which the immune response in the heart leads to autoimmune reactions (Guilherme et al., 1995). Figure 69.1 shows a damaged mitral valve in which verrucae lesions are observed, indicative of an acute rheumatic fever episode. Furthermore, the presence of Aschoff bodies in the myocardium tissue allowed for histological diagnosis of an active episode of rheumatic disease. *In vitro* tissue culture of small pieces of the surgical fragment allowed the isolation of infiltrating T cells.

The *in vitro* analysis of these tissue infiltrating T cells showed their ability to recognize several streptococcal-M protein peptides and self antigens by molecular mimicry mechanisms. We identified some mitral valve-derived proteins such as vimentin, PDIA3 (protein disulfide isomerase ER-60 precursor), and HSPA5 (78 kDa glucose-regulated protein precursor) that were recognized by both peripheral and intralesional T cell clones (Faé et al., 2008).

The identification of heart-M protein cross-reactive T cell clones directly from rheumatic valvular lesions established their involvement in the pathogenesis of the disease.

PATHOLOGIC EFFECTOR MECHANISMS

The term “molecular mimicry” was introduced in 1964 by Damian to define the mechanism by which self antigens are recognized after an infection by cross-reactivity (Damian, 1964).

Pathogen and self antigens can be recognized by T lymphocytes and antibodies through molecular mimicry by four different mechanisms. They can recognize (1) identical amino acid sequences, (2) homologous but non-identical sequences, (3) common or similar amino acid sequences of different molecules (proteins, carbohydrates), and (4) structural similarities between the microbe or environmental agent and its host (Peterson and Fujinami, 2007).

RF/RHD is the most convincing example of molecular mimicry in human pathological autoimmunity, in light of the cross-reactions between streptococcal antigens and human tissue proteins, mainly heart tissue proteins, that follow throat infection by *S. pyogenes* in susceptible individuals.

The inflammatory process that follows an *S. pyogenes* throat infection in individuals with genetic predisposition leads to intense cytokine production by monocytes and macrophages that trigger the activation of B and T lymphocytes.

Several heart-reactive antibodies described from 1945 until nowadays (reviewed by Cunningham, 2000 and Guilherme et al., 2011) also play role in the development of the disease.

Streptococcal and heart tissue cross-reactive antibodies activate the heart tissue valvular endothelial cells, increasing the expression of adhesion molecules such as VCAM1, which facilitates cellular infiltration by neutrophils, monocytes, B and T cells (Yegin et al., 1997). The “rolling” of leukocytes through vessels is triggered by chemokines expressed by activated endothelial cells that induce the expression of integrins, selectins, and subsequent trans-endothelial migration. Recently we identified increased expression of ICAM, another adhesion molecule, and a few chemokines (CCL-1, CCL-3, and CCL9), as well as some integrins (P- and E-selectins) in the myocardium and valvular tissue of RHD patients (Guilherme, L. in preparation). All of these molecules are involved with the inflammatory process and T and B lymphocyte infiltration leading to rheumatic valvular tissue damage.

CD4⁺ infiltrating T cells are predominant in heart rheumatic lesions (Raizada et al., 1983; Kemeny et al., 1989), and the first evidence of the molecular mimicry between streptococcus and heart tissue was obtained through an analysis of these heart tissue-infiltrating T cells. Three immunodominant regions of the M5 protein (residues 1–25, 81–103, and 163–177), heart tissue proteins (myocardium and valve-derived proteins, as well as vimentin), and synthetic peptides of the beta chain of cardiac myosin-light meromyosin region (LMM) were recognized by cross-reactivity by intralésional T cell clones (Guilherme et al., 1995, 2001; Ellis et al., 2005; Faé et al., 2006). Peripheral T cell clones also recognized human purified myosin, tropomyosin, laminin, and cardiac myosin-derived peptides from LMM and S2 regions (Guilherme et al., 1995).

Employing a proteomics approach, we characterized a number of mitral valve proteins identified by molecular weight (MW) and isoelectric point (pI). Four valve-derived proteins with molecular masses ranging between 52 and 79 kDa and different pI cross-reacted with the M5 immunodominant peptides, and were recognized in proliferation assays by intralésional T cell clones from patients with severe RHD. Vimentin was one of the identified proteins, a result that reinforces the role of this protein as a putative autoantigen involved in the rheumatic lesions. Novel heart tissue proteins were also identified, including disulfide isomerase ER-60 precursor (PDIA3) protein and a 78-kDa glucose-regulated protein precursor (HSPA5). The role of PDIA3 in RHD pathogenesis and other autoimmune diseases is not clear (Table 69.2) (Faé et al., 2008).

The analysis of the T cell receptors (TCRs) of auto-reactive T lymphocytes that infiltrate both myocardium and valves allowed us to evaluate the V β chains usage of TCR and the degree of clonality of heart tissue infiltrating T cells (Guilherme et al., 2000). In the heart tissue (myocardium and valves) of both chronic and acute RHD

patients, several expanded T cell populations with an oligoclonal profile were found. Such oligoclonal expansions were identified by T cell receptor (TCR) analyses (Guilherme et al., 2000). The finding of oligoclonal T cell populations is in contrast with the peripheral blood scenario, which contains polyclonal TCR-BV families. The fact that a high number of T cell oligoclonal expansions could be found in the valvular tissue indicates that specific and cross-reactive T cells migrate to the valves (Guilherme et al., 2000) and proliferate upon specific cytokine stimulation at the site of the lesions.

Cytokines are important secondary signals following an infection because they trigger effective immune responses in most individuals and probably deleterious responses in patients with autoimmune diseases. Three subsets of T helper cytokines are currently described. Antigen-activated CD4⁺ T cells polarize to the Th1, Th2, or Th17 subsets, depending on the cytokine secreted. Th1 is involved with the cellular immune response and produces IL-2, IFN- γ , and TNF- α . Th2 cells mediate humoral and allergic immune responses and produce IL-4, IL-5, and IL-13.

Another lineage of CD4⁺ T cells, namely Th17 cells, have been more recently described and produce a complex set of cytokines initially identified as IL-17, TGF- β , IL-6, and IL-23. This subset of cells has been described in and associated with several autoimmune diseases (reviewed by Volin and Shahrara, 2011).

In RHD in both myocardium and valvular tissue, we found large numbers of infiltrating mononuclear cells secreting the inflammatory cytokines IFN- γ and TNF- α . However, mononuclear cells secreting IL-10 and IL-4, which are regulatory cytokines, were also found in the myocardium tissue; nonetheless, in the valvular tissue, only a few cells secrete IL-4, suggesting that low numbers of IL-4-producing cells may contribute to the progression of valvular RHD lesions (Guilherme et al., 2004).

Recently, using immunohistochemistry, we identified IL-17⁺ and IL-23⁺ infiltrating cells in both myocardium and valvular tissue. The expression of these cytokines was also observed in the valvular endothelium (manuscript in preparation), confirming that Th17 cells also play an important role in the inflammatory process in RHD heart lesions.

AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

Several streptococcal and human cross-reactive antibodies have been found in the sera of RF patients and immunized rabbits and mice over the last 50 years and have been recently reviewed (Cunningham, 2000; Guilherme

TABLE 69.2 Mitral Valve Proteins Identified by 2D Gel Electrophoresis and Mass Spectrometry Analysis Recognized by Peripheral and Intralesional T Cells

| Protein | Accession number | Coverage (%) | Masses matched/total | MW/pI |
|--|------------------|--------------|----------------------|----------------------|
| Vimentin | P08670 | 34 | 20/23 | 53.0/5.4 53.7/5.1 |
| Vimentin | P08670 | 49 | 23/87 | 51.0/5.9 |
| PDIA3 Protein disulfide isomerase | P30101 | 45 | 19/92 | 56.0/6.7 |
| ER-60 precursor | | | | 56.0/6.0 |
| HSPA5 78 kDa glucose-regulated protein precursor | P11021 | 43 | 27/69 | 68.0/5.9 |

MW: molecular weight; pI: isoelectrical point; coverage (%): percentage of matched peptides identification in terms of amino acid residues.
Adapted from Faé et al., 2008.

et al., 2004). N-acetyl β -D-glucosamine, which is present in both the streptococcal cell wall and heart valvular tissue, is one of the major targets of the humoral response in RF/RHD, and antibodies against this polysaccharide displayed cross-reactivity with laminin, an extracellular matrix alpha-helical coiled-coil protein that surrounds heart cells and is also present in the valves (Cunningham et al., 1989; Cunningham, 2000).

Cardiac myosin is the most important protein in the myocardium and by using affinity purified anti-myosin antibodies, Cunningham's group identified a five amino acid residue (Gln-Lys-Ser-Lys-Gln) epitope of the N-terminal M5 and M6 proteins as being cross-reactive with cardiac myosin (Cunningham et al., 1989).

The permanent rheumatic lesions that damage the valves and antibodies against vimentin, an abundant protein in the valvular tissue, probably play a role in the valvular lesions (Cunningham, 2000).

In conclusion, antibodies against N-acetyl β -D-glucosamine, some epitopes of cardiac myosin, and vimentin can be considered as immunological markers of the disease.

CONCLUDING REMARKS—FUTURE PROSPECTS

RF/RHD is the most convincing example of molecular mimicry in which the response against *S. pyogenes* triggers autoimmune reactions with human tissues. RF/RHD lesions result from a complex network of several genes that control both innate and adaptive immune responses after an *S. pyogenes* throat infection. An inflammatory process permeates the development of heart lesions, in which adhesion molecules and specific chemokines facilitate the valvular tissue infiltration by B and T cells. CD4⁺ T lymphocytes are the prime

effectors of heart lesions. Several self antigens such as vimentin, myosin, and other mitral valve-derived proteins are recognized by molecular mimicry of streptococcal immunodominant peptides, particularly in individuals with genetic predisposition. Production of inflammatory cytokines (IFN- γ , TNF- α , IL-17, and IL-23), and low numbers of IL-4 producing cells, a regulatory cytokine, lead to local inflammation.

All this information creates a new scenario for the development of RHD, opening new possibilities for immunotherapy. Molecular knowledge of the autoimmune reactions mediated by intralesional T cells will certainly assist in the choice of streptococcal protective epitopes for the construction of an effective and safe vaccine.

HISTORICAL BACKGROUND

The role of autoimmunity in cardiovascular disease has long been a topic of investigation in the clinic and the laboratory. Years of research effort were devoted to establishing a link between streptococcal infection and rheumatic heart disease on the basis of an autoimmune response (see Chapter 69). Chagas' disease is still believed to be based on a cross-reaction of antibodies to *Trypanosoma cruzi* with myocardial or cardiac conductive tissue (Coura and Borges-Pereira, 2012). Finally, post-pericardiotomy syndrome and post-myocardial infarction syndrome are sometimes cited as instances of an autoimmune response instigated by damaged or necrotic tissue (Maisch et al., 1979). This chapter reviews the evidence linking autoimmunity with two important forms of heart disease, myocarditis and dilated cardiomyopathy (DCM). It must be stated, *ab initio*, that immunologic testing has so far not been effective in allowing a clear distinction between autoimmune and other etiologies of these diseases.

The classic description of myocarditis was given by Corvisart in 1812 (referenced in Gravanis and Sternby, 1991), but for many years progress in studying the disease was impeded by the uncertainties of clinical diagnosis. Definitive diagnosis was dependent upon autopsy examination. Interest in the disease increased in recent years

because of the availability of better antemortem diagnostic tools, especially the endomyocardial biopsy, greater understanding of the role of cardiotropic viruses, and the potential of new modalities of therapy.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Myocarditis

While myocarditis may be asymptomatic, the major features include arrhythmias (palpitations, dizziness, syncope, or sudden cardiac death), embolic events, congestive heart failure, or cardiogenic shock. These clinical findings can be supported by electrocardiographic changes, such as nonspecific ST-T wave abnormalities and atrial or ventricular arrhythmias. Two-dimensional echocardiography, a noninvasive way of evaluating heart size and function, may show normal ventricular size with thick walls and decreased contractility early in the illness or progressive heart enlargement with thinning of the muscle in chronic cases. Biventricular enlargement is seen in chronic cases. A pericardial rub may be detected, indicating pericardial irritation with or without a pericardial effusion. As the disease progresses, gallop rhythms and signs of congestive

heart failure appear. The patient may recall a recent viral illness with symptoms of malaise, chills and fever, upper respiratory or gastrointestinal symptoms, myalgia, and chest pain. The majority of cases, however, cannot be traced back to an obvious preceding illness. Most patients with myocarditis present with either left ventricular failure or arrhythmias as their only clinical signs.

Studies of the occurrence of myocarditis in North America, Europe, and Japan have suggested that the incidence varies widely in different areas (Jacobson et al., 1997). Prevalence figures of 1.06, 3.5, 5.4, and as high as 10 have been reported in different series (Gravani and Sternby, 1991). The reasons for these wide differences are not known, but may be related to the differing diagnostic criteria used or may reflect exposures to different types and strains of cardiotropic viruses, as well as genetic differences in the host populations. The 5-year survival of biopsy-proven acute or chronic myocarditis in adults is only 56% (Grogan et al., 1995). In pediatric populations, the prevalence and mortality are even higher. Noren et al. (1976) described histologic evidence of latent myocarditis in 4.2% of accidental deaths of children and 16.7% of unexplained, unexpected deaths, suggesting that unsuspected myocarditis may be a significant cause of unexpected death in children (Liberthson, 1996). Fabre et al. describe myocarditis in up to 12% of cases of sudden death in young adults (Fabre and Sheppard, 2006). Prospective studies have also revealed a grave prognosis for myocarditis patients, with a 5- to 10-year survival rate of 25–46%, mostly due to manifestations of DCM and sudden cardiac death (Dec et al., 1985; McCarthy et al., 2000; Magnani et al., 2006; Caforio et al., 2007).

The clinical diagnosis of myocarditis remains a challenge (Schultheiss and Kuhl, 2011). Myocarditis can be classified by etiology, histology, immunohistology, clinical pathologic, or clinical criteria (Table 70.1). Felker et al. (2000) and McCarthy et al. (2000) have demonstrated that the prognosis of cardiomyopathy in patients with myocarditis is dependent on the clinical pathologic classification of their initial disorder. Patients with fulminant myocarditis, who do not die within the first 2 weeks, have a survival rate which is virtually identical to that of age-matched controls. Patients with subacute myocarditis who develop persistent left ventricular dysfunction have an outcome that is virtually identical to that of patients with idiopathic DCM. Patients with chronic persistent myocarditis, while they continue to have myocardial inflammation, have no deterioration in ventricular function and usually have a normal survival. Patients with chronic active myocarditis and who have ongoing inflammation and fibrosis develop a restrictive cardiomyopathy severe enough to require transplantation within

TABLE 70.1 An Exemplary Classification Scheme for Myocarditis (Modified from Sagar et al., 2011)

| Etiologic | Histologic | Clinicopathologic |
|--|---------------|--------------------|
| Viral, such as enteroviruses (e.g., Coxsackie B), Erythroviruses (eg, Parvovirus B19), adenoviruses, and Herpes viruses | Eosinophilic | Fulminant |
| Bacterial, such as <i>Corynebacterium diphtheria</i> , <i>Staphylococcus aureus</i> , <i>Borrelia burgdorferi</i> , and <i>Ehrlichia</i> species | Giant cell | Acute |
| Protozoal, such as <i>Babesia</i> | Granulomatous | Chronic active |
| Trypanosomal, such as <i>Trypanosoma cruzi</i> | Lymphocytic | Chronic persistent |
| Toxic: alcohol, radiation, chemicals (hydrocarbons and Arsenic), and drugs, including doxorubicin | | |
| Hypersensitivity: sulfonamides and penicillins | | |

2–3 years (Lieberman et al., 1991). Patients with giant cell or necrotizing eosinophilic myocarditis (Sagar et al., 2012) develop rapidly progressive mildly dilated but severely hypofunctional cardiomyopathy and have a life expectancy, without vigorous treatment, that is measured in months.

The so-called Dallas criteria, the consensus of a group of cardiovascular pathologists, led to better standardization of the histopathologic examination (Aretz et al., 1986). Active myocarditis requires the presence of mononuclear inflammation associated with adjacent myocyte damage (Figure 70.1). Myocyte damage can take the form of necrosis or myocyte vacuolization. The term borderline myocarditis is applied when an unequivocal diagnosis of myocarditis cannot be made either because the inflammatory infiltrate is too sparse or because the damage to the myocyte is not clearly demonstrable (Figure 70.2). The terminology used for subsequent biopsies is ongoing, resolving, or resolved myocarditis. Ongoing myocarditis indicates persistent myocardial inflammation associated with myocyte damage. Resolving myocarditis resembles borderline myocarditis, but reparative fibrosis is evident. Resolved or healed myocarditis is diagnosed if no inflammatory infiltrate is seen. The Dallas criteria also require that myocarditis be distinguished from the histologic pattern of myocardial injury evident in ischemic heart disease. The inflammatory infiltrate in myocarditis is composed primarily of mononuclear cells, although in the

FIGURE 70.1 Lymphocytic myocarditis. There is a heavy infiltrate of large activated lymphocytes throughout the myocardium. Myocyte necrosis is noted in the middle of this image. Fibrosis is present on the right side of the image. (H&E 400×)

more acute phases polymorphonuclear cell infiltration is common. Giant cells and prominent eosinophilia are seen in some cases of myocarditis and often indicate a dire outcome.

The Dallas criteria, which have been used extensively for clinical trials, may be too insensitive to diagnose many patients with inflammatory heart disease. In one trial, only 9.6% of 2233 patients with a clinical diagnosis of myocarditis were positive by the rigid Dallas criteria (Mason and O'Connell, 1989). Utilizing the Dallas criteria even in patients who have died of myocarditis, and with five tissue samples, it is only possible to establish a histologic diagnosis of myocarditis in 54% of patients (Chow et al., 1989; Hauck et al., 1989). Additionally, in Towbin et al.'s (1994) study of children with suspected clinical myocarditis (67% of these patients had adenoviral infection), 13 of the 26 patients positive for viral nucleic acid by the polymerase chain reaction (PCR) did not display the histopathologic features that would allow the diagnosis of myocarditis to be established. The standard Dallas criteria are further limited by variability in interpretation as well as low sensitivity. These limitations have led to alternative pathological classifications. Wojnicz et al. (2001) and Frustaci et al. (2003), utilizing upregulation of HLA by endomyocardial biopsy or the presence of antiheart antibodies as markers of an autoimmune response, identified patients with suspected myocarditis who appeared to respond to immunosuppressive therapy.

Additional criteria rely on cell-specific immunoperoxidase stains for surface antigens, such as anti-CD3, anti-CD4, anti-CD20, anti-CD68, and anti-human leukocyte antigen (HLA) (Herskowitz et al., 1990; Maisch et al., 2000). Criteria that are based on immunoperoxidase staining have greater sensitivity and may have prognostic value.

Nevertheless there is the diagnostic lack due to sampling error. Noninvasive cardiac magnetic resonance imaging (MRI) may provide additional diagnostic value (Jesirich et al., 2010). With the unique potential for tissue characterization using T1- and T2-weighted images, cardiac MRI can evaluate three important markers of tissue injury: (1) intracellular and interstitial edema; (2) hyperemia and capillary leakage; and (3) necrosis and fibrosis (Mahrholdt et al., 2004; Abdel-Aty et al., 2005; Gutberlet et al., 2008; Friedrich et al., 2009). In practice, although the number of medical centers performing endomyocardial biopsy has been increased, it is still not routinely performed in all patients and all centers.

There are several distinct histologic forms of myocarditis (Basso et al., 2012). Drug- or allergy-mediated myocarditis is characterized by an eosinophilic infiltrate. Fulminant myocarditis demonstrates intense infiltration in virtually all sections with marked myocyte necrosis (Figure 70.3). Chronic active myocarditis reveals ongoing myocardial inflammation associated with fibrosis and occasional giant cells (Lieberman et al., 1993). Giant-cell myocarditis is a rare but frequently fatal form of myocarditis (Figure 70.4) (Elamm, et al., 2012). The victims are primarily young, healthy adults who die suddenly of heart failure or ventricular arrhythmia. Although cardiac transplantation may be curative, several instances of recurrent disease in the transplanted heart have been reported. Histologic findings in giant-cell myocarditis are diffuse myocardial necrosis with numerous multinucleated giant cells and a mixed inflammatory infiltrate of lymphocytes and macrophages. Collections of eosinophils are seen in some of these patients.

Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is a chronic form of heart disease characterized by left and right ventricular dilatation and impaired contraction (Gravanis and Ansari, 1987). The clinical spectrum is broad, ranging from individuals with asymptomatic cardiomegaly to patients who present with severe congestive heart failure. Patients may also display symptoms or signs of arrhythmia or systemic embolization with or without congestive heart failure. Other signs include systemic or pulmonary venous congestion, cardiomegaly, gallop rhythms, and mitral or tricuspid regurgitation. The diagnosis requires exclusion of heart failure due to other causes, such as coronary artery disease, toxic exposure, drug allergy, medication (adriamycin) effect, or physical agent injury. Once heart failure is established in a patient with DCM, the expected outcome is poor, with a 5-year mortality of 46% (Grogan et al., 1995). D'Ambrosio et al. describe in long-term follow-up studies in patients with acute myocarditis the development of DCM in 21% of patients over a mean follow-up period of 3 years (D'Ambrosio et al., 2001).

FIGURE 70.2 Borderline myocarditis. (A) A single cluster of perivascular lymphocytes is present. No myocardial damage is identified. (H&E 400 \times). (B) A CD8 immunohistochemical stain highlights the infiltrating T lymphocytes. (H&E 400 \times)

FIGURE 70.3 Fulminant myocarditis. The myocardium is replaced by a marked polymorphous inflammatory infiltrate composed predominantly of lymphocytes and macrophages with rarer eosinophils and neutrophils. Global myocyte injury and loss is noted. No giant cells are present. (H&E 100 \times)

Several studies have investigated the frequency of familial dilated cardiomyopathy. Petretta et al. report in their meta-analysis an estimated clinically confirmed FDC of 23% (95% confidence interval 0.17 to 0.31) was found (Petretta et al., 2011). Furthermore, a large number of other etiologic agents have been associated with DCM (Felker et al., 2000), including infections and metabolic, endocrinologic, and nutritional disturbances, as well as toxins and drugs. However, in approximately 50% of patients, no specific etiology can be identified. The same pathologic process probably results from a number of different etiologies.

Evidence for pathophysiologic relevance of autoimmunity in DCM has substantially increased over the past

years. Several circulating autoantibodies, some of them heart specific, have been described in animal experiments and first clinical pilot studies suggest that antibodies, including antibodies to the β_1 -adrenoceptor, play a crucial role in the induction and progression of heart failure. But the precise mechanisms on how these autoantibodies perpetuate or even induce an organ-specific autoimmune response are not yet fully understood (Leuschner et al., 2008; Deubner et al., 2010; Kaya et al., 2010, 2012). Clinical observations on prognostic relevance of autoantibodies have prompted therapeutic trials focused on nonspecific removal of autoantibodies from the circulation via immunoadsorption. There are early reports on a beneficial outcome in patients treated by immunoadsorption (Felix and Staudt, 2006).

To address cardiac autoimmunity the prospective Etiology, Titer-Course, and effect on Survival (ETiCS) of cardiac autoantibodies has been initiated. It is the largest European clinical diagnostic study initiated so far in the field of cardiac autoimmunity. ETiCS will enhance current knowledge on autoimmunity in human heart disease and promote endeavors to develop novel therapies targeting cardiac autoantibodies (Deubner et al., 2010).

In 1985, the prevalence of DCM in Olmsted County, Minnesota, was 36.5 in 100,000. African American race and male gender were associated with increased risk (Cetta and Michels, 1995). The incidence of DCM in Malmö, Sweden, was reported to be 10 in 100,000 per year (Torp, 1981), and estimated in Great Britain at 0.7–7.5 in 100,000 per year, with a prevalence in 1985 of 8.3 cases in 100,000 (Williams and Olsen, 1985). In a nationwide study in Finland, the incidence of DCM among children and adolescents was 0.34 in 100,000 per

FIGURE 70.4 Giant cell myocarditis. The myocardium is infiltrated by a patchy and diffuse inflammatory infiltrate composed primarily of lymphocytes and macrophages. Multiple collections of giant cells are seen within the infiltrate along with eosinophils. There is significant injury and loss of myocytes in areas of inflammation, while adjacent myocardium is relatively uninvolved. (H&E 50×).

year, with a prevalence in 1991 of 2.6 in 100,000. In children, the incidence is higher in boys than girls, and higher in babies younger than 1 year than in older children (Jefferies and Towbin, 2010). Although the male predominance in this disease is not great, it stands in contrast to most autoimmune disorders that occur more frequently in females. The basis of the male predominance is still not clearly understood, but appears to be related to sex-based differences in cytokine formation. The number of new cases increased each year over the 10-year study period (Arola et al., 1997). Since a number of these patients utilize significant medical resources in their care or eventually require cardiac transplantation, there is a great need for early and definitive diagnosis.

Cases representing progression from myocarditis to DCM can be termed inflammatory DCM (Maisch et al., 2000); Kline and Saphir (1960) documented progressive myocardial failure and death in a series of patients within months to years after acute myocarditis. Miklozek et al. (1986) found that 12 of 16 patients diagnosed as having viral myocarditis had continued cardiac functional abnormalities. Abelmann (1984) reported that half of 16 patients had cardiac symptoms or physical evidence of persistent cardiac dysfunction after recovery from acute myocarditis. Most symptomatic relatives of DCM patients with left ventricular dysfunction have evidence of myocardial inflammation consistent with early or mild myocarditis (Mahon et al., 2002).

Like myocarditis, DCM may be associated with Coxsackievirus infection. In 50 infants and children with DCM, Ayuthya et al. (1974) found significantly increased titers of neutralizing antibody to Coxsackieviruses B3.

Initially, Bowles et al. (1986) and Kandolf et al. (1987) demonstrated Coxsackievirus B-specific nucleic acid sequences in heart tissue of a small number of patients with DCM. Since then molecular testing has become increasingly sophisticated. Towbin et al. (1994) demonstrated that children with suspected myocarditis were PCR positive for viral etiologies on endomyocardial biopsy (26 of 38 samples from 34 patients). Additionally, the viral sequences demonstrated were more frequently adenoviral (15) than enteroviral (8).

In cases of DCM, the heart assumes a globular shape due to enlargement of all of the chambers, especially the left ventricle (Gravanis and Ansari, 1987). The histologic findings are generally nonspecific, and include myocardial cell hypertrophy and an increase in interstitial fibrous connective tissue. In areas of degeneration of the myocardial fibers, small clusters of lymphocytes may be seen. This finding may blur the distinction of DCM from myocarditis.

AUTOIMMUNE FEATURES AND IMMUNOLOGIC MARKERS

Circulating Antibodies

The ambiguities in diagnosing inflammatory disease of the heart muscle are evident. Although the availability of endomyocardial biopsy has helped to clarify the situation, many cases are still inconclusive. There is, at present, a need for noninvasive, inexpensive diagnostic procedures to distinguish autoimmune from other forms of inflammatory heart disease. Much evidence points to a significant role of autoimmunity in some animal models of heart muscle disease. It is logical, therefore, to propose that serologic tests, based on the demonstration of circulating autoantibodies to cardiac antigens, might be useful in the identification of autoimmune forms of myocarditis and DCM in humans. The literature has been reviewed by Caforio et al. (2002), Cihakova and Rose (2008), and, most recently, Kaya et al. (2012).

Immunofluorescence

Immunofluorescence tests utilize cardiac tissue of rat or human origin. Both frozen sections and isolated myocytes have been employed. Antibody generally localizes at the surface of the myocyte, giving a sarcolemmal or myolemmal pattern, or on the striations, producing a fibrillar pattern. Whether these two immunofluorescent patterns represent antibodies of different specificities is unclear, because both patterns can be seen in sera from mice immunized with purified cardiac myosin. A major problem in the interpretation of indirect immunofluorescence is the high prevalence of reactions obtained with sera

from healthy control subjects. Maisch (1987) found that 91% of patients with myocarditis gave positive reactions with human or rat cardiocytes, but 31–35% of healthy controls showed similar reactions, although generally at lower levels. Neumann et al. (1990) used more conservative criteria, 59% of patients with biopsy-proven myocarditis being positive, as were 20% of patients with DCM. In contrast, none of the healthy controls and only 4% of patients with ischemic heart disease were positive in this test under the conditions used.

Western Immunoblot

The Western immunoblot is potentially more sensitive than immunofluorescence and is capable of identifying particular antigens recognized by heart-reactive antibodies. Neumann et al. (1990) detected heart-reactive antibodies in 48 of 103 samples from biopsy-proven myocarditis or DCM patients by immunofluorescence, whereas 97 of the 103 samples exhibited reactivity by Western immunoblotting. No single pattern of antigen reactivity was unique to patients with myocarditis or DCM, but myocarditis sera showed an elevated prevalence of antibody against myosin heavy chain, whereas cardiomyopathy sera exhibited a greater prevalence of reactivity against cardiac muscle actin. Many normal sera reacted with the same antigen, but generally in lower titers. A quantitative immunoassay, such as an enzyme-linked immunosorbent assay (ELISA) using purified human cardiac myosin heavy chain, therefore, is needed for clinical evaluation of these antibodies.

Immunoassay with Defined Antigens

Among the well-characterized antigens used for the study by immunoassay of antibodies in sera of patients with myocarditis and DCM are myosin (Neumann et al., 1990; Caforio et al., 1992), laminin (Wolff et al., 1989), β 1-adrenergic receptors (Limas et al., 1989), and the mitochondrial components, adenine nucleotide translocator (ANT) protein (Schultheiss et al., 1986) and branched-chain ketodehydrogenase (BCKD) (Ansari et al., 1988).

These results show that many patients with myocarditis and DCM develop autoantibodies to a number of cardiac constituents. Large-scale evaluation is necessary before it can be concluded that detection of any single antibody, or group of antibodies, is sufficiently sensitive and specific to replace the endomyocardial biopsy as a primary diagnostic tool. It does seem, even at this early stage of investigation, that a decline in some antibody titers during treatment may predict a favorable therapeutic response (Müller et al., 2000).

None of these antibodies to cardiac antigens is known to play a direct pathogenic role in the disease. However,

the presence of antibodies to β 1-adrenergic receptors in DCM is highly suggestive of a direct pathogenic effect, since the antigen is accessible on the surface of the myocardiocyte. β 1-Adrenergic receptor antibodies can induce apoptosis in isolated adult cardiomyocytes (Staudt et al., 2003) and antibodies activating the receptors are associated with reduced cardiac function in chronic heart failure (Jahns et al., 2010).

While the pathogenic importance of antibodies is still controversial, the finding that reduction of immunoglobulins in plasma by an immunoabsorption column benefits cardiomyopathy patients provides strong evidence of their involvement (Winters, 2012). Although immunoabsorption does not establish the specificity of the autoantibodies that are depleted, reduction of certain immunoglobulin subclasses (IgG3) may be especially beneficial (Nagatomo et al., 2011). In a preliminary study, absorption columns using β 1-adrenergic receptors benefited patients with the corresponding antibody (Dandel et al., 2012).

Although the role of T cells in the pathogenesis of myocarditis has been difficult to study in humans, animal models have proved to be invaluable in discovering their pathogenic mechanisms. Findings in mice indicate that they play a key role in inducing myocarditis (Smith and Allen, 1991).

Immunologic Assessment of Biopsies

In addition to studies of circulating antibody, immunologic methods can contribute to the diagnosis of heart disease by the identification of immunoglobulin and complement in biopsy specimens. Hammond et al. (1988) found that 55% of patients with active myocarditis had deposits of IgG and complement component C3 in their biopsies. Thirty-nine percent of borderline myocarditis (inflammation without myocyte necrosis) cases and 6% of DCM cases were also positive. Patients with other autoimmune diseases, such as systemic lupus erythematosus and scleroderma, sometimes showed deposits of IgG and C3 in their heart tissue, but these usually were coarse, granular deposits in the interstitial spaces of the myocardium or endocardium, probably representing immune complexes.

Immunofluorescence with defined antisera has been used to identify infiltrating cells in cardiac biopsies. Luppi et al. (2003) found that the myocardium of myocarditis and DCM patients was infiltrated by macrophages and $CD4^+$ and $CD8^+$ T lymphocytes. In the majority of patients, the T cell receptor (TCR) repertoire was restricted with a polyclonal expansion of the Vb7 gene family. Evidence of Coxsackievirus infection was also found.

The expression of MHC class I and class II antigens in biopsy specimens was evaluated by Herskowitz et al.

(1990). In control samples, only low levels of MHC class I molecules were expressed on interstitial cells and vascular epithelium, while MHC class II could not be demonstrated immunohistologically. Increased myocardial expression of MHC class I and *de novo* expression of class II antigens were found in 85% of the myocarditis patients and 33% of the DCM patients.

GENETIC FEATURES

Because of the possible autoimmune origin of myocarditis and DCM in humans, and the well-documented association of experimental myocarditis with the major histocompatibility complex (MHC) in mice (Rose et al., 1988), a number of studies to determine the relationship with the human MHC (HLA) have been carried out. Anderson et al. (1984) reported that DCM patients had an increased frequency of HLA-DR4 and a decreased frequency of HLA-DR6. These findings were corroborated by Limas et al. (1990), who also demonstrated an increased frequency of HLA-DR4 in DCM patients. A genetic predisposition toward cardiac autoimmunity was demonstrated, in that 72% of HLA-DR4⁺ patients had anti- β 1-adrenergic receptor antibodies compared with 21% of HLA-DR4⁻ patients. In the largest study to date, Carlquist et al. (1991) reconfirmed these findings and also found that the DR4-DQw4 haplotype conferred heightened risk of disease. In a meta-analysis of five studies, they confirmed that the DR4 association with myocarditis was sustained among different patient populations. No differences in disease phenotypes have been reported.

A predominance of myocarditis in males has been reported in a number of studies. The proportion of male patients is about 60% (Lieberman et al., 1991; et al., 1995). In this respect, myocarditis differs from most autoimmune diseases, which predominantly affect females.

ENVIRONMENTAL FEATURES

Myocarditis has both infectious and noninfectious causes. As noninfectious agents of myocarditis, a number of drugs have been implicated, acting either directly as toxic agents or as triggers of an allergic response. This section deals with infectious myocarditis; there is less information on cardiac autoimmunity in other forms (see Table 70.1).

Acute myocarditis is associated with infections of many types, including bacterial, rickettsial, viral, mycotic, protozoan, and helminthic. Several viruses have been implicated in this disease and, in some cases, multiple viruses may be detected in the heart. In Europe and North America, among the most common agents are the enteroviruses and the adenoviruses. Grist and Bell (1974)

reported that Coxsackievirus group B infections were associated with at least half of the acute cases of myocarditis. By immunofluorescence, Burch et al. (1968) found Coxsackievirus B antigen in the myocardium of 30.9% of routine autopsy specimens of myocarditis. Serotype B3 is identified most frequently. Other studies have suggested that adenoviruses are more prevalent in pediatric patients (Bowles et al., 2003).

By using molecular genetic methods, enteroviral and adenoviral genomes were detected in 10–35% of endomyocardial biopsies from patients with myocarditis or DCM (Baboonian and McKenna, 2003; Pauschinger et al., 2004). In a study in Europe, 32.6% of biopsies in the study group contained enteroviral RNA, 8.1% adenovirus DNA, 36.6% parvovirus B19 DNA, and 10.5% human herpesvirus type 6 DNA. In 12.2% of the samples, dual infection with PVB19 and herpesvirus was present (Kuhl et al., 2003). A study carried out in the United States identified parvovirus DNA in 12% of samples, but its presence did not correlate with clinical presentation (Stewart et al., 2011).

Like other enteroviruses, Coxsackieviruses enter the alimentary tract and are acid stable. They multiply in the small intestine. Following replication, viremia develops, seeding the infectious agents in selected tissues. As an obligatory intracellular parasite, the virus must enter a cell through receptor-mediated endocytosis. The virus receptor determines the tropism of the virus. Cardiotropic CB3 employs myocyte surface molecules as receptors, whereas hepatotropic or diabetogenic virus strains utilize receptors on hepatocytes or pancreatic islet cells, respectively. The infection may cause cell death directly, or act indirectly to stimulate an immunopathic host response (Huber, 1997). Coxsackievirus B3 RNA can persist in the myocardium for many days after infectious virus is no longer demonstrable (Klingel et al., 1992) and may, even without the ability to multiply, cause ventricular compromise in the face of a stimulated immune system (Wessely et al., 1998; Esfandiarei and McManus, 2008).

The CB3 genome is a single molecule of positive-sense RNA of approximately 7400 nucleotides in length. The genome codes for four capsid proteins as well as for the nonstructural proteins necessary for viral replication. A comparison of cloned cDNA from cardiovirulent and noncardiovirulent strains showed that sites within a non-translated region and in the capsid protein affect virulence (Tracy et al., 1996).

Nutrition also plays a role in determining susceptibility to viral myocarditis. Beck et al. (1995) demonstrated that mice fed a diet deficient in selenium and infected with a noncardiovirulent strain of CB3 developed severe myocardial damage. Virus isolated from the hearts was fully virulent; six point mutations distinguished the virulent strains. The accumulation of these multiple mutations

may be the result of greater viral replication in the hearts of selenium-deficient mice and may be attributable to decreased immune responses compared to selenium-adequate mice (Levander and Beck, 1997). These results may shed light on the etiology of an endemic form of cardiomyopathy known as Keshan disease, seen primarily in selenium-deficient regions of China (Abelmann, 1984).

Chagas' disease is a major cause of heart muscle disease in Latin America, responsible for 8 to 9 million cases annually (Hashimoto and Yoshioka, 2012). It is caused by the hemoflagellate *Trypanosoma cruzi*, which is transmitted to humans via the bite of the reduviid triatomine bug. Most patients initially have only mild, influenza-like symptoms, but 10–30% of infected individuals develop fulminant myocarditis. Chronic Chagas' disease may present with arrhythmias, thromboembolic events, and congestive heart failure. It represents a particularly lethal form of cardiomyopathy, as survival after presentation is two- to four-fold shorter than that of patients with other forms of DCM (Cunha-Neto et al., 2004).

Antibodies to a number of cardiac antigens, including fibronectin, laminin, and myosin, are found in many patients with chronic Chagas' disease, as well as with other forms of DCM (Ballinas-Vedugo et al., 2003). Molecular mimicry between *T. cruzi* and heart disease has been cited as a mechanism to explain the production of autoantibodies during infection (Kalil and Cunha-Neto, 1996). A number of candidate antigens have been described, including a heart-specific epitope of cardiac myosin heavy chain and a 12-amino acid peptide of F1160, a 160-kDa protein on the surface of *T. cruzi* that mimics a similar protein found on mammalian axonal and myenteric plexus cells (Van Voorhis et al., 1991). The latter antibody is of special interest because of the occurrence of megacolon, megaesophagus, and other neuropathies during chronic Chagas' disease. Among the other antigens described as possible initiators of cross-reactive responses are a peptide of the second extracellular loop of the β_1 -adrenergic receptor (Ferrari et al., 1995), a *T. cruzi* ribosomal protein R13 (Motran et al., 2000), a ribosomal P protein (Kaplan et al., 1997), and Cha. The latter antigen is recognized by T cells of patients as well as antibodies (Girones et al., 2001). An early decision about the course of immunity is made during the early innate response determined by activation of Toll-like receptors and macrophage development. The subsequent adaptive immunity may be protective or pathogenic (Pellegrini et al 2012).

Kawasaki syndrome is an acute febrile disease of infants and young children that is often associated with myocarditis (see Chapter 72). In addition to prolonged fever lasting more than 5 days, the principal signs are diffuse mucosal inflammation, bilateral nonpurulent

conjunctivitis, dysmorphic skin rashes, indurative angioedema of hands and feet, and cervical lymphadenopathy (Kuo et al., 2012). Although the etiology is uncertain, available evidence implicates bacterial infection. Cunningham et al. (1999) showed that sera from five of 13 patients with Kawasaki syndrome recognized peptides from the light meromyosin region of human cardiac myosin and had a different pattern of reactivity from acute rheumatic fever sera.

ANIMAL MODELS AND PATHOGENIC MECHANISMS

Since enteroviruses are most often implicated in human myocarditis and DCM, these agents have been widely used to investigate the pathogenic mechanisms of these diseases. Although infections by CB3 are relatively common, the development of clinically significant, ongoing myocardial disease in humans is relatively uncommon, suggesting that differences in host response play a critical role in disease susceptibility. These differences are likely to be genetically determined and may relate to the expression of virus-specific receptor on heart tissue or to the immune response of the host. Because it is difficult to examine the role that genetic polymorphisms play in humans, investigators have developed models of Coxsackievirus-induced myocarditis in mice, for which a large number of genetically different, inbred strains are available.

A model of the timecourse of viral myocarditis is illustrated in Figure 70.5. All strains of mice tested developed acute myocarditis starting 2 or 3 days after CB3 infection. The disease reached its peak on day 7 and gradually resolved so that by day 21 the heart was histologically normal. No infectious virus was found after day 9. In a few strains of mice, however, the myocarditis persisted (Rose et al., 1987; Cihakova and Rose, 2008), but the histologic picture shifted. The first phase was characterized by focal necrosis of myocytes and accompanying a focal acute inflammatory response with a mixed cell infiltrate consisting of polymorphonuclear and mononuclear cells. In those mice that developed the second phase of disease, the inflammatory process was diffuse rather than focal and consisted mainly of mononuclear interstitial infiltrates, including both T and B lymphocytes and little or no myocyte necrosis. In the mice that developed the second phase of disease, heart-reactive autoantibodies were present and shown to be specific for the cardiac isoform of myosin (Neu et al., 1987a). This finding suggested that the second phase represented an autoimmune response initiated by the viral infection. Direct evidence to support this hypothesis was produced by immunizing the susceptible strains of mice with purified cardiac myosin and showing that they developed a very similar histologic picture of myocarditis (Neu et al., 1987b). No heart disease was found in animals

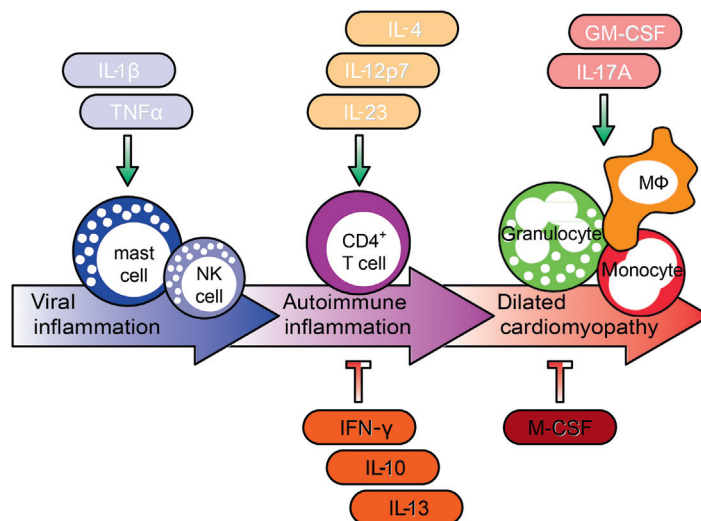

FIGURE 70.5 Schematic of the pathogenesis of viral myocarditis.

that received skeletal myosin and none appeared in the strains of mice that were not genetically susceptible to the second phase. They found evidence that this form of inflammatory heart disease was due to an immune response to cardiac myosin, assembled by inducing specific tolerance to cardiac myosin (Wang et al., 2000; Foustari et al., 2011). This finding suggested that the second phase represents an autoimmune response initiated by molecular mimicry between the virus and heart antigens (Cunningham, 2004). On the other hand, available evidence suggests that the autoimmune response depends upon virus-induced damage to the heart since Horwitz et al. (2000) found that transgenic mice expressing interferon gamma (IFN- γ) in their pancreatic cells failed to produce CB3-induced myocarditis, even though the virus proliferated great in other sites. These findings suggest that the virus infection may serve as an adjuvant for cardiac antigens that have been expressed or liberated during the viral infection of the heart (Rose, 2000). Of importance is the finding that a number of other viruses unrelated to Coxsackieviruses such as cytomegalovirus produce a similar autoimmune myocarditis following infection. The experiments showing that myocarditis can be produced by immunization with cardiac myosin in animals that have not undergone viral infection demonstrate that the disease does not depend upon persisting virus even though it is possible to demonstrate traces of viral RNA in the heart of Coxsackievirus B3 infected animals.

Unless subjected to exercise stress, most mice survived the autoimmune phase of myocarditis whether induced by viruses, infection, or by immunization with cardiac myosin. Gradually the disease waned in severity (Rose and Hill, 1996; Cihakova and Rose, 2008). Under some conditions, however, the histologic picture changed again to

produce a mainly fibrotic disease. As the process continued, there was a thinning of the ventricular cell walls and a large increase in size of the left ventricle. By day 35, after infection or immunization there were definite signs of cardiac insufficiency and by day 60, most of the animals with these changes died of heart failure. This form of the disease, whether induced by viral infection or myosin autoimmunity, replicated the major characteristics of dilated cardiomyopathy, suggesting that DCM can represent an end stage of autoimmune myocarditis in some instances.

The striking finding from the investigations described above was that strains of mice highly susceptible to the autoimmune myocarditis following viral infection were also the strains most susceptible to the myosin-induced disease. On the other hand, other strains were relatively resistant to both forms of myocarditis. These observations indicated that the disease susceptibility was under a large measure of genetic control. As in most autoimmune diseases, genes of the major histocompatibility complex have an important influence on the development and course of autoimmune disease (Li et al., 2008a). Thus, in both the viral and myosin-induced models, the H-2^s, H-2^a, and H-2^b alleles were associated with increased morbidity of autoimmune myocarditis, whereas the H-2^b allele is associated with a relatively low susceptibility. These MHC polymorphisms were further reflected in the prevalence and titer of cardiac-specific autoantibodies. The genetic findings in the mouse can be related to human myocarditis through experiments by Hayward et al. (2006) and Taneja and David (2009), who demonstrated a spontaneous myocarditis model in NOD mice carrying the transgenically introduced human HLA-DQ8 allele associated with greater susceptibility to human

DCM. Like many autoimmune diseases in animals and humans, non-MHC genes play a determining role in susceptibility to myocarditis. To determine the non-MHC genes that affect susceptibility to myosin-induced myocarditis, genome-wide linkage analysis was carried out and revealed at least two prominent loci that had significant effects on susceptibility to autoimmune myocarditis. A putative susceptibility gene, *eam1*, was located on the proximal end of chromosome 1 and *eam2* on the distal region of chromosome 6. Both of these chromosomal segments bore genes determining susceptibility to a number of other autoimmune diseases such as autoimmune encephalomyelitis and autoimmune arthritis as well as spontaneous diabetes.

In addition to lending themselves to genetic studies, the experimental models of autoimmune myocarditis provide the opportunity of following the inflammatory process from the beginning to the end (Rose, 2011). The first major question to be considered was the basis of the susceptibility to autoimmune myocarditis following the virus infection. Studies show that two critical cytokines, IL-1 β and TNF- α , were both necessary and sufficient for the progression from viral myocarditis to autoimmune myocarditis. Blocking either one of these two cytokines prevented the transition from viral to autoimmune myocarditis even in the most highly susceptible strains. Even more important was the demonstration that providing either of these two cytokines in recombinant form allowed normally resistant mice to develop the autoimmune form of myocarditis just like their genetically susceptible counterparts. The earlier signs of susceptibility to autoimmune myocarditis become evident very early in the course of viral infection. In fact, significant elevations of IL-1 β were found as early as 8 hours after viral infection (Fairweather et al., 2004a,b). Thus, the innate immune response to the virus is the determining factor in later susceptibility to autoimmune disease. Some evidence points to the mast cell as particularly important in producing the mediators that determine the course of innate immunity to the virus. In addition, NK cells which are also activated during the innate immune response are responsible for downregulating susceptibility to the autoimmune response.

An important lesson to be learned from these experiments is that the early steps in innate immunity determine the later course of adaptive autoimmune diseases. Adoptive transfer experiments using myosin or myosin peptide-induced disease have shown that the induction of autoimmune myocarditis depends upon myosin-specific CD4 T cells (Smith and Allen, 1991; Li et al., 2008b; Chen et al., 2012). The course of the inflammation during autoimmune myocarditis can be traced to the relative proportions of certain key cytokines. Severe forms of autoimmune myocarditis are associated with

greater production of IL-12 P40 (a Th1 signal), IL-4 (a Th2 signal), and IL-23 (a signal of the Th17 response) (Rose, 2011). On the other hand, IFN- γ , a signature of Th1 responses, definitely retards the development of autoimmune myocarditis as do two cytokines associated with Th2 responses, IL-10 and IL-13. These findings are striking examples of the cytokine “interactome”; they further suggest a balance of cytokines affects not only the severity, but the profile of inflammation. For example, IL-4 promotes a particularly severe form of eosinophilic giant-cell myocarditis in A/J mice. IL-17A, a cytokine associated with neutrophilic inflammation in some other autoimmune conditions, has little impact on the severity of inflammation in the myosin-induced autoimmune disease. It is, however, critical for the later progression to dilated cardiomyopathy; animals deprived of IL-17A fail to develop the subsequent fibrotic disease. The disease can actually be prevented by administering antibody to IL-17A earlier in the course of inflammation. This key role of IL-17 may be related to its established ability to increase granulocyte proliferation as well as to activate macrophages. A cytokine acting with IL-17, i-GM-CSF, stimulates both granulocytes and monocytes. On the other hand, M-CSF, which acts only to increase monocytes, retards the development of dilated cardiomyopathy.

An issue critical to understanding the pathogenesis of autoimmune myocarditis is the dynamic balance of mediators tending to favor inflammation and cardiomyocyte injury with mediators that reduce or retard inflammation. In contrast to some other experimental models of autoimmune disease, IFN- γ is downregulatory in myocarditis and its deficiency produces a particularly severe form of the disease. IL-10 and IL-13 are also downregulatory whereas IL-4 and IL-5 contribute to severity of the disease. In fact, elevated IL-5 production induces a disease with a Th2 phenotype and extensive infiltration by eosinophils, like the disease in humans, eosinophilic myocarditis in mice tends to be rapidly fatal.

As mentioned previously, other cardiac-specific antigens can induce autoimmune myocarditis. Goser et al. (2006) demonstrated the provocation of an autoimmune response to cardiac troponin I, which induces severe inflammation in the myocardium of mice followed by fibrosis and heart failure, with marked mortality. These investigators identified two sequence motifs of cardiac troponin I that induced inflammation and fibrosis in the myocardium (Kaya et al., 2008). Interestingly, these same animals eventually developed immunity to cardiac myosin following at least 90 days of inflammation. Thus, autoimmune myocarditis, like most autoimmune diseases, is characterized by the production of multiple organ-specific autoantibodies.

TREATMENT AND OUTCOME

Until recently, the only treatment for myocarditis and DCM was supportive therapies, such as bedrest and treatment of heart failure, arrhythmias, and embolic events if present. In many centers, cardiac transplantation has become the eventual treatment of choice in patients with refractory heart failure. In patients whose condition deteriorates despite optimal medical management, mechanical circulatory support, such as ventricular assist devices or extracorporeal membrane oxygenation, serve as a bridge to transplantation or recovery.

The role of immunosuppressive therapy in myocarditis remains controversial (Maisch et al., 2004). Numerous reported studies on relatively small numbers of patients have generally found that, while some individuals respond well to immunosuppression (prednisone and cyclosporine), others fail to respond or even have serious adverse reactions that preclude continued treatment. The major problem at present is surely the difficulty in distinguishing immune-mediated cardiac disease from infectious, genetic, or toxic forms of the disease. Obviously, until there are reliable biomarkers to distinguish autoimmune myocarditis/DCM, treatment cannot be rational or capable of statistical evaluation.

A placebo-controlled study of the treatment of idiopathic DCM was performed by Parrillo et al. (1989). The study demonstrated that unselected patients with DCM overall did not benefit substantially from immunosuppressive therapy, but a small, if transient, benefit was demonstrated in patients who had histologic evidence of active inflammation by biopsy.

Mason et al. (1995) assigned a series of patients with a histopathologic diagnosis of myocarditis (based on the Dallas criteria) and a low left ventricular ejection fraction to receive conventional therapy, with or without a 24-week course of prednisone plus cyclosporine or azathioprine. The outcome assessed was improvement in the left ventricular ejection fraction at 28 weeks compared with a placebo control group. No significant functional improvement was seen with immunosuppressive therapy. It should be noted, however, that during the establishment of the trial as many as 2233 patients with a clinical and pathologic diagnosis of myocarditis were presented for entry by their cardiologists, but only 111 met the strict Dallas criteria; i.e., some 95% of patients with a preliminary diagnosis of myocarditis failed to fulfill the Dallas criteria. The patients who would be expected to benefit most from immunosuppressive treatment are those with primarily autoimmune rather than viral myocarditis.

This interpretation is favored by the report of Kühl and Schultheiss (1995), who selected 48 patients presenting with mild-to-severe heart failure and immunohistologic evidence of an active immunologic process on biopsy.

After a 6-month treatment with 6-methylprednisolone, 23 experienced objective improvement in cardiac function. The suggestion of this study is that in a subgroup of patients with an active immunopathologic process immunosuppressive treatment will confer clinical benefit.

Wojnicz et al. (2001) evaluated 202 patients with idiopathic DCM by endomyocardial biopsy. Eighty-four of these 202 on biopsy had expression of HLA class II molecules. Those patients were randomized to immunosuppressive therapy or placebo. While the major outcome of the trial (death, transplantation, or hospitalization) was unchanged by treatment, the ejection fraction in the treated population rose from 24 to 36%, while it was virtually unchanged in the placebo group (25 to 27%). In addition, subjective parameters of improvement were noted at 3 months in 72% of the immunosuppressive therapy patients compared with only 21% of the control group. Frustaci et al. (2003) identified 112 of 652 patients with new-onset left ventricular compromise who had a presentation compatible with myocarditis. Forty-one of the 112 had progressive heart failure despite standard heart failure management. This patient population was treated with prednisone and azathioprine. Twenty of the 41 patients responded while 21 did not. The investigators determined retrospectively that those who responded had antiheart antibodies by immunofluorescence, and those who failed to respond had persistent virus demonstrated by PCR analysis of the endomyocardial biopsy. Additionally, Jones et al. (1991) demonstrated that in 20 patients with Dallas criteria-positive myocarditis, those with borderline myocarditis had a greater improvement in their ejection fraction by echocardiography and stroke work index from right heart catheterization than those with frank myocarditis. These studies suggest that there soon may be more sensitive and specific biomarkers for immune-mediated heart disease than are currently available by the Dallas criteria.

Different myocarditis populations may respond differently. Patients with fulminant myocarditis usually resolve spontaneously and there is suggestive evidence that immunosuppressive therapy may worsen the outcome. In contrast, the treatment of giant-cell myocarditis with immunosuppression may improve the prognosis by slowing progression of the disease (Cooper, 2002), suggesting that this form of the disease is an autoimmune variant.

Other therapeutic approaches have been based on the possible pathogenic role of humoral antibodies. As described above, several investigators reduced the level of circulating immunoglobulin by means of an immunoabsorption column, and showed improvement in cardiac function. McNamara et al. (2001) demonstrated in a trial of 72 patients with new onset cardiomyopathy that 2 g/kg of intravenous immunoglobulin failed to

improve ejection fraction or survival when compared with placebo-treated patients. Early trials have shown promising results using extra corporeal immunoadsorption of antibodies to the p1-adrenoreceptor in the IgG3 subclass (Staudt et al., 2002, 2003; Winters, 2012).

On the premise that many patients with myocarditis or idiopathic DCM have an undisclosed persistent viral infection, Miric et al. (1994) treated a series of 180 patients with IFN- α or thymomodulin. Left ventricular function, exercise tolerance, and survival rate were significantly improved in patients given the immunomodulatory therapy. Kühl et al. (2003) treated 22 patients with proven viral myocarditis with IFN- β . The treatment was well tolerated. All patients cleared the viral genome and showed improved left ventricular function.

The above studies make it obvious that treatment of myocarditis and DCM is still problematic. As more is learned about the pathogenic mechanisms in these diseases, treatments can be individualized.

PERSONAL THOUGHTS

The diseases described in this chapter exemplify the broad range of cardiovascular disorders with which autoimmune responses have been implicated. Until very recently the role of autoimmunity in cardiovascular diseases had been rather neglected. Yet, before the early 1960s, rheumatic fever was a major topic of investigation. Although the decline of rheumatic fever in the 1960s accounted for a loss of interest in this topic, it must be recognized that the studies of rheumatic fever were the stimulus for many current concepts of autoimmunity and autoimmune disease. A renaissance in cardiovascular immunology followed efforts to define the role of autoimmunity in myocarditis and DCM. There is now a substantial challenge in developing reliable and robust *in vitro* assays that define autoimmune heart disorders with the same sensitivity and specificity now available in autoimmune disorders affecting other major organs. These studies will also serve as the impetus to delineate the contribution of autoimmunity to other enigmatic cardiovascular diseases such as atherosclerosis (see Chapter 71). Further, they provide as a general model for studying the steps relating infection to the onset of autoimmune disease (see Chapter 19).

ACKNOWLEDGMENTS

The figures were prepared by Dr. Marc Halushka and Dr. Jobert Barin, Department of Pathology, Johns Hopkins School of Medicine. The authors dedicate this chapter to their late colleague, Kenneth Baughman, a co-author of the original chapter.

INTRODUCTION

Atherosclerosis is a chronic inflammatory disease of large and medium sized arteries initiated by entry of low density lipoprotein (LDL) into the arterial intima. Atherosclerotic lesions are characterized by progressive accumulation of chronic inflammatory cells in the intima leading to development of vulnerable plaques characterized by large necrotic cores and thin fibrous caps (Tabas, 2011; Yla-Herttuala et al., 2011). Rupture of vulnerable plaques initiates thrombotic occlusion, end-organ infarction, heart attacks, and strokes—leading causes of death in our community.

An *autoimmune basis* for development of inflammatory lesions in atherosclerosis is supported by the

presence of cognate immune cells, demonstration of autoimmunity to antigens localized within atherosclerotic plaques, attenuated atherosclerosis with establishment of tolerance to putative autoantigens, a family history, association with DRB1 (Gonzalez-Gay et al., 2007) and aggravated lesions in systemic lupus erythematosus (Asanuma et al., 2003; Roman et al., 2003), and rheumatoid arthritis (Shoenfeld et al., 2005; Steen et al., 2009).

Using mouse models, a reductionist approach has identified culprit autoantigens and roles of atherogenic and atheroprotective cells of the innate and adaptive immune system in atherogenesis.

DEVELOPMENT OF ATHEROSCLEROTIC LESIONS

Atherosclerotic lesions develop early intimal thickening due to proliferation of intimal smooth muscle cells (Ross and Glomset, 1973) thus forming the “soil” in which atherosclerotic lesions develop. Initial steps in atherosclerotic lesion formation involve lipid accumulation within the intima together with activation of the endothelium. P-selectin and vascular cell adhesion molecule-1 (VCAM-1) are focally expressed by endothelial cells at sites of lesion development in hypercholesterolemic rabbits before intimal accumulation of macrophages and T cells (Sakai et al., 1997). Fatty streaks, the initial stages of atherosclerosis, involve accumulation of macrophages and T cells with macrophages accumulating lipids to form foam cells. Subsequently, multiple types of immune cells accumulate driving these early lipid-rich lesions to develop into atheromas containing necrotic cores and subsequently to more complex lesions that may be either stable fibrous plaques or unstable, rupture-prone, soft-centered lipid laden lesions with thin collagen and vascular smooth muscle cell caps (Figure 71.1) (Davies, 1996; Yla-Herttuala et al., 2011).

MOUSE MODELS OF ATHEROSCLEROSIS

Murine models have proved powerful tools in identification of the roles of immunocytes and potential autoantigens in atherogenesis. Although wild-type strains of mice are relatively resistant to atherosclerosis development even on high-fat diets, gene knockout approaches have given two useful models. The apolipoprotein E knockout (ApoE^{-/-}) mouse, generated in 1992, develops atherosclerotic lesions on standard chow diet, which is greatly accelerated by a high-fat “Western” diet and the LDL receptor (LDLR) deficient mouse develop small lesions on standard chow diet and robust lesions on high-fat diet. ApoE^{-/-} mouse lesions have been most thoroughly characterized. These lesions develop fibrofatty plaques with characteristics similar to those of human plaques but rarely rupture (Jawien et al., 2004). Many variants of ApoE^{-/-} and LDLR^{-/-} mice have been studied (Kleemann et al., 2008), generated by cross-breeding with different knockout and transgenic mice. One mouse model, ApoE^{-/-}SR-B1^{-/-}, deficient in HDL receptor scavenger receptor class B and on a mixed C57Bl/6 × 129 background, develops exceptional severe occlusive coronary artery atherosclerosis, and exhibits spontaneous myocardial infarctions, severe cardiac dysfunction, and premature death (Braun et al., 2002). The mechanisms leading to myocardial infarction in these mice are yet to be elucidated.

CULPRIT AUTOANTIGENS

Three autoantigens have been identified. Whether immune activation by these antigens occurs concurrently or sequentially following intermolecular spreading is unknown. The epitopes that drive the autoimmune response are also unknown.

Oxidized Low-density Lipoprotein (oxLDL)

oxLDL is a major component of atherosclerotic lesions, and T lymphocytes reactive to oxLDL have been recovered from human atherosclerotic plaques (Stemme et al., 1995). It seems likely that the oxidation of oxLDL renders the molecule non-self, thus initiating an autoimmune response. In LDLR-deficient mice, oral feeding of oxLDL induced oxLDL-specific TGF-β, producing Foxp3 regulatory T cells and attenuated development of atherosclerosis, strongly suggesting that oxLDL is an autoantigen in this model (van Puijvelde et al., 2006).

Heat Shock Protein 60 (HSP60)

HSP60 has generated much interest as an autoantigen with potential to drive inflammatory processes in atherosclerosis (Wick et al., 2004; Grundtman and Wick, 2011; Grundtman et al., 2011). Mixed CD4⁺ and CD8⁺ T cells isolated from human carotid endarterectomy specimens show an oligoclonal TCR repertoire and enhanced proliferation to human HSP60 (Rossmann et al., 2008). HSP60 is co-expressed with ICAM-1, VCAM-1, and ELAM-1 in human endothelial cells in response to stimulation by cytokines and oxLDL (Amberger et al., 1997). Atherosclerosis risk factors may act as endothelial stressors to provoke expression of HSP60 that acts as a “danger signal” (Grundtman et al., 2011). Studies in LDLR^{-/-} mice provide evidence that immune responses to HSP60 are atherogenic. Oral feeding of HSP60 (or HSP60 peptides) attenuated atherosclerosis in LDLR^{-/-} mice that correlated with increased Foxp3 regulatory T cells, increased expression of Foxp3, CD25, and CTLA-4 in lesions, and IL-10 and TGF-β production by lymph node cells (van Puijvelde et al., 2007).

β2 Glycoprotein 1 (β2-GP1)

β2-GP1 is a recognized autoantigen associated with antiphospholipid syndrome in humans. It has also been proposed as a potential autoantigen in atherosclerosis, either on its own or complexed with oxLDL (Matsuura et al., 2009; Shen et al., 2011). Human β2-GP1, co-localizing with CD4 T cells, is expressed in human lesions (George et al., 1999). Oral feeding of human or bovine β2-GP1 attenuated atherosclerosis in LDLR^{-/-} mice, inhibited

FIGURE 71.1 Immune cells in adaptive immune response of atherosclerosis. Low density lipoprotein (LDL) entry into the intima through dysfunctional endothelial cells initiates atherosclerosis. After modification to oxidized LDL (oxLDL), it is captured and processed by tissue dendritic cells. Dendritic cells (DCs) with captured antigen activate resident naïve T cells and NKT cells *in situ* in “vascular-associated lymphoid tissue” and/or migrate to draining lymph nodes to activate these circulating lymphocytes. Activated lymphocytes in draining lymph nodes return to the intima to promote inflammation by secreting proinflammatory cytokines and cytotoxins. B cells can also capture antigen to activate immune responses. As local inflammation increases, more immune cells are recruited into lesion areas, and apoptotic cells and necrotic core areas appear and are contained by smooth muscle and collagen caps. Cap disruption initiates thrombotic arterial occlusion leading to heart attacks and strokes. Concomitantly, adventitial DCs and B cells activate an immune response to generate adventitial tertiary lymphoid organs (ATLO).

lymph node cell reactivity to $\beta 2$ -GP1 and oxLDL, and upregulated IL-4 and IL-10 production, indicating tolerance induced by this antigen is atheroprotective (George et al., 2004), but not antigen specific.

IMMUNE RESPONSES IN ATHEROSCLEROSIS

The role of innate and adaptive immunity in atherosclerosis is summarized in Table 71.1.

Innate Immunity in Atherosclerosis

Macrophages

Macrophages are the major leukocyte subset in human and mouse lesions (Woollard and Geissmann, 2010). Several lines of evidence indicate a key role for macrophages in atherogenesis. Treatment of hypercholesterolemic rabbits with clodronate-containing liposomes, which depletes macrophages, markedly reduced atherosclerosis (Oksala et al., 1994). Administering diphtheria toxin to transgenic mice expressing diphtheria toxin receptor regulated by the

macrophage-specific promoter CD11b attenuated early lesions (Stoneman et al., 2007). Inhibiting macrophage apoptosis augments lesion development (Gautier et al., 2009a) while induction of macrophage apoptosis in advanced lesions elevates chemokine expression to further increase monocyte accumulation and lesion size (Gautier et al., 2009a). Monocytes accumulate continuously during atheroma development and this is further increased with hypercholesterolemia (Swirski et al., 2006). In human lesions, macrophages contain PPAR γ that may regulate expression of MMP-9 implicated in plaque rupture (Marx et al., 1998). In mice, atherosclerosis drives rapid influx of inflammatory Ly-6C(+) and patrolling Ly-6C(–) monocytes. Recruited Ly-6C(+) monocytes differentiate to inflammatory macrophages and dendritic cells (Ley et al., 2007). Resident macrophages also probably participate in atherogenesis. LDL entry into the intima is a key event in recruiting macrophages. oxLDL generated by oxidation of LDL is taken up by macrophages via scavenger receptors to form foam cells that accumulate in the intima and are responsible for fatty streaks.

Macrophages produce proinflammatory cytokines including TNF- α , IL-1 α and - β , IL-18, IL-6, IL-12, and

IL-15 (Osterud and Bjorklid, 2003; Tedgui and Mallat, 2006; Ait-Oufella et al., 2011). Macrophages from human plaques produce TNF- α and IL-1 (Tipping and Hancock, 1993). TNF- α -deficient ApoE^{-/-} mice, chimeric ApoE^{-/-} mice transplanted with bone marrow from TNF- α -deficient ApoE^{-/-} mice, or ApoE^{-/-} mice treated with soluble TNF receptor 1 pellets attenuate atherosclerosis (Branen et al., 2004) associated with decreased ICAM-1, VCAM-1, and MCP-1 expression (Ohta et al., 2005). Atherosclerosis is attenuated in IL-1 β -deficient ApoE^{-/-} mice associated with decreased mRNA levels of VCAM-1 and MCP-1

(Kirii et al., 2003). IL-1 α deficiency in ApoE^{-/-} mice also attenuated atherosclerosis (Kamari et al., 2011). IL-18 augments atherosclerosis by secreting IFN- γ (Whitman et al., 2002) while its deficiency in ApoE^{-/-} mice attenuated atherosclerosis (Elhage et al., 2003). Lesions are enhanced in IL-6-deficient ApoE^{-/-} mice (Schieffer et al., 2004). IL-12 has been localized to macrophages of atherosclerotic lesions and daily IL-12 administration increased serum oxLDL antibodies and accelerated atherosclerosis in young ApoE^{-/-} mice (Lee et al., 1999). IL-12 appears atherogenic in early disease in ApoE^{-/-} mice (Davenport and

Tipping, 2003) and selective IL-12 synthesis defect in 12/15-lipoxygenase-deficient macrophages reduced atherosclerosis (Zhao et al., 2002). IL-12 was induced in monocytes *in vitro* in response to oxLDL (Uyemura et al., 1996). IL-15 is associated with oxLDL-positive macrophages and co-localizes with CD40L-positive T cells (Houtkamp et al., 2001a); its deficiency reduced atherosclerosis in LDLR^{-/-} mice (van Es et al., 2011).

Inflammatory macrophages have a short half-life. After undergoing apoptosis, they may be phagocytosed by surrounding macrophages or, if phagocytosis is overwhelmed, can undergo secondary necrosis, forming necrotic cores (Silva, 2010; Ley et al., 2011; Moore and Tabas, 2011; Thorp et al., 2011). In humans, apoptosis in macrophages has been reported in advanced lesions and may contribute to plaque rupture (Geng and Libby, 1995; Bjorkerud and Bjorkerud, 1996). Necrotic cells can further aggravate inflammation through Nlrp3 inflammasome activation (Iyer et al., 2009; Hansson and Klareskog, 2011).

NKT Cells

Given the role of lipid in atherogenesis and in NKT cell activation, these cells are candidates for linking innate with adaptive immunity. Indeed, invariant NKT (iNKT) cells from human plaques produce inflammatory cytokines when stimulated by CD1d expressing antigen-presenting cells presenting α -gal-cer (Kyriakakis et al., 2010). NKT cells recognize lipid antigens presented by the major histocompatibility complex (MHC) class I-like molecule CD1d, producing copious amounts of IFN- γ and IL-4 when activated. In human lesions they accumulate within rupture-prone regions where they co-localize with dendritic cells (Bobryshev and Lord, 2005). NKT cell depletion by neonatal thymectomy ameliorated atherosclerosis while their adoptive transfer to thymectomized mice aggravated atherosclerosis (To et al., 2009). Similarly, J α 18 gene deletion which depletes V α 14 NKT cells also decreased atherosclerosis (Rogers et al., 2008) while adoptive transfer of NKT cells from J α 18V α 14 transgenic mice aggravated atherosclerosis (VanderLaan et al., 2007). Also, CD1d deficiency decreased atherosclerosis whereas NKT cell activation by α -gal-cer aggravated atherosclerosis (Major et al., 2004; Nakai et al., 2004; Tupin et al., 2004). Atherogenic NKT cells have been identified as belonging to the CD4⁺ and not the double negative (DN) subset because adoptive transfer of CD4⁺ NKT cells and not the DN subset to NKT cell-deficient thymectomized mice augmented atherosclerotic lesions (To et al., 2009). The differential effects were not attributable to differences in homing to developing atherosclerotic lesions. DN NKT cells expressed at least three-fold higher levels of inhibitory Ly49 receptors (Ly49A, Ly49C/I, and Ly49G2) than CD4⁺ NKT cells,

and lesions expressed large amounts of their MHC class I ligand. *In vitro* these inhibitory receptors initiated greater effects in DN NKT cells. Culture of each NKT cell subset with TAP-deficient (MHC class I-deficient) dendritic cells and α -gal-cer led to secretion of similar amounts of proatherogenic cytokines IL-2, IFN- γ , and TNF but, when cultured with MHC class I-positive dendritic cells, CD4⁺ NKT cells secreted more of these cytokines.

NK Cells

NK cells secrete proinflammatory cytokines, in particular IFN- γ as well as cytotoxins such as perforin and granzyme B. The LILB1 receptor expressed by human NK cells is associated with human atherosclerotic disease (Romo et al., 2011). The lack of a mouse model with specific genetic deletion of NK cells has made it difficult to define the precise role of these cells in atherosclerosis, although a proatherogenic role might be envisaged. NK cell function is reduced in mice having a beige mutation (Roder and Duwe, 1979). LDLR-deficient mice with a beige mutation exhibit a modest increase in atherosclerotic lesion size suggesting a protective role (Schiller et al., 2002). In contrast, mice deficient in functional NK cells through expression of a transgene encoding Ly49A under a granzyme A promoter exhibit reduced atherosclerosis, suggesting a proatherogenic role (Whitman et al., 2004). However, this transgenic construct also induces overexpression of Ly49A in CD8⁺ T cells, which attenuates their antigen-specific responses (Brawand et al., 2000).

Neutrophils

In humans, neutrophil infiltration in plaques is associated with acute coronary events, with particularly high neutrophil numbers demonstrated in ruptured plaques (Naruko et al., 2002). Neutrophil infiltration is also a feature of culprit lesions in acute coronary syndromes in humans (Naruko et al., 2002); both eroded and ruptured human lesions frequently contained neutral endopeptide expressing neutrophils while they are low in number or largely absent in stable plaques. Hyperlipidemia generated by feeding ApoE-deficient mice a high-fat diet promoted neutrophilia associated with neutrophil infiltration during early stages of atherosclerosis (Drechsler et al., 2010). Neutrophil accumulation peaked at 4 weeks after starting a high-fat diet and declined thereafter and neutropenia reduced early plaque development but not the later stages of atherosclerosis. In LDLR-deficient mice, introduction of a high-fat diet was associated with elevated circulating levels of myeloperoxidase. Neutrophils expressing myeloperoxidase were observed to be attached to atherosclerotic caps and in the adventitial regions of lesions

(van Leeuwen et al., 2008). The precise role of neutrophils in plaque rupture is yet to be defined.

Mast Cells

Mast cells accumulate in all stages of human atherosclerotic lesion development and at sites of coronary lesion rupture, erosion, and neovascularization. In human lesions mast cells produce FGF-2, which promotes vascularization and contributes to lesion progression (Lappalainen et al., 2004). Mast cells in human lesions (Atkinson et al., 1994; Jeziorska et al., 1997) are a common feature of advanced plaques complicated by fissure, hemorrhage, and thrombosis. The chemokines responsible for attracting mast cells to developing lesions are largely unknown. Mast cells have a unique expression of CCR3 which is mainly located intracellularly. Upon activation, CCR3 is relocated to the cell surface enabling them to respond to chemokines such as eotaxin which is produced by macrophages in lesions (Haley et al., 2000; Juremalm and Nilsson, 2005). Mast cells also contribute to lesion development. Mast cell-deficient $Ldlr^{-/-}$ $Kit^{W-sh/W-sh}$ mice have decreased lesions. Transfer of wild-type or $TNF-\alpha$ -deficient but not IL-6- or $IFN-\gamma$ -deficient mast cells restored atherogenesis to $Ldlr^{-/-}$ $Kit^{W-sh/W-sh}$ mice, implying that mast cell-derived IL-6 and $IFN-\gamma$ promote atherogenesis (Sun et al., 2007).

Adaptive Immunity in Atherosclerosis

Th1 CD4 T Cells

Activated oxLDL-reactive T cells have been recovered from human atherosclerotic lesions (Hansson et al., 1989; Stemme et al., 1995). In human lesions, mRNA for the key inducer of Th1 cytokines, IL12p40, and p70 are abundant (Uyemura et al., 1996). In mice, a number of experimental approaches have demonstrated the proatherogenic role of T cells. CD4 lymphocyte depletion using a monoclonal antibody reduced lesion size (Emeson et al., 1996). T cell-deficient nude (nu/nu) mice develop smaller lesions than do their heterozygote litter mates. $ApoE^{-/-}$ mice crossed with immunodeficient $scid/scid$ mice had reduced fatty streaks while transfer of CD4 T cells increased lesions associated with infiltration of transferred T cells into lesions (Zhou et al., 2000). Transfer of CD4 T cells from oxLDL-immunized mice had substantially larger lesions. The increase in serum $IFN-\gamma$ levels was proportional to the accelerated atherosclerosis (Zhou et al., 2006), consistent with involvement of a Th1 cell subset. Indeed, $IFN-\gamma$ colocalizes with CD4 T cells in atherosclerotic lesions and $IFN-\gamma$ -deficient $ApoE^{-/-}$ mice had markedly attenuated atherosclerosis, reduced lesion cellularity, and increased lesion collagen (Gupta et al., 1997), while exogenous $IFN-\gamma$ augmented atherosclerotic lesions (Whitman et al., 2000).

$ApoE^{-/-}$ mice deficient in IL-12 also displayed reduced atherosclerosis (Davenport and Tipping, 2003).

Th2 CD4⁺ T Cells

There are mixed reports of the role of the Th2 cytokine IL-4, with reduced atherosclerosis in mice deficient in IL-4 (King et al., 2002; Davenport and Tipping, 2003) but aggravated atherosclerosis in mice deficient in the Th2 cytokine IL-5 (Binder et al., 2004). IL-10-deficient C57Bl/6 mice fed an atherogenic diet increased lesion size associated with T cell infiltration, $IFN-\gamma$ expression, and decreased collagen content. Transfer of murine IL-10 reduced lesion size (Mallat et al., 1999). Treatment with IL-33, a novel IL-1-like cytokine that signals via ST2, reduced lesions in $ApoE^{-/-}$ mice associated with elevated oxLDL antibody and a Th1–Th2 switch supported by increased levels of IL-4, -5, and -13, but decreased levels of $IFN-\gamma$ in serum and lymph node cells (Miller et al., 2008). Conversely, mice treated with soluble ST2, a decoy receptor that neutralizes IL-33, developed larger plaques in the aortic sinus of $ApoE^{-/-}$ mice. Furthermore, co-administration of an anti-IL-5 mAb with IL-33 prevented reduction in plaque size; IL-33 and ST2 are present in normal and atherosclerotic vasculature of mice and humans. The IL-33 receptor, consisting of ST2 and IL-1 receptor accessory protein, is widely expressed, particularly in Th2 cells and mast cells (Liew et al., 2010). IL-33 can act both as a nuclear factor and as a soluble mediator; however, the precise role of IL-33 within the nucleus is not clear. As a cytokine, IL-33 is suggested to function as an alarmin that is released upon endothelial or epithelial cell damage (Kurowska-Stolarska et al., 2011).

Th17 CD4⁺ T Cells

There are contradictory reports of the role of Th17 in atherosclerosis (Taleb et al., 2010).

An atherogenic role is supported by the report that IL-17 produced concomitantly with $IFN-\gamma$ by human coronary artery-infiltrating T cells, act synergistically to induce proinflammatory responses in vascular smooth muscle cells (Eid et al., 2009). Patients with acute coronary syndrome show increased peripheral Th17 numbers, Th17-related cytokines (IL-17, IL-6, and IL-23), and transcription factor (ROR γ t) levels and decreased Treg number, Treg-related cytokines (IL-10 and TGF- β 1), and transcription factor (Foxp3) levels (Cheng et al., 2008). In $ApoE^{-/-}$ mice, an increased proportion of Th17 cells and higher expression in plaques of IL-17, retinoic acid-related orphan receptor (ROR) γ t, and IL-17A-expressing T cells have been reported. Treatment with neutralizing anti-IL-17 antibody or with adenovirus-produced IL-17 receptor inhibited atherosclerosis development while rIL-17 augmented lesions (Gao et al., 2010; Smith et al., 2010). However, an

atheroprotective role for IL-17A is supported by the report that IL-17A-deficient ApoE^{-/-} mice accelerated unstable atherosclerotic plaque formation after 8 weeks on high-fat diet (Danzaki et al., 2011). An atheroprotective role is also suggested by attenuated atherosclerosis arising from increased IL-17 and IL-10 production with loss of SOCS3 in T cells (Taleb et al., 2009). On the other hand, transplantation of IL-17R bone marrow into LDLR^{-/-} mice attenuated atherosclerosis accompanied by reduced IL-6 but increased IL-10 production (van Es et al., 2009). Attenuated atherosclerosis in Fc γ -chain-deficient ApoE^{-/-} mice is associated with decreased Th17 cells, decreased IL-17 secretion by activated CD4 T cells, decreased IL-6 release by APC, and STAT-3 phosphorylation essential for Th17 cell genesis while regulatory T cells, TGF- β , and IL-10 were increased (Ng et al., 2011).

Foxp3 Regulatory CD4⁺ T Cells

Regulatory T cells and their adoptive transfer suppress atherosclerosis in several mouse models (Ait-Oufella et al., 2006; Mor et al., 2007). TGF- β is implicated in suppression because partial depletion of regulatory T cells ameliorated atherosclerosis in ApoE^{-/-} mice but not in ApoE^{-/-} mice expressing dominant negative TGR- β type 2 receptor under control of the CD4 promoter. Various experimental manipulations modulate atherosclerosis through regulatory T cells. For instance, local delivery of IL-12 attenuated atherosclerosis by expanding regulatory T cells (Dietrich et al., 2011) and CCL17-expressing dendritic cells restrain regulatory T cell homeostasis in ApoE^{-/-} mice (Weber et al., 2011). Caveolin-1 deficiency in ApoE^{-/-} mice attenuated atherosclerosis by hampering leukocyte influx into the arterial wall and generating a regulatory T cell response (Engel et al., 2011). The findings are consistent with a role for caveolin-1 in LDL transcytosis and on inflammation. Amygdalin (vitamin B17) derived from the seeds of a variety of plants reduced atherosclerosis in ApoE^{-/-} mice and increased regulatory T cells and expression of IL-10 and TGF- β (Jiagang et al., 2011). Oral administration of an active form of vitamin D3 (calcitriol) decreased atherosclerosis in ApoE^{-/-} mice and reduced macrophage and CD4 T cell accumulation by increasing Foxp3 regulatory T cells and immature dendritic cells with tolerogenic functions; mRNA for IL-10 was increased while IL-12 was reduced (Takeda et al., 2010). Treatment of ApoE^{-/-} mice with ApoB100 peptides reduced development and progression of established atherosclerosis and increased collagen content indicative of plaque stabilization (Herbin et al., 2012). Conversely, ICOS-deficient LDLR^{-/-}-chimeric mice displayed augmented atherosclerotic lesions accompanied by decreased numbers of Foxp3 regulatory T cells, impaired their suppressive function, and increased CD4 T cells, macrophages, smooth muscle

cells, and collagen content. CD4 T cells from ICOS-deficient chimeras proliferated more and secreted more interferon- γ and tumor necrosis factor- α (Gotsman et al., 2006).

CD8 T Cells

In human lesions, CD8 T lymphocytes are the dominant leukocyte infiltrate, representing up to 50% in advanced plaques (van der Wal et al., 1989; Gewaltig et al., 2008; Rossmann et al., 2008). In mouse lesions, CD8 T cells predominate early (Kolbus et al., 2010) and accumulate throughout lesion development (Roselaar et al., 1996). A role for CD8 T cells remains unresolved (Weber et al., 2008; Galkina and Ley, 2009; Hansson and Hermansson, 2011). Previous studies have given contradictory results. MHC class I-deficient β 2 microglobulin (β 2 m) knockout had increased atherosclerosis, suggesting that CD8 T cells are atheroprotective. However, β 2 m gene disruption affects development of CD8 α/α but not Kb and Db-dependent CD8 α/β CD8 T cells, and CD8⁺ CTL clones have been reported in β 2m-deficient mice (Cook et al., 1995). In ApoE^{-/-} mice rendered CD8 T cell deficient by CD8 gene targeting, no change in lesions was reported (Elhage et al., 2004). Indirect evidence for a damaging role is suggested by increased CD8 T cells in lesions aggravated by treatment with CD137 agonist (Olofsson et al., 2008), PDL1/L2 deficiency (Gotsman et al., 2007), and infection with microbes (Krebs et al., 2007), and in a transgenic mouse model of arterial inflammation and hypercholesterolemia (Ludewig et al., 2000).

Conventional B2 Cells

B lymphocytes accumulate in lesions in humans and mice (Yla-Herttuala et al., 1994; Zhou and Hansson, 1999; Houtkamp et al., 2001b). An atherogenic role for B cells is supported by the observation that their depletion by monoclonal antibody to CD20 ameliorates atherosclerosis (Ait-Oufella et al., 2010; Kyaw et al., 2010). The atherogenic B subset responsible was identified as conventional B2 cells by their adoptive transfer to lymphocyte-deficient or to μ MT B cell-deficient ApoE^{-/-} mice (Kyaw et al., 2010). Augmented atherosclerosis following B2 cell transfer to lymphocyte-deficient mice indicates that B2 cells can potentially promote atherosclerosis development entirely on their own in the total absence of all other lymphocyte populations. Additionally, these B2 cells can also significantly augment atherosclerosis development in the presence of T cells and all other lymphocyte populations because the lesions in mice deficient only in B cells only had a four-fold increase in lesion size compared to transfer to lymphocyte-deficient mice. Attenuated atherosclerosis was also observed in BAFF receptor-deficient ApoE^{-/-}

mice (Kyaw et al., 2012) consistent with the dependence of B2 cells on BAFF for their development and survival (Mackay et al., 2010). Aortic atherosclerotic lesions were decreased and B cells were absent in atherosclerotic lesions of BAFF receptor-deficient ApoE^{-/-} mice as were IgG1 and IgG2a immunoglobulins produced by B2 cells, despite low but measurable numbers of B2 cells and IgG1 and IgG2a immunoglobulin concentrations in plasma. Plasma IgM and IgM deposits in atherosclerotic lesions were also reduced. BAFF-R deficiency in ApoE2/2 mice also potently reduced arterial inflammation as reflected by reduced expression of VCAM-1 and fewer macrophages, dendritic cells, CD4⁺ and CD8⁺ T cell infiltrates and PCNA⁺ cells in lesions, and reduced expression of proinflammatory cytokines, TNF- α , IL-1 β , and proinflammatory chemokine MCP-1.

Innate-like B1a Cells

Transfer of unfractionated spleen B cells to splenectomized mice with aggravated atherosclerosis suggested B cells are atheroprotective but the protective B cell subset was not identified (Caligiuri et al., 2002). The protective B cell subset was identified as peritoneal B1a cells as these cells are specifically depleted in splenectomized mice (Wardemann et al., 2002) and their adoptive transfer to splenectomized mice ameliorated atherosclerosis (Kyaw et al., 2011a). These B1a lymphocytes likely belong to a population designated as regulatory B cells (Fillatreau et al., 2008; Kyaw et al., 2011b). Protection is mediated by IgM secreted by B1a cells because the adoptive transfer of IgM-deficient B1a cells failed to confer atheroprotection. Transfer of IgM-sufficient B1a cells restored plasma total and oxLDL IgM levels and lesion IgM deposits; and potently attenuated atherosclerotic lesions, with reduced lesion necrotic cores, oxidized low-density lipoprotein, and apoptotic cells. The findings are consistent with an atheroprotective role for IgM (Lewis et al., 2009) and for IgM secreted by B1a cells to confer protection by providing a scavenger role in removing apoptotic cells and oxLDL (Binder et al., 2005; Ehrenstein and Notley, 2010). As B1a cells are also major B cell producers of the immunosuppressive cytokine IL-10 (O'Garra et al., 1992) it is possible that IL-10 may also have a suppressive role in atherosclerosis.

Other Key Cellular Players

Smooth Muscle Cells (SMCs)

Although the majority of SMCs in the vessel wall of humans are contained within the medial layer, a significant number exist within the intima in "intimal thickenings" (Doran et al., 2008). Intimal SMCs differ from

medial SMCs in being predominantly synthetic rather than contractile and are major producers of extracellular matrix including collagen. Like macrophages, SMCs have receptors for lipid uptake and can form foam-like cells (Inaba et al., 1992), thereby participating in early accumulation of plaque lipid. Intimal and media SMC express MCSF (CSF1) receptor and proliferate following stimulation with MCSF. Like endothelial cells, SMCs can express adhesion molecules such as VCAM-1 and ICAM-1 to which monocytes and lymphocytes can adhere and migrate into the vessel wall. Through these adhesion molecules, SMCs can also stabilize macrophages and T cells against apoptosis. SMCs also possess functional chemokine receptors, including CCR5, CXCR4, and a receptor for MCP-1 (Schechter et al., 2003) and produce many cytokines such as PDGF, TGF- β , IFN- γ , IL-1, IL-18, MIF, and MCP-1(CCL2), which contribute to the inflammatory response to lipid (Doran et al., 2008). Cross-talk between SMC and monocytes augments the inflammatory response in both cell types as revealed by increased expression of TNF- α , IL-1 β , IL-6, CX3CR1, and MMPs. Upregulation of TNF- α , CX3CR1, and MMP-9 is further increased upon interaction of SMC with activated monocytes and is dependent on the fractalkine/CXCR1 pair (Butoi et al., 2011).

Endothelial Cells

Nitric oxide inhibits oxidation of low-density lipoprotein. A defect in production or activity of nitric oxide leads to endothelial dysfunction, an early marker for atherosclerosis, and is detected before structural changes to the vessel wall are apparent on angiography or ultrasound. Many of the risk factors that predispose to atherosclerosis can also cause endothelial dysfunction, and the presence of multiple risk factors predicts endothelial dysfunction (Davignon and Ganz, 2004). Endothelial cells express the adhesion molecules VCAM-1, ICAM-1, E-selectin, and P-selectin for leukocyte adhesion and a variety of cytokines such as IL-1, IL-6, and IL-8 (Ait-Oufella et al., 2011). IL-1 induces IL-6 expression by human endothelial cells (Sironi et al., 1989) while IL-17F produced by activated T cells induced endothelial cells to produce IL-2, TGF- β , and MCP-1 (CCL2) (Starnes et al., 2001). RANTES (CCL5) can be induced in human endothelial cells by combined TNF- α and IFN- γ stimulation and is inhibited by IL-4 and IL-13 (Marfaing-Koka et al., 1995).

Immune System Activation

Activation Sites

As draining lymph nodes are sites of immune activation in response to infectious microorganisms, the para-aortic

lymph nodes draining the aorta are possible sites of auto-immune activation. Activation at these sites would require antigen-presenting cells in arteries, such as dendritic cells, to capture cognate antigen that then migrate to the draining lymph nodes to activate circulating lymphocytes as they transit through the lymph node. Following activation, the lymphocytes would be required to acquire homing receptors to return to the artery. However, activation at draining para-aortic sites has not thus far been investigated or demonstrated.

The observation that mononuclear cells pre-exist in the intima at bifurcation sites of normal arteries has led to designation of these aggregates as “vascular-associated lymphatic tissue” akin to “mucosa-associated lymphatic tissue.” According to this hypothesis, the vasculature is an integral component of the lymphoid system and activation of the immune system occurs *in situ* in the vessel wall. B and T lymphocytes and some macrophages and dendritic cells are already present in the adventitia of normal/noninflamed mouse aortas and adoptively transfer lymphocytes constitutively homed to the aorta (Galkina et al., 2006) presumably transiting through vasa vasorum.

Whether activation occurs in para-aortic lymph nodes or in vascular-associated lymphoid tissue, concurrently or sequentially, is not known.

Dendritic Cells

Dendritic cells (DCs) in human atherosclerotic intima (Bobryshev and Lord, 1995) probably participate in all phases of atherosclerosis, from early fatty streaks to mature lesions. Small numbers of DCs in healthy arteries dramatically increase with atherosclerosis development. During plaque growth, new DCs are recruited, and egress from vessels is dampened. DCs are also present in adventitial tertiary lymphoid aggregates (Figure 71.1) (Koltsova and Ley, 2011). Given their key role as peripheral sentinels of the immune system, DCs likely play a key role in antigen presentation and activation of the immune system in atherosclerosis (Figure 71.2). In addition, dendritic cells appear to have a role in cholesterol homeostasis in atherosclerosis. Whereas DC expansion decreased plasma cholesterol levels, DC depletion raised these levels (Gautier et al., 2009b). Resident dendritic cells, like their macrophage counterparts, also accumulate lipid and contribute to initiation of the atherosclerotic process (Paulson et al., 2010).

TLR

In human lesions, TLR1, 2, and 4 expression is markedly enhanced (Edfeldt et al., 2002). Atherosclerosis is reduced in mice lacking MyD88 (Bjorkbacka et al., 2004). TLR4 deficiency reduced atherosclerosis with reduced circulating levels of IL-12 and MCP 1, plaque lipid, macrophages,

and cyclooxygenase 2. Endothelial-leukocyte adhesion in response to minimally modified LDL was also reduced in aortic endothelial cells from MyD88-deficient mice (Michelsen et al., 2004). TLR2 deficiency reduced atherosclerosis but loss of TLR2 expression from BM-derived cells had no effect. However, BM-derived cells deficient in TLR2 protected against atherosclerosis aggravated by Pam3CSK4, a TLR2 agonist (Mullick et al., 2005). Increased endothelial TLR2 expression at sites of disturbed blood flow exacerbated early atherosclerosis (Mullick et al., 2008). TLR 3 is atheroprotective as its deficiency augmented atherosclerosis (Cole et al., 2011).

Costimulatory Molecules

B7/CD28 Family

Costimulatory B7.1 and B7.2 are found in human plaques (de Boer et al., 1997). Mice deficient in B7.1 and B7.2 have reduced early lesions and CD4⁺ T cells from these mice secreted lower amounts of IFN- γ in response to mouse HSP60 (Buono et al., 2004). ICOS-deficient mice had augmented lesions displaying increased CD4 T cells, and CD4 T cells from ICOS-deficient chimeras proliferated more and secreted more interferon- γ and TNF- α . FoxP3 regulatory T cells constitutively express high ICOS levels and ICOS-deficient mice had decreased numbers of FoxP3 regulatory T cells and impaired *in vitro* suppressive function (Gotsman et al., 2006). PD-L1/2 deficiency augmented lesions, increased numbers of lesional CD4⁺ and CD8⁺ T cells, activated CD4⁺ T cells, and had higher serum TNF- α levels. PD-L1/2-deficient APCs were more effective in activating CD4⁺ T cells *in vitro* (Gotsman et al., 2007).

TNF/TNF Receptor Family

CD40L is expressed on human macrophages, smooth muscle cells, and endothelial cells (Mach et al., 1997). An atherogenic role for CD40 is indicated by attenuated lesions, fewer lesional macrophages and T lymphocytes, and decreased VCAM-1 expression following treatment with antibody against mouse CD40L (Mach et al., 1998). Targeted mutation of OX40L decreased lesions (Wang et al., 2005), as did treatment with anti-OX40L antibody, whereas overexpression of OX40L increased lesions. CD137 is present on T cells and endothelial cells in human atherosclerotic lesions. Treatment of mice with a CD137 agonist augmented lesions and promoted T cell infiltration (mainly CD8 T cells) and proinflammatory cytokine expression (Olofsson et al., 2008).

Leukocyte Recruitment: Adhesion Molecules

In human atherosclerotic plaques, P-selectin is highly expressed by the endothelium overlying active but not

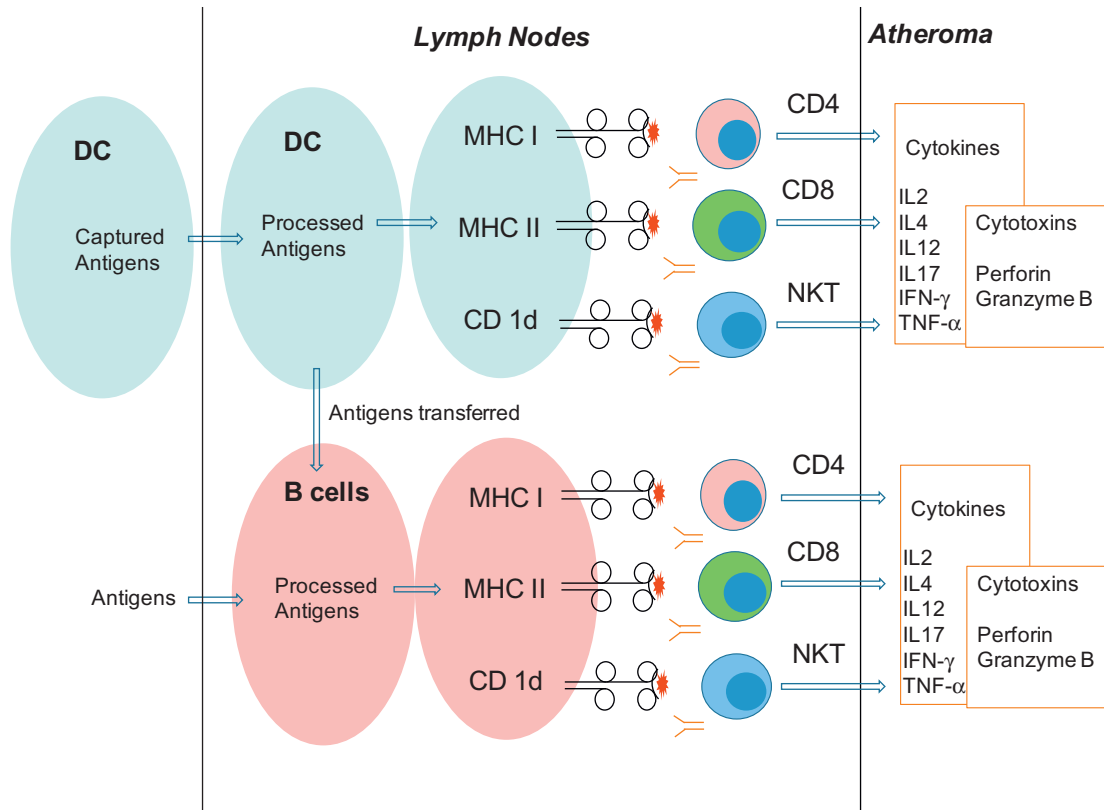

FIGURE 71.2 Activation of naive T and NKT cells in adaptive immunity. Dendritic cells in the intima and adventitia capture and process modified LDL that are presented to naïve T and NKT cells in draining lymph nodes and adventitia leading to formation of adventitial tertiary lymphoid organ formation. Activated T and NKT cells in draining lymph nodes home to the intima where they produce inflammatory and cytotoxic mediators. B cells are shown as functional antigen-presenting cells.

inactive atherosclerotic plaques; its expression correlates with ICAM-1 expression (Bourdillon et al., 2006). In ApoE^{-/-} mice, P-selectin deficiency attenuated atherosclerosis in mice fed a chow but not a high-fat diet (Bourdillon et al., 2006), while lymphocyte traffic into lesions is partially L-selectin dependent. In LDLR^{-/-} mice, VCAM-1 and ICAM-1 are expressed in atherosclerotic lesions but VCAM-1 appears to have the dominant role in leukocyte recruitment because VCAM-1 but not ICAM-1 deficiency in LDLR^{-/-} mice attenuated atherosclerosis

Monocyte Homing

Monocytes utilize CCR2, CCR5, CXCR2, and CX3CR1 chemokine receptors, and CXCR4 as non-cognate ligands of MIF and receptors for MCSF(CSF1) for homing to arteries.

CCL2(MCP-1) and its receptor (CCR2) are critical for macrophage recruitment into lesions as their deficiency in LDLR^{-/-} and in ApoE^{-/-} mice attenuated atherosclerosis accompanied by reduced macrophage accumulation. CCL5 (RANTES) and its receptor CCR5 but not CCR1 is

also implicated in atherosclerosis because CCR5 but not CCR1 deficiency attenuated atherosclerosis. CXCL1, CXCL8 (IL-8), and their receptor CXCR2 are expressed on macrophages, and CXCR2 deficiency in LDLR^{-/-} mice reduced macrophage accumulation and attenuated atherosclerosis. Deficiency of macrophage migration inhibitory factor in LDLR^{-/-} mice also attenuated atherosclerosis. CX3CL1/CX3CR1 is essential for macrophage recruitment with reduced atherosclerotic lesion formation in CX3CR1-deficient ApoE^{-/-} mice, while combined inhibition of CX3CR1, CCL2, and CCR5 abrogates Ly6C(hi) and Ly6C(lo) monocytois and almost abolishes atherosclerosis in hypercholesterolemic mice. Two monocyte subsets are differentiated by different chemokine receptor patterns: CCR2(+)/CX3CR1(+)/Ly-6C(hi) and CCR2(-)/CX3CR1(+ +)/Ly-6C(lo). Blood monocyte counts elevated in ApoE^{-/-} mice were skewed toward an increased frequency of CCR2(+)/Ly-6C(hi) monocytes in ApoE^{-/-} mice fed a high-fat diet. CCR2(+)/Ly-6C(hi) monocytes efficiently accumulated in plaques, whereas CCR2(-)/Ly-6C(lo) monocytes entered less frequently but were more prone to develop into plaque cells expressing the dendritic cell-associated marker

CD11c, indicating that phagocyte heterogeneity in plaques is linked to distinct types of entering monocytes. CCR2(–) monocytes did not rely on CX3CR1 to enter plaques but were partially dependent upon CCR5, which they selectively upregulated, whereas CCR2(+)Ly-6C(hi) monocytes required CX3CR1 in addition to CCR2 and CCR5 to accumulate within plaques.

CXCR2 and CXCR4 were identified as functional receptors for MIF (macrophage migration inhibitory factor). MIF triggered G(alpha)- and integrin-dependent arrest and chemotaxis of monocytes and T cells, rapid integrin activation, and calcium influx through CXCR2 or CXCR4. MIF competed with cognate ligands for CXCR4 and CXCR2 binding, and directly bound to CXCR2. CXCR2 and CD74 formed a receptor complex, and monocyte arrest elicited by MIF in inflamed or atherosclerotic arteries involved both CXCR2 and CD74. *In vivo*, MIF deficiency impaired monocyte adhesion to the arterial wall in atherosclerosis-prone mice, and MIF-induced leukocyte recruitment required Ii8rb (which encodes Cxcr2). Blockade of MIF but not of canonical ligands of Cxcr2 or Cxcr4 in mice with advanced atherosclerosis led to plaque regression and reduced monocyte and T cell content in plaques.

A role for MCSF for monocyte homing is supported by the report of attenuated atherosclerosis in MCSF-deficient ApoE^{-/-} mice (Smith et al., 1995). With GMCSF, there are conflicting reports. On the one hand, GMCSF deficiency in ApoE^{-/-} mice aggravated atherosclerosis by reducing cholesterol efflux through reduction of macrophage PPAR γ and ABCA1. On the other hand, systemic injection of GM-CSF into LDLR^{-/-} mice markedly increased cell proliferation in early lesions, whereas function-blocking anti-GM-CSF antibody inhibited proliferation (Zhu et al., 2009).

T Cell Homing

T cells utilize CCR7, CXCR3, and CXCR6 chemokine receptors as well as CXCR2 and CXCR4 as non-cognate ligands of MIF for homing to arteries.

CCR7 deficiency resulted in reduced atherosclerotic plaque development. CCR7-deficient T cells showed impaired entry and exit behavior from atherosclerotic lesions. Adoptive transfer of C57BL/6 wild-type T cells but not CCR7-deficient T cells primed with oxLDL-pulsed dendritic cells reconstituted atherogenesis in CCR7-deficient LDLR^{-/-} mice. These results demonstrate that both CCR7-dependent T cell priming in secondary lymphoid organs and CCR7-dependent recirculation of T cells between secondary lymphoid organs and inflamed tissue are crucially involved.

CXCR3, a common receptor for CXCL9, CXCL10, and CXCL11, is expressed on activated T cells. CXCR3-

deficient ApoE^{-/-} mice displayed significantly reduced atherosclerotic lesion development within abdominal aortas that correlated with upregulation of anti-inflammatory molecules IL-10, IL-18BP, and endothelial nitric oxide synthase and with an increased number of regulatory T lymphocytes within atherosclerotic lesions. Similarly, LDLR^{-/-} mice treated with a specific CXCR3 antagonist displayed attenuated atherosclerotic lesions, and lymph nodes draining the aortic arch were significantly smaller and enriched in regulatory T cells and contained fewer activated T cells, whereas markers for regulatory T cells within the lesion were enhanced. CXCL10-deficient ApoE^{-/-} mice showed reduced atherosclerotic lesions, a decreased accumulation of CD4⁺ T cells, and CXCR3 expression, but Foxp3 regulatory T cell numbers and activity were enhanced as well as increases in Treg-associated cytokines IL-10 and TGF- β .

CXCR6 expressed on a subset of CD4 T cells. CXCR6-deficient ApoE^{-/-} mice displayed attenuated atherosclerosis accompanied by reduced CXCR6⁺ T cells in the aorta, reduced macrophage accumulation, and reduced IFN- γ in atherosclerotic lesions. Short-term homing experiments demonstrated that CXCR6 is involved in the recruitment of CXCR6⁺ leukocytes into the atherosclerosis-prone aortic wall.

B Cell Homing

Loss of Id3 in ApoE^{-/-} mice resulted in early and increased atherosclerosis with reduced B cells in the aorta but not the spleen, lymph nodes, and circulation. Similarly, B cells transferred from Id3(-/-) ApoE^{-/-} mice into B cell-deficient mice reconstituted spleen, lymph node, and blood, but aortic reconstitution and B cell-mediated inhibition of diet-induced atherosclerosis was significantly impaired. In addition to retarding initiation of atherosclerosis, B cells homed to regions of existing atherosclerosis reduced macrophage content in plaque, and attenuated disease progression. The chemokine receptor CCR6 was identified as an important Id3 target mediating aortic homing and atheroprotection (Doran et al., 2012).

Figure 71.3 sums key events in the immunopathogenesis of atherosclerosis.

Experimental Therapeutics: A Protective “Vaccine” for Atherosclerosis

Vaccination strategies using antigens based on LDL have been explored to expand immunosuppressive populations of regulatory T and B cells to attenuate atherosclerosis. For instance, immunization of ApoE^{-/-} mice with an LDL-associated apolipoprotein B peptide vaccine aBp210 based on amino acids 3136 to 3155 of apoB-100 (p210) is

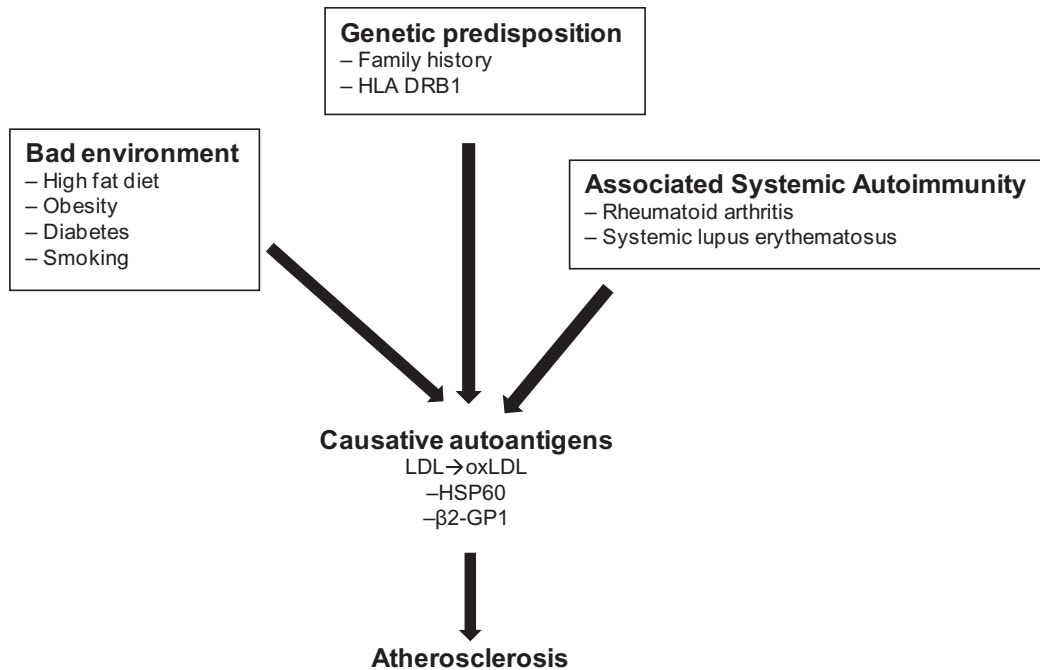

FIGURE 71.3 Immunopathogenesis of atherosclerosis. Interplay of genetic predisposition, bad environment, and systemic autoimmune diseases in initiating an immune response driven by causative autoantigens to generate atherosclerotic lesions.

associated with activation of Tregs. The atheroprotective effect of the vaccine was blocked by administration of antibodies against CD25 that depleted Tregs. These peptide-based vaccines are based on the earlier observation that active immunization with native or modified LDL reduced atherosclerosis in hypercholesterolemic rabbits and mice. As an example of harnessing the immunosuppressive properties of B1a-derived IgM, active immunization in LDLR knockout mice with *Streptococcus pneumoniae* resulted in induction of high levels of oxidized LDL-specific IgM and a modest reduction of atherosclerosis (Binder et al., 2003).

Implications for Clinical Translation

Despite lipid-lowering statins, atherosclerosis-based heart attacks and strokes remain leading causes of deaths; statins reduce cardiovascular risk by around 30%. Recognition of the role of inflammation in atherosclerosis based on studies in genetically modified mice has raised prospects of anti-inflammatory therapy to improve clinical outcomes. Recent clinical trials with statins have also provided evidence for inflammation associated with human atherosclerosis and inflammation associated with myocardial infarction even when cholesterol is “normal.” The importance of inflammation is highlighted by the report that patients with low levels of the inflammatory biomarker C-reactive protein (CRP) after statin therapy have better clinical outcomes than those with higher CRP levels, regardless of the resultant level of LDL cholesterol.

The finding is further reinforced by the report that with apparently healthy persons without hyperlipidemia but with elevated high-sensitivity C-reactive protein levels, rosuvastatin significantly reduced the incidence of major cardiovascular events. Immunopathic cell types in mice are found in human lesions, suggesting that they play similar pathological roles. Nonetheless caution has been expressed in translating mouse studies to humans (Libby et al., 2011). A prospective study in patients treated with methotrexate indicated that methotrexate may provide substantial survival benefit by reducing cardiovascular mortality (Choi et al., 2002). A review of low dose methotrexate in chronic inflammation showed that its use is associated with a lower cardiovascular risk (Micha et al., 2011). To test the hypothesis that anti-inflammatory treatment may reduce cardiovascular risk and open novel therapeutic approaches, the cardiovascular inflammation reduction trial (CIRT) proposed to allocate stable coronary artery disease patients with persistently elevated hsCRP to placebo or very low dose methotrexate (10 mg weekly), a proven anti-inflammatory regimen that reduces TNF- α , IL-6, and CRP levels (Ridker, 2009). Another trial proposed to evaluate whether selective inhibition by IL-1 β by canakinumab, a human monoclonal antibody, can reduce recurrent myocardial infarction, stroke, and cardiovascular death among stable patients with coronary artery disease who remain at high vascular risk due to persistently elevated hsCRP despite contemporary secondary prevention strategies (Ridker et al., 2011). Future potential strategies

include those with demonstrated efficacy in mouse models. These include the deletion of pathogenic inflammatory clones or expansion of regulatory clones (Kyaw et al., 2011b). Potential deletion therapies include B cell (Kyaw et al., 2010; Ait-Oufella et al., 2010) or specific B2 cell deletion. As B2 cells are BAFF dependent, BAFF receptor knockout mice have attenuated atherosclerosis. As BAFF blocking reagents are currently in clinical trials to treat human autoimmune diseases (Moisini and Davidson, 2009). BAFF blockers could be considered as ancillary strategies to treat atherosclerotic-based vascular lesions.

HISTORICAL BACKGROUND

The three major categories of systemic vasculitis are large vessel vasculitis (chronic granulomatous arteritis), medium vessel vasculitis (necrotizing arteritis), and small vessel vasculitis (necrotizing polyangiitis) (Figure 72.1, Box 72.1). A subsequent chapter will review large vessel vasculitis. Necrotizing arteritis was first recognized because of the grossly discernible segmental inflammatory nodular lesions that occur along major arteries (Kussmaul and Maier, 1866). Small vessel vasculitis (SVV) was first recognized

because of the palpable purpura that is caused by inflammation of dermal venules (Willan, 1808).

Necrotizing Arteritis

Kussmaul and Maier (1866) gave the first detailed pathologic and clinical description of systemic necrotizing arteritis. They reported a patient with fever, anorexia, muscle weakness, paresthesias, myalgias, abdominal pain, and oliguria, who was found to have inflammatory

FIGURE 72.1 Overlapping predominant vascular distributions (brackets) of large vessel vasculitis, medium vessel vasculitis, and small vessel vasculitis. Reproduced with permission from *Jennette et al. (2013a)*.

Box 72.1 Names for Vasculitides Proposed by the 2012 International Chapel Hill Consensus Conference on the Nomenclature of Vasculitides

- Large vessel vasculitis (LVV)
 - Takayasu arteritis (TAK)
 - Giant cell arteritis (GCA)
- Medium vessel vasculitis (MVV)
 - Polyarteritis nodosa (PAN)
 - Kawasaki's disease (KD)
- Small vessel vasculitis (SVV)
 - Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV)
 - Microscopic polyangiitis (MPA)
 - Granulomatosis with polyangiitis (Wegener's) (GPA)
 - Eosinophilic granulomatosis with polyangiitis (Churg–Strauss) (EGPA)
 - Immune complex SVV
 - Anti-glomerular basement membrane (anti-GBM) disease
 - Cryoglobulinemic vasculitis (CV)
 - IgA vasculitis (Henoch-Schönlein) (IgAV)
 - Hypocomplementemic urticarial vasculitis (HUV) (anti-C1q vasculitis)
- Variable vessel vasculitis (VVV)
 - Behçet's disease (BD)
 - Cogan's syndrome (CS)
- Single-organ vasculitis (SOV)
- Vasculitis associated with systemic disease
 - Lupus vasculitis
 - Rheumatoid vasculitis
 - Others
- Vasculitis associated with probable etiology
 - Hepatitis C virus-associated cryoglobulinemic vasculitis
 - Hepatitis B virus-associated vasculitis
 - Drug-associated immune complex vasculitis
 - Drug-associated ANCA-associated vasculitis
 - Cancer-associated vasculitis
 - Others

Jennette et al., 2013a.

nodules scattered over medium-sized and small arteries in many organs. They coined the term “periarteritis nodosa” for this process, which, over the following decades, evolved into “polyarteritis nodosa” as it became clear that the inflammation arose in the walls of arteries rather than in the perivascular tissue.

Soon after the recognition of polyarteritis nodosa (PAN), a number of investigators noted that some patients with necrotizing arteritis also had vasculitis affecting arteries that could be seen only by microscopy, and that some patients also had vasculitis affecting glomerular capillaries (glomerulonephritis) and pulmonary capillaries (alveolar

capillaritis) (Arkin, 1930; Davson et al., 1948; Zeek et al., 1948; Zeek, 1952; Godman and Churg, 1954). Davson, and Godman and Churg, called this the “microscopic form of periarteritis,” and Zeek called it “hypersensitivity angiitis.” Today, this form of vasculitis usually is designated microscopic polyangiitis (Jennette et al., 2013a,b).

By the 1950s, Wegener’s granulomatosis and Churg–Strauss syndrome had been recognized as variants of vasculitis that could have necrotizing arteritis combined with granulomatous inflammation and vasculitis in small vessels (Klinger, 1931; Wegener, 1939; Churg and Strauss, 1951; Godman and Churg, 1954). In their landmark publication in 1954, Godman and Churg concluded that the “microscopic form or periarteritis,” Wegener’s granulomatosis, and Churg–Strauss syndrome are pathologically and clinically distinct from PAN, and probably have a related etiology and pathogenesis. This concept has been borne out by the discovery that microscopic polyangiitis, Wegener’s granulomatosis, and Churg–Strauss syndrome are associated with, and are probably caused by, antineutrophil cytoplasmic autoantibodies (ANCA), whereas PAN is not (Jennette and Falk, 1997; Jennette et al., 2013a). These forms of ANCA-associated vasculitis (AAV) now are designated microscopic polyangiitis (MPA), granulomatosis with polyangiitis (GPA), and eosinophilic granulomatosis with polyangiitis (EGPA).

An additional form of necrotizing arteritis was discovered that is associated with the mucocutaneous lymph node syndrome (Kawasaki, 1967; Tanaka et al., 1971). This disease has been called “infantile polyarteritis nodosa” because it almost always occurs in young children (Magilavy et al., 1977); however, the clinical, pathologic, and pathogenetic features of Kawasaki’s disease are clearly distinct from those of PAN (Jennette et al., 2013a).

Purpura and Small Vessel Vasculitis

The evaluation of patients with cutaneous palpable purpura revealed vasculitis involving predominantly small vessels. Although purpura had been described in medical writings at least since the time of Hippocrates, Willan (1808) was one of the first to separate purpura caused by febrile infectious disease from noninfectious purpura. The occurrence of purpura in children with arthralgias and arthritis was reported (Schönlein, 1837). Later, Henoch (1868, 1882) described the association of purpura with abdominal pain, nephritis, small visceral hemorrhages, and pathologic changes in small vessels in the skin and internal organs. These pediatric patients probably had what today would be called Henoch–Schönlein purpura.

At the turn of the 20th century, William Osler (1895, 1914) reported numerous adult patients with a more aggressive form of SVV most consistent with what today would

be called microscopic polyangiitis. These patients had a broad spectrum of SVV manifestations, including purpura, arthritis, peripheral neuropathy, abdominal pain, pulmonary hemorrhage, epistaxis, iritis, and nephritis, including rapidly progressive renal disease with death from uremia in several months and the autopsy finding of glomeruli with “every tuft compressed by a crescentic mass.”

The pathologic findings in SVV of extensive acute inflammation with numerous neutrophils and conspicuous leukocytoclasia that resembled the Arthus reaction suggested a possible “hypersensitivity” pathogenesis (Winklemann, 1958). A hypersensitivity or allergic cause also was supported by the association of SVV with exposure to certain drugs and with serum sickness (Clark and Kaplan, 1937; Zeek et al., 1948; Winklemann, 1958; Alarcon Segovia and Brown, 1964). In the 1960s, the widespread application of immunofluorescence microscopy revealed that certain forms of SVV had substantial vascular localization of immunoglobulins and complement, suggesting an immune complex pathogenesis. Some patients with pulmonary–renal syndrome had linear deposits of immunoglobulin along glomerular and pulmonary capillary basement membranes (Sturgill and Westervelt, 1965), which were shown to be pathogenic autoantibodies directed against basement membrane collagen (Lerner et al., 1967). Patients with circulating cryoglobulins associated with signs and symptoms of SVV, such as purpura and glomerulonephritis, were found to have granular deposits of IgM, IgG, and complement in vessel walls (Meltzer et al., 1966), indicating an immune complex pathogenesis. This concept of immune complex-mediated SVV was further supported by the detection of hepatitis B antigens and antibodies in the walls of vessels in patients with SVV associated with hepatitis B virus (HBV) infection (Gower et al., 1978). Children with Henoch–Schönlein purpura were found to have deposits of IgA and C3 in dermal venules and glomerular capillaries supporting a distinct type of immune complex pathogenesis (Baart de la Faille-Kuyber et al., 1973). Neutrophilic SVV with extensive leukocytoclastic angiitis also was identified in the acute phase of Behçet’s disease (Jorizzo et al., 1985).

By the end of the 1970s, there was a widespread belief that most if not all SVV was mediated by immune complexes (Fauci et al., 1978). However, not all immunohistologic studies of vasculitis showed evidence for substantial vessel wall deposition of immunoglobulins or complement. This was especially true in some of the most common forms of SVV in adults, including Wegener’s granulomatosis (GPA) (Ronco et al., 1983; Weiss and Crissman, 1984). Davies et al., (1982) reported a new type of autoantibody that reacted with neutrophil cytoplasm in patients with SVV who did not have deposits of immunoglobulin or complement in inflamed glomeruli. Three years later, van der Woude et al. (1985) identified

these autoantibodies in patients with GPA. Numerous subsequent studies have documented the association of these ANCA with several clinicopathologic expressions of SVV (MPA, GPA, and EGPA) that are characterized by the absence or paucity of immunoglobulin and complement deposits in the vessel walls, which suggests a pathogenesis that does not involve extensive vascular deposition of immune complexes (Jennette and Falk, 1997; Jennette et al., 2013a). In fact, there is strong evidence that ANCA-associated pauci-immune SVV is caused by direct activation of neutrophils by autoantibodies directed against granule proteins (Jennette et al., 2013b).

POLYARTERITIS NODOSA

Clinical, Epidemiologic, and Pathologic Features

The hallmark of PAN is necrotizing inflammation of medium-sized or small arteries. The prevalence is somewhere between 10 and 30 cases per million population (Mahr et al., 2004; Watts and Scott, 2004). The vascular inflammation initially contains predominantly neutrophils, but within a few days the infiltrates contain predominantly mononuclear leukocytes. Segmental inflammation and necrosis may produce pseudoaneurysms by eroding through the vessel wall into the surrounding tissue. Thrombosis can cause acute ischemia, including infarction. Rupture of pseudoaneurysms results in hemorrhage, which may be severe and life-threatening.

PAN is an acute disease that typically has one major episode with only rare recurrences if remission is attained (Guillevin, 1999). Clinical manifestations include cutaneous erythematous nodules and ulcers caused by dermal and subcutaneous arteritis; peripheral neuropathy (e.g., mononeuritis multiplex) caused by arteritis in epineural arteries; myalgias and elevated circulating muscle enzymes caused by arteritis in skeletal muscle; and pain and dysfunction in virtually any viscera caused by arteritis in the parenchyma. Involvement of the skin and gut is common, whereas involvement of the lungs is rare (Agard et al., 2003). Imaging studies may reveal arterial aneurysms (pseudoaneurysms), visceral infarcts, or gut perforation. Diagnosis of PAN in a patient with necrotizing arteritis requires the exclusion of other diseases that also cause arteritis, including Kawasaki's disease, MPA, GPA, and EGPA (Agard et al., 2003; Mahr et al., 2004; Jennette et al., 2013a). Glomerulonephritis or alveolar capillaritis rule out a diagnosis of PAN and indicate some form of SVV, such as microscopic polyangiitis (Agard et al., 2003; Jennette et al., 2013a). Renal involvement can result in renal insufficiency, hematuria, and low-level proteinuria, but this is the result of infarction and hemorrhage rather

than glomerulonephritis. Myocardial infarction caused by coronary artery involvement is a rare complication.

Corticosteroids and cytotoxic drugs have been the most frequently used therapy for PAN and many other forms of noninfectious vasculitis. Guillevin (1999) advocates the use of corticosteroids alone for patients with PAN who lack all of the following five factors that indicate a worse prognosis: renal insufficiency, proteinuria >1 g/day, cardiac involvement, central nervous system (CNS) involvement, or gastrointestinal involvement. If one or more of these five factors are present, treatment should include combined steroids and cyclophosphamide. If one of these five factors is identified, the 5-year mortality is 25%; if two are identified it is 46%; and if none is identified it is 12%.

The optimal treatment of HBV-associated PAN includes a combination of antiviral and immunosuppressive therapies (Guillevin, 1999; Han, 2004; Janssen et al., 2004). In fact, control of HBV replication may be the most important factor in the resolution of HBV-associated PAN (Janssen et al., 2004). Guillevin (1999) advocates an initial short regimen of corticosteroids to subdue the arteritis, which is most intense during the first weeks of disease. Steroids are then stopped. Continued treatment of the putative immune complex mechanism can be pursued with plasmapheresis if manifestations of arteritis persist. Antiviral therapy also should be instituted, e.g., with interferon (IFN)- α or lamivudine.

Autoimmune Features

Most patients with PAN do not have recognized evidence for an autoimmune pathogenesis. Exceptions are the few patients with systemic lupus erythematosus who have a vasculitis that is pathologically similar to idiopathic PAN (lupus arteritis) (Korbet et al., 1984). PAN is not associated with ANCA (Jennette et al., 2013a). As noted later, the serologic detection of ANCA in a patient who is suspected of having PAN should raise the possibility of pauci-immune SVV instead (Guillevin et al., 1995; Jennette et al., 2013a).

Genetic Features and Environmental Influences

There is no evidence that genetic factors play a substantial role in the development of PAN. Familial occurrences of PAN are rare and may be related to hepatitis B virus (HBV) infection (Reveille et al., 1989; Mason et al., 1994). No genetic features of HBV have been identified that correlate with the induction of PAN (Janssen et al., 2004).

The most commonly recognized environmental factor is infection by HBV (Guillevin, 1999; Janssen et al., 2004). There are anecdotal reports of PAN associated

with other infections, such as hepatitis C virus (HCV), human immunodeficiency virus (HIV), and parvovirus B19, but a statistically significant relationship has been established only for HBV infection.

***In Vivo* Models**

Rich (1942) proposed that PAN was mediated by immunologic mechanisms because he observed arteritis in patients who had serum sickness or had been treated with antibiotics. He acquired support for this hypothesis by inducing necrotizing arteritis in rabbits after injection of horse serum (Rich and Gregory, 1943). However, serum sickness in animals actually is a better model for SVV than for PAN because glomerulonephritis is a very frequent component (Germuth, 1953; Dixon et al., 1958). Interestingly, Pearl Zeek, who was one of the pioneers in delineating the clinical and pathologic features of PAN, studied an animal model of systemic arteritis that resembled PAN and that was induced by implanting pieces of silk in the perirenal tissue of rats (Zeek et al., 1948).

Pathologic Effector Mechanisms

As noted above, at least some examples of PAN are thought to be mediated by immune complex deposition in vessel walls (Figure 72.2). HBV infection may be the source of pathogenic antigens in patients with PAN (Han, 2004; Janssen et al., 2004); however, the vasculitis that is associated with HBV infection often has more features of SVV than necrotizing arteritis alone.

When arterial wall immune complexes are present, they cause inflammation by activating the many interconnected humoral and cellular inflammatory mediator systems; e.g., the complement, kinin, plasmin, and coagulation humoral systems, and the neutrophil, mononuclear phagocyte, lymphocyte, and platelet cellular systems. Endothelial cells and mural smooth muscle cells are capable of modulating vascular inflammation, e.g., by producing lipid metabolites with cytokine activity, and, in the case of endothelial cells, by secreting cytokines, upregulating leukocyte adhesion molecules, and altering surface thrombogenicity (Poher, 1988). This complex interplay of humoral and cellular events results in the influx of inflammatory cells (especially neutrophils), necrosis, and sometimes thrombosis.

Autoantibodies as Potential Immunologic Markers

Serologic testing for ANCA helps distinguish between PAN and AAV (MPA, GPA, EGPA) in a patient with arteritis because <5% of patients with PAN have a positive ANCA (Agard et al., 2003) compared to >80% of

FIGURE 72.2 Direct immunofluorescence photomicrograph demonstrating granular IgG deposits in an artery from the subcutaneous tissue of a patient with hepatitis B-associated polyarteritis nodosa, showing granular vessel wall staining for C3.

patients with pauci-immune SVV. For example, if a patient with mononeuritis multiplex and a peripheral nerve biopsy showing arteritis is ANCA-positive, pauci-immune SVV (e.g., microscopic polyangiitis) is a more likely possibility than PAN. Serologic identification of HBV infection by detection of antigens or antibodies supports a diagnosis of PAN because of the strong association between PAN and hepatitis B (Agard et al., 2003; Janssen et al., 2004) and the rare occurrence of hepatitis B in other forms of vasculitis (Guillevin, 1999).

KAWASAKI'S DISEASE

Clinical, Pathologic, and Epidemiologic Features

Kawasaki's disease is a self-limited febrile illness with systemic necrotizing arteritis that affects predominantly children, usually under 2 years of age (Yim et al., 2013). It was first described in Japan (Kawasaki, 1967), but occurs worldwide. The incidence of Kawasaki's disease in children under 5 years of age ranges from roughly 100 in 100,000 in Japan to 15 in 100,000 in the USA to 10 in 100,000 in Europe (Watts and Scott, 2004).

The clinical hallmark of Kawasaki's disease is the mucocutaneous lymph node syndrome, which is characterized by oral mucosal changes, e.g., erythema of the oropharynx; "strawberry tongue," and dryness, redness or fissuring of the lips; skin lesions, e.g., erythema, indurative edema, or desquamation of the distal extremities, or polymorphous macular exanthema on the trunk; bilateral conjunctivitis; and lymphadenopathy (Kawasaki, 1967; Rauch and Hurwitz, 1985; Newburger and Fulton, 2004).

The vasculitis of Kawasaki's disease involves medium-sized and small arteries, most notably the coronary arteries. The lesions are characterized histologically by segmental mural necrosis with infiltration by predominantly mononuclear leukocytes with less conspicuous neutrophils (Jennette, 2002). Necrosis occurs but typically has less fibrinoid material, more edema, and more macrophages than seen with PAN. Mural thickening, especially from intimal inflammation, may result in narrowing of the lumen and ischemia. Pseudoaneurysms are most common in the proximal coronary arteries and may be occluded by thrombus, resulting in myocardial infarction. Kawasaki's disease is the major cause of myocardial infarction in young children. Kawasaki's disease has surpassed acute rheumatic fever as the leading cause of acquired heart disease in children in the USA (Newburger and Fulton, 2004).

The conventional therapy for Kawasaki's disease is aspirin and intravenous gamma-globulin (Furusho et al., 1984; Nagashima et al., 1987; Rowley et al., 1988; Newburger and Fulton, 2004). If the interaction of anti-endothelial cell antibodies (AECAs) with cytokine-activated endothelial cells is the major pathogenic mechanism in Kawasaki's disease, intravenous gamma-globulin could be acting by reducing, e.g., through negative feedback control, or neutralizing, e.g., by anti-idiotypic binding, AECAs, or preventing cytokine stimulation of endothelial cells. Leung et al. (1989) have studied these possibilities, and have concluded that the beneficial effects of intravenous gamma-globulin result from reduced circulating cytokines and reduced endothelial cell activation, and not from reduced anti-endothelial cell antibodies (AECA) activity. Interestingly, intravenous gamma-globulin therapy but not aspirin is effective in reducing the severity and complications of the coronary arteritis (Newburger and Fulton, 2004), which indirectly supports the role of antibodies in the pathogenesis of the arteritis.

Autoimmune Features

Some investigators have reported evidence that patients with Kawasaki's disease have circulating autoantibodies that react with activated endothelial cells (Leung et al., 1986a,b, 1989; Grunebaum et al., 2002; Kaneko et al., 2004). Kaneko et al. (2004) identified a number of candidate target antigens using a cDNA expression library derived from tumor necrosis factor (TNF)- α -stimulated human umbilical vein endothelial cells. Tropomyosin was the most likely autoantigen recognized by anti-endothelial cell autoantibodies. Mor et al. (2002) have identified autoantibodies to tropomyosin in another form of vasculitis, Behçet's disease.

Cunningham et al. (1999) have reported IgM autoantibodies to cardiac myosin in Kawasaki's disease. These

autoantibodies differ from the antimyosin antibodies of patients with acute rheumatic fever.

Genetic Features and Environmental Influences

A role for genetic factors in the pathogenesis of Kawasaki's disease is supported by the observation that children of parents who had Kawasaki's disease in childhood are at greater risk for developing the disease (Uehara et al., 2003). In addition, a child is at 10-fold greater risk of developing the disease within 1 year of onset of the disease in a sibling (Fujita et al., 1989). However, the genetic basis for this familial susceptibility has not been defined. No definite HLA genotype associations have been detected.

The clinical and epidemiologic features of Kawasaki's disease, especially the temporal clustering and seasonality, suggest an infectious or environmental etiology. However, in spite of extensive efforts over many decades, no specific infectious agent or environmental factor has been identified (Newburger and Fulton, 2004; Burns et al., 2005).

In Vivo Models

Takahashi et al. (2004) have developed an animal model of vasculitis that has a remarkable pathologic similarity to the arteritis of Kawasaki's disease. They injected a *Candida albicans* extract intraperitoneally for 5 consecutive days into a variety of mouse strains. Arteritis developed in 66% of CD-1 mice and most often affected the coronary arteries and aortic root close to the orifice of coronary arteries. The gross distribution and histologic pattern of injury closely mimics coronary arteritis in patients with Kawasaki's disease. Not all strains of mice developed disease, indicating a genetic susceptibility in certain strains.

Duong et al. (2003) have described a similar model of coronary arteritis induced by injection of *Lactobacillus casei* cell wall extract into mice. They hypothesized that the pathogenicity of *L. casei* cell wall extract may derive from its ability to function as a superantigen.

Pathologic Effector Mechanisms

Although not fully verified, AECAs have been incriminated in the pathogenesis of vascular injury in patients with Kawasaki's disease by Leung et al. (1986a,b). They observed that patients with Kawasaki's disease have IgG and IgM AECAs that cause complement-mediated lysis of human umbilical and saphenous vein endothelial cells that had been pretreated with IFN- γ , interleukin (IL)-1, or TNF. From these observations, they hypothesized that the

pathogenesis of vasculitis in Kawasaki's disease entails two events: production of AECAs (possibly related to the polyclonal B cell activation that occurs in Kawasaki's disease) and increased cytokine production (possibly related to the increased activity of CD4 T lymphocytes and monocytes that also occurs in Kawasaki's disease). The AECAs would bind to upregulated endothelial antigens, and cause endothelial death and vascular inflammation.

A role for bacterial superantigen has been postulated because of selective expansion of T cell receptor (TCR) V β families in some patients with Kawasaki's disease (Newburger and Fulton, 2004; Yim et al., 2013). As noted earlier, observations in animal models also support this possibility.

Autoantibodies as Potential Immunologic Markers

No autoantibodies have been recognized that can be used for routine diagnosis of Kawasaki's disease (Newburger and Fulton, 2004). Erythrocyte sedimentation rate and C-reactive protein are consistently elevated but are completely nonspecific.

ANCA-ASSOCIATED VASCULITIS (AAV)

Clinical, Pathologic, and Epidemiologic Features

ANCA-associated vasculitis (AAV) has three major clinicopathologic expressions: microscopic polyangiitis (MPA), granulomatosis with polyangiitis (GPA), and eosinophilic granulomatosis with polyangiitis (EGPA) (Falk and Jennette, 2010; Jennette et al., 2013a) (see Box

72.1). GPA was formerly called Wegener's granulomatosis and EGPA, Churg–Strauss syndrome (Jennette et al., 2013a). All three are characterized by a pauci-immune SVV (i.e., with little or no immunoglobulin in the walls of involved vessels). GPA has necrotizing granulomatous inflammation superimposed on the vasculitis. EGPA has asthma, eosinophilia, and granulomatous inflammation in addition to the vasculitis. MPA has only the vasculitis, without granulomatous inflammation, asthma, or eosinophilia. As the term AAV implies, AAV is associated with circulating ANCA; however, it is important to realize that not all patients with these clinicopathologic expressions of vasculitis are positive in current clinical assays for ANCA.

Patients with all clinicopathologic expressions of AAV share a common pathologic manifestation of small vessel inflammation (Jennette, 1991, 2002; Jennette and Falk, 1998). This lesion is characterized by mural fibrinoid necrosis with karyorrhexis and infiltrating leukocytes (Figure 72.3). Neutrophils predominate in early lesions but are replaced by mononuclear leukocytes as soon as 48 h after the onset of acute lesions.

The clinical manifestations are protean and can affect many different organs individually or in combination. For example, vasculitis affecting dermal venules causes palpable purpura in skin; inflammation of glomerular capillaries causes glomerulonephritis (see Figure 72.3); pulmonary capillaritis causes pulmonary hemorrhage; vasculitis of small vessels in the upper respiratory tract mucosa causes sinusitis and otitis; vasculitis of the small vessels in the uvea (vascular tunic) of the eye causes uveitis; vasculitis affecting small epineural arteries and arterioles causes peripheral neuropathy (usually mononeuritis multiplex); vasculitis in small

FIGURE 72.3 (A) Necrotizing arteritis in a small artery and (B) necrotizing glomerulonephritis in a patient with microscopic polyangiitis. The artery and glomerulus have bright red staining for fibrinoid necrosis in this Masson trichrome stain. The artery and adjacent tissue are infiltrated by neutrophils and mononuclear leukocytes. The glomerulus has a cellular crescent.

TABLE 72.1 Approximate Frequency of Organ System Manifestations in Several Forms of Small Vessel Vasculitis

| Organ system | MPA (%) | GPA (%) | EGPA IgA (%) | Vasculitis (%) | Cryoglobulinemic vasculitis (%) |
|-----------------------|---------|---------|--------------|----------------|---------------------------------|
| Renal | 90 | 80 | 45 | 50 | 55 |
| Cutaneous | 40 | 40 | 60 | 90 | 90 |
| Pulmonary | 50 | 90 | 70 | <5 | <5 |
| Ear, nose, and throat | 35 | 90 | 50 | <5 | <5 |
| Musculoskeletal | 60 | 60 | 50 | 75 | 70 |
| Neurologic | 30 | 50 | 70 | 10 | 40 |
| Gastrointestinal | 50 | 50 | 50 | 60 | 30 |

Jennette and Falk, 1997

vessels in the gastrointestinal mucosa and submucosa causes abdominal pain and blood in the stool; and vasculitis affecting small visceral arteries, e.g., in the liver and pancreas, causes pain, dysfunction, and release of intracellular enzymes into the blood. The different clinicopathologic categories of AAV have overlapping clinical features with each other and with other forms of SVV (Table 72.1). Patients with GPA may have clinical manifestations of the necrotizing granulomatous inflammation, such as pulmonary nodules and cavities, perforation of the nasal septum, or collapse of the nasal septum causing saddle nose deformity.

In a review of multiple studies, [Watts and Scott \(2004\)](#) reported that the prevalence of GPA ranged from 24 to 157 in 1,000,000 adults that of microscopic polyangiitis from 9 to 66, and that of Churg–Strauss syndrome from 2 to 38. In accord with this, [Mahr et al. \(2004\)](#) determined that the prevalence of pauci-immune SVV in 1,000,000 adults in France was 25 for microscopic polyangiitis, 24 for GPA, and 11 for Churg–Strauss syndrome. The incidence in 1,000,000 adults ranged from 5 to 11 for GPA, from 3 to 12 for microscopic polyangiitis, and from 1 to 3 for Churg–Strauss syndrome ([Watts and Scott, 2004](#)).

ANCA vasculitis is usually a very aggressive disease that often will be complicated by end-stage renal disease or life-threatening pulmonary hemorrhage if not treated with high-dose corticosteroids and cytotoxic drugs, especially cyclophosphamide ([Nachman et al., 1996](#); [Jayne, 2003](#); [Little and Pusey, 2004](#); [Falk and Jennette, 2010](#)). Although there is general agreement about the use of corticosteroid and cytotoxic therapy for the induction of remission in patients with pauci-immune SVV, there is controversy over the dose, method of administration, and duration of treatment. Approximately 80% of ANCA SVV patients will enter remission with aggressive immunosuppressive therapy. However, up to 40% will have a relapse within 2 years. There is controversy over how best to treat relapses. A repeat course of corticosteroids

and cyclophosphamide often is used for relapses, but less toxic alternatives are azathioprine or mycophenolate mofetil ([Little and Pusey, 2004](#)).

Intravenous gamma-globulin and plasma exchange may have a beneficial effect on ANCA SVV, especially in patients with aggressive or persistent disease that does not respond well to conventional therapy ([Jordan, 1995](#); [Jayne et al., 2000](#); [Little and Pusey, 2004](#)). Anti-idiotypic antibodies that inhibit ANCA *in vitro* are present in pooled human gamma-globulin preparations, but whether or not an anti-idiotypic effect is the basis for the therapeutic benefits has not been determined. Plasma exchange reduces circulating ANCA levels, which is potentially beneficial if these autoantibodies are in fact pathogenic.

Autoimmune Features

Over 80% of patients with acute untreated pauci-immune SVV have circulating ANCAs ([Jennette and Falk, 1997](#); [Falk and Jennette, 2010](#)). ANCAs are specific for proteins in the cytoplasm of neutrophils and monocytes. When detected by indirect immunofluorescence microscopy using alcohol-fixed neutrophils as substrate, the two major antigen specificities cause two different staining patterns: cytoplasmic (C-ANCA) and perinuclear (P-ANCA) ([Figure 72.4](#)). The perinuclear pattern is an artifact of substrate preparation caused by diffusion of antigens from the cytoplasm to the nucleus ([Charles et al., 1989](#)). When analyzed by specific immunoassays, the most frequent C-ANCA antigen specificity is for proteinase 3 (PR3-ANCA) ([Goldschmeding et al., 1989](#); [Niles et al., 1989](#); [Jennette et al., 1990](#); [Ludemann et al., 1990](#)) and the most frequent P-ANCA specificity is for myeloperoxidase (MPO-ANCA) ([Falk and Jennette, 1988](#)).

T cells with specificity for ANCA antigens are present in patients with ANCA vasculitis ([Griffith et al., 1996](#); [Clayton and Savage, 2000](#)). T cells are probably involved

FIGURE 72.4 Indirect immunofluorescence microscopy photomicrograph of (A) C-ANCA- and (B) P-ANCA-staining patterns on alcohol-fixed human neutrophils.

in the immunogenesis of the autoimmune response, but their role in the pathogenesis of injury is unknown.

Some patients with GPA and MPA have circulating AECAs, often concurrent with ANCA (Chan et al., 1993; Del Papa et al., 1996; Holmen et al., 2004). There is controversy over the diagnostic utility and pathogenic significance of AECAs in pauci-immune SVV.

Genetic Features

A gene-wide association study (GWAS) has revealed a genetic influence on AAV that correlated best with MPO-ANCA and PR3-ANCA autoantigen specificity rather than clinicopathologic phenotype (Lyons et al., 2012). PR3-ANCA was associated with HLA-DP and genes encoding α 1-antitrypsin (SERPINA1) and proteinase 3 (PRTN3). MPO-ANCA was associated with HLA-DQ. These HLA associations suggest that antigen specificity of antigen binding sites on HLA molecules influences the initiation of the autoimmune response.

The predilection for the disease in white persons and the low prevalence in African Americans suggests that a genetic background contributes to disease induction. In accord with a role for MHC antigen specificity in the immunogenesis of ANCA, Cao et al. (2011) found that African Americans with PR3-ANCA AAV had 73.3-fold higher odds of having HLA-DRB1*15 alleles than healthy controls. Further, DRB1*1501 protein binds with high affinity to amino acid sequences of both sense-PR3 and antisense (complementary) PR3, suggesting that the MHC antigen binding site is important in disease induction.

Esnault et al. (1993) and Elzouki et al. (1994) reported the association of α 1-antitrypsin-deficiency phenotypes with PR3-ANCA-positive SVV. The fact that α 1-antitrypsin is the major inhibitor in the blood of PR3 is intriguing, but the relevance of this to the relationship between α 1-antitrypsin deficiency and PR3-ANCA is unknown.

Gencik et al. (2000) identified an association between GPA and a polymorphism in the PR3 promoter affecting a possible transcription factor binding site. In addition, Borgmann and Haubitz (2004) concluded that the neutrophil expression of PR3 is genetically regulated and correlates with onset and relapse of PR3-ANCA-associated SVV.

Environmental Influences

Drug exposure can induce ANCA formation and SVV. For example, a minority of patients who receive propylthiouracil develop ANCAs concurrent with the onset of pauci-immune SVV and glomerulonephritis (Choi et al., 2000). Minocycline and hydralazine also have been associated with the development of ANCA disease (Elkayam et al., 1996; Choi et al., 2000). Cocaine contaminated with levamisole also can cause AAV (McGrath, 2011).

Silica exposure and farming are risk factors for the development of ANCA SVV (Gregorini et al., 1993; Hogan et al., 2001; Lane et al., 2003), possibly by having an adjuvant effect on macrophages in the respiratory tract. For example, Hogan et al. noted that silica dust exposure was reported by 46% of patients with ANCA SVV, compared with 20% of control subjects ($P = 0.001$). The odds ratio of exposure to silica dust was 4.4 times greater for patients with ANCA SVV compared with control subjects ($P = 0.013$) (Hogan et al., 2001).

Approximately two-thirds of patients with GPA are chronic nasal carriers of *Staphylococcus aureus*. This is a risk factor for relapse, and prophylactic treatment with antibiotics that eliminate staphylococcal nasal carriage reduces relapse frequency (Stegman et al., 1996). The mechanistic relationship between staphylococcal infection and ANCA disease onset or exacerbation is not clear. However, observations by Pendergraft et al. (2004, 2005) raise the possibility that exposure to certain pathogens can result in the induction of the autoimmune ANCA response (see Chapter 60). They propose that pathogens can initiate an autoantibody response through induction of an appropriate antibody response to microbial proteins that have an amino acid sequence that mimics the antisense sequence (complementary sequence) of the autoantigen. These antibodies to the complementary peptide in turn induce anti-idiotypic antibodies that cross-react with the autoantigen (i.e., are autoantibodies). In support of this theory, patients with PR3-ANCA disease have circulating antibodies that react with peptides that have an amino acid sequence that is complementary to PR3, and

these antibodies react with anti-PR3 antibodies as an anti-idiotypic pair. Further, immunization of mice with a complementary PR3 peptide induces not only an antibody response to the complementary PR3 peptide but also to native PR3. Interestingly, *Staph. aureus*, which is associated with PR3-ANCA disease, contains a protein that has a sequence that mimics the antisense sequence of PR3. According to the theory of autoantigen complementarity, an antibody response to the *Staph. aureus* peptide that mimics a complementary PR3 peptide results in an anti-idiotypic immune response that targets PR3, resulting in PR3-ANCA production. Also in support of this concept is the association between PR3-ANCA and infection with Ross River virus and *Entamoeba histolytica*, both of which contain proteins with amino acid sequences that mimic complementary peptides of PR3 (Pendergraft et al., 2004).

In Vivo Models

Multiple animal models of MPO-ANCA SVV have been developed, but no widely accepted model of PR3-ANCA SVV has been reported (Jennette et al., 2011). The first convincing animal model of ANCA-induced SVV was described by Xiao et al. (2002). MPO knockout mice were immunized with murine MPO and produced anti-MPO antibodies. Splenocytes (including T and B cells) or isolated antibodies were then transferred from MPO^{-/-} mice that had been immunized with MPO to Rag2^{-/-} mice (lacking functional T and B cells), resulting in the development of necrotizing and crescentic glomerulonephritis in all mice and varying degrees of extrarenal SVV in many mice, including pulmonary capillaritis or necrotizing granulomatous inflammation, leukocytoclastic angiitis in the skin, and necrotizing arteritis in multiple viscera (Figure 72.5). The disease in the mice that received splenocytes is complicated by a background of immune complex localization in glomeruli; however, the Rag2^{-/-} mice or wild-type mice that receive anti-MPO IgG alone develop a pauci-immune glomerulonephritis and vasculitis that is pathologically identical to human ANCA-associated pauci-immune disease. Because this disease can be induced in mice with no functional T cells, T cells are not required for pathogenesis. However, neutrophils are required because elimination of circulating neutrophils with a cytotoxic rat antibody completely abrogates disease induction by anti-MPO IgG (Xiao et al., 2005). Activation of the alternative complement pathway also is required (Xiao et al., 2007).

Pathologic Effector Mechanisms

By definition, pauci-immune SVV has little or no localization of immunoglobulin in vessel walls and thus

FIGURE 72.5 Necrotizing arteritis in a small artery in the dermis of a mouse 6 days after intravenous injection of mouse antimyeloperoxidase IgG. There is a central area of deeply eosinophilic fibrinoid necrosis surrounded by leukocytes with leukocytoclasia (H&E stain).

appears to have a pathogenic mechanism that differs from classical immune complex-mediated vasculitis. The presence of ANCA in the circulation and the correlation of ANCA titers with disease activity raise the possibility that ANCAs have a pathogenic role (Kallenberg et al., 1994; Han et al., 2003; Falk and Jennette, 2010). But not all patients have ANCA detectable by current clinical serologic methods, and disease activity does not correlate very well with the titers obtained with these assays. This may change with the development of more sensitive and activity-specific assays (Roth et al., 2013). Using an epitope-specific assay, Roth et al. (2013) were able to detect three categories of MPO-ANCA epitope specificity: (1) epitope specificity confined to AAV patients with active disease, (2) epitope specificity detected in patients with active disease and in remission, and (3) epitope specificity that was seen in patients as well as in very low titer in healthy controls (natural ANCA). Further, they also were able to detect MPO-ANCA with very restricted epitope specificity in many patients who were ANCA-negative by conventional clinical assays.

The induction of ANCA and pauci-immune SVV by drug exposure, discussed above, is strong clinical evidence for the pathogenic importance of ANCA. The report of a neonate who developed pulmonary hemorrhage and nephritis following transplacental transfer of maternal MPO-ANCA IgG supports a pathogenic role for ANCA (Bansal and Tobin, 2004), but this phenomenon has not been observed in other patients.

In addition to the animal models described earlier, there are numerous *in vitro* observations that support the

pathogenic potential of ANCA IgG (Jennette and Falk, 1998; Rarok et al., 2003; Williams et al., 2005). Incubation of ANCA IgG with primed neutrophils induces the release of toxic reactive oxygen species and lytic granule enzymes (Falk et al., 1990a). Neutrophil priming, as occurs with exposure to certain cytokines, results in the expression of small amounts of ANCA antigens at the surface of neutrophils where they can interact with ANCA. The resultant activation of neutrophils is mediated by a combination of Fc receptor-dependent events (Porges et al., 1994; Mulder et al., 1994), as well as F(ab')₂-mediated events (Kettritz et al., 1997; Williams and Savage, 2005).

In vitro, ANCA-activated neutrophils kill primed endothelial cells (Ewert et al., 1992a; Savage et al., 1992). This process requires adhesion of the neutrophils to endothelial cells via β₂ integrins (Ewert et al., 1992b). Further, Radford et al. (2000) have shown that exposure to ANCA IgG causes rolling neutrophils to adhere to endothelial cells in culture through integrin-mediated adhesion.

Instead of, or in addition to, reacting with antigens expressed on the surface of neutrophils and monocytes, ANCAs might react with antigens (e.g., MPO and PR3) that have become planted in vessel walls. Vargunam et al. (1992) have shown that MPO binds to cultured endothelial cells by a charge-dependent mechanism and can subsequently react with ANCA to form immune complexes *in situ*. If this occurs *in vivo*, the magnitude of vessel wall immune complex formation must be substantially less than in conventional immune complex disease because of the absence or paucity of staining for immunoglobulin in vessel walls in ANCA SVV.

An inflammatory process, such as a viral respiratory tract infection, may cause increased levels of circulating cytokines, which in turn prime neutrophils to interact with circulating ANCAs to induce vasculitis (Jennette and Falk, 1998). With respect to this hypothesis, it is interesting to note that approximately 90% of patients report a “flu-like illness” shortly before the onset of the signs and symptoms of ANCA vasculitis (Falk et al., 1990b). Experimental support for this hypothesis is provided by the observation that injection of bacterial lipopolysaccharide into mice prior to induction of glomerulonephritis with anti-MPO IgG causes more severe injury (Huugen et al., 2005).

In summary, the *in vitro* observations support the hypothesis that antigens (PR3 and MPO) that are expressed at the surface of cytokine-primed neutrophils react with ANCA, causing neutrophil activation through both Fc receptor engagement and F(ab')₂ attachment to antigens, and activation of the alternative complement pathway, resulting in the attachment to and injury of vascular endothelial cells (Figure 72.6) (Jennette et al., 2013b).

AECAs have been detected in some patients with pauci-immune SVV. Del Papa et al. (1996) observed

that AECAs from patients with GPA are not toxic to endothelial cells but cause these cells to upregulate adhesion molecules and to release proinflammatory cytokines. Holmen et al. (2004) reported that patients with GPA have noncytotoxic AECAs that selectively bind surface antigens on unstimulated nasal, kidney, and lung endothelial cells, and that serum from patients with GPA caused agglutination of cytokine-stimulated nasal endothelial cells. AECA could synergize with ANCA to cause disease; however, the pathogenic importance of AECA in pauci-immune SVV has not been clearly delineated.

Autoantibodies as Immunologic Markers

In a patient with signs and symptoms of SVV, serology and/or immunohistology may demonstrate diagnostic immunologic markers that distinguish between vasculitides that have very different prognoses and treatments (Table 72.2). For example, in a patient with purpura, arthralgias, hematuria, and proteinuria, IgA-dominant immune deposits in dermal vessels support a diagnosis of IgA vasculitis (Henoch–Schönlein purpura); serum cryoglobulins and antihepatitis C antibodies support cryoglobulinemic vasculitis; serum anti-DNA and hypocomplementemia support lupus vasculitis; and serum ANCAs support one of the categories of pauci-immune SVV. Similarly, in a patient with hemoptysis and rapidly progressive glomerulonephritis (i.e., pulmonary–renal vasculitic syndrome), serum antiglomerular basement membrane (GBM) antibodies indicate anti-GBM disease, whereas ANCAs indicate one of the ANCA-associated vasculitides.

ANCA testing should include a specific immunochemical method [e.g., enzyme-linked immunosorbent assay (ELISA)] that will detect MPO-ANCA and PR3-ANCA, not merely an indirect immunofluorescence assay for C-ANCA and P-ANCA (Lim et al., 1999; Savage et al., 1999). This improves diagnostic specificity without a significant drop in sensitivity. As mentioned earlier, the studies by Roth et al. (2013) suggest that epitope-specific assays may be more useful for the diagnosis and follow-up of AAV than assays with the whole molecules as substrate.

An added complexity of serologic testing for ANCA disease and anti-GBM disease is the increased frequency of anti-GBM antibodies in patients with ANCA and *vice versa* (Saxena et al., 1991; Jennette, 2003; Levy et al., 2004). Patients with both autoantibodies have a worse prognosis than patients with ANCA alone. When both autoantibodies are present, a patient is at risk for manifesting vasculitic features of ANCA-associated disease that do not occur with anti-GBM disease alone, such as cutaneous, skeletal muscle, or gut

FIGURE 72.6 Putative pathogenic mechanisms for antineutrophil cytoplasmic autoantibody (ANCA)-induced vasculitis. ANCA antigens (granule proteins) that are normally within the cytoplasm of neutrophils are transferred to the surface by cytokine priming, where they can interact with ANCAs. Some antigens also are released and can bind to endothelial cells. These free and bound antigens can also react with ANCAs. The interaction of neutrophils with ANCAs induces full activation with respiratory burst and degranulation, which releases factors that activate the alternative pathway of complement activation. The resultant inflammation causes vascular injury (vasculitis). *Reproduced with permission from Jennette et al. (2013b).*

TABLE 72.2 Differential Diagnostic Features of Several Forms of Small Vessel Vasculitis (SVV)

| Diagnostic feature | MPA | GPA | EGPA | IgA vasculitis | Cryoglobulinemic vasculitis |
|-------------------------|-----|-----|------|----------------|-----------------------------|
| SVV signs and symptoms* | + | + | + | + | + |
| IgA-dominant deposits | – | – | – | + | – |
| Cryoglobulins | – | – | – | – | + |
| ANCAs in blood | + | + | + | – | – |
| Necrotizing granulomas | – | + | + | – | – |
| Asthma and eosinophilia | – | – | + | – | – |

*All of these SVVs can manifest any or all of the shared features of SVV, such as purpura, nephritis, abdominal pain, peripheral neuropathy, myalgias, and arthralgias. Each is distinguished by the presence and, just as importantly, the absence of certain specific features.

ANCAs, antineutrophil cytoplasmic autoantibodies.
Jennette and Falk, 1997

vasculitis. In some patients, the anti-GBM component of their autoimmune disease resolves, leaving more persistent ANCA disease.

Serology alone cannot make the distinction between MPA, GPA, EGPA, or isolated pauci-immune crescentic glomerulonephritis because each syndrome can be associated with either C-ANCA (PR3-ANCA) or P-ANCA (MPO-ANCA). However, the relative frequencies of ANCA specificities vary among the disease variants. For example, most patients with GPA have C-ANCA (PR3-ANCA) and most patients with renal-limited disease have

P-ANCA (MPO-ANCA) (Jennette et al., 2013b) (Table 72.3).

Diseases other than pauci-immune SVV can be associated with ANCAs, especially with ANCAs that are not specific for MPO or PR3. P-ANCAs that do not have specificity for MPO are associated with a number of nonvasculitic inflammatory diseases, such as ulcerative colitis, sclerosing cholangitis, autoimmune hepatitis, and Felty syndrome (Jennette and Falk, 1993; Bartunkova et al., 2002). C-ANCAs that are not associated with SVV occur in patients with cystic fibrosis (Bartunkova et al., 2002).

TABLE 72.3 Approximate Frequency of PR3-ANCA and MPO-ANCA in Patients with Pauci-immune Small Vessel Vasculitis

| | GPA | MPA | EGPA ^a | Renal-limited AAV |
|----------|-----|-----|-------------------|-------------------|
| PR3-ANCA | 75 | 40 | 5 | 20 |
| MPO-ANCA | 20 | 50 | 40 | 70 |
| Negative | 5 | 10 | 55 | 10 |

^aEGPA with glomerulonephritis is >75% ANCA-positive.

CRYOGLOBULINEMIC VASCULITIS

Clinical, Pathologic, and Epidemiologic Features

Cryoglobulinemic vasculitis is characterized pathologically by inflammation in small vessels (Figure 72.7) that is associated with deposits of cryoglobulins and complement in vessel lumens and walls. Skin, joints, gut, and glomeruli often are involved (see Table 72.1). Cryoglobulinemic vasculitis affects vessels of many types, including postcapillary venules (e.g., in the dermis), capillaries (e.g., glomerular and rarely pulmonary alveolar capillaries), arterioles, and rarely small arteries (Ferri et al., 2004). Immunofluorescence microscopy reveals granular deposits of immunoglobulins and complement in vessel walls, and sometimes luminal aggregates of cryoglobulins and complement. The clinical and pathologic manifestations of cryoglobulinemic vasculitis overlap with those of other systemic vasculitides, including purpura with leukocytoclastic angitis, proliferative and membranoproliferative glomerulonephritis, and, in rare severe cases, pulmonary hemorrhage with alveolar capillaritis. As with many systemic vasculitides, arthralgias and arthritis caused by synovitis are common features.

The prevalence of cryoglobulinemic vasculitis is not well defined, but it is more common in southern Europe than in northern Europe or North America (Ferri et al., 2004). There is a close association between HCV infection and cryoglobulinemia (D'Amico and Fornasieri, 1995; Ferri et al., 2004).

If there are circulating pathogenic autoantibodies or immune complexes in patients with vasculitis, theoretically, plasmapheresis combined with immunosuppression would be beneficial. Plasmapheresis has been used in severe cryoglobulinemia (D'Amico and Fornasieri, 1995). Plasmapheresis is combined with corticosteroid and cytotoxic therapy, which makes it difficult to determine what effect plasmapheresis alone is having on the disease. Therapy with IFN- α , in addition to the immunosuppressive drugs, has also been advocated in patients with cryoglobulinemic vasculitis secondary to HCV infection (D'Amico and Fornasieri, 1995).

FIGURE 72.7 Cryoglobulinemic vasculitis affecting a small artery in the kidney. The deeply acidophilic material in the vessel probably is a mixture of thrombus, fibrinoid necrosis, and aggregated cryoglobulins. The vessel wall and adjacent tissue are infiltrated by leukocytes with leukocytoclasia.

Autoimmune Features

Most cryoglobulins that cause vasculitis contain autoantibodies directed against immunoglobulins, i.e., rheumatoid factors (Ferri et al., 2004; Sansonno and Dammacco, 2005). Cryoglobulins are divided into three major types: monoclonal (type I), mixed monoclonal–polyclonal (type II), and polyclonal (type III). Mixed cryoglobulins are more pathogenic than monoclonal or polyclonal cryoglobulins. Monoclonal cryoglobulins usually occur in patients with plasma cell dyscrasias or B cell lymphomas, and cause morbidity primarily by precipitating within vessels and producing occlusion. Monoclonal cryoglobulins are not effective activators of inflammatory mediator systems, and therefore rarely cause overt vasculitis. Mixed cryoglobulins, however, are immune complexes that are capable of activating inflammatory mediators, including the complement system, and therefore characteristically cause systemic vasculitis.

The mechanism of cryoglobulin induction by HCV is not fully elucidated. HCV may initially induce production of polyclonal IgM lacking rheumatoid factor activity that evolves through somatic mutations to monoclonal IgM with anti-IgG reactivity (Sansonno and Dammacco, 2005).

Genetic Features and Environmental Influences

Not all patients with HCV infection develop cryoglobulinemia. The likelihood of developing cryoglobulinemia is not determined by serum HCV RNA titer or HCV genotype; thus, host factors, including genetic susceptibility, are incriminated as risk factors for this complication. In studies of relatively small numbers of patients,

Amoroso et al. (1998) reported an increased frequency of DRB1*11 (DR5) (36% vs. 20%, $P = 0.0035$), Congia et al. (1996) an increased frequency of DRB1*1101-4 (DR5), DQB1*0301, DRB1*0301 (DR3), and DQB1*0201, and Lenzi et al. (1998) an increased frequency of HLA-B8 and HLA-DR3 in patients with cryoglobulinemia compared to healthy controls or patients with hepatitis C but no cryoglobulinemia.

There is a strong association between cryoglobulinemic vasculitis and HCV infection (D'Amico and Fornasieri, 1995; Ferri et al., 2004; Sansonno and Dammacco, 2005). HCV antibodies and RNA are detected in the serum of 75–95% of patients with vasculitis and glomerulonephritis caused by mixed cryoglobulins. The HCV is both hepatotropic and lymphotropic. One hypothesis proposes that infection of B cells by HCV triggers the production of polyclonal and monoclonal rheumatoid factors that participate in cryoglobulin formation (D'Amico and Fornasieri, 1995). Another proposes that HCV lipoprotein induces an IgM response that is initially reactive with a virus–self complex but subsequently mutates to have rheumatoid factor activity (Agnello, 1995).

***In Vivo* Models**

Gyotoku et al. (1987) have described an experimental animal model of cryoglobulinemic vasculitis. They established monoclonal IgG rheumatoid factor-secreting hybridomas from MRL/lpr mice. These monoclonal rheumatoid factor antibodies were capable of forming cryoglobulins, and, when injected into normal mice, caused peripheral vasculitis and glomerulonephritis resembling that seen in patients with mixed cryoglobulinemia. Kikuchi et al. (2002) implanted mice with a hybridoma that secreted an IgG3 anti-IgG2a rheumatoid factor. The mice developed circulating cryoglobulins, acute glomerulonephritis, and cutaneous leukocytoclastic vasculitis.

Pathologic Effector Mechanisms

Cryoglobulinemic vasculitis is mediated by the deposition of mixed cryoglobulins in small vessels. These immune complexes composed of mixed cryoglobulins activate complement and initiate acute inflammation through mechanisms that were discussed above in the section on PAN. In patients with HCV-associated cryoglobulinemic vasculitis, immune complexes contain nonenveloped nucleocapsid proteins and whole HCV virions (Sansonno et al., 2005).

Autoantibodies as Immunologic Markers

The laboratory hallmark of cryoglobulinemic vasculitis is the detection of cryoglobulins in the circulation (see Table 72.2). The most common types of cryoglobulin

contain monoclonal (type II) or polyclonal (type III) autoantibodies (rheumatoid factors) that bind to other immunoglobulin molecules to form large immune complexes that precipitate from serum upon cooling. Type I cryoglobulins are composed of monoclonal IgM. Testing for cryoglobulins requires that the blood be kept warm prior to testing. In a proper clinical setting, hypocomplementemia, positive rheumatoid factor assay, and positive serology for HCV infection support a diagnosis of cryoglobulinemia. The hypocomplementemia characteristically has low C4 but normal or near normal C3, supporting predominantly classical/lectin complement pathway activation rather than alternative pathway activation.

IgA VASCULITIS (HENOCH–SCHÖNLEIN PURPURA)

Clinical, Pathologic, and Epidemiologic Features

IgA vasculitis was previously called Henoch–Schönlein purpura, but the name was changed to reflect the pathogenic role of IgA1 vessel wall deposits in the disease, and to emphasize that the resultant clinical syndrome (e.g., purpura, arthralgias, nephritis, abdominal pain) can be caused by many different forms of SVV (e.g., AAV) (Jennette et al., 2013a).

IgA vasculitis is the most common form of vasculitis in children with an incidence of approximately 20 in 100,000 children, with the highest frequency between 4 and 6 years old (Gardner-Medwin et al., 2002), although it can occur at any age. IgA vasculitis is SVV with IgA-dominant immune deposits affecting small vessels, i.e., capillaries, venules, or arterioles (Jennette et al., 2013a). It typically involves skin, gut, and glomeruli, and is associated with arthralgias or arthritis (Ting and Hashkes, 2004). The purpura typically affects the buttocks and lower extremities. Table 72.1 provides estimates of involvement of different organs, although this differs among cohorts. Immunofluorescence microscopy of dermal venules and renal glomeruli reveals granular vessel wall deposits of predominantly IgA1 and C3, supporting a pathogenic mechanism that involves IgA-dominant immune deposits (Mestecky et al., 2013).

IgA vasculitis usually is a mild, self-limited, vasculitis that does not warrant corticosteroid or cytotoxic therapy (Robson and Leung, 1994; Mestecky et al., 2013). Less than 5% of patients have serious complications, usually progressive renal failure. Patients with rapidly progressive glomerulonephritis or severe CNS disease benefit from immunosuppressive therapy, e.g., with high-dose corticosteroids, cytotoxic drugs, or plasmapheresis (Gedalia, 2004; Ting and Hashkes, 2004). The overall prognosis is excellent even though one-third to one-half of patients

will have one or more recurrences of symptoms, usually within 6 weeks, but rarely years later (Gedalia, 2004).

Autoimmune Features

Davin et al. (1987) detected IgA anti- α -galactosyl antibodies in the serum of children with active IgA vasculitis nephritis and IgA nephropathy. This finding is intriguing because of the known association between IgA vasculitis and infection with pathogens that have α -galactosyl residues on their surfaces, but the relevance of these antibodies to the pathogenesis of IgA vasculitis is uncertain. More recently, incriminating evidence for a role for antibodies directed against abnormally glycosylated IgA1 has emerged in the pathogenesis of IgA nephropathy and IgA vasculitis (Mestecky et al., 2013).

Genetic Features and Environmental Influences

There is evidence from family studies that there may be a genetic predisposition for having circulating potentially pathogenic abnormally glycosylated IgA1 (Boyd and Barratt, 2011; Kiryluk et al., 2011).

No HLA-A, HLA-B, or HLA-C associations were observed in 26 patients with IgA vasculitis (Ostergaard et al., 1990). Amoli et al. (2002a,b) reported an increased prevalence of HLA-DRB101 and a decreased prevalence of HLA-DRB107 among IgA vasculitis patients. They also observed an increased prevalence of HLA-B35 and IL-1 allele polymorphism in IgA vasculitis patients with glomerulonephritis (Amoli et al., 2004). The severity of nephritis and renal outcome were influenced by the IL-1 gene polymorphism.

Approximately 40% of children have an upper respiratory tract infection near the time of onset of IgA vasculitis, most commonly with group A *Streptococcus* (Masuda et al., 2003; Gonzalez-Gay et al., 2004; Ting and Hashkes, 2004). The pathogenic relationship between the infection and the onset of disease is unclear. Theoretically, this association could be because of a specific acquired immune response that is initiated by the infection, or because of a nonspecific amplification of immune activation that augments an underlying pathogenic mechanism, such as production of aberrantly glycosylated IgA (Allen et al., 1998).

In Vivo Models

There is no good animal model for IgA vasculitis. There are a few animal models of IgA nephropathy, which is the glomerular lesion of IgA vasculitis. Many of these involve oral or nasal immunization with dietary or infectious antigens (Amore et al., 2004). Uteroglobin gene

knockout and uteroglobin antisense transgenic mice develop pathologic features of human IgA nephropathy (Zheng et al., 1999), but the relevance of this to human disease is unclear because reduced uteroglobin has not been observed in patients with IgA nephropathy (Coppo et al., 2002). Okazaki et al. (2012) use ddY mice as a model of spontaneously developing IgA nephropathy and have shown that aberrant IgA glycosylation influences progression of this murine IgAN.

Pathologic Effector Mechanisms

A leading hypothesis is that IgA vasculitis is an immune complex vasculitis resulting from a dysregulated mucosal immune response to environmental or infectious antigens in a genetically predisposed individual. IgA-dominant immune complex deposits in vessel walls are the putative mediators of the inflammation. The predominant subclass is IgA1. The major antigen in the complexes, if any, is unknown. Because of the association with infections, an antigen derived from a pathogen has been sought. Masuda et al. (2003) reported the discovery of streptococcal antigens in the glomeruli of patients with IgA vasculitis glomerulonephritis, but this has not been independently confirmed. The IgA1 deposits may contain predominantly self-aggregated IgA1 or IgA1 complexed with anti-IgA1 autoantibodies, without a contribution by a specific exogenous antigen (Mestecky et al., 2013).

Human IgA1 has an O-glycosylated hinge region not present in other immunoglobulin classes, and this hinge region has reduced galactosyl residues in patients with IgA nephropathy and IgA vasculitis (Allen et al., 1998; Lau et al., 2007; Mestecky et al., 2013; Suzuki et al., 2009). This reduced galactosylation may be due to a functional defect in plasma cell β -1,3-galactosyltransferase. The abnormal glycosylation alters IgA1 structure and function, resulting in IgA1 aggregation, greater affinity for matrix proteins in vessel walls (including glomerular mesangium), and greater complement activation, which could result in localization of pathogenic IgA1-dominant deposits in vessel walls with resultant complement activation and vasculitis.

Vessel wall immune deposits contain not only IgA1 but also C3, C3c, C3d, and variable amounts of IgG and IgM, but little or no C1q or C4. The complement profile suggests predominantly alternative pathway activation.

Autoantibodies as Potential Immunologic Markers

The immunohistologic identification of IgA-dominant immune deposits in vessels is currently the only accepted diagnostic marker for IgA nephropathy, and is a defining feature of IgA vasculitis (Jennette et al., 2013a). However, the amount of circulating abnormally

glycosylated IgA1 or IgG autoantibodies specific for abnormally glycosylated IgA1 may become a useful diagnostic marker in the future (Mestecky et al., 2013).

CONCLUDING REMARKS—FUTURE PROSPECTS

A variety of pathogenic immunologic mechanisms, including autoimmune processes, mediate necrotizing arteritis and SVV. Clinically, and even pathologically, identical disease can be produced by distinctly different mechanisms; and a given pathogenic mechanism can produce more than one clinical and pathologic pattern of vasculitis. Because different organs can be affected in different patients, the clinical manifestations of even relatively specific types of vasculitis are extremely variable among patients. Therefore, the diagnosis of systemic vasculitis, including autoimmune vasculitis, is difficult, and requires skillful integration of clinical, pathologic, and laboratory data. Although difficult, precise diagnosis is essential for proper management, because the prognosis and appropriate treatment vary substantially among different categories of vasculitis. As knowledge of pathogenic immunologic mechanisms and inflammatory mediator systems increases, more effective treatments for autoimmune-mediated vasculitis will emerge, which will make precise diagnosis even more important.

VASCULITIDES OF LARGE AND MEDIUM-SIZED BLOOD VESSELS

Among the immune-mediated diseases vasculitides stand out for their potential to rapidly progress to serious, and at times life-threatening, complications. Inflammation in the wall of medium-sized and large blood vessels is considered a medical emergency that requires prompt diagnosis and therapeutic management. Arteritides threaten the host through two different mechanisms (Weyand and Goronzy, 2003b). Destruction of the vessel wall leads to dissection, aneurysm formation, rupture, and hemorrhage. Alternatively, arteritis initiates luminal stenosis with subsequent occlusion, tissue ischemia, and infarct.

Inflammation in venous vessels is rare, whereas the layered wall structure of large arteries appears to be a preferred site for granulomatous vasculitis, such as giant cell arteritis (GCA) and Takayasu's arteritis (TA) (Table 73.1). Both target the aorta and its major branches. However, the overlap in affected vascular territories is only partial, and each entity also manifests in unique arterial beds. Aortitides can be associated with other syndromes, such as relapsing polyarthritis, sarcoidosis, inflammatory bowel disease, and infections; however, GCA and TA are the

most frequent causes of aortic wall inflammation (Rojo-Leyva et al., 2000). Notably, host age is a strong risk factor for each for these vasculitides with the old susceptible to GCA and the young susceptible to TA. The pathologic and radiographic features can be indistinguishable, and clinical information is necessary to allow for proper diagnosis and classification (Gravaniis, 2000).

The etiology of vasculitis in the aorta and its major branches remains unresolved. Both the innate and the adaptive immune system contribute to pathogenesis. Some aspects of the abnormal immunity resemble an autoimmune reaction, but classical autoantigens have not been identified. An emerging concept proposes that vasculitides are one side of the spectrum of vascular inflammation that also includes atherosclerosis (see Chapter 71), with overlap in pathogenic mechanisms but differences in the intensity of inflammation.

GIANT CELL ARTERITIS

Giant cell arteritis is also known as temporal arteritis, cranial arteritis, granulomatous arteritis, polymyalgia arteritis, and Horton's disease. Typically, granulomatous lesions are formed in the wall of medium-sized arteries,

TABLE 73.1 Principal Features of Giant Cell Arteritis and Takayasu's Arteritis

| | Giant cell arteritis | Takayasu's arteritis |
|--------------------------------|--|---|
| Clinical | Subacute disease onset Restricted to individuals older than 50 years Highest incidence in individuals with Northern European ancestry Often combined with polymyalgia rheumatica | Subacute disease onset 90% of patients are female Highest risk in Asian and South American populations Systemic inflammatory syndrome with malaise, fever, arthralgias, and chest pain |
| Preferred vascular territories | Extracranial branches of the carotid artery Subclavian–axillary junction Aorta | Aorta Innominate, carotid, subclavian, mesenteric, renal arteries |
| Severe complications | Blindness Stroke Aortic aneurysm Wasting | Stroke Pulselessness Visual impairment Aortic regurgitation Hypertension |
| Pathogenesis | Key cellular elements in vasculitic lesions: arterial wall dendritic cells, IFN- γ -producing CD4 ⁺ T cells, IL-17-producing CD4 ⁺ T cells, tissue-injurious macrophages Trigger of immune-mediated vascular inflammation unknown Intense systemic inflammation with highly elevated IL-6 and hepatic acute phase reactants | Key cellular elements in the vascular lesions: perforin-producing T cells and natural killer cells Instigator of vessel wall inflammation unknown Systemic inflammatory syndrome |

particularly in the upper extremity and cranial branches of the aorta. CD4⁺ T cells are recruited to the adventitia of affected blood vessels where they interact with tissue-residing dendritic cells (DCs) and undergo *in situ* activation. At least two distinct lineages of CD4 T cells, Th1 cells and Th17 cells, participate in the intramural inflammation. Activated T cells regulate the differentiation of macrophages into tissue-injurious effector cells and orchestrate the production of growth factors intimately involved in the process of intimal hyperplasia. Vessel stenosis/occlusion leads to ischemia, and blindness-inducing ischemic optic neuropathy is one of the most feared clinical manifestations. Variations exist in the vascular inflammation, which translate into differences of the clinical disease profile. The diagnosis can be made by biopsy of the temporal artery. Almost all patients are older than 50 years of age, and the highest incidence has been reported in persons of northern European ancestry. If diagnosed early and treated appropriately, the clinical outcome is excellent (Weyand and Goronzy, 2003a,b). However, recent data strongly suggest that GCA is not a self-limiting disease. The early phase of vasculitis, mediated by Th1 and Th17 cells, partially responds to corticosteroid therapy. The late phase, a Th1-dependent disease process, appears relatively steroid resistant and manifests as a smoldering arteritis.

Historical Background

In 1932, Bayard Horton and colleagues (Horton et al., 1932) reported on two patients admitted to the Mayo Clinic with “fever, weakness, anorexia, weight loss, anemia and painful, tender areas over the scalp and along the temporal vessels.” Histomorphology of the removed temporal artery described periarteritis and arteritis with granulation tissue in the adventitia. Horton recognized that this type of arteritis was distinct from all other vasculitic syndromes and named it “temporal arteritis.” Prior descriptions of temporal artery disease suggest that GCA may be a very old disease. In 1890, the English surgeon Jonathan Hutchinson described a patient with a red and swollen temporal artery who had difficulties wearing his hat (Hutchinson, 1890). In the grave of Pa-Aton-Ern-Hebs, built during the Amarna period (around AD 1350), a blind harpist was shown with nodularity and swelling of the temporal artery. And Ali Ibn Isa (940–1010 BC), an ophthalmologist in Baghdad, recommended removal of the temporal artery not only to treat headaches, but also inflammation of the scalp muscles associated with blindness (Henriet et al., 1989).

Horton deserves credit for recognizing the connection between the constitutional symptoms and the arteritis of the temporal vessels and for introducing temporal artery biopsy as a diagnostic test.

TABLE 73.2 The Clinical Profile in Giant Cell Arteritis

| Sign/Symptom | Frequency (%) | Pathology | |
|--|---------------|-------------------|-----------------------|
| Headaches | 80 | Vascular stenosis | |
| Scalp tenderness | 70 | | |
| Jaw claudication | 30 | | |
| Ocular symptoms (blindness, amaurosis, fugax, motor deficit) | <20 | | |
| Painful dysphagia | <10 | | |
| Cough | <10 | | |
| Limb claudication | 10 | | |
| Absent pulses | <10 | | |
| Asymmetrical blood pressure readings | <10 | | |
| CNS ischemia | <5 | | |
| Peripheral neuropathy | <5 | | |
| Aortic regurgitation | <5 | | Vascular dilatation |
| Intense acute phase response (elevated ESR, CRP, IL-6) | 90 | | Systemic inflammation |
| Anemia | 70 | | |
| Polymyalgia rheumatica | 40 | | |
| Wasting syndrome | 30 | | |
| Synovitis | <5 | | |

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; IL-6, interleukin 6.

Clinical, Pathologic, and Epidemiologic Features

The clinical manifestations of GCA are characterized by two major dimensions: (1) arterial stenosis and occlusion of arteries causing impaired blood flow, ischemia, and tissue infarction; and (2) systemic inflammation leading to a massive increase in acute phase proteins, liver abnormalities, anemia, weight loss, malaise, and fever (Table 73.2) (Evans and Hunder, 2000; Weyand and Goronzy, 2003a). Evidence suggests that the systemic inflammatory syndrome precedes rather than follows vascular inflammation, responds promptly to corticosteroid immunosuppression, and is mediated by a distinct immune abnormality: the excessive production of IL-6 and related cytokines. Clinical symptoms vary depending on the nature of the vascular lesions and the vascular bed is preferentially affected. For clinical purposes it is helpful to subdivide the GCA syndrome into different subtypes, including cranial GCA, nonstenosing GCA, large vessel GCA, and polymyalgia rheumatica (PMR).

In cranial GCA, the major focus of the vasculopathy lies in the branches of the aorta that supply the head and the neck. Most often affected are the superficial temporal artery, the vertebral artery, the ophthalmic and posterior

ciliary arteries, and, less frequently, the internal and external carotid artery. Clinical consequences of vascular insufficiency include headaches, scalp tenderness, claudication of the masseter muscles, and vision loss due to ischemia in the visual pathway. The headaches are often intense, throbbing and sharp in character, and can be combined with temporal tenderness. On physical examination, the temporal vessels are thickened, with nodules and absence of pulses. Other arteries of the scalp can be involved. Vision loss is one of the reasons that GCA is considered a prime ophthalmic emergency. Occlusion in branches of the ophthalmic artery results in ischemic optic neuropathy that causes sudden and pain-free blindness. Amaurosis fugax can precede complete vision loss. Patients with blindness in one eye are at high risk to suffer additional visual loss in the other eye. Vascular insufficiency of arteries supplying the orbita can cause a wide spectrum of ophthalmic complications, but ischemic optic neuropathy remains the most frequent ophthalmic manifestation (Chan et al., 2005). Intermittent claudication of the masseter and temporal muscles is a relatively disease-specific symptom but only affects a fraction of patients (Smetana and Shmerling, 2002). Usually, jaw claudication is induced by chewing or prolonged talking.

Claudication of the tongue and painful dysphagia can occur. Impaired blood flow in the vertebrobasilar and carotid arteries causes ischemia of the central nervous system, e.g., transient ischemic attacks or stroke. Chronic nonproductive cough has been attributed to vasculitis of pulmonary artery branches.

In a subset of patients, the primary targets of vasculitis are the subclavian, axillary, and carotid arteries, and the aorta itself (Brack et al., 1999; Salvarani, 2003). Presenting symptoms of upper extremity vasculitis are claudication of the arms, loss of pulses, paresthesias, and, only rarely, frank gangrene. Temporal artery biopsies are often negative, and, in the majority of patients, symptoms indicative of cranial ischemia are lacking (Brack et al., 1999). Aortitis can coexist with cranial arteritis or large vessel involvement and predominantly manifests in the thoracic aorta. Silent aneurysm, aortic dissection, or rupture is a consequence of destruction of the elastic membranes (Evans et al., 1994; Lie, 1995). Not unusually, histomorphologic evidence of vasculitis is found during surgical repair of aortic aneurysm. Aortic involvement is typically seen in patients many years after the initial diagnosis of GCA, suggesting a smoldering disease process and is associated with increased mortality (Kermani et al., 2012).

Inflammation of medium-sized arteries in GCA does not necessarily lead to vascular stenosis but may manifest as nonstenosing vasculitis. Only in recent years has it become clear that patients with nonstenosing GCA present with a different clinical profile than those who have luminal occlusion (Weyand et al., 1997). In nonstenosing GCA, the dominant features are those of intense systemic inflammation, often manifesting as fever and wasting. Frequently such patients seek medical attention because of nonspecific symptoms such as malaise, depression, anorexia, and weight loss and are subjected to a work-up for underlying malignancy. Lack of cranial symptoms,

such as headaches, scalp tenderness, and abnormal temporal artery, can generate a challenging clinical scenario in which only the experienced clinician will search actively for vasculitis. Temporal artery biopsy is the diagnostic procedure of choice.

The vasculitic component of GCA may remain subclinical with the systemic inflammatory syndrome appearing in isolation (Weyand and Goronzy, 2003a). Signs and symptoms of impaired blood flow are missing, and clinical findings are dominated by myalgias, stiffness, and laboratory signs of heightened acute phase response. This subtype of GCA is best known as PMR, a clinical syndrome that is about two- to three-fold more frequent in incidence than GCA (Doran et al., 2002; Kermani and Warrington, 2013). Polymyalgia rheumatica and GCA are closely related entities, affecting the same patient population. They can occur together, and PMR can precede or follow GCA. Histologic examination of arterial biopsies is unrevealing, but molecular analysis of arterial tissues demonstrates the activation of immune responses in the vessel wall (Weyand et al., 1994a). Lead symptoms are those of shoulder girdle and pelvic girdle pain and stiffness. Synovitis of hip and shoulder joints has been described in some patients with PMR and recent provisional classification criteria have been expanded to include cases with bursitis and synovitis (Dasgupta et al., 2012). The diagnosis of PMR remains founded on nonspecific findings, such as pain and elevated acute phase proteins, and, in some cases, inflammation of joint-related structures. Further widening of the diagnostic category of PMR is suggested by recent reports that the diffuse myalgias associated with statin therapy may also fulfill the criteria for PMR (de Jong et al., 2012). Urgent need exists to replace the non-specific clinical classification criteria with objective, histological, and molecularly based criteria. Until that goal is reached, PMR remains a diagnosis of exclusion and includes an assortment of conditions.

FIGURE 73.1 Giant cell arteritis. Cross-section of the temporal artery from a 78-year-old patient. (A) Transmural inflammation with granuloma formation in the inner media and along the intimal–medial junction. Partial occlusion of the lumen by thickened intima. (B) Detailed view of several multinucleated giant cells, close to the fragmented internal elastic lamina. *Reproduced with permission from Weyand and Goronzy (2003b).*

The Vascular Lesion

In its typical form, GCA is a panarteritis with T lymphocytes and macrophages infiltrating into all layers of the vessel wall (Figure 73.1) (Gravani, 2000). In about half of the cases, granulomatous formations are seen. Giant cells, which give the name to the syndrome, are not necessarily present. They have a tendency to accumulate at the media-intima border, often closely related to the fragmented internal elastic lamina. Inflammatory infiltrates are usually segmental but can be circumferential. Most typical is the focal placement of lesions producing the so-called “skip” pattern of vasculitis. In some patients, the infiltrates are predominantly composed of lymphocytes without granuloma formation. The intima is hyperplastic, obstructing the lumen. Frequently, the adventitia is infiltrated by T cells and macrophages. Clusters of lymphocytes and macrophages in the adventitia, at times arranged as cuffs around vasa vasorum, should be considered sufficient to establish the diagnosis of GCA (Bjornsson, 2002). In some cases, the small vessels in the adventitia are the primary target for the inflammatory infiltrates, leaving the main temporal artery unaffected (Chatelain et al., 2008).

Epidemiology

Among the vasculitic syndromes, GCA is the most frequent in the Western world. Age is the most significant risk factor; the disease almost exclusively occurs in individuals older than 50 years of age, and susceptibility increases as individuals get older (Machado et al., 1988; Salvarani et al., 2004). The female-to-male ratio of patients is 3:1. A characteristic feature of GCA is pronounced geographical variations in prevalence. The range of incidence rates spans between 1 and 25 cases per 100,000 persons aged 50 years and older. Highest incidence rates have been reported in northern Europe, including Iceland, Denmark, and Sweden (Baldursson et al., 1994; Nordborg et al., 2003), as well as in areas of North America settled by populations of Scandinavian origin (Machado et al., 1988), such as Minnesota. Conversely, blacks and Hispanics are infrequently affected (Smith et al., 1983; Gonzalez et al., 1989).

Genetic Features

Giant cell arteritis is an HLA class II-associated disease (Weyand et al., 1992, 1994b). HLA-DR4 confers the highest risk to develop arteritis. Several allelic variants of HLA DR B1*04 are overrepresented among affected individuals. Sharing of sequence polymorphisms in the antigen-binding groove of HLA-DR molecules has been cited as evidence for a role of antigenic peptides in disease initiation. HLA

class II polymorphisms seem not to influence the patterning or severity of the disease. Minor effects of polymorphisms in multiple non-HLA genes, such as corticotrophin-releasing hormone, CCL5 (RANTES), intracellular adhesion molecule 1 (ICAM-1), and interleukin 6 (IL-6), have been reported and larger studies are awaited to confirm or refute such associations (Alvarez-Rodriguez et al., 2011; Rodriguez-Rodriguez et al., 2011a,b). It is possible that the marked geographical variations in disease susceptibility are related to differences in population genetics, for example, the representation of HLA class II haplotypes.

Pathogenic Mechanisms

Progress has been made in deciphering the pathogenic mechanisms relevant for the inflammatory injury of the vessel wall (Weyand, 2000; Weyand and Goronzy, 2003b; Weyand et al., 2012). Data on the systemic component with the massive upregulation of acute phase responses are more limited. A comprehensive pathogenic model would have to explain why individuals of Scandinavian origin develop granulomatous lesions in the walls of selected medium-sized arteries when they reach the seventh to eighth decades of their lives; how panarteritis translates into occlusive vasculopathy; and how vascular insufficiency is related to the clinical profile of the syndrome. Over the last decade, much progress has been made in understanding the pathways of immunostimulation in the artery and how the immune system regulates vessel stenosis/occlusion (Figure 73.2). A concept explaining the target tissue susceptibility of selected arterial territories is emerging.

Principally, GCA is a chronic inflammatory disease in which CD4⁺ T lymphocytes establish stable lymphoid microstructures in the arterial wall and orchestrate the differentiation of tissue-injurious macrophages (Figure 73.2) (see also Chapter 11). The response-to-injury program of the vessel is maladaptive and leads to overshooting proliferation of the intimal layer resulting in luminal occlusion, ischemia, and infarct of dependent organ structures. Age-related changes in the immune system as well as in the arterial system represent risk factors for the development of this granulomatous arteritis (Mohan et al., 2011). Dysfunctional immunity is only one aspect of the pathogenic process; the blood vessel participates as an equal partner in destabilizing the immune protection ordinarily guarding blood vessel walls from inflammation. Vascular cells actively interact with immune cells to break tissue tolerance and provide signals that amplify tissue-destructive feed-forward circuits sustaining vasculitis (Weyand and Goronzy, 2013). Specifically, wall-resident cells, such as endothelial cells and vascular smooth muscle cells, may provide activation and survival signals for

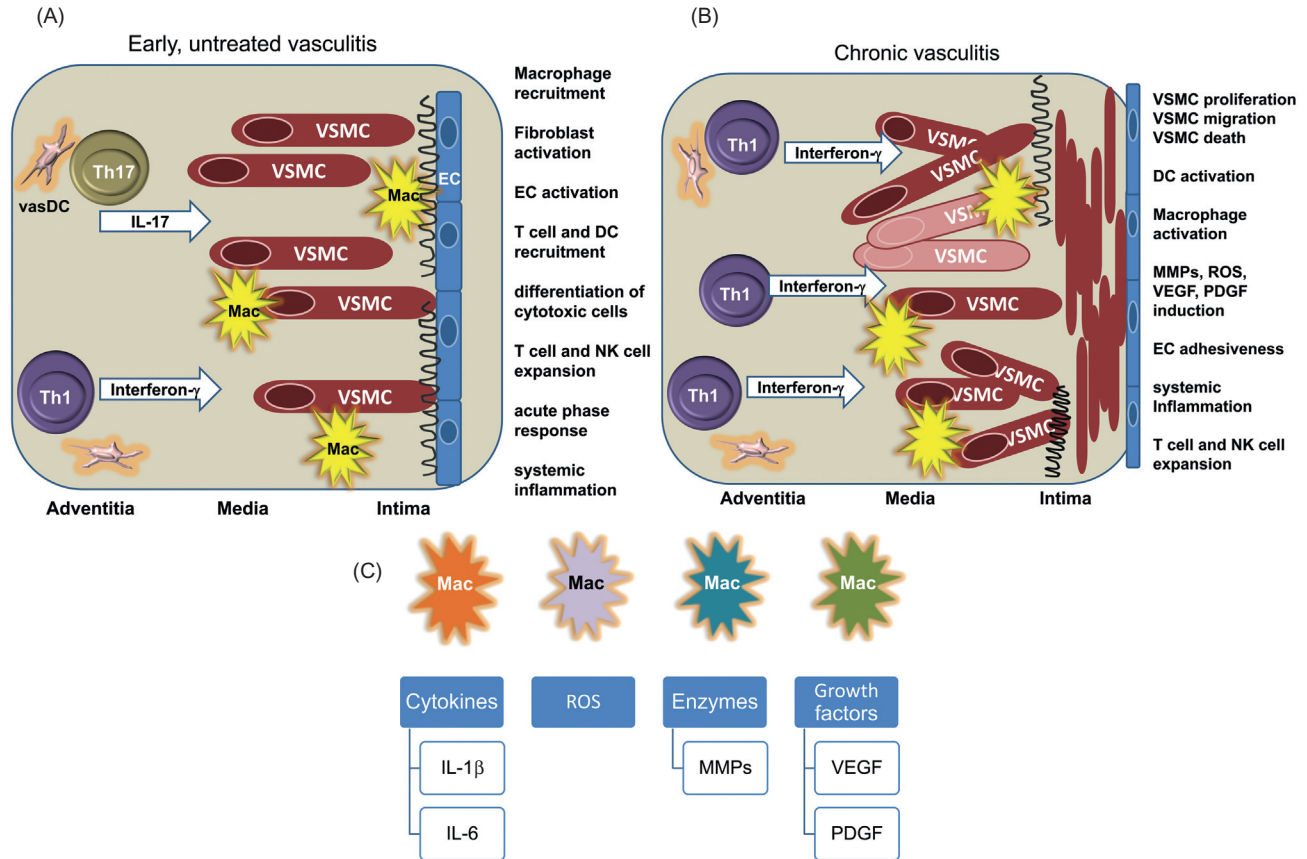

FIGURE 73.2 (A) Medium-sized human arteries host a population of dendritic cells (vasDC) positioned in the adventitia. When stimulated, such vasDC begin to recruit and activate CD4 T cells. In early vasculitis, both IFN- γ -producing Th1 cells and IL-17-producing Th17 cells are represented in the infiltrate. Release of IFN- γ and IL-17 recruits and stimulates macrophages and targets vessel-wall cells (VSMC and EC). The misplaced T cell response amplifies inflammation, creates a permissive microenvironment and organizes the infiltrating immune cells in granulomatous arrangements. (B) Chronic giant cell arteritis. In temporal arteries of corticosteroid-treated patients Th17 cells are rare but Th1 cells dominate the infiltrates. Secretion of IFN- γ into the tissue niche activates macrophages and directs their differentiation into a multitude of proinflammatory and tissue-damaging populations (see [Figure 73.3](#)). VSMC respond to IFN- γ stimulation with proliferation, migration, and secretory differentiation. Activated myofibroblasts form hyperplastic intima, which obstructs the lumen. IFN- γ can also cause VSMC death and thinning of the media. (C) Macrophages in giant cell arteritis. Directed by tissue-infiltrating T cells, macrophages differentiate into several distinct populations, which specialize in different aspects of tissue damage. IL-1 β and IL-6 production supports proinflammatory feed-forward circuits. ROS release damages vessel-wall structures. Enzyme production sustains digestion of elastic membranes. Growth factors promote growth and activity of myofibroblasts and enable neo-angiogenesis through the release of VEGF.

infiltrating immune cells that allow them to be retained in the tissue niche and undergo chronic activation.

T Cells and Antigen-Presenting Cells in Giant Cell Arteritis

The vast majority of T cells in the lesions are CD4⁺ T cells of the memory phenotype ([Andersson et al., 1987](#)). CD4⁺ T cells enter the vessel wall through the vasa vasorum and infiltrate into the adventitia recruited by chemokines that derive from DCs positioned at the adventitia–media border ([Krupa et al., 2002](#)) ([Figure 73.2](#)). Adventitial DCs are an indigenous cell

population that was only recently described ([Ma-Krupa et al., 2004](#)). They form a circumferential ring along the lamina elastica externa. They express typical DC markers, such as CD11c, fascin, and S-100 but lack CD1a and thus are distinct from Langerhans cells in the skin. Functional profiling has demonstrated that they possess Toll-like receptors (TLRs) and respond to pathogen-associated molecular patterns ([Pryshchep et al., 2008](#)).

Toll-like receptors are characteristically found on cells of the innate immune system and typical ligands are lipopolysaccharides, flagellin, viral RNA, bacterial DNA, and also heat-shock proteins (see Chapter 12). The triggering of TLRs, together with additional signals, initiates the maturation of immature DCs. Upon maturation, such DCs

switch their chemokine receptor profile, become migratory, and travel via lymphatic vessels to secondary lymphoid tissues, such as lymph nodes. There they home to the T cell zones, become stationary, start producing T cell-attracting chemokines, and upregulate the expression of antigen-presenting HLA molecules and costimulatory molecules.

It is not known what the physiological role of adventitial DCs is and what they are checking for. Experiments that utilized the implantation of human temporal arteries into immunodeficient mice have revealed that such adventitial DCs respond to LPS and undergo rapid activation when triggered by blood-borne mediators (Ma-Krupa et al., 2004). In GCA, almost all DCs in the arterial wall are highly activated and have adopted a functional profile reminiscent of that in lymph node-positioned DCs (Krupa et al., 2002). They produce high amounts of chemokines, are no longer migratory, and can present antigen to T cells. It has been proposed that one of the pathomechanisms in GCA is the trapping of arterial wall DCs in the tissue instead of allowing them to migrate to lymph nodes, which leads to a misplaced immune response.

Experiments in patients with PMR who lack T cell infiltrates in the temporal artery have supported the concept that DC activation is a very early step in the disease process (Krupa et al., 2002). In fact, DCs in PMR arteries have already acquired the capability to produce T cell-attracting chemokines. If appropriate T cells are made available, they will initiate T cell recruitment and *in situ* activation. How patients with PMR are protected from accumulating T cells in the artery, although tissue-residing DCs have already matured, is not understood.

Once CD4⁺ T cells have made their entrance into the adventitial layer of medium-sized arteries, they undergo local activation (Weyand et al., 1994c; Brack et al., 1997). Studies in right-sided and left-sided temporal artery specimens from the same patient have shown that identical T cell clonotypes emerge in physically separated lesions (Weyand et al., 1994c), providing strong support for antigen-driven selection (Weyand and Goronzy, 1995). Recent studies have emphasized that several functional T cell lineages participate in the vasculitic lesions. A major subset of tissue-infiltrating CD4 T cells produce interferon- γ (IFN- γ) and represent Th1 cells (Wagner et al., 1996; Deng et al., 2010; Samson et al., 2012; Terrier et al., 2012). However, GCA is not a “pure” Th1 disease. Rather, also present in the lesions are Th17 cells (Deng et al., 2010; Samson et al., 2012). Evidence for nonoverlapping actions of both T cell lineages comes from the analysis of consecutive temporal artery biopsies in untreated and treated patients (Deng et al., 2010). Corticosteroids essentially eliminate Th17 cells but leave Th1 cells unaffected. The emerging pathogenic concept distinguishes between early untreated GCA, a

Th1–Th17-driven process and chronic-persistent GCA, a Th1-dependent pathology (Weyand et al., 2011).

CD4⁺ T cells undergo clonal expansion and regulate macrophage recruitment (Figure 73.2). The intensity of IFN- γ production, which could be viewed as a measure of T cell activation in the vasculitic lesions, has been correlated with the clinical manifestations of this disease. Patients with high production of IFN- γ in the artery have more intense intimal hyperplasia, more visual symptoms, and cranial ischemia. Patients with distinctly low production of IFN- γ in the temporal artery sample often lack vessel occlusion and tend to present with fever of unknown origin or other constitutional symptoms (Weyand et al., 1997).

Depletion experiments have indicated that CD83⁺ DCs are the critical antigen-presenting cells and thus have gatekeeper function in the disease (Ma-Krupa et al., 2004). Since DCs sit in a unique position in the artery (outside of the lamina elastica externa), their absence or presence may dictate whether a particular artery is susceptible to be targeted by GCA. Indeed, different arterial beds in the human body carry vascular DC with distinct profiles of pattern recognition receptors (Pryshchep et al., 2008), providing a molecular basis for variations in the target tissues and a possible mechanism for the unusual patterning of temporal arteritis.

Macrophages in Giant Cell Arteritis

There are no data to suggest that T lymphocytes accumulating in the vasculitic infiltrates have direct involvement in wall injury (Weyand and Goronzy, 1999). Rather, multiple pathways have been identified through which macrophages mediate tissue damage (Figure 73.2). Macrophage function is closely related to the positioning in the wall, suggesting a tight interaction between infiltrating macrophages and the cellular and matrix components of the particular microenvironment (Weyand et al., 1996).

Adventitial macrophages focus on the production of proinflammatory cytokines, such as IL-1 β and IL-6. Tumor necrosis factor- α (TNF- α) has been reported to be present in inflamed arteries with the staining pattern suggesting production in the media (Hernandez-Rodriguez et al., 2004). Macrophages in the media specialize in generating reactive oxygen intermediates (Rittner et al., 1999b). Toxic aldehydes, products of lipid peroxidation, have been detected in the medial smooth muscle cell layer (Rittner et al., 1999b). The formation of nitrotyrosine, a marker of nitrosative stress, has also been localized to the media (Borkowski et al., 2002). Interestingly, only endothelial cells of medial neovessels are affected by nitrotyrosine formation. These studies have pinpointed tissue injury pathways, identified the cellular players, and

at least partially described target structures incurring damage.

A noteworthy aspect of the presence of oxidative stress in the media is the induction of protective mechanisms, such as the induction of aldose reductase, a ketoreductase with a role in metabolizing toxic aldehydes (Rittner et al., 1999a). Blocking aldose reductase in GCA lesions increased apoptosis rates of smooth muscle cells, demonstrating a protective role of the enzyme. There is no information about whether patients actually vary in the induction of such protective mechanisms, making them more or less susceptible to oxidative damage.

Other functional properties of media-located macrophages include the secretion of matrix metalloproteinases (MMPs) (Sorbi et al., 1996; Tomita and Imakawa, 1998). CD68-expressing macrophages in the vicinity of the lamina elastica interna are prone to produce MMP-2 as well as MMP-9. Such metalloproteinases almost certainly are the mechanisms underlying the typical fragmentation of the elastic membranes. So far, macrophages captured in the intima have not been assigned to particular injury pathways (Weyand et al., 1996). They have been described as staining positive for NOS-2, but downstream effects of nitrosative stress have not been detected in the intima itself.

Progress in macrophage biology has led to the identification of functionally different macrophage populations, including proinflammatory M1 macrophages and reparative M2 macrophages. IL-33, a cytokine associated with M2 polarization, has been localized in temporal artery biopsies (Ciccia et al., 2013). Why tissue-damaging macrophage functions dominate the vasculitic lesions remains unexplored.

Intimal Hyperplasia

Blockage of the vascular lumen by hyperplastic intima is the mechanism through which GCA causes vascular insufficiency and tissue ischemia (Figure 73.2). Myofibroblasts in the intima proliferate and deposit matrix. They have migrated to the intima from deeper wall layers, either the media or the adventitia. Factors regulating myofibroblast migration and differentiation thus have gatekeeper function in the disease process.

Inflamed temporal artery walls produce platelet-derived growth factor (PDGF), which derives from at least two cell types, CD68⁺ macrophages and resident wall cells (Kaiser et al., 1999). Numerically, the most important sources are macrophages in the media, often close to the lamina elastica interna. Multinucleated giant cells can also produce this growth factor. Fibroblast growth factor has been described to be present in vasculitic lesions; its function is unexplored.

The outgrowth of the expanding intimal layer needs to be supported by the formation of new blood vessels (Kaiser et al., 1998; Cid, 2002). Neovascularization typically affects the media and the hyperplastic intima. Newly formed blood vessels are highly organized. Multinucleated giant cells have been found to secrete vascular endothelial growth factor (VEGF) (Kaiser et al., 1998). In essence, tissue-infiltrating macrophages appear to have a critical role in regulating the process of intimal proliferation and neovascularization. Interestingly, VEGF production is correlated with IFN- γ production, thereby connecting the wall remodeling in the intima and media with the adaptive immune responses in the adventitia.

Immuno-stromal Interactions Promoting Vasculitis

While the immune system participates in vasculitic responses through a multitude of mechanisms, the blood vessel wall is not just an innocent bystander. Vascular cells, including vascular smooth muscle cells (VSMC) and endothelial cells, contribute to the intramural inflammation. Specifically, expression of receptors and ligands of the NOTCH family of molecules enables VSMC to directly communicate with infiltrating T cells and regulate their activity. The majority of CD4 T cells in GCA patients are spontaneously positive for NOTCH1, a receptor that binds to VSMC-expressed ligands in the lesions (Piggott et al., 2011). Blockade of the NOTCH signaling pathway has profound immunosuppressive effects, emphasizing the relevance of T cell–VSMC communications in GCA.

The Systemic Inflammatory Syndrome

Mechanisms driving the systemic inflammatory component of GCA are less well understood. Patients with PMR in whom vascular inflammatory infiltrates are undetectable by standard histology are equally affected by systemic inflammation as GCA patients with full-fledged vasculitis (Wagner et al., 1994; Weyand et al., 1999). This clinical constellation has supported the concept that systemic inflammation is not a “spillover” from the vasculitis.

Typical findings include a massive acute phase response with manifestations in multiple organ systems (Weyand and Goronzy, 2003a). Patients show signs of abnormalities in hematopoiesis, such as anemia and thrombocytosis. Liver function is often abnormal and shows elevation of alkaline phosphatase levels. By affecting the central nervous system, the acute phase response causes fever, malaise, and depression. Profound elevation of the erythrocyte sedimentation rate (ESR), a typical

laboratory marker of GCA, is also a consequence of excessive production of acute phase proteins.

The only known pathomechanism related to the systemic inflammatory syndrome is the production of high amounts of IL-6 (Roche et al., 1993; Wagner et al., 1994; Weyand et al., 2000), a cytokine that has been implicated in inducing acute phase proteins in hepatocytes. In patients with GCA, as well as those with PMR, circulating monocytes are found to be spontaneously activated and produce IL-6 (Wagner et al., 1994). These data suggest initiator function of an activated innate immune system in the syndrome.

Elegant studies in interstitial fluids collected from PMR-affected muscles have shown local enrichment of proinflammatory cytokines and pain-inducing substances, such as glutamate and PGE(2), strongly supporting a pathogenic role of intramuscular abnormalities as a local manifestation of a systemic process (Kreiner et al., 2010; Kreiner and Galbo, 2011).

Treatment, Monitoring, and Outcome

The gold standard for treatment of GCA is the use of corticosteroids. Patients respond explicitly well, with prompt and substantial improvement of symptoms within 24–48 hours. Initial doses of 60 mg of prednisone (or approx. 1 mg per kg body weight) have been found to be effective in almost all patients. Indeed, current discussions center on the question of whether at least some patients could be successfully treated with lower doses (Chevalet et al., 2000).

Once patients are stabilized on high doses of corticosteroids, daily prednisolone doses should be tapered. A reduction of 10–20% every 2 weeks has proven to be a clinically useful guidance. Both clinical symptoms and laboratory markers of inflammation are monitored to guide the tapering process. There is preliminary evidence that IL-6 is a more sensitive marker of disease activity than ESR, but properly designed clinical trials have not been performed (Weyand et al., 2000). A frequent clinical dilemma is a discrepancy between clinical and laboratory findings. To avoid overutilization of corticosteroids, it has been recommended that treatment decisions should not be solely based on laboratory results.

Many patients develop signs of flaring disease when corticosteroids are reduced. Fortunately, severe manifestations, such as sight-threatening ischemic complications, appear to be rare (Weyand et al., 2000; Martinez-Lado et al., 2011). Instead, most disease flares present as PMR or constitutional symptoms. Dose adjustments of corticosteroids can effectively recapture disease control.

Corticosteroids can be discontinued in many patients after about 2 years of therapy. There is evidence that the disease process does not enter remission but continues

with smoldering activity (Uddhammar, 2000; Weyand et al., 2000, 2012). Whether that chronic state of inflammation requires continued immunosuppression or can be managed by watchful monitoring remains a matter of discussion.

One of the serious long-term consequences of GCA is the development of aortic aneurysm (Evans et al., 1994; Kermani et al., 2012). Patients need to be informed about this complication, and monitoring for aortic wall thickness and aortic dimension has been recommended (Mackie et al., 2012). However, population-based data estimating the risk for aortic aneurysm development are lacking and it is unknown whether continuous immunosuppression can prevent aortic wall damage.

With an average age of almost 75 years at disease onset and the duration of therapy for several years, patients are prone to show steroid side effects (Proven et al., 2003). Monitoring of blood glucose and blood pressure is obvious. Also, bone sparing therapy with calcium, vitamin D substitution, bisphosphonates, etc. should be a fixed component of management.

Given the high rate of steroid side effects, efforts have been made to identify steroid-sparing therapies. In an experimental model of GCA with human temporal arteries implanted into immunodeficient mice, aspirin effectively suppressed IFN- γ production and augmented the anti-inflammatory effects of corticosteroids (Weyand et al., 2002). In contrast to other chronic inflammatory diseases, patients with GCA seem not to benefit from methotrexate as an immunosuppressant. Although results of clinical trials have been controversial, a well-designed clinical study with a large cohort of patients could not demonstrate any advantage for methotrexate/corticosteroid combination therapy compared to corticosteroids alone (Jover et al., 2001; Spiera et al., 2001; Hoffman et al., 2002). A meta-analysis has suggested a mild steroid-sparing effect of MTX after 48 weeks of combination therapy for female but not for male patients (Mahr et al., 2007). Similar modest effects have been reported for azathioprine as a steroid-sparing agent (De Silva and Hazleman, 1986). While anti-TNF biologics provide powerful immunosuppression in patients with rheumatoid arthritis, clinical trials testing the use of a combination therapy with corticosteroids plus infliximab compared to corticosteroids alone have been disappointing (Hoffman et al., 2007; Salvarani et al., 2007) and TNF- α blockade is not considered a first-line therapy in this vasculitis. Considering the role of IL-6 as an inducer of the acute phase response, blocking IL-6 has been pursued as a means of treating GCA and encouraging results have been reported for seven patients with large-vessel GCA (Seitz et al., 2011). In more recent reports, results were much less impressive with sustained aortic wall inflammation in patients with

Takayasu's arteritis (Xenitidis et al., 2013). Whether these differences reflect differential response patterns of GCA and TA needs to be addressed in appropriately designed clinical trials. Predictions based on recent progress in understanding the immunopathogenesis of GCA would point towards the importance of IL-6 independent disease mechanisms which cannot be controlled by IL-6 blockade.

Overall, the outcome of GCA is good. No shortening of life expectancy has been reported, emphasizing that highly aggressive therapies may have to be used with caution (Matteson et al., 1996; Gran et al., 2001).

TAKAYASU'S ARTERITIS

Takayasu's arteritis (TA) is a systemic arteritis that predominantly manifests in the aorta and its major branches. It is also known as pulseless disease or occlusive thromboangiopathy. The typical patient is a female of Asian or South American origin presenting with vascular insufficiency and generalized inflammation in the second or third decades of life. But care has to be taken not to miss the diagnosis in males and middle-aged individuals. Inflammatory infiltrates in the wall of large elastic arteries induce thickening of the adventitia, destruction of the media, and hyperplasia of the intima (Figure 73.3) (Gravanis, 2000). Recently, diagnosis and management of TA have benefited from advances in noninvasive imaging methods and more aggressive use of surgical procedures (Luqmani, 2012). Over the last decade, the prognosis of TA has continued to improve with more rapid diagnosis, more aggressive immunosuppression, and fewer vaso-occlusive complications (Ohigashi et al., 2012).

FIGURE 73.3 Takayasu's arteritis. Cross-section of an innominate artery. Note transmurular round cell infiltration with dominance of inflammation along the media–adventitia border. Extensive neovascularization has occurred in the media. The adventitia shows fibrotic expansion.

Historical Background

In 1830, Rokushu Yamamoto reported the first case of TA. In 1905, Mikito Takayasu was the first to describe peculiar optic fundus abnormalities with coronal anastomosis (Takayasu, 1908), which 40 years later were interpreted as neovascularization and anastomosis secondary to ischemia caused by the occlusion of cervical vessels. In 1951, Shimizu and Sano described a cohort of 31 cases and made the connection between pulselessness, coronal anastomosis of retinal vessels, and carotid abnormalities and called it pulseless disease (Shimizu and Sano, 1951).

Clinical, Pathologic, and Epidemiologic Features

Takayasu's arteritis is a rare disease with incidence rates of 1–2 cases in 1 million individuals per year (Watts et al., 2009). The most significant risk factors are female sex, age less than 40 years, and selected ethnic origin. The highest prevalence rates have been reported for Asian countries, including Japan, Korea, China, India, Thailand, and Turkey (Koide, 1992). South American countries, such as Mexico, Brazil, Columbia and Peru, are now also considered higher incidence areas (Dabague and Reyes, 1996). The disease does occur in whites, can affect males, and needs to be kept in mind as a differential diagnosis in older individuals with aortitis or large vessel vasculitis.

Prominent histomorphologic findings include the thickening of the aortic wall which may involve all three layers (see Figure 73.3) but often is most significant in the adventitia (Gravanis, 2000; Bjornsson, 2002). Extensions of inflammatory infiltrates and fibrosis into the periaortic tissues are not unusual. Most often, the aortic lumen is compromised, but stenotic lesions can alternate with aneurysmal dilatation giving rise to fusiform or saccular aneurysms. Also characteristic are “skipped” areas with normal vessel wall next to densely inflamed regions. Besides the aorta and its primary branches, coronary and pulmonary arteries can be involved.

Microscopic examination shows inflammatory infiltrates composed of lymphocytes and plasma cells primarily around the vasa vasorum, causing vasa vasorumitis with luminal stenosis. Lymphocytes, plasma cells, and occasional giant cells accumulate in the media, sometimes complicating the distinction between GCA and TA (Gravanis, 2000). Patches of medial necrosis can occur, and destruction of elastic membranes is typical. Growth of fibroblasts and smooth muscle cells and deposition of acid mucopolysaccharides result in widening of the intimal layer, similar to that found in fibromuscular hyperplasia. Vascular insufficiency in the aortic branches is related to ostial stenosis or more extended involvement.

TABLE 73.3 The Clinical Spectrum in Takayasu's Arteritis

| Organ system | Sign/Symptom | Frequency (%) |
|----------------|-----------------------------|---------------|
| Vascular | Bruit | 70 |
| | Claudication | 70 |
| | Reduced/absent pulses | 60 |
| | Asymmetrical blood pressure | 50 |
| CNS | Dizziness | 40 |
| | Visual abnormalities | 30 |
| | Stroke/TIA | 10 |
| Constitutional | Malaise | 70 |
| | Fever | 30 |
| | Weight loss | 20 |
| Cardiac | Aortic regurgitation | 20 |
| | Angina | 10 |
| | Congestive heart failure | <5 |

Available data suggest that the clinical spectrum of TA is different in distinct geographic areas (Numano, 1997). Japanese, Korean, and North American patients are more likely to present with impairment of cervical, cerebral, and upper extremity blood flow and aortic regurgitation, due to involvement of the ascending aorta and the primary aortic arch branches. Conversely, in Indian patients, the abdominal aorta, including the renal arteries, appears to be the preferred target resulting in renovascular hypertension. Overall, blindness and severe retinal ischemia are less common now than they used to be (Numano, 2002).

Initial presentation may be dominated by a generalized inflammatory syndrome with fever, night sweats, weakness, arthralgias, and chest pain (Kerr et al., 1994). Direct complications of vessel wall inflammation include headaches, syncope, visual disturbances, and face and neck pain from insufficient blood flow in the cervical vessels (see Table 73.3). Stenotic lesions in the brachiocephalic and subclavian arteries lead to arm claudication, pulselessness, and discrepant blood pressure measurements (Figure 73.4). Ischemic heart disease is a result of reduction in coronary blood flow. A feared complication of TA is aortic regurgitation caused by dilatation of the ascending aorta. Congestive heart failure is not unusual (Endo et al., 2003).

Marked progress has been made in imaging modalities, compensating at least partially for the difficulties in accessing tissue to establish the diagnosis of TA and follow its course for patients receiving therapy. Besides conventional angiography, which has been the standard imaging tool for diagnosing and evaluating patients with

FIGURE 73.4 Takayasu's arteritis. Angiography of the aortic arch and the cervical vessels. The native brachiocephalic artery (black arrow) is occluded just distal to its origin. A graft has been placed (white arrows) from the ascending aorta to the right common carotid artery with a separate limb connecting to the right subclavian artery. The left carotid artery and both vertebral arteries are normal.

TA (see Figure 73.4), a number of alternatives have emerged, including magnetic resonance (MR) imaging and MR angiography, computed tomography (CT), Doppler ultrasound, and metabolic imaging with positron emission tomography (PET) (Kissin and Merkel, 2004; Litmanovich et al., 2012; Tezuka et al., 2012; Cheng et al., 2013;). Ultrasound is particularly useful in evaluating the carotid arteries, with high sensitivity for submillimeter changes in wall thickness. The diffuse circumferential thickening (halo) of the carotid artery wall in TA has been named the “macaroni sign” (Keo et al., 2013). CT and MR imaging provide excellent visualization of vessels and their relationship to neighboring structures and demonstrate both luminal and mural abnormalities. Contrast enhancement is necessary for the CT to depict the vessel lumen, but it can provide fast information about the aorta and its wall; MR imaging has inherent multiplanar imaging capabilities, can be used with or without contrast enhancement, and lends itself to the evaluation of the aorta and its major branches (Matsunaga et al., 2003; Nastri et al., 2004). With the potential to assess mural edema and vascularity, it has been hoped that it would be an ideal instrument to monitor disease activity and progress in patients on immunosuppression. However, a recent study has

cast doubt on the utility of edema-weighted MR as a sole means to estimate disease activity (Tso et al., 2002). A role for PET, which detects areas of active glucose metabolism in the vascular wall in identifying early disease, has been suggested (Webb et al., 2004), but no large-scale controlled studies are available. A recent study has reported only moderate sensitivity of 18FDG-PET in estimating disease activity in TA (Cheng et al., 2013), whereas a study of 39 Japanese patients with TA suggested superiority of FDG-PET/CT over use of ESR and CRP values in detecting active disease (Tezuka et al., 2012).

Genetic Features

Like GCA, TA is an HLA-associated disease (Kerr et al., 1994; Salazar et al., 2000). More than half of the Japanese patients carry the HLA A24-B52-DR2 haplotype (Kimura et al., 1996). Nonpolymorphic HLA molecules, specifically MICA, have also been reported to be enriched among patients (Kimura et al., 1998).

Pathogenic Mechanisms

Despite considerable overlap in the histomorphology and clinical presentation of GCA and TA, evidence suggests that pathogenic mechanisms are distinct (Seko, 2002) (Figure 73.5). Whereas CD4⁺ T cells producing IFN- γ have been identified as key regulators in the vascular

lesions of GCA, they appear to be less important in TA. In the vascular infiltrates of TA, $\gamma\delta$ T cells account for 31% of the cells, natural killer cells for 20%, and CD8⁺ cytotoxic T cells for 15% (Seko, 2000). CD4⁺ T cells, macrophages, and B cells were less frequent. In support for the concept that cytotoxic cells directly damage resident cells in the aorta, Seko et al. (1994) have shown cellular expression of perforin and deposition of perforin directly onto wall resident cells. Heat shock proteins, in particular HSP65, have been proposed as the antigen stimulating cytotoxic lymphocytes (Seko et al., 2000). Restricted usage of T cell receptor AV and BV genes in tissue infiltrating T cells also supports the concept of selective expansion of antigen-reactive T cells in the vessel wall infiltrates (Seko et al., 1996). Dense expression of costimulatory molecules is in line with a role for adaptive immune responses driving the disease process. Data suggesting a possible role of metalloproteinases as biomarkers of disease activities refocuses interest on macrophage-dependent disease mechanisms (Matsuyama et al., 2003). Destruction of elastic membranes points towards release of elastolytic enzymes, likely derived from tissue-infiltrating macrophages.

Much less is known about the pathomechanism of the systemic inflammatory syndrome. Cytokine levels of IL-6 and RANTES have been reported to be elevated and to correlate with clinical activity (Noris et al., 1999). Serum IL-18 levels have been correlated with disease activity (Park et al., 2006). IL-18 is a Th1 immunity promoting cytokine, suggesting a role for IFN- γ -producing T cells in this vasculitis. Possible, not yet validated biomarkers of disease activity include pentraxin-3 and MMP-9.

FIGURE 73.5 Immune-mediated tissue damage in Takayasu's arteritis. Multiple damage pathways in the wall of the inflamed aorta have been identified in Takayasu's arteritis. A common denominator is the production of the cytolytic mediator perforin, which allows for cell-mediated cytotoxicity. Damage of VSMC leads to loss of the tunica media. Injury of endothelial cells may cause local ischemia and tissue necrosis. The triggers of perforin release by NK cells and $\gamma\delta$ T cells is not known. Perforin release by CD8 T cells involves recognition of HLA class I molecules and antigen on the surface of antigen-presenting cells (APC).

Treatment and Outcome

Immunosuppressive therapy remains the mainstay of treatment for this arteritis, but, in contrast to GCA, surgical procedures are gaining in importance for managing patients with TA (Perrotta et al., 2012). While endovascular treatment of TA has been associated with poor outcomes with respect to patency, more recent experience with newer endovascular techniques appears to be associated with better results (Qureshi et al., 2011).

As with most rare diseases, randomized controlled treatment trials are explicitly difficult to perform, are missing, or are based on small patient numbers. The immunosuppressants of choice are corticosteroids, which are started at a dose of 40–60 mg/day prednisone. Clinicians in Japan have advocated doses of only 20–30 mg/day (Numano, 2002). Once acute disease activity is controlled, an effort needs to be made to reduce corticosteroids. Tapering by 5 mg/day every 2–3 weeks has been adopted as a useful guideline. However, there has been agreement that a target maintenance dose of

5–10 mg/day should be kept stable over a prolonged period to avoid exacerbation of vascular and generalized inflammation. Although not formally tested, most patients receive aspirin or an alternative agent to reduce platelet aggregation and thrombus formation.

About 50% of patients may be considered to be insufficiently treated with corticosteroid monotherapy (Kerr et al., 1994). Some of these patients may benefit from methotrexate as a steroid-sparing agent (Hoffman et al., 1994). Mycophenolate mofetil has been reported to show clinical efficiency in a small patient cohort (Daina et al., 1999). TNF- α blocking agents have been reported to induce sustained remission in a subset of patients, but about 50% of patients fail treatment with anti-TNF- α (Schmidt et al., 2012). Given the role of IL-6 in driving inflammation in TA, rescue therapy with anti-IL-6 blocking antibodies has been reported for selected cases (Salvarani et al., 2012). More recent reports of persistent aortic wall inflammation despite IL-6-blocking therapy have raised concerns that this therapeutic approach may be less effective than expected (Xenitidis et al., 2013).

Monitoring for and managing hypertension is prudent in patients with TA. There is an ongoing discussion about whether vascular inflammation predisposes for the accelerated development and progression of atherosclerosis, although it may be difficult to separate these disease processes (Numano et al., 2000). Accelerated atherosclerosis demands appropriate monitoring for risk factors and treatment of dyslipidemia.

Critical renal artery stenosis, limiting claudication of extremities, cerebrovascular ischemia, coronary ischemia, and aortic regurgitation may represent indications for surgical intervention. If clinically possible, quiescence of vascular inflammation should be aimed for prior to surgery. Prevention of stroke may be possible if critical stenosis of cervical vessels is bypassed with grafts originating from the ascending aorta. Percutaneous transluminal angioplasty has emerged as an alternative to bypass surgery, specifically for renal artery stenosis (Weaver et al., 2004), and may be useful for preserving the competence of vessels in other territories.

The best outcome data for TA are available from Japan where all patients with TA are registered by the government. Analysis of 897 patients through 1998 showed that more than 70% of patients had well-controlled disease, enjoying almost normal lives. Twenty-five percent of patients had severe complications. Cardiac manifestations have become the most common cause of death among TA patients (Numano, 2002). Modern imaging techniques are enabling close monitoring of vessel wall inflammation. The time between disease onset and diagnosis is shortening (Isobe, 2013) and the overall prognosis is improving.

CONCLUDING REMARKS—FUTURE PERSPECTIVES

Vasculitides are infrequent yet clinically challenging diseases because they threaten blood supply to vital organs. Damage to large and medium-sized arteries immediately puts the host at risk for severe clinical consequences, as compensatory mechanisms for losing the function of the aorta and its major branches are very limited. In contrast to noninflammatory vasculopathies, arteritides are characterized by a combination of ischemic tissue damage and a syndrome of generalized inflammation. Pathogenic mechanisms relevant for these two dimensions of disease may be distinct and respond differentially to therapy. Systemic inflammation is caused by the excessive production of cytokines. In the cases of GCA and TA, induction of an abrupt and massive acute phase response is typical. As part of the acute phase response, patients produce hepatic acute phase proteins that give rise to diagnostically important laboratory abnormalities, such as increases in ESR and C-reactive protein (CRP).

In both GCA and TA, T lymphocytes are the key regulators of tissue injury in the blood vessel wall. They either mediate direct cellular damage, as in the case of TA, or orchestrate the functional activity of tissue-injurious macrophages, as in GCA. Arterial wall injury causes hyperproliferation of myofibroblasts and results in thickening of the intima, the underlying mechanism of vessel stenosis/occlusion. In GCA, tissue-resident dendritic cells have been implicated in initiating T cell activation, possibly after being triggered by blood-borne stimuli (Weyand et al., 2011). There is no evidence that autoantibodies or other B cell-dependent functions contribute to large vessel vasculitis (Martinez-Taboada et al., 1996).

Giant cell arteritis and TA are unique among the chronic inflammatory diseases in that they respond very well to corticosteroids. However, even prolonged therapy can usually not induce complete remission, and side effects are common. So far, alternative immunosuppressive agents have been amazingly ineffective in treating GCA but may have a role in TA. Major progress could be made by targeting disease pathways, such as the oxidative damage of vessel wall resident cells, and the process of intimal hyperplasia (Weyand and Goronzy, 2003a).

Despite advances in noninvasive imaging methods, monitoring patients for disease activity still remains a challenge. Cytokines may be useful biomarkers in assessing the “burden of disease,” at least as far as the systemic inflammatory syndrome is concerned. Well-designed clinical trials are necessary to validate the use of cytokine levels, particularly for IL-6, as a marker of disease in patients.

The ultimate challenge in understanding GCA and TA remains the identification of the initial triggers of the disease process. Although infections have been suspected, scientific evidence for their role in starting arteritis is lacking (Regan et al., 2002; Nordborg and Nordborg, 2003). Local factors intrinsic to the artery itself, such as dendritic cells positioned in the adventitia of medium-sized and large arteries, may be instrumental in breaking tolerance and giving rise to misplaced immune responses (Ma-Krupa et al., 2004; Pryshchep et al., 2008). Also, age is a major risk factor in GCA and TA, suggesting that age-related changes in T cell function may be critical determinants of disease susceptibility (Miller, 1990; Weyand and Goronzy, 2003a; Goronzy and Weyand, 2013).

ACKNOWLEDGMENT

Supported in part by grants from the National Institutes of Health (AR42527, AI44142, AI57266, and EY11916).

INTRODUCTION

Interstitial lung disease is a broad category of heterogeneous diseases which share the common feature of inflammatory and fibrotic changes that primarily affect the alveoli and small airways. The two most common manifestations are idiopathic pulmonary fibrosis (IPF) and cryptogenic organizing pneumonia (COP), both of which can occur as “idiopathic” conditions or in association with several autoimmune diseases. Although both are classified as “lung disorders of unknown etiology,” there are multiple clues suggesting that autoimmune mechanisms play a role in the pathogenesis of both disorders. The focus of this chapter is to explore the link between autoimmune mechanisms underlying COP and IPF as models for autoimmune disorders of the lung. To do so, we will first discuss the history and the clinical features of COP and IPF, followed by a summary of the autoimmune, genetic, environmental features, current concepts

of pathogenesis, and the therapies currently available and under investigation for both disorders.

HISTORY

Although both COP and IPF are inflammatory/fibrotic disorders, because they are centered on the bronchioles and alveoli, respectively, and have different clinical, radiologic, and pathologic features, they have always been considered to be different disorders.

Cryptogenic Organizing Pneumonia

The term “bronchiolitis obliterans” was first used by Lange in 1901 (Lange, 1901), when he described two patients in whom the bronchioles were blocked by plugs of granulation tissue, though those patients likely had what is now known as “cryptogenic organizing

pneumonia.” In 1966, Baar et al. (Baar and Galindo, 1966) used the term “bronchiolitis fibrosa obliterans” to describe concentric rings of fibrotic tissue in the wall of the airways. In 1973, Gosink et al. (Gosink et al., 1973) employed “bronchiolitis obliterans” to describe a group of patients that had submucosal and peribronchiolar infiltrate of granulation tissue resulting in extrinsic narrowing of the bronchiolar lumen. During the 1970s, several rheumatological conditions, particularly rheumatoid arthritis, were recognized to be associated with bronchiolitis obliterans, as were adverse reactions to therapies used for rheumatoid arthritis such as gold and penicillamine (Geddes et al., 1977).

In 1983, Davison et al. (Davison et al., 1983) first used the term “cryptogenic organizing pneumonitis” to describe eight patients that had pulmonary infiltrates and histology similar to bronchopneumonia, yet no organism was identified and they responded to steroids. In 1985, Epler et al. (Epler et al., 1985), similarly described 50 patients with bronchiolitis obliterans, but also with granulation tissue in airways, airway ducts, and alveoli, and coined the term bronchiolitis obliterans organizing pneumonia (BOOP). COP and BOOP are now believed to represent the same disease and COP is the preferred term. Current usage of the term “bronchiolitis obliterans” is reserved primarily for transplant-related lung injury that occurs almost exclusively at the bronchiole.

Idiopathic Pulmonary Fibrosis

The first recognition of the broad category of idiopathic interstitial lung diseases, which includes idiopathic pulmonary fibrosis, is credited to William Osler in 1892, when he described a chronic fibrinoid change occurring between the alveolus and the blood vessels (Osler, 1892). Osler demonstrated great foresight by also noting that there were diverse patterns of the disease that made classification difficult.

Idiopathic pulmonary fibrosis, also referred to as “cryptogenic fibrosing alveolitis,” “idiopathic interstitial pneumonitis,” “usual interstitial pneumonitis,” and “idiopathic interstitial pneumonia,” was first described by the Czech pathologist Sandoz in 1907, but went largely unnoticed (Sandoz, 1907). Hamman and Rich are frequently credited with the first description of IPF in 1935 (Hamman and Rich, 1935), despite the fact that their initial cases were more acute in presentation, unlike classic IPF, and may have been descriptions of acute respiratory distress syndrome. In 1964, Scadding coined the term “cryptogenic fibrosing alveolitis” to describe IPF as a diffuse inflammatory and fibrotic lung disease affecting primarily the alveoli (Scadding, 1964). Scadding advanced the concept that IPF was a slow, progressive disease that

was distinctly different from the relatively acute process described by Hamman and Rich.

IPF was further defined by Liebow and Carrington in the 1960s using histologic criteria. These investigators separated IPF into two morphologic patterns, which they referred to as “usual interstitial pneumonia” (UIP, now often referred to as “usual interstitial pneumonitis”) and desquamative interstitial pneumonia (DIP) (Liebow and Carrington, 1969). The inflammatory component of IPF was characterized by our group using bronchoalveolar lavage to distinguish IPF from other interstitial lung disorders (Crystal et al., 1976; Reynolds et al., 1977). The pathological pattern of UIP was further refined over the next several decades, including the description of nonspecific interstitial pneumonia (NSIP) by Katzenstein and Fiorelli in 1994 as a distinct entity (Katzenstein and Fiorelli, 1994). The classification system developed by the American Thoracic Society and European Respiratory Society in 2001 separates IPF from NSIP and DIP based primarily on pathologic findings (2002).

CLINICAL, PATHOLOGICAL, AND EPIDEMIOLOGICAL FEATURES

Cryptogenic Organizing Pneumonia

Cryptogenic organizing pneumonia is identified pathologically by a proliferation of granulation resulting in near obstruction of the small airways and can extend into the alveoli with a surrounding interstitial lymphoplasmacytic infiltrate (Murray and Nadel, 2000). Overall, there is preservation of the underlying lung architecture and apparent temporal homogeneity, with very little fibrotic changes present. These findings may also be present during the “organizing” phase of a bacterial or viral pneumonia, but when they occur in the absence of an infectious disease, the term used is “cryptogenic organizing pneumonia.” Thus, the definition relies on both pathologic and clinical features.

Individuals with COP usually present with persistent cough and worsening dyspnea on exertion, which can mimic bronchopneumonia. The physical exam is notable for crackles in the affected lobe. Most patients will have a mild obstructive pattern on pulmonary function testing, although the disease can present with normal, restrictive or mixed pattern (King and Mortenson, 1992). Routine chest radiographs may reveal bilateral air-space opacities, peripherally located, which can be migratory. High resolution computed tomography (HRCT) reveals patchy air-space consolidations or ground glass opacities that can be indistinguishable from bacterial pneumonia or eosinophilic pneumonia. Fibrosis or honeycombing is rarely seen. The areas affected by COP are scattered and patchy in distribution. For this reason, transbronchial lung

biopsy is insensitive as a diagnostic tool, as it often misses the involved area, and thus a surgical lung biopsy is often necessary to make the diagnosis.

There have been no epidemiological studies performed to quantify the overall prevalence of COP, although one study found a yearly cumulative incidence of six to seven cases per 100,000 hospital admissions (Alasaly et al., 1995). It is generally considered a rare disease, although it is likely that COP is underdiagnosed and may account for a small percentage of cases misdiagnosed as bacterial or viral pneumonia.

Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (sometimes referred to as “cryptogenic fibrosing alveolitis” in Europe) refers to a distinctive type of chronic inflammatory/fibrotic interstitial lung disorder of unknown cause that is limited to the lungs and associated with a histologic pattern of usual interstitial pneumonia (UIP) (American Thoracic Society, 2002) (see Figure 74.1). The pattern of UIP on surgical lung biopsy is also seen in patients with multisystem autoimmune disease who present with similar pulmonary-related clinical features to those of IPF (Harrison et al., 1991).

Individuals with IPF typically present with the gradual onset of symptoms, most commonly dyspnea on exertion and non-productive cough. Most will have had at least 6 months of symptoms before presentation, with an average duration of 24 months (ATS, 2002). The clinical course typically involves gradual deterioration, occasionally punctuated by periods of rapid decline, although some of the disease stabilizes in some individuals. The best

estimates for life expectancy from time of diagnosis to death are derived from case–control cohort studies, because they are not biased like prevalence studies, which tend to be overrepresented by survivors. According to two such studies, the average survival from the time of diagnosis to death is 3 to 4 years (Hubbard et al., 1998; Mapel et al., 1998).

On physical exam, patients with IPF may have digital clubbing (25 to 50%) and fine, inspiratory, Velcro-like crackles confined to the bases of the lungs. As there is progressive loss of alveoli, and the diffusing capacity drops below 50% predicted, pulmonary hypertension develops, first with exercise, and later at rest (Crystal et al., 1976; McLees et al., 1979). Once established at rest, the pulmonary hypertension is associated with an increased pulmonary component of the S2 on cardiac exam, and eventual fixed split of the second sound. In the late stages of the disease there can be signs of right heart failure, such as peripheral edema.

Pulmonary function testing usually shows a restrictive pattern of ventilatory defects and a decrease in diffusing capacity, although in early stages of the disease, these tests can be normal (Fulmer et al., 1979; Keogh and Crystal, 1980; Cherniack et al., 1995). Individuals with IPF typically have mild to moderate hypoxemia with concomitant low resting oxygen saturation that falls with exercise (Keogh and Crystal, 1980).

Chest radiographs of individuals with IPF are routinely abnormal, with a reticular pattern seen at the periphery and in the bases. Later in the disease there is honeycombing and volume loss in the lower lobes (Staples et al., 1987). In early stages of the disease, chest

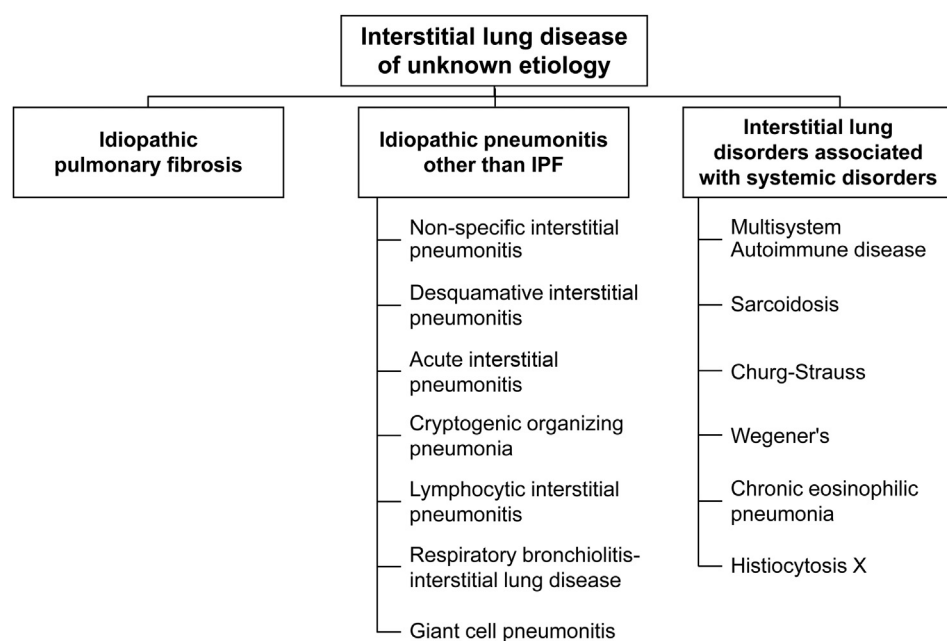

FIGURE 74.1 Relationship of idiopathic pulmonary fibrosis to other idiopathic interstitial disorders. Some of the rare disorders have been left off the lists. see *American Thoracic Society, 2002; Crystal, 1984; Schoenberger and Crystal, 1983* for further details.

radiographs may be normal. HRCT is more sensitive and is the preferred imaging modality. The typical HRCT findings are reticular–nodular opacities (Figure 74.2). Later in the disease, traction bronchiectasis is commonly seen in the peripheral and basal segments of the lower lobes. Volume loss and ground glass opacities are frequently present. As the disease progresses, honeycomb cysts develop and enlarge over time (Staples et al., 1987). The chest X-ray and HRCT appearance of IPF is nearly identical to that seen in pulmonary fibrosis associated with the rheumatic disorders, with the lone exception of possibly more basal involvement seen on HRCT in IPF (Chan et al., 1997).

Transbronchial biopsies are insufficient to diagnose IPF because the biopsy specimen is too small and does not preserve the architecture of the lung. However, transbronchial biopsies may be useful to rule out other conditions, such as sarcoidosis, that can mimic IPF. A surgical

lung biopsy has been required in the past to firmly establish the diagnosis. However, the consensus statement by the American Thoracic Society (ATS) and European Respiratory Society (ERS) permits the diagnosis of IPF when there are typical clinical and HRCT findings of IPF (Hunninghake et al., 2001, ATS, 2002; Raghu et al., 2011). Surgical lung biopsies are still recommended whenever there are atypical clinical or HRCT features.

The histological pattern characteristic for IPF is referred to as usual interstitial pneumonia (UIP) (Figure 74.3). This pattern is distinct from the other forms of idiopathic interstitial lung disorders such as desquamate interstitial pneumonia, lymphocytic interstitial pneumonia, cryptogenic organizing pneumonia, non-specific interstitial pneumonia, and acute interstitial pneumonia (Liebow and Carrington, 1969; Katzenstein and Fiorelli, 1994, ATS, 2002). There is typically a heterogeneous distribution of interstitial fibrosis interspersed within areas

FIGURE 74.2 Diffuse reticular–nodular pattern on high resolution chest tomography commonly observed in idiopathic pulmonary fibrosis. Note areas of honeycombing.

FIGURE 74.3 Histologic pattern of idiopathic pulmonary fibrosis. The patterns are often referred to as “usual interstitial pneumonitis.” (A) Subpleural, paraseptal, and interstitial collagen deposition together with areas of mildly abnormal alveolar parenchyma (hematoxylin and eosin, bar = 1 mm). (B) Thickened interstitium with collagen deposition, mild to moderate alveolar septal mononuclear cell infiltrates, mainly lymphocytes, cuboidalization of the epithelium and a large fibroblastic foci (thick arrow). The fibroblastic foci are composed of spindled mesenchymal cells and are thought to represent the “leading edge” of the progressive fibroinflammatory process (hematoxylin and eosin; bar = 100 μ m).

of normal lung, suggesting different temporal stages of involvement. There is patchy inflammation, dominated by alveolar macrophages, and to a lesser extent lymphocytes, neutrophils, and sometimes eosinophils. The alveolar epithelium undergoes marked changes, referred to as “cuboidalization,” with a loss of type I epithelial cells, and their replacement with cuboidal cells, both alveolar type II epithelial cells and bronchiolar epithelium. One hallmark finding in IPF is the subepithelial “fibroblastic focus,” which is a nodule of spindle-shaped, mesenchymal cells that produce an abundant deposition of extracellular matrix. These “foci” are believed to be the “leading edge” of the fibrotic process. Occasionally, the interstitial fibrosis extends through breaks in the epithelium into the alveolar space to form intra-alveolar fibrosis (Basset et al., 1986). Later in the disease there is architectural destruction and fibrosis with honeycombing. Frequently, the subpleural parenchyma is the most severely involved region. When a biopsy shows areas of both UIP and non-specific interstitial pneumonitis, the default pathologic diagnosis becomes the clinical diagnosis IPF, as these patients have been shown to have behavior similar to that seen in IPF with UIP-only pattern (Flaherty et al., 2001; Raghu et al., 2011).

The histological features of pulmonary fibrosis associated with multisystem autoimmune disease can be classified into the same pathological descriptions of idiopathic interstitial pneumonias put forth by the American Thoracic Society and European Respiratory Society, including usual interstitial pneumonia (UIP), non-specific interstitial pneumonitis (NSIP), desquamative interstitial pneumonia (DIP), and cryptogenic organizing pneumonia (COP) (Figure 74.1). The UIP pattern that is seen with multisystem autoimmune diseases is essentially identical to the pattern seen in the IPF. In polymyositis, dermatomyositis, and scleroderma, NSIP is the most frequently seen histologic pattern followed by UIP (Douglas et al., 2001; Bouros et al., 2002). The prevalence of the different histologic subtypes of idiopathic interstitial pneumonias has not been well characterized in the other multisystem autoimmune diseases.

The estimated annual incidence of idiopathic pulmonary fibrosis is 7 per 100,000 for women and 10 per 100,000 for men. Most patients present between 50 and 70 years of age; however, the incidence, prevalence, and death rate rise with age (Coults et al., 1994).

Several studies have tried to establish the prevalence of pulmonary fibrosis in patients with the multisystem autoimmune diseases, but the results have varied depending on the method by which patients are screened for pulmonary involvement. Studies that utilize autopsy or lung biopsy data are subject to overdiagnosis, since they have been shown to detect subclinical disease that can fail to progress (Cervantes-Perez et al., 1980). Likewise, HRCT

screening studies may also overestimate the prevalence of disease by detecting parenchymal changes that may not be clinically significant. In rheumatoid arthritis, cross-sectional studies using chest radiographs estimate the prevalence to be less than 5% of patients (Hyland et al., 1983). When HRCT is used to screen patients, the prevalence appears to be between 20 and 50%, although these studies are limited by selection bias (Remy-Jardin et al., 1994; Gabbay et al., 1997). Pulmonary fibrosis is most prevalent in scleroderma, where autopsy series have shown it to be present in 70% of cases and chest radiograph series estimate the prevalence between 25 and 65% (Wiedemann and Matthay, 1989; Minai et al., 1998). The prevalence of clinically overt pulmonary fibrosis is 30% in polymyositis and dermatomyositis, 5% in systemic lupus erythematosus, and 10% in Sjögren’s syndrome (Eisenberg et al., 1973; Gardiner, 1993; Schwarz, 1998).

AUTOIMMUNE FEATURES

Cryptogenic Organizing Pneumonia

Cryptogenic organizing pneumonia has been reported in association with many different types of autoimmune disorders, including rheumatoid arthritis (RA), lupus erythematosus, ankylosing spondylitis, Sjögren’s syndrome, and scleroderma (Colby, 1998; Ryu et al., 2003). COP is most frequently seen with rheumatoid arthritis, and in one case series of 40 RA patients undergoing open lung biopsy, COP was the second most common diagnosis behind rheumatoid nodules of the lung (Yousem et al., 1985). In rheumatoid arthritis, bronchiolar involvement typically presents in the fifth and sixth decades of life and is more frequently seen in women (Geddes et al., 1977; Epler et al., 1979; Herzog et al., 1981). Most patients with COP in association with RA have long-standing symptoms of arthritis, though occasionally the pulmonary involvement predates the rheumatologic disease. Occasionally, COP will appear at the same time as a flare in arthritic symptoms and there is a case report of it occurring simultaneously with the onset of pernicious anemia, an autoimmune disease. Further support for the autoimmune basis is the fact that most cases of COP in RA will have a positive rheumatoid factor (85%) and usually have very high titers (Mori et al., 2008). Immunofluorescence stains in affected regions of the lung of patients with RA show IgM and IgG depositions in the alveolar septum (Begin et al., 1982; Yousem et al., 1985), and many cells are positive for S-100 protein (Yoshinouchi et al., 1999).

The bronchoalveolar lavage (BAL) fluid from patients with COP is notable for a marked activation of macrophages and lymphocytes, and an overall Th1 helper response (Cordier, 2006). BAL obtained from patients with COP has elevated levels of tryptase, mast cells, and

interleukins-10, -12, and -18 (Pesci et al., 1996; Forlani et al., 2002). Platelet-derived growth factor and interleukin-8 also appear to play a role in the pathogenesis of COP (Carre et al., 1994; Aubert et al., 1997).

Indirect evidence for autoimmune mechanisms in COP comes from the bronchiolitis obliterans syndrome associated with both lung and allogeneic stem cell transplants. These cases, which can be viewed as *in vivo* human models of bronchiolar disease, have been more extensively studied than COP or rheumatic disease-associated COP. The bronchiolitis obliterans syndrome in association with lung transplantation is the main cause of morbidity and mortality (Arcasoy and Kotloff, 1999). It is a form of chronic lung rejection that is mediated by B cell and T cell activation against mismatched HLA class I and II antigens (Kelly and Hertz, 1997). Bronchiolitis obliterans associated with allogeneic bone marrow transplants is also thought to represent graft versus host disease. The disease progresses from inflammatory changes around the bronchioles to fibrosis and scarring (Ratanatharathorn et al., 2001). It is interesting to note that in bronchiolitis obliterans syndrome associated with lung transplant or with bone marrow transplant, the bronchioles are the more frequent site for chronic rejection, not the lung parenchyma.

Idiopathic Pulmonary Fibrosis

Although the etiology of IPF remains unknown, it has been hypothesized for 30 years that autoimmune mechanisms to external stimuli are the driving force for repeated injury and inflammation that ultimately lead to fibrosis (Crystal et al., 1976, 1981, 1984). Although no clear infectious or environmental agent has been found as the etiology of IPF (Gross and Hunninghake, 2001), there are extensive data regarding autoimmune cellular and humoral processes ongoing in this disorder.

Initial studies in IPF relevant to autoimmunity focused on identifying autoantibodies that target the pulmonary parenchyma. Turner-Warwick demonstrated that 40% of patients with IPF had circulating, non-specific autoantibodies such as anti-nuclear antibodies (ANA) and rheumatoid factor (Turner-Warwick and Doniach, 1965). Increases in circulating ANA and rheumatoid factor were observed in 30% of our patients (Crystal et al., 1976). Similar studies which evaluated the presence of autoantibodies to nuclear antigens, DNA topoisomerase, and cytokeratin detected the antibodies in some patients (Table 74.1). More recent studies have focused on antibodies that are specific to lung proteins, although these studies have also shown variable expression of autoantibodies (Wallace et al., 1994; Robinson et al., 2001). These results raise the possibility that autoantibodies are a secondary consequence of the ongoing immune activation in

the setting of inflammation and tissue damage, rather than the causative mechanism.

Similarly, investigations have evaluated the role that immune complex deposition plays in the pathogenesis of inflammation and fibrosis in IPF. Early studies observed elevated levels of circulating immune complexes in certain subsets of patients with IPF; however, these were performed prior to the current classification system and included patients with other forms of interstitial lung disease (Dreisin et al., 1978; Haslam et al., 1979). Hunninghake et al. (Hunninghake et al., 1981) demonstrated a correlation between the level of immune complexes in bronchoalveolar lavage fluid and the levels of neutrophil chemotactic factor released by alveolar macrophages in patients with IPF. Other studies have also seen elevated levels of immune complex in lavage fluid, but the levels are variable and do not correlate with disease activity.

More recently, attention has turned to immune-based microvascular injury as the ongoing trigger for pulmonary fibrosis. In scleroderma-associated pulmonary fibrosis, studies have shown complement and immunoglobulin deposition in the microvasculature. Some have hypothesized that perhaps anti-endothelial cell antibodies, which are present in the circulation in several autoimmune conditions, may be responsible for the injury. Several studies have correlated the presence of anti-endothelial cell antibodies with the development and severity of IPF (Magro et al., 2007).

The lack of clear evidence for a humoral mechanism as the primary cause for IPF shifted the focus towards cellular immunity. One popular theory is that an unknown stimulus triggers a dysregulated activation of cell-mediated immune response that results in the fibrotic process analogous to that observed in abnormal wound healing. This theory rests on the belief that a normal cell-mediated defense to a pulmonary insult would be a Th1 response, as seen in most infections and in hypersensitivity pneumonitis (Wallace et al., 1995; Lukacs et al., 2001; Kunkel, 2004). The Th1 response is characterized by the release of interferon- γ and the activation of neutrophils and macrophages for efficient clearing of the antigen, as well as suppression of fibroblast activation and collagen deposition. Cytokine profiles in IPF are closer to Th2 response which are typified by elevated IL-4, IL-5, and IL-13 levels, and result in fibroblast activation (Hancock et al., 1998; Wallace and Howie, 1999). Early evidence for this T cell-mediated mechanism in IPF was demonstrated by Kravis et al. (Kravis et al., 1976), who discovered that circulating lymphocytes from patients with IPF would release migration inhibitor factor after exposure to collagen and would lyse collagen-coated sheep red blood cells.

One experimental model used to demonstrate a cell-mediated autoimmune mechanism is the adoptive transfer, hapten immune pulmonary interstitial fibrosis model (Stein-Streilein et al., 1987). In this model, donor mice are

TABLE 74.1 Autoantibodies Associated with Idiopathic Pulmonary Fibrosis¹

| Antigens | Number of patients | Result | Reference |
|--|---|---|-----------------------------------|
| Fresh unfixed lung tissue, rheumatoid factor, nuclear, thyroglobulin, gastric parietal cells | 48 IPF | Sensitivity: Positive titers for: RF 49%, ANA 28%, rat liver homogenate 19%, gastric cells 0%; no autoantibodies specific to lung were detected by immunofluorescence | Turner-Warwick and Doniach (1965) |
| Nuclear ² ANA, nRNP, ds-DNA, Sm, SS-A and SS-B | 68 IPF 54 PF-AID 47 controls | Sensitivity: ANA present in 21% of IPF and 46% of PF-AID. Anti-nRNP present in 15% of IPF and PF-AID. Other antibodies were not significantly different from control group Specificity: ANA 94%, anti-nRNP 98% | Chapman et al. (1984) |
| Nuclear ANA, ds-DNA, ss-DNA, RF ³ | 53 IPF 33 SLE ⁴ 50 controls | Sensitivity: IPF patients had 42% ANA (titer >1/10), 25% anti-dsDNA, and 100% anti-ssDNA titers that were two standard deviations above the normal range; levels did not correlate with disease activity | Holgate et al. (1983) |
| Histidyl-tRNA synthetase (Jo-1 antigen) | 62 IPF 19 PF-AID (myositis) 53 myositis alone | Sensitivity: Antibody present in 68% of PF-AID (myositis) patients compared to 3% IPF alone and 7.5% myositis alone Specificity: >99% normal and 98% autoimmune controls | Bernstein et al. (1984) |
| Topoisomerase II | 41 IPF | Sensitivity: 44% positive. Remained elevated in 17 of 19 follow-up patients. Did not correlate with disease activity | Meliconi et al. (1993) |
| Collagen types I, II, III, IV | 16 IPF 29 controls | Sensitivity: 75% of IPF patients had antibody titers to at least one type of collagen >1:16. Specificity: 83% using cut-off titer 1:16. Negative correlation between antibody level and duration of disease | Nakos et al. (1993) |
| Lung proteins derived from IPF, sarcoid, and normal lung | 17 IPF 17 controls | Sensitivity: 71% of IPF patients had IgG that reacted to lung proteins in the 70–90 kDa range by Western blot; IgG reacted to alveolar lining cells Specificity: 82% | Wallace et al. (1994) |
| Cytokeratin 19 | 26 IPF 11 PF-AID 52 controls | Significantly higher mean serum levels in IPF compared to control. No cut-off value determined by ELISA because of overlap between groups | Fujita et al. (1999) |
| Expressed cDNA library from lung cancer cell line | 11 IPF | Serum from index patient used to probe expressed cDNA library. Antigens recognized were unique to index patient (including anti-alanyl-tRNA synthetase), but not shared with sera from other 10 patients | Robinson et al. (2001) |
| Endothelial cell protein extract | 45 PF-AID (scleroderma) 16 controls | Sensitivity: 93% PF-AID had positive staining using an indirect immunofluorescent assay against rodent lung tissue Specificity: 88% | Wusirika et al. (2003) |

¹Summary of autoantibody studies in patients with idiopathic pulmonary fibrosis (IPF). PF-AID, pulmonary fibrosis associated with autoimmune disease.

²Nuclear antigens: ANA, anti-nuclear antibodies; nRNP, nuclear ribonucleoprotein, Sm, Smith antigen, SS-A and SS-B, Sjögren's syndrome A and B antigens.

³RF, rheumatoid factor.

⁴SLE, systemic lupus erythematosus.

sensitized by a hapten, and then lymph nodes and spleen are transferred to recipient mice. When the recipient mice are then challenged with intratracheal administration of the hapten, they develop pulmonary fibrosis in 7 to 14 days.

Interestingly, when the adoptive transfer with Th1 cells was used, an alveolitis developed, but not fibrosis, thus supporting the Th2 theory regarding the pathogenesis of the fibrotic component of IPF (Irifune et al., 2003).

In pulmonary fibrosis associated with the multisystem autoimmune disease, several serological and genetic markers are linked to the development of lung disease. For instance, patients with rheumatoid arthritis that have high levels of rheumatoid factor and prominent rheumatoid nodules are at increased risk for developing pulmonary fibrosis (Hyland et al., 1983). In systemic sclerosis, the presence of anti-topoisomerase antibodies and diffuse cutaneous involvement are associated with pulmonary fibrosis (Fanning et al., 1998).

Perhaps the best evidence for associating autoantibodies to pulmonary fibrosis is in patients with polymyositis and dermatomyositis, in which antibodies (Targoff, 1993) against the aminoacyl-tRNA synthetases have been shown to be highly correlated with pulmonary fibrosis (Bernstein et al., 1984; Targoff, 1993). At least five known forms of the autoantibodies have been identified, which include anti-alanyl-tRNA synthetase (PL), anti-histidyl-tRNA synthetase (Jo-1), anti-isoleucyl-tRNA synthetase (OJ), anti-glycyl tRNA synthetase, and anti-threonyl tRNA synthetase. The strongest correlation appears to be with anti-Jo-1 antibodies, which have been reported to have a frequency of interstitial lung disease between 50% (Hochberg et al., 1984) and 100% (Yoshida et al., 1983). Patients with polymyositis or dermatomyositis can frequently present with the “antisyntetase syndrome” characterized by pulmonary fibrosis in 50–75% of patients, arthritis, Raynaud’s phenomenon, and fevers. Occasionally, the antisyntetase syndrome can occur in the absence of clinical myositis (Marguerie et al., 1990). There are also several case series of patients with isolated pulmonary fibrosis occurring in association with aminoacyl-tRNA synthetase antibodies (Friedman et al., 1996; Sauty et al., 1997). These patients have been shown to have a CD8 lymphocyte predominant bronchoalveolar lavage and non-specific interstitial pneumonitis pattern on lung biopsy. Most of the patients described in these case series have been more responsive to therapy with cyclosporine and azathioprine than patients with IPF.

GENETIC FEATURES

Cryptogenic Organizing Pneumonia

Given the rarity of COP, there are no studies that demonstrate a genetic predisposition to this condition. The same is true for the autoimmune-associated forms of COP.

Idiopathic Pulmonary Fibrosis

Up to 3% of cases of IPF occur in clusters of families, suggesting that a genetic predisposition may be responsible for susceptibility to disease (Hodgson et al., 2002). A simple pattern of Mendelian inheritance has not been

observed. Familial cases appear to be inherited in an autosomal dominant pattern, although the penetrance is variable. In familial cases of IPF, children of individuals with fibrotic lung disease can have evidence of inflammatory alveolitis in bronchial lavage fluid, without having clinical evidence of disease (Bitterman et al., 1986). There have been several reports of pulmonary fibrosis occurring in separately raised monozygotic twins, underscoring the role of genetic factors (Javaheri et al., 1980; Peabody et al., 1950). Using a candidate gene approach in one large family kindred with IPF, Thomas and colleagues (Thomas et al., 2002) identified a mutation in the highly conserved coding region of surfactant protein C, resulting in aberrant cellular distribution of SP-C in the lung tissue of affected individuals.

In addition to the familial form of the disease, there is evidence for a genetic basis for the more common, sporadic form of the disease. A study from Finland demonstrated a clustering of sporadic cases of IPF in areas where familial cases were found, suggesting a founder’s effect (Hodgson et al., 2002). One prevailing hypothesis is that susceptibility does not lie in one gene locus, but, rather, within multiple genes that interact through inflammatory and fibrotic mechanisms, creating a background genotype of fibrotic potential, yet still requiring an insult to create the profibrotic phenotype. This theory would explain why the familial form of the disease has an earlier age of onset (55 vs. 67), yet still presents relatively later in life, implying that a reduced threshold for the development of fibrosis exists in familial types (Marshall et al., 2000). This theory is also supported by the fact that only a small proportion of individuals who receive drugs known to cause pulmonary fibrosis (such as bleomycin or amiodarone) actually develop the disease (Tisdale et al., 1995).

One major limitation in the search for genetic sources for susceptibility is that the sizes of the association studies are limited because of the rarity of the disease. Polymorphisms in several genes have been explored as potential causes for the inherited susceptibility to IPF; however, these studies utilized a traditional candidate gene approach which is limited by our current understanding of the disease and may lead to false-positive associations. These studies are typically focused on genes involved in the inflammatory pathways, such as interleukin-1 α and tumor necrosis factor- α , and have shown conflicting results (Whyte et al., 2000; Pantelidis et al., 2001). Xaubet et al. (2003) recently demonstrated that transforming growth factor- β polymorphisms were related to disease progression, but they found no association with susceptibility to IPF.

Given recent advances in genomics, microarray analysis, and proteomics, there is an excellent opportunity to perform genome-wide searches for linkage in patients

with IPF to identify novel genes that are involved in pathogenesis and may represent therapeutic targets. Many of these genetic approaches are simply hypothesis generators; however, this may be a necessary first step to decipher the complex interactions of multiple loci. Additionally, microarray technology can be used for “molecular fingerprinting” to identify subclassifications within the general category of IPF.

IN VIVO AND IN VITRO MODELS

Animal models of the classical human Mendelian genetic diseases are relatively easy to produce because the genotype typically involves one affected gene, and knockout models of that gene, in mice for instance, can usually approximate the phenotype. Generating an animal model of a complex polygenic disease poses far more challenges because it involves multiple genes, each exerting a relatively small effect.

Cryptogenic Organizing Pneumonia

The best animal model for COP involves inoculating CBA/J mice with reovirus serotype 1 via intranasal route (Bellum et al., 1997). These CBA/J mice develop intraluminal fibrosis and lymphocytic, peribronchial infiltrates that are identical to the pathologic findings of COP in human disease. Interestingly, the COP pathological changes appear when titers of 10^6 are used; however, when 10^7 titers of the same virus are used, the CBA/J mice develop diffuse alveolar damage, the pathological finding of acute respiratory distress syndrome (ARDS). This suggests that the tendency towards COP vs. ARDS may be due to severity of the initial insult (London et al., 2002a,b).

Other animal models for COP are designed to mimic bronchiolitis obliterans, the transplant-associated form of the disease. One model frequently used is the heterotopic murine tracheal transplant, whereby grafts of trachea and main bronchi are placed subcutaneously into allogeneic mismatched recipients (Hertz et al., 1993). By 21 days, grafts demonstrate fibroproliferation in the airway lumen, a characteristic for the human chronic rejection process. Subsequent studies on this model have shown that this is mediated by cellular and humoral immunity (Kelly and Hertz, 1997). Although this model can successfully mimic the phenotypic changes of IBO, it has limited applicability to understand IBO because the entire graft tracheo-bronchial graft is an immunogenic stimulus, which is not likely the case in the idiopathic or autoimmune-associated forms of the disease.

Idiopathic Pulmonary Fibrosis

There is no animal model for IPF that clearly represents human IPF. However, there are several animal models for

susceptibility to developing experimental pulmonary fibrosis. The susceptibility to bleomycin-induced interstitial lung disease has been correlated with both immune-related (TH2 type) and non-immune-related genes in different strains of mice (Rossi et al., 1987). Transforming growth factor- β has been shown to induce pulmonary fibrotic changes when overexpressed via intratracheal administration of an adenoviral vector (Liu et al., 2001). Likewise, when mice are treated with an adenoviral vector expressing SMAD-7, an inhibitory regulator of TGF- β production, they appear to be protected against bleomycin-induced lung injury (Nakao et al., 1999).

Many different transgenic and knockout mice have also been developed to investigate the molecular pathways that lead to pulmonary fibrosis. One example is mice that overexpress TNF- α and that develop pulmonary fibrosis, and have some of the features of human IPF (Miyazaki et al., 1995). Knockout mice with targeted deletions of genes necessary for fibrosis (e.g., adhesion molecules, ICAM-1, and L-selectin, which facilitate the accumulation of leukocytes) show significantly decreased fibrosis in response to bleomycin (Hamaguchi et al., 2002).

Many of these models are focused on only a select number of candidate genes, which may or may not have relevance to human disease. While these studies have been useful to identify genes that may play a role in susceptibility, the actual human form of the disease is likely far more complex and polygenic, which may prohibit creating a comprehensive animal model that reflects the underlying pathogenesis.

PATHOLOGIC EFFECTOR MECHANISMS

Cryptogenic Organizing Pneumonia

The sequence of events that ultimately leads to organizing pneumonia has been established in multiple studies. The common initial event is airway epithelial injury, with necrosis and denudation of the pneumocytes, but preservation of basal laminae and endothelial cells. This is distinctly different from ARDS, where there is believed to be a breakdown in the basal membrane leading to hyaline membrane formation. The first alveolar changes involve formation of inflammatory cell clusters (macrophages, lymphocytes, and neutrophils) bound together by fibrin. The next stage involves migration of fibroblasts through the basal lamina and proliferation of fibrotic and inflammatory “buds” in the airway. The final stage is when these buds progress to a mature stage and there is less inflammatory component and the alveolar space begins to clear of fibrin (Peyrol et al., 1990; Kuhn and McDonald, 1991; Myers and Colby, 1993). Vascular endothelial growth factor and basic fibroblast growth factor are

highly expressed in COP and this results in a proliferation of capillary tissue as is normally seen in response to wound healing (Lappi-Blanco et al., 2002).

Environmental factors are clearly linked to the development of cryptogenic organizing pneumonia in general, although specific causative environmental factors for COP are difficult to identify. Perhaps the best documented environmental cases of COP occurred after exposure to aerosolized textile dye acramin FWN (Moya et al., 1994; Sole et al., 1996; Camus and Nemery, 1998; Romero et al., 1998).

In addition, inhalational injuries can progress into bronchiolitis obliterans, which is similar pathologically to COP, except the injury is predominantly bronchiolar in location, without necessarily an inflammatory alveolar infiltrate. The mechanism is believed to be due to inflammation caused by the irritant in the bronchioles that progresses into irreversible fibrosis and airway obstruction. Frequently, this occurs after exposure to water-insoluble gases (such as oxides of nitrogen in the case of silo-filler's lung) and organic dusts or fumes, which are not rapidly absorbed in the mucous membranes of the upper airways (Ramirez and Dowell, 1971; Fleming et al., 1979). Nitrous fumes are a significant industrial hazard and can be found in the agriculture, fire-fighting, and chemical industries. The timing of the injury can be delayed from the exposure because the gases are slowly hydrolyzed into acids that act as powerful oxidants which eventually penetrate the small airways and cause severe tissue injury. Clinical symptoms may present as acute, subacute, or chronic. The chronic form usually presents as a new clinical illness, weeks to months after recovery from the initial acute illness (King, 2003).

There have been many case reports of industrial exposures followed by the development of bronchiolitis obliterans in unrelated industries such as battery workers, food flavoring workers, and nylon flock workers (Konichezky et al., 1993; Eschenbacher et al., 1999; Kreiss et al., 2002). It is difficult to prove causation when only a few workers are affected. Kreiss and colleagues (Kreiss et al., 2002) reported a high incidence of bronchiolitis obliterans in 7% (8 out of 117) of workers at a microwave popcorn plant, which was attributed to inhalation of the volatile agent diacetyl in the butter flavoring. This observation was supported by toxicity studies of diacetyl inhalation in rats (Hubbs et al., 2002). Bronchiolitis obliterans has also been described in a truck driver who inhaled fly ash, as well as in a young man with smoke inhalation from a fire (Boswell and McCunney, 1995; Tasaka et al., 1995). Both cases recovered from the acute illness only to have their symptoms recur and progress weeks to months later.

Organizing pneumonia can also occur as a sequela from prior pulmonary infections, most commonly seen with adenovirus, but also associated with other viruses

(RSV, influenza) and mycoplasma (Wright et al., 1992; Penn and Liu, 1993; Chan et al., 1997). When an organizing pneumonia pattern is observed after an infection, it is referred to as "secondary organizing pneumonia." COP has been reported to occur in the contralateral lung in women undergoing breast radiation for breast cancer (Stover et al., 2001). Some medications have been implicated as etiological agents in the development of COP, including amiodarone, amphotericin, bleomycin, mesalazine, methotrexate, phenytoin, and sirolimus (Cordier, 2006). Both gold and penicillamine have been suspected; however, it is difficult to determine if the COP results from the medication or the underlying disease (Geddes et al., 1977).

Idiopathic Pulmonary Fibrosis

The original theory for the pathogenesis of IPF rested on the premise that inflammation of the alveoli was followed by fibrosis (Crystal et al., 1976, 1981, 1984; Hunninghake et al., 1979). There are many observations that support this hypothesis. Early studies that used bronchial lavage demonstrated increased numbers of alveolar macrophages, neutrophils, eosinophils, and lymphocytes (Crystal et al., 1976; Reynolds et al., 1977; Weinberger et al., 1978). Gallium scans, which are non-specific markers of inflammation with macrophages and neutrophils, are positive in about 70% of all patients with IPF (Crystal et al., 1976; Line et al., 1978). Biopsies that are performed in early stages of the disease reveal large amounts of inflammation and alveolar wall derangement compared to biopsies taken in the later stages of disease when fibrosis predominates (Carrington et al., 1978). Alveolar macrophages are believed to play a central role in the inflammatory process through the release of cytokines that affect other cells. Alveolar macrophages from patients with IPF have been shown to secrete neutrophil chemotactic factor, which does not occur in normal non-activated alveolar macrophages (Hunninghake et al., 1980, 1981). Animal models have shown the presence of inflammation preceding fibrosis, and the suppression of the inflammatory response attenuates the progression to fibrosis (Snider, 1986).

More recently, there has been a focus on the fibrotic aspect of the disease as also playing an important role. These theories about the pathogenesis of IPF involve the idea of recurrent, ongoing stimulus and injury to the lung, with abnormal wound healing. The abnormal wound healing is believed to result from a complex interplay of the genetic background of the individual, the predominant inflammatory phenotype (Th1 or Th2), and the environmental triggers. The stimulus that acts as the driving force remains a mystery, as does the mechanism that promotes

a pathological fibrotic response instead of the normal reparative response.

The lung parenchyma regulates its immune and fibrotic processes through cytokine signaling between the cells of the interstitium, including epithelial cells, endothelial cells, fibroblasts, and macrophages, and it is likely that these cells contribute to the pathogenesis of IPF (Martinet et al., 1987; Standiford et al., 1991; Selman et al., 2001). Although the exact sequence of chemokine signaling that leads to the progression of fibrosis is not understood, it has been shown that cytokines are responsible for the cell-to-cell communication and fibroblast activation, proliferation, and collagen production.

One theory is that an imbalance in inflammatory phenotype, shifted towards a Th2 response, is responsible for the fibrotic phenotype. Support for this theory comes from the observation that IL-4 and IL-13, major Th2-type cytokines, have been shown to be major stimuli for fibroblast derived extracellular matrix deposition (Furuie et al., 1997; Hancock et al., 1998). Interferon- γ , one of the major Th1-type cytokines, has been shown to suppress the production of collagen and fibronectin by fibroblasts (Goldring et al., 1986). The increased presence of eosinophils, which have been associated with Th2 cytokine expression in asthma and parasitic infections, in association with fibrotic changes in IPF, is consistent with the concepts of the Th2 paradigm of abnormal healing. Davis et al. (Davis et al., 1984) demonstrated that eosinophils represented greater than 5% of the cells in the lavage fluid of 20% of patients with IPF compared to less than 1% of the normal controls. These eosinophils were shown to have collagenase activity and have the capacity to injure lung parenchymal cells.

The pathogenetic mechanisms that lead to the development of pulmonary fibrosis associated with rheumatic diseases have been most extensively studied in scleroderma. The most common theory, which may or may not be applicable to the idiopathic form, is that an initial environmental injury triggers an ongoing, amplified immune response in the lung. TNF- α and TGF- β have both been shown to be upregulated early in the course of the disease (Corrin et al., 1994; Bolster et al., 1997) and there is a cytokine shift from Th1 to Th2 in helper T cells (Bolster et al., 1997). Bronchoalveolar lavage fluid from patients with scleroderma has increased levels of several inflammatory cytokines such as IL-8, TNF- α , and macrophage inflammatory protein (Southcott et al., 1995). The lavage is also believed to have prognostic value in patients with systemic sclerosis. Scleroderma patients with a neutrophil and eosinophil predominant bronchoalveolar lavage have been associated with more extensive pulmonary fibrosis seen on CT and more rapid clinical deterioration (Rossi et al., 1987; Silver et al., 1990; Behr et al., 1996; Friedman et al., 1996; Witt et al., 1999).

The stimulus that leads to the inflammatory response in the lungs of patients with scleroderma is also unknown, but one hypothesis suggests that aspiration of refluxed esophageal and gastric contents may be the cause. The premise behind this theory arises from the fact that many patients with systemic sclerosis have both esophageal dysmotility and pulmonary fibrosis. This association was initially observed in a relatively small cohort of 12 patients (Johnson et al., 1989a). Subsequent studies have found conflicting results when trying to correlate pulmonary function parameters meant to be a surrogate marker of pulmonary fibrosis (such as total lung capacity and diffusion capacity) with esophageal manometry (Troshinsky et al., 1994; Lock et al., 1998). These studies are limited by confounding factors because both esophageal dysmotility and pulmonary fibrosis may be independent markers of scleroderma disease severity, without having a causal link.

Several environmental factors have been investigated for an etiological role in IPF. The premise of an environmental stimulus that leads to repeated lung injury followed by abnormal wound healing fits nicely into one theory of the pathogenesis of IPF (see below). The search for these stimuli is challenging because the offending agent may be different between individuals based on individual differences in genetic susceptibility. Nevertheless, epidemiological studies have identified links between occupational exposures, medications and infectious agents, and IPF.

Four separate case-control studies have looked at the association between occupational exposure and IPF. Although these studies are limited because of recall bias, there were some consistent observations. Metal dust exposure was significantly associated with IPF in every study and in a dose-response relationship (Iwai et al., 1994; Hubbard et al., 1996; Baumgartner et al., 1997, 2000). Two studies showed a significant association with livestock exposure, farming, and agricultural exposure (Iwai et al., 1994; Baumgartner et al., 2000). Paraquat, a herbicide used in agriculture, has been found to cause fatal pulmonary fibrosis in humans and experimental animals after oral, inhalational, or cutaneous exposure (Schoenberger et al., 1984). Anecdotal case reports have linked cases of IPF with occupations that result in toxic dust or fume exposure such as diamond polishing, dairy work, welding, gold extraction, and dental work (Baumgartner et al., 1997).

Pulmonary fibrosis is a well-known side effect of several medications, most notably bleomycin, amiodarone, methotrexate, and nitrofurantoin (Holmberg and Boman, 1981; Schoenberger and Crystal, 1983; Martin and Rosenow, 1988; Israel-Biet et al., 1991; Sleijfer, 2001). It has also been found as a rare complication of more commonly used medications such as beta blockers,

antidepressants, anti-convulsants, and non-steroidal anti-inflammatory drugs. However, these associations have been difficult to prove given the ubiquity of these medications and the relative rarity of IPF (Coultas et al., 1994).

The effect of smoking on the natural history of IPF is controversial, but of four case–control studies examining the association of smoking with pulmonary fibrosis, three show a significant link between smoking and the development of IPF (Iwai et al., 1994; Hubbard et al., 1996; Baumgartner et al., 1997, 2000). Some studies have shown improved survival in smokers with IPF compared to non-smokers (Cherniack et al., 1995; King et al., 2001). However, this observation may be due to lead time bias in the smoking group, and simply reflect a greater severity of disease in the non-smoking groups.

TREATMENT AND OUTCOME

Cryptogenic Organizing Pneumonia

One of the defining features of COP is that it usually has an excellent response to corticosteroids. Although there have not been any randomized clinical trials to prove their efficacy, there is widespread consensus based on individual experience that corticosteroids are highly efficacious. When patients respond, there is typically complete radiographic and clinical resolution of the organizing pneumonia. There is no consensus on duration of treatment, with some authorities suggesting 6 to 8 weeks, while others advocate 1 year. Spontaneous remissions are unusual, except when a precipitating factor is identified and withdrawn, e.g., new medication. Second line agents, e.g., cytotoxic agents or macrolid antibiotics, can be used when steroids are contraindicated, but high quality data for these are lacking.

Idiopathic Pulmonary Fibrosis

IPF usually portends a poor prognosis and is typically poorly responsive to therapy. Early diagnosis and treatment have traditionally been advocated so that therapy can be initiated and hopefully prevent irreversible fibrosis. Therefore, the typical medications used to treat IPF work through anti-inflammatory and immunosuppressant mechanisms. However, these traditional approaches have failed to show that the inflammatory or fibrotic process can be altered or reversed. As the understanding of the pathogenesis of the disease improves, newer agents are being developed based on cellular mechanisms to inhibit fibrogenesis. No therapy for IPF has been shown in a prospective, randomized, double-blind, placebo-controlled trial to improve survival.

Prior studies have suggested that the prognosis may be favorable for patients with pulmonary fibrosis associated

with systemic sclerosis (Wells et al., 1994). However, Hubbard and Venn (Hubbard and Venn, 2002) demonstrated with actuarial data that the mortality rates for patients with pulmonary fibrosis associated with all rheumatic disorders, predominantly rheumatoid arthritis in their study, are remarkably similar to those that are idiopathic in origin.

Corticosteroids

The most common medications used to treat IPF are corticosteroids, despite the fact that they have not been properly evaluated in a large clinical trial. Early studies showed that 10 to 30% of patients with IPF appear to improve or survive longer when treated with corticosteroids (Stack et al., 1972; Turner-Warwick et al., 1980). Unfortunately, these studies likely included other forms of idiopathic interstitial pneumonia, such as non-specific interstitial pneumonia or cryptogenic organizing pneumonia, which tend to have a more favorable prognosis than IPF. When histopathological criteria are used for the diagnosis of IPF, the clinical response (0–16%) and survival rates are much worse than for the other pathological patterns (Daniil et al., 1999; Ziesche et al., 1999; Nicholson et al., 2000). Despite the lack of evidence for a beneficial role of corticosteroids, many pulmonologists use a 3- to 6-month trial of corticosteroids with close monitoring for radiographic or physiologic improvement. Patients who improve with corticosteroids or who remain stable are then kept on a maintenance dose of 10 to 20 mg of prednisone per day (ATS, 2002). Intravenous pulse corticosteroids for 3 to 5 days are generally recommended for an acute exacerbation of IPF, as Keogh and colleagues (Keogh et al., 1983) have shown that higher doses of corticosteroids can significantly reduce the neutrophil accumulation during an active alveolitis of IPF.

Cytotoxic Agents

Other anti-inflammatory and cytotoxic agents have been investigated for a beneficial role in IPF. Cyclophosphamide, when used in combination with corticosteroids, had promising results towards a survival advantage compared to corticosteroids alone in an early randomized control trial (Johnson et al., 1989b; Baughman and Lower, 1992). Cyclophosphamide has been shown to reduce the neutrophil component of the active alveolitis after 3 and 6 months of therapy (O'Donnell et al., 1987). However, subsequent studies have shown cyclophosphamide to have limited efficacy and a high frequency of side effects when used to treat patients with IPF who failed to respond to corticosteroid therapy (Zisman et al., 2000). Cyclophosphamide may be particularly effective in patients with scleroderma-associated pulmonary fibrosis, as it was shown to improve

pulmonary function testing in this population. Scleroderma patients with a neutrophil predominant bronchoalveolar lavage seemed to have the best outcomes, although these studies were limited by either small sample size, lack of a control group, or selection bias from retrospective review (Silver et al., 1990; Schnabel et al., 1998; White et al., 2000). It is currently considered as a second line drug for patients with progressive IPF. Side effects include leukopenia, thrombocytopenia, and hemorrhagic cystitis.

Azathioprine has been shown to have some efficacy in the treatment for IPF in small prospective case series (Winterbauer et al., 1978; Raghu et al., 1991). Azathioprine exerts cytotoxic effects on lymphocytes and also suppresses the activity of natural killer cells and antibody production. It is also considered a second line therapy for patients who fail corticosteroids, or may be given in conjunction with corticosteroids.

A randomized control trial comparing acetylcysteine vs. placebo in patients with IPF who were also receiving prednisone and azathioprine demonstrated significantly slower declines in both vital capacity and diffusing capacity in the acetylcysteine group. However, there were no improvements in mortality, quality of life, or radiography (Hunninghake, 2005). One possible explanation is that the addition of acetylcysteine simply attenuates the harmful effects of cytotoxic therapy. More studies of this combination therapy are needed before this can be determined.

Anti-fibrotic Agents

Colchicine has been postulated to have a role in the treatment of IPF because it inhibits collagen formation *in vitro* and suppresses the release of alveolar macrophage-derived growth factor (Rennard et al., 1988). Colchicine has been suggested in small randomized control trials to be as effective as corticosteroids in treatment of IPF, but has not been followed up with large, controlled studies (Peters et al., 1993; Douglas et al., 1998).

Interferon γ -1b was used by Ziesche and colleagues (Ziesche et al., 1999) in a 1-year study of 18 patients with IPF randomized to receive interferon γ -1b and prednisolone, compared to prednisolone alone. Interferon γ -1b has been shown to downregulate the expression of TGF- α 1 and inhibit the proliferation of fibroblasts, both of which are considered important roles in the pathogenesis of pulmonary fibrosis (Clark et al., 1989; Narayanan et al., 1992). Ziesche's study (Ziesche et al., 1999) suggested a significant improvement in total lung capacity and partial pressure of arterial oxygen, and a decrease in the level of transcription of TGF- α 1 and connective-tissue growth factor in the individuals who received interferon γ -1b.

This led to a multi-center, double-blind, placebo-controlled trial of interferon γ -1b in patients with IPF who failed to respond to corticosteroids. Interferon γ -1b

did not improve any of the main outcomes: progression-free survival, pulmonary function, or quality of life (Raghu et al., 2004). Additionally, there were more adverse side effects in the group that received interferon γ -1b. There was a trend towards increased survival in the group that received interferon γ -1b (16 out of 162 patients in the interferon γ -1b group died compared with 28 out of 168 patients in the placebo group, an absolute reduction of 7%). However, the relatively short follow up of 1 year, coupled with the fact that this was not a primary endpoint of the trial, raises the concern that this trend may be misleading. At this time, interferon γ -1b should not be considered as a proven therapy for IPF, unless used as part of a clinical trial.

Many other novel strategies have been investigated in the treatment of IPF, including cyclosporin A, pirfenidone, bosentan, and etanercept (Raghu et al., 2011). These therapies focus on different aspects of the pathogenesis of the disease, such as anti-oxidants, inhibitors of cytokines, proteases, and fibroblast growth factors. However, all of these agents have failed to demonstrate clinically meaningful responses and therefore the joint statement by the American Thoracic Society and European Respiratory Society strongly recommended against using corticosteroids, colchicine, interferon γ -1b, cyclosporine, pirfenidone, bosentan, or etanercept for treatment of IPF (Raghu et al., 2011).

Lung transplantation should be considered for individuals who progress despite optimized medical management. Patients should be referred to a transplant center relatively early in their course, since wait times on the list can exceed 2 years due to limited donor availability. Those who receive a successful transplant can experience significant improvement in arterial oxygenation, pulmonary hypertension, and right ventricular dysfunction. Unfortunately, the 5-year survival rates for lung transplant are only about 60%, with death frequently due to graft failure, infection, or bronchiolitis obliterans (Lu and Bhorade, 2004).

CONCLUSIONS

The autoimmune disorders of the lung, notably cryptogenic organizing pneumonia and idiopathic pulmonary fibrosis, have long been recognized as inflammatory and fibrotic processes that are associated with variable prognosis, whether idiopathic in nature or in association with the multisystem autoimmune diseases. Both diseases appear to be mediated through repetitive cell-mediated injury directed at the bronchioles and alveoli/interstitium, followed by wound healing. Recent advances in the classification and diagnostic testing for these diseases have improved our ability to study their incidence, prognosis, and response to therapy. While much progress has been

made, the search for antigenic stimuli and genetic polymorphisms that are responsible for disease pathogenesis continues. Only through a better understanding of the disease process will we be able to offer new therapies for these diseases.

ACKNOWLEDGMENTS

We thank J. Kaplan and N. Mohamed for help in preparing this manuscript.

INTRODUCTION

Previous editions (3rd, 1998, Chapter 37 and 4th, 2006, Chapter 71) described various candidate autoimmune diseases or rare ill-defined conditions with autoimmune features—cameos. Several have been developed as full chapters in the 4th or this present 5th edition. Others together with some new entities are retained as cameos because of their rarity, controversial evidence for an autoimmune causation, or autoimmunity being just one of several contributing elements to pathogenesis.

AUTOIMMUNE/INFLAMMATORY SYNDROME INDUCED BY ADJUVANTS

The “autoimmune/inflammatory syndrome induced by adjuvants” (ASIA) (Shoenfeld and Agmon-Levin, 2011) merits serious attention since the strongly suspected environmental contributors to the occurrence of autoimmunity are proving so hard to identify. The concept of ASIA was derived from a composite of features of four conditions interconnected by their occurrence on a background of medicinally introduced chemical agents, prototypically aluminum hydroxide (alum), used in vaccines as an adjuvant with the capacity to enhance immunizing potency.

Thus the specifications for ASIA were derived from (1) undefined syndromes that can occur after routine vaccinations with preparations that contain aluminum hydroxide (alum); (2) the macrophage myofasciitis syndrome (MMF); (3) the Gulf War syndrome (GWS); and (4) sili-conosis in women after rupture/leakage of cosmetic breast implants.

1. Vaccination against infectious diseases is practiced worldwide and, expectedly, miscellaneous adverse effects do ensue. However, the last widespread illness was in the 1970s when vaccination (against swine flu) was associated with polyneuropathy attributed to adjuvant used in the vaccine. Nowadays vaccines are so well linked to the components of vaccine preparations that adjuvants as a cause *per se* of adverse effects are minimized (see Chapter 20).
2. The post-vaccination myalgia-fatigue (MMF) syndrome, reported particularly from France and investigated by Gherardi and colleagues (Gherardi et al., 1998, 2001), could be adjuvant related and associated with the practice of intramuscular (deltoid muscle) injection of vaccines that contain alum. Histological and ultrastructural studies on deltoid muscle biopsies showed osmiophilic deposits together with inflammatory changes and

macrophage activation; these deposits were membrane bound and had a finely spicular appearance, with potential capacity for inflammasome activation.

3. Those affected by Gulf War syndrome, which is marked by fatigue and fibromyalgia and afflicts veterans of the first Iraq–Persian Gulf conflict in 1991, had received intensive vaccinations. These included six shots of anthrax vaccine with adjuvants that included alum and squalene, which is usually derived from shark liver oil and botanic sources; however, it is synthesized also by animals and humans and thus could be regarded as an autoantigen. It was claimed that vaccine recipients versus non-recipients had serum antibodies to squalene but, in a brief and rather skeptical literature review, squalene was described as a poor immunogen, and antibodies to it were non-discriminatory for disease (Lippi et al., 2010).
4. Silicone is another chemical agent with potential adjuvant activities, and thus discussed in the context of ASIA. Exposure to silicone in humans can occur by rupture/leakage of cosmetic breast implants with a presumed ensuing syndrome of “connective tissue disease”—siliconosis. Silicone-gel prosthetic devices came into use in the 1960s, and were chosen by over one million women in the United States (Gabriel et al., 1994). Some women who experienced illness after cosmetic injection with silicone or paraffin were thought to have “human adjuvant disease” (HAD) (Miyoshi et al., 1964), perhaps akin to the classical adjuvant arthritis model developed in Lewis rats by Pearson and Wood (1959). The features of claimed HAD seemed to resemble those associated with multisystem autoimmune diseases including scleroderma but large surveys of women with breast implants in the United States failed to show any clear association with autoimmune diseases. For example, in a retrospective study by Hennekens et al. (1996) comprising 395,543 female health professionals between 1962 and 1991 there were 10,830 who had had an implant, and 11,805 who reported some form of “connective tissue disease”: the (small) relative risk conferred by a breast implant for “connective tissue disease” was 1.24 (95% CI 1.08–1.41, $p = 0.0015$), but the authors acknowledged possible selection bias in the self-reported nature of the data. Various ideas emerged. First, the silicone-containing breast implant itself might have adjuvant properties sufficient to initiate a multisystem autoimmune disease; second, there existed a “breast implant syndrome” comprising diffuse muscle pains, intermittent fever, fatigue, and other symptoms attributable to the inflammatory potential of silicone leaking from the implant; third, the breast implant and any concurrent diseases were coincidental. Whatever the case, the substantial litigation that followed led to an embargo in 1992 in the United States on silicone breast implants

(Angell, 1996). One point to consider is the overall latency between an inductive stimulus and any ensuing autoimmune disease—in the case of breast implants it could take quite some years before leakage from an implant, then more time for an immune/inflammatory response to be generated, and still more time for occurrence of overt disease. But, whatever the case, several influential academic and governmental agencies refuted the possibility that silicone breast implants confer risk for autoimmune disease (Rosenbaum, 1997), as further established by a meta-analysis of many published studies (Janowski et al., 2000). Whether or not breast implants provoke an autoantibody reaction also has been investigated. Of 24 patients with silicone exposure and rheumatic symptoms, 11 had some defined rheumatic syndrome and 13 did not, and the frequencies of ANA were 10 of 11 and 7 of 13 for the two groups (Press et al., 1992); the ANA specificities in group II were not typical of those seen in any recognized autoimmune disease. The frequency of ANA reactivity in women with breast implants was higher than in controls according to Bridges (1994) and Bar-Meir et al. (1995), but not according to Gabriel et al. (1994). Antibodies to native or denatured collagen types I and II was assessed in our laboratory by Western blot in 70 women with a breast implant, 94 with rheumatoid arthritis, and 133 healthy controls: the frequency in the three groups of antibodies to type I collagen was 26, 23, and 3%, and to type II collagen 23, 36, and 4% (Rowley et al., 1996). So, in brief, large epidemiological studies, albeit with relatively short surveillance periods, appear to exonerate silicone in breast implants as a cause of either recognized multisystem autoimmune diseases, or undifferentiated connective tissue disease but consider in some instances that they may provoke an autoimmune response to tissue constituents including collagen perhaps secondarily to an inflammatory response to the implant.

In conclusion, there does exist persuasive evidence for ASIA including the well-confirmed adjuvant arthritis model inducible in rats by injection of Freund’s complete adjuvant and, given this, the syndrome could be reflective of “human adjuvant disease.” Thus a return to the rat model of adjuvant disease could well be justified.

AUTONOMIC NEUROPATHY

Unmyelinated autonomic nerve fibers that innervate cardiovascular, gastrointestinal, urogenital, thermoregulatory, sudomotor, and pupillary structures are subject to neuropathies of disparate cause affecting nerve fibers or ganglionic structures, resulting in autonomic failure (dysautonomia). It is well recognized that paraneoplastic dysautonomia

occurs usually in association with other paraneoplastic expressions (Freeman, 2005). The accompanying autoantibody is usually to nicotinic acetyl choline receptors (AChR) in autonomic ganglia (Vernino et al., 2000) or to the Hu family autoantigen (ANNA-1) or peripherin, or less often to presynaptic voltage-gated calcium channels (Iorio and Lennon, 2012). Alternatively, an autoimmune autonomic neuropathy occurs spontaneously independently of neoplasia (Vernino et al., 2000). Some 50% of patients with autoimmune gangliopathy are reactive with autonomic ganglia that are similar structurally to AChR pentamers at the neuromuscular junction and, among the spontaneous cases, one or another clinical expression of dysautonomia may be the more prominent, often intestinal hypomotility causing gastric stasis or constipation. In a reported case of neuropathic gastric stasis with type 1 diabetes (T1D), histological examination revealed a complete and presumably autoimmune depletion of interstitial cells of Cajal of the myenteric plexus (He et al., 2001). Experimentally, rabbits immunized with the $\alpha 3$ subunit of the AChR developed an autonomic neuropathy (Lennon et al., 2003) that was passively transferable to mice with IgG from serum of affected rabbits and, from limited data, with sera from diseased humans (Vernino et al., 2004).

BIRDSHOT RETINOPATHY

The slender reasons, additional to the piquancy of the title, for considering this rare ocular disease among the cameos is the presumed dependency for pathogenesis on the retinal S antigen and the remarkably high disease association with the class I MHC molecule, HLA A29. Autoimmune inflammatory eye diseases (see Chapter 55) comprise responses to antigens in uvea or retina but serological responses to a putative characterized autoantigenic molecule are not readily demonstrable as in other autoimmune diseases. Birdshot retinopathy affects predominantly individuals of northern European background and occurs usually in mid-adult life, and there is a slight female excess. It is rare, accounting for only about 1% of all cases presenting clinically as “uveitis.” Birdshot retinopathy is seen at retinoscopy as multiple separate cream-colored spots on the post-equatorial fundus. Opportunity for pathologic examination is most infrequent; the retina is predominantly affected, and microscopy reveals a T lymphocytic and granulomatous infiltrate (Gasch et al., 1999). A claimed serologic reactivity *in vitro* to retinal S antigen is not well documented. The risk conferred by the class I MHC allele HLA A29 (50- to 224-fold) is higher than that for any other disease, and is greater for the A29.1 than the A29.2 subtype of HLA29. There are only a few other human diseases wherein a demonstrable HLA association is with a class I rather than a class II HLA molecule, including

spondyloarthropathies (B27, Chapter 38) and psoriasis (Cw6, Tillikainen et al., 1980). Birdshot retinopathy is attributed to specific reactivity of CD8⁺ cytotoxic T cells against the retinal S antigen. The provocation for this disease is unknown.

CYSTITIS, INTERSTITIAL

Hunner’s report (1914) of chronic recurrent edematous ulceration of the bladder in eight young women is taken to be the first on putative autoimmune cystitis; *interstitial* was subsequently added to accommodate the accompanying diffuse fibrosis of the bladder wall. Hand (1949) described a larger case series, 204 women and 19 men, representing almost 5% of urologically investigated patients in his clinic. Oravisto et al. (1970) reported on 54 cases from a urology clinic over a 10-year period, all female aged 16–80 years, mean 59, with symptoms of urinary frequency and urgency, suprapubic pain, and hematuria; cystoscopic appearances were included comprising a greatly reduced bladder capacity and a bladder wall with stellate scars, clusters of granulations, and punctuate hemorrhages likened to an “angry scratch.” Microscopically, the bladder wall reveals mucosal ulcerations, edema, lymphoid-plasma cell infiltrates and prominence of mast cells (Sant and Theoharides, 1994) and, in longstanding cases, fibrosis. The best evidence for autoimmunity in interstitial cystitis is the disease association with SLE (Fister, 1938; Shipton, 1965; Boye et al., 1979), Sjögren’s syndrome, and autoimmune thyroiditis (Oravisto, 1980). In 129 cases, Peecker et al. (2003) supplemented these associations with cases of “hypersensitivity/allergic disorders,” rheumatoid arthritis, and inflammatory bowel diseases. The high population frequency of interstitial cystitis (1–2 per 1000, overall, predominantly among women, $\approx 90\%$), has led in the USA to a patient support group being founded (Interstitial Cystitis Association). Subtypes of interstitial cystitis are sometimes cited for case classification into ulcerative (typical) or non-ulcerative types, and into primary (sole disorder) or secondary (associated with SLE or other immune-mediated disease) (de la Serna and Alarcon-Segovia, 1981; Alarcon-Segovia et al., 1984). Biomarkers are needed to assess accuracy of diagnosis and efficacy of treatment, with formal criteria for diagnosis being specified by the National Institute of Diabetes and Digestive and Kidney Diseases of the NIH (USA).

Serologic studies have not been helpful. Bladder-specific autoantibodies were reported by Silk (1970), but have not been confirmed. Frequencies of ANA were raised according to Oravisto et al. (1970) and Jokinen et al. (1972). However, in a more contemporary study Ochs et al. (1994) assembled 96 patients whose sera were tested for ANA by immunofluorescence on tissue sections

and on HEp-2 cells, and additionally a cultured bladder epithelial cell line was used for Western blotting. Autoantibodies specific to bladder cells were not demonstrable, but there was an increased frequency, 36% versus 8% in female controls, of non-tissue-specific autoantibodies (cut-off titer 1:40); the reactivities were mostly ANA with staining patterns usually speckled or nucleolar, unlike what pertains in SLE, and tests for AMA were positive in three cases. The findings of Ochs et al. (1994) were not seen as indicative of a primary autoimmune attack on the bladder wall but rather as a consequence of an undefined chronic inflammatory process, with autoantibodies secondarily augmenting this process.

Experimental models of autoimmune cystitis have been attempted in mice and rats, first by direct immunization with bladder wall extracts (Bullock et al., 1992), and later by introduction of transgenically encoded protein antigen (Liu et al., 2007). Immunization of Balb/c AN mice with bladder extract induced cystitis shown histologically by edema, fibrosis, and lymphocytic and mast cell infiltrations; specific reactivities of serum antibodies or T cells were not described, but disease was transferable adoptively by lymphoid cells from affected mice. Cystitis was similarly inducible in Lewis rats, and was adoptively transferable with splenocytes (Luber-Narod et al., 1996). More recently Liu et al. (2007) developed mice that transgenically expressed on bladder epithelial cells the model “self” antigen ovalbumin (URO-OVA). Such mice are unresponsive to OVA stimulation. Adoptive transfer studies were performed wherein naïve OVA-specific T cells showed proliferation and infiltration into the bladder mucosa but no cystitis, whereas transfer of activated OVA-specific T cells did induce an inflammatory cystitis. Their model was further developed to demonstrate that bladder epithelium was capable of presenting a self antigen in association with MHC class I, that activation of T cells occurred in bladder regional lymph nodes, and that features of the ensuing cystitis simulated those of the human counterpart.

In conclusion, human interstitial cystitis remains on the fringe of autoimmunity, since neither pathogenic nor disease-specific marker autoantibodies are regularly demonstrable, immune-mediated mechanisms of bladder wall damage in humans remain obscure, and lacking are genetic analyses and well-controlled studies of efficacy of corticosteroid or immunosuppressive drugs—yet the experimental transgenic models are persuasive. Perhaps there exist as yet undefined co-contributory mechanisms of pathogenesis such as a harmful constituent of urine to which the bladder wall could be persistently exposed.

ENDOMETRIOSIS

Endometriosis was so named to convey the idea that fragments of sloughed uterine endometrium become distributed

in the pelvic peritoneum and sites further afield (Sampson, 1921; Ridley, 1968; Giudice and Koo, 2004). The estimated frequency of this disease is 1–2% of all women and one of five women of reproductive age. Clinical expressions include (1) gynecologic symptoms, pelvic pain, menorrhagia, dysmenorrhea, and dyspareunia, (2) dysfunction of the pelvic colon or bladder, (3) infertility, and (4) repeated pregnancy loss. Definitive diagnosis requires laparoscopic surgery. Unsurprisingly, dysfunctions of the immune system are implicated in pathogenesis at various levels (Giudice and Koo, 2004) and include compromised natural killer cell (NK) activity resulting in decreased surveillance/removal of ectopic tissue (Wilson et al., 1994), activation of peritoneal macrophages and upregulation of proinflammatory cytokines, and there are various pointers to autoimmune reactivity. Thus Weed and Arquembourg (1980) surmised that “non-self” ectopic endometrial implants in the pelvis generated endometrial tissue-specific antibodies, with ensuing infertility. In general, autoimmunity has not been held to explain the actual occurrence of displaced endometrium in the pelvis, but rather particular consequences of this displacement. Yet despite considerable immunological investigation in the 1980s, results were relatively unimpressive (Dmowski, 1987). Even so, impetus was given to the autoimmune concept by Grimes et al. (1985), whose case-control study showed that endometriosis was associated with a two-fold (but non-significantly) increased risk for developing SLE, and by increased frequencies of non-tissue-specific autoantibodies, Gleicher et al. (1987) found that among 59 cases 28.5% gave a positive test for ANA and 45.5% for lupus anticoagulant, and Taylor et al. (1991) compared 71 age-matched cases with 109 control women and reported that there was a very significantly increased frequency of autoantibodies to nuclei, ribonucleoproteins (Ro and La), to smooth muscle antigens, and to anticardiolipin and lupus anticoagulant. While Gleicher et al. (1987) asserted that endometriosis “fulfills all the classic characteristics of an autoimmune disease,” Taylor et al. (1991) took a more reserved interpretation of the reported autoantibody responses. A serological study on 12 patients and various controls, based on immunofluorescence on endometrial tissues sections, and Western blotting on extracts of endometrial tissue, failed to show any disease-specific autoimmune serological reactivity (Switchenko et al., 1991). However, Fernández Shaw Hicks et al. (1993) reported, and convincingly illustrated, results from an improved immunohistochemical procedure by which sera of women with endometriosis specifically reacted with the cytoplasm of endometrial glands whereas all control sera were negative, concluding that the demonstrable anti-endometrial antibodies could be reactive *in vivo* and impair fertility. Mathur et al. (1995) reinvestigated the question of endometrial autoantigens using Western blotting and found that sera did react with

endometrial tissue extracts from affected individuals, observing five reactive components with molecular weights of 34, 46/48, 64, 94, and 120 kDa that were not seen with control sera; moreover sera of rabbits immunized with endometrial extracts, or reactive proteins eluted after electrophoretic separation, bound to the same components as did the patients' sera. Finally, [Walter et al. \(1995\)](#) characterized by Western blotting a 48 kDa molecule from a human endometrial adenocarcinoma cell preparation that was sequenced as *alpha*-enolase, and a recombinant enzyme protein was derived for use in a diagnostic assay (although the utility of this has not been established); also two linear autoepitopes reactive with endometriosis sera were mapped and characterized. However, in the event, interest in endometrium-specific autoimmune reactants over the last decade has faded. The most recent information on the immunopathology of endometriosis, obtained using a gene array procedure, is that of [Hever et al. \(2007\)](#). These authors compared endometriosis tissue with normal endometrium and found that the former was enriched in plasma cells and activated macrophages; the gene arrays did not point to the presence of mature B or T cells, but did show that there was activation of genes for the B cell activating cytokine BAFF/BLyS. The BAFF-driven plasma cells were likely of the marginal zone B-1 type, and the likely source of the various non-tissue-specific autoantibodies described in endometriosis.

In conclusion, endometriosis perhaps has less relevance to autoimmunity than to physiological immunology by indicating that autoantibodies may in fact serve to remove unwanted/ectopic tissue ([Grabar, 1975](#)), in this case displaced uterine endometrium.

EPILEPSY

Autoimmunity became implicated from the early 1990s in seizure disorders when a severe form of childhood encephalitis with seizures (Rasmussen disease, RD) was linked with antibodies to excitatory glutamate receptors in the CNS. Rabbits immunized simply to raise antibodies to glutamate receptor subunit 3 (GluR3) developed seizures and histological encephalitis, and this led to a search for autoantibodies to glutamate receptors in RD in children ([Rogers et al., 1994](#)). This is reminiscent of the discovery of the causation of myasthenia gravis by autoantibody to the nicotinic acetylcholine receptor (AChR) after the unexpected occurrence of myasthenia in rabbits immunized merely to raise an antiserum to AChR ([Patrick and Lindstrom, 1973](#)). However, at present, anti-GluR3 figures much less prominently in autoimmune epilepsy in adults than do autoantibodies to various other neuronal antigens such as glutamic acid decarboxylase of 65 kDa (GAD65). Importantly, recognition in blood or cerebrospinal fluid of such autoantibodies is a distinct directive to immunotherapy.

It was the description of epilepsy-relevant autoantibodies during the 1990s that eventually led to the nomination in 2000 of certain epilepsies—particularly refractory and localization-related types—as “autoimmune” ([Palace and Lang, 2000](#); [Peltola et al., 2000](#)), after which there have been various corroborative reports specifying associated autoimmune reactants notably anti-GAD65 ([Saiz et al., 2008](#)) (and others) in the context of the stiff person syndrome ([Ali et al., 2011](#)), voltage-gated potassium channels (VGKC) ([Irani et al., 2011](#); [Iorio and Lennon, 2012](#); [Quek et al., 2012](#)) in the context of chronic encephalitis syndromes, or N-methyl-D-aspartate receptor (NMDA-R) implicated mostly in neuropsychiatric dysfunctions other than epilepsy ([Diamond et al., 2009](#); [Dalmau et al., 2011](#)). [Quek et al. \(2012\)](#) described 32 patients with an “exclusive or predominant seizure presentation” and suspected neuronal autoimmunity; among these were autoantibodies to VGKC complexes in 56%, GAD65 in 22%, collapsin response-mediator protein in 6%, and NMDA-R in just 3% (one case). “VGKC complexes” is used advisedly as this is a broad term that covers macromolecular assemblies that contain various potentially antigenic constituents ([Iorio and Lennon, 2012](#)). A further neuronal antibody species, often paraneoplastic, was characterized in cases of limbic encephalitis with early and prominent seizures being directed to the B1 subunit of the GABAB receptor; the assay used was a cell line transfected with rodent GABA receptor ([Lancaster et al., 2010](#)).

The two important points are, first, that “autoimmune epilepsy” should now be regarded as a definitive neurological entity for which there are valid serological diagnostic assays, and second, that immunotherapies can provide substantial relief from seizures in cases in which conventional anti-epilepsy drugs have failed.

FATIGUE SYNDROME

The “fatigue syndrome” was derived in 1955 from an outbreak of an unexplainable illness at the Royal Free Hospital in London that affected 292 staff members (Medical Staff of the Royal Free Hospital, 1957). The features were severe fatigue, loss of energy, poor exercise tolerance, muscle discomfort, fibromyalgia, and other nonspecific symptoms including malaise, neck stiffness, lymphadenopathy, and fever. A preceding viral illness was often implicated. The name “myalgic encephalomyelitis” (ME) was proposed by “an unusually uncritical Lancet editorialist” ([Byrne, 1988](#)). “Myalgic encephalomyelitis” faded from use, but the fatigue syndrome attracted ongoing attention from patient support groups and various medical specialties: some argued for a functional basis and others for an unknown organic basis. By the 1980s, the syndrome had become accepted as an entity, and in 1987 was formally designated as chronic fatigue syndrome (CFS), with recommended diagnostic

criteria from the Centers for Disease Control (CDC) in Atlanta, GA (Holmes et al., 1988). The two major criteria for diagnosis were (1) a new onset of fatigue lasting 6 months and reducing activity to less than 50%, and (2) exclusion of any other condition usually producing fatigue, and 11 minor criteria (of which eight should be fulfilled) including eight symptomatic and three physical features, these being mild fever, nonexudative pharyngitis, and palpable cervical or axillary lymph nodes up to 2 cm in diameter. High among claimed causes of CFS are chronic viral infections, notably Epstein–Barr virus; the case for a murine retrovirus, XMRV, has been convincingly refuted. Other candidates are allergies, autoimmunity, hyper-reactive responses to unusual environmental exposures, and psychosomatic disorder. Despite evidence in CFS for immune activation and/or impaired indices of cell-mediated immunity (Lloyd et al., 1989, 1990; Buchwald and Komaroff, 1991), data from the conventional indications of inflammatory activity or tissue destruction (ESR, C-reactive protein) are non-supportive. Benefit from immunomodulatory treatment with intravenous immunoglobulin, of known efficacy in some well-defined antibody-mediated autoimmune diseases, is controversial, either endorsed (Lloyd et al., 1990) or refuted (Peterson et al., 1990).

Analysis of an autoimmune component in CFS encounters issues such as specification of a clear associated diagnosis and a scarcity of affirmative evidence, perhaps indicative of unpublished negative studies, opposed to which is the known occurrence of fatigue in certain well-accepted autoimmune disorders. The major question then is whether, among cases fulfilling CDC criteria for CFS, there can be regularly identified a highly raised level of any autoantibody specificity, particularly antinuclear autoantibody (ANA). Positive studies include that of Behan et al. (1985) (50 cases) and another group (60 cases) (Konstantinov et al., 1996; von Mikecz et al., 1997) which cited a frequency of autoantibodies of 83% versus 17% in a control group, predominantly of ANA specificity, and directed particularly to nuclear envelope proteins, together with cytoplasmic staining patterns of intermediate filament-vimentin type thought to be indicative of viral infection. On the other hand, there are negative results for ANA in CFS (Skowera et al., 2002), or only modestly positive results (Vernon and Reeves, 2005).

It is not the purpose here to review all the varied suppositions on the basis of CFS because none is sufficiently convincing. It can be said that autoimmunity does not provide an explanation for all cases of CFS, that autoantibodies when present might reflect some other as yet unidentified cause, and that autoimmunity likely is but one among a conglomerate of causes for CFS.

FOLATE DEFICIENCY

Maldevelopment of the embryonic neural tube resulting in spina bifida, anencephaly, or other defects occurs in infants at a prevalence of about one in 1000. It has been widely ascertained that periconceptual folic acid supplements to mothers strikingly alleviate this, even though the mothers usually do not have evident folate deficiency (Rothenberg et al., 2004). The observation was made that antiserum to folate receptors in pregnant rats resulted in embryonic mal-development, and this prompted the search for autoantibodies to folate receptors in women in whom a pregnancy had resulted in an infant affected with a neural tube defect (Rothenberg et al., 2004). The procedure used was the specific blocking of (³H) folic acid to folate receptors on placental membranes and to indicator cell lines. The results were that nine of 12 women (versus two of 20 controls) with affected children had a receptor blocking antibody. The same authors (Ramaekers et al., 2005) in a further study investigated infantile-onset cerebral folate deficiency that develops 4–6 months after birth and is expressed as mental and psychomotor retardation, cerebellar ataxia, dyskinesia, seizures, visual disorder, and autism. There were low levels of 5-methyl tetrahydrofolate (5-MTHF) in the cerebrospinal fluid but normal levels in serum, and lack of evidence of extracerebral folate deficiency. Serum from 25 of 28 affected children, versus none of 28 controls, contained high-affinity blocking autoantibodies against membrane-bound folate receptors on the choroid plexus, indicating impediment to the passage of folic acid from serum to brain. This could be normalized by oral calcium folinate that led to clinical improvement. Notably, none of five tested mothers had autoantibodies. Perhaps the induction of the anti-folate receptor antibodies in these affected children was due to soluble folate-binding proteins in milk, or to other unknown antigens (Ramaekers et al., 2005). This story is indeed a legitimate “cameo” in the world of autoimmunity, since anti-folate receptor autoantibody could be generated either in the pregnant mother or the newborn child, causing neural developmental disorders. Indeed Schwartz (2005) was prompted to comment that “autoimmunization lurks behind every pillar.” And there is the added point that the catastrophic consequences in this particular example are remediable by a very simple therapy, folic acid.

LICHEN SCLEROSUS

“Lichen,” a compound plant (fungi in symbiotic union with algae) that spreads on rocks and trees, gives its name to chronic skin diseases seen mostly as thickened but sometimes atrophic inflammatory patches on skin or mucus membranes with, histologically, damage and

cellular infiltration between the epidermis and dermis. There are many variants described of mucocutaneous lichenoid eruptions according to their location and visual appearances. The prototype is lichen planus for which no single specific cause has been identified, although one interesting association is infection with hepatitis C virus (Le Cleach et al., 2010). The lichenoid eruption described as lichen sclerosus is, however, consistently linked to autoimmunity. Lichen sclerosus particularly affects the anogenital skin, and the vulval mucosa in women. The population prevalence is at least ≈ 1 per 1000 with a female:male ratio of at least 6:1; histologically, there is hydropic degeneration of basal keratinocytes with inflammatory changes (Dalziel and Shaw, 2010). The evidence for autoimmunity specified by Oyama et al. (2003) includes familial occurrence, association with the class II HLA allele DQ7 as seen in other mucus membrane/pemphigoid diseases, and co-occurrence with other autoimmune diseases and/or autoantibodies, mainly of the “thyrogastric” cluster, i.e., thyroiditis, pernicious anemia, diabetes, vitiligo, and others, but better immunological data on these disease associations are called for.

Previous findings of “pemphigoid” autoantibodies in skin diseases with basement membrane pathology (see Chapter 65) led a search for analogous autoantibodies to extracellular matrix protein 1 (ECM1) in lichen sclerosus (Oyama et al., 2003). The autoantigen ECM1 was chosen based on the observation that loss-of-function mutations of the gene encoding ECM1 result in a lichen sclerosus-like pathology (lipoid proteinosis, LP). The sera studied were from 86 patients with lichen sclerosus, 85 healthy controls, and 107 “other disease” contrast cases, and the technical procedures included Western immunoblotting (WB) on extracts from normal skin and LP skin that lacks ECM1, and indirect immunofluorescence (IIF) microscopy using affinity purified IgG. In brief, there was a specific signal for anti-ECM1 from lichen sclerosus sera by WB (to the low titer of 1:20), absence of signal using extracts from LP skin lacking ECM1, and specific reactivity by IIF of affinity-purified serum IgG with the basal keratinocyte layer of normal skin. Passive transfer of lichen sclerosus lesions to mice by serum or IgG was a contemplated next step.

LYMPHOCYTIC MASTITIS

The female breast is subject to a non-neoplastic multinodular fibrosing disease expressed clinically by recurrent mastalgia, and histologically by periductular lymphocytic infiltrations. An early report described the case of a woman with a multisystem-like disease in whom there were dense collections of lymphoid cells within diseased breast tissue, with underlying autoimmunity thus implicated (Shelley and Hurley, 1960), but the idea of an

“autoimmune mastitis” was not picked up. The disease (or diseases) characterized by lymphocytic mastitis has acquired several descriptors, granulomatous mastitis—although giant multinuclear cells are actually inconspicuous (Donn et al., 1994), diabetic mastopathy by reason of a frequent association with clinical diabetes (Tomaszewski et al., 1992; Camuto et al., 2000), fibrocystic mastitis, and some cases classed as IgG4 mastitis (Ogura et al., 2010). Lymphocytic mastitis may represent an immunological response to extruded breast milk, or to acinar or ductular breast tissue, but immunocytological examination of the characteristic lymphocytic infiltrates has received rather little attention, so the condition remains “idiopathic.”

METABOLIC—GENETIC STORAGE DISEASES

Batten disease is a rare, recessively inherited, and fatal neurodegenerative disease of children due to a mutation in both copies of a gene *CLN3*, so leading to accumulation of ceroid lipofuscin in neurons. A gene-disruption model in mice revealed altered expression of enzymes required for the synthesis of the neurotransmitter glutamate, and circulating antibodies to brain proteins including GAD65. This prompted a search for anti-GAD65 in human Batten disease, with positive results (Chattopadhyay et al., 2002). As yet, the role (if any) of anti-GAD in the overall pathogenesis of Batten disease is uncertain.

Sandhoff disease is another metabolic autoimmune curiosity. It is a recessively inherited lysosomal storage disease of infancy in which neuronal cell death results from an enzyme deficiency that causes accumulation of gm2 gangliosides in lysosomes of brain cells. A murine equivalent has been created by knockout of the *hexb* gene that encodes the hexosamidase enzyme. It is claimed that antiganglioside antibodies in Sandhoff disease accelerate premature neuronal death, perhaps via complexes of antibody and ganglioside that cause inflammatory activation of microglial cells. Similar events are postulated for the human counterpart (Yamaguchi et al., 2004).

MOVEMENT DISORDERS

A miscellaneous group of movement disorders, observed particularly in children, and sharing the features of an antecedent streptococcal infection, are claimed to have in common the expression of autoantibodies to neurons of basal ganglia in the brain. Prototypic among these is Sydenham’s chorea, marked by frequent unintended jerky movements, and long known to occur occasionally in association with streptococcal-related rheumatic carditis. Others include the Tourette syndrome of motor and vocal tics, and a pediatric autoimmune neuropsychiatric

disorder associated with streptococcal infections (PANDAS) (Shulman, 1999). Speculative extensions have brought in other entities including obsessive–compulsive and attention-deficit disorders. Autoimmunity has been implicated, but on rather slender evidence: (1) the claimed antecedent streptococcal infections that provide a reasoning for the occurrence of autoimmunity similar to that proposed for the onset of rheumatic carditis (see Chapter 69), (2) positive tests for antineuronal autoantibodies particularly to autoantigens of basal ganglia neurons, and (3) a claimed capacity of patients' sera to transfer disease passively after direct injection into the striatum of rats. However, the autoantibody studies are in earlier literature and have not been convincingly confirmed (reviewed by Dale, 2005), and the validity of the data on passive transfer to animals by serum is likewise questionable (Giovannoni, 2005).

NARCOLEPSY

Narcolepsy is a sleep–wake disorder with onset during adolescence in which there is irresistible daytime sleepiness. It is now confidently attributed to deficient neurotransmission dependent on a neurotransmitter that sustains wakefulness, known according to the discoverers as either hypocretin or orexin. Deficiency of this transmitter, synthesized by neurons in the hypothalamus, is the underlying fault—in canines with narcolepsy there is a profound loss of hypocretin-secreting neurons in the hypothalamus. *Prima facie*, narcolepsy would seem hardly likely as an autoimmune disease, yet there is a long-known extreme and puzzling co-association with the class II MHC allele, HLA DQB1*0602. Inconveniently for theorists, an autoantibody relevant to narcolepsy against hypocretin/orexin, or the cognate receptor, has not been demonstrated by conventional assays. However, some evidence for a serum factor was obtained by a bioassay based on passive transfer to mice of IgG from narcolepsy patients, by a readout of increased contractile responses of detrusor muscle strips (Smith et al., 2004); but these preliminary bioassay data would seem to require further work. There is a published personal account of a narcolepsy sufferer annotating the curious symptoms, together with comments on the occurrence of narcolepsy in inbred Doberman Pinscher dogs (although this is attributed to a genetically faulty cell receptor, see below), the extreme immunogenetic HLA D locus bias (DQ6//DQB1*0602 &/or DR2/DRB11501) and seasonal (spring-time) peak incidences suggesting an antecedent infection (Nicholls, 2012). Suspected infections include either H1N1 influenza, or streptococcal throat infection substantiated by raised levels in childhood narcolepsy of anti-streptolysin O, as implicated also in movement disorders of childhood described above.

A possible disease pathway can now be specified based on the interaction of hypocretin/orexin and the cognate receptor. The first hints in the 1990s came from the identification of hitherto unknown hormone-like agents in the brain of rats and mice, hypocretins/orexins, and one group further identified the structure of the orexin receptors (Sarkurai et al., 1998), although these authors directed their attention to the role of the orexin system in energy balance and eating behavior rather than sleep patterns. However, it was evident from other investigations that the hypothalamic cells that secrete hypocretin/orexin hormones provide also send “stay awake” messages to other cells in the CNS via the orexin-receptor pathway. Reliable detection of antibody or T cell reactivity to hypocretin/orexin or to the cognate receptor is still awaited. Meanwhile further immunogenetic and immunological anomalies have come to light (reviewed by Faraco and Mignot, 2011) and include polymorphism of the alpha chain of the T cell antigen receptor (Hallmayer et al., 2009), with three single nucleotide polymorphisms within the TCRA locus showing significant association with narcolepsy syndromes across various ethnic groups; another susceptibility locus is the gene for the P2RY11 purinergic receptor. There is an autoantibody association too, depending on the tribbles2 homolog protein (trib2), in 14–26% of DQB1 (cataplexy-associated) cases, but trib2 is a ubiquitously expressed protein, and there are no indications that antibodies to it are related to narcolepsy. One wonders how the story will eventually pan out!

OSTEOARTHRITIS

Osteoarthritis (OA) is prototypically a “degenerative” articular disease with usually a late-in-life onset and a relationship to articular stresses and previous trauma, but there can be an early inflammatory phase with an obviously acute onset. In tests for specificity of serological reactants used for the diagnosis of rheumatic diseases, i.e., autoantibodies to citrullinated peptides or native collagen type II (nCII), a degree of reactivity is usually observed. In regard to anti-nCII, Xiang et al. (2004) reported that sera from patients with osteoarthritis reacted more with denatured than with native CII, and Burkhardt et al. (2002) found that OA sera were reactive but, in contrast to rheumatoid arthritis (RA), sera engaged different antibody epitopes of nCII, notably CII-F4 located at the C-terminal region of nCII, rather than the characteristic RA-related epitopes, CII-C1 and CII-M2139. Interestingly, a murine anti-CII-F4 monoclonal antibody (mAb), in contrast to other mAbs reactive with specific epitopes of nCII, is not pathogenic on passive transfer in mice but actually inhibits the adverse effects (matrix disruption) of mAbs that do react with nCII epitopes other than F4 (Burkhardt et al., 2002). Xiang et al. (2004)

further found that those OA sera, as well as reacting with CII-F4, reacted with an antigen of different provenance, triose phosphate isomerase. In regard to pathogenicity, the capacity of autoantibodies to nCII to perpetrate articular damage remains an open question.

T lymphocytes have not been neglected in OA, according to a recent review by Sakkas and Platsoukas (2007). T cell infiltrates are demonstrable in the affected articular cartilage, and particularly in the synovial membrane, appearing as nodular aggregates suggestive of an antigen-driven process, although a provocative cartilagenous autoantigen has not so far been identified, despite much search and speculation. Curiously, erosive effects of cartilage/synovial inflammation associated with activated T lymphocytes infiltrating subchondral bone, as seen in rheumatoid arthritis, are not evident in OA. The T cells demonstrable in synovial membrane in OA are of the Th1 subtype and their activated phenotype is revealed by transcripts for cytokines such as IL-12, detectable in synovial fluid. Sakkas and Platsoukas (2007) discuss the utility of future procedures to assess the degree of clonality of T cell infiltrates in joints in OA.

However, while few of the conventional markers (particularly reactivity with an “accepted” autoantigenic structure) are fulfilled, it remains difficult to ascribe OA to an adaptive autoimmune response. In addition, results of a large (and latest) GWAS that included stratified cases of OA defined some eight candidate loci for association with OA, although none could be aligned with those often associated with autoimmune disease (*arcOGEN Consortium and arcOGEN Collaborators, 2012*).

Hence it is of interest to consider a new slant on the immunological contribution to OA, namely an inflammatory association with an anomaly of the complement cascade. Wang et al. (2011) found in mice that injury to articular cartilage in the setting of dysregulation of complement gene expression in joint tissues led to formation of the membrane attack complex (MAC) on chondrocytes, with either killing or production of matrix degrading enzymes, so linking OA to such age-related diseases as macular degeneration and Alzheimer’s disease. Possible applications of this concept to define subsets of human OA are awaited. This theme was developed in a recent review in which various components of innate immunity were implicated, without recourse to an adaptive response (Haseeb and Haqqi, 2013). So perhaps OA may be better placed in the category of autoinflammatory diseases (see Chapter 4).

PARATHYROID DISEASE

An autoimmune basis for hypoparathyroidism was proposed by Solomon and Blizzard (1963), and then by Seemann (1967), whose histological study revealed lymphocyte–plasma cell infiltrates—hence “lymphocytic

parathyroiditis.” In our first edition of this text, Maclaren and Blizzard (1985) described autoimmune polyendocrine syndrome (APS) types 1 and 2. For type 1 the three major components appeared usually in a uniform sequential order: candidiasis, hypoparathyroidism, and Addison’s disease. Autoimmune hypoparathyroidism, despite being a characteristic feature of APS type 1, did not occur in any of 224 cases of APS type 2. However, serological reactivity with parathyroid tissue was insufficiently convincing to generate clinical laboratory assays, although accompanying autoantibodies were reported to bind to the cell surface of human parathyroid cells and to inhibit parathyroid cell secretion. Perhaps these autoantibodies were related to those revealed by a monoclonal antibody raised by immunizing mice with parathyroid tissue and shown to react with a parathyroid cell surface antigen called PTA (Cance et al., 1986). An autoimmune basis was strengthened when Li et al. (1996) demonstrated, in both APS1-associated and sporadic cases of hypothyroidism, serological reactivity with the ubiquitous calcium-sensing receptor (Ca-SR) on the parathyroid cell surface; an immunoprecipitation assay showed that the extracellular domain of the Ca-SR contained the reactive epitopes. This autoimmune reactivity, anti-Ca-SR, was demonstrable in 56% of 25 cases and was far more frequent among females than males. Also, cases were recognized wherein antibodies to the parathyroid Ca-SR had an inactivating effect, so rendering the glands insensitive to ambient calcium, such that the ensuing oversecretion of parathyroid hormone had effects like those seen with parathyroid adenomas, causing hypocalciuric hypercalcemia (Pallais et al., 2004). These antibodies were functionally active but non-destructive, were of the IgG4 subclass, and in one case were associated with autoimmune pancreatitis, perhaps illustrating another facet of “IgG4 disease” (see Chapter 64). Thus the clinical expressions of autoimmune parathyroiditis with anti-Ca-SR reactivity may be either hypoparathyroidism if the antibodies are non-blocking as pertains when the glands are subject to lymphocytic-mediated destruction, or hyperparathyroidism if the antibodies are blocking and the glands retain functional activity.

In 2008 a novel autoimmune reactant was discovered by screening a cDNA expression library with serum samples from cases of APS type 1, identified as the NACHT leucine-rich-repeat protein 5 (NALP5) (Alimohammadi et al., 2008). These authors, in their Introduction, negated the role of other described autoantigens in parathyroiditis, although anti-Ca-SR reactivity in parathyroiditis had been well established in earlier studies (see Gavalas et al., 2007). The authors of the NALP5 study decisively showed that autoantibody was limited to cases of APS type 1 hypoparathyroidism with AIRE mutations, was not demonstrable in “isolated” (sporadic) hypoparathyroidism, and was detectable as a subcellular autoantigen only

in the chief and not the oxyphilic cells of the parathyroid gland. Still to come are studies on patterns of T cell reactivity to NALP5, and the relative contributions of defective thymic deletional tolerance versus Treg-mediated suppressive tolerance to this putative parathyroid autoantigen.

POLYCHONDRITIS, RELAPSING

Relapsing polychondritis (RP) was so named by [Pearson et al. \(1960\)](#) to designate recurring inflammatory damage to, and degradation of, (mainly) type II collagenous cartilage throughout the body ([Michet et al., 1986](#)). More particularly vulnerable is cartilage of nasal, auricular, tracheobronchial, and audiovestibular sites than is articular cartilage. However, there is a very wide distribution of lesions to non-cartilaginous sites, such as ocular sclera, heart valves, skin, and others, and therefore RP is called “an autoimmune disease with many faces” ([Lahmer et al., 2010](#)). There is clustering in some 30% of cases with one or another systemic autoimmune rheumatic disease, notably rheumatoid arthritis and SLE. Lymphoid cell accumulation is prominent at affected sites. There is a weak association with the MHC class II allele HLA DR4, and clear benefit accrues from prednisolone ([McAdam et al., 1976](#)). Thus polychondritis has most of the hallmarks of an autoimmune process.

Specific antibodies to cartilage were detected using IIF and cartilage substrate from mouse leg, or from human costochondral and tracheal cartilage, after preincubation with hyaluronidase to remove masking proteoglycan ([Dolan et al., 1976](#); [Foidart et al., 1978](#)). Autoantibodies were more readily detected in the acute stages, were of IgG class and non-complement-binding, and levels correlated with disease severity. Absorption exclusively with type II collagen removed reactivity with cartilage from serum. Using a direct immunofluorescence procedure, and serum from in a single case, [Bergfeld \(1978\)](#) detected deposits *in vivo* of IgG, IgA, and C3 in affected cartilage. In a subsequent study, positive results were reported in six of nine patients for antibodies to cartilage, and there was association with organ (thyroid)-specific autoantibodies as well ([Ebringer et al., 1981](#)). Assays for T cell-mediated immune responses to cartilage proved indecisive ([Foidart et al., 1978](#); [Ebringer et al., 1981](#)).

Reactivity of serum with type II collagen (CII) has been investigated in polychondritis. This was rather low by ELISA among Japanese patients, 202 with rheumatoid arthritis, 26 with polychondritis, and 92 with other rheumatic diseases, positivity being only 42%, 11%, and 0.3%, respectively ([Terato et al., 1990](#)). In tests using peptides derived by cyanogen bromide (CB) digestion of CII, polychondritis sera reacted preferentially with the CB 9.7 kDa peptide, unlike the anti-CII reactivity of sera

from other diseases, and the species of anti-CII antibody detectable in polychondritis lacked the epitope specificity of sera from patients with erosive articular inflammation ([Burkhardt et al., 2002](#)). However, subsequent studies have indicated that the primary reactant in polychondritis might not be CII, since reactivity of serum antibodies and T cells was greater with collagens IX and XII ([Yang et al., 1993](#)). Moreover, in NOD mice carrying a human HLA DQ1 transgene and immunized with CII, there developed an auricular chondritis that simulated the abnormality seen in human polychondritis, and sera reacted to CIX as well as CII ([Taneja et al., 2003](#)). Perhaps, then, in polychondritis, anti-CII occurs secondarily by epitope spreading.

The cartilage protein matrilin is another suggested autoantigen in polychondritis ([Hansson et al., 2004](#)). Matrilin is a cartilage-specific protein abundant at sites affected in polychondritis (trachea, ears) but sparse in sites that are spared (joints). A model of polychondritis induced in mice by active immunization with matrilin I showed that functional B cells and complement factor V were required for disease expression, and that passive transfer could be accomplished by a mAb to matrilin I suggesting that polychondritis, in this model at least, is essentially an antibody-mediated autoimmune disease ([Hansson et al., 2004](#)).

The disease itself, and in particular expressions of it, limit survival, e.g., after 10 years to 55%. Therapists have relied mainly upon corticosteroid drugs that are of variable efficacy, supplemented with the conventional immunosuppressives. Successful use of TNF antagonists is reported but in very limited case studies ([Lahmer et al., 2010](#)) and a recent review on the utility of biological therapies identified some benefits with the authors deploring the limitations of the data available ([Kempta Lekpa et al., 2012](#)).

PROSTATITIS

Aging men become afflicted by the urinary obstructive effects of benign prostatic hyperplasia due to prostatic cell proliferation. Often a component of inflammation is demonstrable histologically despite no evident infection. The question thus has arisen whether BPH is an “immune inflammatory disease” ([Kremer et al., 2007](#)), or even whether autoimmunity is implicated. From the earlier days, prostate-specific autoantigens were demonstrable by immunization of rabbits with a saline extract of prostate tissue that provoked an autoantibody response ([Shulman et al., 1965](#)) but histological data were not provided.

However, interest waned, as judged by a lapse in citations on inflammatory prostatitis even until the post-2000 era, according to [Penna et al. \(2009\)](#). These authors implicated stromal cells in the prostate as having the properties of immune accessory cells, i.e., antigen-presenting cells,

that induced expression of MHC class II molecules, costimulatory molecules and demonstrability of high levels of the two inter-related cytokines, IL-12p75 and IL-23p40, as well as other cytokines and chemokines characteristic of immunoinflammatory reactivity (see Chapter 22). Penna et al. (2009) also cited publications on the detection in semen from cases of chronic prostatitis of proinflammatory cytokines IL-6, IL-8, IL-1beta, and TNF-alpha, together with other data suggesting that products of immunoreactive cells in the prostate foster chronic inflammation and prostate cell growth. A credible sequence for an autoimmune prostatitis would require a candidate prostate-specific autoantigen; among those cited is the controversial cancer marker, prostate-specific antigen (PSA). There is clearly more work needed, but considerations such as the high frequency of prostatitis among aging males and its dependency on hormonal influences leave open the idea of an autoimmune component to prostate disease in men.

SARCOIDOSIS

An early suspicion that sarcoidosis could have an autoimmune connection (Mackay and Burnet, 1963) proved not sustainable, although few other more credible pathogeneses have emerged. Epidemiological data implicate an environmental influence, with possible person-to-person transmission, or a shared response to a provocative transmissible agent (Newman et al., 1997).

The disease expressions depend on non-caseating granulomatous lesions in multiple sites—skin, lymph nodes, lung, liver or CNS, and pathogenicity depends either on inflammatory fibrosis as in the lungs, or pressure effects of lesions as in the CNS. The immune system is clearly implicated as judged by the Th1-directed granulomatous histopathology. Also, there is solid evidence from a comparative population study in Italy of co-association with other autoimmune diseases, notably autoimmune thyroiditis, although the strength of this association is questionable (Antonelli et al., 2006).

Ho et al. (2005) drew on the known Th1-biased CD4⁺ T cell response in sarcoidosis, together with possible involvement of the natural killer T (NKT) cell system. NKT cells are activated by glycolipid antigens presented by CD1 molecules on antigen-presenting cells (APCs) (Chapter 8). There is a particular class of CD1 (CD1d) that, after interaction with NKT cells with an invariant receptor (Va24/JaQ, paired with Vb11), can exert regulatory effects. Also, in mice at least, the CD1-restricted repertoire includes autoreactive T cells (Park et al., 2001). Ho et al. (2005) ascertained in sarcoidosis a deficiency (for unknown reasons) of Va24 NKT cells, with ensuing loss of their normal regulatory effect on CD1d-dependent reactivity. However, for sarcoidosis to be confidently

ascribed to autoimmunity, depletion of Va24 NKT cells would need to be associated with persistent stimulation of the Th1 T cell pathway by some endogenous autoantigen, for which the evidence is meager, at best.

INTRODUCTION

Research on purified cytokines started in the late 1970s following the development of technologies for analyzing minute amounts of proteins and producing recombinant cytokines, and was soon followed by reports of human autoantibodies against human cytokines in infections, cancer, and autoimmune diseases. Shortly thereafter, autoantibodies against the specific cytokines, IFN- α , IL-1 α , and IL-6 were reported in healthy normal humans, in various frequencies, probably reflecting differences in affinity and the sensitivity of the assay (Bendtzen et al., 2000). Neutralizing autoantibodies against a cytokine would be expected to be pathogenic by reducing the development of mature, differentiated cells or reducing activation of effector cells dependent on it, and if resistance to a certain pathogen is dependent on that cytokine, such autoantibodies might make the patient unusually susceptible.

Antibodies against cytokines that neutralize the bioactivity of the cytokine *in vitro* can block the biological action of the cytokine *in vivo* when present in high concentrations (Finkelman et al., 1993; Kawade et al., 2003). On the other hand, antibodies against cytokines in low concentrations can sometimes prolong their half-lives, which are typically short, by acting as carrier-proteins in the plasma and extracellular fluid. This may occur whether they neutralize the bioactivity of the cytokine (Finkelman et al., 1993; Boyman et al., 2006) or not (Rosenblum et al., 1985; Jones and Ziltener, 1993). Following the discovery of autoantibodies against cytokines in healthy humans, it was proposed that they might act as physiological regulators of cytokine action (Jeffes et al., 1989; Bendtzen et al., 1990; Ross et al., 1990; Hansen et al., 1995; van der Meide and Schellekens, 1997), but this notion is unproven.

The mechanisms that result in the formation of autoantibodies against cytokines are still poorly understood, and it is conceivable that autoantibodies against specific cytokines may have different etiologies and different biological consequences. We will explore some examples in the following section.

AUTOANTIBODIES AGAINST CYTOKINES IN HUMANS

Autoantibodies Against Type I and Type II Interferon

The first report of natural autoantibodies against cytokines was in 1981, when an aged woman with a varicella zoster infection was found to have autoantibodies against the type I interferon interferon-alpha (IFN- α) (Mogensen et al., 1981). A year later, neutralizing autoantibody against IFN- α was found in one out of six female patients with systemic lupus erythematosus (Panem et al., 1982),

and the following year it was noted that two cancer patients had natural autoantibodies against IFN- α (Trown et al., 1983). One report examined 200 sera from normal humans and all contained autoantibodies that neutralized the antiviral bioactivity against type I IFN (IFN- α and IFN- β) and type II IFN (IFN- γ) (Ross et al., 1990). The autoantibodies were also detectable in immunoglobulin pools. Autoantibodies against IFN- γ have been shown to be increased in viral infection but these did not neutralize the antiviral activity of IFN- γ (Caruso et al., 1990). Autoantibodies against IFN- α were found at high levels in 12/15 preparations of pharmaceutically prepared pooled IgG (Ross et al., 1995). The autoantibodies neutralized IFN- α and to a less extent IFN- β , but not IFN- γ .

Autoantibodies Against IL-1 α

Autoantibodies against another cytokine, IL-1 α , were found in the sera of 10% of healthy humans (Svenson et al., 1989) and 75% of people with autoimmune diseases (Hansen et al., 1991a). These autoantibodies against IL-1 α increased with age (Ohmoto et al., 1997). High affinity autoantibodies against IL-1 α that neutralized the bioactivity of IL-1 α were also found in pharmaceutically prepared immunoglobulin pools (Svenson et al., 1993).

The first human monoclonal autoantibody against a cytokine was immortalized with Epstein–Barr virus from a human who had high levels of autoantibodies against IL-1 α (Garrone et al., 1996). This monoclonal autoantibody specifically recognized and neutralized the bioactivity of IL-1 α but did not recognize IL-1 β or IL-1 receptor antagonist (IL-1RA). It was found to be somatically mutated and bound with high affinity ($K_d = 1.2 \times 10^{-10}$ M).

Autoantibodies Against Tumor Necrosis Factor (TNF)

Autoantibodies against TNF and against lymphotoxin have been found in healthy humans and it was speculated that these autoantibodies might be therapeutic in certain diseases (Jeffes et al., 1989). Autoantibodies against TNF that were affinity purified from a patient with rheumatoid arthritis neutralized the bioactivity of TNF in a tumor cell killing assay (Sioud et al., 1994). However, no high-affinity, neutralizing autoantibodies against TNF were observed in batches of pharmaceutically prepared immunoglobulin prepared from normal healthy humans (Svenson et al., 1993; Wadhwa et al., 2000).

Autoantibodies Against IL-6

Hansen et al. (Hansen et al., 1991b) found autoantibodies against IL-6 in about 10% of healthy humans. The autoantibodies were polyclonal, and two IgG molecules could

bind to one IL-6 molecule. In another study, autoantibodies against IL-6 were found in 9/52 patients with systemic sclerosis, whereas $\approx 2\%$ of normal people or 0–5% of people with rheumatoid disease exhibited autoantibodies against IL-6 (Takemura et al., 1992). The difference in incidence in normal people between these two studies (10% versus 2%) presumably reflects differences in sensitivity of the assays used. Autoantibodies against IL-6 that inhibited the bioactivity of IL-6 and bound to IL-6 with high affinity have been found in pharmaceutical human immunoglobulin preparations (Svenson et al., 1993).

Autoantibodies against Granulocyte-Macrophage Colony-Stimulating Factor

Autoantibodies against granulocyte-macrophage colony-stimulating factor (GM-CSF) were found in 5 of 300 normal humans (Ragnhammar et al., 1994). Later, autoantibodies against GM-CSF were found in pharmaceutically prepared pooled immunoglobulin (Svenson et al., 1998). All batches of pharmaceutically prepared pooled immunoglobulin contained detectable autoantibodies against GM-CSF, but when 1258 single plasma samples were tested only four were positive. The fact that the antibodies were detectable when diluted by a factor of about 300 (1258/4) suggests that the titer in the four positive samples must have been quite high. The authors also demonstrated that circulating autoantibodies against GM-CSF were detectable in the patients treated with a batch of immunoglobulin. Another group has also demonstrated that autoantibodies against GM-CSF in pharmaceutically prepared pooled immunoglobulin neutralized the bioactivity of GM-CSF (Wadhwa et al., 2000).

The largest panel of pathogenic human monoclonal autoantibodies against cytokines so far described is that cited in our recent publication which documented 19 monoclonal autoantibodies against GM-CSF from six patients with idiopathic pulmonary alveolar proteinosis (IPAP) (Wang et al., 2013). The monoclonal autoantibodies against GM-CSF were genetically unrelated, with multiple clonotypes in individual patients. The characteristics of these antibodies will be discussed later in this chapter.

PATHOGENICITY OF AUTOANTIBODIES AGAINST CYTOKINES—GENERAL COMMENTS

Formal evidence that autoantibodies against cytokines are pathogenic (Sakagami et al., 2009) exists only for the rare autoimmune disease IPAP (Kitamura et al., 1999; Trapnell et al., 2009), although there is also strong evidence that autoantibodies against erythropoietin can cause pure red aplasia (Casadevall et al., 1996). There is

suggestive evidence that autoantibodies to various cytokines are pathogenic in specific infectious diseases (Browne and Holland, 2010a,b; Burbelo et al., 2010; Kisand et al., 2010; Puel et al., 2010; Kampitak et al., 2011; Browne et al., 2012a).

Most pathogenic autoantibodies against cytokines occur against a single cytokine, such as autoantibodies against GM-CSF in IPAP (Kitamura et al., 1999), or against erythropoietin in pure red aplasia (Casadevall et al., 1996), or autoantibodies against IFN- γ (Browne and Holland, 2010a). In patients with IPAP, there are autoantibodies against GM-CSF but not autoantibodies against IFN- α or against IFN- γ (Burbelo et al., 2010). There are reports of autoantibodies against IFN- γ in humans with non-tuberculous mycobacterial infections, but those patients exhibited no autoantibodies against IFN- α (Burbelo et al., 2010).

However, autoantibodies against clusters of cytokines have been documented. Patients with APECED/APS-1 had autoantibodies against IFN- α , IL-17A, IL-17F, and IL-22 but not against other cytokines like IL-10, IL-18, or transforming growth factor beta (TGF- β) (Kisand et al., 2010; Puel et al., 2010). A patient with a thymoma and chronic mucocutaneous candidiasis had similar findings (Kisand et al., 2010). A second report described patients with thymoma who had autoantibodies against IFN- α but no autoantibodies against IFN- γ or GM-CSF (Burbelo et al., 2010).

Autoantibodies Against GM-CSF Cause Idiopathic Pulmonary Alveolar Proteinosis

Idiopathic pulmonary alveolar proteinosis (IPAP) is a lung disease caused by the accumulation of surfactant protein in the alveoli leading to severe respiratory distress (Trapnell et al., 2009). The role of GM-CSF in the syndrome was first documented in mice in which the GM-CSF gene had been disrupted (Dranoff et al., 1994; Stanley et al., 1994), but in humans this is caused by autoantibodies that neutralize the bioactivity of the GM-CSF (Kitamura et al., 1999; Tanaka et al., 1999; Uchida et al., 2003), although congenital cases of pulmonary alveolar proteinosis are caused by mutations in the GM-CSF receptor (Trapnell et al., 2009).

The bioactivity of GM-CSF is necessary for the proper maturation of alveolar macrophages, which normally catabolize surplus surfactant in the alveoli (Stanley et al., 1994; Nishinakamura et al., 1995). Formal proof of the role of autoantibodies to GM-CSF was obtained by transfer of affinity-purified autoantibodies to GM-CSF from patients suffering from IPAP into non-human primates, which caused the development of the characteristic features of IPAP, including milky bronchoalveolar lavage

(BAL) fluid, increased concentration of surfactants in BAL fluid and serum, and increased pulmonary leukocytosis (Sakagami et al., 2009).

Additional evidence that the IPAP is caused by a deficiency in the bioactivity of GM-CSF is amelioration of IPAP by GM-CSF nebulized into the lungs or delivered systemically (Bonfield et al., 2002; Seymour et al., 2003). The disease is also ameliorated by reducing the concentration of autoantibodies against GM-CSF by plasmapheresis (Luisetti et al., 2009) or the anti-CD20 monoclonal antibody rituximab (Borie et al., 2011).

Autoantibodies against GM-CSF have also been implicated in Crohn's disease (Han et al., 2009) but in contrast, antibodies against GM-CSF were found to ameliorate a mouse model of colitis (Griseri et al., 2012). Autoantibodies against GM-CSF have also been implicated in opportunistic infection in IPAP (Browne and Holland, 2010a).

Autoantibodies Against Erythropoietin Cause Pure Red Cell Aplasia

Pure red cell aplasia is often associated with thymomas, and is cured in a quarter of cases by thymectomy (Jacobs et al., 1959). The reason remained obscure until 1967, when an inhibitor of erythropoiesis was discovered in the plasma of patients with pure red aplasia (Krantz and Kao, 1967). It is now clear that the inhibitor consisted of autoantibodies to erythropoietin (Casadevall et al., 1996).

Very rarely, patients treated with human recombinant erythropoietin make antibodies against both human recombinant erythropoietin and endogenous erythropoietin, producing pure red aplasia (Casadevall et al., 2002). Supporting evidence that autoantibodies against erythropoietin cause pure red cell aplasia comes from reports that rituximab, which depletes B lymphocytes, ameliorates pure red cell aplasia (Behler et al., 2009).

Autoantibodies Against IFN- γ Cause Mycobacteria Infections

There is suggestive evidence that autoantibodies to IFN- γ are pathogenic. Patients who had autoantibodies to IFN- γ were susceptible to disseminated *Mycobacterium tuberculosis* and *Mycobacterium chelonae* infections (Madariaga et al., 1998; Doffinger et al., 2004). Autoantibodies to IFN- γ were also associated with severe infections with *Burkholderia cocovenenans* and *Mycobacterium chelonae* (Hoflich et al., 2004). Patients with autoantibodies to IFN- γ who had infections with non-tuberculous mycobacteria and who were treated with rituximab resolved their infections and inflammation in parallel with reduction in autoantibodies to IFN- γ (Browne et al., 2012b).

Chi et al. found that patients with autoantibodies against IFN- γ had a higher frequency of the HLA alleles DRB1*16:02 and DQB1*05:02 (Chi et al., 2013), and suggested that these MHC class II polymorphisms permitted the formation of T cell epitopes that cross-reacted between the peptide of a hypothetical pathogen antigen and peptides from IFN- γ .

Autoantibodies Against IL-17A, IL-17F, and IL-22 Correlate with Mucocutaneous Candidiasis in Autoimmune-Polyendocrinopathy-Candidiasis-Ectodermal Dystrophy

Many subjects with autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) suffer from chronic mucocutaneous candidiasis. Th17 cells produce IL-17 family members, IL-22, GM-CSF, and TNF and can damage or protect in autoimmune disease (Gaffen, 2011; Iwakura et al., 2011; Marwaha et al., 2012). In APECED, autoantibodies against IL-17A, IL-17F, and IL-22 strongly correlated with candidiasis (Kisand et al., 2010; Puel et al., 2010). Kisand et al. (2010) reported that there were reduced numbers of cells that synthesized IL-22 and IL-17F in APECED patients with chronic mucocutaneous candidiasis. They speculated that cell-mediated attack on Th17 subsets, perhaps by antibody-dependent cellular cytotoxicity reactions or by T cells, could produce a deficiency of IL-22 and IL-17F.

Opportunistic Infections in Patients with a Thymoma

Patients with opportunistic infections with a thymoma were found to have autoantibodies against 16 of 39 cytokines tested (Burbelo et al., 2010). The autoantibodies blocked *in vitro* the bioactivity of IFN- α , IFN- β , IL-1 α , IL-12p35, IL-12p40, and IL-17A. Kisand et al. (Kisand et al., 2010) found autoantibodies against IL-17 and IL-22 in two patients with thymoma that had chronic mucocutaneous candidiasis, but they did not find autoantibodies against IL-17 and IL-22 in 33 patients with a thymoma without chronic mucocutaneous candidiasis. This is suggestive evidence that autoantibodies against IL-17 and IL-22 patients with a thymoma cause chronic mucocutaneous candidiasis.

Autoantibodies Against the Bioactivity of Osteoprotegerin

Osteoprotegerin is a member of the TNF receptor family but it is secreted and acts like a cytokine. Osteoprotegerin is the decoy receptor which binds and thereby opposes RANK ligand, another cytokine which activates

osteoclasts and causes bone resorption (Riches et al., 2009). One report contains suggestive evidence of pathogenic autoantibodies against osteoprotegerin that cause osteoporosis (Riches et al., 2009). The patient was found to have neutralizing autoantibodies against the bioactivity of osteoprotegerin (Riches et al., 2009). A further 3/15 patients with celiac disease had autoantibodies against osteoprotegerin but none of the healthy controls had autoantibodies against osteoprotegerin (Riches et al., 2009).

Autoantibodies Against IL-8

Autoantibodies against IL-8, a chemokine, were reported in BAL fluid in adult respiratory distress syndrome (Kurdowska et al., 1996). The autoantibodies against IL-8 were high affinity and blocked IL-8 binding to its receptor. Autoantibodies against IL-8 have also been reported in heparin-associated thrombocytopenia (Amiral et al., 1996) and in association with ovarian cancer (Lokshin et al., 2006).

Autoantibodies Against IL-1 α

Autoantibodies that neutralized the bioactivity of IL-1 α have been believed to ameliorate disease in rheumatoid arthritis (Graudal et al., 2002; Miossec, 2002) and chronic polyarthritis (Jouvenne et al., 1997), but the entire role of IL-1 α in arthritis is still unknown.

Autoantibodies Against IL-6

It has been suggested that patients with alcoholic cirrhosis had more infections and a higher risk of death if they had autoantibodies against IL-6 (Homann et al., 1996). A child with staphylococcal cellulitis and abscesses was found to have high titers of autoantibodies that neutralized the bioactivity of IL-6 (Puel et al., 2008).

What Is the Therapeutic Benefit of Autoantibodies against Cytokines from Pharmaceutically Prepared Immunoglobulin?

Most batches of pharmaceutically prepared immunoglobulin had detectable amounts of antibodies against GM-CSF (Svenson et al., 1998), IL-1 α (Svenson et al., 1993), IL-6 (Svenson et al., 1993), IFN- α (Ross et al., 1990, 1995), IFN- γ (Ross et al., 1990), and IL-10 (Svenson et al., 1998). High-affinity, neutralizing autoantibodies against cytokines were found in pharmaceutically prepared IgG against IL-1 α , IFN- α , IL-6 (Svenson et al., 1993), and against GM-CSF (Svenson et al., 1998), but no high-affinity, neutralizing autoantibodies against IL-1 β or TNF were observed (Svenson et al., 1993). Wadhwa et al. (2000) also demonstrated that batches of immunoglobulin neutralized the bioactivity of IL-1 α and IFN- α ,

IFN- β , and IFN- ω . They found no neutralizing autoantibodies to granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), stem cell factor (SCF), IL-1 β , IL-2, IL-3, IL-4, IL-6, IL-9, IL-10, IL-12, TNF, oncostatin M, or IFN- γ (Wadhwa et al., 2000).

Svenson et al. (1998) also tested pharmaceutically prepared immunoglobulin for other autoantibodies against other cytokines, including G-CSF, IL-1RA, IL-2, IL-3, IL-4, IL-5, and IL-10. Only one batch tested positive for high-avidity autoantibodies against IL-5 and 13/15 batches bound weakly to IL-10, agreeing with Menetrier-Caux et al. that there exist rare autoantibodies to IL-10 (Menetrier-Caux et al., 1996).

In the light of all these observations, the suggestion was made that some of the therapeutic benefit of treating humans with pharmaceutically prepared immunoglobulin (intravenous immunoglobulin: ivIg) could be due to autoantibodies against certain cytokines (Svenson et al., 1993; see also Bendtzen et al., 2000). Patients with autoimmune diseases treated with human IgG preparations had higher titers of autoantibodies against IFN- α , IL-1 α , IL-6 (Ross et al., 1997), and GM-CSF (Svenson et al., 1998). It is unclear whether these antibodies had any effect on the disease. It seems unlikely that they were present in sufficient amounts to give therapeutic effects, and the question addressed by Svenson et al. (1993) is probably answered in the negative.

ARE ANTI-CYTOKINE AUTOANTIBODIES AGAINST A RANGE OF CYTOKINES IN ALL HEALTHY HUMANS?

Early studies reported that significant numbers of healthy humans have autoantibodies against IL-1 α (10%) (Svenson et al., 1989), IFN- α , IFN- β , and IFN- γ (100%) (Ross et al., 1990), IL-6 (10%) (Hansen et al., 1991b), and GM-CSF (0.3–1.7%) (Ragnhammar et al., 1994; Svenson et al., 1998). Neutralizing autoantibodies against cytokines were also found in pharmaceutically prepared immunoglobulin pools, IFN- α , IFN- β , and IFN- γ (Ross et al., 1990), IL-1 α (Svenson et al., 1993), IL-6 (Svenson et al., 1993), and GM-CSF (Svenson et al., 1998; Wadhwa et al., 2000).

More recently, it was reported that all of 15 healthy humans had autoantibodies against IL-2, IL-8, TNF, vascular endothelial growth factor (VEGF), and G-CSF (Watanabe et al., 2007). These authors dissociated autoantibody complexes with cytokine by treating the sera with low pH buffer (pH 2.7), separated the cytokines from autoantibodies by size, and measured the separated autoantibodies by ELISA (Watanabe et al., 2007).

Autoantibodies against IL-4, IL-6, IL-10, and IFN- γ were at a lower frequency and there were no autoantibodies against IL-3, osteopontin, and macrophage-colony stimulating factor (CSF-1) (Watanabe et al., 2007).

The same group also reported a surprisingly high incidence and concentration of autoantibodies against GM-CSF in 72/72 healthy humans, once again using the technique of acid treatment (Uchida et al., 2009). They also found extremely high concentrations of the total GM-CSF concentration in normal plasma, 99.9% of which was bound by neutralizing autoantibodies against GM-CSF, and concluded that autoantibodies against GM-CSF can scavenge free GM-CSF and thereby block myeloid functions. They calculated the levels of autoantibodies against GM-CSF that correlated with pathogenesis and the onset of IPAP, and concluded that the difference between healthy individuals and IPAP patients was a pathogenic increase in levels of autoantibodies against GM-CSF rather than a novel autoantibody response.

For many reasons, we believe that these results should be regarded with caution. The concentration of GM-CSF complexed with autoantibodies claimed in normal plasma in these studies was surprisingly high, but paradoxically its free concentration was so low that it would be totally inactive. Moreover, protocols in which serum is treated with acid and neutralized have received substantial criticism on many grounds (Bazin et al., 2010; Meager et al., 2010; see also response by Uchida et al., 2010). In particular, acid treatment has been well documented to cause partial degradation of specificity, presumably due to incomplete refolding or chemical modification. It is also well known that treatment of antibodies by acid and subsequent neutralization results in the formation of aggregates (Goding, 1996) which can cause substantial errors in ELISA and other assays.

If Watanabe and his colleagues are correct that there are autoantibodies against all of these cytokines, GM-CSF, IL-2, IL-8, TNF, VEGF, and G-CSF in healthy humans, then these could be assayed by different techniques, rather than using low pH buffer to separate the autoantibodies/cytokine complexes. An alternative assay is to measure the frequency of memory B autoantibodies specific for these cytokines when memory B cells from peripheral blood are polyclonally activated (Wen et al., 1987; Pinna et al., 2009) at limit dilution. Autoantibodies against each cytokine could be measured by ELISA and the frequency calculated by Poisson's distribution. If there is an ongoing autoantibody response, the high-affinity memory B cells specific for these cytokines will be in the lymph nodes and not in the peripheral blood. Another assay would be to test the plasmablasts in the blood (Odendahl et al., 2005) or bone marrow plasma cells that are secreting autoantibodies against cytokines by an Elispot assay.

ANALYSIS OF A PANEL OF NEUTRALIZING MONOCLONAL ANTIBODIES TO GM-CSF

The Advantage of Studying Monoclonal Autoantibodies with Natural and Authentic H and L Chain Pairing

It is generally accepted that at least for B cells, most autoimmune reactions are polyclonal. Accordingly, the analysis of autoantibodies from serum is fraught with the difficulties of dealing with a poorly defined chemical mixture. Moreover, the assessment of the nature, origin, and importance of serum autoantibodies to cytokines depends greatly on the sensitivity and specificity of the assays used, and published results have shown marked variation between investigators. Phage-display monoclonal antibodies have been generated from peripheral blood mononuclear cells with H and L chain genes from many autoimmune diseases. However, the data are compromised because random pairs of H and L chain genes have been selected with autoantigens. Multiple monoclonal antibodies with authentic H and L chains that bind to autoantigens would have many advantages. Monoclonal antibodies that have authentic H and L chain pairs are pure, chemically defined entities and their V genes can be sequenced and somatic mutations identified with ease. If they use multiple V genes rather than preferred V genes and consist of multiple clonotypes, epitope mapping can determine whether they bind to multiple non-overlapping epitopes.

Pathogenic monoclonal autoantibodies should take the analysis of autoimmunity to a higher level of precision and may shed light on some central questions. Does B cell tolerance to cytokines exist? Are autoantibodies driven by antigen? If so, are they driven by their self-antigen or the cytokine, or are they initiated and perpetuated by a cross-reacting exogenous antigen? And what can monoclonal antibodies tell us about the role of helper T cells in autoantibody generation?

We have generated a panel of 19 anti-GM-CSF-secreting cell lines from six patients with IPAP and have used them to conduct a detailed characterization of clones secreting autoantibodies to GM-CSF (Wang et al., 2013). Our results may help in the understanding of the origin of pathogenic autoantibodies in general.

The Autoantibodies Against GM-CSF were all Polyclonal, Excluding a "Forbidden B Cell Clone"

The monoclonal autoantibodies against GM-CSF were polyclonal and genetically unrelated. Multiple clonotypes against GM-CSF existed in different patients with IPAP,

excluding a single “forbidden” clone for pathogenic autoantibodies in one patient (Burnet, 1972; Mackay, 2008).

No Preferred V-gene Usage in Autoantibodies to GM-CSF

There is no suggestion of preferred V-gene usage in autoantibodies to GM-CSF (Wang et al., 2013). Monoclonal pathogenic autoantibodies with authentic H and L chains that bind to desmoglein-3 and cause pemphigus vulgaris also had no preferred V-gene usage (Di Zenzo et al., 2012). In contrast, monoclonal autoantibodies against transglutaminase-2 that are diagnostic for celiac disease use preferred V genes (Di Niro et al., 2012).

Multiple Epitopes Recognized by Pathogenic Monoclonal Autoantibodies to GM-CSF

The pathogenic monoclonal autoantibodies against GM-CSF bound to four non-overlapping, conformational epitopes on GM-CSF and one that overlapped two of the non-overlapping epitopes (Wang et al., 2013). There were at least three non-overlapping epitopes in two patients with IPAP.

All 19 monoclonal autoantibodies against GM-CSF from IPAP patients were conformational and dependent on the native structure. None of the autoantibodies against GM-CSF bound to reduced, boiled GM-CSF on an immunoblot (Wang et al., 2013), and all neutralized the bioactivity of GM-CSF (Wang et al., 2013).

B cell epitopes are conformational and depend on the three-dimensional structure of the protein. The area buried in a protein–antibody complex is 600–935 square Å (Laver et al., 1990), and although it can only be determined through direct crystallography (Laver et al., 1990), a great deal of useful information can be obtained by combining molecular modeling based on known structures with site-directed mutagenesis and physico-chemical analysis.

Mechanism of Pathogenicity of Monoclonal Autoantibodies to GM-CSF

All autoantibodies to GM-CSF neutralized the bioactivity of GM-CSF (Wang et al., 2013) but they bound to five epitopes. How did each monoclonal autoantibody to GM-CSF block the signaling of GM-CSF? The signaling complex of the GM-CSF:GM-CSF receptor is a dodecamer and contains four GM-CSF molecules, four GMR α and four β c subunits (Hansen et al., 2008). The fraction of the total surface area of GM-CSF buried by the GMR α is 19%. The one molecule of the GM-CSF in the signaling complex interacts with two β c subunits, domain 1 of β c

and domain 4 of a different β c monomer. The total surface area of GM-CSF buried by domain 1 of β c is 4% and the total surface area of GM-CSF buried by domain 4 of a different β c is 7% (Wang et al., 2013). The total surface area of GM-CSF buried by the ternary complex is \approx 30 %.

In view of their neutralizing activity, we hypothesized that these autoantibodies against GM-CSF bound to the surfaces of GM-CSF that bind to the GM-CSF receptor subunits, the GM-CSF receptor alpha (GMR α) and two binding sites on different beta common (β c) subunits. Using site-directed mutagenesis of GM-CSF, we were able to map two non-overlapping receptor-binding epitopes, one that interacted with the α subunit of the GM receptor, and the second that interacted with the β c subunit. The potential for steric hindrance by autoantibodies binding GM-CSF is great because the signaling GM-CSF:GM-CSF receptor complex contains 12 proteins, four GM-CSF molecules, four GMR α molecules, and four GMR β c molecules.

There was an overall correlation between affinity/off-rate and the potency of neutralizing the bioactivity of GM-CSF, but the highest-affinity autoantibody against GM-CSF was not the most potent at neutralizing the bioactivity of GM-CSF (Wang et al., 2013). The autoantibody against GM-CSF that was most potent at neutralizing the bioactivity of GM-CSF bound to an overlapping epitope that spanned the two non-overlapping epitopes (Wang et al., 2013).

Inhibitory Activity Is Strengthened by Formation of Stable High-avidity Complexes Comprising Multiple Antibodies Binding to Multiple Epitopes

Although GM-CSF is a monomer, IgG is bivalent, and it has been shown that two different IgG molecules can bind to distinct epitopes on two cytokine molecules to form a circular complex, with each cytokine bound by two non-overlapping epitopes (Moyle et al., 1983). If one antigen-binding site of the IgG dissociates from the cytokine and the other arm of IgG is still bound to the same epitope on another cytokine of the circular autoantibody–cytokine complex, the antigen-binding site of the IgG will be in high molar local concentration and will therefore probably reassociate. Thus, if autoantibodies against cytokines bind to multiple epitopes, multiple molecules of the cytokine and autoantibodies are likely to form high-avidity complexes (Moyle et al., 1983). Hansen et al. (Hansen et al., 1991b) found that in healthy humans, two IgG autoantibodies against IL-6 could bind to one IL-6 molecule.

We have shown that three individual IgG molecules could bind a single molecule of GM-CSF (Wang et al., 2013), and the probability of cytokine bound by three

immunoglobulin molecules dissociating will be small; accordingly the free cytokine concentration will be low.

Somatic Mutation of Autoantibodies to GM-CSF

Affinity maturation of IgG antibodies in secondary responses requires T cell help, and is mediated by passage through germinal centers, somatic hypermutation, and Darwinian selection based on competition for antigen on follicular dendritic cells (Nossal, 1992). A high-affinity human monoclonal autoantibody against IL-1 α in a healthy human showed evidence of somatic mutations (Garrone et al., 1996).

All the autoantibodies against GM-CSF exhibited high levels of somatic mutation (Wang et al., 2013), indicating T cell help and passage through germinal centers. We observed a high number of somatic mutations in the *IGHV* gene and the *IGKV* and *IGLV* genes (Wang et al., 2013). The median rate of somatic mutations in *IGHV* was 30, compared with typical observed rates for memory B cells and germinal center B cells of 13.6 ± 4.8 (Wrammert et al., 2008). The highest number of somatic mutations in *IGHV* of all of the autoantibodies against GM-CSF was 52 and correlated with the highest affinity antibody, which had a K_d of 3.7×10^{-11} (Wang et al., 2013), indicating that memory B cells had probably re-entered the germinal center many times. This is confirmed by the high levels of somatic mutations found in monoclonal pathogenic autoantibodies with authentic H and L chains that bind to desmoglein-3 in pemphigus vulgaris (Di Zenzo et al., 2012). It may be concluded that these two pathogenic classes of monoclonal autoantibodies need the help of follicular helper T cells.

Is Antibody Autoreactivity a Consequence of Somatic Mutation?

It seems virtually inevitable that some somatic mutations that increase affinity for exogenous antigens will by chance react with self-antigens, but the crystallographic studies of somatically mutated antibodies show that affinity-matured antibodies are very different from germline antibodies. In a germline antibody the CDR loops are flexible and the antigen-binding site or paratope has a diversity of conformations, and the single paratope is to a degree polyspecific, binding many antigens (Manivel et al., 2000). Since only one of these conformations is likely to bind to a single antigen, the association rate of a germline antibody to bind to a single antigen is low. If a germline antibody binds to a single antigen and the paratope is thereby locked in a single conformation, there is a big entropy reduction because there is a loss of freedom

for the CDR loops (Manivel et al., 2000). In contrast, in an affinity-matured antibody, the CDR loops are less flexible, supported by somatic mutations, the antigen-binding site is more rigid, and the association rate may be higher—the affinity-matured antibody interaction with antigen is like a lock and key rather than a handshake. In addition, of course, affinity-matured antibodies show greatly decreased dissociation rates.

Conformational freedom of germline CDRs is likely to account for the observation that 55–75% of the expressed recombinant antibodies from early immature B cells bind to self-antigens (Wardemann et al., 2003). Many of the early immature B cells that are self-reactive are purged and only a small fraction of the expressed recombinant antibodies from mature naïve B cells bind to intracellular self-antigens in human Hep-2 cells, although about 47% of expressed recombinant somatically mutated antibodies from IgG memory B cells from healthy humans showed low levels of self-reactivity with intracellular antigens of HEp-2 cells (Tiller et al., 2007). It is concluded that affinity-matured antibodies that react with intra-cellular self-antigens are low affinity and non-pathogenic. The same group subsequently showed that there is a reduced frequency of plasma cells in the bone marrow that make antibodies that react with HEp-2 cells, although plasma cells had higher somatic mutation rates than IgG memory B cells (Scheid et al., 2011).

Di Zenzo et al. proposed that the pathogenic autoantibodies that bind to desmoglein-3 and cause pemphigus vulgaris were initiated by an unrelated exogenous antigen that started the affinity-maturation process, and fortuitous somatic mutations made the antigen-binding site react with desmoglein-3 (Di Zenzo et al., 2012). However, the authors observed that the autoantibodies bound to at least three to four non-overlapping, conformational epitopes on desmoglein-3 (Di Zenzo et al., 2012). The probability that chance somatic mutations against an unrelated exogenous antigen would create multiple unrelated clonotypes binding to multiple conformational epitopes seems vanishingly small. Two crystallographic studies (Thomson et al., 2008; Schmidt et al., 2013) showed that the antigen-binding site of germline antibodies and affinity-matured antibodies has the same general conformation and it is unlikely that fortuitous somatic mutations of an affinity-maturation process initiated by a single antigen could change the general conformation of the antigen-binding site.

Could Autoantibodies Arise in Response to a B Cell Epitope on a Pathogen Antigen that Mimics a Self-antigen GM-CSF?

It has been suggested that autoantibodies might arise in response to a B cell epitope on a pathogen-associated

antigen that mimics a self-antigen (Rowley and Jenkin, 1962). This scenario might envisage a pathogen antigen that cross-reacts with GM-CSF initiating an antibody response which is followed by GM-CSF-driven affinity-maturation via somatic mutations. However, crystallography has demonstrated that a low-affinity, unmutated antigen-binding site has the same general conformation as the high-affinity somatically mutated antibody and has similar antigen contacts (Thomson et al., 2008; Schmidt et al., 2013). Accordingly, the B cell epitope of the pathogen antigen cross-reacting with GM-CSF must overlap the original epitope of the pathogen antigen, but our monoclonal autoantibodies against GM-CSF bound to four non-overlapping, conformational epitopes on GM-CSF, with at least three non-overlapping epitopes in two patients with IPAP. It would therefore seem very improbable that antigens from a pathogen could mimic three to four non-overlapping, conformational B cell epitopes on GM-CSF.

AUTOANTIBODIES TO GM-CSF: IMPLICATIONS FOR B CELL TOLERANCE TO CYTOKINES

General B Cell Tolerance

Contact with self-antigens early in B cell development leads to cell death (Hartley et al., 1993), anergy (Glynne et al., 2000; Zikherman et al., 2012), or receptor editing (Nemazee and Hogquist, 2003). Presumably because signaling via membrane immunoglobulin requires cross-linking, tolerance is most easily induced in B cells by membrane-associated antigens which are by their very nature presented in a multivalent form (Hartley et al., 1993; but see Akkaraju et al., 1997). In contrast, most cytokines are soluble and monomeric, and tolerance to monomeric and monovalent soluble antigens is much less robust (Adelstein et al., 1991). There are several known and perhaps many as yet unknown checkpoints for self-reactive B cells which may allow some self-reactive B lymphocytes to be functional in protecting against pathogens without harming the host (Goodnow, 2007).

In humans, 55–75% of early immature B cells make antibodies that bind to self-antigens and about 50% of these early immature B cells are deleted (Wardemann et al., 2003), leaving 5–25% of the naïve B cell repertoire reactive with self-antigens. If a V gene facilitates protective antibodies against important pathogens, there will be evolutionary pressure on retaining that V gene even if it reacts with a self-antigen (Wardemann et al., 2003). It may be hypothesized that low-affinity self-reactive B cells may do no harm, and their complete deletion may leave the species vulnerable to infectious pathogens. For example, we have reported that the germline ancestor

of a hypermutated protective human mAb that neutralized human cytomegalovirus (HCMV) was autoreactive (McLean et al., 2006). On the other hand, there may be a counter-evolutionary pressure for pathogen antigens to resemble human self-antigens so that their hosts are tolerant to the self-antigens and cannot respond (Rowley and Jenkin, 1962).

Antibodies Binding to Multiple Epitopes on GM-CSF Suggest that B Cells Lack Tolerance to Cytokines

A critical question concerns the lower limit of concentration below which a protein antigen is simply not seen by B cells, and therefore for which there can be no B cell tolerance. There is experimental evidence for B cell anergy for soluble protein antigens at serum concentrations greater than 100 pM (Adelstein et al., 1991), but since most soluble cytokines are present at very low or sub-picomolar levels in normal plasma they are unlikely to produce B cell tolerance or anergy. Indeed, there is no experimental evidence for induction of B cell tolerance or anergy to cytokines, and thus we assume that there is no B cell anergy or no B cell tolerance for these self-antigens.

If there is no B cell tolerance to cytokines, we would anticipate the entire surface of each cytokine to be potentially immunogenic, and we would expect to find antibodies that bind to multiple epitopes on the cytokine, and this is what is observed. In healthy humans who had autoantibodies against IL-6, autoantibodies bound to two non-overlapping epitopes on IL-6 (Hansen et al., 1991b). Uchida et al. (2003) observed that autoantibodies against GM-CSF in IPAP patients bound to multiple epitopes. In our panel of 19 human monoclonal autoantibodies against GM-CSF cloned from six IPAP patients we observed three monoclonal autoantibodies against GM-CSF that bound to three non-overlapping epitopes, and three monoclonal autoantibodies were able to bind simultaneously to a single monomer of GM-CSF (Wang et al., 2013). The formation of stable, high-avidity, multi-molecular complexes formed by autoantibodies against GM-CSF is entirely compatible with the idea that B cells show no tolerance to this cytokine and, by inference, no B cell tolerance to any cytokine.

The production of B cell memory and high-affinity IgG production requires T cell help, and as long as the corresponding T cells are tolerant, there would seem to be no compelling reason why B cell tolerance to all self-cytokines would be a biological necessity. Without T cell help, the worst that might happen might be transient IgM responses which may do little if any harm. On the other hand, lack of tolerance to a particular

self-cytokine in B cells leaves the body open to the possibility of autoimmunity if for any reason a T cell of the appropriate specificity becomes activated. Indeed, such a scenario may explain many aspects of autoantibody production against cytokines, as will be discussed in the next section.

ROLE OF T CELLS AND THE THYMUS IN PATHOGENESIS OF AUTOANTIBODIES TO CYTOKINES

We have already discussed the evidence that production of high-affinity IgG autoantibodies to cytokines requires T cell help (see above).

General T Cell Tolerance

The thymus plays a major but incomplete role in the establishment of self-tolerance via a sequence of positive and negative selection steps in which the T cell receptor (TCR) for antigen recognizes linear peptides in the groove of MHC proteins on the surface of specialized thymic epithelial cells. Because the thymus is largely isolated from the exterior of the body, the overwhelming probability is that these peptides will be “self.” The first step involves positive selection for T cells that are capable of at least weak interaction with MHC–peptide complexes. T cells that are incapable of this interaction die by apoptosis. A second step involves apoptotic deletion of potentially harmful T cells with strong reactivity to these MHC–self-peptide complexes.

If every protein that the body is capable of making were expressed in the thymus, such a mechanism would have the potential to generate a set of mature T cells capable of defending the body against any intruder, while avoiding attack against the body. However, if any proteins synthesized elsewhere in the body are not expressed in the thymus, mature T cells reactive to these proteins could emerge, and they would have the potential to cause autoimmunity. Cytokines may represent a case in point.

Most cytokines are tissue-restricted self-antigens that might not be expressed in the thymus. Many are synthesized only in emergencies such as infection or trauma, while some are synthesized continuously at local sites such as skin and mucous membranes which bacteria colonize, for example IFN- α in the gut (Abt et al., 2012; Ganai et al., 2012).

Role of the AIRE Gene in T Cell Tolerance

A unique mechanism exists to deal with this problem. An unusual transcription factor with very broad activity on many promoters is present in thymic medullary epithelial

cells and acts as an autoimmune regulator (AIRE) by causing transcription of many genes that would otherwise not be expressed in the thymus, allowing deletion of T cells that would otherwise have the potential to cause autoimmunity in tissues or organs where there are tissue-restricted antigens.

The AIRE gene was discovered by mapping and cloning the mutant gene causing autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), also known as autoimmune polyglandular syndrome 1 (APS-1) (Nagamine et al., 1997) (see Chapter 43). It was found that AIRE is expressed in medullary thymic epithelial cells (Zuklys et al., 2000), where it would be ideally situated to mediate negative selection of self-reactive T cells.

A mouse with a deletion of the AIRE gene developed APECED-like multi-organ autoimmune disease (Anderson et al., 2002), but the mechanism by which AIRE controls promiscuous expression of tissue-restricted self-antigens in medullary thymic epithelial cells and in the secondary lymphoid organs is still under investigation (Akirav et al., 2011).

T Cell Tolerance to Cytokines

AIRE has the potential to facilitate induction of tolerance to any cytokines that are not expressed in the thymus. However, its role in tolerance to cytokines is still unclear, and Meager and colleagues (Kisand et al., 2010) comment that functional AIRE is not necessary to produce T cell tolerance against IFN- α or IL-17. They point out that IFN- α is made by macrophages and dendritic cells in the thymus (Meager et al., 2006) and that IL-17 is made by thymocytes (Marks et al., 2009). Other cytokines are made in the thymus without the need for tolerogenic AIRE, including IL-7 and chemokines such as CCL25, CXCL12, CCL19, CCL21, CCL17, and CCL22 that direct thymocyte migration to different parts of the thymus to make mature T cells. We will return to speculate on the possible role of AIRE later in this chapter.

T Cell Tolerance is Incomplete and Breakable

Notwithstanding the expression of ubiquitous proteins and many more tissue-restricted proteins in the thymus via AIRE, deletion of self-reactive T cells in the thymus is incomplete, as is the case for B cell tolerance in the bone marrow or spleen (Akkaraju et al., 1997; Wardemann et al., 2003). And even if intrathymic purging of these dangerous T cells is complete, the process could be reversed by a rare event such as a somatic mutation in a mature T cell that alters its specificity or activation threshold, or an encounter with a rare pathogen.

Perhaps for this reason, a further layer of protection against autoimmunity is provided by the so-called regulatory T cells (Tregs). Tregs are characterized by high levels of expression of CD25 and the transcription factor *Foxp3*. Kim et al. constructed a mouse in which the 3' untranslated region of the mRNA for *Foxp3* contained a gene for the receptor for diphtheria toxin driven by an internal ribosome entry site (IRES), so that cells expressing *Foxp3* could be killed by administration of diphtheria toxin, to which mice are normally resistant. Interestingly, when Tregs were eliminated in this way, mice were found to die from autoimmunity with splenomegaly and lymphadenopathy within 10–21 days (Kim et al., 2007), indicating/suggesting that potentially pathogenic autoreactive T cells do indeed escape the thymus but are normally kept in check by Tregs.

Yet, in spite of all the mechanisms in place to prevent or control autoimmunity, “the best-laid schemes o’ mice an’ men gang aft a-gley.” There is a chance that a pathogen might be able to stimulate a T cell that cross-reacts with a peptide on a self-antigen, especially if the pathogen antigen comes with danger-associated molecular patterns that stimulate a Toll-ligand receptor or an inflammasome that “licensed” antigen-presenting cells (Heath and Carbone, 2001). The self-cytokine T cell epitope need not correspond to the amino acid sequence of the T cell epitope in the pathogen, because the T cell antigen receptor (TCR) is polyreactive and multiple peptides of different sequences on the MHC class II can be recognized by the same TCR (Felix et al., 2007).

If AIRE were to control T cell tolerance to most cytokines, how could autoantibodies be made without T cell help? The probable answer is that T cell deletion is incomplete, and low-avidity T cells reactive with self-peptides from cytokines do escape from the thymus. All that is needed is an infection in a local site with a pathogen that stimulates cytokine production in the local site and that has pathogen-associated molecular patterns. This stimulates an antigen-presenting cell and if it has receptors for the cytokine, the antigen-presenting cell endocytoses the cytokine, proteolyzes it, and presents a T cell cytokine epitope to activate low-avidity T cells. Antigen-presenting cells have receptors for IFN- α , IFN- β , IL-1 α , IL-6, and GM-CSF, and a percentage of healthy humans have autoantibodies against these cytokines (see above). If there is no B cell tolerance to most cytokines, the B cells specific for the cytokine will endocytose the cytokine and present a/the peptide of the cytokine bound to MHC class II to the activated T cells.

An alternative scenario is that a pathogen antigen has a higher-avidity T cell epitope that cross-reacts with a low-avidity T cell epitope of a cytokine and activates T cells. B cells that make antibodies that bind to the cytokine will endocytose the cytokine and present the

low-avidity, cross-reactive T cell epitope of the cytokine to get help from those T cells activated by higher-avidity T cell epitopes of the pathogen antigen.

To take an example, healthy humans very frequently produce autoantibodies against IFN- α . The microbiome in the gut normally stimulates the gut to produce IFN- α (Abt et al., 2012; Ganal et al., 2012), and if local antigen-presenting cells exhibit receptors for IFN- α and if they are stimulated by pathogen-associated molecular patterns, they will present a T cell epitope from the IFN- α to activate low-avidity T cells that have escaped from tolerance mechanisms in the thymus.

We speculate that in the case of IPAP a pathogen cross-reactive with a T cell epitope in GM-CSF will present pathogen-associated molecular patterns to antigen-presenting cells and activate T cells. If the pathogen stimulates the release of GM-CSF from macrophages and nearby GM-CSF-specific B cells endocytose GM-CSF, they will present the low-avidity GM-CSF peptide–MHC complex to the T cells activated by the pathogen high-avidity T epitope. The frequency of IPAP is increased in smokers. Cigarette smoke is an irritant causing chronic inflammation and recurrent infection in the lung, and is also a potent source of mutagens that cause cancer in the lung and elsewhere. The putative pathogen does not have to be in the lung. It could be in the gut or the skin where perhaps an unusual bacterium colonizes. Even if there is no pathogen antigen cross-reactive with a T cell epitope in GM-CSF, a pathogen with a pathogen-associated molecular pattern may activate the antigen-presenting cell, which has receptors for GM-CSF and can present a low-avidity T cell epitope of GM-CSF to a low-avidity T cell that has not been tolerized in the thymus.

Autoantibodies against Cytokines in APECED

APECED is caused by mutations in AIRE, although the onset of the disease expression is highly variable (Perheentupa, 2006). Among the many autoantibodies seen in this syndrome, Meager et al. found high titers of neutralizing autoantibodies against IFN- α or IFN- ω (Meager et al., 2006). On the other hand, autoantibodies against IFN- γ , IL-10, and IL-12 were rarer and did not neutralize.

The pathogenesis of chronic mucocutaneous candidiasis has been associated with defects in the so-called Th17 cytokine family IL-17A, IL-17F, and IL-22. It is therefore of interest that neutralizing autoantibodies to these cytokines are particularly prevalent in APECED patients, particularly those with chronic mucocutaneous candidiasis (Kisand et al., 2010; Puel et al., 2010).

It has been suggested that the AIRE mutation in APECED may have caused a loss of T cell tolerance for IL-17A, IL-17F, and IL-22 (Puel et al., 2010). If there is

no B cell tolerance to those cytokines, a lack of T cell tolerance could explain how the autoantibodies against IL-17A, IL-17F, and IL-22 were generated. However, the selective incidence of autoantibodies against Th17 cytokines is difficult to understand given that mutations in AIRE do not seem to result in a global loss of tolerance to cytokines. Autoantibodies were only weakly present in low titers against IL-6, IL-9, IL-12, IL-21, IL-23, IL-26, IL-29, or RANTES and no autoantibodies were found in APECED patients against IL-1, IL-2, IL-4, IL-8, IL-10, IL-18, TGF- β , or TNF (Kisand et al., 2010). Similarly, Puel et al. (2010) found no autoantibodies against GM-CSF, IFN- γ , IL-6, IL-1 β , IL-10, IL-12, IL-18, IL-21, IL-23, IL-26, IFN- β , TNF, or TGF- β in APECED patients. Control experiments found no autoantibodies against IL-17A, IL-17F, and IL-22 in plasma from the control group of 37 healthy individuals or 103 patients with various other autoimmune conditions (Puel et al., 2010).

Autoantibodies against Cytokines in Patients with Thymoma

Thymomas are tumors of thymic epithelial cells. They rarely metastasize and generally behave in a relatively non-malignant fashion, although in advanced cases they may show local invasion. They are frequently associated with autoimmunity, most commonly with myasthenia gravis and related disorders, but also with a variety of other autoimmune paraneoplastic syndromes (Marx et al., 2010) (see Chapters 54, 57, and 58). These associations are particularly remarkable given that the thymus is the classical site of tolerance induction (Marx et al., 2010). The clue seems to be that thymomas are often capable of supporting thymopoiesis of T cells, but in a disorganized environment (Buckley et al., 2001; Marx et al., 2010). It may be significant that they do not seem to support the production of Tregs (Strobel et al., 2004). In addition, thymomas are almost devoid of AIRE expression (Offerhaus et al., 2007; Scarpino et al., 2007; Strobel et al., 2007). Thymomas usually have low or absent MHC class II expression, and frequently there is loss of heterozygosity at the MHC region which would be expected to limit their ability to present self-peptides (Marx et al., 2010).

Patients with thymoma and autoimmune disease have been found to have neutralizing antibodies against numerous cytokines including IL-12 (Shiono et al., 2003) and all 12 types of IFN- α and IFN- ω , which has 60% amino acid identity (Meager et al., 1997; Shiono et al., 2003; Marx et al., 2010).

Neutralizing autoantibodies to Th17 cytokines are also very prevalent in patients with thymoma, especially those with chronic mucocutaneous candidiasis, reminiscent of

similar findings in patients with mutant AIRE-associated APECED (Kisand et al., 2010; Browne and Holland, 2010b; see earlier). Autoantibodies that bind GM-CSF were occasionally associated with thymoma and autoimmune disease but only a small fraction neutralized the bioactivity of GM-CSF (Meager et al., 1999).

Marx et al. (2010) commented that the neutralizing ability of autoantibodies to cytokines in thymoma strongly implies autoimmunization by the cells expressing the native molecules (Marx et al., 2010); the finding that the titers increased markedly when the thymomas recurred in 12 of the 13 cases studied supports this concept (Buckley et al., 2001; Marx et al., 2010). They speculated that disorganized thymopoiesis in thymoma may have resulted in immunization of T cells rather than tolerance induction.

Alternatively, we speculate that in thymoma, thymocytes may not be completely deleted of thymocytes reactive with tissue-restricted self-cytokines. If there are self-reactive T cells against cytokines, the cytokine-specific T cells may be activated if a pathogen stimulates dendritic cells. If there is no B cell tolerance to cytokines, they will endocytose the cytokines and present cytokine peptides to cytokine-specific T cells.

INDUCTION OF AUTOANTIBODIES AS A CONSEQUENCE OF THERAPY WITH RECOMBINANT CYTOKINES

According to Rossert et al. (2004), “There is probably not a single recombinant molecule used in clinical medicine that has not been found to induce antibody formation in at least some cases” (see also Macdougall et al., 2012). This situation might be seen as a loss of self-tolerance rather than a classical immune response to a foreign entity, and is a puzzle for immunologists and a serious concern for physicians and patients. Humans treated with human recombinant IFN- α made antibodies against human recombinant IFN- α that affected therapy (von Wussow et al., 1987; Antonelli et al., 1996). Patients who were injected with recombinant cytokines in some cases made antibodies against the recombinant cytokines and the natural cytokine.

If there is no B cell tolerance to cytokines and deletion of self-reactive T cells in the thymus is incomplete, potentially self-reactive helper T cells specific for cytokines could emerge from the thymus. Even if the self-reactive T cells are normally kept in check by regulatory T cells, it is not inconceivable that this “fail safe” mechanism could break down.

All cytokines are glycosylated *in vivo*, but the great majority of therapeutic recombinant cytokines are synthesized in *E. coli* and therefore non-glycosylated. When

non-glycosylated human recombinant GM-CSF produced in *E. coli* was injected into non-immunocompromised patients, 95% of the patients developed antibodies that bound to GM-CSF (Ragnhammar et al., 1994). The presence of antibodies against GM-CSF significantly reduced the GM-CSF-induced increase of neutrophils, the therapeutic effect the clinicians were aiming for (Ragnhammar et al., 1994).

A native glycosylation site on a naturally produced cytokine could prevent T cell tolerance to a T cell epitope in many different ways. The native glycosylation site could: (1) prevent access to the TCR to the peptide in the groove on the MHC; (2) prevent binding of the T cell epitope to the MHC; and (3) interfere with proteolysis of a cytokine to make a short linear T cell epitope. If any of these things happen with the endogenous cytokine, the T cell epitope might be invisible to thymocytes and hence the T cells would not be tolerant of that particular T cell epitope. If a recombinant human cytokine is produced in *E. coli* or a mammalian cell-line with a different size of glycan chain and if the recombinant cytokine produces a new T cell epitope, it would be regarded as clearly non-self. If there were no B cell tolerance to the cytokine, the T cell activated by this epitope could provide help for B cells for the formation of autoantibodies against both the recombinant and endogenous forms. If this scenario is correct, cessation of therapy with the recombinant cytokine might result in gradual waning of the antibodies.

Rarely, humans treated with human recombinant erythropoietin (EPO) have been found to make antibodies against human recombinant erythropoietin and endogenous erythropoietin, producing severe anemia and pure red aplasia (Casadevall et al., 2002). Many possibilities have been considered, but this apparent loss of tolerance to an endogenous protein is still not well understood. Differences in glycosylation of recombinant EPO have been considered but have not been incriminated. The formation of aggregates has been frequently raised as a possible means by which immunogenicity could be increased, although this would only apply to B cells; but since the relevant form seen by T cells is a short linear peptide in the MHC groove, it is hard to see how the presence of aggregates in the therapeutic preparation could circumvent T cell tolerance.

The route of immunization has been raised as a possible association with the formation of autoantibodies to EPO; autoantibody formation seems to have been more common after subcutaneous administration as compared to intravenous administration, but the data are not clear-cut. Extraneous material in recombinant EPO has included human serum albumin, polysorbate 80 and “leechates” from rubber stoppers (Macdougall et al., 2012). None of these has been definitively implicated. Leechates from the stoppers have been shown to have adjuvant

activity when tested with mice immunized with ovalbumin, but have not been shown to be involved in loss of tolerance to EPO.

The ingredient with the greatest index of suspicion is tungsten in trace amounts resulting from the way that the syringes are manufactured. Evidently tungsten can promote protein denaturation and the formation of disulfide-bonded aggregates which might be seen as foreign to T cells, but at present there is no definitive answer (Macdougall et al., 2012).

The fact that instances of autoantibodies against endogenous EPO as a result of therapy are so rare means that the search for a universal external cause may be futile, and we may need to consider host factors. In a few cases in Thailand, certain HLA alleles have been found to be overrepresented, but this finding is not general (Macdougall et al., 2012). A somatic mutation in a mature T cell would have a great deal of explanatory power, and its relative rarity would also fit the observed rarity of this perplexing condition.

CONCLUSIONS AND FUTURE PROSPECTS

The concept of a cross-reacting environmental antigen seems to be contradicted by the emerging evidence that autoantibodies against cytokines involve multiple conformational epitopes, which would be extremely unlikely. Another concept of the generation of autoantibodies is that an unrelated, exogenous antigen initiated the immune response and started the affinity maturation process and that, by chance, somatic mutations change the conformations of the antigen-binding site so it binds to multiple, conformational B cell epitopes on a cytokine. Given that the two crystallographic analyses of antigen-binding sites of germline antibody and somatically mutated antibody derived from the same germline antibody have the same general conformation, this concept is very improbable. We have concluded from the literature that there is no B cell tolerance to cytokines but definitive experiments need to be undertaken in the future. If the production of a particular cytokine is constant, there will be a continuing source of antigen and the process of antigen-driven autoantibody production will be ongoing. There is abundant evidence that the process of autoantibody formation against cytokines is antigen driven, and shows all the features of a typical secondary immune response with passage through germinal centers, somatic mutations, and affinity maturation, all of which require T cell help. When the autoantibodies are associated with thymoma, removal of the thymoma often results in a decline in the autoantibody titer, and the titer may rise again if the thymoma recurs. In the case of type 1 diabetes mellitus, when the pancreatic islets are destroyed, the

autoantibodies against insulin fade away to undetectability, as might be expected for an antigen-driven process.

We conclude from the literature that T cell tolerance in the thymus is leaky and that T cells with specificity for low-avidity T cell epitopes of self-cytokines exist. What initiates the autoimmune process? It has been suggested that the simultaneous exposure to a cross-reacting exogenous antigen and the adjuvant effects of “danger signals” from a rare pathogen might break self-tolerance at the T cell level for a cytokine, but this remains a theoretical possibility for which there is no direct experimental evidence. Inflammation may be essential for normal immunity, and does not usually lead to autoantibodies. Autoantibodies provoked by the injection of a recombinant cytokine that cross-reacts with the natural cytokine might be explained by the fact that native cytokines are glycosylated while recombinant cytokines are generally not. This could lead to a lack of T cell tolerance for recombinant cytokines. However, there are no hard data.

In the future there will many more studies of pathogenic or non-pathogenic monoclonal autoantibodies against cytokines with authentic H and L chain pairs, including attempts to map the T cell epitopes in cytokines. It remains a mystery why APECED patients that lack functional AIRE show production of autoantibodies against certain cytokines but not against others. Perhaps autoantibodies against cytokines in healthy humans will inform us of how these processes are initiated.

| Clinical Practice Guidelines | 1167 | References | 1170 |

INTRODUCTION

The history of autoantibodies (aab) dates back more than a century to Ehrlich's description of "horror autotoxicus" (Ehrlich, 1900) and the development of Wasserman test for syphilis that was initially based on agglutination and complement fixation (Wassermann et al., 1906). Despite this long history, the detection of aab lagged from about 1900 to 1950 and was largely relegated to organ-specific autoimmune diseases (reviewed in Conrad et al., 2011). However, in the following 50 years (1950–2000) autoantibodies achieved prominence in the laboratory and clinical settings.

The more recent advances in aab testing dates to the seminal observation of the lupus erythematosus (LE) cell phenomenon in 1948 (Hargraves et al., 1948) and then the advent of the LE cell test (Conn, 1994). In the ensuing 20 years, a number of techniques such as indirect immunofluorescence (IIF), immunodiffusion (ID), hemagglutination, and complement fixation were developed and refined (reviewed in Fritzler, 1986). IIF was described by Coons, Kaplan and Weller in the early 1950s (Warde, 2011) and this assay stands out as one of the few techniques that is still widely used today in clinical diagnostic laboratories, particularly as a screening test in the diagnosis of systemic autoimmune rheumatic disease (SARD) (reviewed in Fritzler and Wiik, 2006).

In the 60 years following the inception of IIF, a variety of substrates were utilized, but cryopreserved sections of rodent organs became the mainstay for the first 25 years (Holborow et al., 1957; Beck, 1961; Hijmans et al., 1964; Kunkel and Tan, 1964). In the mid-1970s it was discovered that human tissue culture cells such as HeLa and HEP-2 were superior to organ sections in the identification of aab in SARD primarily because they had larger nuclei, they expressed target antigens in various stages of the cell cycle, and kits using these substrates were relatively economical to manufacture (Nakamura et al., 1984; Nakamura and Tan, 1977). The adoption of tissue culture cells (e.g., almost exclusively HEP-2 cells) as the substrate of choice for IIF led to what some regard as the "golden age" of aab detection (Fritzler, 2012).

The increased sensitivity of the IIF techniques using tissue culture cells became an issue of concern that led to a study by the Serology Subcommittee of the International Union of Immunology Societies/World Health Organization/Arthritis Foundation (IUIS/WHO/AF) who recommended that sera should be screened at dilutions of 1/40 and 1/160 but that a cut-off of 1/160 was the most appropriate to achieve a balance of sensitivity and specificity for the diagnosis of adult SARD (Tan et al., 1997). This advice achieved limited acceptance because many laboratories preferred to screen at serum dilutions that provided the

appropriate balance of sensitivity and specificity in their clinical environment.

An unanticipated advantage of using HEp-2 cell substrates was the identification of novel aab targets that were weakly expressed, selectively expressed, or not expressed in highly differentiated tissues. This led to the identification of novel aab targets and also provided cell and molecular biologists with valuable probes for studies of novel cell structures and macromolecules (Tan, 1991; Luqmani et al., 2011). These included anti-proliferating cell nuclear antigen (PCNA) and other cell cycle-related targets (Mahler et al., 2010), anti-centromere (Fritzler et al., 2010), and a number of targets in nucleoli (Reimer et al., 1987; Welting et al., 2003), nuclear envelope (Enarson et al., 2004), and cytoplasm (Stinton et al., 2004; Fritzler et al., 2007). The identification of these novel targets occurred in parallel with the emergence of new assays, such as immunoblotting (IB), expression cloning, and rapid and economical DNA sequencing.

The remarkable advances in identifying and cataloguing the molecular targets bound by aab led to the next generation of diagnostic technologies that included antigen-specific immunoassays using novel platforms including enzyme linked immunoassays (ELISA) (Halbert et al., 1981; Reichlin and Harley, 1986; Tonuttia et al., 2004), dot blots (Stott, 1989; Nezlin and Mozes 1995), line immunoassays (LIA) (Pottel et al., 2004; Damoiseaux et al., 2005), and multiplexed immunoassays such as addressable laser bead immunoassays (ALBIA) (Fritzler 2006; Fritzler and Fritzler, 2009) and chemiluminescence (CLA) (Mahler et al., 2011b) (Table 77.1). Other emerging technologies include lateral flow (Renger et al., 2010), antigen arrays on planar surfaces (Baker et al., 2004; Balboni et al., 2008; Chandra et al., 2011), and nanobarcodes (Freeman et al., 2005). Such advances are progressively being adopted by modern diagnostic laboratories because they are automated and contribute to high throughput and shortened turnaround times resulting in considerable laboratory cost savings. In addition, some of these platforms, such as lateral flow, have applications in point of care diagnostics.

The continued use of IIF has many advantages, but the limitations of this technology in the context of ever-changing clinical algorithms should not be overlooked. Numerous studies have pointed to deficiencies of IIF assays (reviewed in Fritzler, 2011a,c, 2012). In the context of new and emerging technologies and the background of the more familiar IIF, it has become clear that, depending on the assay used, the results from any one immunoassay can be at considerable variance with other assays. This has prompted concerns about the relative value of old and new diagnostic platforms where the implications of false-negative and false-positive test results are being debated (reviewed in Fritzler, 2011c). Many clinicians prefer to adhere to assay results that are easily understood, fit within existing diagnostic paradigms, and

are clinically relevant. Hence, for the present time, some prefer test results derived from IIF on specified substrates (i.e., HEp-2 and certain tissue sections) and regard them as the “gold standard” for aab testing (Satoh et al., 2009; Meroni and Schur, 2010).

One of the arguments supporting continued use of IIF on HEp-2 substrates is that this substrate contains more than 100 different target antigens, whereas newer screening technologies such as ELISA, LIA, or ALBIA are currently limited to less than 20 (American College of Rheumatology, 2011). However, it is obvious that IIF does not detect all aab in a given human sera even when they are directed to an autoantigen that is highly expressed in HEp-2 cells. For example, a significant proportion of sera that have aab directed to Jo-1 (histidyl tRNA synthase), ribosomal P proteins (Mahler et al., 2004, 2008), PCNA (Mahler et al., 2010), GWB (Stinton et al., 2010), and PM/Scl (Mahler and Fritzler, 2009) (to name a few) are scored as negative in IIF test results derived from HEp-2 substrates. It has been suggested that these “false-negative” IIF results are likely attributable to low aab titers, hidden or cryptic epitopes, secondary antibodies, and/or characteristics of the substrate (i.e., cell density, growth media, fixation protocols). However, the evidence to support these contentions is not well documented. In addition, even when IIF results are read and interpreted by the same cadre of technologists on different manufacturer substrates and using a characterized set of SARD sera, the agreement of five assays from different manufacturers was only 78% (Coppole et al., 2012). And within the specific groups of serum samples, agreement ranged from only 44% for SSc samples to 72% agreement for the SLE sera but, reassuringly, 93% for healthy control sera. In this particular study, variations in slide and substrate quality (i.e., clarity, consistency of fluorescence, cell size, number and quality of mitotic cells) from different manufacturers were also noted. Therefore, along with problems of subjective interpretation, IIF on HEp-2 substrates are subject to problematic standardization issues that are akin to other methods for ANA screening (Coppole et al., 2007).

It is interesting that some of the issues plaguing IIF assays, particularly subjective reader bias, are being addressed through the development of technology platforms that provide automated, digital reading of IIF slides (Hiemann et al., 2009; Egerer et al., 2010). This technology has advantages of machine learning algorithms and being able to archive digital images of the IIF result for subsequent review. However, disadvantages of current iterations of this technology include limited throughput capacity (fewer than 10 slides loaded per run) and difficulty distinguishing IIF patterns in sera where multiple or less common aab are present.

Taken together, the rapid proliferation of aab specificities and the emergence and adoption of novel technologies has created a dilemma for standardization of aab testing

TABLE 77.1 Contemporary and Emerging Technologies Used to Detect Autoantibodies in Human Sera

| Assay | Essential technology | Applications |
|---|---|--|
| Indirect immunofluorescence (IIF) | <ul style="list-style-type: none"> • Tissue or cell substrates • Fluorochrome-labeled secondary antibodies • Microscope fitted with UV source and optics | Screening test Specific aab detection by staining pattern |

protocols and the results that are communicated to clinicians (Fritzler et al., 2003a; Wiik et al., 2004). Rapid advances in diagnostic technologies have made it difficult for even the most modern laboratory to keep abreast of the changes, not to mention clinicians who are hard pressed to keep abreast of new diagnostic paradigms that follow the adoption of the newer technologies.

SPECTRUM OF AUTOANTIBODIES

In a single chapter, it is virtually impossible to cover the spectrum of aab that are now in wide use as diagnostic and

prognostic biomarkers, although many of the clinically relevant aab are covered in earlier chapters of this book or summarized in other publications (Conrad et al., 2007, 2011). Given the variation of observations with the same technology or between different technologies, the spectrum of aab and their associated sensitivity or specificity is much wider than can be summarized in Table 77.2. Such information needs to be interpreted in the context of the reader’s own clinical and laboratory setting. As an example of the complexity of data sets, there are now over 10 different diagnostics platforms (Table 77.1) and in autoimmune conditions such as systemic lupus erythematosus (SLE) there are now

TABLE 77.2 Autoantibodies Used in Diagnosis of Autoimmune Diseases

| Autoantibody | Disease | Sensitivity/Specificity | Assay |
|---|---|--------------------------------|---------------------------------|
| dsDNA | SLE DIL ^a | 45–60/80–90 | IIF, ELISA, IP |
| Sm (U2–U4-6 RNP) | SLE | 10–20/95 | ELISA, ID, IP, ALBIA, LIA, CLA |
| U1RNP | MCTD SLE | 90/90–95 40/30 | ELISA, ID, IP, ALBIA, LIA, CLA |
| SS-A/Ro 60 | SjS SLE | 50–70/80 45/25 | ELISA, ID, IP, ALBIA, LIA, CLA |

| Histone/chromatin | SLE DIL | 70/20 80/20 | ELISA, IB, ALBIA, LIA, CLA |
| Topoisomerase I/Scl-70 | SSc | 20/90 | ELISA, IB, IP, ALBIA, LIA, CLA |
| U3 RNP/Fibrillar | SSc | 15/95 | IIF, IP, LIA |
| Centromere | SSc | 50–60/90 | IIF, ELISA, IB, ALBIA, LIA, CLA |
| Jo-1/histidyl tRNA synthetase | PM/DM | 20–30/90–95 | ELISA, IB, IP, ALBIA, LIA, CLA |
| Citrullinated peptides and proteins | RA | 65–85/85–95 | ELISA |
| Proteinase 3 | GPA | 60–70/90–95 | ELISA, IB, LIA, CLA |
| Myeloperoxidase | MPA | 65/80 | ELISA, IIF, CLA (pANCA) |
| Pyruvate dehydrogenase complex (M2) | PBC | 75–80/85 | IIF, IB, ELISA, IP, LIA, CLA |
| Smooth muscle F-actin | Chronic active hepatitis | 70/25 | IIF, ELISA |
| Intrinsic factor | Pernicious anemia | 90/70 | IIF, ELISA |
| Human tissue transglutaminase | Celiac disease | 85/90 | IIF, ELISA |
| Cardiolipin complex | APS | 80/50 | ELISA |
| β2-glycoprotein I | APS | 80/90 | ELISA |
| Basement membrane (α4 domain of type IV collagen) | Anti-GBM disease (Goodpasture's syndrome) | 80/80 | IIF, ELISA |
| Acetylcholine receptor | Myasthenia gravis | 80/90 | ELISA, IB |
| Thyroid microsomes (thyroid peroxidase) | Hashimoto's thyroiditis | 90/75 | IIF, ELISA |
| Cadherins | Pemphigus vulgaris | 90/90 | ELISA |
| Skin basement membrane zone | Bullous pemphigoid | 80/80 | ELISA |
| Yo/Purkinje cell | PCD | 70/95 | IIF, IB, LIA |
| Hu | PEM | 70/90 | IIF, IB, IP, LIA |
| Aquaporin 4 | NMO/Devic's disease | 75/85 | CBA, ELISA |
| NMDA/NR1 receptor | Autoimmune encephalitis | MSR | CBA, ELISA |
| PLA2R | Membranous glomerulonephritis | MSR | CBA, ELISA, ALBIA |

^aSome patients treated with anti-TNF and other biological therapeutics develop features of drug-induced lupus and anti-dsDNA and other aab. Abbreviations: ALBIA, addressable laser bead immunoassay; APS, anti-phospholipid syndrome; CBA, cell-based assay; CLA, chemiluminescence assay; DIL, drug-induced lupus; ELISA, enzyme linked immunoassay; GBM, glomerular basement membrane; GPA, granulomatosis with polyangiitis—formerly Wegener's syndrome; IB, immunoblotting; IIF, indirect immunofluorescence; IP, immunoprecipitation; LIA, line immunoassay; MCTD, mixed connective tissue disease; MPA, microscopic polyangiitis; MSR, more studies required; NMDAR, N-methyl-D-aspartate (glutamate) receptor; NMO, neuromyelitis optica; NPSLE, neuropsychiatric systemic lupus erythematosus; PBC, primary biliary cirrhosis; PCD, paraneoplastic cerebellar degeneration, PEM, paraneoplastic encephalomyelitis; PLA2R, phospholipase A2 receptor; PM, polymyositis; RNP, ribonucleoprotein; SARD, systemic autoimmune rheumatic diseases; SjS, Sjögren's syndrome; SLE, systemic lupus erythematosus; SSc, systemic sclerosis; TRIM, tripartite motif.

over 150 autoantibodies catalogued (Sherer et al., 2004; Sherer and Shoenfeld, 2007) and over 30 in scleroderma (Ho and Reveille, 2003; Walker and Fritzler, 2007; Mehra et al., 2013), with not infrequent overlaps between these two and other SARD. In most organ-localized diseases, the autoantibodies tend to be directed to only one or a few antigens that tend to be harbored in the affected organ (Conrad et al., 2011).

One of the relatively new arrivals on the aab scene are a class of autoimmune diseases referred to as IgG4-related disease (IgG4-RD) that encompasses a variety of clinical entities once regarded as being separate diseases (Khosroshahi et al., 2011; Nirula et al., 2011; Carruthers et al., 2012; Stone et al., 2012) (see Chapter 64). Clinical manifestations of IgG4-RD have been reported in virtually all organ systems where they display consistent histopathological similarities: diffuse lymphoplasmacytic infiltrates, abundant IgG(4)-positive plasma cells, modest tissue eosinophilia, and extensive fibrosis (Khosroshahi et al., 2011). Polyclonal elevations of serum IgG4 are found in approximately 70% of patients and in some cases IgG4 aab directed to specific targets are found (Bruschi et al., 2011; Debiec and Ronco, 2011; Hofstra et al., 2011; Klooster et al., 2012).

ASSAYS AND TECHNOLOGIES FOR AUTOANTIBODY TESTING

As mentioned above, the IIF technique using HEp-2 or other cellular substrates continues to be the preferred screening immunoassay to detect aab in SARD. However, as also referenced above, it is important to appreciate that a negative IIF screen does not necessarily exclude the presence of a wide spectrum of autoantibodies (reviewed in Fritzler, 2012). Therefore, in the setting of high clinical suspicion of a SARD or another autoimmune disease and a negative IIF test, the identification of aab should include a more specific and sensitive assay that includes an array of relevant autoantigens. Such tests could be reflexed to newer technologies as described in more detail below (Fritzler and Fritzler 2006, 2009; Mahler et al., 2011a). The strength of aab associations with autoimmune disease subgroups can vary according to the diagnostic techniques being used but also depends on demographic and genetic factors (Fritzler, 2006; Fritzler and Fritzler, 2009). With the emergence of more sensitive immunoassays, care must be taken to ensure that cutoffs are based on appropriate local normal and comparative disease controls (Fritzler et al., 2003a; Shoenfeld et al., 2007; Bossuyt et al., 2008). Also the source and characteristics (i.e., recombinant vs. native, peptide vs. full length) of the autoantigen used in newer assays can affect the results. Despite years of attempts, standardization of aab assays continues to be a

major challenge (Kessenbrock et al., 2007; Satoh et al., 2009; Mahler and Fritzler, 2010; Mahler et al., 2011a). Because the evolution of clinically recognizable SARD and other autoimmune conditions can span decades before a full clinical picture is evident or a diagnosis is firmly established, long-term longitudinal studies are ideally required to reach definitive conclusions about aab specificities.

Many laboratories rely on commercial aab assay kits that employ a variety of technologies such as IIF, ID, IP, IB, LIA, ELISA, and more recently ALBIA, CLA (Mahler et al., 2011b) and antigen arrays (Fritzler, 2002; Robinson et al., 2002; Sokolove et al., 2012). The use and application of these diagnostic platforms has been attended by certain considerations that are not always apparent to the clinician (Box 77.1). One of the more popular assay platforms is based on the ELISA because it offers high sensitivity, efficient throughput and relatively low cost while requiring only modest equipment to perform the assay. Unfortunately, little has been done to standardize these kits (Feltkamp, 1996; Tan et al., 1999; Fritzler et al., 2003b) and post-marketing surveillance and quality assurance is largely left to the manufacturers (Fritzler et al., 2003a). Although the ELISA kits are constantly being improved, some high titer aab to a variety of autoantigens (i.e., fibrillarin, PM/Scl, centromere, nuclear envelope) are often not detected. Hence, a report that indicates a

Box 77.1 Considerations Regarding the Clinical Interpretation of Autoantibody Testing

- Sera from first degree relatives, infectious diseases, malignancies, and normal individuals contain autoantibodies
- Disease-specific autoantibodies can antedate diagnosis
- Definition of a positive autoantibody test is based on an empirically defined threshold
- Some assays such as IIF are based on subjective interpretation
- While IIF is a good screening test for some autoantibodies, it is less sensitive for others
- There is a lack of standardized antibodies and reagents
- There is a growing variety of immunoassays and diagnostic assay platforms
- High throughput assays are often adopted before validation of local performance
- The advent of electronic medical records is enhancing the autoantibody reporting system
- Short-term cost and budget restraints on autoantibody testing have an impact
- Long-term impact of autoantibody testing on total health care costs and quality adjusted life years are mostly unknown

“negative ELISA” screen should not be interpreted as “negative for all relevant autoantibodies,” because they might otherwise be detected by IIF and/or other diagnostic technologies.

While the experience with ALBIA is not nearly as extensive as ELISA, there is evidence indicating that these assays are far from perfect (Shovman et al., 2005a; Fritzler and Fritzler, 2009; Hanly et al., 2010), especially when comparing the results for specific analytes such as anti-dsDNA although they have generally good agreement with other platforms (Shovman et al., 2005b; Avannis-Aghajani et al., 2007; Caramaschi et al., 2007; Bardin et al., 2009; Albon et al., 2011). There is general consensus that because there is considerable variation in the sensitivity of the various commercial diagnostic kits, the identity of the particular assay used to generate the test result should be made available to the clinician (Meroni and Schur, 2010; American College of Rheumatology, 2011). In addition, because of the growing trend to use automated immunoassay systems that provide quantitative results, these laboratories should follow standards of chemistry instrumentation including a requirement to demonstrate analytical measured ranges and periodic calibrations. Clinical laboratories that adopt multiplexed assays (i.e., ALBIA) must establish reference ranges and cutoff values for each analyte, and the sensitivity and specificity must be established with care as the laboratory findings may present a difficult problem for the clinician who has to interpret the results.

CLINICAL INTERPRETATION AND APPLICATION OF AUTOANTIBODY TESTING

As referred to earlier, it is important to appreciate some considerations and certain limitations that impact on the interpretation and clinical application of aab tests (Box 77.1). Many of these issues are due to a lack of thorough knowledge of autoimmunity, such as the perpetuation and perturbations of aab production, and the continuum of B cell responses that span innate to acquired immunity (Fritzler, 2012). It is firmly established that any human serum contains a wide range of aab of varying concentrations (Rose, 1996). It is also important to understand that the measurement and assignment of an abnormal or elevated aab test requires an empirically defined threshold that is dependent on numerous factors such as the equipment used to generate the assays, secondary antibodies, and adherence to manufacturer’s protocols (Fritzler et al., 2003a; Wiik et al., 2004). Of significant clinical relevance, some disease-specific autoantibodies can antedate and predict overt disease by many years (reviewed in Bizzaro et al., 2007; Rose, 2007; Fritzler, 2008, 2011a;

Meroni and Shoenfeld, 2008; Kallenberg, 2011). For example, antibodies to centromere proteins (CENPs) may antedate the clinical diagnosis of SSc by many years (Kallenberg et al., 1988; Wigley et al., 1992) and antibodies to Scl-70 (topoisomerase I) have been linked to the development of pulmonary fibrosis and higher mortality (Kuwana et al., 1994; Scussel-Lonzetti et al., 2002). These and numerous other examples in the literature should certainly give pause to clinicians before labeling an aab test result as a “false-positive” test. The performance characteristics of each test must be known to avoid misinterpretation, incorrect diagnosis, and potentially harmful treatment, a feature that is commonly reflected in so-called “false-positive” tests. It is equally important to consider the impact of “false-negative” tests that can lead to delayed diagnoses and unnecessary morbidity (Fritzler, 2011c). Therefore, to achieve significant clinical utility, it is important to perform aab tests that discriminate between disease and the absence of disease, between emerging or subclinical disease, or between disease and confounding clinical conditions (Conrad et al., 2012).

As very few prospective, unbiased, and multicenter studies have been published, the clinical accuracy of many aab tests is still uncertain. Studies based on literature review and meta-analysis have been published as “evidence-based guidelines” (Kavanaugh and Solomon, 2002; Solomon et al., 2002; Reveille et al., 2003) but the translation of this information is limited because of the wide variety of newer assays and assay parameters that have come into wide use since these studies and recommendations were published.

Decades of clinical experience and research have led to the development of classification and diagnostic criteria to support a diagnosis of a number of autoimmune diseases, many of which include aab biomarkers (Masi et al., 1980; Kasukawa, 1987; Alarcon-Segovia and Cardiel, 1989; Cassidy et al., 1989; Leavitt et al., 1990; Jennette et al., 1994; Savige et al., 1999; Wilson et al., 1999; Petri et al., 2013). Since SARD are characterized by multiple organ system involvement, separate sets of criteria are required to support accurate classification. As a consequence, it is rare that a single pathognomonic criterion can be translated into certainty that a given diagnosis is correct. To ensure that results from the immunology laboratory gain maximum utility for clinicians, it is important to study the performance of each aab assay as an aid to diagnostics in early disease because that is the time at which a serologic result would impact prognostic and diagnostic considerations the most (Fenger et al., 2004; Conrad et al., 2012). Since the clinical diagnosis often may be established only after months or years of clinical follow-up, the more knowledgeable the clinician is with regard to the clinical and laboratory characteristics of diseases, the greater the chance that a correct diagnosis will be made.

Many of the diseases listed in [Table 77.2](#) have clinical subgroups with somewhat dissimilar manifestations and, hence, prognosis. Of relevance to this discussion, these subgroups are often associated with different aab profiles and specificities ([Permin et al., 1978](#); [Cervera et al., 1993, 2002](#); [Kuwana et al., 1994](#); [Mustila et al., 2000](#); [Wiik, 2001](#); [Scussel-Lonzetti et al., 2002](#); [Targoff, 2002](#)). Therefore, certain aab are valuable biomarkers of a disease subgroup with markedly different clinical features, end organ involvement, and prognosis. Accordingly, the information imparted by aab profiles, in combination with other biomarkers, is likely to be valuable in the future as an approach to tailoring therapeutic strategies (i.e., personalized or prescriptive medicine) ([Franssen et al., 1998](#); [Andrade, 2009](#); [Fritzler, 2011b](#); [Plenge and Bridges, 2011](#); [Tak, 2012](#)).

In the entire spectrum of aab described to date, those with high disease specificity, regarded as disease-specific markers, tend to be rare ([von Muhlen and Tan, 1995](#)). This is especially true today when newer diagnostic platforms (ELISA, ALBIA, CLA) have achieved higher sensitivity than older immunoassays. Thus, with the introduction and adoption of newer diagnostic technology platforms, aab that were thought to be specific for one disease based on older or even outdated technologies, may subsequently turn out to be associated with a variety of autoimmune diseases ([van Eenennaam et al., 2002](#)). The appreciation that multiple disease-related aab occur in a single serum and that aab expression may change over time in individual patients ([von Muhlen and Tan, 1995](#); [Blass et al., 1999](#); [Vasiliauskiene et al., 2001](#); [Visser et al., 2002](#)) holds potential that aab serology in combination with other biomarkers (i.e., genomics, cytokines, metabolomics, transcriptomics) may lead to an earlier and more accurate diagnosis, and, by extension, more effective therapeutic interventions ([Fritzler, 2011b](#); [Plenge and Bridges, 2011](#)). While some evidence indicates that certain aab are stable over the disease course ([Ippolito et al., 2011](#)), other evidence indicates that aab profiles as determined by array technologies will likely change over time (reviewed in [Fritzler, 2012](#)). Evidence supporting this notion includes observations that aab to RNA helicase occur only early in the course of SLE ([Yamasaki et al., 2007](#)), and only clinically distinct neuropsychiatric events attributed to SLE that occurred around the time of diagnosis were found to be associated with anti-P antibodies and the lupus anticoagulant (anti-phospholipid, anti-cardiolipin) ([Hanly et al., 2008](#)). Hence, multiplexed and autoantigen array technologies that are now emerging provide more extensive aab profiles in a given patient ([Kessenbrock et al., 2007](#); [Mahler and Fritzler, 2010](#)) are altering approaches to diagnostics and therapeutics ([Fritzler, 2002](#); [Robinson et al., 2002](#); [Schachna et al., 2002](#)).

CLINICAL PRACTICE GUIDELINES

Because of the complexity of modern autoimmune serology, there continues to be a pressing need for clinical practice guidelines (CPG) that outline the appropriate and economic use of serologic testing. If a limited number of clinicians are involved in ordering diagnostic testing, it is easier to achieve a consensus on testing strategies. However, there is a growing trend toward amalgamated regional and national laboratories that provide service to a widening spectrum of health care providers. Thus, clearly articulated CPG are required to lay out criteria for aab screening and an evidence-based testing algorithm that limits unnecessary testing ([Wiik et al., 2004](#)). A related strategy is to develop aab order forms in such a way that the doctor chooses between tentative diagnoses, after which only evidence-based tests are done. It is important to realize that the pre-test probability to detect a useful diagnostic laboratory result increases dramatically when each clinical feature or diagnostic criterion has been incorporated into the tentative diagnosis ([Keren and Nakamura, 1997](#)).

LABORATORY REPORTS, ELECTRONIC MEDICAL RECORDS, AND COST ANALYSIS

Many laboratories use an aab testing algorithm that includes a rapid and inexpensive screening test (i.e., IIF) followed by more specific tests (i.e., LIA, ALBIA, ELISA) as an approach to evidence-based screening for serum aab. For example, the IIF test or whole cell lysate ELISAs are often used to detect autoantibodies in SARD and other diseases (reviewed in [Stinton and Fritzler, 2007](#); [Fritzler, 2011c, 2012](#)). This serves two purposes: first, as an approach to triage for further reflex testing; second, if the IIF or screening ELISA test is negative, unless there is a compelling clinical evidence to do so, no further testing is required and the result is reported accordingly. However, as discussed earlier there is a caveat inasmuch as the sensitivity of IIF testing is not as high as some presume and is attended by significant “false-negative” results ([Fritzler, 2011c](#)). Third, many autoantibodies can be quite accurately identified solely by an IIF screening approach ([Table 77.3](#)).

It is very important that aab test results should be validated and, in this context, borderline (low positive) results can be especially troublesome. It is recommended that borderline positive results must be confirmed or refuted by use of a second well-established independent technique to ensure that only certified positive results are reported to the physician or clinic. If controversy about the result persists, the laboratory should add a note of caution to the clinician that the result may have little significance in supporting a diagnosis and/or may

TABLE 77.3 Autoantibodies Determined by IIF Patterns that may be Useful in Clinical Diagnostics

| Cellular structure/IIF staining pattern | Molecular targets | Disease associations |
|---|---|---|
| Coiled bodies | p80 coilin | Localized SSc, Raynaud's syndrome |
| Golgi complex | Golgins, giantin | SLE, SjS, RA overlap syndromes, malignancy, viral infection |
| Mitotic spindle apparatus – Centrioles – NuMa pattern – Spindle microtubules | enolase, pericentrin, ninein NuMa 235 HsEg5 | SSc, SjS, post-viral syndromes, <i>Mycoplasma</i> infection SLE, SjS SjS, SLE |
| Multiple nuclear dots | Sp-100 | Primary biliary cirrhosis |
| Nuclear envelope | Lamins A/C, B1, B2, LAP1/2 | SLE, SjS, CAH, APS, SNP |
| Nuclear pore complex | p62, gp210, Tpr | PBC, SjS |
| GW bodies | GW182, hAgo2, Ge-1/Hedls, RAP55 | SjS, sensory/motor neuropathy, SLE, PBC |
| Dense fine speckles | DFS70/LEDGF | Rare in SARD, in isolation, may rule out diagnosis of SARD |

Abbreviations: APS, anti-phospholipid antibody syndrome; CAH, chronic active hepatitis; DFS, dense fine speckles; LEDGF; lens epithelium derived growth factor; NuMA, nuclear mitotic apparatus; PBC, primary biliary cirrhosis; RA, rheumatoid arthritis; SARD, systemic autoimmune rheumatic diseases; SjS, Sjögren's syndrome; SLE, systemic lupus erythematosus; SNP, seronegative polyarthritis; SSc, systemic sclerosis; Tpr, translocated promoter region.

recommend retesting a new serum sample in 1 to 3 months. Some regulatory agencies mandate that borderline positive tests should be reported as positive until proven otherwise after repeat or follow-up testing at appropriate intervals. High and intermediate positive results of a single credible technique can be reported without independent confirmation by a second technique. To aid in the interpretation of laboratory results the chosen limit for positivity should be stated in the report along with ranges of low, intermediate, and strong positivity.

A problem is that easy-to-perform and high throughput techniques are often adopted by clinical laboratories without proper clinical validation. Screening for aab by ELISA that have adsorbed complex mixtures of native and/or recombinant autoantigens or nuclear extracts is now used by many laboratories instead of IIF ANA screening (Meroni and Schur, 2010; Fritzler, 2011a,c). This practice continues despite data showing that many patients with Sjögren's syndrome (SjS), systemic sclerosis (SSc), autoimmune myopathies, and juvenile idiopathic arthritis (JIA) score negative for ANA using such composite ELISA screening techniques (Keren and Nakamura, 1997; Fawcett et al., 1999). While the technology has remarkably improved in the last few years, HEp-2-IIF screening of these "false-negative" sera reveals that many of these sera contain aab to nucleoli, nuclear matrix, nuclear envelope, nuclear pores, coiled bodies, promyelocyte leukemia (PML) domains, cell cycle-specific antigens such as proliferating cell nuclear antigen (PCNA) and mitotic spindle apparatus components, or

other cytoplasmic organelles and structures such as mitochondria, Golgi apparatus, signal recognition particles or ribosomal proteins (Bayer et al., 1999; Wiik, 2003a,b; Stinton et al., 2004) (Tables 77.2 and 77.3).

Studies using older screening ELISAs have shown that some of these aab are readily recognized by experienced technicians (Wiik and Lam, 2001) but are missed by ELISAs for ANA screening (Bayer et al., 1999). Some of these aab have defined clinical associations and should be identified as such (Table 77.3). It needs to be emphasized that newer technologies and wider testing have not supported clinical associations of some aab. For example, anti-PCNA aab once thought to be highly specific for SLE, have recently been shown to lack specific disease associations (Vermeersch et al., 2009; Mahler et al., 2012b). Aab that lack proven clinical value should be reported but it must be clearly stated that neither their diagnostic specificity nor their value has been clearly established.

It is important to point out that not all aab are diagnostic of or associated with clinically apparent autoimmune diseases. This goes beyond established evidence that disease-specific aab can be detected in first-degree relatives of autoimmune diseases patients, in a variety of bacterial and viral infections, or in apparently unrelated conditions and normal individuals. Several lines of evidence indicate that approximately 20% of serum samples from healthy individuals have a positive ANA test, the majority of which produce an IIF pattern known as dense fine speckles (DFS) (Mahler et al., 2012a). The typical IIF DFS staining pattern is typically observed as small

FIGURE 77.1 IIF pattern of dense fine speckles (DFS) on HEP-2 cell substrate. Anti-DFS antibodies (left panel) typically stain the nucleus and metaphase chromatin (arrow) as compared to antibodies to Sm/U1RNP (right panel) which also stain the nucleoplasm but do not stain the metaphase chromatin (arrow). It is important to appreciate that consistent staining characteristics of anti-DFS sera can vary from manufacturer to manufacturer of HEP-2 substrates. ImmunoConcepts HEP-2000 substrate; original magnification 250 \times .

Box 77.2 Advantages and Disadvantages of the EMR

Advantages

- Improved turnaround time and accessibility to laboratory results
- Eliminating part of “paper trail”: improved accuracy of reporting
- Increased knowledge of the patient’s disease status
- Improved interaction of patient with health care providers
- Increased patient safety
- More knowledgeable patients involved in self-management
- Enhanced communication with health care team
- Elimination of lower security multiple paper records and mailed/faxed paper reports
- Higher security of health information

Disadvantages

- Challenges interpreting reports and data
- Additional security protocols and standard operating procedures add extra workload
- Consultation content changed
- Altered face-to-face patient–provider interactions

speckles that are somewhat uniformly distributed throughout the nucleus and on metaphase chromatin (Figure 77.1). Of note, the DFS staining pattern has been reported in 33% of ANA-positive healthy individuals, but not in ANA positive SARD sera (Mariz et al., 2011). Since their first description, anti-DFS70 antibodies have been found in the sera of patients with a variety of chronic inflammatory conditions, such as interstitial cystitis and atopic dermatitis, as well as in cancer patients and in healthy individuals (reviewed in Mahler et al., 2012a). The target autoantigen is a 70-kDa protein. This autoantigen was initially termed DFS70, but the primary autoantigen

was eventually identified as the lens epithelium-derived growth factor (LEDGF) (reviewed in Ganapathy and Casiano, 2004). As the intended use of the ANA HEP-2 test is to primarily serve as a screening test to aid in the diagnosis of SARD, the reporting of anti-DFS70 antibodies as a positive test significantly reduces the specificity and the positive likelihood of the ANA IIF test. This has important implications for ANA test algorithms because if these results are widely validated, it suggests that aab associated with DFS70/LEDGF can be used to rule out the diagnosis of SARD (Mahler et al., 2012a).

When aab are detected, the positive result is usually communicated in a printed report that is sent directly to the requesting physician or the referring laboratory. Unfortunately, in some jurisdictions, regulatory constraints (i.e., Health Protection Act and Freedom of Information Protection Act) prohibit the transmission of a digital report directly to the referring physician’s computer or other digital devices. Nevertheless, there is a trend in many jurisdictions to rapidly adopt electronic medical records (EMR) that will accommodate uploading encrypted or otherwise secure data files directly to online or “cloud” storage of patient medical records. For many laboratories, this has added another layer of protocols and standard operating procedures that are intended to protect patient confidentiality. Efforts to develop consensus on the format and structure of the EMR, along with consensus terminology and content of aab results, would be an important step forward in standardizing the aab testing system (Vogt et al., 2004; Pincus et al., 2009; Malaviya and Gogia, 2010; Wiik et al., 2010). A number of advantages and disadvantages of the EMR have been identified (Liao et al., 2010; van der Vaart et al., 2012) (Box 77.2). At the present time, the question regarding unlimited access of patients to their EMR is unsettled (van der Vaart et al., 2012). While information on diagnosis, treatment plan, and consultations might be released for patient access, more complex data, such as physical examinations, laboratory results, and radiographic images, are more controversial. There is some thought that providing patients random access to their EMR might be an important step to empowering and enhancing patient service, provided that clinical and personal data and information security is optimal, and content and presentation of data are constructed so that they are clearly understood by patient and physician alike. A description of the most common diagnostic associations related to an aab found in diagnostic testing should be included with the result. Also, the level (titer) of the aab or the strength of expression should be mentioned together with how these relate to cut-off values and how they were established (i.e., disease controls, normal controls, and the range of credible measurements).

There is a serious deficiency in our knowledge of the actual costs incurred through inappropriate laboratory testing, although the actual costs of laboratory diagnostic testing can readily be calculated. In Scandinavia, the estimated cost of all types of *in vitro* diagnostic testing in laboratories is between 2 and 3% of the total budget for health care. The prospects for health care financing are intimately linked to the three overarching tenets of clinical medicine: (1) disease prevention is of utmost importance, (2) an early and accurate diagnosis is the next most important, and (3) appropriate, effective treatment follows the first two. Many health care providers and payers jump from (1) to (3) without much consideration of (2). An estimation of long-term costs related to early accurate diagnosis and therapeutic intervention compared to a missed or a wrong diagnosis, with or without treatment, needs to be performed to highlight the value of high quality laboratory diagnostics.

STANDARDIZATION AND QUALITY ASSURANCE

A number of jurisdictions have recognized the importance of standardizing aab testing (Wiik et al., 2006; Shoenfeld et al., 2007) and a set of standardized sera provided by the IUIS/AF/WHO/CDC Serology Committee (www.autoab.org) have been made available through the CDC in Atlanta (Chan et al., 2007). The reference sera available through this program are continually monitored and more recent additions to the reference sera available include those with defined aab directed to cardiolipin/ β 2-glycoprotein I, RNA polymerase I/III, ribosomal P proteins, proteinase 3, and myeloperoxidase (c- and p-ANCA, respectively). Sera used as standards for a particular methodology or technology platform need to be reviewed from time to time as exemplified by the re-evaluation of AF/CDC reference sera by a variety of contemporary techniques (Smolen et al., 1997; Copple et al., 2012). Although it would likely decrease inter-laboratory variation in performance, standardized secondary antibodies are not widely available.

All clinical laboratories should participate in quality assurance and quality improvement programs such as the one administered by the College of American Pathologists (www.cap.org). The Clinical Laboratory Improvement Amendments of 1988 set standards for all laboratories engaged in clinical testing. These standards include requirements for trained and competent supervisory and testing personnel, record keeping and instrument maintenance, daily quality control practices, result reporting, and laboratory inspection and maintenance. It is not clear that these standards are being met in routine practice. In Europe the most widely used quality assurance and management program (DS/EN ISO/IEC 17025:2000)

additionally sets laboratory standards aimed to prove that an assay actually gives results that are useful for clinical diagnostics.

CONCLUSIONS AND FUTURE PROSPECTS

The detection of aab can serve as biomarkers that focus the clinician's attention to involved tissues or organs using classical diagnostic tools such as histopathology, imaging techniques, and organ function testing. Clinical practice guidelines to facilitate the communication between clinicians and laboratories need to be formulated, along with mutually accepted algorithms for test ordering and interpretation. The emergence of the EMR is a significant step forward but is attended by some challenges.

In contemporary medical practice, changes in laboratory diagnostics and new technologies to detect aab are being introduced at a rapid pace. This is attended by concerns that certain key matters, such as clinical utility, are not thoroughly addressed. In many cases, the manufacturer has often been assumed to be the root cause for shortcomings in aab testing; however, the use of commercial kits and their appropriate application in a clinical setting involves a rather complex set of contingencies (Fritzler et al., 2003a; Fritzler, 2012). It has been suggested that a higher level of commitment and partnership between all of the participants is required to achieve the goal of improving the quality of patient care through the use of aab testing and analysis (Wiik et al., 2004).

| | | Acknowledgments | 1186 |
| | | References | 1186 |

Many autoimmune diseases are chronic in nature with a long asymptomatic preclinical period marked by laboratory abnormalities (e.g., the presence of autoantibodies; [Table 78.1](#)) and are associated with particular genetic markers. Therefore, individuals with asymptomatic disease can be identified prior to developing tissue destruction with immunologic and immunogenetic testing. Given the prevalence of autoimmune disorders, immunologic and immunogenetic testing is likely to become an important component of what has been termed “personalized medicine.” In this review, we will emphasize studies of endocrine autoimmunity, especially type 1 diabetes (T1D) where techniques for disease prediction have dramatically developed over the past two decades. Disease prevalence and characteristics of the test influence positive and negative value of test results ([Table 78.2](#) and [78.3](#)).

TYPE 1 DIABETES MELLITUS AS A MODEL FOR PREDICTION OF AUTOIMMUNE DISEASE

The chronic disease model for T1D ([Figure 78.1](#)) is a useful model for the prediction of T1D. In this model, the mass of insulin-producing pancreatic beta cells is depicted on the

y-axis and time on the x-axis ([Eisenbarth, 1986](#)). As the disease progresses, the beta cell mass decreases and markers of autoimmunity such as autoantibodies against islet-specific proteins and islet specific T cells emerge. As the beta cell mass diminishes, metabolic abnormalities develop and ultimately clinical diabetes manifests. Studies can be performed at each step along the way to identify individuals at risk for clinical diabetes. This model, however, could not until recently be verified by the direct observation of pancreatic pathology in individuals with T1D and/or islet autoimmunity. The investigation of the pathogenesis of T1D has been traditionally hindered by the difficult access to the pancreas in affected individuals. Following initial studies of autopsy pancreata, recent initiatives have awakened interest in the pathology of the pancreas in T1D. The JDRF-sponsored nPOD initiative and a similar European study are utilizing the pancreata of organ donors with diabetes and islet autoimmunity to correlate the disease status with morphological changes in the islets of Langerhans. The findings of these studies as they pertain to prediction of T1D are summarized below.

THE PANCREATIC PATHOLOGY IN TYPE 1 DIABETES MELLITUS AND ISLET AUTOIMMUNITY

In T1D there are two fundamental patterns of beta cell pathology, namely pattern A and pattern B, characterized

[†] With their deepest regret the Editors note the death of Dr George Eisenbarth during the composition of this text. The Editors' Preface contains a tribute to his many valued achievements and contributions. The corresponding author is Jennifer Barker.

TABLE 78.1 Representative Disease-associated Autoantibodies

| Disease | Autoantibodies |
|----------------------|---|
| Type 1 diabetes | Islet cell autoantibodies Insulin, GAD65, IA-2 |
| Thyroid disease | Anti-thyroid peroxidase Anti-thyroglobulin |
| Addison's disease | Anti-21-hydroxylase |
| Celiac disease | Anti-tissue transglutaminase |
| Neuromyelitis optica | Anti-aquaporin 4 |
| Rheumatoid arthritis | Rheumatoid factor (IgM anti-IgG) Anti-cyclic citrullinated peptide |

TABLE 78.2 Sensitivity, Specificity, and Positive (PPV) and Negative Predictive Value (NPV)

| Study | Disease | |
|---------------------------|--------------------|--------------------|
| | Present | Absent |
| Positive | A (true positive) | B (False positive) |
| Negative | C (false negative) | D (True negative) |
| Sensitivity = $A/(A + C)$ | PPV = $A/(A + B)$ | |
| Specificity = $D/(B + D)$ | NPV = $D/(C + D)$ | |

respectively by the presence or absence of pseudo-atrophic islets (i.e., islets without any residual insulin-positive cells).

In pattern A there is usually complete beta cell loss but in some cases residual beta cells can be found. In particular, approximately 30% of individuals with long-standing T1D have residual beta cells; in these cases the pancreas contains both normal and pseudo-atrophic islets in various

proportions in different cases. Islet antibody positivity (as determined by radioassay to the four autoantigens to be described below) is strongly associated with pattern A. In contrast the majority of subjects with pattern B are negative for islet autoantibodies and do not express high-risk DR alleles. The pancreata with pattern A, but not the pancreata with pattern B, contain, in some instances, islets infiltrated by mononuclear cells (insulinitis). Thus, it appears that islet autoantibody positivity defines a subset of T1D with autoimmune pathogenesis while autoantibody negativity is probably associated with different etiologies. Therefore, it is likely that the true sensitivity for autoimmune diabetes of islet antibodies is higher than previously thought since in new-onset antibody-negative subjects diabetes might be due to non-autoimmune etiology.

From the above findings it is clear that T1D of autoimmune etiology is associated with pseudo-atrophic islets and insulinitis. The ability of islet antibodies to predict the disease likely signifies that the changes seen in the pancreata of subjects with T1D are also present in the pancreata of islet autoantibody-positive prediabetic individuals, in particular subjects positive for more than one antibody (positivity for one antibody has a lower positive predictive value than positivity for multiple antibodies). Data from a Belgian group confirmed these predictions by showing that insulinitis is present in organ donors positive for multiple antibodies but absent in single antibody positive. In addition we and others have identified pseudo-atrophic islets in multiple islet antibody-positive subjects (unpublished observation) suggesting that in these individuals there is chronic beta cell destruction before the clinical onset of diabetes. Of note, we have identified a subset of individuals previously classified as having a clinical diagnosis of type 2 diabetes mellitus that display pattern A beta cell pathology and, in some cases, islet antibody positivity. It is likely that these subjects correspond to the group previously classified as LADA (latent-onset diabetes of the adult, see also below).

TABLE 78.3 Effect of Disease Prevalence on Positive (PPV) and Negative Predictive Value (NPV) with Identical Test Specificity (99%) and Sensitivity (90%)

| | Low Prevalence (0.3%) | | | High Prevalence (5%) | | | |
|----------|------------------------|--------|---------|-----------------------|---------|--------|---------|
| | Disease | | | Disease | | | |
| Test | Present | Absent | | Test | Present | Absent | |
| Positive | 270 | 997 | 1267 | Positive | 4500 | 950 | 5450 |
| Negative | 30 | 98,703 | 98,730 | Negative | 500 | 94,050 | 94,550 |
| | 300 | 99,700 | 100,000 | | 5000 | 95,000 | 100,000 |
| PPV | 270/1267 = 21.3% | | | 4500/5450 = 82.6% | | | |
| NPV | 98,703/98,730 = 99.97% | | | 94,050/94,550 = 99.5% | | | |

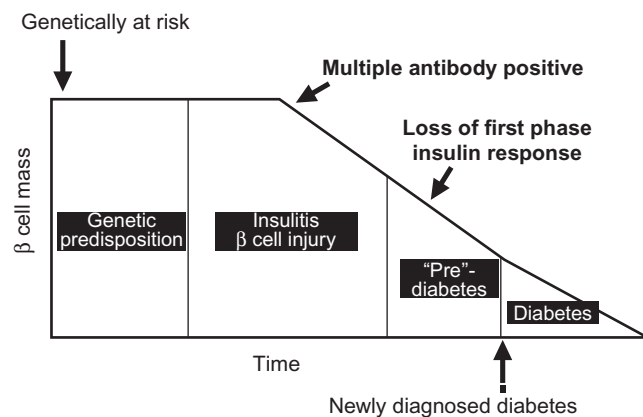

FIGURE 78.1 A model for the natural history of the autoimmunity leading to type 1A diabetes. Individuals who are genetically susceptible to disease are triggered to initiate insulinitis or beta cell injury. This is marked by the production of autoantibodies against the pancreas. As loss of beta cell mass continues, metabolic abnormalities such as a loss of first phase insulin response begin and ultimately when enough beta cells are lost, diabetes develops.

As mentioned earlier and discussed more in detail later, positivity for one islet autoantibody has a lower positive predictive value for T1D than positivity for two or more antibodies. This observation has an interesting correlate in the lack of insulinitis in single antibody-positive subjects and raises the question of the etiology of single antibody positivity. It is possible that single antibody-positive subjects might have a pathological lesion, which has the potential to result in T cell-mediated islet autoimmunity and T1D but does not necessarily do so in all cases. If this hypothesis is correct, one should be able to detect morphological islet changes in single islet antibody positive but not in control subjects.

Genetics

Although greater than 85% of individuals with T1D do not have a family history of T1D, the risk for diabetes in a first-degree relative of an individual with T1D is approximately 15 times greater than that of individuals from the general population (6% vs. 0.4%) (Tillil and Kobberling, 1987). The major histocompatibility complex (MHC) located on chromosome 6 (6p21.3) is thought to contribute 50% of the genetic risk for T1D (Nerup et al., 1974). Noble et al. (1996) and Erlich et al. (1993) have shown that both DQ and DR alleles have been associated with T1D. HLA haplotypes associated with the highest risk for T1D are DR3, DQ2 (DQA1*0501, DQB1*0201), and DR4, DQ8 (DQA1*0302 DQB1*0302) (Ziegler et al., 1991).

It is estimated that approximately 6% of the population with DR3-DQ2/DR4-DQ8 will develop T1D. However, the risk of diabetes in first-degree relatives with this high-risk HLA genotype is much higher. Approximately 40% of siblings of patients with T1D with DR3-DQ2/DR4-DQ8

will develop T1D. This suggests that other genetic loci within the MHC also contribute to risk of T1D in that relatives with high-risk HLA alleles usually share complete MHC haplotypes. These high-risk genotypes also impact the age at which T1D develops. Approximately 50% of those who develop T1D prior to 5 years of age are heterozygotes for DR3-DQ2/DR4-D8 compared to 2.4% of Colorado newborns (Redondo et al., 2001).

Specific HLA haplotypes protect individuals from disease. Similarly to many studies, Pugliese et al. (1995) have reported that DR2 (DRB1*1501, DQA1*0102, DQB1*0501) and DR7 with DQA1, DQB1*0301 and DRB1*1401 are protective for the development of T1D.

Additional genetic loci such as the insulin gene (Bell et al., 1984; Bennett et al., 1997), CTLA-4 (Lowe et al., 2000; Nistico et al., 1996), and PTPN22 (Bottini, et al., 2004), and more than 50 other loci, have also been associated with T1D.

HLA haplotypes and to a lesser extent insulin gene polymorphisms are the only genetic markers that have been used to identify individuals from the general population at high risk for the development of T1D. Studies such as the Diabetes Autoimmunity Study in the Young (DAISY) in Denver, Colorado, USA (Rewers et al., 1996), and the Finnish Type 1 Diabetes Prediction and Prevention project (DIPP) (Kupila et al., 2001) follow children from the general population who are at high risk for the development of T1D based upon the presence of moderate or high-risk HLA genotypes.

The presence of high-risk HLA genotypes increases the likelihood of T1D by an order of magnitude. In the general population those with the highest-risk HLA haplotypes have a risk for T1D of approximately 6%, compared with a risk of 0.4% in the general population (Tillil and Kobberling, 1987). In first-degree relatives this risk increases from approximately 6% to approximately 40% in those with the highest-risk HLA genotypes. However, risk is not absolute with a significant subset of individuals with high-risk HLA genotypes never developing islet autoimmunity. Further evaluation, including the use of anti-islet autoantibodies, will refine prediction.

LABORATORY MARKERS OF AUTOIMMUNITY (INCLUDING AUTOANTIBODIES AND T CELL ASSAYS)

Since the discovery of islet cell autoantibodies (ICA), detected by incubation of serum with sections of frozen human pancreas (Bottazzo et al., 1980; Lendrum et al., 1975), autoantibodies have been used to identify individuals at risk for T1D. ICA is measured in Juvenile Diabetes Foundation (JDF) units with positive often defined as ≥ 10 JDF units. Bonifacio et al. (1990) and

(Chase et al., 1991) have showed that the risk for diabetes increases as the ICA level increases. In first-degree relatives, the risk for T1D increases from 40% with a low cut-off (≥ 4 JDF units) to 100% (in one study) with a high cut-off (≥ 80 JDF units) (Bonifacio et al., 1990). The relationship between level and PPV for diabetes has also been observed in cohorts without an affected first-degree relative (Chase et al., 1991).

The specific antigens of ICA include the glutamic acid decarboxylase (GAD65), the protein tyrosine phosphatase ICA512 (IA-2), and ZnT8. Insulin autoantibodies are not detected with the staining of frozen pancreas. These autoantibodies are the current so-called biochemical autoantibodies. Sensitive and specific radioimmunoassays (RIA) have been developed for autoantibodies to insulin, GAD65 IA-2. More recently, antibodies to Znt8 were discovered and are also used for both the prediction and the diagnosis of diabetes. In particular, antibodies to Znt8 identified a subset at higher diabetes risk in individuals with one antibody to GAD, IA-2, or insulin (Yu et al., 2012).

When ICA is present in the company of biochemical autoantibodies, the risk for T1D increases. Individuals who expressed ICA alone were at a much lower risk for T1D (less than 5%) compared with those positive for ICA and biochemical autoantibodies (66.2%) (MacLaren et al., 1999). This is probably related to higher prevalence of false-positive ICA in subjects without biochemical antibody. Yu et al. (2001) demonstrated that higher levels of ICA are associated with expression of one or more biochemical autoantibodies. Previous reports have described heterogeneity among islet cell antibodies with better predictive value for diabetes in the subset reacting to multiple autoantigens. Therefore, the risk conferred by ICA can also be identified through testing for biochemical autoantibodies.

Life-table analysis has shown that expression of multiple biochemical autoantibodies is associated with a greater risk for T1D (Figure 78.2). Individuals who express three anti-islet autoantibodies are at an approximately 70% risk for T1D after 5 years, compared with 12% for those who express one anti-islet autoantibody (Verge et al., 1996).

A number of population-based prospective studies such as DAISY and the German babyDIAB study have established that islet autoimmunity can appear years before the onset of diabetes and can occur as early as the first year of life. The risk for T1D does not appear to dissipate over time for individuals with multiple autoantibodies. Gardner et al. (1999) followed first-degree relatives with multiple autoantibodies and found a progressive increase in incidence of T1D over time such that at 15 years, 66% had developed diabetes. The development of diabetes did not appear to be decreasing at the end of the study. This has led to the hypothesis that all

FIGURE 78.2 First-degree relatives of individuals with T1D were followed for development of diabetes. Those relatives who expressed more than two or three autoantibodies were at a greater risk for the development of diabetes compared with those who expressed one autoantibody (Verge et al., 1996).

individuals who express multiple autoantibodies will develop diabetes given enough time. In contrast, the expression of a single biochemical autoantibody is associated with a long-term risk of less than 20% in relatives of patients with T1D. Transient expression of autoantibodies in the DAISY study was not associated with high-risk genotypes or family history of diabetes and the development of T1D (Barker et al., 2004).

LaGasse et al. (2002) have used biochemical autoantibodies to screen school children in Washington State, USA. Approximately 4500 school children were screened, 12 children were found to have two or three positive autoantibodies. Six children developed diabetes during 8-year follow-up. All expressed at least two autoantibodies. None of the children with zero or one autoantibody developed diabetes. This indicates that autoantibodies can be used in a large population to screen for disease.

The DAISY study has identified children with biochemical autoantibodies and followed them for the onset of diabetes. Children diagnosed with this intensive screening program tend to be found at an earlier stage of disease and have less diabetic ketoacidosis (Barker et al., 2004). These children also have lower blood glucose levels at the time of diagnosis (Figure 78.3).

The use of autoantibody assays has identified individuals previously classified as type 2 diabetics as having an autoimmune process associated with a faster progression to insulin dependency compared with autoantibody-negative individuals. Approximately 45% of such adults positive for ICA required insulin at 6 years post onset of diabetes compared to 5% of those with no autoantibodies. This so-called latent autoimmune diabetes of adults (LADA) was analyzed in the UKPDS study. Similarly, Fuchtenbusch et al. (1997) have demonstrated that in women with gestational diabetes,

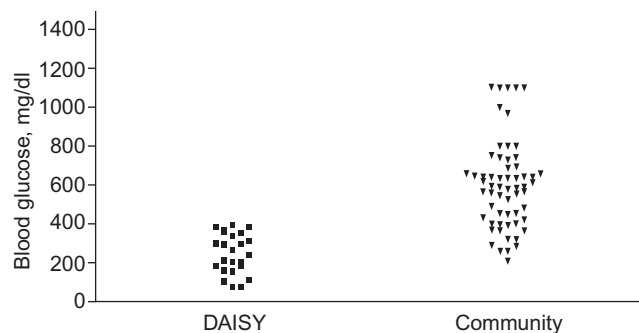

FIGURE 78.3 Blood glucose levels at diagnosis of diabetes in individuals diagnosed with diabetes through an intensive screening program compared with those diagnosed from the community.

the presence of one, two, or three autoantibodies conferred a risk for insulin dependency of 17%, 61%, and 84%, respectively, during follow-up of approximately 2 years. Autoantibodies can be used in adults diagnosed with diabetes as a prognostic factor for insulin dependency.

Multiple international workshops evaluating different assay formats for islet autoantibodies in mouse models of T1D and humans indicate that standard ELISA formats are inadequate in contrast to fluid phase radioassays. For example, ELISA anti-insulin autoantibody assays could detect insulin antibodies following subcutaneous insulin therapy but could not detect pre-diabetic insulin autoantibodies (Greenbaum et al., 1992) (Figure 78.4).

More recently, however, GAD and IA-2 antibody-modified ELISA have achieved sensitivity and specificity equivalent to in-house RIA and an electrochemiluminescence IAA assay was recently reported to be more sensitive than IAA radioassay (Yu et al., 2012).

T1D is known to be a T cell-mediated disease. Autoantibodies are likely only a marker of the autoimmune process and are not themselves directly pathogenic. Therefore, efforts are underway to develop reliable T cell assays for T1D. Tetramer analysis has allowed for the detection of T cells that react to beta cell antigens. Tetramer analysis employs the use of multimeric peptide–MHC complexes to detect T cells. Using this technology, soluble HLA-DR401 or DR404 tetramers with a GAD65 epitope were found to react with T cells of newly diagnosed T1D and individuals at risk for T1D (Reijonen et al., 2002, 2003). In 2011, the Immunology of Diabetes Society conducted two workshops to validate class I and class II antigen-specific tetramers. For class I, peripheral blood T cell responses were measured by multiple centers in 35 patients with newly diagnosed T1D using both tetramers and pentamers encompassing epitopes of preproinsulin and GAD. All epitopes were recognized by T1D patients with a prevalence ranging from 5 to 25%.

Class II GAD and proinsulin epitopes were similarly evaluated and found to be positive in at least 74% of patients. Of note, only a minority of patients tested by tetramer and ELISPOT were positive for both assays.

ELISPOT (enzyme linked immunoabsorbent spot) is utilized to monitor CD4⁺ and CD48⁺ lymphocyte response to antigens.

In particular, a CD8 T cell response to a peptide of islet amyloid polypeptide (IAPP) has been described (Panagiotopoulos et al., 2003). More recently, French groups have demonstrated reactivity to epitopes of the islet autoantigens Znt8 in 80% of children with T1D but only 18% of controls (Énée et al., 2012). Similarly, Dang and coworkers identified a CD4 Znt8 response in the peripheral blood of patients with T1D (Dang et al., 2011).

Further refinement of both tetramer and ELISPOT are needed for these technologies to significantly contribute to the prediction of T1D.

Metabolic Studies

Metabolic abnormalities begin to appear as the beta cell mass diminishes to the point at which it cannot appropriately respond to a glucose load. An early metabolic abnormality is the loss of the first phase insulin response (FPIR) on the intravenous glucose tolerance test (IVGTT). The FPIR is the sum of the insulin levels at 1 and 3 minutes after an intravenous glucose load. In the presence of islet autoantibodies, levels that are less than the first percentile of age-matched normal controls identify individuals that are at a 50% risk of the development of overt diabetes at 5 years and 90% at 10 years (Bingley et al., 1992; Bleich et al., 1990). This relationship remains true in individuals who are positive for anti-islet autoantibodies (Bleich et al., 1990). In the DIPP study, Keskinen et al., 2002 followed children with multiple anti-islet autoantibodies and showed that they have lower FPIR than children with ICA only (Figure 78.5) and that half of the children with abnormal FPIR developed overt diabetes during the time period of the study. The metabolic state of an individual at risk for T1D is dynamic and beta cell loss may be ongoing, so repeat evaluation is necessary in order to be maximally sensitive. In addition to being able to correctly identify individuals at risk for overt diabetes, an FPIR greater than the 10th percentile has a good negative predictive value. Relatives with FPIR greater than the 10th percentile rarely progress to T1D over a 3-year period. Using the FPIR in addition to autoantibody data led to the development of a model of risk for T1D. In this model, the time remaining before the development of T1D was dependent upon the FPIR and IAA level (Jackson et al., 1988).

The FPIR is not without problems. It is a measure of beta cell function, and thus only an indirect measure of beta cell mass. As such, situations that increase insulin resistance such

FIGURE 78.4 Percentage of positive IAA (defined as $\geq 3SD$ above the mean) healthy individuals who became diabetic ($n = 8$). Numbers along the x-axis indicate different laboratories. Open bars are laboratories using RIA and closed bars are those using ELISA (Greenbaum et al., 1992).

FIGURE 78.5 Level of FPIR is associated with number of positive autoantibodies; children with three autoantibodies expressed the lowest FPIR. The dotted line represents the first percentile in age-matched normal controls (Keskinen et al., 2002).

as puberty and obesity may affect the results. In addition, there is significant intra-subject variability with coefficients of variation ranging between 4 and 36% (Allen et al., 1993; Arslanian et al., 1993; Smith et al., 1988). The timing of loss of FPIR differs in the progression to T1D in different groups. For example, in young children who express autoantibodies, the FPIR may already be lost at the time of first autoantibody expression (Keskinen et al., 2002) and some individuals maintain FPIR into their first year of diagnosis of T1D.

As the beta cell mass continues to diminish, the metabolic abnormalities become more pronounced and may be detected in routine oral glucose tolerance testing, initially with impaired glucose tolerance (glucose 2 hours after oral glucose ≥ 140 mg/dl and < 200 mg/dl). It is of

note that early in the time course of T1D, the metabolic abnormality might not be observed in the fasting state. At this point, the individual is not symptomatic but may rapidly progress to symptomatic diabetes. Useful prognostic metabolic information can be obtained by careful analysis of C-peptide secretion and subclinical abnormalities of glucose excursions of oral glucose tolerance testing (Sosenko et al., 2008).

ORGAN-SPECIFIC AUTOIMMUNE DISEASES

Thyroid

Autoimmune thyroid disease (AIT) manifested as either hypothyroidism or hyperthyroidism is very common in the general population. Approximately 5% of the population is hypothyroid and 1.3% hyperthyroid (Hollowell et al., 2002). AIT occurs at an increased frequency in individuals with T1D (28% (Umpierrez et al., 2003)), Addison's disease (AD) (14–21% (Betterle et al., 2002; Kasperlik-Zaluska et al., 1998; Zelissen et al 1995; Lendrum et al., 1975)), celiac disease (CD) (up to 12% (Ansaldi et al., 2003)), and other autoimmune diseases. Therefore, the first step in prediction requires knowledge of the individual's medical history. Routine screening for thyroid disease is generally recommended in these individuals as there is a high pretest probability of disease and the studies are relatively non-invasive.

Risk for AIT is weakly related to HLA genotypes that vary dependent upon the population. Santamaria et al. (1994) reported that DRB1*0201 increased the risk for AIT in T1D. Kim et al. (2003) reported that DQB1*0401 increased the risk in the Korean diabetic population. DQB1*0302 has been associated with AIT in the Czech diabetic population (Sumnik et al., 2003). DR3 and DR5 have been associated with thyroid autoimmunity in German blood donors (Boehm et al., 1993).

FIGURE 78.6 The development of hypothyroidism in the diabetic population is dependent upon the production of thyroid autoantibodies. Individuals who express TPO are at a much higher risk for hypothyroidism compared with those who do not (Umpierrez et al., 2003).

AIT is accompanied by autoantibodies to thyroid antigens, anti-thyroid peroxidase (TPO), and anti-thyroglobulin (TG) (Vakeva et al., 1992). These autoantibodies are positive in approximately 10% of the general population (Hollowell et al., 2002) and in around 90% of the hypothyroid population (Vakeva et al., 1992). Prospective follow-up by Vanderpump et al. (1995) in the Whickham study has shown that women with positive TPO autoantibodies and normal TSH have a 2.1% per year risk of developing hypothyroidism with an overall risk of 27% of hypothyroidism at 20 years.

In high-risk populations such as T1D, progression to AIT is related to the presence of TPO and TG antibodies, with approximately 80% of T1D positive for TPO antibodies progressing to AIT compared to 15% of those TPO negative (Umpierrez et al., 2003) (Figure 78.6). Of note, individuals with negative TPO autoantibodies still progressed to AIT but at a much lower rate.

Similarly to T1D, in which abnormalities of glucose metabolism identify individuals at a greater risk for clinical diabetes, individuals who have abnormalities of thyroid metabolism are at an increased risk for the development of overt hypothyroidism. Of those with an elevated TSH and normal thyroid hormone, 55% were hypothyroid at 20 years, with a 4.3% yearly incidence.

Screening for thyroid autoimmunity in high-risk populations such as T1D with TPO and/or TG autoantibodies may identify individuals at an increased risk for autoimmune thyroid disease for closer monitoring. The efficacy of this screening has not been fully evaluated.

Addison's Disease

Addison's disease (AD) is an autoimmune endocrine disease resulting in primary adrenal insufficiency. It is a rare

disease in the general population, occurring in approximately 1/10,000 individuals. However, it does occur with other autoimmune endocrine diseases including T1D and AIT. The combination of two of the three autoimmune diseases (T1D, AD, and/or AIT) is known as autoimmune polyendocrine syndrome II (APS-II).

Genetic risk for AD is conferred by the major histocompatibility complex (MHC) on chromosome 6. This includes the HLA class II region. AD is associated with DRB1*0404 DQ8 (Yu et al., 1999). Gambelunghe et al. (1999), Park et al. (2002), and Baker et al. (2011) have shown that polymorphisms of other loci within the MHC including HLA-B15 MIC-A are associated with AD both in the diabetic and non-diabetic populations.

AD is accompanied by the production of autoantibodies against the adrenal cortex (Anderson et al., 1957). Winqvist et al. (1992) and Baumann-Antczak et al. (1992) have identified the cytochrome p450 enzyme 21-hydroxylase as the major antigen for these antibodies. Falorni et al. (1997) has shown that 21-hydroxylase autoantibodies are highly sensitive and specific for AD. Reflecting the increased risk for AD in people with T1D, individuals with T1D express adrenal autoantibodies at a rate of 1–2% (Brewer et al., 1997; Peterson et al., 1997; Yu et al., 1999). Recently, the first international serum exchange for the determination of 21-hydroxylase antibodies (Falorni et al., 2011) showed good agreement between participating laboratories but also revealed important discrepancies in individuals' specimens. These results demonstrate the need for an international 21-hydroxylase antibody standardization program.

Formal adrenal function is tested using cortrosyn (ACTH) stimulation. We have recently demonstrated that moderately elevated ACTH is a more useful early indicator of impending AD than 21-hydroxylase AA, PRA, or peak cortisol in the 2 months to 2 years preceding the onset of AD (Baker et al., 2012). Thus annual measurement of ACTH is likely sufficient to monitor individuals with 21-hydroxylase autoantibodies, reserving cortrosyn testing for those with moderately elevated ACTH or Addison's symptoms.

Celiac Disease

Celiac disease (CD) is an autoimmune disease characterized by gluten insensitivity. Symptoms range from malabsorption, diarrhea, and stunted growth to less specific symptoms of fatigue and malaise. Celiac disease can be found in the company of T1D and AIT, occurring in as many as 10% of individuals with T1D (De Vitis et al., 1996) and AIT (Ansaldi et al., 2003).

Celiac disease occurs in association with specific HLA genotypes. In individuals with T1D who are

FIGURE 78.7 The production of tissue transglutaminase autoantibodies is highly dependent on the presence of HLA DR3 (Hoffenberg et al., 2003).

homozygous for HLA DQ2, approximately one-third are positive for autoantibodies to tissue transglutaminase (tTG) (Bao et al., 1999). Ninety-five percent of individuals with CD have HLA DQA1*0501, DQB1*0201, compared with 36% of the general population (Hall et al., 1991). DQA1*0501, DQB1*0201 generally occurs with DR3-DQ2 (DQA1*0501DQB1*0201) and DR5, DR7 heterozygotes (DRB1*0701 DQA1*0501). Hoffenberg et al. (2003) have prospectively followed neonates from the general population with the high-risk DR3-DQ2 HLA haplotypes in Denver, Colorado. Children with high-risk haplotypes were enrolled and followed for the development of autoantibodies to tTG. At age 5 years, 3.2% of children DR3/3 homozygous developed positive tTG compared with 3.4% of heterozygotes and 0.3% of children negative for DR3 (Figure 78.7).

Celiac disease is associated with the expression of autoantibodies. Autoantibodies against gliadin (IgG and IgA) are sensitive but not specific and therefore have a low positive predictive value (deamidated gliadin autoantibodies are more specific). In contrast, antiendomysial autoantibodies (EMA) are highly sensitive and specific. EMA are detected with indirect immunofluorescence against human umbilical cord. Recently tTG has been identified as the autoantigen of EMA and highly sensitive and specific assays have been developed to detect tTG autoantibodies (Dieterich et al., 1997; Fasano et al., 2001; Gillett et al., 2001). Bonamico and coworkers (Bonamico et al., 2011) have demonstrated the feasibility of large-scale screening of the general population for salivary anti-transglutaminase antibodies as determined by radioassay.

Diagnosis of celiac disease is made by biopsy of the small intestinal mucosa showing the characteristic pathologic changes and confirmed with resolution of these findings on biopsy after institution of a gluten-free diet. Because of the invasiveness of the procedure, biopsy should be performed only in individuals with a high likelihood of being positive. Factors that increase the pretest probability of disease include individuals who are symptomatic of disease and individuals with higher levels of autoantibody as measured by the radioimmunoassay. Liu et al. (2003) showed that higher levels of tTG in a radioimmunoassay had a higher PPV for biopsy. The standard cut-off of 0.05 (99% specificity) had a PPV of 76% compared with 96% with a cut-off of 0.5. In addition, the level of tTG autoantibody has been shown to correlate with severity of findings on biopsy (Liu et al., 2003). Therefore, level of autoantibody can be incorporated in an algorithm to decide whether or not to perform the biopsy. The autoantibody levels also decrease on a gluten-free diet and are used to monitor compliance with therapy.

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic autoimmune disease resulting in neurologic deficits. It occurs in the setting of specific HLA alleles. DRB1*1501 has consistently been shown to predispose to MS (Allen et al., 1994; Laaksonen et al., 2002). In a large group of patients, this has been shown to have a dose effect with two copies of the susceptible haplotype associated with a higher risk of MS compared with one or none. Those individuals who express DRB1*1501 on both HLA DRB1 alleles tend to have a more severe disease course (Barcellos et al., 2003).

Autoantibody determinations in these groups are less well defined compared with the other autoimmune disease discussed. In contrast, a variant of multiple sclerosis termed neuromyelitis optica is strongly associated with autoantibodies reacting with aquaporin 4.

NON-ORGAN SPECIFIC DISEASE

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a systemic autoimmune disease. It is characterized by joint inflammation ultimately leading to joint destruction and disability. At diagnosis, individuals often show signs of advanced joint destruction. Landewe et al. (2002) have shown that early treatment decreases disease severity. Therefore, the ability to predict disease and diagnosis in individuals early would have high clinical utility.

RA is associated with HLA-DR4 (HLA-DRB1*0401 and DRB1*0404), with the strongest association to DRB1*0404 (Silman and Pearson, 2002).

RA is accompanied by the production of autoantibodies. Rheumatoid factor (RF) and anti-cyclic citrullinated peptide (CCP) autoantibodies are commonly identified. Rheumatoid factor is an IgM (rarely IgG) autoantibody directed against IgG. Citrulline is an amino acid that is generated by post-translation modification of arginine by the enzyme peptidylarginine deiminase (PAD) (Vossenaar et al., 2003). Polymorphisms of the gene PAD4 are associated with RA (Vossenaar et al., 2004). Cyclic citrullinated peptide (CCP) autoantibodies are detected in 80% of patients with RA and are produced within the synovium and may have some impact on disease processes (Suzuki et al., 2003). Molecular modeling has shown that DRB1*0401 binds citrullinated peptides (Hill et al., 2003) and the presence of DRB1*0401 is correlated with autoantibodies to CCP (Goldbach-Mansky et al., 2000). Hill et al. (2003) have associated the genetic risk for RA to the presence of anti-CCP.

RA is thought to have a long preclinical phase that is marked by the presence of autoantibodies without the symptoms of arthritis. Aho et al. (1991) followed over 7000 Finnish individuals over the age of 30 years for the development of RA. Twenty-one individuals developed RA, 15 of whom had positive RF in serum samples prior to the development of disease. Halldórsdóttir et al. (2000) have prospectively determined that persistently positive RF is associated with development of disease. Nielen et al. (2004) retrospectively studied frozen serum samples obtained prior to the diagnosis of RA. Approximately 50% of individuals were positive for either RF or CCP a median of 4.5 years prior to symptom onset compared with approximately 1% of the general population control. The sensitivity of positivity for RF or CCP was 36.5%, with a specificity of 98.1%. The positive predictive value for a high-risk population of either RF or CCP autoantibody positive was 43.8%.

Rantapää-Dahlqvist et al. (2003) showed similar findings. However, the PPV of CCP autoantibodies with an estimated population prevalence of 1% was 16%. Therefore, the majority of individuals positive for these autoantibodies in the general population will not progress to disease and may not be candidates for early therapy. Majka and Holers (2003) have postulated that these autoantibodies may have a better utility in individuals with a high pretest probability of disease such as those with high-risk HLA haplotypes or those with a family history of disease.

New second generation anti-CCP antibody-automated assays have demonstrated a better correlation with clinical RA (Elrefaei et al., 2012) than previous ELISA formats. Despite these advancements, however, a recent large study,

using a combination of anti-CCP antibodies and the American College of Rheumatology 1987 criteria, failed to improve early rheumatoid diagnosis in a community-based very early arthritis cohort (Le Loët et al., 2011).

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease characterized by multi-organ involvement. The disease can have a relapsing–remitting course or become persistent with fulminant organ involvement.

Genetic risk is conferred by HLA class II alleles, in particular DR2 or DR3. In addition C4-null alleles occur in increased frequency in individuals in many ethnic groups (Christiansen et al., 1991).

Autoantibodies are produced in SLE and are characteristic of the disease. However, many of the autoantibodies are also produced in individuals who never develop disease. The anti-nuclear antibody is a good screening test for disease in that 95% of individuals with SLE will be positive for this antibody. However, as much as 5% of the general population will also be positive for this autoantibody, albeit at a low titer. Therefore, it is a sensitive but not specific marker of disease. Anti-double stranded DNA antibodies are more disease specific. Specific autoantibodies and quantification using radioimmunoassays have been associated with disease activity. For example, Yamamoto et al. (2000) described a radioimmunoassay for RNPs and found that in individuals with SLE 44% were positive and there was a correlation with SLE nephritis. The use of combinations of autoantibodies can improve sensitivity and specificity for SLE and levels of autoantibodies can be associated with disease activity scores (Ignat et al., 2003).

CONCLUSIONS

Effective prediction of autoimmune disease requires an understanding of the epidemiological concepts of sensitivity, specificity, PPV, NPV, and Bayes' theorem and, usually, assays with specificities $\geq 99\%$. Although assays and algorithms for T1D prediction are routinely set at this level of specificity, for most rheumatologic disorders immunohistochemical or ELISA assays with lower specificities are standard. It is likely that newer fluid phase methodologies would also improve prediction for these disorders. The use of laboratory studies in populations that are at a high risk for disease, defined by family history or the presence of a high-risk HLA haplotype, may also help improve prognostication for these individuals.

Prediction of disease is especially important when early diagnosis and intervention positively impact the patients. For RA, early treatment modifies the disease course and portends a better outcome in patients. For T1D, the early

identification of individuals at risk for disease by positive autoantibodies decreased the hospitalization for ketoacidosis compared with controls (Barker et al., 2004). As effective prevention measures are developed for autoimmune diseases, the ability to correctly identify individuals at a high risk for disease will become more important.

Autoimmune diseases are often accompanied by the production of autoantibodies. Certain characteristics of autoantibody production such as level, affinity, duration of positivity, and epitope recognition may be associated with disease development. Autoantibody assays can be used in a cohort of susceptible individuals to identify people at an increased risk for the development of disease. Autoantibody production can precede the development of disease for many years and some individuals who are autoantibody positive may never develop disease. Therefore, precise prognostication for a single individual is difficult. For T1D, the presence of two or more anti-islet autoantibodies is associated with very high risk of progression.

The presence of one autoimmune disease identifies an individual at a high risk for a second autoimmune disease (Pearce and Leech, 2004). The heightened risk for disease in this group increases the pretest probability of disease. Therefore, using autoantibody assays and/or T cell assays in this group will be more efficacious. A positive result will have a high post-test probability of disease in a single individual.

Many autoimmune diseases are T cell dependent. The development of reliable T cell assays that are sensitive and specific for autoimmune disease will be a major advance in the ability to predict disease. When used in combination with autoantibody assays, the T cell assays may refine our diagnostic ability and improve PPV and NPV.

The use of predictive algorithms that incorporate genetic risk expressed by HLA haplotypes or family history of disease, autoantibody production, and early physiological changes such as abnormal FPIR (T1D), mildly elevated TSH (AIT), or elevated ACTH (AD) will identify individuals at different points along the natural history of disease with increasing risk for disease development. These algorithms can be used to identify individuals who might benefit and be willing to participate in intervention studies and change the course of disease. We believe it is likely that most autoimmune disorders are preceded by a long prodrome and that waiting for clinical presentation can be associated with irreversible morbidity (bone erosions at diagnosis of patients with rheumatoid arthritis, osteoporosis with celiac disease, or presentation with T cell lymphoma) or even mortality (e.g., death from cerebral edema at onset of T1D, or hypotensive crisis of Addison's disease). As the field of "personalized" medicine progresses, utilizing knowledge

of personal risk factors (genetic, laboratory, clinical) to guide individual care, we believe that early detection of autoimmune disease risk will be increasingly important and will depend on improved tests as well as the development of preventive therapies.

INTRODUCTION

Autoimmune disease can be prevented to varying degrees in rodent models housed under standardized experimental conditions, by a range of approaches including autoantigen-specific induction of immune tolerance (reviewed in Faria and Weiner, 1999; Harrison and Hafler, 2000; Krause et al., 2000). However, translation to outbred, free-living human populations remains a major challenge and has not yet met with success. Possible reasons for this are discussed later. No potential therapeutic approach to prevention can be assumed initially to be completely safe and therefore prevention is predicated on the ability to identify, with a high degree of positive prediction, individuals likely to progress to clinical disease. It has been known since the 1980s that disease-associated autoantibodies presage the clinical onset of autoimmune thyroid disease, type 1 diabetes (T1D), systemic lupus, primary biliary cirrhosis, celiac disease, and other autoimmune diseases (reviewed in Leslie et al., 2001; Rose, 2008). However, refinement of autoantibody-based disease prediction by longitudinal studies of genetically susceptible individuals, leading to the selection of participants for prevention trials, has only been accomplished in T1D, partly because of the nature of the disease itself and partly due to the concerted efforts of T1D investigators and their supporters.

T1D is currently the best paradigm for autoimmune disease prevention, and the approaches developed in T1D are applicable to other autoimmune diseases. In T1D, susceptibility to autoimmune-mediated destruction of the insulin-secreting beta cells in the pancreatic islets is polygenic but dominated by genes in the major histocompatibility complex, and (increasingly) enhanced by the environment. In the majority of cases, T1D begins months to years before major loss of β cell function leads to hyperglycemia and symptoms (Figure 79.1). Progress in understanding mechanisms of β cell destruction, the ability to identify individuals at high risk for T1D, and proof-of-principle for preventive therapies in the non-obese diabetic (NOD) mouse model have set the scene for prevention of T1D in humans. Arresting immune-mediated β cell damage is relevant not only to individuals at risk but to those with clinical diabetes, in order to preserve residual β cell function, permit possible β cell regeneration, and prevent recurrent autoimmune disease after therapeutic β cell replacement or regeneration.

Experiments in rodent models have contributed substantially to our understanding of the pathogenesis of T1D and the expectation that it should be preventable (Leiter et al., 1987). The inbred, NOD mouse, the most widely used animal model of T1D, shares many features with human T1D, including polygenic inheritance dominated by genes for antigen-presenting major

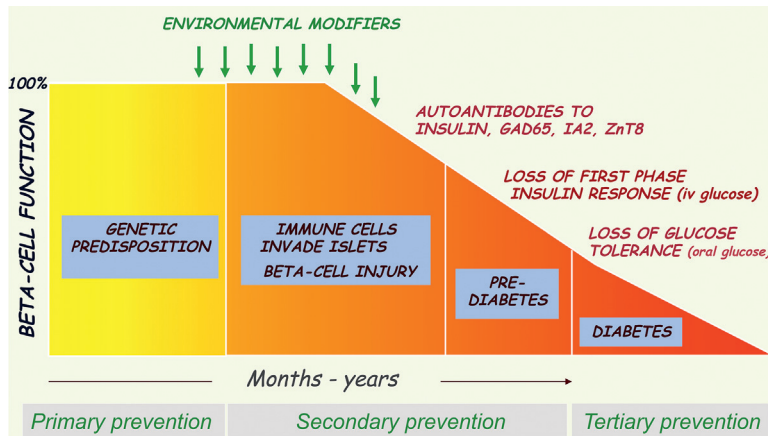

FIGURE 79.1 The natural history of type 1 diabetes.

histocompatibility complex (MHC) and other immune molecules, autoimmunity to insulin and glutamic acid decarboxylase (GAD), transfer of disease by bone marrow, and a protracted preclinical stage (Adorini et al., 2002). Many immune and other interventions reduce the incidence of diabetes in NOD mice (Atkinson and Leiter, 1999), but few totally prevent disease and many are ethically unsuitable in humans. Ideally, the burden of T1D and other autoimmune diseases would be reduced by primary prevention aimed at the environmental factors thought to precipitate disease in genetically at-risk individuals. Recent evidence implicates the contemporary “obesogenic” environment as a risk factor not only for T2D but also T1D (Wentworth et al., 2009). The incidence of T1D is increasing, particularly in overweight individuals with lower risk genes (Furlanos et al., 2008), and insulin resistance, associated with obesity, is a risk factor for progression to clinical disease in individuals with preclinical islet autoimmunity (Furlanos et al., 2004). Population-wide strategies to prevent obesity are therefore applicable to the prevention of both T2D and T1D.

Prevention strategies are likely to be most effective early in preclinical autoimmune disease, yet at that time prediction is less exact. Whether to intervene early or later when prediction is more certain but intervention less likely to be effective hinges on the balance of safety and efficacy. Potentially toxic immunosuppressive agents used (for “tertiary prevention”) after the clinical presentation of systemic autoimmune diseases such as lupus erythematosus or rheumatoid arthritis could well be effective in stemming islet autoimmunity but are generally ethically unacceptable in asymptomatic individuals, especially children at risk of T1D. On the other hand, other agents such as autoantigens administered to induce immune tolerance, while relatively safe, may be ineffective later in preclinical disease. With the onset of clinical diabetes the safety versus efficacy dilemma is less of an

issue, but the major loss of β cell function and mass at this time militates against efficacy. However, if conventional immunosuppressive agents could decrease the burden of pathogenic, effector T cells at the onset of clinical T1D this may allow induction of efficacious protective immune tolerance, and the potential for β cell recovery and possible regeneration.

Secondary prevention after onset of the autoimmune disease process but before clinical diagnosis and tertiary prevention after diagnosis (or intervention) have received considerable attention. Individuals at high risk for T1D can be identified by the presence of circulating autoantibodies to pancreatic islet autoantigens, allowing for the possibility of secondary prevention. However, the number of candidate agents that meet scientific and ethical criteria for trials in such at-risk individuals is limited, and recruiting these individuals is a major logistical exercise. Consequently, of the many clinical trials undertaken for “prevention” of T1D since the 1980s most have been tertiary trials in individuals with recent-onset T1D. A comprehensive listing of these trials is provided (Table 79.1), in which classification by agent necessitates combining the categories of secondary and tertiary prevention. The primary outcome measure in primary and secondary trials is (the absence of) clinical diabetes; in tertiary trials it is residual β cell function, measured by the increase in plasma C-peptide after either i.v. glucagon or a mixed meal tolerance test. C-peptide is secreted in equimolar proportions to insulin following cleavage of proinsulin in the β cell and is a surrogate for insulin when exogenous insulin or insulin antibodies could interfere with the measurement of endogenous insulin. A number of agents (from azathioprine to cyclosporine to monoclonal antibodies against CD3 and CD20) have been shown to slow the decline of β cell function after diagnosis, but their effect was transient and without ultimate clinical benefit (Table 79.1). Here we will adhere to the strict

TABLE 79.1 Trials for Prevention of T1D

| | Participants (n) | Follow-up (months) | Outcome | Reference |
|--|----------------------------|--------------------|--|---|
| Primary Prevention | | | | |
| Gluten elimination | AR (7) | 24 | No effect on islet antibody levels. | Hummel et al. (2002) |
| Cows' milk elimination (trial to reduce IDDM in the genetically at-risk TRIGR) | HLA at-risk infants (230) | 120 | Reduced incidence of islet autoantibodies; similar incidence of diabetes. | Hummel et al. (2011) |
| Cows' milk elimination (multicenter TRIGR) | HLA at-risk infants (2159) | 120 | Ongoing. | Knip et al. (2011) |
| Secondary and Tertiary Prevention | | | | |
| <i>Non-Specific Immune Suppression</i> | | | | |
| Azathioprine (2 mg/kg/day) | RD (24) | 12 | Higher basal and glucagon-stimulated C-peptide, and more remissions. | Harrison et al. (1985) |
| Cyclosporine (7.5 mg/kg/day) | RD (122) | 9 | More remissions. | Feutren et al. (1986) |
| Azathioprine (2 mg/kg/day) + prednisolone (reducing dose) | RD (46) | 12 | Higher meal-stimulated C-peptide and lower insulin dose. | Silverstein et al. (1988) |
| Cyclosporine (20 mg/kg/day) | RD (188) | 12 | Higher glucagon C-peptide and more remissions, especially in recently diagnosed. | Canadian-European Randomized Control Trial Group (1988) |
| Azathioprine (2 mg/kg/day) | RD (49) | 12 | Higher meal-stimulated C-peptide. | Cook et al. (1989) |
| Azathioprine and thymostimulin | RD (45) | 12 | Higher glucagon-stimulated C-peptide and more remissions. | Moncada et al. (1990) |
| Cyclosporine | RD (219) | 24 | Higher meal stimulated C-peptide and more remissions. | Assan et al. (1990) |
| Cyclosporine (10 mg/kg/day, 4 months) | RD (43) | 36 | No difference in glucagon-stimulated C-peptide, HbA1C, or insulin dose. | Chase et al. (1990a) |
| Prednisolone (15 mg/day, 8 months); indomethacin (100 mg/day, 8 months) | RD (25) | 24 | Lower insulin dose and higher urine C-peptide in prednisolone group. | Secchi et al. (1990) |
| Cyclosporine (10 mg/kg/day) | RD (23) | 12 | Higher meal- but not glucagon- or glucose-stimulated C-peptide. No difference in insulin dose. | Skyler and Rabinovitch (1992) |
| Anti-CD5 mAb/ricin A chain (unblinded) | RD (15) | 12 | Higher meal-stimulated C-peptide. | Skyler et al. (1993) |
| Glucocorticoid | RD (32) | 12 | Higher glucagon-stimulated C-peptide, but no remissions. | Goday et al. (1993) |
| Anti-CD4 mAb + glucocorticoid | RD (12) | 12 | No difference in insulin dose, or islet antibody titers. | Kohnert et al. (1996) |
| Methotrexate (unblinded) | RD (10) | 36 | No effect on basal or meal-stimulated C-peptide. Insulin dose higher. | Buckingham and Sandborg (2000) |
| Anti-CD3 mAb (hOKT3) (unblinded) | RD (18) | 12 | Increase in meal-stimulated C-peptide in first year. IL-10 detected in serum. | Herold et al. (2002) |
| Teplizumab (OKT3 (Ala-Ala) anti-CD3 mAb) | RD (42) | 24 | Improved C-peptide response to mixed meal, lower HbA1c, and reduced insulin dose. | Herold et al. (2005) |
| CH Agly anti-CD3 mAb | RD (80) | 48 | Improved C-peptide response to glucose. Clamp/glucagon up to 36 months. Reduced insulin dose with similar HbA1c. | Keymeulen et al. (2005, 2010) |

(Continued)

TABLE 79.1 (Continued)

| | Participants (n) | Follow-up (months) | Outcome | Reference |
|---|------------------|--------------------|---|--------------------------|
| Mycophenolate mofetil ± daclizumab (anti-IL-2 receptor mAb) (MMF/DZB) | RD (126) | 24 | No effect on basal or meal-stimulated C-peptide. Similar HbA1c and insulin dose. | Gottlieb et al. (2010) |
| Rituximab (anti-CD20 mAb) | RD (87) | 12 | Increased C-peptide response to mixed meal. Reduced HbA1c and insulin dose. | Pescovitz et al. (2009) |
| IL-2 + rapamycin | RD (7) | 12 | Transient decrease in C-peptide response to mixed meal associated with increased numbers of circulating regulatory T cells. | Long et al. (2012) |
| Abatacept (anti-CTLA-4 mAb) | RD (112) | 24 | Increased C-peptide response to mixed meal. Reduced HbA1c and insulin dose. | Orban et al. (2011) |
| Teplizumab (OKT3 (Ala-Ala) anti-CD3 mAb) | RD (516) | 12 | No difference in HbA1c or insulin dose. | Sherry et al. (2011) |
| Canakinumab (anti-IL-1 mAb) | RD (69) | 12 | No effect on mixed meal-stimulated C-peptide | Moran et al. (2013) |
| Anakinra (IL-1 receptor antagonist) | RD (69) | 9 | No effect on mixed meal-stimulated C-peptide | Moran et al. (2013) |
| Teplizumab (OKT3 (Ala-Ala) anti-CD3) | AR (170) | 48–72 | Ongoing | TrialNet |
| Non-Specific Immune Stimulation | | | | |
| BCG vaccine | RD (26) | 18 | No effect on glucagon-stimulated C-peptide, insulin dose, or HbA1c. | Elliott et al. (1998) |
| BCG vaccine | RD (94) | 24 | No effect on mixed meal-stimulated C-peptide, insulin dose, or HbA1c. | Allen et al. (1999) |
| Q fever vaccine | RD (39) | 12 | No effect on glucagon-stimulated C-peptide or insulin dose. | Schmidli R (unpublished) |
| Non-Specific Immune Regulation | | | | |
| Thymopoietin | RD (32) | 6 | Lower insulin antibodies and insulin dose. More remissions. No difference in C-peptide or HbA1c. | Giordano et al. (1990) |
| Gammaglobulin | RD (16) | 6 | Higher basal C-peptide. Lower insulin dose, unchanged HbA1c. | Panto et al. (1990) |
| Linomide | RD (63) | 12 | Lower HbA1c and insulin dose. No difference in glucagon-stimulated C-peptide. | Coutant et al. (1998) |
| HSP60 p277 peptide (DiaPep) | RD (35) | 10 | Decrease in glucagon-stimulated C-peptide and insulin dose in placebo but not treated group. | Raz et al. (2001) |
| 1,25-dihydroxy vitamin D3 | RD (20) | 18 | No effect on C-peptide response to a mixed meal or insulin requirement. | Walter et al. (2010) |
| HSP60 p277 peptide (DiaPep) | RD (146) | 12 | No effect on C-peptide response to a mixed meal. | Buzzetti et al. (2011) |
| Antigen-Specific Immune Regulation | | | | |
| Parenteral insulin (i.v. vs. s.c. 2 weeks) | RD (26) | 12 | Higher meal-stimulated C-peptide, lower HbA1c. | Shah et al. (1989) |
| Parenteral (s.c.) insulin | RD (49) | 60 | Higher glucagon-stimulated C-peptide and improved insulin sensitivity and glycemic control. | Linn et al. (1996) |

(Continued)

TABLE 79.1 (Continued)

| | Participants (n) | Follow-up (months) | Outcome | Reference |
|--|------------------|--------------------|--|--|
| Parenteral insulin (i.v. vs. s.c. 2 weeks) | RD (19) | 12 | Higher meal and glucagon-stimulated C-peptide and lower HbA1c. | Schnell et al. (1997) |
| Parenteral (s.c.) insulin | RD (10) | | Higher C-peptide response to oral glucose, HbA1C unchanged. | Kobayashi et al. (1996) |
| Parenteral (s.c.) insulin and sulfonylurea (glipizide) | RD (27) | 12 | Higher basal and glucagon-stimulated C-peptide, more remissions. | Selam et al. (1993) |
| Oral insulin | RD (80) | 12 | No effect on basal C-peptide, HbA1c, insulin dose, or insulin antibodies. | Pozzilli et al. (2000) |
| Oral insulin | RD (131) | 12 | No effect on basal, glucagon- or meal-stimulated C-peptide, HbA1c, insulin dose, or islet antibody levels. | Chaillous et al. (2000) |
| Parenteral (s.c.) insulin | AR (14) | 84 | Delay in onset of diabetes. No effect on islet antibody levels. | Füchtenbusch et al. (1998) |
| Parenteral (s.c.) insulin (Diabetes Prevention Trial Type 1—DPT-1) | AR (339) | 44 | No effect on diabetes development. | Diabetes Prevention Trial-Type 1 Diabetes Study Group (2002) |
| Intranasal insulin (Melbourne Intranasal Insulin Trial—INIT I) | AR (38) | 48 | Increased antibody and decreased T cell responses to insulin. | Harrison et al. (2004) |
| Oral insulin (DPT-1) | AR (372) | 52 | No effect on diabetes development overall. Post-hoc analysis revealed >4 year delay in diabetes onset in participants with insulin autoantibodies. | Skyler et al. (2005) |
| Parenteral (s.c.) insulin B chain in incomplete Freund's adjuvant | RD (12) | 24 | No effect on C-peptide response to mixed meal. Development of sustained insulin-specific antibody and T cell responses. | Orban et al. (2010) |
| Parenteral (s.c.) insulin B chain 9–23 “altered peptide ligand” NBI-6024-0101 (“Neurocrine”) | RD (188) | 25 | No effect on C-peptide response to mixed meal. | Walter et al. (2009) |
| Intranasal insulin (Diabetes Prediction and Prevention Project—DIPP) | AR (224) | 21 | No effect to delay progression to diabetes. | Nanto-Salonen et al. (2008) |
| Intranasal insulin (Intranasal Insulin Trial II—INIT II) | AR (120) | 60 | Ongoing. | Harrison, L.C. |
| Intranasal insulin (Intranasal Insulin Trial III—INIT III) | RD (52) | 24 | No effect on metabolic parameters. Suppression of T cell responses to insulin and antibody responses to subcutaneous insulin. | Fourlanos et al. (2011) |
| Parenteral (s.c.) GAD65-alum | RD (47) | 6 | Increase in fasting and stimulated plasma C-peptide with intermediate dose of 20 micrograms. | Agardh et al. (2005) |
| Parenteral (s.c.) GAD65-alum | RD (70) | 30 | | Ludvigsson et al. (2008) |
| Parenteral (s.c.) GAD65-alum | RD (334) | 15 | Delay in loss of C-peptide secretion, in those treated within 6 months of clinical diagnosis. No effect on metabolic parameters. | Ludvigsson et al. (2012) |
| Parenteral (s.c.) GAD65-alum | RD (145) | 12 | No effect on C-peptide response to mixed meal. | Wherrett et al. (2011) |
| Parenteral (i.m.) proinsulin plasmid DNA | RD (80) | 12 | Transient improvement in C-peptide response to mixed meal concomitant with a decrease in the CD8 T-cell response to proinsulin. | Roep, B.O. |
| Parenteral (s.c.) GAD65-alum | AR (50) | 60 | Ongoing. | Elding Larsson, H. |

| <i>β Cell Protection</i> | | | | |
| Nicotinamide | RD (20) | 12 | Higher glucagon-stimulated C-peptide at 45 days, then decline. No difference in remissions. | Mendola et al. (1989) |
| Nicotinamide | RD (23) | 9 | Higher basal and glucagon-stimulated C-peptide. | Vague et al. (1989) |
| Nicotinamide | RD (35) | 12 | No difference in basal or glucagon stimulated C-peptide | Chase et al. (1990b) |
| Nicotinamide | RD (56) | 12 | Higher glucagon-stimulated C-peptide in subjects >15 years old. | Pozzilli et al. (1995) |
| Nicotinamide ± cyclosporine | RD (90) | 12 | Lower insulin dose. No difference in remissions. | Pozzilli et al. (1994) |
| Nicotinamide ± parenteral insulin | RD (34) | 12 | No difference in glucagon-stimulated C-peptide. | Vidal et al. (2000) |
| Nicotinamide versus vitamin E (no control group) | RD (84) | 12 | No difference in basal or glucagon-stimulated C-peptide, HbA1c, or insulin dose. | Pozzilli et al. (1997) |
| Nicotinamide (Deutsche Nicotinamide Intervention Study—DENIS) | AR (55) | 36 | No effect on diabetes development. | Lampeter et al. (1998) |
| Nicotinamide (European Nicotinamide Diabetes Intervention Trial—ENDIT) | AR (552) | | No effect on diabetes development. | Philips et al. (2002) |
| Octreotide | RD (20) | 12 | Higher glucagon-stimulated C-peptide at 6 and 12 months; no difference in HbA1c or insulin dose. | Grunt et al. (1994) |
| Diazoxide | RD adults (40) | 18 | Higher basal C-peptide. | Bjork et al. (1996) |
| Diazoxide | RD children (56) | | Higher stimulated C-peptide at 12, not 24, months. | Bjork et al. (2001) |
| Antioxidants | RD (46) | 30 | No difference in meal-stimulated C-peptide, insulin dose, or HbA1c. | Ludvigsson et al. (2001) |

Abbreviations: AR, islet autoantibody-positive first-degree relative; RD person with recently diagnosed diabetes. Participant numbers are shown in parentheses.

definition of prevention and discuss only studies attempting to prevent clinical T1D. All randomized primary, secondary, and tertiary trials are summarized in Table 79.1, and more recent trials are registered on ClinicalTrials.gov.

Progress in preventing T1D is likely to be incremental, analogous to the evolution of combination treatment regimens for cancer or HIV infection, but more constrained by regulatory considerations. T1D prevention trials have taught us that: treatment will need to begin as early as possible in the preclinical stage; monotherapy is unlikely to be successful; there is a pressing need for mechanistic immune markers, especially of islet

autoantigen-reactive T cells, and for non-invasive means of evaluating islet pathology and β cell function.

PEOPLE AT RISK FOR TYPE 1 DIABETES

Neonatal screening for high-risk HLA class II susceptibility genes can identify over half of those destined to develop T1D (Kimpimäki et al., 2001). However, the modest predictive value of genetic testing would only justify a primary intervention that was safe, e.g., diet modification or vaccination. Secondary prevention has focused on first-degree relatives of a T1D proband, who have autoantibodies against one or more islet autoantigens:

Box 79.1 Markers of Risk for Diabetes in an Islet Autoantibody-positive Relative

- Number of antigen specificities of islet autoantibodies
- Antigen specificity of islet autoantibody
- Level of islet autoantibody
- Age at detection of islet autoantibody
- First phase insulin response (FPIR) to i.v. glucose
- Insulin resistance, e.g., estimated as HOMA-R
- HLA alleles for risk or protection
- HLA haplotype sharing with proband
- Kinship with proband

insulin, glutamic acid decarboxylase mol. wt. 65,000 isoform (GAD65), tyrosine phosphatase-like insulinoma antigen 2 (IA-2), and zinc transporter 8 (Verge et al., 1996; Bingley et al., 1999; Colman et al., 2000; Harrison, 2001; Wenzlau et al., 2007). A prerequisite for intervention in asymptomatic individuals is a high likelihood of developing clinical disease. Prediction of risk is determined by measuring autoantibody and metabolic markers of T1D (Box 79.1). In young first-degree relatives, the 5-year risk of diabetes is of the order <25%, 25–50%, and >50% if autoantibodies are present to 1, 2, and 3 islet antigens, respectively. For single specificities, autoantibodies to insulin (IAA) are the most predictive. A measure of insulin secretion, first phase insulin response (FPIR) to intravenous glucose, further refines risk prediction. In addition, in autoantibody-positive relatives with normal FPIR, the highest risk was shown to be independently associated with insulin resistance (Furlanos et al., 2004). This may reflect the increasing incidence of T1D in the “obesogenic” environment and has important implications for lifestyle approaches to prevention. Moreover, stratification of autoantibody-positive individuals based on insulin resistance deserves consideration in the design of prevention trials.

While detection of autoantibodies is fundamental to preclinical diagnosis and disease prediction, about 10% of new-onset T1D patients have no detectable antibodies. Moreover, while first-degree relatives who share susceptibility genes and environmental risk factors have at least a 10-fold higher prevalence of T1D than the background population they represent no more than 15% of people diagnosed with T1D. Identifying the other 85% using available predictive tests is more challenging because the lower prevalence of disease in the general population reduces the predictive value of screening tests compared to relatives (Bayes’ theorem). The predictive value of islet autoantibodies in the general population has not been widely investigated but will be important if effective means of secondary prevention are found.

Population heterogeneity is a critical consideration in the design and interpretation of clinical trials. In addition to HLA genes, over 50 genetic loci are associated with classical, juvenile-onset T1D, but very little is known

about how they contribute to disease development in different environments, or influence prevention strategies. Although a restricted set of HLA genes is shared among individuals with T1D, HLA-based heterogeneity in T1D progression and age at clinical presentation is well known (Honeyman et al., 1995; Tait et al., 1995). This suggests that T1D comprises disease subtypes and that prevention will most likely require a more “personalized” approach. Indeed, it is known that the natural history of declining β cell function after diagnosis depends on age, HLA status, autoimmune status including number and level of islet autoantibodies, residual β cell function, and insulin resistance (Greenbaum and Harrison, 2003). Inclusion of T1D relatives in secondary prevention trials has been based on age (<40) and islet autoantibodies (≥ 2), for a predicted 5-year incidence of $\approx 40\%$, but more refinement is possible by building subtype analysis into trial design. Up to 10% of adults presenting with diabetes have what appears to be a slowly progressive form of T1D, associated mainly with GAD65 autoantibodies, that initially is non-insulin-requiring (Hagopian et al., 1993; Tuomi et al., 1993; Gottsater et al., 1995; Turner et al., 1997). They have higher residual β cell function at diagnosis than younger patients with classical T1D, which implies a wider and perhaps more penetrable therapeutic window for secondary prevention (Furlanos et al., 2005).

The “personalized” approach requires new robust surrogate assays of disease mechanisms to identify people most likely to benefit from a specific therapy and allow the design of more practical, cheaper, and efficient boutique trials, rather than larger, expensive trials powered on the endpoint of diabetes. The application of insulin as an immune tolerizing agent in T1D (see below) may afford an example. Considerable evidence implicates insulin as the key, primary autoantigen driving β cell destruction in the NOD mouse, and possibly in children with classic T1D (Narendran et al., 2003). The insulin locus (IDDM2) maps to a variable number of tandem repeats (VNTR) upstream of the proinsulin gene. Long (class III) and short (class I) VNTR alleles are associated, respectively, with lower and higher susceptibility to T1D (Bennett et al., 1995). The length of the VNTR correlates with the level of proinsulin gene transcription in the thymus (Pugliese et al., 1997) and in a peripheral population of myeloid cells (Narendran et al., 2006), and may determine the extent of deletion of proinsulin-specific T cells during their intra-thymic development. The frequency of proinsulin peptide-specific T cells in human blood was reciprocally related to VNTR length (Durinovic-Bello et al., 2010), although an earlier study (Sarugeri et al., 1998) found no association between VNTR allelism and immunity to insulin. Nevertheless, it remains to be determined if IDDM2 VNTR typing would identify individuals most likely to benefit from (pro)insulin-specific immunotherapy.

PRIMARY PREVENTION

Primary prevention targets environmental factors that could precipitate islet autoimmunity in genetically at-risk individuals. The evidence for an etiological role of environment in T1D is persuasive (Wentworth et al., 2009) but will not be detailed here.

Diet and the Intestinal Environment

The hypothesis that early exposure of the infant to cow's milk and/or the lack of breastfeeding predisposes to T1D dates from the 1980s. Two meta-analyses of multiple studies in which T1D prevalence was associated retrospectively with infant feeding revealed only a marginal increase in relative risk (Gerstein, 1994; Norris and Scott, 1996). In the Denver-based Diabetes Autoimmunity Study in the Young (DAISY), infant feeding patterns retrospectively analyzed up to 6 months of age were not related to the development of islet autoantibodies up to 7 years of age (Norris et al., 1996). In the Australian BabyDiab Study (Couper et al., 1999) and the German BabyDiab Study (Hummel et al., 2000), there was no association between infant feeding patterns and the development of islet autoantibodies. Nevertheless, to answer whether cows' milk exposure is a risk, the multi-country Trial to Reduce IDDM in the Genetically at-Risk (TRIGR) was initiated. Newborns with a T1D first-degree relative and with HLA risk alleles, initially exclusively breast-fed, have been randomized to either a casein hydrolysate formula ("Neutramigen") comprising milk proteins of reduced complexity or a conventional cows' milk-based formula until 6 to 8 months of age, and are being followed for 10 years. Initially, casein-based formula was reported to reduce the risk of developing islet autoantibodies (Knip et al., 2010), implying it provided protection against T1D, but TRIGR will not be completed until 2017. Whatever the outcome, it does not mean that milk formula is superior to breast milk for preventing T1D. We sought to reframe the cow's milk hypothesis around mucosal immune function in T1D (Harrison and Honeyman, 1999). The essential role of a normal mucosal immune system in maintaining immune homeostasis is illustrated by the effect of a germ-free versus conventional "dirty" environment on diabetes incidence in NOD mice. The incidence of spontaneous diabetes in NOD mice differs greatly between colonies around the world and appears to be inversely correlated with exposure to microbial infection (Pozzilli et al., 1993). The high incidence of diabetes in NOD mice housed under pathogen-free conditions is reduced by conventional conditions of housing and feeding (Suzuki, 1987; Funda et al., 2005). Under such conditions, bacterial colonization of the intestine is accompanied by maturation of mucosal immune

function (Kawaguchi-Miyashita et al., 1996). Emerging evidence indicates that the gut microbiome differs in composition and function between children at risk for T1D and case controls (Brown et al., 2011). Supplementary to the microbiome, breast milk contains growth factors, cytokines and other immunomodulatory agents that promote functional maturation of the intestinal mucosa and mucosal immune system. Breast milk also contains endogenous insulin (Shehadeh et al., 2001), which could induce "oral tolerance" to insulin and so protect against the development of T1D (see below). Thus, rather than cows' milk promoting T1D, human milk could be protective, by immune maturational effects and/or by delivering human insulin to the "tolerogenic" mucosal immune system.

Dietary gluten has also been implicated as an environmental trigger of T1D. Antibodies to wheat gluten proteins are found in a proportion of T1D patients at the time of diagnosis (MacFarlane et al., 2002) and celiac disease and T1D share the HLA risk haplotype A1-B8-DR3-DQ2 and often coexist. In addition, the prevalence of autoimmune diseases, including T1D, in individuals with celiac disease was reported to correlate with duration of exposure to gluten (Ventura et al., 1999). However, in the German BABYDIET Study, delaying the introduction of gluten beyond 12 months of age had no effect on the cumulative incidence of islet autoantibodies or clinical T1D (Hummel et al., 2002). At the population level, compelling evidence links vitamin D deficiency to T1D and other autoimmune diseases. Vitamin D is derived primarily from ultraviolet B light-induced synthesis in the skin and its deficiency is increasingly recognized, not just in populations living furthest from the equator but in people anywhere who avoid sunlight, work and play mainly indoors, are dark-skinned and living in temperate climates, or cover their skin for cultural or religious reasons. The recommended daily allowance of vitamin D has decreased over the past 50 years from 5000 IU to 400 IU (Hypponen et al., 2001). This is the minimum dose required to prevent rickets following adequate prenatal intake but is inadequate for the physiological immune modulating and anti-inflammatory actions of vitamin D (Holick, 2004). Three European studies demonstrated an inverse relationship between vitamin D intake and the incidence of T1D. In a birth cohort study from northern Finland, an area with only 1900 hours' direct sunlight annually and the highest incidence of T1D in the world, T1D status was related to prerecorded data on infants 7–24 months of age given vitamin D in doses below, above, or at the then recommended 2000 IU daily (Hypponen et al., 2001). The 2000 IU dose was associated with a low relative risk of 0.12 (95% CI 0.03–0.47). In a multinational European case-control study, the odds ratio for T1D was significantly reduced in children given

vitamin D (EURODIAB Substudy 2 Study Group, 1999). The risk for T1D in Norwegian children was significantly lower if their mothers had taken cod liver oil (a source of vitamin D) during pregnancy (Stene et al., 2000). Randomized controlled trials of vitamin D supplementation in individuals at risk for T1D are required but may never be undertaken given the contemporary public awareness of vitamin D deficiency and the widespread availability of vitamin D.

Viruses

Evidence for viruses in T1D has been reviewed elsewhere (Honeyman, 2005). Viruses could potentially trigger or promote islet autoimmunity in several ways: by directly infecting β cells, infecting the exocrine pancreas with bystander death of β cells, or expressing proteins with sequences that mimic diabetogenic T cell epitopes (molecular mimicry). If a particular virus was clearly implicated, vaccination of children early in life, provided it was safe, should provide protection.

The first virus associated with T1D was rubella (Forrest et al., 1971). Children with congenital rubella born to mothers who contracted rubella early in pregnancy had evidence of infection in the brain, pancreas, and other tissues, and 20% developed insulin-dependent diabetes (Menser et al., 1978). Subsequently, almost twice this proportion of such children were reported to develop islet cell autoantibodies (Ginsberg-Fellner et al., 1985). Children with congenital rubella and ensuing diabetes were noted to have a higher frequency of the T1D susceptibility haplotype HLA-A1-B8-DR3-DQ2 (Menser et al., 1974). Rubella vaccine has virtually eliminated congenital rubella but whether it also represents the first example of primary prevention of T1D is debatable (Gale, 2008). Clearly, other environmental factors are involved because the incidence of T1D has continued to rise. Despite a report of rubella-GAD mimicry (Ou et al., 2000), strengthened by the finding of islet autoantibodies in children infected with rubella virus (Lindberg et al., 1999), there is no evidence from multiple studies (Hummel et al., 2000; DeStefano et al., 2001) that the vaccination with attenuated rubella virus is associated with islet autoimmunity.

Enteroviruses, which commonly infect children, are of ongoing interest in T1D (Honeyman, 2005; Roivainen and Klingel, 2010). Over 70 enterovirus serotypes are recognized with many thousands of strain variants and, except for poliovirus, vaccines are not available. However, if diabetes-associated strains were to be clearly implicated, they would be candidate vaccines for genetically at-risk children.

Strong sequence similarities between T cell epitopes in IA-2 and GAD65 and the VP7 protein of rotavirus in

islet antibody-positive relatives (Honeyman et al., 1998) suggested that molecular mimicry with rotavirus might precipitate islet autoimmunity. Rotavirus epidemics occur each winter particularly in kindergartens and are the most common cause of gastroenteritis in children. Rotavirus provides a profound inflammatory stimulus to the gut until sufficient IgA develops, by about 5 years of age. In the Australian BabyDiab Study, rotavirus infections were temporally associated with increases in islet autoantibodies in 24 children before they developed diabetes (Honeyman et al., 2000). It was then shown that rotavirus could infect β cells in islets from mice, pigs, and monkeys (Coulson et al., 2002). A more recent study (Honeyman et al., 2010) found that RV peptides homologous to IA-2 and GAD65 islet autoepitopes were CD4T cell epitopes in the context of HLA DR4, consistent with molecular mimicry. While ubiquitous rotavirus infections could drive cross-reactive immunity to islet autoantigens, this alone is unlikely to be diabetogenic. Mimicry may, however, complement and sustain the immune response to direct infection of β cells. Rotavirus vaccines, initially withdrawn because of safety concerns following cases of intestinal intussusception, are now routinely administered to infants. In countries like Australia where >90% of infants are covered by rotavirus vaccination it will be important to determine if this is associated with a change in the incidence of T1D. As a rider, it should be said that infection by rotavirus or other potentially diabetogenic viruses in a non-inflammatory context, such as during breastfeeding, could conceivably protect against T1D.

SECONDARY PREVENTION

The ideal prevention strategy in autoimmune disease is autoantigen-based immunotherapy, in which an autoantigen is administered to induce protective immune tolerance, also termed “negative vaccination” (Harrison, 2008). The rationale is that autoantigen-driven immunoregulatory mechanisms are physiological and can be boosted or restored to prevent pathological autoimmunity. Approaches include administration of an autoantigen by a “tolerogenic” route (e.g., mucosal), cell type (e.g., resting dendritic cell), mode (e.g., with blockade of costimulation molecules), or form (e.g., as an “altered peptide ligand”), all of which have been shown to prevent or suppress experimental autoimmune diseases in rodents (Faria and Weiner, 1999; Harrison and Hafler, 2000; Krause et al., 2000). Mechanisms encompass deletion and/or induction of anergy in potentially pathogenic effector T or induction of regulatory T cells (iTreg). Autoreactive T cells that are activated strongly by antigen may undergo apoptotic cell death and deletion, while those that survive or respond “partially” may become anergic (von Herrath and Harrison, 2003). Of potential importance clinically is the

ability of iTreg generated to specific antigen to exert antigen-non-specific “bystander suppression.” Thus, in response to specific antigen iTreg can, by direct cell contact or release of soluble immunosuppressive factors, impair the ability of antigen-presenting dendritic cells to elicit effector T cell responses to any antigen locally at the site of the lesion or in the draining lymph nodes. Bystander suppression does not require that the autoantigen used to induce tolerance is necessarily the major or primary pathogenic autoantigen.

Mucosa-mediated Antigen-specific Tolerance

Most attempts to induce clinical autoantigen-specific tolerance have been mucosa based. Numerous studies have shown that NOD mice can be partially protected from diabetes by mucosal administration of islet autoantigens. Zhang et al. (1991) initially reported protection after oral porcine insulin. Bergerot et al. (1994) then showed that human insulin induced CD4 Treg that could transfer protection to naïve mice. Protection following oral insulin was later found to be associated with decreased expression of IFN- γ -secreting Th1 T cells in the pancreas and pancreatic lymph nodes (Hancock et al., 1995; Ploix et al., 1998). Oral insulin-induced CD4 Treg have also been shown to prevent immune-mediated diabetes induced by lymphocytic choriomeningitis virus (LCMV) infection of mice expressing the viral nucleoprotein of LCMV under control of the rat insulin promoter in their β cells (Homann et al., 1999). The majority of T cells in the islets of oral insulin-treated mice without diabetes were shown to secrete Th2 (IL-4, IL-10) and Th3 (TGF- β) cytokines, in contrast to IFN- γ -secreting Th1 cells in islets of mice developing diabetes. The protective effect of oral insulin was enhanced by simultaneous feeding with IL-10 (Slavin et al., 2001), bacterial component OM-89 (Bellmann et al., 1997; Hartmann et al., 1997), or schistosome egg antigen (Maron et al., 1998), all of which promote Th2 responses. Fusion of insulin to cholera toxin B-subunit (CTB) significantly improved the ability of oral insulin to prevent diabetes (Bergerot et al., 1997). Oral CTB-insulin conjugates in NOD mice induced a shift from a Th1 to a Th2 immunity associated with the induction of regulatory CD4 T cells (Ploix et al., 1999). NOD mice were protected from diabetes by feeding them with potatoes that transgenically express CTB-insulin conjugates (Arakawa et al., 1998). Oral GAD65 has also been shown to suppress diabetes development in NOD mice (Ma et al., 1997). Although it is generally believed that neonates are less susceptible to mucosal tolerance induction, oral administration of insulin, insulin B-chain, or GAD65 peptide during the neonatal period still suppressed diabetes development in NOD mice (Maron et al., 2001). This suggests that mucosal administration of islet

autoantigen, e.g., in milk, could be used to treat very young infants at risk of developing T1D.

NOD mice are also protected from diabetes by naso-respiratory administration of islet autoantigens. This route of direct administration to the mucosa avoids antigen degradation in the stomach. When insulin was administered as an aerosol to NOD mice at 8 weeks of age, after the onset of subclinical disease, insulinitis and diabetes incidence were both significantly reduced (Harrison et al., 1996). Aerosol insulin induced novel anti-diabetic CD8 $\gamma\delta$ T cells that suppressed the adoptive transfer of diabetes to non-diabetic mice by T cells of diabetic mice. The type of Treg induced by (pro)insulin depends on the route and form of antigen. Naso-respiratory insulin, non-degraded and conformationally intact, induced CD8 $\gamma\delta$ Treg, whereas oral insulin degraded to peptides, or intranasal or oral (pro)insulin peptides, induced CD4 Treg (Hänninen and Harrison, 2000; Martinez et al., 2003). Intranasal administration of the insulin B-chain peptide (aa9-23), an epitope recognized by islet-infiltrating CD4 T cell clones capable of adoptively transferring diabetes to naïve mice, induced CD4 Treg and protected NOD mice from diabetes (Daniel and Wegmann, 1996). A peptide that spans the B-C chain junction in proinsulin also induced CD4 Treg after intranasal administration (Martinez et al., 2003). This peptide, like insulin B9–23, binds to the NOD mouse class II MHC, I-A^{g7} (Harrison et al., 1997), and is a T cell epitope in NOD mice (Chen et al., 2001) and humans at risk for T1D (Rudy et al., 1995). T cell epitope peptides from GAD65 administered intranasally were also protective, and associated with the induction of regulatory CD4 Treg and with reduced IFN- γ responses to GAD65 (Tian et al., 1996). These “proof-of-principle” studies in the NOD mouse indicate that islet autoantigen proteins or peptides are candidate mucosal “vaccines” for prevention of T1D in humans, but this promise remains to be fulfilled (see below).

Trials of Islet Autoantigen-specific Vaccination in Humans

The large multi-center Diabetes Prevention Trial 1 (DPT-1) was launched in the United States in 1994 to determine whether antigen-specific therapy with either systemic or oral insulin would delay or prevent diabetes onset in at-risk first-degree relatives. Previously, intensive systemic insulin therapy had been reported to prolong the “honeymoon phase” after diagnosis (Shah et al., 1989) and a pilot study of prophylactic systemic insulin had suggested that this approach might be of benefit in at-risk relatives (Keller et al., 1993). Whether systemic insulin acted only as a hormone to control blood glucose and “rest” β cells (making them less sensitive to immune attack) or also as an antigen to induce immune

tolerance was not clear, and read-outs to identify immune mechanisms were not employed. In DPT-1, low dose systemic insulin (annual intravenous insulin infusions and daily subcutaneous injections) was given to a high-risk group of relatives (>50% risk of diabetes over 5 years), matched with an untreated but closely monitored control group, but it had no effect on diabetes incidence (Diabetes Prevention Trial—Type 1 Diabetes Study Group, 2002). In the subsequent randomized controlled DPT-1 trial of oral insulin, relatives with a 25–50% 5-year risk of diabetes were given 7.5 mg human insulin or placebo daily for a median of 4.3 years. There was no effect overall, but post-trial hypothesis testing revealed a significant delay of approximately 4 years in diabetes onset in participants who were unequivocally positive for insulin autoantibodies at entry (Skyler et al., 2005) (Figure 79.2). That oral insulin only benefited participants with insulin autoimmunity suggests that allelism at the insulin gene susceptibility locus (IDDM2) could determine the immune response not only to endogenous insulin as a target autoantigen but also to oral insulin as a potential therapeutic tool. A follow-up international trial of oral insulin in at-risk relatives using the same 7.5 mg dose is in progress, under the auspices of TrialNet. Ideally, this would have incorporated a higher dose as well since on a body weight basis the 7.5 mg dose equates to only a few micrograms in the mouse, and milligrams of gavage insulin were required to induce anti-diabetogenic CD4 Treg in NOD mice. Two trials of oral insulin (up to 7.5 mg daily for 12 months) in recently diagnosed patients, attempting tertiary prevention (see below), showed no protective effect on residual β cell function (Chaillous et al., 2000; Pozzilli et al., 2000).

Why have trials of oral insulin in T1D, as well as oral myelin basic protein in multiple sclerosis (Weiner et al.,

1993) and oral collagen in rheumatoid arthritis (Trentham et al., 1993; McKown et al., 1999), failed to show clinical effects? The answer is probably for a combination of reasons: selection of subjects with end-stage disease; inadequate dose or bioavailability of the agent, possibly related to the route of administration; co-induction of pathogenic T cells; and genetic heterogeneity. Antigen-specific tolerance on its own is clinically ineffective in end-stage disease. If a balance between pathogenic and protective T cells determines clinical outcome, then antigen-specific tolerance should be most effective in early preclinical disease, or earlier. The question of dose is discussed below. Oral administration may not be optimal for mucosa-mediated tolerance because proteins are degraded after ingestion and the concentration or form of peptide reaching the upper small intestine may be inadequate to induce mucosa-mediated tolerance. Even for a small peptide, mucosal responses occurred after naso-respiratory but not oral administration (Metzler and Wraith, 1993). In the mouse, nasal administration of the model antigen, ovalbumin, elicited antigen-specific T cell responses in cervical, mediastinal, and mesenteric mucosal lymph nodes, whereas oral administration elicited responses only in the mesenteric nodes (Hänninen et al., 2001). Irrespective of route of administration, antigen presentation to the mucosa may be a “double-edged sword” simultaneously inducing both iTreg and pathogenic cytotoxic CD8⁺ T cells and a clinical effect may not be seen without suppression of the latter, e.g., by transient costimulation blockade with anti-CD40 ligand antibody (Hänninen et al., 2002). Insulin contains potentially pathogenic cytotoxic T cell epitopes but whether mucosal insulin induces cytotoxic CD8⁺ T cells as well as protective Treg is

FIGURE 79.2 Oral insulin vaccination delays development of diabetes in at-risk T1D relatives. Source: Adapted from Skyler et al. 2005.

FIGURE 79.3 Nasal insulin vaccination suppresses insulin antibody response to subcutaneous insulin. Source: Adapted from *Fourlanos et al. 2011*.

unknown, but needs to be ascertained. A proinsulin B-C chain peptide that induces CD4⁺ Treg in NOD mice is a “combitope” of CD4⁺ (I-A^{g7}-restricted) and CD8⁺ (K^d-restricted) T cell epitopes, and was significantly more protective after nasal administration when the C-terminal p9 anchor residue for binding to K^d was deleted or mutated (*Martinez et al., 2003*).

None of the oral autoantigen trials sought evidence for an immune effect and there is a pressing need to evaluate immune responses to mucosal autoantigens in human trials. Without this, it is not clear that the antigen dose used was bioactive/available. How might a response to oral insulin have been assessed? Insulin antibodies are a marker of bioavailability observed after aerosol insulin in NOD mice (*Harrison et al., 1996*) and intranasal insulin in humans (*Harrison et al., 2004*). Irrespective of whether or not they are a marker of immunoprotection, induction of insulin antibodies demonstrates that the insulin dose used was bioactive. Insulin autoantibodies are a risk marker for T1D and an increase in insulin antibodies after naso-respiratory insulin seems counterintuitive. However, this is not the case and in both the NOD mouse and humans at risk for T1D naso-respiratory insulin, although associated with a small but significant increase in insulin antibodies, was also associated with a decrease in T cell responses to insulin. This observation is consistent with the earliest descriptions of mucosal tolerance and with later landmark studies in humans using keyhole limpet hemocyanin (KLH) as a model antigen. When KLH was administered nasally to human volunteers it elicited a modest antibody response, but after challenge with subcutaneous KLH both antibody and T cell responses decreased (*Waldo et al., 1994*). In a recent randomized trial of nasal insulin in people with recent-onset T1D not requiring insulin

treatment at diagnosis, those who received nasal insulin had markedly blunted insulin antibody responses after eventually commencing on subcutaneous insulin treatment (*Fourlanos et al., 2011*) (*Figure 79.3*). It will be important to determine if nasal insulin induces insulin-specific regulatory T cells and to demonstrate that nasal insulin like nasal KLH suppresses T cell responses to rechallenge, indicative of T cell tolerance.

The recent evidence for nasal insulin-induced immune tolerance (*Fourlanos et al., 2011*) cannot be extrapolated to endogenous “autoantigenic” insulin but it provides a mechanistic rationale for randomized trials of nasal insulin vaccination in individuals at risk for T1D. One trial, the T1D Prediction and Prevention Project (DIPP) trial in Finland, has been reported on (*Nanto-Salonen et al., 2008*); the other, the Type 1 Diabetes Prevention Trial, also known as the Intranasal Insulin Trial II (INIT II) in Australia, New Zealand, and Germany (see stopdiabetes.com.au), is ongoing. In the DIPP trial, nasal insulin (1 U/kg daily) had no effect on progression to diabetes in islet autoantibody-positive children less than 3 years of age. The children were a very high-risk group and many appear to have had borderline β cell function judged by low first phase insulin response to i.v. glucose, suggesting they would have been unlikely to respond. As in the oral insulin trials, markers of immune responses to insulin were not reported. In INIT II, nasal insulin (440 U) or nasal placebo is being administered daily for 7 days and then weekly for a year, with a further 4-year follow-up, in T1D relatives aged 4–30 with autoantibodies to at least two islet antigens ($\approx 40\%$ risk of diabetes over 5 years). The primary outcome is diabetes development, secondary outcomes being measures of metabolic and immune

function. The insulin dose in INIT II is substantially higher than in the DIPP trial and the participants are older and have less advanced preclinical disease. INIT II aims to complete enrollment by the end of 2013. The question of timing applies even to secondary prevention and antigen-specific vaccination might be most effective before the onset of the disease process. To address this, a trial of oral insulin vaccination in children genetically predisposed to T1D (Pre-POINT trial), with no evidence of underlying islet autoimmunity, has commenced (Achenbach et al., 2008).

In concluding, a few comments on GAD65 vaccination trials are in order. Although GAD65 autoantibodies are a marker of T1D, their singular presence is associated with relatively indolent islet autoimmunity, as seen in latent autoimmune diabetes in adults (LADA) (Fourlanos et al., 2005). Nevertheless, based on evidence that the incidence of diabetes was lowered by systemic GAD65 (Petersen et al., 1994; Tisch et al., 2001) or nasal GAD65 peptides (Tian et al., 1996), a Swedish company, Diamyd P/L, produced recombinant GAD65 and initiated trials of a subcutaneous GAD65-alum (aluminum hydroxide) vaccine (summarized in Table 79.1). Although the initial trials were encouraging, subsequent larger trials failed to substantiate a clinical effect of the vaccine. As discussed above, it is no surprise that the GAD-alum vaccine showed no effect after the onset of clinical diabetes. However, these trials appear to have established the safety of the vaccine and, based on GAD65 antibody responses, its bioactivity, thereby justifying a secondary prevention trial (DIAPREV-IT) of the vaccine in islet autoantibody-positive at-risk children, which is ongoing.

EPILOGUE

Prevention of genetically complex and environmentally shaped autoimmune diseases will require more than a single “magic bullet.” Progress towards prevention will occur incrementally and involve a combination of agents tailored to genotype and disease mechanisms, disease stage, and risk status. Environmental agents that precipitate or exacerbate autoimmune disease are likely to be ubiquitous and therefore a single strategy, e.g., vaccination against a specific virus, is unlikely to be the answer. A prerequisite is the identification of at-risk individuals in early life, for which T1D is a paradigm. Prevention strategies must be safe as well as effective. In this regard, autoantigen-specific vaccination as applied in the oral and nasal insulin trials in T1D provide a glimmer of promise. Lessons learnt from the preclinical diagnosis, prediction, and prevention of T1D should be applicable to other autoimmune diseases.

Treatment of Autoimmune Disease: Established Therapies

Bevra H. Hahn and Jennifer K. King

University of California, Los Angeles, Division of Rheumatology, Rehab Center, Los Angeles, CA, USA

Chapter Outline

| | | | |
|---|-------------|--|-------------|
| Principles of Immune Suppression | 1209 | Cyclophosphamide | 1214 |
| General Considerations | 1211 | Mycophenolate Mofetil (Cellcept) | 1214 |
| Non-Specific Anti-Inflammatory Drugs | 1211 | Azathioprine (Imuran) | 1215 |
| NSAIDs | 1211 | Cyclosporin A | 1215 |
| Glucocorticoids | 1212 | Other Treatment Options | 1216 |
| Established Treatments of Rheumatic Diseases | 1212 | B Cell Suppressive Therapies | 1216 |
| Antimalarials | 1212 | IVIg | 1216 |
| Sulfasalazine | 1213 | Moving Towards Biological and Molecular Therapies | 1216 |
| Leflunomide | 1213 | References | 1217 |
| Methotrexate | 1213 | | |

Rapid advances in immunology and greater understandings of disease etiology and pathogenesis have made the treatment of autoimmune diseases a dynamic and swiftly evolving field. Older, established therapies such as glucocorticoids and non-specific immunosuppressive, chemotherapeutic agents are now being tested against newer, more targeted biologic and molecular therapies. Progress in elucidation of basic mechanisms of autoimmune diseases has led to rapid development of targets on antigen-presenting cells, T/B lymphocytes, cytokines, and costimulatory molecules. In addition, improved measures of defining clinical response and identification of biomarkers reflecting clinical outcomes and prognosis have accelerated the development of treatment options for autoimmune diseases. The goal of this chapter is to review established therapies of autoimmune diseases, with a focus on rheumatic diseases. We will highlight traditional therapies that form the foundation of current clinical practice (see [Table 80.1](#)), while laying out a context for which newer biologic and molecular targets are now evolving into the current standard of care (see Chapter 81).

PRINCIPLES OF IMMUNE SUPPRESSION

As with our oncology colleagues, the goals for physicians treating autoimmune diseases are to induce improvement (remission or low disease activity), while arresting irreversible organ damage and minimizing treatment side effects. Although definitive cure and restoration of permanent immunological tolerance would be ideal, most treatments now do not achieve that goal. Treatments are often non-specifically anti-inflammatory and/or immunosuppressive. Thus, the substantive side effects that accompany such treatments require balancing the risks of infection, bone marrow suppression, and other organ toxicity with potential efficacy.

In recent years, the paradigm of “tight control” has emerged, in which goal-directed treatments are based on quantitative and disease-specific measurements that guide providers to rapidly achieve low disease activity or remission. Notably, “tight control” in rheumatoid arthritis (RA) was illustrated in the TICORA study ([Grigor et al., 2004](#)) in which 111 patients were randomly assigned to either

TABLE 80.1 Established Immunosuppressives for Autoimmune Diseases

| Drug | Primary Mechanism of Action | Side Effects | Indications |
|-----------------------|--|--|--|
| Antimalarials | Inhibition of TLR-3/7, raising of lysozyme pH affecting antigen processing | Headache, pruritus, rash, neuropathy, corneal deposition, retinopathy | Systemic lupus erythematosus, rheumatoid arthritis, juvenile idiopathic arthritis, Sjögren's, juvenile dermatomyositis, palindromic rheumatism |
| Sulfasalazine | Inhibition of prostaglandin synthesis, inhibition of NF κ B transcription, reduction of TNF, suppression of B cells | Elevated liver enzymes, leukopenia, agranulocytosis, megaloblastic anemia, GI or CNS side effects | Inflammatory bowel disease (ulcerative colitis), mild rheumatoid arthritis, psoriatic juvenile idiopathic arthritis |
| Leflunomide | Inhibits dihydroorotate dehydrogenase, affecting <i>de novo</i> pyrimidine synthesis | Elevated liver enzymes, diarrhea, rash, hair loss, hypertension, interstitial pneumonitis, class X teratogen | Rheumatoid arthritis |
| Methotrexate | Inhibits dihydrofolate reductase, interfering with purine and pyrimidine metabolism and amino acid synthesis | Elevated liver enzymes, oral ulcers, diarrhea, mild hair loss, pneumonitis, infections, bone marrow suppression | Rheumatoid arthritis, psoriasis and psoriatic arthritis, seronegative spondyloarthropathies, arthritic manifestations of systemic lupus erythematosus, granulomatosis with polyangiitis, steroid sparing agent |
| Cyclophosphamide | Alkylating agent that inhibits cell division by cross-linking DNA and reducing DNA synthesis | Infections, bladder toxicity, secondary malignancy, premature ovarian failure, infertility, neutropenia | Systemic lupus erythematosus nephritis or other life-threatening manifestations, transverse myelitis, systemic sclerosis, granulomatosis with polyangiitis, polyarteritis nodosa, rheumatoid vasculitis |
| Mycophenolate mofetil | Inhibits inosine monophosphate dehydrogenase, affecting <i>de novo</i> purine synthesis in activated lymphocytes | Diarrhea, gastrointestinal upset, infection, bone marrow suppression, neoplasia, rash, tremor | Systemic lupus erythematosus nephritis, myasthenia gravis |
| Azathioprine | Purine antagonist and inhibits synthesis of DNA, RNA, proteins, cellular metabolism | Bone marrow suppression, infection, gastrointestinal upset, nausea, neoplasia | Maintenance therapy for systemic lupus erythematosus nephritis, ulcerative colitis, Crohn's disease, ANCA-positive vasculitis |
| Cyclosporine | Inhibits transcription of IL-2 production and proliferation of T lymphocytes | Renal toxicity, hypertension, neurologic side effects, skin or lymphoproliferative disorders, significant drug–drug interactions | Refractory ocular and mucocutaneous Behçet's disease, adult systemic lupus membranous nephritis, systemic sclerosis, severe ulcerative colitis, myasthenia gravis; typically not first-line therapy |
| Rituximab | Anti-CD20 monoclonal antibody against B cells | Infusion reaction, infection, reduced vaccination response, mucocutaneous reactions, malignancy, rare progressive multifocal leukoencephalopathy (PML) due to JC virus | Rheumatoid arthritis, granulomatosis with polyangiitis, microscopic polyangiitis |
| Belimumab | Inhibits cytokine B lymphocyte stimulator protein (BLys) necessary for B cell proliferation, survival, and differentiation | Nausea, diarrhea, fever, insomnia, depression, leukopenia, angioedema, hypersensitivity | Mild to moderate non-renal or non-central nervous system lupus |
| IVIg | Interference with Fc receptors, anti-idiotypic antibodies, inhibition of reticuloendothelial clearance | Rate-related infusion reactions, headache, aseptic meningitis, acute renal failure, thrombosis, urticaria, anaphylaxis in IgA-deficient patients | Guillain–Barré syndrome, myasthenia gravis, autoimmune peripheral neuropathies, rheumatic hematologic autoimmune thrombocytopenia, or hemolytic anemia |

an intensive or a routine management group. Intensive management consisted of monthly office visits, measurements of disease activity scores (DAS), steroid injections of swollen joints, and every 3-month escalation of treatment by a defined protocol if moderate or high disease activity persisted. In contrast, the routine management group was seen every 3 months, without DAS measurement, and steroid injections and treatment escalation were based on the clinical judgment of the clinician, in contrast to predefined formal targets. After 18 months, patients in the tight control/intensive group showed significantly improved disease activity, physical function, and quality of life, as well as less radiographic progression of arthritis—all at no additional cost compared to routinely managed patients. The BeST study (Goekoop-Ruiterman et al., 2005, 2007) and others (Mottonen et al., 1999; Rantalaiho et al., 2009) similarly illustrated greater remission rates and earlier functional improvement in RA arthritis patients with early, goal-directed therapy emphasizing aggressive treatment to achieve tight control of disease. Given the clear advantages of intensive treatment, the tight control paradigm is reflected in the 2012 update of the American College of Rheumatology's recommendations for the use of disease-modifying antirheumatic drugs and biologics in the treatment of RA (Singh et al., 2012). With greater integration of quantitative measurements and disease activity scores to define targets for treatment remission, goal-directed therapy as demonstrated in RA may serve as a harbinger for tight control treatment algorithms under study in other autoimmune diseases. Already, there is interest in working groups for establishing similarly objective “tight control” measures for seronegative spondyloarthropathies, systemic lupus erythematosus (SLE), and others.

GENERAL CONSIDERATIONS

For many autoimmune disorders, chronic inflammation can lead to a variety of non-specific, constitutional symptoms that include fatigue, muscle pains, weight loss, and/or fever. In fact, 40–80% of patients with systemic lupus erythematosus (SLE, lupus) experience such constitutional symptoms at any one time (Von Feldt, 1995). Furthermore, constitutional symptoms are present in a variety of other disorders such as multiple sclerosis, RA, multisystem autoimmune diseases, and vasculitis. General therapeutic principles focus on treating reversible causes of fatigue, weakness, and weight loss, such as checking for anemia, drug toxicities, and ruling out other potential etiologies such as malignancy, infections, or thyroid/endocrine disorders. Proper muscle conditioning with appropriate aerobic exercise, good sleep management, and pain control may improve symptoms in some

patients. Some studies have shown that stress may induce or exacerbate pre-existing lupus symptoms (Otto & Mackay, 1967; Blumenfeld, 1978), in which overall stress reduction may be beneficial (Greco et al., 2004).

In addition, management of precipitating environmental factors such as sun exposure and tobacco smoke is important. UV light in SLE patients induces increased apoptosis in skin cells, thus enhancing self-antigenicity of keratinocytes to express self-antigens on their surface that may stimulate an inflammatory response and autoantibody production leading to photosensitivity, cutaneous SLE, and/or generalized flares (Jones, 1992; Casciola-Rosen et al., 1994). Furthermore, genetically prone RA patients that carry an epitope in the hypervariable region of the HLA-DR chain, known as the “shared epitope,” have a higher risk of developing RA if they smoke cigarettes (Padyukov et al., 2004). The relative risk for development of RA in current smokers is 2.3–5.6-fold higher than for non-smokers. In another study, the relative risk for developing RA was 20-fold higher in those with two alleles of the shared epitope, a smoking history, and anti-cyclic citrullinated peptide (anti-CCP) antibodies (Klareskog et al., 2006). Smoking may also increase disease severity (Saag et al., 1997; Wolfe, 2000). The mechanism of interaction between smoking and the shared epitope may primarily affect citrullination of proteins in inflamed synovial tissue. The association between smoking and RA was most robust in patients with anti-CCP autoantibodies detected in blood (Klareskog et al., 2006). Studies have shown an association with smoking and development of autoantibodies, such as ANA (Regius et al., 1988). Smoking may also be associated with increased risk for development of SLE (Ghaussy et al., 2001) and Crohn's disease, although it may lessen the risk of developing ulcerative colitis (Tobin et al., 1987; Mahid et al., 2006). Hence, simple but important lifestyle changes such as reducing sun exposure (for SLE) and avoiding tobacco (for RA, SLE, and Crohn's disease) are important therapeutic considerations in management of autoimmune diseases.

NON-SPECIFIC ANTI-INFLAMMATORY DRUGS

NSAIDs

Non-steroidal anti-inflammatory drugs are widely used throughout the world either over the counter or via prescription. All major NSAID classes share the common mechanism of inhibiting cyclooxygenase, which metabolizes arachidonic acid to cyclic endoperoxidases to form prostaglandins. Prostaglandins' role in inflammation includes induction of swelling, erythema, neutrophil trafficking, changes in vascular permeability, and inhibition

of apoptosis (Lu et al., 1995; Harris, 2002). In addition, other non-prostaglandin mechanisms include NSAID inhibition of nuclear factor kappa B (NF κ B)-dependent transcription (Amin et al., 1995), thus decreasing nitric oxide that normally may lead to increased vascular permeability and immune cell trafficking. NSAIDs are used commonly in multisystem autoimmune diseases to treat constitutional symptoms, fever, arthritis, serositis, and headache. The potential adverse effects of NSAIDs often limit their use, particularly induction of gastritis (often with bleeding), reduced glomerular blood flow, hypertension, peripheral edema, and the association of high doses with increased risk for myocardial infarction (Solomon, 2012). Thus, for safety concerns, they are recommended most commonly for as-needed rather than continual use.

Glucocorticoids

Glucocorticoids (GC) have a broad range of anti-inflammatory and immunosuppressive effects on both the innate and adaptive immune system. GC bind to an intracellular receptor, where they can directly affect gene transcription, resulting in inhibition of production of inflammatory cytokines, and effects on post-translational mRNA stability. Anti-inflammatory effects include downregulation of nitric oxide synthesis resulting in reduced blood vessel permeability, decreased leukocyte migration to peripheral tissues, inhibition of inflammatory mediators such as eicosanoids, inhibition of collagenases, and suppression of inflammatory cytokines. Effects of GC on immune cells include inhibition of signaling for T cell activation and IL-2 synthesis, downregulation of antigen-presenting cells via blockade of costimulatory molecules, immune deviation toward Th2 cytokines, and induction of T cell apoptosis (Kirouka, 2007). GC are often used to control acute manifestations of inflammatory and autoimmune disorders, dosed on a mg/kg basis depending on the severity of the disease. Typical dosing regimens may be divided as follows from most potent to least: (1) pulse intravenous (IV) therapy with methylprednisolone 500–1000 mg per day, (2) very high-dose oral GC at 1–2 mg/kg/day prednisone or equivalent, (3) high-dose oral GC at 0.6–1 mg/kg/day prednisone or equivalent, (4) medium-dose GC at 0.125–0.5 mg/kg/day prednisone or equivalent, or (5) low-dose GC at <0.125 mg/kg/day prednisone or equivalent (King and Hahn, 2007). Organ threatening manifestations of disease in SLE, dermatomyositis, large and small vessel vasculitis, and multiple sclerosis often require pulse IV steroids as part of the initial induction therapy for acute flare control.

ESTABLISHED TREATMENTS OF RHEUMATIC DISEASES

Antimalarials

Antimalarial medications such as hydroxychloroquine, chloroquine, and quinacrine can be used to treat mild to moderate manifestations of SLE or RA and other rheumatic disorders. Various mechanisms of action may contribute to their utility in immune modulation, including (1) inhibition of activation of intracellular Toll-like receptor (TLR)-3 and TLR-7, (2) blockade of antigen processing by raising intracytoplasmic pH in lysosomes with resultant decreased lymphocyte proliferation, autoantibody production, and NK cell activity, and (3) inhibition of formation of immune complexes (Fox, 1993; Fox and Kang, 1993; Kyburz et al., 2006). In addition, anti-inflammatory effects include inhibition of phospholipases, prostaglandins, blockade of superoxide secretion, suppression of destructive proteolytic enzymes by synoviocytes, and blockade of UV light to protect keratinocytes from increased antigenicity (Wallace, 2007). Hormonal actions may impair insulin release, anti-proliferative effects may inhibit graft versus host disease, and intercalation with DNA may block synthesis to allow degradation of ribosomal RNA (Wallace, 2007). Hydroxychloroquine and chloroquine can also inhibit platelet aggregation and adhesion (Ernst et al., 1984; Jancinova et al., 1994; Edwards et al., 1997), adding to their utility for SLE patients with coexisting anti-phospholipid syndrome and/or platelet abnormalities.

In SLE, antimalarials are most useful in treating constitutional symptoms, skin lesions, and arthritis, and for prevention of disease flare. In addition, the 2007 LUMINA trial illustrated an association between hydroxychloroquine and improved survival (Aларcon et al., 2007). Pregnant mothers with anti-Ro may use hydroxychloroquine to reduce risk of antibody-associated cardiac neonatal lupus (Izmirly et al., 2010). In RA, antimalarials are typically used in combination with other disease modifying agents, such as methotrexate or sulfasalazine. A large observational study indicated reduced risk of diabetes mellitus among patients who were taking hydroxychloroquine for RA compared to those not taking the medication (Wasko et al., 2007). Antimalarials may also decrease antibody levels in Sjögren's syndrome, as well as improve sicca symptoms by inhibiting glandular cholinesterase (Dawson et al., 2005). Hydroxychloroquine has also been used in systemic onset juvenile idiopathic arthritis (Still's disease), juvenile dermatomyositis, and palindromic rheumatism. One study found that the use of antimalarials in palindromic rheumatism patients was associated with a 20% decreased risk of progression to RA or other connective tissue disease (Gonzalez-Lopez

et al., 2000). Side effects vary with specific antimalarials (in general the highest risk of important adverse effects is associated with chloroquine). These side effects include neuromuscular and cardiac toxicity, skin changes (particularly hyperpigmentation with all, and yellow discoloration with quinacrine), aplastic anemia (quinacrine), and rare ocular effects, including macular damage. Regular ocular screening of patients treated for more than 6 months with chloroquine or hydroxychloroquine is recommended (Marmor et al., 2011).

Sulfasalazine

Sulfasalazine (azulfidine) was originally proposed for use in RA, although ultimately great benefit was seen in treatment for inflammatory bowel disease (IBD). After oral ingestion, the majority of the intact drug reaches the large intestine and is reduced to sulfapyridine and 5-aminosalicylic acid (5-ASA). For IBD, and specifically ulcerative colitis (UC), 5-ASA acts locally in the colon to decrease inflammatory responses via inhibition of prostaglandin synthesis. Sulfasalazine is effective for maintaining remission in ulcerative colitis (Dissanayake and Truelove, 1973; Mulder et al., 1988). Interestingly, in contrast to UC, the active metabolite in RA patients is sulfapyridine, although the exact mechanism of action has not been clearly identified. Studies involving RA patients taking sulfapyridine (and not 5-ASA) have been linked to improvement of disease parameters with decreases in erythrocyte sedimentation rate and C-reactive protein (Pullar et al., 1985; Taggart et al., 1986). In addition, studies suggest that the parent sulfasalazine drug inhibited NF κ B transcription, may inhibit tumor necrosis factor- α in macrophages by inducing apoptosis, and may suppress B cell function (Wahl et al., 1998; Rodenburg et al., 2000; Hirohata et al., 2002; Lee et al., 2004). In RA, sulfasalazine is often used in combination therapy with other disease modifying antirheumatic drug (DMARDs) for optimal treatment. Adverse effects include elevated liver function tests, leukopenia, agranulocytosis, megaloblastic anemia, and gastrointestinal or central nervous system effects.

Leflunomide

Leflunomide (LF) is an oral medication that, once absorbed, is metabolized into its active form known as teriflunomide. The main mechanism of action of teriflunomide is to inhibit the mitochondrial enzyme dihydroorotate dehydrogenase (DHODH), which is an enzyme involved in the *de novo* pyrimidine synthesis pathway of ribonucleotide uridine monophosphate pyrimidine (rUMP). Disruption of DHODH prevents activated lymphocytes from moving from the G1 to S phase (Fox,

1998). In addition, the immunomodulatory effects of LF are broad, including inhibition of leukocyte adhesion to endothelial cells and infiltration into synovium, which may be of particular importance in RA (Dimitrijevic and Bartlett, 1996; Salmi et al., 1997; Grisar et al., 2004). In addition, LF preferentially inhibits memory self-reactive lymphocytes, affects dendritic cell antigen presentation, and blocks NF κ B activation (Zhang et al., 1997; Manna and Aggarwal, 1999;). LF blocks protein tyrosine kinases Jak1 and Jak3, which affect T cell stimulation via IL-2 receptor activation (Siemasko et al., 1998). LF may also increase the production of transforming growth factor (TGF) beta, which is a known anti-inflammatory cytokine (Cao et al., 1996). Common side effects include diarrhea, rash, hair loss, and elevated liver enzymes. Less common side effects include hypertension, interstitial pneumonitis, leukopenia, hematologic toxicities, and peripheral neuropathy. LF is contraindicated in pregnant and nursing women and in patients with pre-existing liver disease.

Leflunomide is approved by the United States Food and Drug Administration for the treatment of RA. In RA, trials have demonstrated efficacy of LF as monotherapy, with comparable outcomes to those of methotrexate or sulfasalazine monotherapy (Smolen et al., 1999; Emery et al., 2000). In lupus, a controlled trial in patients with mild to moderate disease activity showed benefit of LF treatment after 6 months of treatment compared to placebo (Tam et al., 2004). Other trials have shown efficacy in psoriatic arthritis, juvenile polyarthritis, and resistant dermatomyositis, but not ankylosing spondylitis.

Methotrexate

Methotrexate (MTX) is a folate antagonist that has been used effectively in a variety of autoimmune conditions. Competitive binding blocks the enzyme dihydrofolate reductase from reducing dihydrofolic acid to folinic acid, the active intracellular metabolite involved in purine/pyrimidine metabolism and amino acid/polyamine synthesis. However, at the doses used in rheumatic conditions, which are often lower than in oncologic chemotherapeutic regimens, the exact mechanism of action is uncertain. Animal models suggest that methotrexate increases extracellular concentrations of adenosine in inflammatory tissue, which has anti-inflammatory effects via dephosphorylation of adenosine nucleotides (Cronstein, 1996; Morabito et al., 1998). Other possible mechanisms include inhibition of DNA methylation necessary for cell proliferation, induction of apoptosis of activated peripheral T cells, regulation of IL-1 β , increased IL-10 synthesis, inhibition of leukotriene B2 formation and cyclooxygenase-2, and interference with neutrophil function (Cronstein, 1996; Genestier et al., 1998; Mello et al., 2000; Seitz et al., 2001). Methotrexate can be taken

orally, subcutaneously, or intramuscularly. Side effects include elevation of liver enzymes, especially when concurrently ingesting alcohol, oral ulcers, post-ingestion nausea, diarrhea, and hair loss. More severe complications include pneumonitis, infections due to immune suppression, bone marrow suppression, and hepatic fibrosis. Folic or folinic acid is often used as supplementation to reduce hematologic and other side effects, although folinic acid may interfere with efficacy. Pregnancy should be avoided, as MTX is a known teratogen.

Methotrexate is used in a variety of rheumatic conditions, most prominently in RA, but also in psoriasis/psoriatic arthritis, peripheral joint disease in seronegative spondyloarthropathies, SLE, granulomatosis with polyangiitis (formerly called Wegener's granulomatosis), and other large vessel vasculitides. Barring contraindications or allergy, methotrexate can be considered one of the cornerstones of disease modifying antirheumatic drugs (DMARDs) for the treatment of RA. Studies have shown both short-term and long-term efficacy in RA disease measurements, such as joint pain and swelling, quality of life, objective laboratory markers of inflammation, and radiologic progression of disease (Weinblatt et al., 1992, 1994; Rich et al., 1999), as well as possible improvement in survival (Choi et al., 2002). Methotrexate can be used in monotherapy, but more often in combination therapy with the regimens of (1) sulfasalazine and hydroxychloroquine (O'Dell et al., 1996), or (2) anti-tumor necrosis factor (anti-TNF) inhibitors for greatest efficacy (Lipsky et al., 2000). Numerous trials have demonstrated the value of methotrexate in combination therapy on disease activity measures, reduction of radiographic progression, and functionality. Methotrexate is often used in other disorders to treat peripheral joint arthritis symptoms, such as in psoriasis, seronegative spondylarthritis disorders, and joint manifestations in lupus patients. In vasculitides such as granulomatosis with polyangiitis, oral methotrexate can be used as initial therapy for non-organ threatening, non-renal disease, although its use is associated with a higher relapse rate compared to cyclophosphamide. Thus, methotrexate is a reasonable alternative for patients who cannot tolerate other more toxic (but more effective) treatment regimens (De Groot et al., 2005; Mukhtyar et al., 2009). In addition, methotrexate may be used as a steroid-sparing agent in the large vessel vasculitis in giant cell arteritis, although there is conflicting evidence of its efficacy in this setting (Jover et al., 2001; Hoffman et al., 2002).

Cyclophosphamide

Cyclophosphamide (CYC) is a potent alkylating agent, used most often to treat life-threatening or organ-threatening manifestations of autoimmune and inflammatory diseases.

It can be administered orally or intravenously, and is metabolized by the liver mitochondrial P-450 enzyme into several active metabolites with both therapeutic and toxic effects. CYC has direct effects on DNA resulting in cell death, and modulates T cell activation (McCune and Fox, 1989; Fox and McCune, 1994). The significant side effects often limit more widespread use, and include an increased risk for opportunistic infections such as *Pneumocystis jiroveci* pneumonia and fungal infections, bladder toxicity with hemorrhagic cystitis and carcinoma of the bladder, neutropenia, increased risk of infertility or premature ovarian failure, and development of malignancy. Short-term therapeutic use of CYC aims for rapid control of the underlying inflammatory process (over a period of a few weeks to months), while seeking replacement of CYC when possible with an acceptable alternative to avoid the significant long-term toxicities.

Cyclophosphamide has been used effectively in the treatment of lupus nephritis, interstitial lung disease in multisystem autoimmune disease, and medium and small vessel vasculitis. In patients with severe lupus nephritis, initial landmark trials from the National Institute of Health demonstrated the superiority of monthly high-dose IV CYC (500–1000 mg/m²) for 6 months, followed by two quarterly pulses with glucocorticoids, versus glucocorticoid therapy alone in preserving renal function (Austin et al., 1986; Boumpas et al., 1992; Gourley et al., 1996; Illei et al., 2001). Subsequent studies have investigated the role of low-dose CYC regimens (500 mg IV every 2 weeks × 6) and found this regimen compared to the higher dose CYC produces similar rates of renal remission in European patients—for up to 10 years (Houssiau et al., 2002, 2010b). It is not known whether the low-dose regimen is effective in African Americans, Asians, or Latinos with lupus nephritis. Small studies suggest a role for CYC in treatment of central nervous system manifestations of SLE, such as transverse myelitis (Barile and Lavalle, 1992; Neuwelt et al., 1995; Kovacs et al., 2000) (see Chapter 57). CYC has also demonstrated stabilization of pulmonary function, dyspnea, skin thickening, and health-related quality of life in patients with symptomatic systemic sclerosis-related interstitial lung disease (Tashkin et al., 2006). Systemic vasculitides such as granulomatosis with polyangiitis, microscopic polyangiitis, rheumatoid vasculitis, polyarteritis nodosa, and autoimmune-associated mononeuritis multiplex are other indications for CYC in which significant clinical improvement and/or survival benefits have been shown (Stone, 2010).

Mycophenolate Mofetil (Cellcept)

Mycophenolate mofetil (MMF) was used initially in the 1990s for the prevention of allograft rejection in renal transplantation. In the past decade, MMF has been shown

to be an effective therapy in both induction and maintenance of improvement in SLE nephritis, thus allowing for use of an alternative regimen to cyclophosphamide. MMF reversibly inhibits the enzyme inosine monophosphate dehydrogenase, which is necessary for *de novo* purine synthesis in activated lymphocytes. Blockade with MMF results in reduced T and B cell proliferation, less antibody production, induction of apoptosis of activated T lymphocytes, and hindrance of production and function of adhesion molecules important for lymphocyte migration to inflammatory tissues (Allison and Eugui, 2000). Side effects include diarrhea, nausea, gastrointestinal upset, infections, bone marrow toxicity, neoplasia, and rash. MMF compared to CYC is less likely to cause alopecia and amenorrhea, but rates of infection, serious infection, and death are similar with the two treatments (Touma et al., 2011).

The use of MMF has profoundly changed the outcomes and therapeutic landscape in induction therapy of improvement in diffuse proliferative and membranous serious SLE-related glomerulonephritis. Initial studies in Chinese patients suggested that MMF was an effective alternative to CYC (Chan et al., 2000; Hu et al., 2002). Subsequent clinical trials compared cyclophosphamide to MMF. A recent international, randomized controlled trial (ALMS trial) of 370 SLE patients with active nephritis compared MMF (2–3 g/day) to IV CYC (0.5–1 g/m²) monthly for 6 months. This induction therapy showed similar efficacy between the two treatments (Appel et al., 2009). Interestingly, however, proportions of African Americans and Latino Americans responding to cyclophosphamide were lower compared to Caucasians and Asians, whereas responses in all four racial groups to MMF were similar (Isenberg et al., 2010). A subsequent meta-analysis similarly confirmed MMF and CYC to be equivalent in efficacy and side effect profiles (Touma et al., 2011), although MMF was not superior to CYC as suggested by an earlier randomized but not blinded clinical trial (Ginzler et al., 2005). A follow-up analysis from the ALMS trial examining non-renal lupus activity in the same nephritis patients showed similar efficacy between MMF and CYC on non-renal manifestations, thus suggesting MMF as a reasonable alternative to CYC for renal and non-renal SLE (Ginzler et al., 2010). Furthermore, in addition to the above trials demonstrating MMF's utility in induction therapy in SLE, a recent study has demonstrated MMF's superiority in safety and efficacy in maintenance therapy for SLE nephritis compared to CYC (Contreras et al., 2004) and azathioprine (Dooley et al., 2011). The American College of Rheumatology's 2012 recently updated guidelines for treatment and management of classes III, IV, and V glomerulonephritis reflect the current state of the art regarding use of MMF (Hahn et al., 2012). MMF has also been used as a steroid-sparing agent for the treatment of other rheumatic

diseases, and for the treatment of autoimmune hepatitis (see Chapter 61). The US FDA has not approved either cyclophosphamide or mycophenolate mofetil (or the active metabolite of MMF, myfortic acid) for treatment of lupus nephritis or other manifestations of SLE, but all are widely used in the United States for serious or life-threatening SLE.

Azathioprine (Imuran)

Azathioprine (AZA) is a pro-drug that is metabolized to its active component 6-mercaptopurine (6-MP), a purine antagonist that inhibits DNA synthesis and lymphocyte proliferation. Intracellular metabolism of 6-MP results in decreased numbers of circulating lymphocytes, IL-2 secretion, and immunoglobulin production (Wilke, 2010). It is approved by the US Food and Drug Administration for prevention of renal transplant rejection and the treatment of rheumatoid arthritis; however, off-label use is common for maintenance of improvement in lupus nephritis and inflammatory bowel disease, or as a steroid-sparing agent. Adverse effects include nausea, vomiting, bone marrow suppression, increased risk of infection, and malignancy. Individuals with a homozygous genetic polymorphism of the enzyme thiopurine methyltransferase (TPMT) that reduces the metabolism of AZA may be at greater risk for AZA toxicity. Some authorities recommend checking for this genetic polymorphism prior to initiation of therapy. A number of studies have shown efficacy of AZA over placebo in the treatment of RA (Urowitz et al., 1973; Cade et al., 1976; Woodland et al., 1981), although more recent combination therapies of methotrexate plus biologics or other DMARDs are in wider use. In addition, AZA can be used for effective maintenance therapy in lupus nephritis (Contreras et al., 2004; Houssiau et al., 2010a), ulcerative colitis and Crohn's bowel disease (Timmer et al., 2007; Prefontaine et al., 2009), ANCA-positive vasculitis (Pagnoux et al., 2008), and autoimmune hepatitis (see Chapter 61).

Cyclosporin A

Cyclosporin A (CSA) is a cyclic peptide of 11 amino acids that binds with high affinity to cyclophilins, which competitively bind to calcineurin. This leads to inhibition of translocation of transcription factors, NF-AT, thus reducing transcription of early cytokine genes that encode IL-2, TNF- α , interferon- γ , IL-3, IL-4, CD40, and granulocyte-macrophage colony-stimulating factor (Schreiber and Crabtree, 1992; Wiederrecht et al., 1993; Timmerman et al., 1996). Furthermore, CSA interferes with antigen presentation by antigen-presenting cells. The ultimate net effect is reduction of lymphocyte proliferation. CSA is metabolized by the cytochrome P450 3A4

liver enzymes and has a variety of drug–drug interactions that may interfere with blood concentration levels, thus requiring monitoring of CSA levels. Side effects include renal toxicity, hypertension, neurologic side effects such as tremor, encephalopathy, increased risk of skin or lymphoproliferative malignancies, and heightened risk for infection. However, unlike many alkylating agents and purine antagonists, CSA lacks clinically significant bone marrow suppression. CSA has been used in a variety of established and suspected autoimmune disorders, including RA, psoriatic arthritis, ocular and mucocutaneous Behçet’s disease, adult lupus membranous nephritis, systemic sclerosis, atopic dermatitis, severe ulcerative colitis, pemphigus vulgaris, and myasthenia gravis (Magee, 2012). However, concern over long-term side effects, especially of renal toxicity, hypertension, and a myriad of drug interactions, has limited utility in chronic autoimmune diseases, except in patients who have failed more conventional therapies. Tacrolimus, another oral medication that inhibits T lymphocyte activation similarly to cyclosporine, is used widely for prevention of allograft rejection. Because its potential adverse effects are slightly less than those of cyclosporine, it is being used for some autoimmune diseases and is being studied in systemic lupus erythematosus, RA, and autoimmune hepatitis (Li et al., 2012).

OTHER TREATMENT OPTIONS

B Cell Suppressive Therapies

Targeting autoreactive B cells or B cell maturation signals has become successful therapy for autoimmune rheumatic conditions, and will be discussed briefly here and in further detail in Chapter 81. The use of rituximab, a chimeric anti-CD20 monoclonal antibody, causes depletion of B cells via various mechanisms, including Fc gamma receptor-mediated antibody-dependent cytotoxicity, antibody-dependent complement-mediated cell lysis, and B cell apoptosis (Cragg et al., 2005). Rituximab has shown efficacy and is FDA approved for treatment of RA, granulomatosis with polyangiitis, and microscopic polyangiitis. In particular, there is recent excitement over results of the RAVE trial in patients with ANCA(+) vasculitis, which shows that rituximab is an effective and safer alternative to cyclophosphamide, especially in patients with relapsing disease (Stone et al., 2010). However, further studies with long-term data are necessary before drawing definitive conclusions regarding the superiority of rituxan over standard of care cyclophosphamide (Jones et al., 2010), but current results are promising. Of note, rituximab was not shown to be superior to placebo for treatment of SLE patients with active disease (renal or non-renal) who were receiving GC plus

hydroxychloroquine plus an immunosuppressive drug (Merrill et al., 2010; Rovin et al., 2012). Depletion of maturing B cells by inhibition of the cytokine B lymphocyte stimulator protein (BLyS, BAFF), which induces B cell proliferation, survival, and differentiation into plasma cells, has been met with great excitement. In 2011, belimumab, a fully humanized monoclonal antibody that targets BlyS, and hence decreases the availability of BlyS to activate B lymphocytes, became the first drug in 50 years to be approved for the treatment of non-renal and non-central nervous system lupus disease (Furie et al., 2011; Navarra et al., 2011; Hahn, 2013). Of note, belimumab is meant for lupus patients who are anti-nuclear antibody or anti-double stranded DNA positive, and interestingly showed less response in African American patients. A recent study showed that responses are durable for a 4-year period—the follow-up period of the study (Merrill et al., 2012). Ongoing studies will test the efficacy of belimumab over the long term in patients with lupus nephritis and possibly in those with vasculitis.

IVIG

The use of intravenous immune globulin (IVIG) in autoimmune diseases has several possible mechanisms of action, including interference with Fc receptors on effector cells, anti-idiotypic antibody activity against serum autoantibodies, inhibition of reticuloendothelial clearance of antibody-covered platelets via Fc receptors, and regulation of expression of proinflammatory cytokines and adhesion molecules in inflammatory states (Silvergleid, 2011). In addition, other effects of IVIG include solubilization and clearance of immune complexes, altered T cell subsets, and increased T regulatory cells. IVIG is found to be useful in the autoimmune demyelinating Guillain–Barré syndrome, myasthenia gravis, autoimmune peripheral neuropathies, rheumatic hematologic conditions such as autoimmune thrombocytopenia or hemolytic anemia, and antibody-mediated CNS diseases resulting from interference with neurotransmitter function (see Chapter 57). Small studies have also shown that IVIG is a reasonable second-line therapy for refractory dermatomyositis or polymyositis (Dalakas et al., 1993; Cherin et al., 2002). Adverse effects of IVIG treatment include allergic reactions, including anaphylaxis (particularly in males who are IgA deficient), headache, aseptic meningitis, thrombosis, and nausea.

MOVING TOWARDS BIOLOGICAL AND MOLECULAR THERAPIES

Over the past few decades, progressive advancement in our understandings of immunopathogenesis has led to a significant expansion of potential therapeutic targets. This

scientific progress has ushered in widespread use of new biologic and molecular treatments specifically targeting B and T cells, costimulation and signal transduction molecules, maturation factors, cytokines, and Toll-like receptors on antigen-presenting cells. For example, anti-TNF therapy is now routinely used in rheumatoid arthritis and seronegative spondyloarthritides, as monotherapy or in combination therapy with traditional DMARDs as mentioned above (Singh et al., 2012). Such new therapeutic targets are the subject of the next chapter, and continue to improve the standard treatments and outcomes for many autoimmune diseases.

INTRODUCTION

Autoimmune diseases represent a major therapeutic challenge. In many cases, the disease is severe enough to significantly reduce longevity. In other cases, the disease causes major handicaps and discomfort that justify the usage of aggressive treatments generating their own hazards. In the past treatments were mainly palliative (substitutive), anti-inflammatory, or immunosuppressive without any specificity for the pathogenic mechanisms of the disease.

Over the last two decades modern technologies have made new agents available, in particular monoclonal antibodies directed to key immune cell receptors or cytokines, which have created a true revolution with major advancements in the treatment of rheumatoid arthritis, multiple sclerosis, psoriasis, or systemic lupus erythematosus. Our aim is to review these treatments with particular emphasis on the experimental background and the numerous and diversified animal models that led to their discovery and development as well as on the salient results which established them in the clinical arena. In addition, we will also present strategies that are still in development but that may, in a not too distant future, fill

important gaps. In particular, an ambitious goal is that of inducing or, in the case of established autoimmune diseases, restoring immune tolerance to target autoantigens. This may be defined operationally as the possibility to harness the pathologic immune response following a short-term treatment while keeping intact the capacity of the host to respond normally to exogenous antigens. Restoration of self-tolerance has the major advantage of avoiding the side effects linked to chronic immunosuppression and, most importantly, of providing a real cure for the disease.

Last but not least, it will be interesting to present how lessons drawn from the development of novel therapeutic strategies in one particular autoimmune disease may be translated into beneficial therapies for other autoimmune conditions.

THE THERAPEUTIC ARMAMENTARIUM DERIVED FROM BIOTECHNOLOGY

Monoclonal Antibodies (mAbs)

Murine monoclonal antibodies (mAbs) produced by mouse or rat hybridomas (Kohler and Milstein, 1975)

specific for immune cell receptors were introduced in clinical practice more than 30 years ago and their use initially developed in the field of solid organ transplantation. Two major side effects, namely the sensitization against the xenogeneic molecule and the cytokine releasing potential observed with some particular specificities, explain why the use of rodent mAbs remained initially mostly confined to transplantation with only very few attempts in autoimmunity. The advent of human mAbs that are less immunogenic and better tolerated has completely changed the picture and allowed a more widespread use of these interesting therapeutic tools. In fact, at variance with conventional immunosuppressants, some mAbs specific for relevant lymphocyte receptors are unique in their capacity to induce, under adequate circumstances, immune tolerance to soluble proteins, foreign tissue alloantigens, and autoantigens.

Conventional chemicals mostly act through removal and/or the functional inhibition of their targets. In contrast, mAbs display a wide spectrum of pharmacological and biological activities highly relevant to their capacity to “reprogram” the immune system. Thus, depending on their fine specificity, mAbs will remove target cells, inhibit or block the functional capacity of the target without depleting it, neutralize major cytokines, and/or serve as receptor agonists triggering activation signals for specialized T cell subsets, e.g., regulatory T cells (Sakaguchi, 2000; Bach, 2003).

The Problem of Sensitization can be Partly Overcome with Humanized and Human mAbs

The repeated administration of murine mAbs invariably triggered a humoral immune response of which the main clinical consequence was the neutralization of the antibody's therapeutic activity. Interestingly, this was not a global anti-mouse or anti-rat response; it was very restricted in its specificity with essentially anti-isotypic and anti-idiotypic antibodies being produced (Benjamin et al., 1986; Chatenoud et al., 1986a,b). Anti-idiotypic antibodies that compete with the therapeutic antibody for antigen binding represent the neutralizing component of the response while anti-isotypic antibodies are mostly non-neutralizing (Baudrihaye et al., 1984). Another peculiarity of this humoral response is its oligoclonality (Chatenoud et al., 1986b) which explains that, at variance with what is observed in patients immunized to polyclonal anti-lymphocyte globulins, serum sickness was a rare consequence of sensitization to mAbs since the amount of immune complexes formed would be insufficient to elicit a generalized reaction. Anti-monoclonal IgE responses associated with symptoms of anaphylaxis were reported but remained a very uncommon observation (Abramowicz et al., 1992, 1996).

Until humanized mAbs or, more recently, fully human antibodies became available, the only way to cope with the problem of sensitization was to associate adequate doses of chemical immunosuppressants (Hricik et al., 1990). Two types of humanized antibodies have been derived from molecular engineering. Chimeric mAbs express intact rodent variable regions linked to human immunoglobulin constant domains (Elliott et al., 1994a). In fully reshaped or complementarity determining region (CDR)-grafted antibodies, the rodent hypervariable regions interacting with the antigen (i.e., CDRs) are included within human heavy and light chain immunoglobulin frameworks (Riechmann et al., 1988).

Humanized mAbs have significantly reduced, though not totally avoided, the risk of deleterious anti-idiotypic responses. The clinical data available indicate that both chimeric and reshaped humanized mAbs may be immunogenic when administered alone, without associated immunosuppressants, after a single or repeated antibody course (Elliott et al., 1994b; Herold et al., 2002; Keymeulen et al., 2005). It has been the general experience that, as for murine antibodies, combining low doses of chemical immunosuppressants is an efficient way to overcome such sensitization (Nashan et al., 1997; Vincenti et al., 1998; Feldmann, 2002).

Fully human mAbs, which already entered clinical practice, have been produced by different means. First, mice have been invalidated for the expression of endogenous (mouse) immunoglobulin genes and concurrently made transgenic for sufficient human constant and variable immunoglobulin-encoding sequences to provide for antibody diversity; B cells from these immunized mice produce human antibodies that can be used in conventional fusions to obtain hybridomas yielding high-affinity mAbs derived from *in vivo* antigen-driven selection. Second, there is a fully *in vitro* approach using cDNA libraries expressed on filamentous phages to derive high-affinity antibodies to a wide variety of antigens, including those for which the conventional hybridoma technology fails due to poor immunogenicity (Marks et al., 1991). Third, human–mouse chimeras can be established using normal mice irradiated and reconstituted with bone marrow cells from immunodeficient (SCID) mice; after human lymphocytes from presensitized donors are inoculated, these mice are boosted with the antigen of interest, and sensitized human B cells recovered and used for conventional fusions (Lubin et al., 1994).

Further Opportunities are Offered by Genetic Engineering

Engineering Fc Regions of mAbs to Avoid Side Effects and Prolong Half-life

Antibody engineering allows the design of tailor-made antibodies to fit at best therapeutic indications.

Antibodies expressing human Fc portions have a significantly prolonged half-life. In addition, the choice of the human Fc portion will influence the antibody effector capacities, i.e., its activity in terms of complement fixation, opsonisation, and antibody-dependent cell cytotoxicity (ADCC). Furthermore, in the case of CD3 antibodies, humanization can circumvent problems due to their intrinsic mitogenic and cytokine-releasing capacity that leads *in vivo* to a “flu-like” syndrome. This syndrome was regularly observed with murine CD3 mAbs such as OKT3, and although transient it represented a major and troublesome side effect that totally precluded the use of CD3 mAbs for indications other than organ transplantation (Abramowicz et al., 1989; Chatenoud et al., 1990; Chatenoud, 2003). This mitogenic capacity is linked to the ability of the Fc portion of CD3 mAbs to interact with monocyte Fc receptors (Chatenoud, 2003). Thus “non-mitogenic” CD3 antibodies were obtained by inserting adequate mutations into the Fc domains to hamper Fc receptor binding (Bolt et al., 1993; Alegre et al., 1994; Chatenoud, 2003). Clinical use of two different Fc mutated CD3 mAbs, teplizumab (OKT3 γ 1Ala-Ala) and oteelixizumab (ChAglyCD3), in autoimmunity and transplantation, confirmed that their use was free of major side effects (Friend et al., 1999; Woodle et al., 1999; Herold et al., 2002; Hering et al., 2004; Keymeulen et al., 2005; Sherry et al., 2011).

Engineering Variable Regions of mAbs to Increase Affinity

In case the affinity of a given mAb is too low for *in vivo* use, phage display technology is an interesting approach to generate an improved fully human reagent with no requirement for prior immunization or use of hybridoma technology. Phage display can be used to mimic artificially the processes used *in vivo* by the immune system to obtain high-affinity antibodies. This has been achieved by shuffling the heavy or light chains by random or directed mutagenesis of CDR (Barbas et al., 1994), as done by error-prone polymerase chain reaction (PCR) (Gram et al., 1992). Using such artificial affinity maturation of phage antibody repertoires, affinities of mAbs in the nanomolar to picomolar range have been generated that are perfectly suitable for therapeutic use (Barbas, 1995; Foote and Eisen, 1995).

Main Targets

T Cell Antigens

CD3 Antibodies The story of CD3 mAbs is paradoxical and remarkable. They were the first therapeutic antibody introduced in clinical practice in 1981, about 4 years before the molecular complexities and the key functional

role of the CD3 molecule were discovered (Clevers et al., 1988). The OKT3 mAb, a mouse IgG2a (Kung et al., 1979), was initially used to treat and prevent renal allograft rejection (Cosimi et al., 1981a; Vigerel et al., 1986; Debure et al., 1988). This occurred without much *in vivo* preclinical data available due to the tight species specificity of anti-T cell mAbs in general and CD3 antibodies in particular. Chimpanzees are the only non-human primates harboring T lymphocytes cross-reacting with mAbs to human CD3. In addition, antibodies to mouse CD3 were difficult to produce, the first one being characterized by Leo et al. in 1987 (Leo et al., 1987). During the 1980s controlled studies clearly demonstrated that mAb OKT3 was a potent immunosuppressant very efficient at reversing early acute renal allograft rejection episodes (Cosimi et al., 1981b; Ortho Multicenter Transplant Study Group, 1985), an indication for which this mAb was rapidly licensed both in the USA and Europe. Through the study of OKT3-treated patients an enormous body of knowledge was gained on the mode of action of murine anti-T cell monoclonals and their side effects, well illustrated by over 3000 manuscripts published on the topic. These studies have been invaluable for the design of more refined approaches especially using humanized mAbs. Over the last 10 years, as other immunosuppressants developed, the use of OKT3 was progressively abandoned, essentially because of its cytokine releasing potential (Cosimi, 1987; Abramowicz et al., 1989; Chatenoud et al., 1989, 1990).

CD3 mAbs used *in vitro* in functional studies and *in vivo*, both in the experimental and the clinical setting, are specific for the ϵ chain of the CD3 complex. The experimental work conducted in different rat and mouse models suggested that, more than simply depressing all immune responses, CD3 mAbs could also induce immune tolerance to both alloantigens and autoantigens (Hayward and Shreiber, 1989; Nicolls et al., 1993; Plain et al., 1999; You et al., 2012; Goto et al., 2013) and, perhaps more impressively, could restore self-tolerance in established autoimmunity (Chatenoud et al., 1994, 1997; Belghith et al., 2003; Chatenoud, 2003). Based on these data, CD3 mAbs have again entered the clinical arena but now as well-tolerated humanized non-mitogenic mAbs (Bolt et al., 1993; Alegre et al., 1994) used not only in transplantation, but also in autoimmunity in protocols aimed at antigen-specific long-term effects rather than just immunosuppression.

CD3 mAbs and Autoimmune Diabetes Trials have been conducted using anti-CD3 to treat patients with recent-onset type 1 diabetes based on our earlier data on diabetes-prone non-obese diabetic (NOD) mice. Short-term (5 days) treatment of overtly diabetic NOD mice with low doses (5–20 μ g/day) of CD3 mAbs, in either

their mitogenic (whole 145 2C11) or non-mitogenic version (F(ab')₂ fragments of 145 2C11), induces disease remission by restoring self-tolerance (Chatenoud et al., 1994, 1997; Belghith et al., 2003; Chatenoud, 2003). The effect is long-lasting and specific to β cell autoantigens (Chatenoud et al., 1994, 1997). Immune mechanisms mediating this tolerogenic capacity evolve in two distinct consecutive phases (Chatenoud, 2003, 2010; Chatenoud and Bluestone, 2007). The first induction phase coincides with antibody administration and results in clearing of insulinitis, explaining the rapid return to normoglycemia, with a transient Th2 polarization which is irrelevant to the long-term effect since there is prolonged remission of disease after anti-CD3 treatment of IL-4 deficient NOD mice (NOD IL-4^{-/-}) (Belghith et al., 2003; Chatenoud, 2003). The second maintenance phase results in upregulation and/or appearance of specialized subsets of CD4⁺CD25⁺ and CD4⁺CD62L⁺ regulatory T cells that mediate transferable active tolerance, and that effectively control pathogenic effector cells as shown by co-transfer experiments in immunodeficient NOD SCID mice (Chatenoud et al., 1994, 2001; Belghith et al., 2003). The proportions of regulatory CD4⁺CD25⁺ T cells increase in pancreatic and mesenteric lymph nodes of anti-CD3-treated tolerant mice (Belghith et al., 2003). Interestingly, CD4⁺CD25⁺ regulatory T cells induced by anti-CD3 may not be derived exclusively from conventional natural regulatory CD4⁺CD25⁺FoxP3⁺ T cells but also, and perhaps even essentially so, from peripheral CD4⁺CD25⁻ precursors that differentiate into adaptive regulatory T cells (Belghith et al., 2003; You et al., 2007). In fact, CD3-specific mAb treatment induces diabetes remission also in NOD mice deficient for the costimulation molecule CD28 (NOD CD28^{-/-}), *t* are devoid of the thymic natural suppressor CD4⁺CD25⁺ population (Belghith et al., 2003). Also important, the immunoregulatory cytokine TGF- β appears to be a key player in this T cell-mediated regulation although its precise role, whether a mediator of regulation or a growth and/or differentiation factor for regulatory T cells, is not yet determined. Thus, CD4⁺ T cells from mice tolerant after CD3 mAb treatment consistently produce high levels of TGF- β , and *in vivo* neutralization of TGF- β after injection of specific mAbs fully prevents anti-CD3-specific-induced remission (Belghith et al., 2003; Kuhn et al., 2011).

Clinical trials have been conducted to ascertain adequate modalities that will reproduce this remarkable effect. Results from an open trial using teplizumab (OKT3 γ 1 Ala-Ala) in patients that present recent-onset type 1 diabetes were very encouraging (Herold et al., 2002, 2005). Thus, at 1 year after a short-term treatment, a significant preservation of the β cell mass was observed in treated patients compared with controls (Herold et al., 2002, 2005). The results of a European multicentric

randomized placebo-controlled trial using the oteelixizumab (ChAglyCD3) mAb, also in autoimmune type 1 diabetes, which we conducted in collaboration with diabetology centers in Belgium (Belgium Diabetes Registry; Clinical coordinator Prof. B. Keymeulen) and Germany (Prof. A. Ziegler, Munich), fully confirmed the expectations. In fact, results obtained at 18 months of follow-up showed not only a significant preservation of the β cell mass in oteelixizumab- versus placebo-treated patients but also an impressive decrease in the insulin needs that lasted for up to 4 years after the end of the short course treatment (Keymeulen et al., 2005, 2010).

Based on these results, Phase III trials were launched by two biotech companies in association with large pharmaceutical companies using designs that were quite different from that of the previous Phase II studies. The Phase III study using teplizumab (MacroGenics/Eli Lilly trial) had a composite end-point chosen arbitrarily (i.e., insulin requirement ≤ 0.5 units/kg/day and HbA1c $\leq 6.5\%$) that had not been previously validated in a controlled trial and which seemed to be an unfortunate choice (Bach, 2011; Sherry et al., 2011). The Phase III trial using oteelixizumab (Tolerx/GlaxoSmithKline trial) used a reduced dose with the aim of reducing side effects. This dose, which has not been validated for efficacy in a proper Phase II placebo-controlled study, was 16 times lower than the one used in the successful Phase II academic trial (3.1 mg compared to 48 mg). Negative results reported in press releases for both studies caused great discouragement in the diabetes community (see MacroGenics, 2010; GlaxoSmithKline, 2011).

Importantly, a post-hoc analysis of the data from the teplizumab study was performed using the conventional end-points validated by all previous trials in the field, namely C-peptide production and insulin needs, which evidenced a significant therapeutic effect (Sherry et al., 2011). A better response was observed in patients presenting the highest stimulated C-peptide at inclusion and in children. The response was dose dependent, i.e., only observed in patients receiving the higher dose tested of 17 mg (cumulated equivalent for a 70 kg individual) (Sherry et al., 2011; Daifotis et al., 2013).

Efforts to lead at least one of the two CD3 antibodies on the market continue. It is indeed so far the only product that has shown a prolonged therapeutic activity following a short treatment thereby suggesting that it induces an “operational” restoration of immune tolerance. Time will tell if these promising results can be extended to other autoimmune diseases.

For the sake of completeness we may mention before closing that interesting data have also been reported using teplizumab in psoriatic arthritis (Utset et al., 2002). Finally, a fully human CD3 mAb, NI-004, was used in a Phase I study to treat patients with moderate to severe

Crohn's disease with encouraging results (van der Woude et al., 2010).

CD4 Antibodies The tolerogenic capacity of CD4 mAbs in mice was highlighted from the outset, since at variance with other xenogeneic mAbs, anti-CD4 did not elicit the usual anti-globulin response (Benjamin and Waldmann, 1986; Gutstein et al., 1986). In addition, humoral responses to foreign soluble protein antigens were specifically inhibited if delivery was under the cover of brief treatment with anti-CD4. The effect was obtained with both depleting and non-depleting CD4 antibodies, and it could be maintained long term merely by repeating antigen administration at regular intervals in absence of any further anti-CD4 treatment. Importantly, identical results were obtained in non-human primates using a humanized mAb specific for human CD4 and cross-reacting with monkey cells (Winsor-Hines et al., 2004). In this system CD4⁺ T cells, but not B cells, were rendered tolerant and effectively transferred such tolerance to naïve hosts. The single caveat is that only high CD4 mAb dosages are tolerogenic. In the mouse anti-CD4 affords tolerance also to alloantigens (anti-CD4 mAbs are effective alone in the case of cardiac or islet allografts but must be combined with anti-CD8 mAbs in the case of skin allografts) and also often in the case of autoantigens (Wofsy and Seaman, 1987; Shizuru et al., 1988; Qin et al., 1993; Bushell et al., 1995, 2003; Waldmann and Cobbold, 2001; Cobbold et al., 2003). Effective treatment of an ongoing autoimmune disease was demonstrated for murine lupus in NZB/NZW F1 mice (Wofsy and Seaman, 1987), and in established diabetes in NOD mice (Maki et al., 1992), but only when using depleting CD4 antibodies.

The first pilot trials that used mouse mAbs to human CD4 were applied to patients presenting long-standing rheumatoid arthritis (RA), psoriasis, inflammatory bowel disease, and uveitis (Goldberg et al., 1990, 1991; Emmrich et al., 1991; Horneff et al., 1991; Reiter et al., 1991; Wendling et al., 1991; Morel et al., 1992; Bachelez et al., 1998). In these trials partial and short-term disappearance of circulating CD4⁺ cells was observed, together with coating of CD4⁺ T cells and dose-dependent saturation of CD4 binding sites (Goldberg et al., 1990, 1991; Emmrich et al., 1991; Horneff et al., 1991; Reiter et al., 1991; Wendling et al., 1991; Morel et al., 1992; Bachelez et al., 1998). Results in terms of therapeutic effectiveness were encouraging but short-lasting, and were obscured by the anti-globulin response which rapidly developed and prompted trials using humanized CD4 mAbs (Goldberg et al., 1990, 1991; Emmrich et al., 1991; Horneff et al., 1991; Reiter et al., 1991; Wendling et al., 1991; Morel et al., 1992).

The chimeric cM-T412 mAb (human IgG1), a depleting anti-human CD4 mAb, was used in RA with

encouraging results in open studies, especially with high cumulative doses, ranging from 350 to 700 mg (Moreland et al., 1993; Van Der Lubbe et al., 1993, 1994); these results, however, were not confirmed in a large randomized double-blind placebo-controlled study (Van Der Lubbe et al., 1995). Mild sensitization was reported in a majority of the patients (Moreland et al., 1993; Van Der Lubbe et al., 1993, 1994). Of major concern was the persisting CD4⁺ cell depletion observed with mAb cM-T412, up to 60% from baseline for over 18–30 months (Moreland et al., 1994), contrary to what had initially been reported with the parental mouse M-T151 anti-CD4 mAb (Reiter et al., 1991). Apoptosis could mediate, at least in part, this massive depletion (Choy et al., 1993). The disappointing clinical results in ongoing RA are not necessarily surprising, since they are fully in keeping with preclinical data. In fact, in collagen-induced arthritis, a murine model for human RA, anti-CD4 in contrast to mAbs to TNF, to be discussed below, were effective for prevention but not for treatment of ongoing disease (Marinova-Mutafchieva et al., 2000). The cM-T412 mAb has also been used in patients with multiple sclerosis, but here again without any evident clinical benefit (van Oosten et al., 1997).

The non-depleting humanized mAb to CD4, OKT4cdr4A (the CDR-grafted version of OKT4A), was used in patients with severe psoriasis; one open pilot study and a placebo-controlled one were conducted, with promising data (Bachelez et al., 1998; Gottlieb et al., 2000).

Results from open pilot studies suggested that CD4 mAb therapy, especially in combination with antibodies to CD52, could be effective in treating severe forms of vasculitis (Mathieson et al., 1990; Lockwood et al., 1993).

It is fair to conclude with anti-CD4 mAbs by pointing out that their development was seriously hampered by non-scientific considerations linked to patenting and marketing, explaining the incredible gap between the wealth of experimental data accrued and the paucity of controlled clinical trials conducted. It is hoped that CD4 antibodies will someday “revive” and be made available for trials especially designed on the lessons drawn from pre-clinical studies.

CD25 Antibodies CD25, the α -chain of the IL-2 receptor, is expressed on activated T cells (Waldmann, 1989), which explains the interest in it as a therapeutic target. Experimental data suggested an immunosuppressive capacity of anti-CD25 that significantly delayed rejection of heart allografts in the mouse (Kirkman et al., 1985) and of renal allografts in non-human primates (Reed et al., 1989). In autoimmunity, anti-CD25 mAb prevented

onset of collagen-induced arthritis (Banerjee et al., 1988), insulinitis, and diabetes in NOD mice (Kelley et al., 1988) and lupus nephritis in NZB/NZW F1 mice (Kelley et al., 1988). In diabetes-prone Bio Breeding (BB) rats there was reversal of established disease after treatment with anti-CD25 and low-dose cyclosporine (Hahn et al., 1987).

In the clinic mouse mAbs to human CD25 were effective for prevention but not for reversal of renal allograft rejection (Souillou et al., 1990; Kirkman et al., 1991; Kriaa et al., 1993). By the late 1990s two humanized mAbs to CD25, one chimeric (basiliximab/Simulect®) and one CDR grafted (daclizumab/Zenapax®), were shown to be well tolerated and effective as part of induction regimens to prevent organ allograft rejection, and were approved for use as induction therapies in organ transplantation (Nashan et al., 1997; Vincenti et al., 1998; Waldmann and O'Shea, 1998; Bumgardner et al., 2001). Moreover humanized CD25 antibodies appear beneficial for treatment of some severe autoimmune diseases, uveitis in particular (Nussenblatt et al., 1999, 2003, 2005; Yeh et al., 2008).

The use of anti-CD25 was tested for the treatment of multiple sclerosis in a series of non-randomized pilot studies which showed efficacy of daclizumab administered alone or in combination with interferon (IFN)- β (Bielekova et al., 2004, 2009). These results were confirmed in a multicenter Phase II study including 230 patients (Wynn et al., 2010). The addition of daclizumab to IFN- β for maintenance therapy in patients with recurrent/relapsing disease significantly reduced the number of new brain lesions or the progression of existing ones as assessed by magnetic resonance imaging (MRI) when compared to IFN- β monotherapy. Daclizumab was withdrawn from the market in 2009 for commercial reasons, leaving basiliximab as the only available agent.

Last but not least, none of the studies supports a tolerance promoting activity of anti-CD25 perhaps because CD25 is also expressed on a subset of T cells endowed with regulatory/suppressor capacities that are critical in maintaining immune tolerance (Sakaguchi, 2004). Thus elimination or inhibition of the functional capacity of this subset using CD25 mAbs might be counterproductive if the aim is tolerance induction.

Targeting Costimulatory Pathways

The CD28/CD80, 86 (B7.1, B7.2) Pathway Delivery of activation signals through the T cell receptor/CD3 pathway is insufficient to activate naïve T cells. Costimulation signals are required that are transduced through the specialized receptor, CD28, that interacts with its specific ligands CD80 (B7.1) and CD86 (B7.2) at the surface of the antigen-presenting cell (APC). Fusion proteins have been produced using the cytotoxic T

lymphocyte-associated antigen-4 (CTLA-4, CD152) molecule that is homologous to CD28 and expressed on T cells following activation (Linsley et al., 1991). CTLA-4 is also constitutively expressed on the specialized regulatory/suppressor T cell subset CD4⁺CD25⁺ (Read et al., 2000; Takahashi et al., 2000).

Abatacept (CTLA-4Ig) is a fusion protein including the extracellular domain of CTLA-4 combined with the Fc domain of human IgG1 (Linsley et al., 1992), and shows higher avidity for CD80 than CD86. Treatment *in vivo* with CTLA-4Ig effectively blocked immune responses to alloantigens (Lin et al., 1993; Lakkis et al., 1997; Onodera et al., 1997), xenoantigens (Lenschow et al., 1992), and autoantigens. Thus, in NZB/NZW mice treatment with CTLA-4Ig blocked autoantibody production and prolonged mouse half-life (Finck et al., 1994). Mostly CTLA-4Ig was more effective for preventing than reversing established immune responses and generally a robust and long-standing tolerance was not the general rule. Belatacept (LEA29Y) is a CTLA-4Ig derived molecule with two amino acid mutations which confer higher avidity for both CD80 and CD86. This explains why LEA29Y is more potent *in vitro* than CTLA-4Ig.

In the clinic, in a Phase I open-label study on 43 patients with psoriasis, abatacept resulted in >50% sustained (>6 months) improvement in disease activity in 46% of patients (Abrams et al., 1999). Promising results were also obtained in rheumatoid arthritis, according to double-blind placebo-controlled studies using abatacept or belatacept alone (Moreland et al., 2002) or abatacept combined with methotrexate (Kremer et al., 2003, 2005). This explains why abatacept (Orencia®) was first approved by the Food and Drug Administration (FDA) in 2005 for the treatment of rheumatoid arthritis. Abatacept was also tested in a multicenter, double-blind, randomized controlled trial, including patients aged 6–45 years recently diagnosed with type 1 diabetes (Orban et al., 2011). The difference between groups was present throughout the trial, with an estimated delay in C-peptide reduction with abatacept of about 10 months. A decrease in insulin needs was also reported which, however, was noted only for the first 12 months of treatment (Orban et al., 2011). A longer follow-up is needed to assess if, and if yes for how long, the effect is maintained after treatment cessation. Indeed, relevant data in the mouse question the ability of CTLA-4Ig if administered alone to favor immune tolerance thus promoting a long-lasting therapeutic effect. First, regulatory T cells are dependent on CD28 for their thymic development and their survival at the periphery (Salomon et al., 2000). As a consequence, treatment with CTLA-4Ig drastically reduces regulatory T cells and may therefore exacerbate autoimmunity (Salomon et al., 2000). Second, it has been well established that CD28–CD80 (B7) interactions are more

relevant for the stimulation of naïve than of memory T cells (Bluestone et al., 2006) thereby questioning the real effectiveness of CTLA-4Ig in advanced stages of type 1 diabetes.

Presently, belatacept has been validated and approved in transplantation as part of the immunosuppression maintenance regimens to avoid the use of calcineurin inhibitors cyclosporin A (CSA) and FK-506 (Vincenti et al., 2005; Bluestone et al., 2006; Wojciechowski and Vincenti, 2011).

The CD40/CD40 Ligand (CD40L) Pathway CD40 is a member of the TNF receptor superfamily and is constitutively expressed by various cell types including B lymphocytes and antigen-presenting cells. CD40 interacts with CD154 (CD40L), a member of the TNF superfamily expressed at the surface of activated T lymphocytes, activated mast cells, and basophils, and also on activated human and primate platelets. The CD40/CD154 costimulation pathway is essential for both T–B and T–T cooperation. CD40/CD154 interactions lead to germinal center formation and immunoglobulin class switching. Severe immunodeficiency is caused by disruption of this pathway due to gene knockout in mice, or somatic mutations in humans. Initial studies in the mouse and in non-human primates using *in vivo* administration of antibodies to CD154, either alone or in combination with CTLA-4Ig, showed great promise to prolong fully mismatched allograft survival and prevent autoimmune diseases (Larsen et al., 1996; Larsen and Pearson, 1997; Kirk et al., 1999; Bagenstose et al., 2005; Komura et al., 2008), albeit rapidly tempered when the first clinical trials in renal allograft recipients and in patients with systemic lupus erythematosus showed severe thromboembolic events (Kawai et al., 2000; Boumpas et al., 2003; Robles-Carrillo et al., 2010) with one of the mAbs used (humanized 5C8). While such events were not observed with the IDEC-131 mAb, this proved ineffective in patients with SLE (Davis et al., 2001; Kalunian et al., 2002). However, interesting results were observed in immune thrombocytopenic purpura that were confirmed in subsequent studies using either humanized 5C8 or IDEC131 (Kuwana et al., 2004; Patel et al., 2008).

The thromboembolic events were related to the expression of CD40L on activated platelets; there are also data showing that immune complexes of CD40L and humanized anti-CD40L antibodies may induce thrombosis through binding to the human Fc γ RIIIa IgG receptor on platelets. Treatments which prevent this side effect have been described which may open new possibilities (Kawai et al., 2000, 2004; Law and Grewal, 2009). Finally, it has also been proposed that antibodies to CD40L could act by depleting activated T cells rather than blocking

costimulation, which would also open novel perspectives especially in established autoimmunity (Monk et al., 2003).

Adhesion Molecules

The Alpha-4 Integrin VLA-4 Integrins are adhesion molecules of fundamental importance to the recruitment of leukocytes in inflammation. The alpha4beta1 integrin VLA-4 is a leukocyte ligand for endothelial vascular cell adhesion molecule-1 (VCAM-1), fibronectin, and osteopontin. The interaction between VLA-4 at the surface of activated lymphocytes and monocytes with its ligand VCAM-1 is essential for cell migration into inflamed parenchyma. Promising data in experimental models of blockade of VLA-4 prompted use of a specific humanized monoclonal antibody (natalizumab, Tysabri[®]) in randomized placebo-controlled trials, first in multiple sclerosis (Miller et al., 2003). In 213 patients with relapsing–remitting or relapsing secondary progressive multiple sclerosis given natalizumab or placebo every 28 days for 6 months, there was a marked reduction in the number of new brain lesions (gadolinium-enhanced magnetic resonance imaging) in treated patients (Miller et al., 2003).

The same antibody was applied in Crohn's disease (Ghosh et al., 2003). Similarly, in 248 patients with moderate to severe Crohn's disease, two infusions of mAb given 4 weeks apart induced higher remission rates than did placebo and significant improvement in the Crohn's Disease Activity Index, together with improved quality of life (Ghosh et al., 2003). Unfortunately reports indicated that chronic administration of this antibody gave rise to the risk of opportunistic brain infection caused by the JC virus that temporarily stopped the use of natalizumab (Kleinschmidt-DeMasters and Tyler, 2005; Langer-Gould et al., 2005). The first two cases were observed in multiple sclerosis patients receiving natalizumab associated with IFN- β for more than 2 years. The third reported case affected a patient with Crohn's disease treated with natalizumab alone.

An interesting debate has developed in the literature, following the description of these cases, which highlighted that other immunomodulatory biologic agents including rituximab (anti-CD20), efalizumab (anti-CD11a), and TNF blockers (both anti-TNF mAbs such as infliximab and the soluble TNF receptor etanercept) could elicit the same adverse effect (Mohan et al., 2001; Goldberg et al., 2002; Kothary et al., 2011). Thus, already in 2001, nearly 20 instances of clinical signs of demyelination had been reported in patients with inflammatory arthritis treated with infliximab or etanercept (Mohan et al., 2001). A brain biopsy in one of them showed that there was in fact no demyelination but authentic progressive multifocal leukoencephalopathy (PML) (Roos and Ostor, 2006).

Concerning natalizumab, in 2006 a panel of experts assessed 3417 patients with multiple sclerosis, Crohn's disease, or RA, who had received the antibody for an average of 17 months, and did not identify additional cases of PML (Yousry et al., 2006). Given the beneficial effect of the antibody on the progression of multiple sclerosis, this reassuring assessment led to the antibody being reintroduced. However, since the reintroduction of natalizumab, as many as 102 new cases of PML have been reported (Tavazzi et al., 2011). The incidence of PML appears related to the duration of treatment, with a peak incidence of 2.41 cases per 1000 patients treated for 2 years or more. The benefit/risk ratio of the drug being regarded as positive, natalizumab remains a therapeutic option of interest in multiple sclerosis and Crohn's disease, subject, however, to strict patient selection and follow-up (Fontoura, 2010; Ford et al., 2011; Iaffaldano et al., 2011).

Leukocyte Function-associated Antigen (LFA)-1 A humanized mAb, efalizumab (Raptiva[®]), specific for the CD11a subunit of LFA-1, has been tested in psoriasis. When administered subcutaneously once a week, improvement was observed within 2–4 weeks, and lasted for up to 2 years (Leonardi, 2004). Results from three randomized, placebo-controlled trials in patients exhibiting moderate to severe plaque psoriasis likewise showed promising results (Menter et al., 2004); here the follow-up lasted for 12 weeks as a double-blind trial and there was an additional 12 weeks of extended treatment phase (Menter et al., 2004). Based on these results efalizumab was approved in 2003 by the FDA for this indication. However, in 2009, it was withdrawn from the European and North American market due to three cases of PML out of a total of 46,000 treated patients and based on a benefit/risk ratio considered as unfavorable (Korman et al., 2009; Tavazzi et al., 2011).

B Cell Antigens (CD20)

Rituximab is a human–mouse chimeric mAb, specific for the CD20 B cell antigen, which causes rapid depletion of B lymphocytes. Rituximab was approved in the United States in 1997 and in Europe in 1998 (MabThera[®]) to treat severe refractory CD20-positive non-Hodgkin's B cell lymphoma. The use of anti-CD20 has been extended to first-line therapy and maintenance therapy in lymphoma, for stem-cell transplantation procedures and also for a variety of autoimmune disorders, including RA, immune thrombocytopenic purpura, autoimmune hemolytic anemia, systemic lupus erythematosus, vasculitis, dermatomyositis, multiple sclerosis, and type 1 diabetes (De Vita et al., 2002; Leandro et al., 2002; Silverman and

Weisman, 2003; Looney et al., 2004a,b; Rastetter et al., 2004; Pescovitz et al., 2009).

Among these there are indications that are obvious since the physiopathology of the disease involves pathogenic autoantibodies and therefore it seems appropriate to destroy the B cells producing these autoantibodies. The surprise was that in some of these indications, such as systemic lupus erythematosus, the effectiveness of CD20 antibody was rather disappointing compared to the very encouraging results observed in multiple sclerosis or type 1 diabetes, two conditions wherein pathogenic T cells and not autoantibodies are regarded as the main actors. At a fundamental level, these results highlight the pathogenic role of B lymphocytes not only as antibody-producing cells but also as antigen-presenting cells, and which hitherto had been considered of marginal importance in some of these autoimmune diseases.

In systemic lupus erythematosus, a first report, further supported by a series of off-label trials, described that B cell depletion was successfully obtained in patients using rituximab and that disease remission could be achieved (Leandro et al., 2005). However, two multicenter randomized placebo-controlled trials, one in patients with moderate to severe non-renal disease and the other in proliferative lupus nephritis, did not confirm such benefit (Merrill et al., 2010; Rovin et al., 2012). The reasons which may explain such a discrepancy are numerous and have been recently critically reviewed by Furtado and Isenberg (Furtado and Isenberg, 2013).

The quest to find agents that will better and more efficaciously target B cells continues. Among other B cell-directed antibodies that have been or are being tested are ocrelizumab (anti-CD20) (Cang et al., 2012) and epratuzumab (anti-CD22). In addition, major hope is focused on antibodies blocking factors that sustain B cell differentiation and/or activation such as belimumab (Benlysta[®]), a monoclonal antibody to BlyS/BAFF, which was tested in two Phase III studies and was recently approved by the FDA to treat systemic lupus erythematosus (Navarra et al., 2011). In combination with standard therapies belimumab achieved improvement in both disease remission and time to flare with, in addition, a good safety profile.

New molecules that achieve B cell depletion/blockade have been recently introduced and include inhibitors of survival factors. Among these atacept is a recombinant molecule (formerly referred to as TACI-Ig) coupling a human Fc fragment and soluble TACI that is the receptor for the cytokines BlyS/BAFF (B lymphocyte stimulator) and APRIL (a proliferation-inducing ligand) (Ginzler et al., 2012).

In RA, Phase II randomized, double-blind, placebo-controlled trials showed that treatment with anti-CD20 was safe and led to major and sustained clinical responses (Edwards et al., 2004; Emery et al., 2006). Results were

confirmed and, as a consequence, led to the licensing of the drug in 2006 for this indication. In the USA rituximab is indicated for treatment of patients with moderate to severe disease who have failed other disease modifying anti-rheumatic drugs and at least one TNF inhibitor always in conjunction with methotrexate. Indeed, the efficacy and the duration of the benefit are significantly more pronounced when rituximab is combined with methotrexate (Tak et al., 2012). In Europe rituximab is approved for severe disease.

In multiple sclerosis, a Phase II trial showed that a single course of rituximab reduced inflammatory brain lesions and clinical relapses (Hauser et al., 2008). Presently the question is whether rituximab will be developed further in this indication or if second generation CD20 antibodies such as ocrelizumab (Cang et al., 2012), which is currently being tested in Phase II studies, will be selected instead for marketing.

In type 1 diabetes compelling evidence has been accumulated to demonstrate that the pivotal role of B lymphocytes is due to their capacity to act as autoantigen-presenting cells. Indeed, NOD mice expressing a genetic inactivation for the gene encoding the μ immunoglobulin chain are devoid of B cells and are fully protected from disease (Serreze et al., 1996). Based on this rationale CD20 antibodies were tested almost in parallel in the NOD mouse and in clinical trials. Due to lack of available anti-mouse CD20 antibodies, transgenic NOD mice expressing the human CD20 on B cells were used (Hu et al., 2007). Treatment of these mice with a single cycle of an anti-human CD20 monoclonal antibody temporarily depleted B cells and significantly reduced and delayed the onset of diabetes. Furthermore, disease could be reversed in about one-third of overtly diabetic mice (Hu et al., 2007). In patients presenting recent-onset type 1 diabetes, rituximab administered on days 1, 8, 15, and 22 of study showed a significant effect on β cell function at 1 year of follow-up (Pescovitz et al., 2009). The level of C-peptide was significantly higher in the rituximab group compared to the placebo group. The rituximab group also had significantly lower HbA1c levels and required less insulin. Unfortunately, the effect was not long-lasting as immune tolerance was not induced. Moreover, immunological monitoring studies showed a significant yet reversible incapacity of treated patients to mount efficient antibody responses for several months after treatment, linked to the deep and prolonged B cell depletion observed. However, this trial was considered important as it paves the way to the combination of therapies targeting T and B cells (Hu et al., 2013).

Leukocyte Antigens (CD52)

Antibodies to CD52 target a small (12 amino acids) glycosylphosphatidylinositol (GPI)-anchored protein of

undefined function expressed at the surface of human B and T cells and monocyte/macrophages. Anti-CD52 mAbs are highly depleting and have potent efficacy in long-term acceptance of organ allografts and maintaining remission in established and otherwise intractable autoimmune diseases, notably multiple sclerosis, vasculitis, and rheumatoid arthritis (Mathieson et al., 1990; Lockwood et al., 1993, 1996; Calne et al., 1999).

The first rat mAb to CD52, Campath-1H, was characterized in 1983. A fully reshaped humanized version, Campath-1H (human IgG1), was derived by genetic engineering (Riechmann et al., 1988) and is marketed as alemtuzumab (Lemtrada[®]). Its depleting capacity has led to its extensive use *in vivo* to treat CD52⁺ hematologic malignancies, and *in vitro* to purge bone marrow transplants to prevent graft versus host (GVH) disease. Upon the first injection, Campath-1H triggers an acute self-limited cytokine release that causes a transient flu-like syndrome.

Campath-1H has been given to patients with rheumatoid arthritis, 50% of whom, after 3 and 6 months, showed improvement in the Paulus score (Isaacs et al., 1992). Campath-1H also proved very effective in severe systemic small vessel vasculitis in which the pathogenesis depends mainly on T cell-mediated mechanisms (Mathieson et al., 1990; Lockwood et al., 1993, 1996). The long-term remissions that were obtained when combining antibodies to CD52 and CD4 were particularly impressive (Mathieson et al., 1990; Lockwood et al., 1993, 1996).

Results with anti-CD52 in multiple sclerosis were also very promising and the drug has been recently approved for this indication (Moreau et al., 1994; Coles et al., 1999a,b). The initial trials included patients with long-standing relapsing/remitting multiple sclerosis unresponsive to conventional treatments. Long-term follow-up showed a marked decrease in the appearance of new lesions in the central nervous system as assessed by MRI scanning that correlated with the persisting and significant depletion of peripheral CD4⁺ T lymphocytes (Moreau et al., 1994; Coles et al., 1999a,b, 2004). These results were confirmed in Phase II studies including one that showed the superiority of alemtuzumab compared to IFN- β monotherapy (CAMMS223 Trial Investigators et al., 2008). Phase III trials have been completed and alemtuzumab has been approved for treatment of relapsing/remitting multiple sclerosis (Cohen et al., 2012).

Treatment with alemtuzumab elicits some side effects including a long-lasting profound lymphopenia (which, importantly, is not associated with increased rate of opportunistic infections) and a cytokine release syndrome after the first injection (which may be prevented by corticosteroids), and a neutralizing anti-idiotypic immunization is observed in a significant proportion of patients. Another more unexpected side effect was the

development of autoimmune disorders, particularly autoimmune thyroiditis (in up to 30% of patients with multiple sclerosis) or more rarely autoimmune cytopenias (Coles et al., 1999b; CAMMS223 Trial Investigators et al., 2008; Walsh et al., 2008; Jones et al., 2009). In one of the trials in multiple sclerosis several cases (2.8%) of idiopathic thrombocytopenic purpura have been reported (CAMMS223 Trial Investigators et al., 2008; Cuker et al., 2011). The occurrence of these complications is independent of the therapeutic effect of the antibody, but appears to be related to treatment-induced lymphopenia. Interesting data suggest that these autoimmune manifestations occur in patients in whom homeostatic cell proliferation following depletion induced by the antibody is more important. This phenomenon is dependent on IL-21, a cytokine for which circulating levels are increased before treatment in patients who will develop the post-treatment autoimmune manifestations. Therefore it has been proposed to use IL-21 pre-treatment levels to serve as a predictive parameter to identify patients at risk of this type of side effect (Jones et al., 2009).

In conclusion, alemtuzumab appears to be a treatment of choice in relapsing/remitting multiple sclerosis and also for severe autoimmune diseases refractory to other treatment.

Cytokines

Blocking TNF Pathways Humanized mAbs to TNF proved a major breakthrough in the treatment of rheumatoid arthritis, consequent on the pioneering experimental and clinical work of Feldmann and Maini (Elliott et al., 1994a; Feldmann, 2002). The seminal finding was that neutralizing antibodies to TNF significantly decreased the production of most of the proinflammatory cytokines, i.e., IL-1, IL-6, IL-8, GM-CSF, normally produced in *in vitro* cultures of cells that infiltrate synovial membranes in RA (Brennan et al., 1989; Brennan and Feldmann, 1992; Feldmann, 2002). The relevance of this finding to events *in vivo* was validated in mice that express a human TNF transgene and develop a form of chronic arthritis fully preventable by mAbs to TNF (Brennan and Feldmann, 1992; Feldmann, 2002). In addition, in collagen-induced arthritis, neutralizing antibodies to murine TNF given at onset of disease decreased the severity of objective and histopathological features (swollen joints and bone erosions) (Piguet et al., 1992; Williams et al., 1992, 1994). An unexpected but potentially relevant observation was that, in established arthritis, combination of a suboptimal dose of anti-TNF (which had no significant effect *per se*) with anti-CD4 greatly improved joint inflammation and helped heal paw swelling and bone erosions (Williams et al., 1994; Marinova-Mutafchieva et al., 2000). Thus

neutralizing inflammation, as with anti-TNF, effectively “sensitizes” the immune system to T cell-directed immunointervention: this could be relevant to various autoimmune diseases other than RA.

The first randomized placebo-controlled, double-blind study showing effectiveness of the chimeric neutralizing antibody to TNF, cA2 [human IgG1, now termed infliximab (Remicade[®])] in long-standing rheumatoid arthritis was reported in 1994 (Elliott et al., 1994a); there was significant therapeutic benefit lasting for several weeks after the end of treatment. Some patients with relapse of RA underwent two or more courses of treatment; the mean duration of remissions progressively diminished due to sensitization to the mAb (Elliott et al., 1994b). In further studies, anti-TNF was combined with methotrexate thus avoiding sensitization and obtaining longer-lasting remissions (Maini et al., 1998; Feldmann and Maini, 2001; Feldmann, 2002). Data from a Phase III trial showed that anti-TNF arrested joint damage in more than 50% of patients; the effect was noted by 6 months after beginning of treatment and lasted for the 2 years of the study (Maini et al., 1999; Lipsky et al., 2000). Infliximab was thus approved for use, in combination with methotrexate, both in the USA and Europe.

Given these results with infliximab, other biologic agents against TNF were developed. Another chimeric anti-TNF mAb named CDP571 also was clinically effective (Rankin et al., 1995), as were two fusion proteins linking the TNF receptor molecules p55 or p75 to a human IgG constant region (lenercept and etanercept/Enbrel[®], respectively) (Moreland et al., 1996, 1997; Furst et al., 2003). However, only etanercept was actively developed in the clinic and became approved. Other interesting candidates are on the way, one being the fully human D2E7 antibody (adalimumab), which has shown efficacy in Phase II and III trials (Kempeni, 1999; den Broeder et al., 2002).

Also mAbs to TNF were used successfully in severe Crohn’s disease and have been approved for this use (Van Dullemen et al., 1995; Present et al., 1999). Although the pathophysiology of Crohn’s disease remains unclear (see Chapter 60), inflammatory cytokines are significantly involved (Van Deventer, 1997). The therapeutic benefit derived from anti-TNF treatment correlated with a decreased production of IFN- γ by mononuclear cells infiltrating the lamina propria of the colon (Plevy et al., 1997). Interestingly, at variance with what is observed in RA, TNF receptor fusion proteins were not effective in Crohn’s disease.

Subsequently, data from trials using anti-TNF in juvenile arthritis (Lovell et al., 2000), ankylosing spondylitis (Brandt et al., 2000), psoriatic arthritis (Mease et al., 2000), and psoriasis have been published (Chaudhari et al., 2001).

One adverse effect reported, especially in patients undergoing repeated treatments with infliximab, was the increased incidence of tuberculosis (at both pulmonary and extra-pulmonary sites) (Keane et al., 2001; Gomez-Reino et al., 2003). This is one reason why combination therapy with drugs aimed at neutralizing TNF and IL-1 has been recently disallowed by the FDA. Other side effects that have been related to TNF blockers include the induction of autoantibodies and the occurrence of non-Hodgkin's lymphoma (Brown et al., 2002; Wolfe and Michaud, 2004). Autoantibody formation is commonly seen in patients receiving prolonged treatment with infliximab (Louis et al., 2003; Caramaschi et al., 2006). These include anti-nuclear antibodies, anti-Sm, anti-RNP, and in a few cases anti-double stranded DNA autoantibodies; their presence is usually not associated with clinical signs of systemic autoimmune rheumatic disease. Concerning the occurrence of lymphoma, Wolfe and Michaud reported an extensive study on 18,572 patients with RA who were enrolled in the National Data Bank for Rheumatic Diseases (Wolfe and Michaud, 2004). The overall standardized incidence ratio for lymphoma in RA patients not receiving methotrexate or biologics was 1.0 (95% confidence interval [95% CI] 0.4–2.5), 2.9 (95% CI 1.7–4.9) in patients treated with TNF blockers, 2.6 (95% CI 1.4–4.5) in patients receiving infliximab (with or without etanercept), and 3.8 (95% CI 1.9–7.5) in patients receiving etanercept, with or without infliximab (Wolfe and Michaud, 2004). The authors concluded that current data are insufficient to firmly establish a causal relationship because lymphomas are increased in RA independently from the treatment. Although the risk appears higher when TNF blockers are administered, differences between therapies are slight, and confidence intervals for treatment groups overlap.

There is no doubt that the story of anti-TNF antibodies in RA is a beautiful one that constituted a real revolution in the field (Taylor and Feldmann, 2009).

Antibodies to Interferon (IFN)- γ Treatment with antibodies to IFN- γ has been attempted in several experimental autoimmune diseases on the rationale that the central effects of IFN- γ in Th1-mediated immune responses include macrophage activation and upregulation of major histocompatibility complex molecules. mAbs to IFN- γ successfully prevented autoimmune diabetes in BB rats and NOD mice (Nicoletti et al., 1990; Debray-Sachs et al., 1991). In (NZB \times NZW) F1 mice, anti-IFN- γ treatment when started early (by 4 months of age) delayed the onset of glomerulonephritis and significantly prolonged survival; anti-IFN- γ appeared to act by inhibiting production of anti-DNA autoantibodies rather than affecting immune complex formation.

In patients with RA a randomized double-blind trial compared the effectiveness of treatment with anti-IFN- γ vs. anti-TNF or placebo (Sigidin et al., 2001). Promising data were obtained which, unfortunately, are still awaiting confirmation.

Fontolizumab, a human anti-IFN- γ antibody, was tested for the treatment of Crohn's disease (Hommes, 2006; Reinisch, 2006; Reinisch et al., 2010). The first trials showed a therapeutic efficacy of antibodies after two infusions 4 weeks apart (Hommes, 2006; Reinisch, 2006). In contrast, a Phase II controlled study did not show efficacy at 4 weeks after a single infusion of the antibody, followed by three monthly subcutaneous injections (Reinisch et al., 2010). However, the significant decrease in C-reactive protein (CRP) observed in all patients and the higher proportion of partial or complete remissions seen in the subgroup of patients who received the highest doses of subcutaneous antibody leaves room for substantial improvements in the protocol design which may ameliorate the outcome.

Antibodies to Interleukin (IL)-12 (p40) Interleukin (IL)-12 promotes the differentiation of helper Th1 lymphocytes that are IFN- γ and IL-2 producers. Interleukin 12 is constituted by the p40 and p35 subunits. The p40 subunit is shared by another cytokine, IL-23 (p40/p19), which participates in the differentiation of Th17 cells. The importance of the IL-12/IFN- γ and IL-23/IL-17 pathways in the pathophysiology of psoriasis, multiple sclerosis, and Crohn's disease fostered the development of antibodies directed to the p40 subunit which could therefore inhibit both IL-12 and IL-23 (D'Elia et al., 2010; Damsker et al., 2010). Ustekinumab, a human anti-p40 antibody, proved successful in psoriasis, psoriatic arthritis, and Crohn's disease, but not in multiple sclerosis.

In psoriasis the efficacy of ustekinumab (Stelara[®]) is clear according to three Phase III clinical trials (Tsai et al., 2011; McInnes et al., 2013) and the clinical response is accompanied by significant improvement in quality of life. The drug was approved in the United States and in Europe for this indication. Another important Phase III clinical trial demonstrated the superior efficacy of ustekinumab (regardless of dosing regimen) in psoriasis compared with high-dose etanercept at week 12 (Griffiths et al., 2010). Long-term efficacy has been demonstrated over 3 and even up to 5 years with a good safety profile (Kimball et al., 2012; Kumar et al., 2013). Ustekinumab is also beneficial in psoriatic arthritis according to Phase II and III clinical trials, providing further guidance on management of concurrent disease (McInnes et al., 2013).

In Crohn's disease recent results from a randomized placebo-controlled trial on 526 patients showed that ustekinumab induces a high rate of remission in patients with

moderate to severe disease resistant to TNF blockers (Sandborn et al., 2008, 2012).

In multiple sclerosis, and challenging data supporting a major role of IL-12 and IL-17 pathways in this disease, treatment did not reduce the cumulative number of MRI-identifiable lesions (Segal et al., 2008).

Antibodies to Interleukin (IL)-6 In the 1990s, IL-6 had been identified as the key growth factor for plasma cells and multiple myeloma B cells. Circulating levels of IL-6 and soluble receptor for IL-6 are used as prognostic parameters in this lymphoproliferative disease. These observations have stimulated the clinical use of IL-6 neutralizing antibodies which proved effective in inhibiting tumor growth. However, a major problem was that IL-6/anti-IL-6 complexes were not eliminated, which, in fact, prolonged the half-life of the cytokine (Lu et al., 1992). This difficulty was overcome by targeting the IL-6 receptor (IL-6R) by development of the humanized antibody tocilizumab.

Tocilizumab (Actemra[®]) was approved by the FDA for refractory rheumatoid arthritis in 2010 and for systemic juvenile arthritis in 2011. The antibody is also used in Castleman's disease.

In rheumatoid arthritis tocilizumab induces rapid and sustained improvement including normalization of indices of inflammation (CRP), a reduction of radiological joint damage, and inhibition of B cell hyperactivity (Emery et al., 2008; Karsdal et al., 2012).

Other Soluble Receptors and Protein Fusion Conjugates

The use of soluble receptors to TNF and CTLA-4Ig is discussed above and also in Chapter 36. Another human fusion protein, alefacept, was developed by coupling LFA-3 to human IgG1 to provide an agent that binds to CD2 on T lymphocytes. In controlled multicenter studies, this agent was used weekly in chronic plaque psoriasis for one or two 12-week courses. The drug was well tolerated, and a minimal 75% reduction of the disease score (PASI index) was observed 2 weeks from the last dose, lasting for 7 months (Krueger, 2003; Lebwohl et al., 2003). Alefacept (Amevive[®]) was approved by the FDA in 2003 for this indication.

Two recent meta-analyses have compared the safety profile and efficacy of various biological agents used for the treatment of psoriasis (Brimhall et al., 2008; Kimball et al., 2012). Results showed that alefacept was less effective than efalizumab, etanercept, or infliximab in terms of reduction in PASI scores. Based on these data alefacept was withdrawn from the market.

A recombinant human IL-1 receptor antagonist (IL-1Ra), anakinra, has been tested in severe rheumatic

diseases with encouraging results in patients with systemic juvenile arthritis resistant to other drugs (Verbsky and White, 2004). Favorable data were also reported in refractory SLE (Moosig et al., 2004). In RA large placebo-controlled trials including international multicenter studies demonstrated the safety of the drug as well as sustained clinical improvement (Nuki et al., 2002; Fleischmann et al., 2003) and, importantly, IL-1Ra significantly reduced radiologic progression of bone erosions (Jiang et al., 2000).

Atacept, the recombinant soluble fully human recombinant fusion protein described above, inhibits B cell-stimulating factors APRIL and BLYS/BAFF. These cytokines are members of the TNF superfamily and potentiate B cell survival and antibody production. Levels of BLYS and APRIL are increased in patients with SLE which explains why trials are under way to test the effectiveness of atacept in SLE and also in RA (Bracewell et al., 2009; Looney, 2010; Furtado and Isenberg, 2013).

SOLUBLE AUTOANTIGENS

Immunological tolerance to a wide spectrum of antigens (and autoantigens) can be induced by parenteral, nasal, or oral delivery of a soluble antigen. This approach has proven to be successful in several animal models of autoimmunity, either spontaneous or experimentally induced by immunization against autoantigens. Thus the onset of diabetes in NOD mice can be prevented by administration: of insulin or GAD using various routes of administration s.c., i.v., nasal, or oral. Similarly, experimental autoimmune encephalomyelitis (EAE) is preventable by administration of the soluble myelin antigen which is ultimately used to induce the disease.

The details of the underlying mechanisms are the subject of another chapter (see Chapter 79), but mention can be made that autoantigen-induced tolerance, whether using proteins, peptides or altered peptide ligands, is beset by a number of obstacles. These include limitation of the treatment to early disease stages; loss of therapeutic effectiveness as disease progresses; a long lag time to achieve efficacy, which may represent a problem in the case of acute autoimmune responses; risk of disease acceleration by triggering rather than downregulating the autoimmune response; and sensitization with potential risks of anaphylaxis and/or production of neutralizing antibodies leading to serious problems when the autoantigen molecule, e.g., insulin, is physiologically relevant.

BONE MARROW TRANSPLANTATION

Autoimmune diseases include genetic components expressed in the lymphoid and macrophage lineages and thus qualify as stem cell disorders (Ikehara et al., 1990).

Hence patients with serious autoimmune diseases can be considered for high-dose immunosuppression followed by hematopoietic stem cell transplantation (HSCT) (Marmont et al., 1997; Tyndall et al., 1997; Ikehara, 1998). This strategy was initially based on clinical observations in patients with malignancies and concurrent autoimmune diseases (McAllister et al., 1997) as well as results of HSCT in experimental models (Karussis et al., 1992, 1993; van Bekkum, 1998). The latter showed that all types of HSCT, whether allogeneic, syngeneic, or autologous, may induce high remission rates provided adequate conditioning regimens are administered. For example, excellent results were obtained in murine models of spontaneous autoimmunity such as autoimmune diabetes in the NOD mouse or BB rat, and lupus in (NZBxNZW) F1 mice (Ikehara et al., 1985). The mechanisms involve both central and peripheral chimerism. Although successful, the strategy is, however, hardly applicable in humans, due to the hazards associated with conditioning regimens and potential GVH disease.

More attention has been given in serious autoimmune diseases to transplantation of autologous bone marrow-derived stem cells, with the initial aims to induce very deep immunosuppression by reason of the protection afforded by bone marrow cell reconstitution, to reduce the disease activity, or even provide a cure. Other modes of action may be operative, such as the resetting of immunoregulatory circuits. Thus regulatory T cells may recover before effector cells, or benefit may come from the initial elimination of the latter. There is also the possibly useful role of G-CSF (granulocyte-colony stimulating factor), usually administered pre-transplant to mobilize stem cells, or post-transplant to accelerate reconstitution. G-CSF could be beneficial by downregulating effector cells as shown for NOD mice (Kared et al., 2005) and mice with EAE (Zavala et al., 2002).

The First International Symposium on Haemopoietic Stem Cell Therapy in autoimmune diseases took place in 1996 (Tyndall et al., 1997), and inaugurated collaborations including publication by the European Group for Blood and Marrow Transplantation (EBMT), the European League Against Rheumatism (EULAR), and the European Charcot Foundation of consensus reports of guidelines for autologous HSCT in autoimmune diseases, and reports by participating centers on their results to the EBMT registry. These recommendations have recently been updated (Daikeler et al., 2011). In addition, a record compiled by the EBMT has been established so that all centers performing this procedure can cumulate and compare their results. A similar registry was created in North America (Center for International Blood and Marrow Transplant Research, CIBMTR). To date, the estimation is that more than 3000 patients with autoimmune diseases have received hematopoietic stem cells.

The source of the stem cell transplant is mostly mobilized cells from peripheral blood, as these appear to afford a faster and more complete recovery compared with bone marrow-derived stem cells. Mobilization of blood stem cells is performed using cyclophosphamide in combination with hematopoietic growth factors, G-CSF alone, or combined with GM-CSF. According to different studies, the grafts are either purged of mature T cells, which may contain autoreactive effectors, by selection of CD34⁺ cells with or without additional mAb-dependent T cell depletion, or are not manipulated. Pre-transplant conditioning regimens, for which the aim is to ablate as completely as possible the diseased (autoreactive) component of the immune system, include chemotherapy-based regimens, such as BEAM (BCNU, etoposide, cytosine arabinoside, melphalan), cyclophosphamide with or without antilymphocyte globulins and with or without other drugs, or total body irradiation and busulfan (Daikeler et al., 2011).

Phase I/II studies have been reported in a wide range of autoimmune diseases, including multiple sclerosis, systemic sclerosis (scleroderma), SLE, rheumatoid arthritis, Crohn's disease, and type 1 diabetes. A recent retrospective analysis in 900 patients who received a first autologous bone marrow transplant indicates an overall 5-year survival rate of 85% and a disease-free survival rate of 43% (Farge et al., 2010). Reports provide a conspectus of results on HSCT in rheumatic diseases and multiple sclerosis.

Farge et al. reported on 57 patients with systemic sclerosis in European Phase I–II studies from 1996 up to 2002 with a response in two-thirds of these over a follow-up of 36 months, which was durable and with an “acceptable” morbidity/mortality risk (Farge et al., 2004). At 5 years, the probability of progression was 48% and the projected survival was 72% (Farge et al., 2004). Despite proven toxicity and a significant risk of early mortality, these results and those obtained in other pilot studies justified the performance of larger trials: three prospective studies and randomized controlled studies have been launched. The results of one of these have been reported: in 10 patients with diffuse systemic sclerosis, including lung or visceral disease who received an autologous stem cell transplant, significant clinical improvement was observed in all cases after 1 year of follow-up whereas there was sustained disease progression in 8/9 “control” patients treated with monthly courses of cyclophosphamide (Burt et al., 2011). The two other multicenter studies are in progress.

Since 1996 several hundred patients with multiple sclerosis have received an autologous bone marrow transplant. The first studies performed in patients with severe disease with significant functional disability allowed assessment of risk/safety ratio but not of efficacy. Subsequently, with the implementation of the procedure in patients with less severe disease, significant clinical benefit was observed in some groups of patients, including those with aggressive

recurrent/relapsing forms of the disease (Atkins, 2010). In addition, a better selection of patients along with an increasing expertise of the centers involved resulted in a reduction of treatment-related mortality, estimated at 1.3% between 2001 and 2007 (Mancardi and Saccardi, 2008). One of the first multicenter studies included 85 patients who showed a retrospective probability of survival without relapse at 3 years of 74% for primary progressive, 78% for secondary or recurrent/progressive relapsing forms, and 89% in younger patients (under 40 years of age) (Fassas et al., 2002). In a Phase I/II study on 21 patients with severe recurrent/relapsing forms not responding to IFN- β , none of the patients showed any signs of disease progression after a follow-up of 24 to 48 months, and clinical improvement was observed in 81% of cases with no treatment-related mortality (Burt et al., 2009). The long-term data of another Phase I/II trial started in 1995 and including 35 patients have been recently reported (Daikeler et al., 2011). The survival disease-free rate at 15 years was 44% for patients enrolled with active MRI-evident neurological damage but only 10% for patients without active lesions. These results and those from the retrospective analysis of data from the EBMT registry indicate that autologous bone marrow transplantation is an option only in patients with severe and active multiple sclerosis unresponsive to other treatments (Daikeler et al., 2011).

Patients with severe SLE received an autologous stem cell transplantation. Two major studies reported a disease-free survival rate at 5 years of 50% (Jayne et al., 2004; Burt et al., 2011). The transplant not only induced an improvement in serological markers of disease activity but also a prolonged remission (at least 5 years) of lung damage and of the associated antiphospholipid syndrome. Treatment-related mortality was 4–12%. It should be noted that the EBMT registry data indicate a greater frequency of severe infections in patients with SLE receiving transplants compared to other groups of patients (39% vs. 22%) (Farge et al., 2010).

Before the introduction of biological therapies (monoclonal antibodies or fusion proteins blocking TNF), rheumatoid arthritis was one of the first indications for autologous stem cell transplantation. The procedure was well tolerated and induced good clinical responses (Van Laar and Tyndall, 2003), with best results in seronegative disease. Currently, given the progress with TNF blockers and other new biological therapies, autologous stem cell transplants have become rare (Moore et al., 2002; Snowden et al., 2004, 2008; Verburg et al., 2005).

New indications for autologous stem cell transplantation have recently been explored, as in refractory celiac disease at high risk of developing lymphoma, and type 1 diabetes. In the first instance, 18 patients with refractory celiac disease were selected; 13 received a stem cell transplant that induced clinical and biological

improvement (Al-toma et al., 2007; Tack et al., 2010). The advantage of this strategy is suggested by the fact that the five enrolled “control” patients who did not receive a transplant all succumbed to T cell lymphoma.

In type 1 diabetes a prospective study included 23 patients (aged 13–31 years) (Couri et al., 2009). Hematopoietic stem cells were mobilized with cyclophosphamide and GCSF, collected by leukapheresis and cryopreserved. The cells were injected intravenously after conditioning with cyclophosphamide and rabbit anti-thymocyte globulin. During the long-term follow-up 20/23 were weaned from insulin treatment. Of these, 12 patients were insulin independent for 14–52 months showing stimulated C-peptide response levels significantly greater than pretreatment values. Eventually all became insulin dependent again. In terms of side effects, two patients developed bilateral nosocomial pneumonia, three developed late endocrine dysfunction, and nine developed oligospermia. Thus this therapy may afford disease remission with, in about 50% of patients, insulin independency for 1–4 years. However, the type of conditioning regimen required is quite heavy, similar to that used in life-threatening autoimmune diseases. Considering the risk/benefit ratio it is difficult to recommend such a strategy for wide application in type 1 diabetes even limited to adolescents and adults. For obvious reasons it is inappropriate for use in children.

CELL THERAPY AND GENE THERAPY

Cell Therapy

The culture *in vitro* of specialized subsets of immune cells that can be reinfused into a subject with an autoimmune disease is another emerging therapy that has benefited from experience with tumor immunology. Two cell types in particular have elicited interest: tolerogenic dendritic cells and regulatory T cells.

Dendritic cells are normally potent stimulators of immune responses but, when appropriately manipulated *in vitro*, express powerful tolerogenic properties shown by suppression *in vivo* of alloimmune and autoimmune responses. Several factors influence this tolerogenic capacity of dendritic cells, including the precise subset of dendritic cell considered, and their degree of differentiation/maturation: immature or “semi-mature” dendritic cells are tolerogenic whereas mature dendritic cells are immunogenic (see Chapter 12). Several *in vitro* procedures have been described to derive tolerogenic dendritic cells, including treatment with CTLA-4Ig (Lu et al., 1999), IL-10 (Takayama et al., 1998), vitamin D3 (Adorini, 2004), or TGF- β (Alard et al., 2004).

The cellular and molecular mechanisms that drive the modulatory capacity of such tolerizing dendritic cells

vary, depending on the model studied, and although at best only partly understood, these mechanisms mostly rely on a capacity to initiate states of peripheral tolerance: anergy, immune deviation, or induction of regulatory T cells.

The culture of regulatory T cells is another option. According to recent data, *in vitro* expanded CD25⁺ regulatory T cells were highly effective in reversing established diabetes in NOD mice (Bluestone and Tang, 2004; Tang et al., 2004; Fischbach et al., 2013).

Gene Therapy

It is tempting to treat autoimmune diseases by administration of immunoregulatory cytokines according to data from experimental models, including IL-4 and IL-10 in NOD mice (Rapoport et al., 1993; Goudy et al., 2001) and IL-10 in rats with EAE (Rott et al., 1994), clinical application remains problematic, perhaps except for IL-10 in Crohn's disease (Tilg et al., 2002). Gene therapy has successfully been used in several settings in animal models. Transduction with genes for regulatory cytokines, notably IL-4 (Yamamoto et al., 2001), IL-10 (Moritani et al., 1996), and TGF- β (Piccirillo et al., 1998) protects mice from autoimmune diabetes (NOD), and also from EAE (Tarner et al., 2003). In some cases, immune cells were transduced, with the idea that these cells would deliver the cytokine *in situ* after they had homed to the affected target organ (Yamamoto et al., 2001; Tarner et al., 2003). It has also been possible to inhibit the progression of advanced diabetes in NOD mice by genetic induction of large amounts of an ICAM-1 fusion protein (Bertry-Coussot et al., 2002).

The difficulties associated with clinical application of gene therapy are considerable. These include the selection of an efficacious and safe vector, long-term maintenance of the expression of the transduced gene, difficulties in controlling the amount of protein produced with risks of uncontrollable hyperproduction, and uncertainty about the site of delivery of the expressed protein (see Bottino et al., 2003 for review). Ingenious procedures are being developed in genetic diseases, and in cancer, where the need for gene therapy is urgent. Perhaps only when the problems are solved in these settings will gene therapy become applicable to human autoimmune diseases. Meanwhile use should be encouraged in animal models of autoimmunity to provide original information on disease mechanisms and prepare for future clinical applications.

There are as yet early experimental studies aiming at promoting target cell reconstitution, applicable to islet cells in diabetes, by antecedent administration of precursor cells and subsequent genetic manipulation to commit them to the β cell lineage. There is a double caveat: the intrinsic difficulty of the procedure, and the likelihood of

relapse of the autoimmune process on newly generated cells (Bottino et al., 2003).

PERSPECTIVES FOR THE FUTURE

In addition to policies based on disease severity (risk/benefit ratio), the overall policy will vary according to the phases of progression of a particular autoimmune disease and perceptions of urgency at its onset. When there is urgency, as pertains in recently diagnosed type 1 diabetes or multiple sclerosis, the hope is that the autoimmune destruction can be halted before irreversible lesions develop. Currently, patients with type 1 diabetes are not given immunotherapy because of the availability of a substitutive treatment with insulin, but an anti-T cell mAb, of which the most promising is anti-CD3, is an attractive approach: anti-CD3 acts rapidly and the effect is long-lasting after a short therapeutic course (Herold et al., 2002; Keymeulen et al., 2005; Sherry et al., 2011).

When inflammation is the more prominent feature, interest turns to the new anti-inflammatory protocols exemplified by mAbs to TNF or IL-1 RA. However, these agents that counter inflammation have relatively short-term effects and may come to supplement rather than replace other approaches discussed above, notably in rheumatoid arthritis.

When an autoimmune disease exposes the patient to a risk of major morbidity, examples being multiple sclerosis, severe SLE, vasculitis, or rapidly progressing systemic juvenile arthritis, high-risk treatments must be considered such as potent biological agents, high-dose non-specific chemical immunosuppression, or even autologous bone marrow transplantation.

As a conclusion, it is hoped—if not anticipated—that emergent therapies based on the progress of biotechnology, including gene and cell therapy, will progressively complement and perhaps replace conventional treatments. The rapidity with which anti-TNF antibodies have become accessible to patients with rheumatoid arthritis and Crohn's disease is most encouraging. Nevertheless, there are still numerous problems concerning the development and evaluation of the various drugs being studied. The multitude of these drugs and their potential clinical applications are remarkable.

Major efforts should be made to identify the best applications and promote their development for the benefit of patients beyond commercial constraints.

- Rheumatic heart disease (RHD)
 autoantibodies as markers, 1029–1030
 autoimmune features, 1024
 genetic polymorphism associated with, 1026
 genetic predisposition, 1024–1027
 HLA association, 1025
 pathologic effector mechanisms, 1028–1029
 T cells activation, 1029
- Rheumatic fever (RF), 26
 adaptive immune response, 1025–1027
 autoantibodies as markers, 1029–1030
 cardiac myosin, 1030
 N-acetyl β -D-glucosamine, 1029–1030
 autoimmune features, 1024
 clinical, pathologic, and epidemiologic features, 1023–1024
 genetic polymorphism associated with, 1026
 genetic predisposition, 1024–1027
CTLA4 genes, 1027
DRB1, *DRB3*, *DQB1* *DQA1* genes, 1027
Fc γ RIIA gene, 1025
Ficolin gene, 1025
IL-10 gene, 1027
IL-1Ra gene, 1027
MBL2 gene, 1024–1025
 single nucleotide polymorphisms (SNPs), 1027
TGF- β 1 gene, 1027
TLR-2 gene, 1025
TNF- α gene, 1027
 HLA association, 1025
in vivo and *in vitro* models, 1027–1028
 incidence of ARF, 1024
 innate immune response, 1024–1025
 pathologic effector mechanisms, 1028–1029
 polyarthritis and carditis manifestations in, 1023
Streptococcus pyogenes, role of, 1024
 Sydenham's chorea in, 1023
- Rheumatoid arthritis (RA), 20, 22, 25–26, 72, 111–112, 333, 389–390, 679, 1184–1185
 activated phenotype of RASFs, 389–390
 affected joints, 511–512
 autoantibodies, 517–519
 anticitrullinated-protein antibodies (ACPA), 517–519
 citrullinated antigens, 517–519
 autoimmune features, 512–514
 citrullinated peptides, 513, 515
 rheumatoid factor (RF), 512–513
 basophils, role of, 208
 causes of, 511
 clinical characteristics of, 511–512
 collagen-induced arthritis, animal model, 373–374
 complement system, involvement of, 223
 environmental factors, role of, 511
 epidemiologic features, 511–512
 genetic features, 514–515
 HLA-DRB1 alleles, 514
 human leucocyte antigen (HLA)-DRw4, 514
 major histocompatibility complex (MHC)
 class II gene, 514
PTPN22 gene, 514–515
 signal transducers and activators of transcription (STATs), 515
 SNPs, 515
 tumor necrosis factor, alpha-induced protein 3 (*TNFAIP3*) genes, 515
 HLA-DQ6 alleles associated with, 374
 hyperacetylation and hypoacetylation in, 389
in vivo models, 515–516
 adjuvants, 515
 cellular immune responses, 515
 collagen-induced arthritis (CIA), 515
 IL-1 receptor antagonist (IL-1ra) deficiency, 516
 KRN mouse model, 515–516
 “non-immune” models, 516
 SKG model, 515–516
 transgenic T cell receptor (TCR) mouse, 515–516
 miRNAs, role of, 390
 pathogenic role of neutrophils, 205
 pathologic effector mechanisms, 516–517
 antigen presenting cells (APC), role of, 516
 bone destruction, 517
 cartilage damage, 516–517
 fibroblast-like synovial cells (FLS), role of, 516
 osteoclast differentiation and activation, 517
 Th1 and Th17 cells, role of, 516
 T or B cell activation, 516–517
Porphyromonas gingivalis (*P. gingivalis*) and, 370
 small ubiquitin-like modifiers (SUMOs), role of, 390
 Th1, role of, 71
 Rheumatoid factor-negative polyarthritis, 527
 Rheumatoid factor (RF)-positive rheumatoid arthritis, 526
 RIG-I helicase receptor (RLR), 166
 (RIG-I)-like helicases (RLH), 263–264
 RIG-like helicases, 166
 Rituximab, 458, 1228–1229

 upregulation of ECM production, 472
 gastrointestinal (GI) complications, 464
 genetic features, 466
 immunological abnormalities, 470–472
 autoantibodies, 471
 B cells, role of, 471
 chemokines, 472
 cytokines, 472
 T cells, role of, 470
 inflammatory cell infiltration, 464
 pathogenic mechanisms, 469–473
 cellular abnormalities, 470
 cytokine abnormalities, 470
 microvascular EC injury and apoptosis, 469–470
 platelet activation, 469–470
 vascular endothelial growth factor (VEGF), role of, 470
 vasculopathy, 469–470
 pathologic features, 464
 spectrum of changes of affected skin, 464
 tissue fibrosis, 464
- Systemic vasculitides
 pathogenic role of neutrophils, 204–205
 in ANCA-associated vasculitis, 205
 neutrophils and vasculitic organ damage, 204–205
- T**
- Takayasu's arteritis (TA)
 clinical manifestations of, 1089–1090
 clinical spectrum in, 1097*t*
 corticosteroid monotherapy, 1099
 genetic features, 1098
 histomorphologic findings, 1096
 historic background, 1096
 imaging modalities, 1097–1098
 immunosuppressive therapy, 1098–1099
 inflammatory infiltration in, 1096
 pathogenic mechanisms, 1098
- Target-organ antigen, 24
- T-bet, 70, 73–74
- TCDD, 72–73
- T cell developmental defects, 403–406
 combined immune deficiencies (CID), 404–405
 DiGeorge syndrome (DGS), 405
 severe combined immunodeficiency (SCID), 403–404
 Wiskott–Aldrich syndrome (WAS), 405–406
- T cell differentiation, 23–24
- T cell lymphopenia, 25
- T cell receptor (TCR) with a peptide–MHC complex, 26, 60–61
- T cells
 $\alpha\beta$, 59–61
 $\gamma\delta$, 59–61
 activation
 cytokine expression, 27
 epitopes of self-antigen and, 27
 by foreign-peptide–self-MHC complex, 26
 viral infection and, 71
 activation of immune system, 20
 antiself reactive, 24
 autoimmune thyroiditis, 559–560
 B Cell interactions, 148–149
 bullous pemphigoid (BP), 963
 CD4⁺, 60, 74–76
 CD8⁺, 60
 CD25⁺, 74
 development, 59–60
 “double positive,” 59–60
 effector, 303–306
 functional activities, 60–61
 in giant cell arteritis (GCA), 1092–1093
 helper, 61
 independent antibody responses, 150–151
 mediated cytotoxicity, 61
 microvascular determinants of recruitment, 297
 migratory routes of, 299*f*
 in pemphigus foliaceus, 961
 in pemphigus vulgaris (PV), 958–959
 peripheral, 26
 primary sclerosing cholangitis (PSC), 931
 response to antigenic stimulation, 21
 in sexual dimorphism, 320
 subpopulations, 62*f*
 systemic lupus erythematosus (SLE), role in, 451
 in thymus, 368–369
 trafficking of regulatory, 303
- Terminal deoxynucleotidyl transferase (TdT), 59, 62
- TGF- β , 71–72, 316
- Th1 cells, 70–71, 303
 differentiation, 70
 IFN- γ production, 70
 IL-12 and, 70
 imbalance between Th1/Th2 subsets, 71
 immune responses to extracellular pathogens, 70
 role in inflammation and autoimmune pathology, 71
- Th17 cells, 71–74, 303, 314–315
 differentiation, 71–72, 74
 discovery and differentiation, 71–72
 function, 72
 IFN- γ production, 73–74
- IL-10 and, 73
 IL-23 and, 73–74
 lineage-specific transcription factor, 71–72
 pathogenicity and plasticity, 73–74
 reciprocal relationship with Tregs, 72–73
 regulation in the intestine, 74
 signature cytokines IL-17A and IL-17F, 72
 specific chemokine receptor CCR6, 71–72
 survival/expansion of pathogenic, 73
 tissue inflammation and neutrophil recruitment, role in, 72
 transcriptional program, 73
- Theile's murine encephalomyelitis virus (TMEV), 440
- T helper cells (Th)
 in autoimmune hemolytic anemia (AIHA), 656
 effector, 314–315, 315*t*
 effector mechanisms, 69–70
 generation and function of, 70*f*
 self-reactive CD4⁺, 69–70
 Th1 cells, 70–71, 303
 differentiation, 70
 IFN- γ production, 70
 IL-12 and, 70
 imbalance between Th1/Th2 subsets, 71
 immune responses to extracellular pathogens, 70
 role in inflammation and autoimmune pathology, 71
- Th2 cells, 78, 303
 role in eosinophil recruitment and mast cell activation, 78
- Th9 cells, 78
- Th17 cells, 71–74, 303, 314–315
 differentiation, 71–72, 74
 discovery and differentiation, 71–72
 function, 72
 IFN- γ production, 73–74
 IL-10 and, 73
 IL-23 and, 73–74
 lineage-specific transcription factor, 71–72
 pathogenicity and plasticity, 73–74
 reciprocal relationship with Tregs, 72–73
 regulation in the intestine, 74
 signature cytokines IL-17A and IL-17F, 72
 specific chemokine receptor CCR6, 71–72
 survival/expansion of pathogenic, 73
 tissue inflammation and neutrophil recruitment, role in, 72
 transcriptional program, 73
