INTRODUCTION

It has become increasingly clear that many of the well-characterized primary immune deficiency disorders are not only associated with recurrent infections but also present with immune dysregulation that manifests as autoimmune disease. The clinical findings together with delineation of the genetic basis for many of these “experiments of nature” have led to an expanded understanding of various pathways involved in immune homeostasis and the maintenance of self tolerance. In this chapter the principal primary immune deficiency disorders associated with immune dysregulation and autoimmunity are presented, paying particular attention to the lessons provided by the etiologic genetic defects.

T CELL DEVELOPMENTAL DEFECTS

Severe Combined Immunodeficiency

Severe defects in T cell immunity can be associated with autoimmunity and an increasing appreciation for the

association of T cell developmental defects producing a combination of immune deficiency and dysregulation has emerged. This has been most clearly delineated in the setting of hypomorphic mutations in genes associated with severe combined immunodeficiency (SCID). Typically in classical SCID, there is marked T cell lymphopenia with varied effects on B cells and natural killer (NK) cells depending on the genetic defect. The resulting immune deficiency is of such severity that without immune reconstitution via hematopoietic stem cell transplantation early in life, the patient has a very high likelihood of developing failure to thrive and recurrent opportunistic infections that result in death within the first 2 years of life. However, when hypomorphic mutations in *RAG1* and *RAG2* were identified in patients presenting with Omenn syndrome (OS) (Marrella et al., 2011), genes that had originally been associated with classic T-/B-/NK⁺ SCID, it first became evident that the clinical phenotype of mutations affecting genes associated with typical SCID could vary. OS was initially recognized in the 1960s based on a presenting

clinical phenotype of susceptibility to opportunistic infections, together with generalized erythroderma involving lymphocytic infiltration, alopecia, and other forms of autoimmunity, particularly autoimmune hepatitis and other gastrointestinal tract processes. Additional findings include hepatosplenomegaly, lymphadenopathy, increased serum IgE, and eosinophilia suggesting an involvement of a Th2 polarized immune response. Unlike classical SCID, these patients also have significant numbers of circulating T cells but rather than expressing a wide array of T cell receptors, the circulating T cells are oligoclonal (evaluated by spectratyping) and highly activated based on CD45RO and HLA-DR expression. The circulating cells appear to be primarily autoreactive and prove to be incapable of providing appropriate T cell responses to microbial pathogens. Thus, hypomorphic mutations in SCID associated genes can produce a varied clinical phenotype with severe defects in host defense that require immune reconstitution similar to typical SCID but with the additional clinical findings of autoreactivity. The genetic defects associated with OS are now known to also include mutations in other SCID associated genes including genes encoding Artemis, DNA ligase IV, common gamma chain, IL-7 receptor alpha chain, adenosine deaminase, zeta-chain associated protein kinase 70 (ZAP70), and the ribonuclease mitochondrial RNA processing (RMRP) complex (Villa et al., 2008).

The association of multiple SCID genotypes with an altered clinical phenotype set the stage for investigations that have uncovered further expansion of the clinical phenotypes linked to hypomorphic (“leaky”) defects in *RAG1* and *RAG2*. The range of findings appears to be linked to the level of protein function with the less severe phenotypes at the level of infectious susceptibility associated with mutations that result in residual protein activity. Autoimmunity has evolved as a major common feature in these varied clinical presentations that often includes autoimmune cytopenias. More recently there have been descriptions of later onset disease having less severe immune deficiency with autoreactive processes manifesting as granulomatous inflammation involving various organs including the skin (Niehues et al., 2010). Recently it has been recognized that some patients with hypomorphic *RAG1/RAG2* mutations can present with a mid-line granulomatous process that has many features overlapping with Wegner granulomatosis (WG) (DeRavin et al., 2010). The initial report of a WG-like presentation described a patient who first presented in adolescence with myasthenia gravis and a history of recurrent sinopulmonary infections while his older sister, who died at age 5 of sepsis, had a history of autoimmunity with cytopenias, antinuclear antibody (ANA) positive vascular disease, and symptoms consistent with myasthenia gravis.

Taken together, these findings clearly establish that genetic defects impacting T cell development not only compromise host defense but can also result in T cell dysregulation with the development of autoimmunity, albeit involving a limited range of target organs. The combination of autoimmunity and immune deficiency associated with defective T cell development may be explained by abnormalities in the thymic stroma found in experimental models of “leaky” SCID (Rucci et al., 2011). The predominant finding in these models is a reduction in the pool of medullary thymic epithelial cells (mTECs). This reduces the level of self antigen expression in the thymic medulla, which appears to diminish the effectiveness of negative selection of self reactive T cells during thymopoiesis. There also appears to be a contribution of defective B cell tolerance associated with *RAG* gene mutations (Walter et al., 2010). In addition, findings in these models also identify a marked reduction in natural regulatory T (Treg) cells, an observation that is also likely to be contributing to the development of autoimmunity (Cassani et al., 2010). Finally, the immunological process termed homeostatic proliferation may have a role in the development of autoimmunity in congenital disorders that impact T cell development (Goyal et al., 2009). It is known that normal naïve T (and B) cells turn over slowly but in the face of significant lymphopenia undergo far more rapid cell proliferation. This process of augmented proliferation is theorized to generate an increased frequency of autoreactive T cells for reasons that have not been clarified. Thus, impaired negative thymic selection, B cell tolerance, Treg development, and/or homeostatic proliferation may largely account for the development of autoimmunity in these patients.

Combined Immune Deficiencies

Combined immune deficiencies (CID) represent T cell-based immune disorders with a somewhat less significant defect when compared to SCID. One form of CID is associated with a defect in the surface expression of class I major histocompatibility complex (MHC) proteins (often referred to as the bare lymphocyte syndrome) that presents with low levels of CD8 T cells and recurrent infections. In addition, this very rare disorder is associated with a high incidence of vasculitis-like complications including granulomatous inflammation pyoderma gangrenosa-like cutaneous manifestations, which presumably represent an autoimmune process (De la Salle et al., 1999; Villa-Forte et al., 2008). The underlying defect in this disorder is associated with mutations in genes for specific proteins (i.e., *TAP1*, *TAP2*, *TAPBP*) required for the transport of antigenic peptides to the endoplasmic reticulum necessary to assemble the MHC protein–peptide complex that is normally expressed on the cell surface.

A second CID based on a defect in the enzyme, purine nucleoside phosphorylase (PNP), a member of the purine salvage pathway, is associated with a progressive loss of T cells accompanied by an increasing risk of infection. These patients also have a high incidence of neurologic disease presumably related to the specific defect in the purine salvage pathway as well as autoimmunity typically presenting as autoimmune hemolytic anemia (AIHA) (Notarangelo, 2009). The basis of autoimmunity in patients with this enzymatic defect is not known but clearly must be linked in some fashion to the toxic metabolite's impact on T cell (and possibly B cell) function.

A more recently identified CID is associated with a defect in the stromal interaction molecule 1 (STIM1), a calcium sensing protein present in the endoplasmic reticulum that is required for the function of the calcium release activated channel (CRAC) necessary for normal T cell activation. These patients have infectious histories similar to SCID patients but also develop autoimmune cytopenias, lymphadenopathy, and hepatosplenomegaly as well as ectermal dysplasia and congenital myopathy (Shaw and Feske, 2012). One presumed mechanism of autoimmunity in this disorder is a reduction in Treg cells based on observations in one patient as well as a murine model with T cell-specific deletion of *stim1* and *stim2* demonstrating reduced numbers and diminished function of Treg cells. In the murine model, correction of the immune dysfunction evidenced by reversal of the lymphoproliferative process is accomplished by the transfer of normal syngeneic Treg cells. However, this model does not result in the aggressive autoimmune processes seen in murine *foxp3* deficiency (scurfy mouse) associated with absent Tregs, a difference presumed to be due to the defective T cell effector function associated with the abnormal calcium channel function.

A unique syndrome associated with *PLCG2* deletions was recently identified that manifests with immunodeficiency, autoimmunity, and cold urticaria (Ombrello et al., 2011). The deletions in this gene are associated with a gain of function in the signaling protein PLC γ 2 causing either excessive or deficient immune functions of multiple leukocyte subsets. The autoimmunity reported includes autoimmune thyroiditis, granulomatous rash, and increased ANAs in association with a common variable-like immunodeficiency and cold urticaria. The underlying cause of autoimmunity remains to be defined in this disorder.

DiGeorge Syndrome

The DiGeorge syndrome (DGS) results from defective third and fourth pharyngeal pouch development during embryogenesis, which in many cases is associated with a chromosome 22q11.2 deletion. As a result of the

developmental abnormality, patients with DGS typically have a combination of right-sided cardiac defects, defective parathyroid function often resulting in neonatal tetany, and dysmorphic facial features (e.g., low set ears, shortened philtrum, high arched or cleft palate). In addition, patients with DGS have an increased incidence of autoimmunity including cytopenias, systemic autoimmunity (particularly rheumatoid arthritis and autoimmune thyroid disease) (Zemle et al., 2010; Gennery, 2012). From an immunologic perspective, a small minority of DGS patients (1–2%) has thymic aplasia that results in marked T cell lymphopenia with increased susceptibility to opportunistic infections and among this patient group chromosomal microdeletions are only found in about 50% of patients. This group is referred to as complete DGS and among these patients is a subgroup that carries a diagnosis of complete atypical DGS with a clinical phenotype that is virtually indistinguishable from OS (Markert et al., 2004). Due to the severity of the infectious complications associated with complete (including atypical) DGS, thymic transplantation is indicated to cure the T cell deficiency. However, due to the autoreactive T cells present in the complete atypical DGS presentation, aggressive immunosuppression is required to control the autoreactive cells prior to initiating the thymus transplantation. Alternatively allogeneic bone marrow transplantation has been used and in this case reconstitution is presumably derived from long-lived donor T cells since there is no thymus present for new T cell development. Long-term follow-up studies of complete DGS (including atypical complete DGS) patients post successful thymic transplantation have demonstrated an increased incidence of autoimmune thyroid disease as well as autoimmune cytopenias. The mechanism underlying the development of autoimmunity in DGS is currently unknown but may mimic some of the immunopathogenic mechanisms thought to cause autoimmunity in “leaky” SCID.

Wiskott–Aldrich Syndrome

The Wiskott–Aldrich syndrome (WAS) is an X-linked primary immunodeficiencies (PID) that variously presents with thrombocytopenia involving small platelets, eczema, recurrent infections, autoimmunity, and malignancies (Notarangelo et al., 2008; Thrasher and Burns, 2010). Affected patients are particularly susceptible to infections with encapsulated bacteria and herpes viruses. This disorder is caused by mutations within the gene encoding the WAS protein (WASP), a critical factor in actin polymerization and skeletal remodeling initiated by cellular activation. In particular, the above-described clinical phenotype is caused by mutations that lead to abrogation of WASP expression. By contrast, hypomorphic mutations that typically affect exons 1 and 2 allow for some WASP

expression and generally lead to a milder clinical phenotype characterized by X-linked thrombocytopenia (XLT). As WASP is expressed in all non-erythroid hematopoietic cells, it is not surprising that affected individuals present with a number of immunological abnormalities. These include progressive T cell lymphopenia; impaired *in vitro* T cell proliferation and IL-2 production following T cell receptor cross-linking; low serum IgM levels often associated with elevated serum IgA and IgE levels; impaired IgG antibody responses to both T-dependent and T-independent antigens; impaired migratory responses of monocytes, dendritic cells, T and B cells and neutrophils to chemokines; and impaired NK cell cytolytic activity.

Autoimmune disease affects as many as 70% of WAS patients with clinical presentation in rank order including AIHA, immune thrombocytopenia purpura (ITP), vasculitis, renal disease, Henoch–Schonlein-like purpura, and inflammatory bowel disease (Notarangelo et al., 2008; Thrasher and Burns, 2010). Autoimmunity most commonly occurs in patients with WAS but occasionally is also present in patients with XLT. Early explanations for the pathogenesis of autoimmunity referred to possible contributions of recurrent exposure to microbes and chronic inflammation as well as reduced IL-2 production and impaired clearance of apoptotic cells/bodies and debris due to the defective migration of phagocytic cells. More recently, it has become apparent that both WAS patients and WASP deficient mice are characterized by impaired natural Treg (nTreg) activity (Marangoni et al., 2007). Although the molecular basis for this abnormality remains to be established, it is tempting to speculate that impaired IL-2 secretion impacts the development and function of nTregs (Koreth et al., 2011). However, it is likely that the explanation for the development of autoimmunity extends beyond the nTreg story. A very recent report identified an intrinsic defect in WASP-deficient mouse B cells that accounted for the production of auto-antibodies, including anti-DNA antibodies following cross-linking of B cell antigen receptors or Toll-like receptors and provision of T cell-help (Becker-Herman et al., 2011). This may contribute to the findings that post hematopoietic stem cell transplantation, autoimmunity is particularly problematic in patients who remain mixed chimeras for B cells suggesting that the WASP negative B cells may be mediating autoimmunity in this situation.

As is true for many immunodeficiency disorders, the clinical phenotype of WAS does not show consistent fidelity with the genotype. This was demonstrated recently in a report of monozygotic twins, associated with WAS including autoimmune disease in one twin and a milder XLT phenotype in the other (Buchbinder et al., 2011). Interestingly, CpG methylation, diminished WASP gene transcripts, diminished WASP expression, and more impaired cellular function were detected in the more

symptomatic twin. These findings are consistent with the previously reported effects of epigenetic changes on the clinical expression of genetically-based autoimmune and primary immunodeficiency disorders.

ANTIBODY PRODUCTION DEFECTS

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA) was the first primary antibody deficiency identified and is now known to be caused by mutations in Bruton's tyrosine kinase (*BTK*) gene necessary for B cell differentiation and signaling (Tsukada et al., 1993; Vetrie et al., 1993). Development of the B lymphocyte lineage is arrested at the pro- to pre-B cell stage of differentiation resulting in a marked deficiency of circulating B cells and panhypogammaglobulinemia but intact T cell function. Affected individuals usually present clinically by 5–6 months of age with recurrent sinopulmonary infections involving encapsulated bacteria following the loss of maternally transferred IgG antibodies.

Up to 15% of XLA patients develop autoimmune disease including rheumatoid arthritis, inflammatory bowel disease, scleroderma, alopecia, AIHA, and type 1 diabetes (Verbruggen et al., 2005; Howard et al., 2006; Winkelstein et al., 2006). The absence of B cells and immunoglobulins in these patients suggests that, other than in autoimmune AIHA, immunoglobulin-independent, *BTK*-dependent processes may be involved in the pathogenesis of autoimmune disorders.

Regulatory B cells, described in mice and humans, appear to contribute to suppression of the development and expression of inflammatory reactions, particularly those mediated by T cells suggesting an important role in immune homeostasis and prevention of autoimmune and inflammatory diseases (Klinker and Lundy, 2012). In both mice and humans, B-regulatory cells comprise a small subset/s of the peripheral B cell pool and are identified by their expression of characteristic cell surface markers. In both species, regulatory B cell subsets appear to mediate immunosuppression via secretion of IL-10 and absence of these cells in XLA could also contribute to the risk of developing autoimmunity.

Common Variable Immunodeficiency

Common variable immunodeficiency (CVID) is a primary immunodeficiency that leads to a variety of clinical syndromes associated with hypogammaglobulinemia (Young et al., 2011). This is caused by a failure of terminal B cell differentiation and a decrease in the number of antibody-producing plasma cells. As a result, patients with CVID have low serum IgG and frequently low IgA and/or IgM

as well as an inability to make specific antibodies to protein and carbohydrate antigens. This immunologic impairment accounts for the most characteristic clinical phenotype, namely, recurrent upper and lower respiratory tract infections caused by encapsulated bacteria. However, CVID is quite heterogeneous with regard to clinical presentation. Autoimmune disorders occur in approximately 20–40% of patients including ITP and AIHA, pernicious anemia, polyarthropathy, hypothyroidism, autoimmune hepatitis, biliary cirrhosis, and inflammatory bowel disease (Cunningham-Rundles and Bodian, 1999; Chapel et al., 2008). One of the unsolved paradoxes is how CVID patients produce IgG autoantibodies (e.g., anti-red cell) yet are unable to produce protective IgG antibodies against microbial antigens. Autoimmune disorders may appear several years prior to or after the diagnosis of CVID is made. The fact that (1) autoimmune diseases may antedate the onset of recurrent infections and (2) many CVID patients are not afflicted with autoimmune disease strongly suggests that recurrent infections are not the sole provocateurs of this complication.

In addition, upwards of 10% of patients in most series suffer from inflammatory processes including granulomatous inflammation and lymphoid hyperplasia, the latter manifested in part by lymphadenopathy and/or splenomegaly. CVID patients are at risk for non-Hodgkin lymphoma (~7%) and gastric carcinoma (~1%). Taken together, the heterogeneous clinical manifestations of CVID underscore a major role for immune dysregulation in the immunopathogenesis of this syndrome.

The most common autoimmune conditions observed in CVID are ITP and AIHA with the frequency of these disorders ranging from 5 to 8% (Cunningham-Rundles and Bodian, 1999; Chapel et al., 2008). Some patients also suffer from Evans syndrome, a concurrence of both autoimmune cytopenias. As is true for most of the autoimmune disorders, the appearance of these hematologic conditions may predate or manifest after the diagnosis of CVID. Splenomegaly is a frequent concomitant of CVID, noted at the time of diagnosis in one series in 17.5% of the cases and may not be associated with immune cytopenias.

The most common rheumatic complications include a symmetrical polyarthropathy typically involving the hands, knees, and ankles. The coexistence of systemic lupus erythematosus (SLE) and CVID is uncommon with SLE typically antedating the appearance of CVID. In many of these cases, SLE clinical activity diminished following the onset of CVID, as might be expected in an autoimmune disorder whose pathogenesis is autoantibody dependent.

Granulomatous inflammation is found in 5–10% of CVID patients. The granulomas are non-caseating involving the lungs, liver, spleen, lymph nodes, and skin. These

findings mimic sarcoidosis, particularly when there are pulmonary signs and symptoms but no history of recurrent pyogenic infections. Of note, patients with sarcoidosis, unlike CVID, demonstrate polyclonal hypergammaglobulinemia at the time of presentation. The pathogenesis of CVID granulomatous disease remains a mystery without evidence for an infectious etiology and it is often associated with autoimmune disease, particularly ITP. The finding of a characteristic single-nucleotide polymorphism (SNP) in the tumor necrosis factor (TNF) α gene and elevated serum levels of TNF α in CVID patients with granulomas suggested that this cytokine may be involved in these pathologic lesions. Non-caseating lung granulomas are sometimes found along with lymphocytic interstitial infiltrates and follicular bronchitis and bronchiolitis. This pathologic picture, dubbed granulomatous interstitial lung disease (GLID), portends a poor prognosis with survival in one series reduced by 50% versus CVID patients lacking this complication.

Several autoimmune/inflammatory processes have been reported in the gastrointestinal tract of CVID patients. Inflammatory bowel disorders have been reported in 5% of patients including atrophic gastritis, nodular lymphoid hyperplasia, a gluten-insensitive enteropathy, and inflammatory bowel disease (Cunningham-Rundles and Bodian, 1999; Agarwal and Cunningham-Rundles 2009; Ahn and Cunningham-Rundles, 2009; Young et al., 2011). Putative autoimmune liver disorders include biliary cirrhosis and hepatitis (Cunningham-Rundles and Bodian, 1999; Agarwal and Cunningham-Rundles 2009; Ahn and Cunningham-Rundles, 2009; Young et al., 2011). Nodular regenerative hyperplasia (NRH) is the most common pathologic liver condition and is typically associated with cholestasis and in some series significant portal hypertension (Ward et al., 2008; Malamut et al., 2008). Histologic analysis reveals small, hyperplastic nodules in the liver parenchyma in the absence of fibrous septa around the nodules. When lymphocytic infiltrates are seen, they are predominated by CD8⁺ T cells raising the possibility that T cell-mediated cytotoxicity somehow contributes to the pathological picture (Malamut et al., 2008). Patients with NRH were found to have a higher incidence of lymphoproliferation, granuloma, enteropathy, or cytopenias (Ward et al., 2008; Malamut et al., 2008).

Much attention has been focused on the mechanisms responsible for immune dysregulation in CVID patients. Many abnormalities in phenotype and function of B cells, T cells, and innate immunity have been reported and some track with the appearance of autoimmune disease possibly serving as biomarkers and/or pathogenic factors (Ahn and Cunningham-Rundles, 2009; Young et al., 2011; Warnatz and Voll, 2012). For example, a more pronounced defect in isotype-switched memory B cells and a

decrease in naïve T cells is observed in CVID patients developing autoimmune cytopenias, lymphoid hyperplasia, splenomegaly, granulomatous disease, or chronic enteropathy (Agarwal and Cunningham-Rundles 2009; Ahn and Cunningham-Rundles, 2009). Additional studies indicate that autoimmunity and lymphoproliferation track with increased numbers of activated CD4⁺ T cells, decreased numbers of Treg cells, and increased percentages (>20%) of CD21^{low} B cells (Warnatz and Voll, 2012). The majority of the latter subset appears to be comprised of mature naïve B cells. In one study, they were found to express unmutated IgM germline genes, which encode largely polyspecific autoreactivity to targets such as nuclear and cytoplasmic components, insulin, and lipopolysaccharide (Isnardi et al., 2010). However, it remains unclear whether or how the expanded CD21^{low} B cell subset relates to the development of autoimmunity in CVID. They have the phenotypic and functional properties of anergic B cells and their specificities are directed at autoantigens that are not targets in patients with CVID (Isnardi et al., 2010).

Genetic defects have been demonstrated in approximately 10–15% of CVID (Young et al., 2011). These include mutations in a number of B cell signaling or survival molecules including transmembrane activator and calcium-modulating ligand interactor (TACI), the inducible costimulator (ICOS), BAFF, C19, and CD20. Those with TACI deficiency (7–10%) would appear to be particularly informative since this mutated gene is clearly associated with the development of autoimmune disease, lymphoid hyperplasia, and splenomegaly in addition to antibody deficiency and recurrent infections (Young et al., 2011). Heterozygosity for TACI C104R, one of the most common TACI mutations, appeared to show the strongest association. However, family members and rare healthy control subjects who lacked immune abnormalities shared the same heterozygous mutations (Young et al., 2011). This finding clearly suggests that other, presumably environmental and/or epigenetic, factors interact to promote the CVID clinical phenotype. Moreover, patients with homozygous TACI deficiency have less severe disease compared to patients with heterozygous TACI deficiency. This observation has spawned the hypothesis that monoallelic TACI deficiency may permit the survival of autoreactive B cell clones (Young et al., 2011). Nevertheless, homozygous TACI deficient mice develop a fulminant autoimmune syndrome, lymphadenopathy, splenomegaly, and lymphoma; findings consistent with TACI contributing to immune homeostasis. Recently, a genome-wide population-based study of CVID patients revealed an association between organ-specific autoimmunity and SNX31, a nexin possibly involved in protein sorting. Of interest SNX protein subunits are required for CD28-mediated costimulation of T cells but the biologic

significance of this association remains to be determined (Orange et al., 2011).

Another study suggested that protein tyrosine phosphatase nonreceptor type 22 (*PTPN22*) gene is linked to the development of autoimmunity in CVID (Chew et al., 2013). The *PTPN22*; R620W SNP was found with increased frequency in CVID, particularly in patients with coexistent autoimmune disease. This is of great interest since this SNP exhibits one of the strongest and most consistent associations with sporadic autoimmune diseases. Accordingly, this finding is consistent with the proposition that autoimmunity arises through a similar mechanism in patients with and without CVID. In the latter, it has been hypothesized that the associated SNP may promote the development of autoimmunity by interfering with the central deletion of autoreactive cells or the emergence of Tregs.

Two other possible mechanisms contributing to the autoimmunity seen in CVID, as yet not studied, relate to the function of B cells seen in the peripheral tissues of CVID patients. It is known that normal B cells, when activated, can secrete a myriad of cytokines including those with proinflammatory activity, e.g., IL-6 and TNF α . Thus, it is possible that B cells in CVID patients with autoimmunity and/or non-infectious inflammatory processes may contribute to the associated pathology by secreting large amounts of these molecules in the absence of sufficient counter-regulation. In addition, it is also known that a small subset/s of B cells with regulatory function contributes to immune homeostasis and suppression of inflammatory and autoimmune processes (see discussion under X-linked agammaglobulinemia). However, it is not known whether the function of these B cells is preserved in CVID patients.

Selective IgA Deficiency

Selective IgA deficiency is the most common primary immune deficiency affecting humans defined solely on the basis of serum immunoglobulin levels (Geha et al., 2007). To qualify for the diagnosis, patients must be older than 4 years and have a serum IgA of <7 mg/dl in the absence of deficits of other Ig isotypes and definable immune deficiencies. The prevalence of selective IgA deficiency varies across studied ethnic populations with a high of 1:143 on the Arabian Peninsula to a low of 1:18:500 in Japan. In the USA, the range is 1:223–1:1000 in community studies. There is considerable variability in clinical presentation with the majority of patients reported as being asymptomatic. The most common clinical manifestation occurring in the roughly 10–15% symptomatic patients is recurrent sinopulmonary infections caused by encapsulated bacteria (Geha et al., 2007). IgA deficient patients are also considered to have

an increased frequency of allergic disorders and this is particularly true in younger patients (4–32 years of age) where a prevalence of 84% was reported in one study.

There is an increased prevalence of autoimmune disorders in selective IgA deficient patients with ITP occurring most commonly (Edwards et al., 2004; Jacob et al., 2008). Additional autoimmune associations include juvenile idiopathic arthritis (JIA), thyroiditis, Henoch–Schonlein purpura, type 1 diabetes mellitus, SLE, and serological positivity for a number of self-antigens including cardiolipin, Jo-1, phosphatidylserine, and collagen despite the absence of clinical pathology. First degree relatives of IgA deficient patients display an increased frequency of autoimmune disorders. In addition, patients are at risk for development of gastrointestinal complications including gluten-sensitive celiac disease caused by IgG autoantibodies specific for gliadin, tissue transglutaminase, or endomyosial proteins; lactose intolerance; nodular lymphoid hyperplasia; giardiasis; malabsorption; chronic active hepatitis; and ulcerative colitis.

The pathogenesis of IgA deficiency remains obscure in that patients have immature B cells that express surface IgA as well as IgM and IgD, but fail to differentiate into IgA secreting plasma cells (Conley and Cooper, 1981). Whereas some investigators have provided evidence of an intrinsic B cell defect, others have reported impaired IgA-specific T cell help mediated by a variety of cytokines including TGF- β , IL-4, IL-6, IL-7, IL-10, and IL-21 (Yel, 2010). These heterogeneous results create a murky picture concerning the relative importance of individual cytokines in human B cell IgA isotype switch and/or IgA secretion by IgA deficient B cells. The variation in results likely reflects differences in the *in vitro* culture techniques as well as cells studied.

No single genetic defect has been reported in IgA deficient patients although a small number of TACI deficient patients have been found with selective IgA deficiency (Castigli et al., 2005). Indeed the same TACI mutation has been found in IgA deficient patients and patients with CVID. Some patients with IgA deficiency progress to developing full-blown CVID, adding support to the contention that both disorders fall along a continuum of the same overarching PID (Aghamohammadi et al., 2008). Further support for this argument is the observation that both IgA deficiency and CVID are associated with the same common extended MHC haplotype, HLA A1, B8, DR3, and DQ2 (Mohammadi et al., 2010).

The basis of the association of this PID and autoimmunity has yet to be elucidated, although several hypotheses have been entertained. It has been posited that absent IgA results in enhanced absorption of exogenous substances at mucosal barriers, particularly in the gastrointestinal tract, that are cross-reactive with self-antigens and breach immunological tolerance to self (Cristina et al.,

2008). Such exogenous antigens may include foods and viruses. This hypothesis presupposes that additional factors must conspire to promote the development of autoimmune reactions. An alternative hypothesis relies on the knowledge that monomeric IgA, the molecular form in serum, can exert anti-inflammatory activity (Castigli et al., 2005). Once bound to Fc α receptors on phagocytic cells, IgA recruits the inhibitory tyrosine phosphatase, SHP-1, leading to a downregulation of the cellular responses mediated by activating heterologous Fc γ receptors that have been engaged by IgG-containing immune complexes. Accordingly, inflammation mediated by such heterologous activating Fc receptors would be expected to be exaggerated in IgA deficiency.

Yet another possible mechanism derives from our understanding of the important role played by TGF- β in B cell IgA isotype switch and production of IgA (Stavnezer, 1995; Cazac and Roes, 2000) and the induction and/or maintenance of immunologic tolerance (Wan and Flavell, 2008). TGF- β provides essential signals for the early induction of IgA isotype switch recombination and development of IgA secreting plasma cells in both mouse and human B cells. Interestingly, TGF- β deficient mice show a partial block in IgA production and develop a multifocal inflammatory disease with clinical autoimmune features and the production of autoantibodies. Moreover, inhibition of TGF- β expression in T cells leads to a similar but somewhat less severe autoimmune phenotype. Furthermore, mice whose TGF- β type II receptors were conditionally knocked out on their B cells developed B cell hyperplasia in Peyer's patches, elevated serum immunoglobulins, exaggerated IgG responses to a weak immunogen, anti-DNA antibodies, and an almost complete absence of serum IgA (Cazac and Roes, 2000). Finally, it is well accepted that TGF- β is a critical player in the development and maintenance of oral tolerance. Antigens delivered via the gastrointestinal tract lead to the development of CD4⁺ Th3 regulatory cells whose suppressive activity is mediated by secreting TGF- β (Faria and Weiner, 2005). Taken together, the above findings raise the theoretical possibility that an impaired TGF- β /TGF- β type II receptor signaling apparatus might contribute to the development of not only IgA deficiency but also autoimmune complications.

Immunodeficiency with Hyper-IgM Syndrome

Immunodeficiency with hyper-IgM (HIGM) syndrome is a heterogeneous group of disorders caused by defects in genes that are critically involved in immunoglobulin B cell isotype switch recombination and somatic hypermutation (Notarangelo et al., 2006; Jesus et al., 2008). These

include genes encoding CD40L and CD40, two cell surface proteins involved in cognate T cell/B cell and antigen presenting cell (APC) interactions as well as other genes that encode enzymes, which mediate the process of isotype class switch recombination and somatic hypermutation of B cells. These latter disorders are B cell-specific defects involving either activation-induced cytidine deaminase (AID) or uracil DNA glycosylase (UNG). The serological hallmark of all of these disorders is a normal to increased serum level of IgM in the face of decreased levels of IgG, IgA, and IgE.

X-linked CD40L deficiency is the most common of these disorders (65–70%) and manifests clinically with recurrent pyogenic infections as well as with an increased risk of infections with certain viruses, fungi, and parasites, most notably *Pneumocystis jiroveci* and *Cryptosporidium* species (Notarangelo et al., 2006; Jesus et al., 2008). In addition, a substantial number of patients develop autoimmune disorders (Jesus et al., 2008). In particular autoimmune neutropenia occurs in up to 50% of patients, which may be complicated by oral ulcers. Patients are also at risk for developing AIHA, severe biliary tract disease (ascending cholangitis) associated with *Cryptosporidia* infections, as well as gastrointestinal tract malignancies. The rare form of hyper-IgM associated with an autosomal recessive CD40 deficiency recapitulates the clinical phenotype of CD40L deficiency.

A review of the function of CD40L, a member of the TNF superfamily, provides a context for understanding these seemingly unrelated clinical phenotypes (Jesus et al., 2008). It is expressed transiently on activated T cells and interacts with its counter-receptor, CD40, on B cells, dendritic cells, and macrophages. The engagement on B cells is a critical proximal step in the isotype switch of naïve B cells following their encounter with T-dependent antigens. This cognate interaction initiates the activation of a number of downstream signaling molecules including TNF receptor-associated factor 2 (TRAF2), TRAF3, and TRAF6, which leads to the activation and nuclear translocation of nuclear factor- κ B (NF- κ B) and the expression of the genes *AID* and *UNG* triggering isotype class switch. In the absence of CD40L, patients have low serum IgA and IgG levels, normal to elevated levels of IgM, and show impaired IgG antibody responses to T-dependent antigens together with a marked reduction of circulating isotype-switched memory B cells. Lymph nodes show primary lymphoid follicles that are devoid of germinal centers. The engagement of CD40 molecules expressed on B cells, macrophages, and dendritic cells is required for the upregulation of CD80/CD86 on these populations of APCs. The interaction of these costimulatory molecules with CD28 on the collaborating T cells leads to full T cell activation and promotes their survival. Thus, it is not surprising that X-linked CD40L

deficient patients experience opportunistic infections and develop malignancies in tissues infected by the prototypic organisms.

Deficiency of UNG (5%) and AID (10%) represent autosomal forms with an infectious phenotype consisting of recurrent sinopulmonary infections with encapsulated bacteria but without opportunistic infections (Jesus et al., 2008). AID deficient patients typically present with enlarged tonsils and lymph nodes presumably related to expansion of the B cells attempting to undergo class switch as evidenced by massive germinal center expansion. Patients with UNG deficiency clinically resemble those with AID deficiency.

Two additional gene defects have more recently been associated with a hyper-IgM serological picture. Both genes are essential for activation and translocation of NF- κ B to the nucleus, resulting in activation of AID and UNG. A hypomorphic mutation in one of these genes, NF- κ B essential modulator (*NEMO/IKK γ*), affects males who present with hypogammaglobulinemia (Jesus et al., 2008). The phenotype is varied and includes HIGM serologic findings (~25%), hypohydrotic ectodermal dysplasia (~75%), lymphedema (<5%), pyogenic infections (~85%), mycobacterial infections (~40%), and serious viral infections (~20%). These patients also develop a range of inflammatory and autoimmune conditions. This association suggests that in addition to defective host defense there is also some degree of immune dysregulation in this disorder. A defect in a second molecule, $\text{I}\kappa\text{B}\alpha$, involved in the same pathway, may also lead to the development of a HIGM phenotype (Jesus et al., 2008). Approximately 25% of patients presenting with an HIGM phenotype have no discernible genetic defects.

HIGM patients with any of the associated gene defects have a proclivity for developing autoimmune diseases (Jesus et al., 2008). This association has been best characterized in X-HIGM patients where the largest surveys have shown that substantial numbers of patients have suffered from neutropenia, ITP, AIHA, inflammatory bowel disease, and seronegative arthritis (Levy et al., 1997; Winkelstein et al., 2003). However, autoimmune disorders including ITP, AIHA, type 1 diabetes, hepatitis, seronegative polyarthritis, inflammatory bowel disease, uveitis, and the appearance of IgM autoantibodies have also been reported in 20–25% of patients with AID deficiency (Quartier et al., 2004; Durandy et al., 2005). Similarly, inflammatory and autoimmune disorders including inflammatory bowel disease, arthritis, and AIHA have been described in patients with NEMO deficiency (Orange et al., 2005).

Several mechanisms pertaining to immunologic tolerance induction and maintenance may account for autoimmune disorders in these patients (Jesus et al., 2008). The CD40L–CD40 interaction in the thymus appears to be

important in the selection of the T cell repertoire as CD40L is expressed on developing thymocytes and CD40 is constitutively expressed on thymic APCs including B cells, dendritic cells, and cortical and medullary epithelial cells. Mouse models have provided evidence that the CD40L–CD40 interaction is not only important for negative selection of autoreactive T cells but also for the development of Treg1 cells and the negative selection of peripheral autoreactive B cells. Humans with CD40L deficiency appear to have intact central tolerance in the bone marrow but impaired peripheral B cell tolerance. In addition they have been reported to have a reduced frequency of CD25⁺FOXP3⁺ Treg cells compared to healthy control subjects. Finally, serum levels of BAFF, a molecule that promotes B cell survival, are increased in X-linked CD40L deficiency, offering another factor that might contribute to the expression of B cell autoimmunity.

INNATE IMMUNE DEFECTS

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) includes a group of genetic defects affecting the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase system in neutrophils (and other cells) that results in recurrent bacterial and fungal infections. NADPH oxidase is the enzyme complex that produces superoxide and other reactive oxygen species upon neutrophil ingestion of microbes required for killing a variety of bacteria and fungi. This disorder is also characterized by dysregulated inflammation resulting in an inflammatory process that typically affects the gastrointestinal and genitourinary tracts often producing strictures (Rosenzweig, 2008; Kang et al., 2011). In addition, these patients may develop wound dehiscence and an inflammatory bowel disease that resembles Crohn's disease. The latter condition can be seen in upwards of 25% of CGD patients and in rare instances is the initial clinical presentation for CGD (Rosenzweig, 2008; Kang et al., 2011). The histology of the gastrointestinal (GI) lesions in CGD differs from Crohn's disease with the development of well-defined granulomata that are surrounded by dense lymphocytic infiltrates. CGD patients may also develop chorioretinal lesions that appear as asymptomatic "punch-out" retinal scars localized along retinal vessels. The mechanism underlying the increased inflammatory responses is unknown and has been observed more commonly in CGD patients with defects in the membrane bound components of NADPH oxidase (gp91phox, p22phox) that are generally associated with a greater degree of compromised NADPH oxidase function. This suggests that the oxidase pathway is not only involved in host protection but also

in controlling inflammation. However, the actual explanation for the inflammatory responses is more complicated since X-linked carriers of CGD, who show mosaicism in their neutrophils, are at increased risk for discoid lupus, oral ulcers, and other evidence of immune dysregulation, whereas the majority of carriers do not have an increased risk for infections.

Early Complement Component Deficiency

Humans with congenital deficiency of C1q, C1r/C1s, C4, or C2 are at an increased risk of developing autoimmune disease, particularly SLE (Barilla-LaBarca and Atkinson, 2003). Indeed, individuals deficient in C1q, C4, or C2 have a 90%, 75%, and 20% chance of developing SLE, respectively. Patients homozygous for C1q or C1r/s deficiency are typically younger than 20 years of age when they present predominantly with cutaneous and renal manifestations of SLE. The vast majority of patients are ANA positive with specificity for extractable nuclear antigen but anti-dsDNA antibodies are usually not detectable. Similarly, patients with homozygous C4 deficiency also present with a lupus-like disease with cutaneous manifestations and glomerulonephritis, albeit milder than in C1q deficiency. Positive ANAs are found in approximately 75% of these patients with anti-Ro and anti-La specificities being most commonly detected. Homozygous (but not heterozygous) C2 deficiency is associated in 10–20% incidence of SLE typically a milder form involving cutaneous and renal manifestations with positive ANAs associated predominantly with anti-Ro antibodies. In contrast, C3 deficiency typically manifests with recurrent bacterial infections, but there is also an increased risk of autoimmune disease including SLE-like disease and membranoproliferative glomerulonephritis. Taken together, these observations underscore the importance of the early components of the classical complement pathway in the induction and/or the maintenance of B cell tolerance or control of the inflammatory process. This relationship appeared quite paradoxical since the classical complement cascade had historically been considered to be necessary for the expression of the clinicopathologic features seen in immune complex-mediated diseases like SLE.

Transgenic mouse studies reported in the late 1990s provided a possible explanation, suggesting immature B cells encountering low levels of soluble antigen develop tolerance via anergy (Gommerman and Carroll, 2000). By contrast, immature B cells encountering membrane bound antigen were deleted. Using an adaptation of this transgenic approach, investigators discovered that the induction and maintenance of B cell anergy to a soluble self-protein required the expression of the proteins CD21/CD35 on the surface of self-reactive B cells and the protein C4. In the mouse, one gene (*Cr2*) encodes both

CD35 (Cr1) and CD21 (Cr2), whereas in humans there are two genes: one coding for CR1 (CR1) and another for CR2 (CR2). Thus, mice deficient in CD21/CD35 would lack both Cr1, which binds C4b and C3b, and Cr2, which binds iC3b and C3d,g (Erdei et al., 2009). Furthermore, the absence of these complement receptors and the C4 protein, but not C3, in a mouse strain genetically prone to develop a lupus-like disease produced increased anti-double-stranded DNA antibodies and resulted in a more highly expressed immune complex-mediated glomerulonephritis (Gommerman and Carroll, 2000). Taken together, these results implicated CD21/CD35 and C4 in the development and the maintenance of B cell immunological tolerance to self-proteins. However, results of a later study conducted in C1q^{-/-} mice provided conflicting results (Cutler et al., 2001). Thus, if the early complement components do indeed promote B cell self-tolerance, it is presumed that their silencing function is exerted when the self-reactive B cells encounter autoantigen at critical checkpoints in the bone marrow and peripheral lymphoid compartment, respectively.

A second and perhaps more compelling (but not mutually exclusive) mechanism to account for autoantibody-mediated disease relates to the role played by these molecules in the clearance of immune complexes, apoptotic bodies, and the debris released by cells undergoing apoptosis (Erdei et al., 2009). C4b and C3b are considered to be important in the uptake of immune complexes by phagocytic cells. Thus, it was reasoned that absent C1q, C4, C2, or C3 means more complexes are available to deposit in tissues where they can elicit inflammation. Currently there is more focus on the role played by these complement components, particularly C1q, in the clearance of apoptotic cells/debris. A large body of evidence indicates that such cellular rubbish must be decorated with C1q and other proteins before it can be removed by phagocytic cells like macrophages. Absent this removal, the debris, particularly nucleic acids exposing cryptic epitopes, becomes available to stimulate self-reactive B cells that have escaped self-tolerance, thereby leading to autoimmunity.

The removal of such apoptotic debris by phagocytic cells is critically important for controlling inflammation and possibly even maintaining peripheral self-tolerance. For example, studies have shown that the process of removing apoptotic neutrophils by macrophages at sites of inflammation, referred to as efferocytosis, is critical for the resolution of the inflammatory process (Bratton and Henson, 2011). A by-product of the macrophage ingestion of apoptotic neutrophils is the elaboration of a number of anti-inflammatory molecules including TGF- β , IL-10, VEGF, HGF, and PGE2. As noted above, C1q and a number of complement receptors, as well as a number of other molecules, promote tethering of apoptotic

neutrophils to their refuse collectors. The release of TGF- β by macrophages and immature dendritic cells may have yet another related effect, on orchestrating suppression of inflammatory reactions. For example, the uptake of apoptotic T cells by macrophages and immature dendritic cells was reported to lead to the production of TGF- β , which in turn induced the development of adaptive Tregs (Perruche et al., 2008). Although it remains to be determined whether early complement components are essential for the efferocytosis of apoptotic T cells or neutrophils, there is emerging evidence that complement contributes to the control of inflammation induced by self-antigens.

Toll-Like Receptor 3 (TLR3) Polymorphism and Autoimmunity

A recent report identifies that a particular variant of TLR3 (I412F) is associated with mucocutaneous candidiasis, increased susceptibility to cytomegalovirus, and autoimmunity. The autoimmune phenomena include endocrinopathies, autoimmune cytopenias, alopecia, vitiligo, arthritis, and enteritis (Nahum et al., 2012). This variant appears to diminish TLR3 mediated NF- κ B activation by its natural ligand, double-stranded RNA, as well as the synthetic ligand poly I:C. The exact basis for the increase in autoimmunity is currently under investigation but is another example of specific immune dysfunction being linked to autoimmune processes.

MONOGENIC DEFECTS AFFECTING IMMUNE HOMEOSTASIS AND/OR TOLERANCE

Autoimmune Polyendocrinopathy, Candidiasis, Ectodermal Dystrophy

Autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy (APECED), also referred to as autoimmune polyendocrinopathy syndrome type 1 (APS1), is a human disorder affecting the immune system that typically presents with a triad of findings including hypoparathyroidism, adrenal insufficiency, and mucocutaneous candidiasis (CMC). Additional autoimmune features may include gonadal failure, hepatitis, type 1 diabetes, celiac disease, pernicious anemia, keratitis, vitiligo, and others. These patients also present with ectodermal dystrophy that most commonly presents as nail dystrophy.

APECED is an autosomal recessive disorder caused by mutations in the gene encoding the autoimmune regulator (AIRE) protein. There is a higher incidence of APECED in certain populations including Iranian Jews (1:9000), Sardinians (1:14,000), and Finns (1:25,000)

with lower prevalence in Slovenia (1:43,000), Norway (1:80,000), and Poland (1:129,000) (Kisand and Peterson, 2011). In these settings there tend to be predominantly specific *AIRE* mutations. Importantly, the same mutation in different patients can present with varied clinical phenotypes, pointing out that additional factors impact on the clinical presentation. The *AIRE* protein is a transcription factor that is involved in the ectopic expression of a wide array of tissue-specific autoantigens by the medullary thymic epithelial cells (mTECs) (Rucci et al., 2011). The expression of autoantigens by the mTECs is critical in the negative selection of antigen-specific autoreactive T cells within the thymic medulla. It is now known that *AIRE* protein is also expressed in peripheral lymphoid tissue with the specific role played by *AIRE* in the periphery related to self-tolerance currently being investigated (Poliani et al., 2010). *AIRE* also appears to play a role in Treg cell development and studies in APECED patients have identified a decrease in forkhead box P3 protein (FOXP3) expression together with diminished *in vitro* suppressive capacity of circulating Treg cells (Laakso et al., 2010). It is clear that in APECED patients many of the autoimmune disorders are accompanied by the production of autoantibodies that in some cases may be linked to disease and in others simply serve as biomarkers of disease. Recently, the explanation for CMC in this disorder was linked to the development of high affinity, neutralizing autoantibodies to IL17A and IL-22 (Puel et al., 2010). This finding was noted in all APECED patients evaluated but was not detected in any other conditions tested. This finding fits well with prior descriptions of autoantibodies to another cytokine (α -interferon) found in the majority of these patients. The finding of the neutralizing anticytokine antibody establishes a new paradigm with an autoantibody inhibiting the activity of a critical cytokine resulting in the development of a specific host defense defect. This type of autoimmune process (i.e., anticytokine autoantibody) has also been linked to susceptibility to non-tuberculous mycobacterial infections associated with high titer, neutralizing autoantibodies to gamma interferon.

Immunodysregulation, Polyendocrinopathy, Enteropathy X-Linked

Immunodysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome is a severe disorder of immune function presenting during infancy with a clinical triad of enteritis, endocrinopathy, and dermatitis (Ochs et al., 2007; D'Hennezel et al., 2012). The GI disease produces intractable diarrhea and malabsorption causing failure to thrive. The histopathology of the enteropathy includes villous atrophy and lymphocytic infiltration of the mucosa.

The endocrinopathy typically presents as insulin-dependent type 1 diabetes mellitus and the dermatitis is a generalized eczematous-like rash. Additional autoimmune features include cytopenias, thyroid disease, renal disease, and hepatitis. Immunologic laboratory findings include eosinophilia and hypergammaglobulinemia including elevation of serum IgE, as well as the presence of a variety of autoantibodies (Tsuda et al., 2010). Early recognition of this syndrome is crucial as mortality is extremely high without therapy, which initially consists of aggressive immunosuppression to control the autoreactivity followed by hematopoietic stem cell transplantation to provide curative immune reconstitution and a source of Tregs.

The underlying genetic basis for IPEX is an X-linked recessive defect in the gene encoding FOXP3, a member of the forkhead/winged helix family of transcription factors located at Xp11.23. There have been a wide range of mutations found including single base substitutions, deletions, and splicing mutations. Defective FOXP3 expression leads to a defect in Treg cell production and this is reflected by the virtual absence of circulating CD4⁺/CD25⁺/FOXP3⁺ T cells in these patients.

Confirmation that the underlying immunopathology of IPEX is related to the mutation in FOXP3 and the absence of Treg cells is supported by a murine model, the scurfy mouse. This mouse carries a mutated *foxp3* gene and has a constellation of autoimmune disorders similar to patients with IPEX. In addition, these mice, similar to IPEX patients, demonstrate markedly impaired Treg cell development. In this model, the autoimmunity can be prevented by correcting the *foxp3* defect in the scurfy mouse using retroviral vector-based gene therapy and the same autoimmune syndrome can be created by artificially knocking down *foxp3* expression in otherwise normal strains. The actual mechanism(s) mediating the immunosuppressive activity of Treg cells in humans is not fully understood although it appears to involve both inhibition by cell–cell contact and the secretion of immunomodulatory cytokines including TGF- β and IL-10. The consistently targeted organs in the IPEX syndrome suggest that Treg cell function is particularly important in developing and maintaining self-tolerance in the GI tract, (selected) endocrine organs, blood cells, and skin. However, owing to the severity of this syndrome, it is unclear if autoimmunity to other target organs could arise over time in this patient population.

There are two additional genetic defects that present with clinical findings that include significant phenotypic overlap with IPEX. The first involves an autosomal recessive defect in the gene encoding the CD25 protein, a component of the IL-2 receptor heterotrimer (IL-2 receptor alpha chain). In this disorder, patients not only have an autoimmune phenotype that resembles IPEX but also develop an SCID-like picture with early onset of

opportunistic infections (Claudy et al., 2007). Findings in the murine model of CD25 deficiency suggest that Treg cell development is normal but the survival, maintenance, and competitive fitness of these cells is defective due to the absence of IL-2 signaling associated with the defective IL-2 receptor. The second overlap syndrome is an autosomal recessive disorder that involves mutations in the gene encoding STAT5B. In this disorder the patients also have an IPEX-like clinical picture together with a marked immune deficiency and growth hormone resistant dwarfism (Bernaconi et al., 2006). These patients typically present with additional distinct clinical findings including a prominent forehead, a saddle nose, and a high pitched voice. The underlying basis for this disorder is the requirement of STAT5B for effective signaling by IL-2 as well as by growth hormone. Studies in these very rare patients have demonstrated decreased numbers of circulating Treg cells that expressed diminished levels of FOXP3 and were functionally ineffective when tested *in vitro*.

Autoimmune Lymphoproliferative Syndrome

The autoimmune lymphoproliferative syndrome (ALPS) is a human disorder associated with a triad of findings that includes lymphoproliferation, increased alpha-beta TcR double negative T cells, and abnormal lymphocyte apoptosis (Oliveira et al., 2010). Clinically, ALPS patients have a high incidence of autoimmune cytopenias and a substantially increased risk for the development of non-Hodgkin and Hodgkin lymphoma. The typical course of disease in ALPS patients begins during childhood with the development of nonmalignant lymphadenopathy and splenomegaly. In many of the patients the lymphoid accumulation is followed by the development of autoimmunity that is almost exclusively immune-mediated cytopenias, most commonly AIHA and ITP. Some ALPS patients also develop neutropenia and dermatologic findings that can include an urticarial rash. Rare autoimmune findings reported in ALPS include glomerulonephritis, Guillain–Barré syndrome, autoimmune hepatitis, and polyneuropathy. A very significant problem in the most common genetic form of ALPS that is associated with a defect in the *FAS* gene linked to the increased risk for the development of Hodgkin and non-Hodgkin lymphoma (relative risk ~51- and ~14-fold, respectively).

The underlying defect in the majority of ALPS patients is an abnormality in the extrinsic apoptotic pathway linked to defective signaling via the FAS receptor (Lenardo et al., 2010). This homotrimeric receptor is a member of the TNF receptor superfamily and plays a critical role in lymphocyte homeostasis as well as in immune-mediated cytotoxicity following receptor engagement by FAS ligand (FASL). Among patients diagnosed with ALPS, ~65–70% have a heterozygous defect in the *FAS* gene that acts as a

dominant negative mutation in most patients (i.e., is autosomal dominant). These patients are now categorized as ALPS-FAS with the majority having a heterozygous germline mutation. However, more recently it has been appreciated that a significant minority of ALPS-FAS patients have a heterozygous somatic mutation affecting *FAS* (categorized as ALPS-sFAS) that can be detected primarily in the circulating alpha-beta double negative T cells. There are additional, less common genetic causes of ALPS including mutations in the genes encoding FASL (categorized as ALPS-FASL) and caspase-10 (categorized as ALPS-CASP). In addition, there remain ~20% of patients with an ALPS clinical phenotype who do not have a defined genetic defect (categorized as ALPS-U). In all ALPS cases with genetically defined mutations there is a defect in the death inducing signal mediated by FAS. This can be analyzed *in vitro* and the degree of the apoptotic defect varies based on the site of the *FAS* mutation with those affecting exons coding for the intracellular part of the protein generally conferring more severe disease with higher disease penetrance. More recently biomarkers have been identified that are strongly linked with both germline and somatic *FAS* mutations including elevation in soluble FASL, IL-10, and vitamin B12. Combining an elevation in one of these biomarkers with increased alpha-beta double negative T cells yields a greater than 95% likelihood of a *FAS* mutation (either germline or somatic).

The defect in the FAS-dependent extrinsic apoptotic pathway presumably interferes with peripheral tolerance and the normal control of specific autoreactive T cells (and possibly autoreactive B cells). Clearly, based on varied penetrance observed in extended family pedigrees, the *FAS* gene defect requires additional (currently unidentified) factors for the development of clinical disease. This situation is analogous to the murine model of autoimmunity associated with a FAS defect, the *lpr* mouse, where strain variations can significantly impact the degree of autoimmunity. As is seen in other specific genetic defects, the range of autoimmunity in ALPS is quite limited and suggests that the FAS-mediated pathway of tolerance has a more restricted role in controlling self-reactivity and the increased risk of lymphoma in ALPS patients suggests that FAS also serves as a tumor suppressor pathway.

CONCLUSION

Although at one time a perplexing paradox, coexistent autoimmunity and primary immunodeficiency now stand as two sides of the coin of immunologic dysregulation. In most of the monogenic defects that confer a primary B cell, T cell, or combined immunodeficiency, autoimmunity occurs primarily as a consequence of the impairment of one of more critical checkpoints in the development/maintenance of immunologic self-tolerance. This situation

is relevant to the development of autoimmunity in certain types of SCID, STIM1 deficiency, DiGeorge syndrome, WAS, IPEX, ALPS, and immunodeficiency with hyper-IgM where various single-mutated genes lead to defects in central T cell silencing and/or peripheral T cell regulation (Table 29.1). By contrast, in APECED, the converse

TABLE 29.1 Autoimmune Manifestations of Select Primary Immunodeficiency Syndromes.

Abbreviations: SCID, severe combined immunodeficiency; mTEC, medullary thymic epithelial cells; ND, not determined; WAS, Wiskott–Aldrich syndrome; RA, rheumatoid arthritis; AIHA, autoimmune hemolytic anemia; IBD, inflammatory bowel disease; ITP, immune thrombocytopenic purpura; X-HlgM, X-linked immunodeficiency with hyper-IgM; NLH, nodular lymphoid hyperplasia; JRA, juvenile rheumatoid arthritis; GLILD, granulomatous interstitial lung disease; SLE, systemic lupus erythematosus; DLE, discoid lupus erythematosus; CGD, chronic granulomatous disease; APS1, autoimmune polyendocrinopathy type 1; APECED, autoimmune polyendocrinopathy candidiasis, ectodermal dystrophy; CMC, chronic mucocutaneous candidiasis; IPEX, immunodysregulation, polyendocrinopathy, enteropathy X-linked; ALPS, autoimmune lymphoproliferative syndrome; ?, possible.

is true, i.e., autoimmunity conferred by a mutated *AIRE* gene, which impairs central T cell tolerance, leads not only to autoimmunity directed at specific end organs but also to autoimmunity that manifests as immunodeficiency presenting with chronic mucocutaneous candidiasis. Autoimmunity and inflammatory disorders arising from monogenic defects in the innate immune system that cause repeated bacterial infections, like CGD and early complement component deficiency, may be due, in part, to the failure of a principal mechanism for resolving inflammation, namely, the clearance of apoptotic debris and/or other inflammatory regulatory processes. Less clear are the reasons why autoimmunity is a fellow traveler of the two most common primary deficiencies of the adaptive immune system, whose molecular basis is less understood. Both selective IgA deficiency and CVID, which share some genetic origins, feature sizable subsets of patients who are afflicted with autoimmune disorders common to each. Although immunologic defects appear to be more expansive in CVID, immune dysregulation is a feature of both syndromes and may represent the driving force for autoimmunity.

It is important to add that the above formulation is the product of a reductionist approach. All of the primary deficiency disorders discussed are impacted by additional aberrant immune mechanisms to those summarized above. Most importantly, all of these immunodeficiency disorders, even those that are monogenic, can be quite heterogeneous with regard to their clinical phenotype whether or not they are complicated by autoimmunity. Therefore, an understanding of the molecular basis for the nexus between autoimmunity and primary immunodeficiency must await the elucidation of the matrix of factors/mechanisms, which alter gene expression in ways that influence the emergence of these respective clinical phenotypes. At the top of the list are epigenetic mechanisms including DNA methylation, histone modification, and microRNA activity through which such disease modifiers as age, gender, and environmental factors operate. Although study of these epigenetic processes in primary immunodeficiency is in its infancy, it is proceeding at a brisk pace in autoimmunity.

INTRODUCTION

Animal models have greatly facilitated the study of systemic autoimmune diseases, notably systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA), and helped to develop rational new treatments. In addition, autoimmunity-prone mice have served as important tools in the study of genes involved in the expression of autoimmunity and related disease. Genes that facilitate or inhibit disease have been identified and these have in turn facilitated the study on immunogenetics and immunopathogenesis of human systemic autoimmune diseases. The etiology of both SLE (Tsokos, 2011) and RA (McInnes and Schett, 2011) is heterogeneous and complicated, but animal models bring a consistent understanding of disease pathogenesis. Mouse models of systemic autoimmune disease can be grouped into three types: spontaneous, gene manipulation derived, and induced.

SPONTANEOUS MODELS OF SYSTEMIC AUTOIMMUNITY

Commonly studied spontaneous models of lupus include the MRL-Fas^{lpr/lpr} (MRL/lpr), (NZB×NZW)F1, and BXSB mice. These murine models that develop SLE spontaneously have generated significant information on the role of hormones (Roubinian et al., 1978; Fernandes

and Talal, 1986; Dhaher et al., 2000; Svenson et al., 2008) and the contribution of aberrant immune regulation (Handwerger et al., 1994) in the expression of the disease. Lastly, they have been used to identify loci that contribute to the genetic pool required for the development of disease (Drake et al., 1995; Reilly and Gilkeson, 2002; Kono and Theofilopoulos, 2006). Gene complementation studies have shed light on the epistatic interactions of genes (Wakeland et al., 1997; Morel and Wakeland, 1998). Candidate genes have been identified including those of the CD2 family (Wandstrat et al., 2004), the interferon (IFN)-inducible genes (Rozzo et al., 2001), and the complement receptor gene *Cr2* (Boackle et al., 2001). Other studies have pointed to recommendations for novel treatments. For example, it has been shown that introduction of an IFN- α/β receptor null gene into New Zealand Black, H-2_d (NZB) mouse results in decreased production of anti-erythrocytic antibodies (Santiago-Raber et al., 2003). Because IFN- α has been found to be increased in patients with SLE and to promote dendritic cell maturation (Blanco et al., 2001), a case can be made for the construction of biologics to limit the action of type I IFNs in systemic autoimmunity. Moreover, identification of contributing genes and loci in animal models has guided the search for orthologs in humans with systemic autoimmune diseases (Tsao et al., 1997, 2002; Gaffney et al., 1998, 2000; Harley et al., 1998; Moser et al., 1999).

The NZB mouse develops anemia due to anti-erythrocyte antibody. Hybrids with NZW (H-2^Z), (NZB×NZW) F1 mice, develop systemic autoimmune disease with high titer of anti-DNA antibodies and severe glomerulonephritis (GN) that becomes apparent at 5–6 months of age. The decreased average lifespan of these mice is 8 months for females and 13 months for males (Vyse et al., 1998; Ibnou-Zekri et al., 1999). Among New Zealand Mixed (NZM) mice generated by (NZB×NZW) F1 and NZW backcross and sib mating, NZM2328 and NZM2410 were found to develop lupus-like disease. Importantly, three lupus susceptibility loci, *Slc1-3*, were identified by the lupus linkage analysis of NZM2410 mice (Morel et al., 1994). From the findings in mice, variations in many genes in these loci have been directly associated with human SLE. *Slc1b* corresponds to polymorphisms in four signaling lymphocytic activation molecule (SLAM) family member genes (Wandstrat et al., 2004), including Ly108, which was directly implicated in the regulation of B cell tolerance (Kumar et al., 2006). Variants of SLAMF3 (Ly9) and SLAMF4 (CD244) have been associated with human SLE and RA (Cunningham-Graham et al., 2008; Suzuki et al., 2008).

The MRL mouse strain was derived from several inbred lines that included LG/J (75%), AKR/J (12.6%), C3H/Dehi (12.1%), and C57BL/6 (0.3%). MRL-Fas^{lpr/lpr} (MRL/lpr) mice, bearing two doses of mutation in the Fas gene, develop accelerated autoimmune disease characterized by severe lymphadenopathy due to the accumulation of CD3⁺CD4⁻CD8⁻B220⁺ (double-negative) T cells. Disease onset with severe dermatitis and/or lymphadenopathy is seen from 10 to 12 weeks and death occurs at around 25 weeks. Disease is severe in the female and the average lifespan for female MRL/lpr mice is from 17 to 35 weeks depending on the environment. Mice display high concentrations of immunoglobulins including elevated levels of autoantibodies such as antinuclear antibodies (ANA), anti-ssDNA, anti-dsDNA, anti-Sm, and rheumatoid factors (Andrews et al., 1978). B cells and T cells from these mice have a defect in apoptosis due to the lack of functional Fas receptor (Reap et al., 1995). A mutation of Fas ligand gene leads to generalized lymphoproliferative disease (gld) similar to that caused by the *lpr* mutation (Takahashi et al., 1994). In humans, defective Fas signaling can lead to the development of autoimmune lymphoproliferative syndrome (ALPS) which shares many manifestations with SLE. Further study of the intense lymphoproliferation has enabled the identification of genes whose products are central to expression of systemic disease. For example, while deletion of the cyclin-dependent kinase inhibitor p21 does not lead to autoimmunity (Lawson et al., 2002, 2004), transfer of the *p21* null gene into the MRL^{lpr/lpr} mouse results in reduced autoimmune disease by allowing T cell death and

decreasing the accumulation of G0/G1 arrested lymphocytes cells (Lawson et al., 2004). Expression of the *lpr* mutation in non-autoimmune strains such as C3H/HeJ and C57BL/6 leads to the development of lymphoproliferation and autoantibody production but limited glomerulonephritis in female mice.

Male only BXSB mice develop severe glomerulonephritis and autoantibodies. The genetic locus responsible for the expression of the disease is located in the Y chromosome and is known as *Yaa* (Y chromosome-accelerated autoimmunity) (Izui et al., 1995). *Yaa* was first identified from a cross between a C57BL/6 female and a SB/Le male that produced the BXSB hybrid line. BXSB mice develop SLE at much higher incidence and with earlier onset in males compared to females, whereas mice from the reciprocal cross (SB/LE female and B6 male) do not show the same acceleration of disease in males. The disease is heavily dependent on the presence of the H-2b allele, because its replacement with the H-2d allele results in prolonged survival. Of interest, the (BXSB×NZW) F1 mouse develops thrombocytopenia and coronary artery disease accompanied by the presence of antiphospholipid antibodies (Kono and Theofilopoulos, 2006). Toll-like receptor 7 (TLR7), a single-stranded RNA-binding innate immune receptor, was identified as a gene responsible for the Y chromosome-linked autoimmune accelerator, as duplication of the *Tlr7* gene in *Yaa*⁺ mice was shown to be associated with the induction of autoreactive B cells (Pisitkun et al., 2006). Moreover, deletion of the endogenous copy of *Tlr7* from X chromosome abrogates *Yaa*-induced monocytosis, lymphoid activation, splenomegaly, and glomerulonephritis, with decreased mortality (Deane et al., 2007; Santiago-Raber et al., 2008). Consistently, a human allele of the *Tlr7* gene was recently reported to be associated with increased risk for SLE development in males (Shen et al., 2010).

Palmerston North (PN) mice develop spontaneous autoimmunity manifested by the production of multiple autoantibodies, vasculitis, and glomerulonephritis. PN X NZB F1 mice develop more severe disease (Luzina et al., 1999).

Mice homozygous for the *ank* mutation, *Ank/ank* mice, develop early-onset joint ankylosis in the spine and peripheral joints resembling human spondyloarthritis (Krug et al., 1989). The *Ank* gene encodes a transmembrane protein expressed in joints that controls pyrophosphate levels and may be irrelevant to autoimmunity.

K/BxN T cell receptor mice, a spontaneous mouse model of autoimmune arthritis, generated fortuitously by crossing a TCR transgenic line with the non-obese diabetic (NOD) strain (Monach et al., 2004), spontaneously develop an autoimmune disease with most (although not all) of the clinical, histologic, and immunologic features

of RA in humans. The murine disease is critically dependent on both T and B cells and is joint specific, but it is initiated and perpetuated by T and B cell autoreactivity to a ubiquitously expressed antigen, glucose phosphate isomerase (GPI). Transfer of serum (or purified anti-GPI immunoglobulins) from arthritic K/BxN mice into healthy animals regularly provokes arthritis within a few days, even when recipients are devoid of lymphocytes. Complement components, Fc receptors, and mast cells are important for the expression of the disease. The relevance of the K/BxN model to human RA is supported by one report showing that serum from almost two-thirds of patients with RA contain anti-GPI antibodies, which are absent from serum from normal individuals or of patients with Lyme arthritis or Sjögren's syndrome (Matsumoto et al., 2003). However, not all investigators agree. The K/BxN model has been particularly useful in illustrating the role of immune-inflammatory components in the development of arthritis and notably the characterization of the role of mast cells (Lee et al., 2002); yet, this model offers little evidence that autoantibodies are involved in the pathogenesis of RA.

SKG mice spontaneously develop T cell-mediated arthritis due to a mutation of the gene encoding a Src homology 2 (SH2) domain of ζ -associated protein of 70 kDa (ZAP-70), a key signal transduction molecule in T cells. The disturbance in the thymic T cell selection from absence of ZAP-70 results in the generation of arthritogenic T cells. Besides synovitis, SKG mice develop extra-articular lesions, including pneumonitis and vasculitis. Serologically, they develop high levels of rheumatoid factor (Marshall et al., 2003) and autoantibodies specific for type II collagen (Sakaguchi et al., 2003). A molecule termed synoviolin/Hrd1 was found to play a key role in the development of synovitis. This represents an E3 ubiquitin ligase, which, by promoting the growth of synovioytes, facilitates the development of arthritis. Mice lacking synoviolin are resistant to arthritis (Amano et al., 2003).

Mice that develop spontaneous autoimmunity have helped our understanding of hormonal and immunoregulatory influences in autoimmunity, but obvious restraints limit direct transfer of this information to human disease. Human disease develops in individuals with a permissive genetic background in conjunction with environmental and stressful factors, possibly acting over a long period. However, these murine models allow us to analyze disease mechanisms and are very useful in testing potential therapies. Moreover, analysis of gene-manipulated mice in these genetic backgrounds enable investigators to identify a number of molecules involved in the development of disease pathogenesis. A number of cytokine/cytokine receptor signals are reported to be important for the pathogenesis of SLE, including IFN- γ /IFN- γ R (Haas et al.,

1997; Balomenos et al., 1998), IL-6 (Cash et al., 2010), IFN α R (Santiago-Raber et al., 2003), IL-21/IL-21R (Bubier et al., 2009; Herber et al., 2007), and IL-23R (Zhang et al., 2009; Kyttaris et al., 2010). Intracellular signaling molecules such as phosphoinositide 3-kinase gamma (PI3K γ) (Barber et al., 2005), mammalian target of rapamycin (mTOR) (Lui et al., 2008), spleen tyrosin kinase (Syk) (Deng et al., 2010; Bahjat et al., 2008), and calmodulin-dependent kinase IV (CaMKIV) (Ichinose et al., 2011) were also identified to be involved in the development of lupus. These molecules could represent therapeutic targets for the treatment of human SLE and numerous clinical trials are currently in progress. What are the trials assessing?

GENETICALLY MANIPULATED MODELS OF SYSTEMIC AUTOIMMUNITY

Loss of tolerance is a fundamental immunologic abnormality in SLE. Numerous studies of mice with genetic manipulation such as gene deletions and transgenes that develop autoantibodies and other features of SLE on non-autoimmune genetic backgrounds have provided great insights into mechanisms that govern tolerance and autoimmunity and suggested novel rational treatments.

Lymphocyte Activation Molecules

Human SLE T cells are known to express less TCR- ζ chain (Lioussis et al., 1998) and to use alternative signaling through the FcR- γ chain (Enyedy et al., 2001). Mice that lack the TCR- ζ chain develop autoimmune manifestation and display disturbed positive and negative thymic selection (Yamazaki et al., 1997), and the phenotype can be rescued successfully by introducing the FcR- γ chain (Shores and Love, 1997). The pathophysiology for the murine and human phenotypes may well differ and, although in mice lack of the ζ chain may lead to autoimmunity by altering early thymic events that limit the export of autoimmune T cells, in humans the rewiring of TCR with the newly upregulated FcR- γ chain will lead to increased TCR-mediated signaling processes (Tsokos et al., 2003).

The B7-CD28/CTLA-4 costimulatory pathway is pivotal for T cell activation. Signaling through this pathway is complex due to the presence of at least two B7 family members, CD80 (B7-1) and CD86 (B7-2), and two counter-receptors CD28 and CD152 (CTLA-4). CTLA-4-deficient mice rapidly develop lymphoproliferative disease with multi-organ lymphocyte proliferation and tissue destruction, with particularly severe myocarditis and pancreatitis, and die by 3–4 weeks of age (Tivol et al., 1995; Waterhouse et al., 1995). CTLA4-Ig limits effectively murine lupus (Finck et al., 1994) and the use of CTLA-4-Ig biologics has helped

patients with RA (Kremer et al., 2003) and psoriatic arthritis (Abrams et al., 2000).

Programmed death-1 (PD-1) is a member of the CD28 family of receptors and its intracytoplasmic domain defines an immunoreceptor tyrosine-based inhibition motif (ITIM); engagement of PD-1 with its ligands PD-L1 and PD-L2 delivers a negative signal. Mice lacking the PD-1 gene develop either autoantibody-mediated cardiomyopathy in BALB/c (Okazaki et al., 2003) or glomerulonephritis on a C57BL/6 background (Nishimura et al., 2001). PD-1 polymorphism has been identified among SLE patients (Prokunina et al., 2002) and/or RA patients (Lin et al., 2004). PD-L1 deficient mice show accelerated autoimmune inflammation in MRL/MpJ and MRL/lpr mice (Lucas et al., 2008).

Src homology 2-containing phosphatase 1 (SHP1) is one of the best-characterized protein tyrosine phosphatases (PTPase). SHP inhibits cell activation through its recruitment by negative regulatory molecules containing ITIM. The homozygous loss of ITIM in mice leads to the “moth-eaten” phenotype characterized by spotty hair loss and abnormalities in the immune system that lead to systemic autoimmunity and skin inflammation (Kozlowski et al., 1993; Tsui et al., 1993; Bignon and Siminovitch, 1994). T lymphocytes from these mice are hyper-responsive to TCR stimulation (Pani et al., 1996). Since neutrophils from moth-eaten mice demonstrate increased oxidant production, surface expression of CD18, and adhesion to protein-coated plastic, the autoimmune phenotype in these mice may not directly reflect lymphocyte aberrations (Kruger et al., 2000). Furthermore, a recent report shows that only B cell specific deletion of SHP1 leads to systemic autoimmune disease (Pao et al., 2007).

Mice with beta1,6 N-acetylglucosaminyltransferase V (Mgat5) deficiency display decreased glycosylation of T cell membrane proteins, which prevents galectin binding and thereby disrupts the galectin–glycoprotein lattice leading to increased clustering of the TCR (Demetriou et al., 2001). Increased TCR clustering in these autoimmune mice provides a phenotype to some degree comparable with human SLE, involving lowered T cell activation thresholds and increased TCR signaling. In the case of T cells in human SLE, increased association of the TCR- ζ chain with lipid rafts, as well as membrane clustering, are claimed to lead to decreased tolerance and abnormal signaling (Nambiar et al., 2002; Krishnan et al., 2004). Thus, defects in the expression and function of glycosylation processes may predispose to autoimmunity and, along the same lines, glycosylation of the transcription factor Elf-1, which enables the 80-kDa form to transform to the DNA-binding 98-kDa form, is defective in human SLE T cells (Juang et al., 2002).

Other lines of evidence suggest T cells from lupus-prone mice that are transgenic for a specific receptor have

decreased antigen-initiated T cell stimulation thresholds (Vratsanos et al., 2001; Bouzahzah et al., 2003). A similar concept of an “over-excitabile” antigen-initiated proximal lymphocyte signaling phenotype has been proposed for human SLE (Tsokos et al., 2003).

A state of B lymphocyte hyperactivity resembling SLE is seen in mice lacking the src family kinase Lyn. Lyn is an essential inhibitory component on B cell receptor (BCR) signaling. Negative regulation of the BCR is a complex quantitative trait in which Lyn, the co-receptor CD22, and the tyrosine phosphatase SHP-1 are each limiting elements (Cornall et al., 1998). Lyn deficient mice display decreased numbers of mature peripheral B cells, greatly elevated serum IgM and IgA (Bignon and Siminovitch, 1994), and production of autoantibodies that cause autoimmune glomerulonephritis reminiscent of SLE (Chan et al., 1997). Sustained activation of Lyn *in vivo* using a targeted gain-of-function mutation (Lyn^{up/up} mice) led to the development of autoantibodies and lethal autoimmune glomerulonephritis. Interestingly, B cells show a heightened calcium flux in response to BCR stimulation (Hibbs et al., 2002). These data in humans and mice suggest that mechanisms that lead to sustained BCR signaling may override control mechanisms and lead to autoimmunity.

Antigen presented in the context of immune complexes engages not only the BCR but also the Fc γ RIIb, which results in the phosphorylation of the ITIM defined by its intracytoplasmic domain. Recruitment of the phosphatases SHIP (Src homology 2 domain-containing inositol-5-phosphatase) and SHP1 suppresses signaling. Introduction of the Fc γ RIIb null phenotype into the C57BL/6 background caused production of autoantibodies and glomerulonephritis (Bolland and Ravetch, 2000) and Fc γ RIIb deficiency exacerbates autoimmunity in B6/lpr mice (Yajima et al., 2003). Yet the same null phenotype on the BALB/c background did not result in autoimmunity. Although SHIP is considered responsible for Fc γ RIIb-mediated suppression, the SHIP null phenotype does not result in autoimmunity (Helgason et al., 2000). In humans, polymorphisms of the Fc receptors have been associated with systemic autoimmunity and particularly with SLE, and granulomatous polyangiitis (formerly called Wegener’s disease) (Kimberly et al., 1995).

Ubiquitination-Protein Ligases

The Cbl-b and Cbl adaptor proteins are E3 ubiquitin ligases that inhibit receptor and non-receptor tyrosine kinases by promoting ubiquitination (Bachmaier et al., 2000). Loss of Cbl-b rescues reduced calcium mobilization of anergic T cells, which was attributed to Cbl-b-mediated regulation of PLC γ -1 phosphorylation. Loss of Cbl-b in mice results in impaired induction of T cell

tolerance both *in vitro* and *in vivo* and shows exacerbated autoimmunity (Jeon et al., 2004). Moreover, mice with B cell-specific deficiency of Cbl/Cbl-b exhibit impairment of anergy to self-antigen and develop lupus-like disease with anti-dsDNA, ANA, massive leukocytic infiltrates in multiple organs, and immune complex GN (Kitaura et al., 2007).

Roquin (Rc3h1), a RING-type ubiquitin ligase family member, was identified as a negative regulator of follicular helper T (Tfh) cell development. This molecule is identified by a novel forward genetic strategy: male C57BL/6 mice were treated with ethylnitrosourea (ENU), a mutagenic agent, bred the variant genome sequences to homozygosity, and progeny were screened for autoimmunity. M199R mutation within the ROQ domain of Roquin was generated by ENU mutagenesis that resulted in ANA, anti-dsDNA, glomerulonephritis, necrotizing hepatitis, anemia, and immune thrombocytopenia (Vinueza et al., 2005). This mouse displays increased germinal center formation and expansion of memory/effector CD4⁺ T cells, particularly Tfh cells. Tfh cells have been established as a T helper (Th) cell subset specialized for providing help to B cells in GCs (King et al., 2008). Overrepresentation of Tfh cells is associated with the development of systemic autoimmunity (Linterman et al., 2009) and expansion of circulating Tfh-like cells was also detected in human SLE and associated with severe disease (Simpson et al., 2010).

Cytokines and their Receptors

Mice that are deficient in IL-2 and IL-2a have disrupted immunological homeostasis that eventually leads to fatal autoimmune manifestations (Nelson, 2002). Specifically, these mice develop autoimmune hemolytic anemia and colitis with lymphoproliferation, expansion of effector/memory phenotype T cells, polyclonal hypergammaglobulinemia, and autoantibodies. IL-2RB^{-/-} mice likewise develop anemia, splenomegaly and lymphadenopathy, but not colitis. In humans, IL-2 deficiency is clinically manifested as severe combined immunodeficiency, whereas a patient lacking IL-2a was declared immunocompromised, and several organs were infiltrated with inflammatory cells (Sharfe et al., 1997). The autoimmune manifestations depend on the presence of both T and B cells and environmental antigens since, if the mice are kept under pathogen-free conditions, they do not develop autoimmunity. Activation-induced cell death (AICD) is central for the elimination of activated autoreactive cells, and this depends on IL-2 signaling. Defective AICD obviously plays a role in the development of autoimmunity. Humans with SLE have defective AICD that appears to be multifunctional: defective tumor necrosis factor (TNF)- α (Kovacs et al., 1996) and IL-2 production

(Tsokos et al., 1996). The downregulation of IL-2 production in SLE patients was found to be mediated by Ser/Thr protein phosphatase 2A (PP2A). PP2A dephosphorylates transcription factor SP-1, which results in strong binding of cyclic-AMP responsive element modulator (CREM) to the IL-2 promoter (Juang et al., 2011). T cells from patients with SLE have increased PP2A (Katsiari et al., 2005). Overexpression of PP2A in T cells in B6 mice does not lead to autoimmunity but only to granulocytosis and increased levels of IL-17 and, when challenged with an anti-glomerular basement membrane antibody, they developed exuberant glomerulonephritis (Crispin et al., 2012). Furthermore, IL-2 plays a central role in the development and maintenance of regulatory T (Treg) cells, which have been proven to be of pathogenic relevance in the development of autoimmune disease (La Cava, 2008). Low dose IL-2 treatment in patients of chronic GVHD (Koreth et al., 2011) and of hepatitis C virus-induced vasculitis (Saadoun et al., 2011) was reported to be effective with an accompanying increase of Treg cells. Vaccinia virus-mediated *in vivo* IL-2 introduction ameliorates disease progression in MRL/lpr mice (Gutierrez-Ramos et al., 1990). These results indicate that correction of IL-2 production could have therapeutic potential by restoring the function of T cells.

The tumor necrosis factor/receptor (TNF/TNFR) system acts on the homeostasis of the immune system in different ways. Among them, TNFSF13B (BAFF, BlyS) and TNFRSF13B (TACI) are implicated in the development of autoimmune disease. BAFF is critical for B cell survival and BAFF-transgenic or TACI-knockout mice show lupus-like disease. Moreover, serum BAFF is elevated in both BWF1 and MRL/lpr mice and blocking BAFF function with a soluble TACI-IgGfc protein can inhibit proteinuria and prolong survival (Gross et al., 2000). Surprisingly, T cell deficient BAFF-transgenic mice can develop lupus-like disease indistinguishable from that of BAFF-transgenic mice and the development of disease is dependent on MyD88 (Groom et al., 2007). Clinical trials using the chimeric molecule TACI-Ig (Ataccept) in SLE are now ongoing and the clinical use of anti-BAFF/BlyS (Belimumab) for active SLE patients was recently approved (Navarra et al., 2011).

The successful clinical introduction of treatment with anti-TNF α confirmed the biologic relevance of TNF α function in chronic inflammatory diseases, particularly RA and Crohn's disease. The introduction of a modified human TNF-globin hybrid transgene in mice was the first demonstration in animal models that TNF has arthritogenic properties. These mice (Tg197) spontaneously develop (with 100% penetrance and a predictable time of onset) a chronic, erosive, inflammatory polyarthritis with histologic lesions resembling human RA (Holmdahl et al., 1986; Kontoyiannis et al., 1999). Adenylate uridylylate-rich

elements (Holmdahl et al., 1986) are important for TNF α mRNA destabilization and translational repression in hematopoietic and stromal cells. Development of two specific pathologies in mutant mice—chronic inflammatory arthritis and colitis akin to Crohn's disease—suggests a defective function in analogous human pathologies. These mice have proven quite informative in dissecting the pleiotropic effects of TNF α on immune responses and on the expression of various forms of autoimmune pathology.

Complement and Complement Receptor Proteins

Activation of the classical pathway typically starts by interaction of C1q with immune complexes and the action of complement is the main effector mechanism of antibody-mediated immunity. The complement system also has an important role in clearing immune complexes from the circulation. It can also bind apoptotic cells and helps to eliminate these cells from tissue (Taylor et al., 2000). If the complement system fails in this function, waste material can accumulate and evoke an autoimmune response. Deficiencies of the classical pathway are associated with an increased risk of developing SLE or allied diseases in human (Manderson et al., 2004). More than 90% of individuals with C1q and C1r/C1s deficiency develop an SLE-like disorder, and 10–20% of individuals with C2 deficiency develop SLE (Truedsson et al., 2007). These phenotypes in humans do not parallel in full those in mice. Deficiency of C1q in C57BL/6 mice does not lead to the development of autoimmunity. By contrast, C1q deficient MRL/MpJ mice display accelerated disease onset and increased levels of ANA and of glomerulonephritis, particularly in females which developed severe crescentic glomerulonephritis. Moreover, C1q deficient mice on a B6x129 genetic background were shown to develop higher levels of autoantibodies compared to strain-matched controls and to develop glomerulonephritis by 8–10 months of age (Manderson et al., 2004). Thus, the expression of autoimmunity in C1q deficient mice is strongly influenced by additional background genes (Botto et al., 1998; Botto and Walport, 2002).

The B6/*lpr* mouse develops minor autoimmune features. Deficiency in this strain of the complement receptor 1 and complement receptor 2 (CR1/CR2, CD35/CD21), encoded by the Cr2 gene, permits development of intense autoimmune features (Boackle and Holers, 2003), indicating that complement receptors are important in the elimination of B cells that display reactivity with self antigens. This explanation assumes that self antigens initiate a strong B cell signal, which leads to B cell death and the absence of the CR2-mediated enhancement of the signal

permits their survival (Tsokos et al., 1990; Dempsey et al., 1996). CR1 and CR2 have been proposed to play a role in the development of SLE. Patients with SLE have around 50% lower levels of these receptors on their B cells (Levy et al., 1992; Marquart et al., 1995). MRL/*lpr* mice exhibit lower levels of these receptors on B cells prior to the onset of overt disease, suggesting that the reduction of CR1/CR2 expression may be pathogenic (Takahashi et al., 1997). Also, evidence for the involvement of Cr2 in systemic autoimmunity comes from the NZM2410 mouse. The congenic interval corresponding to *Slc1c*, one of the SLE susceptibility loci, *Slc1*, contains the Cr2 gene. NZM2410/NZW Cr2 exhibits a single nucleotide polymorphism that introduces a novel glycosylation site, resulting in higher molecular weight proteins. This polymorphism, located in the C3d binding domain, reduces ligand binding and receptor-mediated cell signaling. Molecular modeling based on the CR2 structure in complex with C3d has revealed that this glycosylation interferes with receptor dimerization (Boackle et al., 2001).

Since disruption of the C1q, C4, and CR1/CR2 leads to reduced selection against autoreactive B cells and to impaired humoral responses, C1 and C4 could act through CR1/CR2 to enhance humoral immunity and suppress autoimmunity, but each complement component appears to act independently. High titers of spontaneous ANA and SLE-like autoimmunity develop in all C4^{-/-} mice and most male mice but not in Cr2^{-/-} mice. The fact that the clearance of circulating immune complexes is impaired in pre-autoimmune C4^{-/-} but not Cr2^{-/-} mice favors the role of nuclear antigen-ANA immune complexes in the development of autoimmune disease (Chen et al., 2000).

Clearance of Dead Cells

Effective degradation of nucleotides from dead cells and digestion of cellular components by macrophages allow non-inflammatory clearance and a recycle of dead cells (Nagata et al., 2010). DNaseI is the major nuclease present in the blood, urine, and secretions. DNaseI deficiency in non-autoimmune background mice was reported to increase the incidence of SLE manifestations, including positive ANA, anti-DNA, and immune complex glomerulonephritis (Napirei et al., 2000). Reduced DNaseI activity is observed in the sera of lupus patients, which may contribute to SLE susceptibility (Tsukumo and Yasutomo, 2004). Intriguingly, an identical heterozygous nonsense mutation in DNASE1 was detected in two SLE patients (Yasutomo et al., 2001).

Deficiency in the clearance of apoptotic cells is proposed to be one of the causes of SLE. Unengulfed apoptotic cells are present in the germinal centers of the lymph nodes of some SLE patients and macrophages from these

patients often show a reduced ability to engulf apoptotic cells (Gaipf et al., 2006). Milk fat globule-EGF factor 8 (MFG-E8) protein functions as a bridging protein between phosphatidylserine (PS) on apoptotic cells to avb3 or avb5 integrins on phagocytic cells (Hanayama et al., 2002). MFG-E8 is primarily expressed on CD68-positive tingible body macrophages within germinal centers. MFG-E8 deficient female mice on a B6 x129 gene background develop SLE-like autoimmune disease with anti-dsDNA, ANA, and glomerulonephritis by 40 weeks of age (Hanayama et al., 2004).

TAM family members (Tyro3, Axl, and Mer), which are tyrosine kinase receptors expressed on antigen-presenting cells (APCs), promote clearance of apoptotic cells and mice expressing a kinase-dead mutant of Mer (MerKD) develop SLE-like autoimmunity (Scott et al., 2001). TAM receptors negatively regulate the innate immune reaction and TAM-deficient dendritic cells overproduce IL-6, IFN, and TNF α , which might be responsible for the induction of autoimmunity (Lemke and Rothlin, 2008).

Innate Immune Cell Signaling

Recent studies demonstrate that DNA and RNA in apoptotic material can activate B cells and dendritic cells through TLR9, TLR7, and TLR8 (Leadbetter et al., 2002; Boule et al., 2004; Vollmer et al., 2005). As described above, overexpression of TLR7 is responsible for the development of autoimmune diseases in BXSB mice. These results indicate that TLR signaling is linked to the development of autoimmune disease and aberrant activation of innate immunity may contribute to systemic autoimmune diseases including RA and SLE (Marshak-Rothstein, 2006).

TANK (also known as I-TRAF) is a TNF receptor-associated factor (TRAF)-binding protein and binds to TRAF1, 2, 3, 5, and 6, all of which are crucial for TLR signaling. TANK is a negative regulator of proinflammatory cytokine production induced by TLR signaling and TANK deficient mice spontaneously develop lupus-like autoimmune diseases with fatal glomerulonephritis, ANA, and anti-dsDNA. Autoantibody production in TANK deficient mice is abrogated by antibiotic treatment or the absence of IL-6 or MyD88, indicating that TANK controls TLR signaling by intestinal commensal microbiota (Kawagoe et al., 2009).

Zc3h12a is an RNase activated by TLR signaling that promotes the degradation of mRNA. Zc3h12a deficient mice have early mortality associated with severe hemolytic anemia, lymphoproliferation, and ANA with an increased number of activated B cells, T cells, and plasma cells due to excessive cytokine transcription notably IL-6 and IL-12 (Matsushita et al., 2009).

INDUCED MODELS OF SYSTEMIC AUTOIMMUNITY

Information has been acquired over many years from the study of models based on induction of autoimmunity, including immunoregulatory events that lead to the expression of clinical disease and proximal events associated with triggering of autoimmune disease.

The isoprenoid alkane pristane (2, 6, 10, and 14 tetramethylmentadecane) induces autoantibodies characteristic of SLE, including anti-Sm, anti-dsDNA, and anti-ribosomal P in BALB/c and SJL/J mice and CD1d deficiency exacerbates lupus nephritis induced by pristane (Satoh and Reeves, 1994). Pristane induces type I IFN production from Ly6C^{hi} monocyte through Toll-like receptor 7 (TLR7) and myeloid differentiation factor 88 (MyD88) pathway and triggers autoantibody production (Lee et al., 2008). Also, IL-12, IFN γ , but not IL-4, are involved in the development of pristane-induced lupus, indicating that T helper type 1 (Th1) responses are dominant. For unexplained reasons, the *lpr* and *gld* mutations protect mice from the production of antibodies routinely induced by pristane. In addition to nephritis, hemorrhagic pulmonary capillaritis and arthritis have also been observed in pristane-treated mice (Wooley et al., 1989; Chowdhary et al., 2007). The arthritis symptoms in this model include synovial hyperplasia, periostitis, and progressive marginal erosions. Pristane-induced arthritis is TNF α mediated, as treatment with neutralizing anti-TNF α antibody ameliorates the arthritis symptoms (Beech and Thompson, 1997).

Graft-versus-host-disease (GVHD)-induced models of systemic autoimmunity involve the injection of parent cells into F1 offspring and clarified early events in the induction of autoimmunity. When lymphocytes from DBA mice are transferred into (B6 X DBA) F1 mice, donor CD4⁺ cells are stimulated by recipient major histocompatibility complex (MHC) class II cells, which presumably present a chromatin-associated nuclear antigen and produce initially IL-2 and later on IL-4 and IL-10, while the generation of CD8⁺ CTL cells is silenced. These responses result in chronic GVHD with autoantibody and immune complex-mediated glomerulonephritis. When donor B6/H-2bm12 lymphocytes, whose MHC class II locus confers a three amino acid substitution in H-2^b, are transferred into B6 hosts, there is also development of chronic GVHD with autoantibodies and GN. This model works equally with opposite donor and recipient strains (Morris et al., 1990).

Injection of allogeneic collagen type II (CII) or certain peptides of this protein in complete or incomplete Freund's adjuvant into susceptible strains of rats or mice results in collagen-induced arthritis (CIA) resembling RA. The role of MHC in the expression of CIA is indicated, only in H-2^d mice after injection of chicken CII, whereas

H-2^f mice are susceptible to pig CII (Stuart et al., 1983; Watson et al., 1987). CD4⁺ cells and various cytokines including IL-1 and TNF- α , as well as antibody to CII, have been shown to participate in the expression of CIA.

Immunization of BALB/c mice with partially deglycosylated human aggrecan induces chronic progressive polyarthritis and spondylitis (Glant et al., 2003). This proteoglycan (aggrecan)-induced arthritis (PGIA) resembles RA, as judged by observation, laboratory tests, radiography, and histopathology of the peripheral joints. The occurrence of PGIA depends on the development of cross-reactive T and B cell responses between the immunizing human and self (mouse) cartilage aggrecan. CIA and PGIA are two most commonly used RA models for quantitative trait locus (QTL) mapping for the identification of RA susceptibility loci.

Collagen antibody-induced arthritis (CAIA) is induced by injection of specific monoclonal CII antibodies (Holmdahl et al., 1986). The model was developed based on the findings that serum from arthritic mice or RA patients could transfer arthritis to naïve mice (Stuart and Dixon, 1983; Wooley et al., 1984). CAIA resembles CIA but is more acute and has a rapid onset, a few days after injection. Normally, the disease heals after a month and mice remain healthy. CAIA is inducible independently of MHC and T and B cell interaction (Nandakumar et al., 2004).

CONCLUDING COMMENTS

Animal models of systemic human autoimmune disease have served us well for understanding autoimmunity. Human systemic autoimmune diseases are highly

FIGURE 30.1 Pathogenesis of systemic autoimmunity and molecules involved in the development of autoimmune disease, compiled from studies on mice and humans with systemic lupus erythematosus (SLE). Similar to organ-specific autoimmunity, systemic autoimmunity is a function of a deleterious combination of genetic and environmental factors that lead in concert to the loss of self tolerance. T cells display numerous aberrations in the form of impaired cytokine productions, defective immunoregulatory function, and increased ability to provide help to B cells to produce autoantibodies. In systemic autoimmunity, autoantigens are frequently directed against nuclear antigens, with which they form immune complexes. Defective clearance of such immune complexes is the result of defective expression of Fc and complement receptors, and increased levels of nuclear materials may propagate the autoimmune responses. A number of cytokines including IFN α , IL-6, IL-21, IL-17, BAFF, and their receptors play critical roles for the development of lupus. IFN, interferon; IL, interleukin; MHC, major histocompatibility complex.

heterogeneous both at the clinical and pathogenic level to the point that we do not serve the field properly by lumping them along antedated criteria-counting approaches. We have presented a critical review of the animal models which have been used to understand disease processes [Figure 30.1](#) and perform preclinical trials of putative new drugs [Table 30.1](#) and biologics.

1. No animal model represents any systemic autoimmune disease.
2. Spontaneous models of disease can be used to obtain early insight on the consequences of lost tolerance in terms of organ damage.
3. Spontaneous models may serve preclinical testing of new rationally developed new drugs and biologics

although their predictive clinical value has been rather disappointing.

4. Animals which develop systemic autoimmune disease after modulation of a specific molecule known to be important in the control of maintenance of tolerance or of the immune response may only serve to address specific mechanistic questions.
5. In the study of these animals, the concepts of autoimmunity and autoimmunity-associated organ damage should be carefully considered separately.
6. Construction of animals in which modulated molecules previously identified as important in the aberrant function of SLE or RA immune cells may provide valuable information on the development of putative specific new drugs.
7. These novel animals constructed with intelligence generated from the study of human cells should provide definitive information on the relative contribution of each aberrantly expressed molecule in the expression of human systemic autoimmune disease. The B6.CD2.PP2Ac mouse is such an example (Crispin et al., 2012).

WHAT CAN ANIMAL MODELS TEACH US ABOUT ORGAN-SPECIFIC AUTOIMMUNITY?

Without aiming to be exhaustive, we will first list some examples of scientific questions that are typically answered with the aid of animal models.

The Inciting Autoantigen

Despite intensive research over the past decades, there are some crucial elements in organ-specific autoimmunity that we do not comprehend yet. One major problem is that for many organ-specific autoimmune diseases we do not know the targets of the initial autoimmune response, while in some, such as in pemphigus vulgaris (Lin et al.,

1997), myasthenia gravis (Fambrough et al., 1973), and autoimmune gastritis (Karlsson et al., 1988), the driving autoantigen has been defined. In animal models, advantages such as homogeneous genetic background and accessibility of the target organ in theory should facilitate the search for such primary autoantigens. In the non-obese diabetic (NOD) mouse model for type 1 diabetes (T1D) it was indeed suggested that proinsulin is the primary antigenic trigger (Nakayama et al., 2005). The eventual heterogeneity in individual T and B cell repertoires, even in these inbred mice, is likely responsible for the fact that only very rarely do all individual mice exhibit the same course and severity of disease (Sercarz, 2000). In keeping with the latter theory, recent evidence from human leukocyte antigen (HLA)-A2 transgenic NOD mice reveals that individual inbred mice develop unique

patterns of CD8 T cell autoreactivity (Jarchum et al., 2007). Deciphering the underlying heterogeneity in autoreactive repertoires will be key to understanding and predicting development of autoimmune diseases. Identifying autoaggressive T-cell specificities on an individual basis is in fact emerging as an important disease biomarker (Velthuis et al., 2010).

Antigen-specific Tolerization Strategies

From a translational angle, it is still unclear whether tolerizing the “driver” T cell clones would be sufficient to reverse an ongoing autoimmune process and have therapeutic value. Some reports suggest a striking oligoclonality, which in turn indicates that deletional immunotherapy using one or a few autoantigenic determinants might be feasible (Kent et al., 2005). Animal models also suggest that T cell receptor (TCR) avidity plays a pivotal role, as it was shown that low-avidity clonotypes can act protectively (Han et al., 2005). Numerous other reports, however, suggest that low affinity clones might in fact be the driving force. Data in the rat insulin promoter (RIP)-lymphocytic choriomeningitis virus-derived proteins (LCMV) diabetes model demonstrate that, in a slow-onset variant of the model, low affinity T cells are responsible for disease induction (von Herrath et al., 1994). In human T1D, similar conclusions were drawn from studies using a preproinsulin-specific human CD8 T cell clone that is capable of inducing beta cell death (Skowera et al., 2008). Remarkably, the TCR of this clone was of extraordinarily low affinity, redefining the understanding of what constitutes a functionally relevant TCR–pMHC interaction (Bulek et al., 2012).

Animal models were used to evaluate antigen-specific therapies that are now in clinical trials, such as ECDI–peptide-coupled cell therapy in multiple sclerosis (Kennedy et al., 1990). Likewise, the NOD mouse was employed to predict responses to antigen-specific therapy based on prior antibody status (Mamchak et al., 2012). With the advent of antigen-specific therapies, mouse models will thus continue to serve as important tools for the pre-clinical validation of suitable therapeutic regimens.

Other Immune Therapies

The recent surge in clinical trials aimed at immunomodulation in large part leans on supportive data from animal models. What is remarkable is that many of the new biologics show efficacy in multiple organ-specific autoimmune diseases. One example is the positive results that were obtained with the B cell-depleting agent infliximab in entirely distinct conditions such as T1D (Pescovitz et al., 2009) and multiple sclerosis (Hauser et al., 2008). Tumor necrosis factor (TNF) inhibition, a common

treatment for autoimmune conditions such as rheumatoid arthritis and psoriasis, was pursued in T1D (Mastrandrea et al., 2009). These results from clinical trials to some extent confirm what we had learned from their respective animal models, i.e., that disease development is characterized by overlapping immune pathways.

Can animal studies faithfully predict the success of immune intervention strategies in humans? Of course mice and men are not the same, but we conclude that data from animal models are not always fully taken into account in the clinical translation process. One example in the T1D arena is CTLA-4Ig therapy, which is able to prevent diabetes in the NOD mouse when given early but is incapable of reversing clinical disease (Lenschow et al., 1995). In a recent clinical trial, 2-year continued administration in recently diagnosed patients only showed effect in the initial few months, which to some extent only serves to confirm what was predicted by the animal data (Orban et al., 2011). Thus, choice of drug and trial design does not always seem to be rationally based upon animal research and is often more governed by the availability of certain drugs.

Gene Function

In the immunogenetic arena, animal models have provided useful insights. For diseases that are determined by one or a few genes, and where no major epigenetic factors are involved, we have learnt much from immunodeficient animals as well as humans. However, in some cases the respective human immunodeficiency will yield a different phenotype than the genetic knockout mouse, illustrating differences between men and mice that are likely linked to epigenetic and environmental factors. For example, ICOS deficiency in humans has immunologic consequences that are found in some patients with common variable immunodeficiency (Grimbacher et al., 2003). In contrast, the ICOS deficient mouse has a rather uniform phenotype involving immune deviation of T cell responses and their cytokine production, as well as effects on B cell function (Dong et al., 2001). Overall, comparison between mouse models and humans deficient in respective genes greatly contributes to our understanding of autoimmunity (e.g., AIRE, fox-P3, CD25), even if complete phenotypic homology between knockout mice and the respective human genetic deficiency is lacking.

Understanding the Complexity of Organ-Specific Autoimmunity

Animal models have helped us understand the complexity of biologic processes and be cautious in predicting the outcome of therapeutic interventions in humans (Roep et al., 2004). For example, in T1D, animal models have shown us that there are many different pathways to kill

beta cells. If one of them is inactivated (i.e., perforin or interferon-gamma knockout), others will take over. The consequence is that it will be very difficult to engineer a “death-defying” beta cell that could be used for islet transplantations, since too many death pathways have to be eliminated in order to achieve resistance to immune destruction (Thomas and Kay, 2001). Present strategies therefore focus on physically shielding the transplanted islets from the immune system, an approach for which, once again, animal models have proven to be of exceptional value (Lee et al., 2009).

ANIMAL MODELS—ADVANTAGES AND DISADVANTAGES

As illustrated in Box 31.1, and as outlined above, there are several areas of investigation, where we have learned much from animal models of organ-specific autoimmunity. The first is investigation of immune responses at locations that are inaccessible in humans. Moreover, in these diseases much of what we know has often been derived from peripheral blood samples but it is unsure how this correlates to immune status at the target organ. We, for instance, were able to pioneer the *in vivo* visualization of immune responses at cellular resolution in the mouse pancreas during autoimmune diabetes development (Coppieters et al., 2012). Such information could never be gathered in human target organs with any of the technologies currently available.

Second, it is difficult to establish proof of concept in humans. Many techniques that are frequently used to unequivocally identify cellular subsets that are important in the etiology or progression of autoimmunity are impossible to implement in a clinical setting. Examples include adoptive transfers, knock-out technologies, bone marrow chimeras and many more.

Lastly, of course, the use of animal experimentation is at this point frequently indispensable to providing initial pre-clinical support for novel drugs and to defining dose ranges and regimens for immunotherapies.

How far reaching should the conclusions that we draw from observations in a given animal model be? The

prevailing attitude is still that once a discovery has been made in one of the animal models thought to faithfully represent the human disease (e.g., the NOD mouse for diabetes or the experimental autoimmune encephalomyelitis (EAE) model for multiple sclerosis (MS)) there is no urgent need to look at this issue in other model systems. If the same result is found, it is considered “confirmatory,” if a different result is discovered, the “secondary” model is frequently labeled as not-as-good or even flawed, for which various reasons are cited. This, we believe, can be treacherous and may hamper translation of research performed in animal models, because our pathogenetic insight into human diseases is often still rather limited due to ethical constraints. For example, only about 10% of patients with T1D exhibit the same clinical features as the NOD diabetic mouse, which is characterized by a polyglandular autoimmune syndrome affecting thyroid, salivary glands, and testes (Atkinson and Leiter, 1999; Roep et al., 2004). However, there are also striking similarities between NOD and human diabetes, for example, the occurrence of autoantibodies that precedes the development of clinical disease in NOD mice and humans (Pietro Paolo and Eisenbarth, 2001).

We can now be certain that one single genetic defect or polymorphism will not be the cause for most human autoimmune disorders. We have learnt from the multitude of genome-wide association studies (GWAS) that the far more common scenario is a substantial degree of polygenic complexity. This would involve many protective and predisposing genes that act in concert, leading to disease manifestation in a fraction of their bearers. In addition to major histocompatibility complex (MHC) class II molecules that are found in association with several organ-specific autoimmune diseases such as MS and T1D, many less frequent polymorphisms in immune-related genes contribute to the expression of autoimmune disease (Bluestone et al., 2010). Immunogenetic studies in genetically identical mice can therefore not be expected to fully mimic the diverse arrays of polymorphisms that lead to disease in genetically distinct human subjects. Thus, seeking direct relevance to the human disorder becomes very important, and the assumption that there is a necessity to identify genetic defects in

Box 31.1 What Can Animal Models Teach Us that We Cannot Learn Otherwise?

- *In vivo* immune kinetics at sites that are difficult to access in humans.
- *Proof of concept* using techniques that cannot be used in humans, i.e., adoptive transfers, genetic knockouts, bone marrow chimeras, etc.
- Pre-clinical *drug validation*, large-scale assessment of *dose range*, *toxicity*, and immunization sites in drug and vaccine development.

Reasons to be Cautious with Animal Data.

- A single model is unlikely to cover all aspects of human pathology, concepts should therefore ideally be confirmed in multiple models.
- Genetic knockout models do not mimic the subtle and complex genetic imbalances that are thought to underlie human diseases.
- Environmental factors are usually not known and thus cannot be mimicked.

animal models in order to obtain the best pathways to cure human disease may not be correct. Indeed, in today's medicine, there is little evidence that the optimal treatment for a given disease is always the elimination of its cause. Immunogenetics in animal models might still help the adoption of novel predictive strategies and subclassifications for autoimmune diseases, which might in the future allow for more individualized treatments.

Finally, most of these genetic associations are weak enough to allow for the possibility that environmental factors in addition to genetic ones determine penetrance of disease. These factors, however, are poorly defined in most organ-specific autoimmune diseases. In the NOD mouse there appears to be a role for the gastrointestinal microbiome (Wen et al., 2008), although under normal specific pathogen-free conditions, diabetes develops without the need for an external stimulus. In human T1D, the strongest evidence for a potential trigger points toward enteroviral infection (Yeung et al., 2011). While viral infection can accelerate disease in the NOD, it is normally not required for onset. It is thus obvious that the NOD mouse does not faithfully integrate the environmental factors that seem to characterize disease in humans. Similar discordances are present in models for MS, where neuronal antigens are often injected in adjuvant to induce demyelinating disease. Such non-physiological conditions should always be kept in mind when interpreting results from animal models.

ANIMAL MODELS FOR ORGAN-SPECIFIC AUTOIMMUNE DISEASES

Again, our overview here does not intend to be complete. Instead, we will limit ourselves to a discussion of certain models that are uniquely informative on one point or another.

Spontaneous Models of Organ-Specific Autoimmunity

The Non-Obese Diabetic Mouse

The widely utilized NOD mouse expresses multiple autoimmune features in various organs—sialitis, T1D, orchitis, thyroiditis (Anderson and Bluestone, 2005)—and is prone to develop other autoimmune disorders including autoimmune cholangitis in NOD congenics (Wakabayashi et al., 2009), EAE (Winer et al., 2001), or neuritis in B7.2 deficient NOD strains (Salomon et al., 2001). The NOD strain was originally discovered in Japan and exhibits spontaneous diabetes penetrance of 20–100% depending on the environment. In addition, females develop diabetes about four times as frequently as males. In contrast to

most patients with diabetes, the NOD mouse develops multiglandular and other organ-specific autoimmunity.

The immunologic causes for diabetes development are uncertain, but the genetic composition of the NOD has been studied extensively and is strikingly similar to the genetics of human T1D (Wicker et al., 2005), particularly in MHC class II molecules linked to disease expression. In addition, susceptibility loci that contain, among others, the genes for interleukin (IL)-2 and CTLA-4 have been linked to disease or protection. In the case of CTLA-4, polymorphisms have been described in the NOD mouse that might play a similar role in the human disease.

In both humans and NOD mice, environmental factors strongly influence disease expression. Monozygotic twins exhibit discordance in T1D penetrance, and NOD mice do not develop diabetes unless they are kept under specific pathogen-free (SPF) conditions. Data in the NOD mouse indicate that viral infections can have both enhancing (Serreze et al., 2000) and protective (Filippi et al., 2009) effects and an extensive meta-analysis recently confirmed the association between enteroviral infections and human T1D (Yeung et al., 2011). A growing body of evidence emphasizes the role of the intestinal microbiome in disease development in the NOD mouse (Wen et al., 2008).

Immunologically, it is still unclear to what degree NOD mice and humans with T1D are similar. The appearance of autoantibodies predicts the risk to develop islet autoimmunity and, in many cases, T1D on an individual basis; the antigens targeted, however, differ—those for NOD mice autoantibodies almost exclusively recognize insulin, whereas anti-GAD and anti-IA2 are present in humans (Eisenbarth, 2003). T lymphocytes with a Th1-like profile correlate with destructive insulinitis in the NOD and also in humans (Arif et al., 2004). The Th17 immune cell subset, the discovery of which has reshaped our understanding of disease pathways in autoimmunity, was found to contribute to immunopathology in the NOD (Emamaullee et al., 2009). The question of which functional Th profile characterizes an “optimal” autoaggressive T cell is not resolved. Transfer studies in the NOD model have shown that Th1 as well as Th2 cells can cause disease in immunodeficient NOD/SCID or NOD/RAG hosts, when sufficient cell numbers are transferred (Pakala et al., 1997). In this context it should be mentioned that it appears that these Th subsets show remarkable plasticity, as was shown by Th17 cell conversion in favor of a Th1 profile in the NOD (Bending et al., 2009).

The functionality of regulatory T cells (Tregs) has been studied particularly well in the NOD mouse. Tregs are thought to control most immune responses and can be antigen induced (adaptive, i.e., peripherally generated) or “natural” (thymus derived and characterized by constitutive Foxp3 expression). In NOD mice, such cells can mediate protection from diabetes, as is the case after anti-CD3

therapy (Bresson et al., 2006). Furthermore, Tregs were shown to be involved in protection conferred by viral infection (Filippi et al., 2009). For clinical purposes, the NOD mouse has been instrumental in defining the clinical potential of future Treg cell-based immune interventions (Battaglia et al., 2006).

Finally, the predisposition to autoimmunity in the NOD mouse could also be linked to defective thymic selection and/or presentation of autoantigens in the thymus (Stratmann et al., 2003). Here, the predisposing MHC class II allele may play a role by the insufficient or inappropriate presentation of self-peptides, resulting in suboptimal elimination of a variety of autoreactive T cell specificities.

Genetically Engineered Animal Models for Organ-Specific Autoimmunity

Genetically engineered defects involving the systemic deletion or overexpression of a distinct molecule will rarely result in a disease that is limited to a single target organ. Systemic knockouts that “take the brakes off” the immune system such as *foxp3* (defective Tregs), AIRE (defective thymic negative selection), or tumor growth factor (TGF)- β (defective regulation) usually result in disease affecting multiple organs and are, therefore, discussed in Chapter 30 on systemic autoimmune diseases (Shull et al., 1992; Brunkow et al., 2001; Anderson et al., 2002). There are, however, a few exceptions, one being the CD86-(B7.2) deficient NOD strain (Salomon et al., 2001). The autoimmunity that is usually directed towards the pancreatic islets in the NOD was redirected to attack peripheral nerves, resulting in neuritis. The reason may be altered local regulation of costimulatory molecules as well as defective thymic selection, resulting in higher levels of naïve T cells that can recognize neuronal antigens. One notable mouse strain with a systemic genetic defect that is commonly employed as a model for organ-specific autoimmunity, namely Crohn’s disease, is the IL-10 deficient mouse (Kuhn et al., 1993). Mice are viable and develop a chronic form of enterocolitis which responds to agents such as TNF inhibitors that are clinically applied in Crohn’s disease (Scheinin et al., 2003).

A more subtle variant of genetic modification includes tissue-specific gene deletion or overexpression. Here, one intends to avoid widespread autoimmunity when testing the influence of a certain gene on a specific target organ. One representative example is the series of recent papers on the *in vivo* role of the anti-inflammatory, ubiquitin-editing enzyme A20 that acts downstream of the TCR and BCR. A20 deficient mice spontaneously develop multiorgan inflammation and cachexia and die within 2 weeks of birth (Lee et al., 2000), which makes them rather irrelevant tools in the context of organ-specific autoimmunity. However, when this gene is deleted only

in specific organ systems, it is possible to mimic the development of organ-specific autoimmunity. Indeed, whereas A20 deletion in myeloid cells triggers arthritic disease (Matmati et al., 2011; a “systemic” disease), deletion in enterocytes sensitizes to organ-specific autoimmune colitis (Vereecke et al., 2010). Thus, specific gene deletion in certain tissues or organs can sometimes provoke or enhance organ-specific autoimmunity and teach us on gene function in the target organ.

An alternative approach is the introduction of a disease-provoking T cell specificity by generating TCR-transgenic animals. RIP-OVA mice express membrane-bound ovalbumin (OVA) under the control of the rat insulin promoter in the thymus and pancreas. When crossed with mice expressing an OVA-specific MHC II-restricted T cell receptor transgene (DO11.10), the double transgenic DO11.10xRIPmOVA (DORmO) mice are spontaneously diabetic, with 100% of animals becoming hyperglycemic by 20 weeks of age (Clough et al., 2008). TCR-transgenic strains that spontaneously develop EAE were also designed (Goverman et al., 1993; Pollinger et al., 2009). While these studies could yield information on some important aspects on certain driver T cells in organ-specific autoimmunity, they are clearly an oversimplification given the vast repertoire complexity in human disease.

In summary, although systemic immune defects will likely lead to more severe autoimmunity affecting multiple organs, there are exceptions to the rule. In humans, a combination of genetic factors leads to an overall predisposition state, yet not necessarily to actual clinical disease. It is thought that manifestation of organ-specific autoimmunity in most instances only occurs after a localized inflammatory insult, either a virus infection or other events that could lead to expansion of autoaggressive T cells. A thought-provoking hypothesis that was recently proposed by Wasserfall and colleagues is the “threshold hypothesis” which pictures the combined risk due to genes and environment as a continuum (Wasserfall et al., 2011). Only in extreme cases can either genes or environmental factors independently provoke autoimmunity such as is the case with *Foxp3* mutations (genes only) (Brunkow et al., 2001; Bennett et al., 2001; Wildin et al., 2001) or pancreatectomy (environment only) (Lampeter et al., 1995). This theory is in agreement with the fact that in most animal models an environmental trigger is required to break tolerance, and that purely genetic models only rarely result in organ-specific autoimmunity.

Induced Animal Models for Organ-Specific Autoimmune Diseases

Breaking Tolerance is Not Easily Achieved

Provoking autoimmunity usually requires a strong artificial trigger that breaks self-tolerance. This can be

achieved in susceptible mouse strains which carry a complex set of predisposing genes (e.g., SJL mice for EAE). Alternatively, many antigen-specific models for diabetes and other organ-specific autoimmune disorders are based on transgenic technology to express a defined autoantigen under the control of a tissue-specific promoter—e.g., the RIP to direct expression to beta cells or the keratin promoter to direct expression to the skin (McGargill et al., 2002). For diabetes, examples include the mouse models RIP-OVA (no spontaneous diabetes unless TCR transgenic, see above) and RIP-LCMV (Ohashi et al., 1991; Oldstone et al., 1991). Such antigen-specific models have the advantage that the initiation of the autoaggressive response can be defined precisely, and at least the initial autoaggressive “driver” T cell is known. Notably, these mice do not develop spontaneous disease and even immunization with the protein antigen does not lead to diabetes in any of the RIP-antigen models. One could argue that according to the “threshold hypothesis” as mentioned above, these inducible models often tend to resemble the extreme end of the spectrum where genetic predisposition becomes unimportant. Despite this etiological shortcoming, inducible models are still frequently used to study effector mechanisms and test potential therapeutics. They fundamentally illustrate that breaking tolerance is generally not easy to achieve, even in the presence of a predisposing genotype.

Environmental Triggers Employed to Break Tolerance

Viral Infection

In some models, infection with a virus expressing the self-protein (transgene) or immunization in conjunction with Toll-like receptor (TLR) stimuli leads to T1D reliably (RIP-LCMV mice). These models mimic the scenario where effector T cells directly cross-react with a known autoantigen and redirect their cytotoxic action after viral clearance.

Alternatively, infection with Theile’s murine encephalomyelitis virus (TMEV), which preferably replicates in neurons, results in a poliomyelitis-like syndrome reminiscent of MS (Lipton, 1975). Only certain mouse strains survive the primary infection and become persistently infected which results in a chronic progressive inflammatory demyelinating disease. The disease is initiated by virus-specific CD4 T cells while autoreactive myelin-specific CD4 T cell responses arise by epitope spreading and contribute to chronic pathology (Miller et al., 1997). Indeed, it was shown that T cell responses to the immunodominant self epitope were not a direct consequence of molecular mimicry, but rather originated from the *de novo* priming of self-reactive T cells to sequestered autoantigens released as a consequence of virus-specific T

cell-mediated demyelination. Epitope spreading is therefore considered an alternate mechanism that can link viral infection to organ-specific autoimmune diseases (Figure 31.1).

Another excellent example of a virus-triggered autoimmune disease model is the model of autoimmune myocarditis which is induced by inoculation with heart-passaged coxsackievirus B3 (Fairweather and Rose, 2007). For an in-depth discussion on this model we refer the reader to Chapter 70.

Protein/Peptide and Adjuvant

Multiple Sclerosis

The earliest evidence that encephalomyelitis could be triggered by challenging the immune system with self proteins came from side effects associated with the use of Pasteur’s rabies vaccine (Mackay, 2010). The vaccine, made from the dried spinal cord from rabies-infected rabbits, in some cases led to ascending paralysis. This post-vaccinal encephalomyelitis was later also shown to occur in rabbits with extracts of normal human spinal cord, or sheep brain. In the 1940s, it was more formally demonstrated that encephalomyelitis could be provoked in animals via a short course of injections of normal brain combined with Freund’s complete adjuvant (FCA).

Today, the EAE model is one of the best known and most widely used examples in this category. EAE, which is primarily CD4 T cell driven, is induced in susceptible mice (SJL, PL/J) by immunization with neuronal proteins, or their respective MHC class II-restricted epitopes together with FCA and pertussis toxin (Fletcher et al., 2010). The clinical outcome is a relapsing remitting disease with severe neurologic implications. Central nervous system (CNS) histopathology shows T cell infiltration, anaphase-promoting complex (APC) and microglia activation, and disruption of the blood–brain barrier. Alternating periods of demyelination and remission characterized by remyelination occur.

Thyroiditis

Thyroid-specific autoimmunity underlies the development of Hashimoto’s thyroiditis (hypothyroidism) and Graves’ disease (hyperthyroidism) (Stassi and De Maria, 2002). Hashimoto’s thyroiditis is the most common organ-specific autoimmune disease and is seen as a paradigm for other T cell-mediated organ-specific autoimmune diseases. Of historical interest is the series of studies by Noel Rose and Ernest Witebsky in the mid-1950s which centered on the induction of thyroid mononuclear infiltration after immunization with thyroid extracts in rabbits (Rose and Witebsky, 1956; Witebsky et al., 1957; Mackay, 2010).

FIGURE 31.1 The development of T cell-driven organ-specific autoimmunity. (1) While defective thymic selection may confer additional susceptibility, every individual has a certain repertoire of self-reactive cells. Under normal conditions, peripheral tolerance mechanisms governed by Treg prevent the activation of these cells. (2) When an environmental agent (here a virus) infects cells of a specific organ and causes (limited) cell death, phagocytes such as macrophages will drain self antigens to the lymph nodes. In the lymph nodes of normal individuals, Treg still maintains tolerance, whereas in susceptible individuals effector T cells are generated. Alternatively, a peripheral infection may directly activate autoreactive cells via mechanisms such as mimicry. (3) The effector T cells (here CTL) will home to their target tissue, recognize presented self antigens and initiate cellular cytotoxicity. (4) Chemokine production will enhance Teff influx, leading to more cell death and antigen drainage. This, in turn, will provoke new rounds of T cell activation which expands the reactivity profile beyond the inciting antigen, a process termed “antigen spreading.” As soon as a sufficient amount of target cells is killed, clinical disease typically becomes manifest.

Since the experimental outcome resembled Hashimoto’s disease in humans, sera from such patients were analyzed and these, like the immunized rabbits, contained antibodies to thyroglobulin (Campbell et al., 1956).

Other experimental autoimmune thyroiditis (EAT) models have been described which rely on genetic predisposition or transfer of cells primed with thyroid antigen, collectively confirming the central role of $CD4^+$ T cells in the immunopathology (Stassi and De Maria, 2002).

In Graves’ disease, $CD4^+$ T cells stimulate B cells to produce antibodies specific for the thyroid-stimulating hormone (TSH) receptor, which leads to uncontrolled thyroid hormone production. The disease can be modeled in specific mouse strains by immunization with fibroblasts that express the TSH receptor (Shimojo et al., 1996), or with an expression vector that contains the TSH receptor complementary DNA (Costagliola et al., 2000).

Myasthenia Gravis

Myasthenia gravis is an autoimmune disease where neuromuscular transmission is impaired, leading to fatigable muscle weakness in patients and, in some cases, acute respiratory failure. The cause of the disorder is the development of autoantibodies against nicotinic acetylcholine

receptors (AChR) (Spillane et al., 2012). Thus, the causal antigen is well defined.

The principal animal model of the disease, experimental autoimmune MG (EAMG), is typically induced in mice, rats, guinea pigs, or rabbits by immunization with either *Torpedo californica* or electric eel AChR in adjuvants (Lennon et al., 1975; Wu et al., 2001). In mice, strain differences greatly influence disease susceptibility, with an important role for MHC (H-2)-linked genes. In addition to current first-line therapies such as acetylcholinesterase inhibition, there is an interest in designing antigen-specific tolerization therapies such as through oral feeding of AChR antigen (Baggi et al., 1999; Im et al., 1999) which protects from disease progression in the EAMG model.

What makes this model particularly interesting is that the pathogenesis of mouse EAMG closely resembles human myasthenia gravis. We will not elaborate on the full list of corresponding pathological features, which are reviewed in Christadoss et al. (2000). Nevertheless, it is interesting to point out the conceptual difference with other immunization-based animal models such as for instance the collagen-induced arthritis (CIA) model for rheumatoid arthritis. Both EAMG and CIA are fundamentally artificial in the sense that the underlying cause of the disease in humans is unknown and does not involve

an injection of antigen in adjuvant. In rheumatoid arthritis, however, collagen-specific autoimmunity can be a contributing factor, yet collagen is not the key autoantigen that drives disease progression. In myasthenia gravis, since the key autoantigen is so well defined, immunization in the EAMG model leads not only to similar disease manifestations but arguably also a more similar underlying immunopathology. Analogous induction protocols including a combination of a defined autoantigen and adjuvant are used to induce diseases such as pemphigus vulgaris (Dsg3 immunization; Fan et al., 1999). A common shortcoming of these models is the major extent of external manipulation required to break tolerance.

Autoimmune Uveitis

Autoimmune uveitis in humans represents a heterogeneous condition with variability in both clinical presentation and disease course. The disease is typically associated with the occurrence of immune responses to retinal antigens, with retinal arrestin (S-antigen) being the most prevalent target. Notably, patients that respond to the same retinal antigen(s) do not necessarily share the same clinical symptoms (Caspi, 2011). Furthermore, it is unknown whether these uveitis-specific responses are causative or rather secondary.

In animals, different antigens were shown to result in distinct pathological outcomes (Caspi, 2006). The most widely used model is the experimental autoimmune uveitis model (EAU), which is induced by immunizing susceptible rodent strains with interphotoreceptor retinoid-binding protein (IRBP) in adjuvant (Caspi et al., 1988). Although EAU—or any other uveitis model—clearly does not reproduce the complexity of autoimmune uveitis in patients and is therefore hard to align with any clinical counterpart, the model has been informative in pre-clinical testing of new therapeutic concepts such as oral tolerance and more recently IL-2 receptor blockade (Caspi et al., 2008).

Chemicals

Chemical triggers usually rely on some sort of structural resemblance to non-hazardous substances that are normally taken up specifically by the target cells. The widely used model of streptozotocin (STZ)-induced diabetes is based on the structural similarity of the compound to glucose, which makes it particularly toxic to beta cells. STZ is an alkylating agent that causes DNA damage and is taken up by a glucose transporter that is specific to beta cells. While a single high dose causes non-immune beta cell deletion, a course of repeated low-dose administration mimics an autoimmune form of disease (Like and Rossini, 1976).

Another popular model is the dextran sodium sulfate (DSS) autoimmune colitis model (Okayasu et al., 1990). The exact mechanism through which DSS initiates colitis is unknown but one possible mechanism may be interference with gut permeability.

Finally, certain chemicals such as cyclophosphamide have the capacity to trigger autoimmunity, in this case diabetes, in susceptible mice (Harada and Makino, 1984). It was shown that this particular agent acts by reducing the Treg population and thus tipping the balance in favor of autoimmunity (Brode et al., 2006).

Cell Transfer or Depletion

Multiple Sclerosis

Adoptive transfer of a pathogenic “driver” T cell population is a frequently used strategy to model disease and to dissect the roles of certain functional subsets or T cell reactivities. EAE can be passively induced by adoptive transfer of T cells isolated from mice primed with myelin antigens into naïve mice (Stromnes and Goverman, 2006). This approach was instrumental in showing that myelin-specific CD8 T cells function as effector cells in MS-like pathogenesis (Huseby et al., 2001).

Type 1 Diabetes

Likewise, autoimmune diabetes can be induced by the transfer of certain diabetogenic driver clones. One approach uses the BDC2.5 CD4 T cell clone, which upon transfer rapidly triggers diabetes onset in the NOD mouse (Haskins and McDuffie, 1990). The BDC2.5 TCR is specific for a recently described pancreatic islet β -cell antigen, chromogranin A (Stadinski et al., 2010). This model offers the opportunity to study a genuine diabetogenic driver clone in the NOD and has been used for intravital imaging studies (Tang et al., 2006) or to examine functional Th plasticity (Bending et al., 2009).

Inflammatory Bowel Disease

Several key scientific breakthroughs on the role of Treg in controlling autoimmunity were based on the study of the CD45Rb transfer model for autoimmune colitis. Briefly, transfer of CD4⁺CD45Rb^{high}T cells from wild-type donor mice into immunodeficient SCID or RAG^{-/-} recipients leads to wasting disease and intestinal inflammation, starting 3–5 weeks after transfer (Powrie et al., 1993). In contrast, transfer of unfractionated CD4 T cells, or transfer of the CD4⁺CD45Rb^{low} subset, does not provoke disease. When both the CD45Rb^{low} and CD45Rb^{high} subset are co-transferred, no disease develops, which at the time indicated that certain cells with

potent regulatory function (now known as Treg) were able to control the pathogenic cells (Powrie et al., 1994).

Autoimmune Gastritis

Autoimmune gastritis is characterized by the development of a mononuclear cell infiltrate, destruction of parietal and zymogenic cells, and presence of autoantibodies specific for gastric H^+/K^+ ATPase (Field et al., 2005). Experimental autoimmune gastritis (EAG) occurs spontaneously in certain mouse strains (Alderuccio and Toh, 1998) or can be induced by a variety of methods such as immunization with gastric H^+/K^+ -ATPase in FCA (Scarff et al., 1997). The latter model was instrumental in the identification of the β -subunit of the H^+/K^+ ATPase as a key autoantigen in autoimmune gastritis.

Rather than cell transfer, depletion of certain regulatory cell subsets can also lead to autoimmunity. Of major conceptual importance was the notion that neonatal thymectomy leads, in addition to a range of other autoimmune conditions, to autoimmune gastritis in 40–50% of Balb/c mice (Kojima and Prehn, 1981). Later investigations demonstrated that the early development of Treg in the thymus is essential to maintain self-tolerance later in life (Sakaguchi and Sakaguchi, 1990). This population, commonly termed “natural Treg,” is now known as an essential gatekeeper against autoimmunity and in maintaining overall immune homeostasis.

General Conclusions from Induced Models

Breaking tolerance to an autoantigen is a “numbers game” and $CD8^+$ cytotoxic T lymphocytes (CTLs) can eliminate target cells such as keratinocytes or islet beta cells, when activated and able to enter the organ in

sufficient numbers. Interesting differences emerge here for different target organs that express the same antigen: the pancreas and skin more readily show clinical signs of autoimmunity, but the brain appears to be capable of suppressing activated autoaggressive T cells, even after they cross the blood–brain barrier, as evidenced by mild disease in MBP-LCMV-Ag transgenic mice despite intracerebral infiltration (Evans et al., 1996). Thus, induction of organ-specific autoimmunity can be expected to follow quantitative rules and reduction of autoaggressive T cells beyond a certain threshold level will abrogate disease development.

Inflammation within any specific target organ induced by means of a local viral infection can activate macrophages and “set the stage” for further development of disease (von Herrath and Holz, 1997). Thus, breaking of tolerance might require the association with localized specific or non-specific inflammatory processes that could have, in addition to viral infections, a variety of other causes. The “fertile field” hypothesis is based on these observations and assumes that infections are required to “shape” the local target milieu and create conditions that are permissive for autoimmunity (von Herrath et al., 2003).

Regulatory cells can generally prevent autoimmune disease. Using transfer models one can clearly delineate the concept of bystander suppression, namely that a Treg with one antigenic specificity can downmodulate aggressive T cells with other antigenic specificities. This is a concept that is instrumental in the concept of antigen-specific immunotherapy. Indeed, there is a need for bystander suppression when T-cell populations with multiple autoaggressive specificities act in concert, and it might be necessary to dampen many to see an effect (Figure 31.2).

FIGURE 31.2 The influence of Treg on autoimmunity. In autoimmune diseases, an unknown antigen activates naïve T cells, which differentiate into pathogenic Th subsets (or CTL) and eventually kill target cells. Treg may prevent this process by direct modulation of APC function. Some studies even show Treg-mediated APC killing. Alternatively, Treg may inhibit activation or act suppressive on Th effectors. Finally, Treg can interfere with target killing and as such protect from clinical disease.

Finally, a close look at many of the induced autoimmune models suggests that the destruction of the attacked cell type or organ can occur via a variety of pathways that are not mutually exclusive. In addition, the autoaggressive response exhibits plasticity in the sense that blocking of one specific effector arm, e.g., killing of CTL by Fas or perforin or inflammatory cytokines, will result in the emergence of alternative pathways.

Comparison of Organ-Specific Autoimmune Disease in Animal Models and Humans

Every model will reflect certain aspects of the human disease and for this reason will be suited for some but not all of the scientific questions. Two examples of this are T1D and MS.

Type 1 Diabetes

The NOD model, although still considered the best model for T1D, resembles human T1D in many but not all aspects. It is evident that it lacks insufficient stringency to vigorously test preventive therapies: some 190 interventions can prevent T1D in the NOD mouse when given early enough, while many have been unsuccessful in humans (Shoda et al., 2005). Reversal of recent-onset disease, however, is much more difficult to achieve and only the most potent immune intervention regimens (e.g., anti-CD3) appear to be able to accomplish remission. Consequently, we should experimentally increase the stringency of the animal model test, and evaluate potential candidate interventions, both in NOD mice with recent-onset diabetes and in other diabetes models.

A major difference is the histopathology of the target site, the pancreatic islets. In mice, pancreatic islets are literally engulfed by a massive inflammatory infiltrate, while in humans this appears to be much more subtle. In fact, some previous studies on human cadaveric sections defined a threshold as low as five immune cells to define insulinitis (Coppieters and von Herrath, 2009). Moreover, whereas prediabetic NOD mice exhibit clear signs of insulinitis long before onset, studies in humans find very little evidence of ongoing pathology (In't Veld et al., 2007).

Finally, NOD mice develop antibodies to insulin, as do most patients with T1D. Some evidence was reported showing that NOD mice also develop antibody responses to GAD and IA-2. The current consensus, however, is that insulin, but not GAD and IA-2, is targeted by humoral immune response in NOD mice (Bonifacio et al., 2001). These findings indicate that there are important differences in the humoral antigenic repertoire between mouse model and human disease.

Multiple Sclerosis

In striking similarity to the NOD model for T1D, more than 90% of animal research on MS utilizes the EAE model. The model parallels MS on various levels, including genetic susceptibility in the MHC, occurrence of lesions populated by CD4 and CD8 T cells, a role for antibodies and complement, damage to the myelin sheath, and axonal degeneration.

In some instances, the EAE model shows a corresponding clinical response to treatment, as in the case of interferon (IFN)-beta therapy (Yu et al., 1996). Notable divergences, however, include TNF-alpha inhibition and IFN-gamma therapy, which are both effective in EAE but not MS (Steinman and Zamvil, 2005). Finally, in the EAE model, antibodies to myelin antigens are present in cerebrospinal fluid, while in patients these are infrequent and do not constitute the antigen specificity of the oligoclonal IgG bands that often characterize the disease (Weber et al., 2011). Whereas in animals, CNS-reactive antibodies were found to contribute in a pathogenic manner, the precise role in human disease is far from certain.

CONCLUSIONS

Today, many well-characterized models for organ-specific autoimmunity are available which together mimic a broad spectrum of human disease features. Our message is that a given animal model is only as good as the question it is used to answer, and particular models are well suited for some but not all questions. Consequently, a careful choice is needed in advance. Inbred mouse strains that are used to limit variability of *in vivo* studies will essentially tell the story of just one or a few human patients—for translating findings in animal models to human therapy, this is a particularly important realization—and a much higher degree of variation can be expected in human populations. In addition, it follows that each model will only reflect certain aspects of a given autoimmune disease accurately and, therefore, immunotherapeutic approaches should be validated in more than one model if possible. Nevertheless, the numerous animal models that are available to us are indispensable tools to study *in vivo* pathogenesis and treatments, and are a crucial step when moving from the bench to the bedside.

INTRODUCTION

Systemic lupus erythematosus (SLE), an autoimmune disease that affects many organ systems, has no known etiology and a complex pathogenesis. It is more prevalent in females, has an human leukocyte antigen (HLA)-D association and presents clinically in diverse ways. Organs and tissues commonly affected include muscle and joints, brain and peripheral nervous system, lungs, heart, kidneys, skin, serous membranes, and components of the blood. Virtually any organ can be affected. Clinical manifestations are protean, overlap with other illnesses, and are often subtle.

PATHOGENESIS

The pathogenesis of lupus is enigmatic. Although primarily immunological, the pathogenesis of the disease is influenced and modified by non-immune systems like the endocrine or clotting systems (Shapiro and Long 1999; Simantov et al., 1999). At this time, the predilection of this disease for females cannot be explained; but pathogenetic factors like sex steroids or gonadotropins play a role in the severity of disease and the different clinical presentations between the genders. Factors such as drugs, diet, and environmental toxins have been implicated in the pathogenesis of SLE through epigenetic mechanisms (Ballestar et al., 2006; Richardson, 2009) (see Chapter 28).

There are formidable roles for both T and B cells in our understanding of SLE. Patients with active SLE have lower percentages of CD4⁺CD25⁺ T cells than healthy controls and those with active disease (Zheng et al., 2004). Production of interleukin (IL)-2 and tumor growth factor (TGF)-beta is lower in SLE patients than in controls (Ohtsuka et al., 1998, 1999). In mice various methods can be used to reverse the autoimmune process by stimulating regulatory T (Treg) cell production. In murine experiments the transfer of *ex vivo*-induced Treg cells leads to tolerance with suppressive activity. This Treg population is induced with IL-2 and TGF-beta and produces enough autologous Treg cells to suppress disease activity (Baecher-Allan et al., 2002, 2003). By far the greatest progress in SLE therapy in the last few years comes from the studies of B cells (Grimaldi et al., 2005). B cells are responsible for autoantibody production and immune complex deposition that leads to tissue injury. B cells also serve as antigen presenting cells, secrete proinflammatory and immunoregulatory cytokines, IL 10, and regulate T cell activation, anergy, proliferation and the differentiation of T cells and follicular dendritic cells. The consensus of investigators was that B cells could be modulated using antigen-specific interventions or disrupting B and T cell interactions. We will discuss these pathogenetic interactions under therapy (Garaud et al., 2011; Marino and Grey, 2012).

GENETICS

Specific immune response genes in the major histocompatibility complex (MHC) class II or class III regions on chromosome 6 are associated with SLE (Johannesson and Alarcon-Riquelme, 2001). Genetic associations include other loci that are constitutive. Genetic MHC II alleles are associated with certain autoantibody groups and inherited complement deficiencies develop variants of lupus with specific clinical characteristics. There are class II antigens and HLA-D locus associations to other diseases as well. These include rheumatoid arthritis, multiple sclerosis, idiopathic thrombocytopenic purpura (ITP), and rheumatic fever; overlap syndromes such as Sjögren's, scleroderma, thyroiditis, and the inflammatory diseases of muscle. Genetic influences on the development of SLE in humans are described in Chapter 26, and in murine models in Chapter 30.

EPIDEMIOLOGY

There are several worldwide studies concerning the epidemiology of SLE. Incidence varies according to the characteristics of the population studied (age, race, gender, ethnicity, period of time considered, and diagnostic criteria used). In the USA the annual incidence of SLE is estimated as 2.2 cases per 100,000 persons per year in rural Rochester, Minnesota (Michet et al., 1985). In San Francisco, California, the incidence rises to 7.6 cases per 100,000 (Fessel, 1974). In Europe the annual incidence differs from country to country: 2.2 cases per 100,000 in Spain to 5.8 cases per 100,000 cases per year in Iceland (Hochberg, 1987). The prevalence of the disease also varies with the methods involved in case ascertainment. There are undoubtedly genetic and environmental factors that affect differences of prevalence between various locales. Even the sex distribution and age changes could affect prevalence. Hochberg reported a prevalence of 12.5 cases per 100,000 women in England and Wales and a prevalence of 17.7 cases per 100,000 among those who were 15–64 years old. In the USA the prevalence of SLE ranges from 14.6 cases per 100,000 in New York to 78.5 cases per 100,000 in Wisconsin. These variations could be explained by the variations of disease expression as well as difficulty with diagnosis of the disease.

Age is an important consideration for lupus since the incidence rates vary by age in some studies (McCarty et al., 1995). Peak rates are reported in women during the childbearing years (15–44 years). Men tend to have an onset of the disease at an older age (50–65 years). The ethnic differences in SLE are significant (Carbone and Lohr 2002; Fessler et al., 2005; Krishnan and Hubert 2006; Anderson et al., 2008; Jurecnak et al., 2009). There are significant differences with regard to black versus

white people with the disease. A study from the UK showed that age-adjusted incidence of SLE in Afro-Caribbean patients was 25.8 versus 4.3 cases per 100,000 persons per year. The prevalence was 112 and 21 per 100,000 cases per year for the same cohort. The incidence and prevalence rates of SLE in the Asian population of the UK were 20.7 and 46.7 cases per 100,000 persons, respectively.

AUTOANTIBODY

Although there are a few nonimmunologic laboratory characteristics of SLE, these are not specific (Aranow et al., 2011; Reeves et al., 2011). Immunological tests, which are specific to most autoimmune diseases such as lupus, include the presence of specific cytotoxic lymphocytes and a variety of autoantibodies, including a persistently positive antinuclear antibody (ANA). The diagnostic utility of test procedures for ANA is described in Chapter 77. Laboratory data in the form of an isolated false-positive syphilis test, a low platelet count, elevated partial thromboplastin time (PTT), or leukopenia may suggest many other diseases that are often considered before SLE. SLE is a clinical diagnosis that depends on a careful history and physical examination. Autoantibodies are frequently associated with no disease and occur in normal people; they alone support but are not diagnostic of the disease. A history of specific medication is particularly important, as reversible drug-induced lupus is responsible for some 10% of cases (Yung and Richardson, 2011) and is often seen in older patients, particularly males. Lupus can be related to other illnesses that can occur in the patient's family such as rheumatoid arthritis (RA), ITP, and multiple sclerosis.

Depending on the clinician, more complex immunologic laboratory tests may solidify the diagnosis when suspected clinically or contribute to the erroneous diagnosis of SLE in the absence of clinical signs.

The widespread availability of such testing, the lack of standardization, and inappropriate application of such tests may contribute to diagnostic confusion. The most useful tests for SLE are the fluorescent antinuclear antibody test, antinative DNA assay, the total hemolytic complement (CH50), and C3 and C4. All of these tests are subject to wide variation: the ANA because of substrate variability, and the tendency to use enzyme-linked immunosorbent assay (ELISA) and other nonspecific modalities; the anti-DNA because of single-stranded DNA contamination and cross-reactivity with phospholipids; and the CH50, C3, and C4 because of the temperature sensitivity of complement components (Liang et al., 1989).

One can find other reactive antibodies, such as anti-Ro, anti-La, and other ribonucleoprotein antibodies in the absence of an ANA. Antibodies to native DNA (Aranow et al., 2011) and antibodies to Smith (Sm) antigen, a

nuclear ribonucleoprotein, are also quite specific for SLE. Relevant autoantibodies and their associations are given in [Table 32.1](#) (Stahl et al., 1979).

Common laboratory assays can aid the physician in establishing the diagnosis. Most useful is the white blood cell count (WBC), which often shows leukopenia and lymphopenia (Lahita, 1992). Anemia of chronic disease or in rare instances autoimmune hemolytic anemia can be differentiated by the examination of red cell indices, a reticulocyte count, a peripheral smear, or a positive Coombs test. An abnormal urinalysis with the appearance of WBCs, red blood cells, granular casts, and proteinuria can also be helpful and raise a suspicion of lupus nephritis. While blood urea nitrogen (BUN) and creatinine levels are not usually elevated at the outset of the disease, they can be useful as baseline values in a patient who progresses to azotemia and acute renal failure. A chest X-ray and electrocardiogram should be obtained initially to rule out pulmonary pathology, to explain an enlarged cardiac silhouette, and note electrocardiographic signs of pericarditis, enlarged cardiac chambers, or signs of ischemia. This is of particular importance since accelerated atherosclerosis and early heart and vascular disease is common to this condition (Manzi, 2000) and the most common cause of death.

TABLE 32.1 Association of Specific Antibodies with Specific Clinical Findings.

| Antibody | Clinical Manifestation |
|--|---|
| Anti-native DNA | Lupus nephritis, active disease |
| Anti-Smith (SM) and high ribonucleoprotein | SLE, scleroderma, mixed connective tissue disease |
| Anti-RO (SSA) and LA (SSB) | Sjögren's, SLE, neonatal lupus, subacute cutaneous lupus, C2 deficiency |
| Anti-ribosomal P protein | Neuropsychiatric lupus |
| Anti-histone | Drug-induced disease |
| Anti-phospholipid | Clotting, livido reticularis, false positive syphilis test |

CLINICAL

The nature of the general symptoms associated with the disease includes fatigue, weight loss, and fever (Stahl et al., 1979; Robb-Nicholson et al., 1989). Often the initial complaints, they can be mistakenly attributed to causes other than lupus at first glance. Fatigue is well recognized and is the most common and often the most debilitating symptom of SLE; similar to a bout of influenza. A curious pattern of fatigue is described in SLE when compared to patients with other multisystem autoimmune diseases (Godaert et al., 2002). In SLE, fatigue decreased in the morning and increased in the evening in contrast to other conditions such as scleroderma where the opposite is true. Weight loss is common in patients with lupus and worsened when there is malabsorption due to overlapping illnesses such as CREST syndrome (calcinosis, Raynaud's, esophageal dysmotility, sclerodactyly, and telangiectasia), mixed connective tissue disease (MCTD), or scleroderma. Although anorexia is common in severely debilitated patients with associated organ disease such as renal failure, it is not an isolated finding in SLE. The fever of lupus is usually low grade and rarely exceeds 39°C (102°F), unless patients are taking immunosuppressive drugs and have a concurrent infection.

The diagnosis of SLE should be made on clinical grounds with the support of laboratory tests, not the other way around. While diagnostic criteria have been proposed for the classification of SLE (Hochberg, 1997), they are not universally applied in practice. Eleven criteria have been designated by the American College of Rheumatology (ACR) (Box 32.1) for classification. The presence of four or more criteria out of the 11 possible is mandatory for the appropriate classification of SLE. When used, these are of value in clinical practice and are 96% sensitive and specific (Parodi and Reborja, 1997). In some studies of patients with cutaneous lupus, ACR criteria showed a sensitivity of 88%, a specificity of 79%, a positive predictive value of 56%, and a negative predictive value of 96% (Asherson et al., 1991). The diagnosis of SLE is given routinely to patients in practice who fail to meet any criteria (Gilboe and Husby, 1999). Patients

Box 32.1 Classification Criteria for Systemic Lupus Erythematosus.

1. Malar rash
2. Discoid rash
3. Photosensitivity: skin rash as a result of sun exposure
4. Oral ulcers: painless
5. Arthritis (nonerosive): two or more peripheral joints with swelling and effusion
6. Serositis: pleuritis or pericarditis
7. Renal disorder: persistent proteinuria or cellular casts
8. Neurologic disorder: seizures or psychosis
9. Hematologic disorder: hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia
10. Immunologic disorders: positive antiphospholipid antibody, or anti-DNA, or anti-SM, or a false positive test for syphilis
11. Antinuclear antibody (ANA): in the absence of drugs that cause lupus

who fail to meet four of the 11 criteria have what many call lupus-like syndrome or incomplete lupus and such patients may have a related autoimmune disease. Lupus criteria can be acquired over a period. The revised ACR criteria for lupus is the standard for establishing eligibility of subjects for epidemiologic and clinical lupus studies, but exclude patients with limited disease. In 2002, the Boston weighted criteria for clinical studies were established, and these criteria were compared to the clinical rheumatologists' diagnosis of SLE. Using these criteria, the investigators were able to identify a larger number of cases with SLE. The criteria had a sensitivity of 93% and specificity of 69% compared to the ACR criteria, and 7% more patients with lupus were identified (Costenbader et al., 2002). In 2001, Wilson et al. published the criteria for antiphospholipid syndrome. These criteria, which may need revision over time, are very helpful to this important variant of SLE, which can be primary or secondary to SLE (Wilson et al., 2000).

MEASUREMENT OF CLINICAL ACTIVITY

Lupus is such a heterogeneous disease that classification of the disease and measurement of disease activity poses problems for the clinician and researcher. Over 40 instruments have been developed over many years. Recently, most observational clinical studies have used the SLEDAI and/or the BILAG in the measurement of SLE activity (Bombardier et al., 1992; Isenberg et al., 2005). These validated instruments are sensitive to change and can measure change with time. The BILAG-2004 is the latest version of this British instrument and is based on the clinician's intention to treat; there are five categories of disease severity. The SLEDAI was developed in Canada and included 37 variables for defining SLE activity. This validated measurement system was further modified during the safety of estradiol in SLE national assessment (SELENA). Descriptors were changed to insure that organ system involvement included ongoing disease activity. Additionally criteria were developed to measure flares using the BILAG 2004 index. Subsequent efforts to use the SELENA-SLEDAI index to measure flares were successful and provided a way to quantitate this aspect of the disease with particular note of specific organ involvement.

Musculoskeletal

Patients with SLE can present with isolated arthralgias, Reynaud's phenomenon, hypercoagulable states, fever of unknown origin, and respiratory symptoms such as dyspnea and pleural effusions or overt renal failure. The protean clinical manifestations of this illness can make the diagnosis difficult and if access to specialty care is

unavailable the patient may elude diagnosis for many years.

The arthritis of SLE is a nonerosive, nondeforming, symmetric arthropathy. Multiple joints are involved, and 80–95% of them are tender, swollen, and effusive joints. The joints are the most frequently involved organs in SLE. The most frequently involved joints are the proximal interphalangeal, metacarpal phalangeal, wrists, and knees. The deforming arthritis of Jaccoud can occur in the lupus patient, and in such patients, swan neck deformity and profound ulnar deviation can be found. This form of joint involvement lacks erosive changes and can be differentiated from RA. The most frequent musculoskeletal X-ray changes are soft tissue swelling, acral sclerosis, and periarticular demineralization. When rare erosions of bone occur, one must consider a form of overlap syndrome (van Vugt et al., 1998). Joints such as the temporomandibular and the sacroiliac may also be involved (the latter particularly in males) in the SLE patient. Rheumatoid nodules can occur in SLE with the presence of a high rheumatoid factor (Schwartz and Grishman, 1980; Hassikou et al., 2003) but this is rare. Erosive joint changes can contribute to confusion about making a diagnosis of SLE, particularly in the elderly patient, where SLE is distinctly uncommon (Foadd et al., 1972). Avascular necrosis is a particular source of joint pain in SLE patients and should be a part of every differential diagnosis. It is a feature found in patients who are ingesting corticosteroids and those with phospholipid antibodies (Murphy Nancy et al., 1998). Avascular necrosis (AVN) is commonly found in the hips, carpal bones of the wrist, and heads of the humerus and the knees. Less commonly, the shafts of the long bones can be affected. Anywhere from 5 to 10% of patients with SLE can have AVN and these findings are not always associated with steroid use. In many cases, AVN can be asymptomatic and detected by routine X-ray evaluation. In decreasing order of sensitivity, magnetic resonance imaging (MRI), bone scan (Tc99), and plain X-ray are useful in detecting AVN; however, MRI is often positive when all other diagnostic modalities are negative. Septic arthritis must also be considered as a cause of SLE joint pain, particularly when there is swelling and intense warmth of a joint coupled with peripheral leukocytosis. An aspiration of an effusive SLE joint with subsequent culture is mandatory and can be lifesaving. Myositis is present in 3–5% of SLE patients with the creatinine phosphokinase (CPK) being greater than 1000 (Yood and Smith, 1985), but clinical features such as myalgias distinct from fibromyalgia can be found in as many as 50% of patients. The CPK is rarely elevated above 1000, but an electromyogram (EMG) can be very abnormal. Biopsy of the muscle is rarely required for a definitive diagnosis, but if the CPK is exceptionally high or there is diagnostic confusion,

alternative diagnoses must be considered and anti-aldolase and anti-synthetase antibodies should be measured. The lymphocytic, monocytic, and plasma cell infiltration found in primary immune myopathies can be observed in varying degrees with SLE patients. A vacuolar myopathy is rare in SLE, but may be found in untreated patients in distal as well as proximal muscles. Myopathy in SLE can also be secondary to corticosteroid therapy, and a form of myopathy can be found in patients ingesting antimalarials (Askari et al., 1976; Posada et al., 2011).

Renal

Clinical evidence of kidney involvement is found in one-half to two-thirds of patients with SLE (Balow et al., 1999). Biopsy evidence of immune complex deposition is found in all kidneys of all patients with SLE, regardless of urine sediment. Various forms of glomerular disease listed by the World Health Organization (WHO) are helpful in establishing activity and chronicity as well as degrees of severity. Both diffuse proliferative glomerulonephritis and progressive forms of focal proliferative nephritis have poorer prognoses than membranous and mesangial forms of the disease. Each renal lesion in a lupus patient has activity and, dependent on the activity, is the need to treat the patient aggressively with large-dose steroids or immunosuppressive agents. Patients with inactive lesions (i.e., membranous nephropathy, sclerotic glomeruli, fibrous crescents, tubular atrophy, or interstitial fibrosis) may not require immunosuppressive therapy. A renal biopsy must be done to gauge the extent of disease and include two components: light microscopy and immunofluorescence. Serial renal biopsy has prognostic value and is recommended for the regulation of chemotherapy in some patients (Ginzler and Antoniadis, 1992; Yoo et al., 2000). A biopsy with immunofluorescent analysis and electron microscopy is also recommended. An adequate number of glomeruli should be obtained for verifiable diagnosis. Hypothetical problems encountered with the renal biopsy include (1) that the biopsy is static or reflective of one point in time, (2) the efficacy of the activity/chronicity index is questionable in designing treatment, and (3) no single glomerular lesion can reflect the entire renal picture.

The most serious complications of renal biopsies include pericapsular hemorrhage or clot obstruction in those patients with lupus procoagulants. In those patients with WBC, erythrocyte, hyaline, or granular casts, a BUN and creatinine are helpful in order to assess renal function. For most patients, renal function early in the course of the disease is normal despite abnormal urine sediment. If the activity of the disease progresses unchecked, these parameters change rapidly. When proteinuria is found qualitatively by urine dipstick (1 g or greater), a 24-h urine

protein and a creatinine ratio should be obtained to quantify the amounts. Urine protein is a useful measure of renal lupus activity. An incremental change of 500 mg of protein excretion is significant to predict worsening renal pathology just as a decrement can herald clinical improvement. Other reasons for decreased renal function in SLE include concomitant infections, use of aspirin, non-steroidal anti-inflammatory drugs (NSAIDs), or angiotensin-converting-enzyme (ACE) inhibitors; all affect renal circulation, as well as obstruction or thrombosis of the renal vein. Sonograms, contrast studies, or renal scans can be helpful in the evaluation of renal function when causes other than lupus nephropathy are suspected, and it is suggested that ultrasound might be of utility in the prediction of worsened renal disease (Platt et al., 1997).

Less common forms of renal involvement in SLE include interstitial nephritis, which can be the result of immune complexes (Appel et al., 2005) or the result of drug therapy. This form of renal disease may not present as a glomerulopathy but rather as a disorder of acidification and potassium transport or regulation (DeFronzo et al., 1977). Renal pathology could indicate that thrombosis of the glomerulus (Uwonkunda et al., 1998) and intraglomerular thrombi (Bhandari et al., 1998) are alternate causes of proteinuria and renal failure in SLE. Renal transplantation in lupus is as successful as that in the non-SLE population. However, renal disease can occur again in the transplanted kidneys (Amend et al., 1981). For unknown reasons, the alleviation of overall disease activity of lupus erythematosus after dialysis for chronic renal disease has been reported.

Neuropsychiatric

Neuropsychiatric manifestations can be found in as many as 66% of patients with SLE (Feinglass et al., 1976; Calabrese and Stern 1995). The pathophysiology of this clinical manifestation is not widely understood; however, thrombosis and vasculitis are not responsible for the large number of neuropsychiatric manifestations observed. It is possible that components that are both non-immunologic and immunologic might be involved, such as hormones or a direct effect of antibody. Central nervous system (CNS) manifestations include seizures, psychiatric illness, and disorders of the cranial nerves (McCune and Golbus, 1988). The frequency of organic CNS manifestations in SLE has been reported as between 35 and 75% (Jennekens and Kater, 2002a, b). The peripheral nervous system is involved in as many as 18% of patients.

Seizures are found in 15–20% of SLE patients (Johnson and Richardson, 1968). These can be the result of the disease process, such as lupus vasculitis or acute thrombosis, steroid therapy and its attendant hypertension, or a resulting metabolic problem such as uremia, seizures,

or infection. Grand-mal tonic–clonic seizures are most common, although other seizures, such as Jacksonian, psychomotor, and absence attacks, have all been reported. On rare occasions, patients with SLE can present with status epilepticus. Treatment of seizures in SLE requires anticonvulsants. Corticosteroid therapy when given as pulse therapy is a cause albeit rare of status epilepticus and hence should be used with caution. Lupus can cause profound psychiatric disturbances in 50–67% of patients. Overt psychosis can occur in 12% of cases as well as a variety of organic brain syndromes. Severe depression is common to lupus patients and is thought to be a disease manifestation rather than reactive depression from chronic disease. Sleep disturbances are common in lupus and not usually related to depression. Steroid psychosis is common in lupus patients on high-dose steroids for long periods (Kohen et al., 1993).

Antiribosomal P protein antibodies are positive in over 60% of patients with SLE-related psychosis (Bonfa et al., 1987) and may help distinguish these patients from those with steroid psychosis, although there is no specific antibody associated with cerebral SLE. Ten percent of patients can have cranial nerve abnormalities, and they can be the presenting symptom in a small number. Although spinal cord involvement in SLE is rare, three types of cord involvement are seen: transverse myelitis (Lavalle et al., 1990), demyelination, and spinal cord infarction because of thrombosis (Nakano et al., 1989). These three spinal manifestations are all commonly associated with antiphospholipid antibodies. In the first 5 years of the disease, the incidence of cerebrovascular accident (CVA) is high (6.6% occurring in the first year alone) (Ginsburg et al., 1992). Patients with antiphospholipid antibodies also have an increased risk of stroke. Even though movement disorders are not common in lupus, chorea is common in children with SLE and is found in adults and children with phospholipid antibody (Lahat et al., 1989). It is virtually indistinguishable from Sydenham's chorea. Parkinsonism and cerebellar ataxia are rare. Rarer forms of CNS involvement include pseudo tumor cerebri, hypothalamic dysfunction (especially due to thalamic infarcts), aseptic meningitis (particularly related to NSAID use), myasthenia, Eaton–Lambert syndrome, a thrombotic thrombocytopenic purpura-like syndrome, and hyperprolactinemia.

Peripheral nervous system disease is found in 3–18% of patients and is largely a sensory only or combined sensorimotor neuropathy (Florica et al., 2011). Guillain–Barré syndrome, mononeuropathy, or mononeuritis multiplex has also been reported (Santos et al., 2010).

The laboratory diagnosis of central nervous system disease in SLE is difficult. Spinal fluid pleocytosis and/or high spinal fluid protein levels are the only helpful indicators that CNS disease is present. MRI and position

electron tomography (PET) scanning show the most promise for diagnosing disease of the brain. Use of the newer modalities, such as Tc-99-HMAAQ brain SPECT, may have better utility in the diagnosis of CNS SLE (Colamussi et al., 1997). Infarctions and demyelinating lesions of the brain are best found with these modalities. CT scans are good for detecting focal lesions but are often unreliable. Antibodies to ribosomal P protein and anti-neuronal antibodies, as well as the finding of cytotoxic lymphocytes against myelin in blood, may eventually prove useful, but now are not very specific for cerebritis. An exciting development in the area of lupus cerebritis is the discovery of antibodies to the glutamate receptors in the brain. Originally based on a murine model of neuropsychiatric lupus and an antibody that cross-reacted with dsDNA and the N-methyl-D-aspartate (NMDA) receptors, the antibody from human SLE patients causes neuronal apoptosis when injected into mouse brains and causes significant brain pathology.

Cardiac

Cardiac involvement is very common in SLE, and some 30–50% of patients suffer from some form of heart disease (Petri, 1999; Costenbader et al., 2004). Pericarditis, the most common form of acute heart disease, occurs in 19–48% of patients. Pleural-pericardial pain can occur at any time. Echocardiography is the best diagnostic test for this manifestation. Pericarditis in SLE can be managed with NSAIDs and/or low doses of corticosteroids. Myocarditis is rare in SLE, involving only 5–10% of patients and usually presents with fever, conduction abnormalities, elevated CPK, skeletal myositis, and serositis (Lemos et al., 2008). SLE in the human results in a higher incidence of myocardial infarction because of accelerated atherosclerosis, coronary vasculitis, or coronary emboli (Manzi, 2000). Systolic cardiac murmurs are heard in up to 70% of SLE patients. These may be related to anemia, fever, or hypoxemia and are found with Libman–Sacks endocarditis, a component more frequent with antiphospholipid antibodies. The mitral and aortic valves are most commonly involved. Pulmonary arterial hypertension is common in patients with phospholipid antibodies (Bayraktar et al., 2001), and a pulmonic murmur or a loud second heart sound in the presence of an elevated PTT are clues to this diagnosis, which should be confirmed by echocardiography or cardiac angiography. Vasculitis is common in SLE and may be reflected in the presence of splinter hemorrhages, digital infarcts, or ecthymic skin lesions. Involvement of small- and medium-sized arteries may mimic polyarteritis nodosa and produce localized signs. Raynaud's phenomenon in SLE is not as common as in scleroderma or primary

antiphospholipid syndrome (APLS) and is present in only 20% of patients.

The most common cause of death in SLE is early onset cardiovascular disease (CVD).

Risk factors for accelerated atherosclerotic CVD are under intense study (Svenungsson et al., 2001) (see Chapter 71). The antioxidant capacity of normal high-density lipoproteins (HDL) is lost during inflammation and the dysfunctional HDLs predispose to atherosclerosis. These dysfunctional HDLs are thought to be the single factor that increases the risk of developing subclinical atherosclerosis in SLE.

Pulmonary

The lungs are commonly affected in lupus patients (Keane and Lynch, 2000; Hughson et al., 2001a). Over 50% of SLE patients have some form of pleural disease and pleural effusions in their lifetime. These effusions are mostly exudative (> 3 g protein) and less common than the pain and findings associated with simple pleuritis.

Parenchymal lung involvement can present suddenly as acute pneumonitis, dyspnea, or pleuritic pain. SLE parenchymal disease of the lung can be treated with high-dose corticosteroids, and improved pulmonary function is the desired result. Pulmonary capillaritis is also part of parenchymal disease (Franks and Koss, 2000). Hemoptysis and overt pulmonary hemorrhage are emergencies in SLE patients and are either the result of pneumonitis or pulmonary embolus, which are reversible. There is also an association of alveolar hemorrhage with renal microangiopathy (Hughson et al., 2001b).

Hematology

Sixty to 80% of lupus patients have anemia of chronic disease. Other kinds of anemia, such as autoimmune hemolytic anemia, are rare and are found in fewer than 10% of patients; however, a positive Coombs test can be found in 20–60% of patients (Simantov et al., 1999). Leukopenia can be found in over 50% of patients with SLE and is associated with either granulocytopenia or lymphopenia. Antibodies are directed to either of these cellular elements at any point in their maturation pathways. When directed against stem cells, these antibodies cause aplastic anemia. Most low cell counts in SLE can be reversed with immunosuppressive therapy. Leukopenia is often a good general sign of disease exacerbation but also occurs in response to cytotoxic agents used in lupus therapy. Platelet transfusions are contraindicated in most SLE patients except on occasions where platelets reach dangerous levels, because of the possibility that patients will be exposed to new platelet antigens that make them more refractory. Anticlotting factor antibodies have been

found in SLE and are often associated with bleeding. Antibodies are directed most commonly to factors II, VIII, IX, XI, or XII. Acquired von Willebrand syndrome is also seen. Lupus anticoagulants are found commonly in patients with SLE and are associated with mild to profoundly elevated partial thromboplastin times. This abnormality is usually associated with hypercoagulation and not with bleeding (Cockerell and Lewis, 1993). Associations have been observed, and the triad of the lupus anticoagulant, recurrent abortions, and the presence of false positive tests for syphilis is often found in patients. Patients with lupus can be hypercoagulable for a variety of reasons other than procoagulant antibodies and these include hereditary deficiencies of factors C, S, or antithrombin III. One acquired reason for hypercoagulability is the loss of antithrombin III in the urine of patients with nephrotic syndrome. If in rare instances a patient requires a splenectomy to control thrombocytopenia, laparoscopy is the best way to remove the spleen. Open laparotomy is not advisable in any except the most complicated cases.

Dermatology

Ninety percent of lupus patients have some involvement of the skin. Only 40% of patients experience sensitivity to ultraviolet (UV) light and these are mostly Caucasians (Zecevic et al., 2001). The actual percentage prevalence is 57% Caucasian vs. 11% African American. The lupus band test is the definitive test for cutaneous lupus. A biopsy shows immunoglobulin and complement deposition at the dermal/epidermal junction in nonlesional skin in greater than 60% of patients with SLE (Piette et al., 2001). However, false-positives are encountered in rosacea, RA, MCTD, renal diseases, and many other disorders. Its true value is the differentiation of discoid lupus from SLE. In discoid lupus, only lesional skin stains positive, whereas in SLE both lesional and nonlesional skin stain with immunoglobulin at the dermal epidermal junction.

Acute cutaneous lupus (30–50%) and subacute cutaneous lupus (10–15%) comprise the vast majority of patients with dermal disease. The butterfly malar rash found in 40% of patients is part of acute cutaneous lupus. Subacute cutaneous lupus (SCLE) is an annular, widespread, non-scarring, or papulosquamous/psoriasis-form lesion that is worsened by sun exposure. This form of lupus is associated with HLA-DR3, anti-Ro antibody, and high titers of ANA. SCLE has also been associated with complement component deficiencies of C2, C1q, and C1s. Chronic forms of lupus skin disease include several forms of discoid lupus and lupus profundus. These discoid lesions are usually localized to the head, scalp, and external ear, but more widespread involvement is possible. Patients with isolated discoid lupus have a 2–10% chance of developing systemic disease, whereas 10–20%

of SLE patients have discoid lesions. Discoid LE is more common in African Americans.

Alopecia can occur in all patients with SLE at some time in their disease presentation and can also be the result of therapy or hypothyroidism, which is very common in patients with SLE. Livido reticularis and livido racemosa, a more significant form of skin lesion, are found in the antiphospholipid syndrome.

Gastroenterological

The most common manifestation of gastrointestinal lupus is the occurrence of ulcers in the nose and mouth of patients. Many patients develop these ulcers at some time during the course of their disease and they indicate a flare of disease. Esophageal ulcerations and dysphagia are rarely found (Tatelman and Keech, 1966). Abdominal pain can result from a variety of causes. Pancreatitis (Baron and Brisson, 1982), ischemic bowel, perforation, or mesenteric vasculitis can suggest a surgical abdomen and mandate a laparotomy. The tumor marker CA125 can be elevated in cases of SLE-induced gastrointestinal ischemia (Koh et al., 2002). Serositis and, in some cases, vasculitis may also simulate a surgical abdomen.

Lupus peritonitis (Luman et al., 2001) is the result of small vessel involvement in the bowel serosa or retro peritoneum or the result of actual perforation of the bowel. Parenchymal liver disease as a result of lupus is uncommon and more likely represents autoimmune (chronic active) hepatitis with or without cirrhosis.

ENT and Eye

The eye is not commonly involved in SLE. Only 10% or less of patients have episcleritis or conjunctivitis. In a prospective study, retinopathy was detected in 7% of SLE patients. This retinopathy consists of microangiopathic lesions with cotton wool spots and hemorrhages that can be a significant problem in someone with a bleeding diathesis or one who is anticoagulated.

Optic neuritis, papilledema, and retinal vein occlusion are also major problems (Wong et al., 1981). Lupus retinopathy is common in patients with active SLE (88%) and in those with lupus cerebritis (73%). Patients can also have uveitis, cytooid bodies, and angle-closure glaucoma.

Less common in the patient with SLE is sicca syndrome. Patients who are older are particularly affected. Patients with lupus can have asymptomatic parotid gland enlargement with abnormal labial biopsies that suggest Sjögren's syndrome. Many of these patients have a positive anti-Ro antibody and a Sjögren's syndrome overlap. Patients with lupus may have vocal cord paralysis or

present with hoarseness because of vasculitis of the recurrent laryngeal nerve. Lupus may be a cause of sensorineural hearing loss. The mechanism of ear damage is not known.

LUPUS THERAPEUTICS

Besides rest and anti-inflammatory agents, the treatment of lupus involves immunosuppressants. Corticosteroids and antimalarials are the mainstay of therapy. Other drugs like mycophenolate mofetil, methotrexate, and azathioprine can be used to treat active disease. Cyclophosphamide is reserved for serious organ system involvement like renal and central nervous system disease. Standard and established therapies are described in Chapter 80.

Based upon pathogenetic mechanisms there are B cell targeted therapies that have had significant success (Furie et al., 2011). These agents include rituximab, ocrelizumab, belimumab, epratuzumab, and atacicept. Rituximab is a chimeric antiCD20 monoclonal antibody that had potential for the treatment of lupus, but did not meet its therapeutic endpoints when compared to placebo and was not approved by the Food and Drug Administration. Trial design was the likely cause of the drug's negative results. There is general agreement that the drug is a good therapeutic option. Ocrelizumab is a humanized antiCD20 antibody. The study of ocrelizumab in SLE was halted because of significant serious opportunistic infections. Belimumab is a fully humanized monoclonal antibody directed against B lymphocyte stimulating factor known as BLyS or BAFF (see Chapter 10). BLyS is part of the tumor necrosis factor (TNF) superfamily. Belimumab binds to soluble BLyS which is elevated during periods of active disease and associated with increased anti-native DNA antibody and lowered levels of complement components, both important biomarkers for disease. Belimumab was approved in 2011 by the FDA as the first biological agent approved for use in the treatment of SLE in 40 years. Epratuzumab is a humanized monoclonal antibody against CD22, an antigen involved in B cell signaling, and atacicept is another monoclonal antibody directed to a member of the TNF superfamily APRIL. Both agents are in phase II and III clinical trials as potential additions to the biological therapy of SLE. Biological therapies for SLE are further considered in Chapter 81.

The complexity of lupus along with the various instruments that have to be validated in order to ascertain clinical improvement make the evaluation of new drugs challenging. The additional need for standard therapy during clinical trials to avoid loss of patients on placebo is an additional factor for FDA consideration. Fortunately, the trial designs for the future will allow more rapid development of SLE-effective biological therapies.

INTRODUCTION

Scleroderma is derived from the Greek word *skleros* which means hard and *derma* which means skin. The first detailed description of scleroderma was in the early 1750s in Italy by Carlo Curzio who described the skin of these patients as dry hide and wood-like. We now know that scleroderma is a chronic, autoimmune, systemic, potentially lethal disease characterized by vasculopathy, immunological abnormalities, and excessive fibrosis that involves the skin and internal organs. The cause of scleroderma is still unclear; however, various environmental and/or genetic factors are thought to trigger complex pathogenic mechanisms that interact with each other at different levels.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Clinical Features

Swelling and tightening of the skin and other connective tissues is the hallmark of scleroderma, a group of related diseases (Black, 1993; Medsger, 2001). Scleroderma can be localized or systemic. Linear scleroderma and morphea are examples of the localized subtype, where the pathology is confined to the skin. Involvement of the internal organs in addition to the skin is called systemic sclerosis (SSc) (LeRoy et al., 1988; Medsger, 2004). Based solely on the extent of skin involvement, which was shown to be related to the degree of internal organ damage early in

the disease, SSc can be divided into two forms differing in the clinical course and outcome, the limited and diffuse cutaneous systemic sclerosis (lcSSc and dcSSc, respectively) (LeRoy et al., 1988; Medsger, 2004; Clements and Medsger, 2004). lcSSc is characterized by cutaneous changes affecting the extremities distal to the elbows, knees, and clavicles. CREST syndrome (calcinosis, Raynaud's phenomenon (RP), esophageal dysmotility, sclerodactyly, and telangiectasias) is an old synonym for lcSSc. The cutaneous changes in dcSSc are more proximal, and it has more severe and rapid progression than the limited subtype (LeRoy and Medsger, 2001).

Whether limited or diffuse, the early symptoms of SSc are non-specific and require a high index of suspicion to make the diagnosis. The majority of patients develop RP for variable periods of time before the appearance of skin changes. Patients may complain of fatigue, joint pain, and hand swelling early in the disease. Esophageal dysmotility, manifested as gastroesophageal reflux disease (GERD) or dysphagia, is also among the early features of SSc (LeRoy et al., 1988; Steen, 2001; Wigley, 2001).

The affected skin displays a spectrum of changes starting with edema, typically on the hands and fingers, progressing through shiny, thick, sclerotic skin that is tightly fixed to the underlying structures with loss of hair and sweat glands and ending with atrophic tethered skin. Areas of hypo- and hyperpigmentation may develop, giving a salt and pepper appearance. Telangiectasias and calcinosis may also occur (Charles et al., 2006).

Nailfold capillaroscopy can demonstrate dilated and giant capillary loops denoting impaired repair mechanisms of the injured blood vessels. Drop-out areas can also be seen classically with dcSSc. Severe vasospasm and vascular occlusive changes can lead to ulceration, infarction, and gangrene of the digits (Chandran et al., 1995). Those, as well as the gastrointestinal (GI) complications, interstitial lung disease, pulmonary hypertension, and renal involvement are responsible for the morbidity and mortality in SSc. dcSSc can display severe organ involvement that develops early in the disease. For this reason, patients should be monitored closely during the first 3–4 years of the disease for the signs and symptoms of visceral involvement (Steen and Medsger, 2000).

Pathologic Features

The pathologic picture of the involved tissues in SSc shows considerable variation depending on the stage of the disease. The understanding of these changes can help manage the patients by targeting the predominant mechanism at that particular stage.

Endothelial cell (EC) injury and apoptosis may be the earliest event in the pathogenesis of SSc (Sgonc et al., 1996). It can be detected in clinically “normal” skin.

These changes have different consequences on the integrity of the vascular and perivascular homeostasis. Perivascular edema can develop early in the disease, predisposed by increased vascular permeability.

Inflammatory cell infiltration is also among the early findings of SSc. Skin biopsies display perivascular cellular infiltration in the reticular dermis (Prescott et al., 1992). CD4⁺ T cells and monocytes represent a major part of the cell infiltrate. Mast cells and eosinophils can also be detected but to a lesser degree (Mavilia et al., 1997). In contrast, CD8⁺ T cells predominate in the lung tissues in addition to plasma cells, macrophages, and eosinophils (Yurovsky et al., 1996). Interestingly, the vascular pathology of the established disease is characterized as non-inflammatory obliterative vasculopathy (not vasculitis) and it shares some degree of similarity with chronic allograft arteriopathy (Furst et al., 1979; Prescott et al., 1992; Varga and Denton, 2008). Intimal thickening is caused by increased α -smooth muscle actin (α -SMA) positive myofibroblasts and upregulation of collagen and other matrix protein synthesis. These vascular changes in the lung tissues and kidneys are behind the development of pulmonary artery hypertension (PAH) and renal crisis, respectively, in SSc (Varga and Denton, 2008; Batal et al., 2010).

Tissue fibrosis develops with further progression of the disease; dermal thickening and loss of skin appendages like hair follicles and sweat glands are caused by excessive collagen production, mainly in the deep dermal layers, followed by fat cell entrapment as a result of extension to the subcutaneous layers of skin (Varga and Denton, 2008).

Atrophy, thinning, and flattening of the rete pegs are noted in the epidermis of long-standing SSc. The dermis becomes acellular, intensely packed with dense hyalinized collagen and other extra-cellular matrix (ECM) proteins, with loss of the microvasculature, and subcutaneous fat (Davies et al., 2006).

Atrophy is more prominent than fibrosis in muscular organs like skeletal muscles and the gastrointestinal tract (GIT) (D'Angelo et al., 1969).

Epidemiologic Features

The prevalence of SSc is lower in Asia (China 10 per 100,000) (Li et al., 2012) and higher in the USA and Australia (27.6 and 23.3 per 100,000, respectively) (Roberts-Thomson et al., 2006; Helmick et al., 2008). The prevalence in Europe seems to follow a north–south gradient, with the lowest prevalence in northern European countries (Norway 9.9 vs. Italy 34.1 per 100,000) (Lo Monaco et al., 2011; Hoffmann-Vold et al., 2012). SSc shows female predominance with a female to male ratio of around 4.6:1 (Helmick et al., 2008).

A genetic influence is supported by the clustering of disease. The Choctaw Indians group in Oklahoma (66 cases per 100,000) (Arnett et al., 1996) and familial frequencies (relative risk: 15 for siblings) point towards genetic factors that increases the susceptibility for the disease (Arnett et al., 2001). African Americans may have an earlier onset and more severe disease (Helmick et al., 2008). On the other hand, case–control studies in other groups with high prevalence suggest exposure to different environmental factors including silica dust and solvents (Barnes and Mayes, 2012). These epidemiologic studies indicate a complex mix of genetics and environment which predispose to phenotypic disease.

Disease survival appears to be improving over the years, an effect that can be attributed to early detection and improved treatment (Steen and Medsger, 2007). However, other meta-analyses studies show a stable standardized mortality ratio (SMR) of 3.5 per various 10–20 year periods between 1960 and 2010 (Elhai et al., 2012). A US-wide study of the period between 1979 and 1998 showed an overall mortality rate from SSc of 3.9 per million; it is 3.5 times higher in women than men. African American women have the highest death rate from SSc (Krishnan and Furst, 2005).

Late age of onset, the diffuse cutaneous subset, anti-Scl-70 positive antibody, and cardiopulmonary involvement are associated with a poorer prognosis (Joven et al., 2010; Kim et al., 2010). Recently pulmonary fibrosis, PAH, and cardiac causes account for the majority of disease-related mortality (Steen and Medsger, 2007).

AUTOIMMUNE FEATURES AND IMMUNOLOGIC MARKERS IN DISEASE

SSc is associated with the presence of several autoantibodies, some of which may play a role in the pathogenesis of SSc and others appear to have diagnostic and prognostic value.

Potential Pathogenetic Antibodies

There are antibodies, found in SSc patients, which may play a role in SSc pathogenesis.

Tsk1 mice, an animal model of SSc, have an abnormal fibrillin-1 protein and also express *antifibrillin-1 antibodies* which might play a role in the fibrotic process of these models (Murai et al., 1998). Normal dermal fibroblasts upon exposure to these antibodies differentiate into a profibrotic phenotype. This may occur through the release of transforming growth factor beta (TGF- β) from fibrillin-1-containing microfibrils in the ECM (Zhou et al., 2005a,b). These antifibrillin-1 antibodies are of interest because a significant percent of SSc patients are positive for antifibrillin-1 antibodies and show strong

ethnic differences (100% in Choctaw American Indians, 80% in African Americans and Japanese patients, in contrast to 42% in Caucasians) (Tan et al., 2000).

Also, *antifibroblast antibodies*, which bind to antigens on the fibroblast surface, induce their activation and stimulate the production of profibrotic and angiogenic cytokines. These antibodies are more frequent in dcSSc than lcSSc (72 vs. 37%, respectively) (Chizzolini et al., 2002).

Finally, matrix metalloproteinase-1 (MMP-1)-dependent breakdown of ECM was shown to be blocked by *anti-MMP-1 IgG*, found mainly in the sera of dcSSc. The presence of the antibodies correlates with the degree of fibrosis in SSc patients (Sato et al., 2003).

Diagnostic and Prognostic Antibodies

A number of antibody tests may be useful in clinical care.

DNA topoisomerase I is an enzyme responsible for the relaxation of coiled DNA. *Anti-topoisomerase I antibodies* (also called *anti-Scl-70 antibodies*) are directed against different epitopes on this enzyme (Simon et al., 2009). Although they are considered highly specific to SSc, recent studies demonstrated the presence of these antibodies in the sera of rare healthy patients as well as patients with systemic lupus erythematosus (SLE) (up to 25%) (Spencer-Green et al., 1997; Mahler et al., 2010). Anti-Scl-70 antibodies are found in 30–40% of dcSSc (Spencer-Green et al., 1997; Derk and Jimenez, 2003) and <5% of patients with the limited disease (using highly specific assays). Seropositive patients have a higher mortality rate and are at increased risk of developing complications, including pulmonary fibrosis and cardiac involvement (Murata et al., 1998; Jacobsen et al., 2001). The level of anti-Scl-70 antibodies correlates with disease activity and skin score (Hu et al., 2003).

Anticentromere antibodies (ACA) are more specific for lcSSc and are found in up to 45–50% of these patients (Castro and Jimenez, 2010), while it can be detected in $\leq 5\%$ of dcSSc (Steen et al., 1984). It recognizes different centromeric proteins (e.g., CENP-A, -B, -C) (Derk and Jimenez, 2003). Granzyme B-generated CENP-C fragments, rather than the intact CENP-C molecule, generated higher affinity antibodies in patients with ischemic digital loss (Schachna et al., 2002). This may indicate that the apoptotic process may expose hidden epitopes as targets for autoantibody production. The production of ACA is mediated by *human leukocyte antigen (HLA)-DRB1* and *HLA-DQB1* alleles (Mayes and Reveille, 2004).

Patients who are ACA positive have improved outcomes and lower mortality compared to those with anti-Scl-70 (Ho and Reveille, 2003). Moreover, ACA seropositivity was an independent protective factor for interstitial lung disease, supported by radiological and physiological studies (Kane et al., 1996; McNearney et al., 2007).

Patients who are seropositive for ACA have more recurrent and severe digital ulceration, and digital loss compared to ACA seronegative patients (Wigley et al., 1992).

Antihistone antibodies (AHA) are a heterogeneous group of antibodies directed against different histone complexes and components. IgM antibodies to H1 are related to mild clinical SSc features, while IgG antibodies to the inner core molecules of native histone, such as H2B or H2B-containing complexes, may be associated with severe pulmonary, cardiac, and renal SSc involvement (Parodi et al., 1995; Hasegawa et al., 1998).

Different studies investigated the clinical significance of antinucleolar antibodies in SSc. Antibodies directed against RNA polymerases (*anti-RNAP antibodies*) I, II, and III are highly associated with dcSSc (40%). Anti-RNAP III antibodies confer a number of risks: scleroderma renal crisis (33% are anti-RNAP III positive), systemic hypertension, synovitis, myositis, joint contracture, and malignancy within 5 years of skin manifestations (Mouthon et al., 2011; Nikpour et al., 2011).

Anti-polymyositis/scleroderma (anti-PM-Scl) antibodies are present in up to 24% of patients with polymyositis/SSc overlap syndrome. These patients tend to be younger and have pulmonary fibrosis and clacinosiis as well as respond to steroids (Marguerie et al., 1992). Anti-PM-Scl positive patients follow a benign course; they have a 10-year cumulative survival rate of 91% compared to 65% of anti-PM-Scl negative patients (Koschik et al., 2012).

RNase MRP and RNase P are small nucleolar ribonucleoprotein particles (snoRNPs) that are involved in the processing of precursor ribosomal RNA (pre-rRNA) and precursor transfer RNA (pre-tRNA). Both of these snoRNPs contain Th/To antigens (Van Eenennaam et al., 2002). *Anti-Th/To antibodies* are developed against these antigens. They are associated with lcSSc and are mutually exclusive with ACA (Kuwana et al., 2002). Interestingly, anti-Th/To patients have milder skin, vascular, and esophageal involvement than lcSSc who are ACA positive. Anti-Th/To antibodies are also associated with an increased risk of developing PAH, pulmonary interstitial fibrosis, renal crisis, puffy fingers, small bowel involvement, and hypothyroidism. The survival is lower for these patients compared to ACA positive patients (Okano and Medsger, 1990; Mitri et al., 2003; Grassegger et al., 2008).

GENETIC FEATURES

In mono- and dizygotic twins the concordance rate for the molecular features of SSc is high, although it is low for clinical disease (Kuwana et al., 2001; Feghali-Bostwick et al., 2003; Zhou et al., 2005) For the last few years, genome-wide association (GWA) studies uncovered the potential relationship of some single nucleotide polymorphisms

(SNPs) that involve HLA and non-HLA loci with the development of SSc. Most of these genes are involved in the modulation of the immune system through signal transduction, cytokine production, and cell survival and proliferation. The association of *HLA-DPA1/B1*, *HLA-DQB1*, *HLADRB1*, *HLA-DRA* in addition to *NOTCH4*, which play a role in the TGF- β -induced pulmonary fibrosis and vascular damage, were all clearly associated with different serological and clinical subtypes of the disease (Gorlova et al., 2011). Associations of SSc with *STAT4*, *BLK*, *CD247*, *TNFSF4*, *BANK1*, and other non-HLA genes are supported by separate studies (Rueda et al., 2009, 2010; Gourh et al., 2010a,b; Radstake et al., 2010; Bossini-Castillo et al., 2011).

Some of these genes have an impact on specific serological variations and aspects of the clinical course of SSc. For instance, *SOX5* is associated with ACA positive patients, *RPL41/ESY1* with dcSSc and *GRB10* and *IRF8* with the limited form of the disease (Gorlova et al., 2011). Separately, a certain polymorphism in the promoter region of the *IRF5* gene that downregulates *IRF5* expression is found in milder interstitial lung disease (ILD) and is associated with better long-term outcome (Sharif et al., 2012).

ENVIRONMENTAL INFLUENCES

Environmental factors can induce SSc-like syndromes by means of different mechanisms including loss of self-tolerance, direct activation of the immune system, and cytokine production or cross-reaction through molecular mimicry (Mora, 2009).

Toxic-oil syndrome traced to the consumption of colza oil (Terracini, 2004), vinyl chloride disease due to occupational exposure (Wilson et al., 1967), eosinophilia–myalgia syndrome linked to the ingestion of L-tryptophan supplements (Lindgren et al., 1991), and bleomycin-induced fibrosis are a just few examples from a long list (Adamson, 1976).

Viral triggers, like environmental effects, have been investigated. While parvovirus B19 (Ferri et al., 1999) and Epstein–Barr virus (EBV) (Arnson et al., 2009) were examined, the most interesting possibility was with cytomegalovirus (CMV). The UL94 late protein of human CMV shares some degree of similarity with an epitope on the topo-1 in patients with SSc and molecular mimicry may result in fibrogenic cytokine production (Lunardi et al., 2000).

A meta-analysis of 16 studies suggested the possibility that silica (not silicone) exposure may be a risk factor for the development of SSc, specifically in males and the male predominance may reflect an occupational bias. While interesting, the data are only associational (McCormic et al., 2010).

Recent meta-analytic studies of silicone were clear in showing no relation between silicone breast implants and SSc or other rheumatic autoimmune diseases (Janowsky et al., 2000).

Microchimerism is the presence of cells from one individual in another with each being genetically distinct. Fetomaternal microchimerism is an example of this phenomenon. It is thought that these cells might cause SSc-like disease through triggering a graft versus host (GvH)-like reaction and an increased number of microchimeric cells are found in SSc patients, associated with increased risk of disease. This fascinating possibility requires further research (Cockrill et al., 2010).

ANIMAL MODELS OF SSc

Animal models are an important way to better understand human diseases and SSc is not an exception. There have, however, been difficulties establishing an animal model

that matches the human disease with all of its phenotypic and pathological features (Table 33.1).

UCD200 Chickens

Within 1–2 weeks of hatching, UCD200 chickens spontaneously start to develop a condition somewhat similar to human SSc. They develop skin edema and Raynaud's-like features, followed by skin thickening and ischemic lesions of the toes. The disease may also involve internal organs within a few weeks. Likewise, the pathologic picture can mimic parts of SSc. Vascular obliteration, mononuclear cell infiltration, and fibroblast activation with excessive ECM production are all displayed in the lesional tissues. Furthermore, there can be detected in the serum autoantibodies including antinuclear antibodies (ANA), rheumatoid factor (RF), anticardiolipin antibodies, and anti-endothelial cell antibodies (AECA). Vascular EC apoptosis was shown to be induced by the

TABLE 33.1 Animal Models and their Similarity to Human SSc.

| Models | Fibrosis | Vasculopathy | Inflammation | Autoantibodies | Principal Organs Involved | Dissimilarity to SSc |
|-------------------------------|----------|--------------|--------------|----------------|--|--|
| UCD200/206 | ++ | +++ | ++ | ++ | Skin, lungs, kidneys, heart, esophagus, and toes | The skin involvement is mostly confined to the comb with severe inflammation and necrosis. The skin fibrosis is not followed by sclerosis |
| Tsk1 | + | 0 | 0 | + | Skin and heart | Hypodermal hyperplasia rather than dermal fibrosis. Unclear vascular and inflammatory changes |
| Scl-GvHD | +++ | 0 | +++ | + ^a | Skin, lungs, kidneys, liver, and parotid glands | Emphysematous lung changes rather than fibrosis |
| Bleomycin-induced | ++ | + | + | + | Skin, lungs (by endotracheal tube), esophagus, stomach | No vascular involvement. No GI involvement |
| TGF- β , CTGF, bFGF | +++ | 0 | ++ | 0 | Skin | Absence of typical vascular changes. Respond to anti-inflammatory agents that are not effective in human SSc. Changes confined to the site of injection and need very high doses to see systemic involvement |
| Fra2 transgenic mice | +++ | +++ | ++ | 0 | Skin, heart, and lungs (promising model to study PAH and different signaling pathways) | Require continuous growth factor injection. Absence of vascular and autoimmune changes. No systemic involvement |
| T β RII Δ k mice | +++ | + | + | 0 | Skin, lungs, heart, aorta, and colon | No autoimmunity. Unknown GI involvement |
| | | | | | | Pathogenesis depends mainly on TGF- β . Incomplete understanding of the vascular and inflammatory changes. Absence of autoantibodies |

^aOnly in modified Scl-GvHD models; +++: highly similar to human SSc; ++: moderately similar to human SSc; +: low similarity to human SSc; PAH: pulmonary artery hypertension.

AECA (Gershwin et al., 1981; Gruschwitz et al., 1993). However, this model is highly inflammatory with a combination of necrosis and widespread destruction, thus lessening its applicability to human SSc. UCD206 chickens are similar to UCD200 chickens but with more severe disease (Sgonc and Wick, 2008).

Tsk1 and Tsk2 Mice

Both tight skin mice (Tsk) type 1 and type 2 (Tsk1 and Tsk2, respectively) develop “TSK syndrome.” As an autosomal dominant trait this syndrome is lethal when it is homozygotic; the homozygotes die *in utero* by 8–10 days of gestation (Green et al., 1976; Christner et al., 1995). Heterozygous mice survive and are used as an SSc model.

The mutation in Tsk1 mice was mapped on chromosome 2, and it involves the fibrillin-1 (*FBNI*) gene, resulting in an abnormally large fibrillin-1 protein that expresses more TGF- β -binding motifs (Li et al., 1993; Siracusa et al., 1996). Fibrillin-1 is a major component of the microfibrils in connective tissues and is essential for regulating the bioavailability of TGF- β (Isogai et al., 2003). In addition, Tsk1 mice produce autoantibodies to fibrillin-1 (Murai et al., 1998). Shortly after birth, heterozygous Tsk1 mice develop diffuse thickening and tethering of the skin. These changes are due to hyperplasia of the subcutaneous tissues rather than the dermis, thus not strictly mirroring human SSc. Although there is some internal organ fibrosis, the lungs develop emphysematous rather than restrictive changes (Green et al., 1976). The absence of vascular changes, the subcutaneous skin changes, and the lack of clear immune system involvement limit the usefulness of this model. The mutation in Tsk2 was mapped to chromosome 1. Tsk2 models exhibit fibrosis, inflammatory cell infiltration, and autoantibody production (Christner et al., 1995). The frequencies of ANA, anti-Scl-70, ACA, and other autoantibodies are high in this model (Gentiletti et al., 2005). However, the pathological mechanisms behind these changes are unclear.

Scl-GvHD

Manipulation of the immune system by transplantation of bone marrow (BM) or spleen from B10.D2 mice donors into intensely γ -irradiated BALB/c mice can induce a GvH reaction in Scl-GvHD models, another animal model of SSc (McCormick et al., 1999). The development of skin and lung fibrosis by the 21st day after transplantation is preceded by donor-derived monocyte and T cell infiltration with an activated phenotype. Increased TGF- β and CCL-2 are also found, promoting the production of large amounts of type I collagen mRNA and protein (Zhang

et al., 2002). Although it simulates the fibrosis and inflammation of the human disease, the absence of vascular involvement and autoimmunity, in addition to the technical difficulties of producing this model, limit the use of these models. A modified GvHD model, obtained by injection of spleen cells from B10.D2 mice into RAG-2 knockout mice, show some evidence of autoimmunity; however, lung involvement is absent in this model (Ruzek et al., 2004).

TGF- β , CTGF, and bFGF

The growth factor-induced fibrosis model of SSc is developed by subcutaneous injection of TGF- β in newborn mice which rapidly induces fibrosis that is maintained by subsequent serial application of connective tissue growth factor (CTGF) or basic fibroblast growth factor (bFGF). This demonstrates the role of TGF- β in inducing the fibrotic process and CTGF and bFGF as essential in maintaining it (Shinozaki et al., 1997; Mori et al., 1999). Transient early elevation of mast cells and constant increase in the number of macrophages was demonstrated in these models (Chujo et al., 2005).

Bleomycin-Induced Fibrosis

The murine models of bleomycin-induced fibrosis are widely used in SSc studies. Repetitive subcutaneous injection of bleomycin induces pathological changes closely similar to the human disease (Mountz et al., 1983). The skin changes are confined to the injection site and remain more than 6 weeks after the last dose of bleomycin. Various mouse strains respond differently to bleomycin, in terms of duration and intensity of fibrosis. C3H/He, DBA/2, B10.D2, and B10.A show susceptibility to bleomycin (Yamamoto et al., 2000; Oi et al., 2004). Early inflammatory cell infiltration of the dermis with T cells, monocytes/macrophages, and mast cells, followed by dermal sclerosis with accumulation of thick collagen bundles, and homogeneous materials are demonstrated in the skin. Autoantibodies can also be detected in the sera of these models (Yamamoto et al., 1999). Vascular wall thickening in the deep layers of the dermis was reported in some studies (Yamamoto and Katayama, 2011). Lung involvement with alveolar wall infiltration and thickening are among the early findings. TGF- β was shown to influence fibroblasts, myofibroblasts, and other cells to adopt a profibrotic phenotype with upregulation of collagen and other ECM materials (Yamamoto et al., 1999).

Various transgenic animal models of SSc are generated by genetic manipulation. The offspring of such models spontaneously acquire the phenotypic features of SSc.

Fra2-Transgenic Mice

Fra2 is a transcription factor that is upregulated in SSc; it acts as a downstream mediator of TGF- β and platelet-derived growth factor (PDGF) signaling (Reich et al., 2010). For the last few years, the Fra2-transgenic mouse has engendered much interest as an animal model for SSc, as it shows dermal and lung fibrosis very similar to SSc by the age of 12 weeks (Maurer et al., 2012). Joint, renal, and GI involvement have not been examined, as far as we know.

T β RII Δ k Mice

T β RII Δ k mice have fibroblast-specific and kinase-deficient TGF- β receptors II. These fibroblasts show increased proliferation, myofibroblast transdifferentiation, and expression of plasminogen activator inhibitor-1 (PAI-1), CTGF, SMAD3, SMAD4, and SMAD7 (Denton et al., 2003). By an unclear mechanism, this results in increased TGF- β signaling and leads to excessive ECM production that involves the skin, lungs, colon, heart, and aortic smooth muscles (Denton et al., 2003; Derrett-Smith et al., 2010; Thoua et al., 2012). This is an exciting model with great possibilities.

Wnt-10b-Transgenic Mice

Although thus far only under investigation, Wnt-10b-transgenic mice represent a promising animal model of skin affected by SSc. Dermal fibroblasts from this model shows persistent Wnt/ β -catenin signaling with upregulation of collagen and α -SMA gene expression leading to dermal fibrosis and progressive loss of subcutaneous adipose tissue (Wei et al., 2011). The generalizability of this model and the extent to which the viscera are involved has not been published, nor have details of immune dysfunction.

PATHOGENIC MECHANISMS

Vasculopathy

RP, digital ischemia/ulcers, PAH, and renal crisis are all clear evidence of a vascular aspect to SSc and are probably among the earliest events in the disease.

SSc vasculopathy presents a wide range of changes that involve different aspects of the vascular system, including EC, capillaries, micro- and macro-vessels, and elevation of endothelium-associated adhesion molecules exemplify these effects.

For example, high intracellular adhesion molecule-1 (ICAM-1) expression and low ICAM-3 expression on the peripheral blood mononuclear cells from SSc patients

suggest that adhesion molecules may be involved in some aspect of SSc (Sawaya et al., 2009). Also, endothelin-1 (ET-1), among the strongest vasoconstrictors known and with mitogenic and inflammatory effects, contributes to TGF- β -associated pulmonary fibrosis in SSc (Shi-wen et al., 2007). The use of endothelin receptor inhibitors like bosentan, ambrisentan, and sitaxentan is effective in treating SSc-PAH and this effect may be mediated through both the vasodilatory and antifibrotic effect of ET-1 (Denton et al., 2006; Shetty and Derk, 2011). The level of other adhesion molecules like thrombomodulin also correlates with the disease activity (Mercié et al., 1997).

Further, endoglin, a coreceptor for TGF- β that modulates TGF- β signaling, may well be involved in the pathogenesis of SSc (López-Casillas et al., 1991). Endoglin gene abnormalities are responsible for hereditary hemorrhagic telangiectasia which shares several features with SSc, especially the limited cutaneous subtype (McAllister et al., 1994). Studies demonstrate significantly elevated endoglin levels in limited cutaneous SSc patients compared to those seen in dcSSc, SLE, or normal controls (Fujimoto et al., 2006).

Beyond cytokines, EC abnormalities show that vasculopathy may be a central and early aspect of SSc. In a study of UCD 200/206 chickens (see above), skin EC are the first cells to undergo apoptosis, even prior to inflammation and fibrosis (Sgonc et al., 1996).

Although the mechanism of EC apoptosis is not clear, multiple pathways have been investigated as a potential cause for the EC injury, including immunological, viral, and ischemic causes (Kahaleh, 2008).

Platelet Activation

Microvascular EC injury and apoptosis can increase vascular permeability and dysregulate control of vascular tone through the release of vasoactive mediators. The edematous phase of cutaneous SSc may be a manifestation of these changes and RP is clearly a result of dysregulated vascular tone (Kahaleh and LeRoy, 1999; Generini and Matucci Cerinic, 1999). EC damage, in turn, provokes the migration of vascular smooth muscle cells and pericytes to the intimal layer of blood vessels where they transdifferentiate into collagen secreting myofibroblasts. The resulting intimal proliferation leads to intimal thickening, luminal narrowing, and blood vessel obliteration (Rajkumar et al., 1999).

Platelets are actively involved in the pathogenesis of SSc. EC injury/activation induces platelet activation, aggregation, and thrombus formation that lead to occlusion of the already narrowed blood vessels, further exacerbating tissue ischemia and necrosis (Kahaleh and LeRoy, 1999). The activated platelets also produce PDGF

and TGF- β which mediate the fibrotic process and collagen synthesis (Assoian et al., 1983). On the other hand, platelets from SSc patients show increased expression of non-integrin receptors for type 1 collagen which may, in part, explain the increased platelet aggregation in SSc (Chiang et al., 2006).

Cytokine Abnormalities

Vascular endothelial growth factor (VEGF) is a potent angiogenic mediator and would be expected to be low, given the decreased angiogenesis found in SSc. Strangely, the expression of VEGF and its receptors VEGFR1 and 2 are upregulated in SSc, despite ineffective vascular repair mechanisms (Mackiewicz et al., 2002; Distler et al., 2002, 2004; Choi et al., 2003; Manetti et al., 2010). This apparent paradox was explained by recent studies which revealed the presence of VEGF isoforms with different functional properties. An angiogenic factor, VEGF165, and an angiostatic factor, VEGF165b, are the result of alternative splicing of the terminal exon of VEGF-A, pre-mRNA. VEGF165b is significantly upregulated in SSc and is responsible for the elevation of the “total” VEGF level in SSc. Like VEGF165b, the angiogenesis inhibitor endostatin is elevated in SSc (Manetti et al., 2011).

The interaction of urokinase-type plasminogen activator (uPA) with its receptor uPAR is important in mediating the interaction of the EC with the ECM during angiogenesis. MMP-12 is responsible for cleaving domain 1 of uPAR in SSc EC, resulting in truncated and nonfunctioning receptors and thus impairing EC movement and effective new blood vessel formation (D'Alessio et al., 2004).

Cellular Abnormalities

As a physiological response to tissue ischemia, endothelial progenitor cells (EPC) can mobilize from the BM to the site of vascular lesions and differentiate into a variety of mature cells. This is a dynamic and highly complex process that requires mobilization, chemotaxis, adhesion, proliferation, and differentiation of the progenitor cells (Asahara et al., 1999). Although it is poorly understood, cytokines, tissue hypoxia, and angiogenic growth factors including granulocyte monocyte-colony stimulating factor (GM-CSF) and VEGF seem to play a major role in driving progenitor cells to the damaged tissue (Zamaretti and Zisch, 2005).

Avouac et al. (2008) demonstrated increased blood levels of EPC in SSc, supporting mobilization from the BM. Furthermore, the subset of patients with digital vascular lesions and high severity score for disease expression displayed low levels of EPC, suggesting increased

homing at this stage. Other data showed a significant reduction in the number of EPC in patients with diffuse SSc when compared with healthy controls and rheumatoid arthritis patients (Kuwana et al., 2004).

Recent studies demonstrated a reduction in the differentiation capacity of EPC in SSc patients, implying impaired vasculogenesis and inadequate vascular repair mechanism (Del Papa et al., 2006).

Human mesenchymal stem cells (MSC) are multipotent cells that are present in the BM of adults and might be another source of EPC. The *in vitro* differentiation potential of MSC in patients with SSc reveals early senescence and decreased capacity to perform specific endothelial activities such as capillary morphogenesis and chemoinvasion, suggesting that endothelial repair may be impaired in SSc. Furthermore, the possibility that this impairment can be partially reversed using VEGF and stromal cell-derived factor 1 suggests that these cells might be helpful in future regenerative treatment (Cipriani et al., 2007).

Immunological Abnormalities

Activation of the immune system plays a crucial role in the vasculopathy and fibrosis of SSc (Figure 33.1).

T Cells

Macrophages and activated T cells represent a large part of the cellular infiltrates in the affected tissues of SSc. The initiation of the presumed autoimmune response in SSc could be the result of interaction between the two limbs of the immune system, innate and adaptive immunity. IL-4 and IL-13 are secreted from macrophages and monocytes as part of the early activation of the innate immune system. These two cytokines are necessary for the differentiation of T helper cells Th0 into Th2 cells; the latter are predominant in SSc. Upon binding of IL-4 to its receptors on Th2, stimulation of the STAT6/GATA3 system occurs, leading to the production of IL-4, IL-5, and IL-13 with further activation of Th2 through autocrine and paracrine signaling (Higashi-Kuwata et al., 2009; O'Reilly et al., 2012). In addition, levels of regulatory T cells (CD4⁺ Foxp3⁺ T_{regs}), one of the major mechanisms for maintenance of self-tolerance, were low in one study (Klein et al., 2011).

The peripheral blood levels of CD3⁺, CD4⁺, CD8⁺, and CD19⁺ cells were variously low, normal, or high compared to normals, so this area remains quite controversial (Fiocco et al., 1993; Artlett et al., 2002; Ercole et al., 2003; Ingegnoli et al., 2003; Mitsuo et al., 2006; Gambichler et al., 2010).

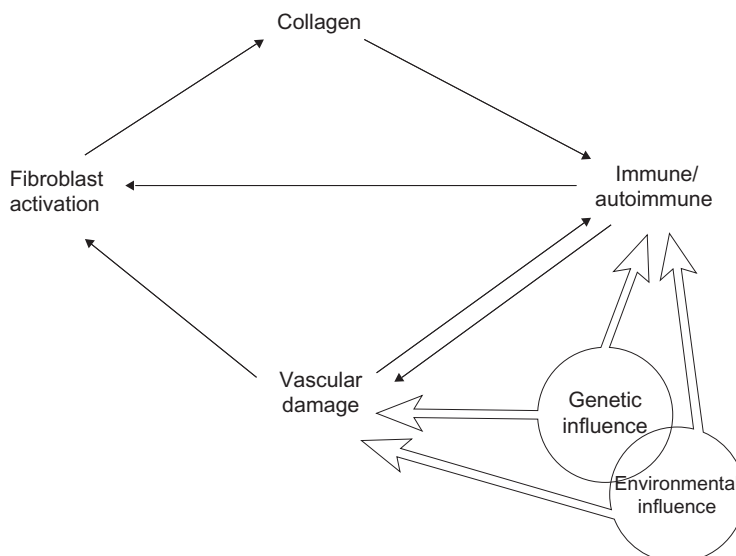

FIGURE 33.1 Relationship of potential triggering factors and the pathogenetic mechanisms involved in the development of systemic sclerosis.

B Cells

A growing body of evidence points towards the role of B cells in the initiation of the immune response in SSc. The B cell can act as an antigen presenting cell through interaction of antigen with low affinity B cell receptors (BCR) (Constant et al., 1995). CD19 is a cell surface molecule expressed on the surface of B cells that interacts with the BCR, lowering the threshold for antigen-dependent stimulation of the BCR (Carter and Fearon, 1992). The expression of CD19 was increased in SSc B cells and also in the animal models of the disease (Sato et al., 2000).

The use of rituximab (RTX) in newborn Tsk mice significantly suppresses the development of skin fibrosis, autoantibodies, and hypergammaglobulinemia, although this did not pertain when used in established disease (Hasegawa et al., 2006). In uncontrolled case reports RTX was effective in some but not all patients and a controlled trial of B cell depletion in SSc is under way (Lafyatis et al., 2009).

Antibodies

The sensitivity and specificity of different methods used in detecting autoantibodies can affect, to a certain extent, the strength and frequency of these antibodies in SSc patients (Walker and Fritzler, 2007). Indirect immunofluorescence (IIF) using rapidly dividing cell-lines is the most frequently used assay to screen for autoantibodies. Despite it being more specific, it is slower and more expensive. The use of enzyme-linked immunosorbent assay (ELISA) is becoming more popular. It is automated and also easier to use for multiple antibodies. However, it is less specific (Wiik et al., 2004).

There is a wide range of autoantibodies found in SSc and nuclear antigens represent the primary target for these antibodies. ANA are found in more than 90% of SSc patients (Medsker and Steen, 1996). Anti-Scl-70 and ACA are highly specific for SSc and support the clinical diagnosis of the disease (Reveille et al., 2003). The virtual mutually exclusive existence of these antibodies in different disease subtypes and their correlation with certain disease complications raises the likelihood that different disease processes lead to the development of these serological variations (Castro and Jimenez, 2010; Bunn and Black, 1999).

Both PDGF receptor-specific antibodies and AECA seem to be involved in SSc pathogenesis. PDGF plays an important role in the fibrotic process of SSc. Stimulatory autoantibodies against PDGF receptors were detected in SSc sera (Baroni et al., 2006); upon binding to the receptors, the RAR-ERK1/2 pathway is induced and increases the level of reactive oxygen species (ROS), and the persistence of ROS and ERK1/2 favor an increased collagen gene expression (Svegliati et al., 2005).

Although it can be detected in other diseases, AECA are present in 40–50% of SSc cases (Kahaleh, 2008) and may be linked to the development of pulmonary fibrosis in this disease (Lewandowska et al., 2013). These AECA are directed against IgG- and IgM-related antigens or CENP-B (García de la Peña-Lefebvre et al., 2004; Tamby et al., 2005; Servettaz et al., 2006). As EC apoptosis is one of the earliest events in SSc, AECA-dependent cell-mediated cytotoxicity may be an important mediator between antibodies and cellular abnormalities (Sgonc et al., 2000).

Cytokines

Various cytokines which mediate EC damage and fibrosis are elevated in SSc. Interleukin (IL)-6 receptors are expressed on the surface of monocytes, neutrophils, and B cells (Jones and Rose-John, 2002). The effect of IL-6 on EC, fibroblast, and some subsets of T cells are through a trans signaling process. This process ultimately activates STAT3 which contributes to EC injury/activation and induces the expression of adhesion molecules (Romano et al., 1997). The production of sIL-6R is mediated in part by IL-8 and leukotriene B4 (LTB4) (Marin et al., 2002). IL-6, sIL-6R, and IL-8 are elevated in SSc serum (Reitamo et al., 1993; Hasegawa et al., 1998), and LTB4 levels are elevated in the bronchoalveolar lavage (BAL) fluid of these patients (Kowal-Bielecka et al., 2005).

Like many other proinflammatory and profibrotic cytokines, the soluble receptors for IL-2 (sIL-2R), IL-6 (sIL-6R), and TNF- α (sTNF- α RI) are elevated in SSc and are linked to the activity and progression of the disease (Lis and Brzezińska-Wcisło, 2003). In all cases, however, it is not clear if these cytokines play a primary or secondary role in SSc. Further work on these proteins is necessary and is, in fact, under way.

IL-4 and IL-13 are profibrotic cytokines which mediate the production of collagen and ECM in a direct and indirect fashion via the stimulation of TGF- β . The serum levels of both IL-4 and IL-13 are elevated in SSc (Hasegawa et al., 1997).

Chemokines

Inflammatory chemokines play a major role in the pathology of SSc. They induce trafficking and accumulation of cells at the lesional sites and the expression of chemokines and their receptors are increased in SSc.

CXCR4 is expressed on the surface of multiple cell types including monocytes and fibrocytes. CXCR4 induces cell migration to lesional sites under the influence of its ligand CXCL12. Both CXCR4 and CXCL12 are elevated in the lung tissues of SSc-ILD and in the edematous skin lesions of both dcSSc and lcSSc. Fibrocytes express other receptors that respond to a wide range of chemokines and, thus, fibrocytes may play a role in the fibrotic process (Cipriani et al., 2006; Tourkina et al., 2011).

The function of chemokines goes beyond chemoattraction. CCL5 (also known as regulated upon activation, normally T cell expressed and secreted (RANTES)), for example, directly activates T cells and stimulates them to produce INF- γ (Appay et al., 2000). High levels of circulating CCL2 correlated with the modified Rodnan skin score (mRSS) (Bandinelli et al., 2012).

Fibrosis

A wide range of cells play different roles in the process of fibrosis, either directly or indirectly, through cell–cell interaction or the production of mediators. Fibroblasts act as the pivotal cells in the process of fibrous tissue production, both physiologically and pathologically, as in SSc. Proliferation of local cells and migration of others, with subsequent *in situ* differentiation to fibroblasts and myofibroblasts, tend to expand the pool of cells and upregulate ECM production (Abraham and Varga, 2005; Abraham et al., 2007). We will describe the multiple factors that affect fibrosis in SSc.

PDGF, ET-1, CTGF, and especially TGF- β , through different signaling pathways, mediate the transdifferentiation of fibroblasts and other cells into myofibroblasts, a specialized form of fibroblasts with some features of smooth muscle cell; they express α -SMA stress fibers, the ED-A variant of fibronectin, and Thy1 glycoprotein on their surface, all strongly linked to SSc. Myofibroblasts are able to contract and mechanically remodel the newly formed ECM. The persistence of active myofibroblasts is assumed to play an important part in the fibrotic process of SSc through upregulation of ECM production and increased cytokine secretion that leads to further stimulation by means of autocrine and paracrine signaling (Abraham and Varga, 2005; Abraham et al., 2007).

The ECM plays an active and complex role in influencing the survival, development, migration, proliferation, shape, and function of cells that contact it (Alberts et al., 2002). In SSc the normal equilibrium of collagen synthesis and degradation is oriented toward synthesis (Varga and Bashey, 1995).

Type I collagen is the most common collagen type and represents the major structural component of dermal ECM. It is composed of two α 1 chains and one α 2 chain, encoded by *COL1A1* and *COL1A2* genes, respectively (Sykes and Solomon, 1978; Huerre et al., 1982). The transcription of these genes involves the interaction of regulatory elements with transcription factors, such as specific protein 1 (Sp1), specific protein 3 (Sp3), CCAAT-binding factor (CBF), collagen-kroppel box (c-Krox) and nuclear factor- κ B (NF- κ B) (Kypriotou et al., 2007; Beachef et al., 2012).

Although human c-Krox (hc-Krox) suppresses type I collagen genes (both *COL1A1* and *COL1A2*) (Widom et al., 2001), recent data suggest that hc-Krox has a transactivating role on human *COL1A1* gene in normal and pathological dermal fibroblasts, interacting with other transcription factors to upregulate type I collagen synthesis (Kypriotou et al., 2007).

Separately, c-Krox promotes CD4⁺ T cell lineage differentiation rather than CD8⁺ T cells during intrathymic

T cell positive selection, indicating that c-Krox has an early role in the pathogenesis of scleroderma (Sun et al., 2005).

TGF- β plays a major role in the pathogenesis of fibrosis in SSc. TGF- β is secreted by numerous cell types including fibroblasts, immune cells, and platelets. TGF- β is a potent inducer of collagen synthesis and other ECM proteins and at the same time suppresses degradation of the matrix. TGF- β is vital in wound healing and tissue repair physiologically. However, dysregulation of TGF- β at different levels can lead to fibrosis and a wide spectrum of other diseases, including cancer and SSc (Varga and Bashey, 1995; Branton and Kopp, 1999).

The expression degree, serum/tissue levels, and activity of TGF- β is significantly altered in SSc compared to normal control groups and depends on the clinical features, stage, and type of SSc. For example, the level of TGF- β 1 (one of three isoforms) is significantly elevated in the BAL fluid from patients with SSc lung disease, while the level of TGF- β 2 (another isoform) is significantly less than the control group (Ludwicka et al., 1995). There were no significant differences in the levels of total serum TGF- β among dcSSc, lcSSc, and normal, but active TGF- β 1 was significantly lower in dcSSc compared to the other two groups and was negatively correlated to the skin score (Dziadzio et al., 2005). This, and the evidences of increased expression of TGF- β receptors in SSc, point toward the sequestration of active TGF- β 1 in affected sites (Yamane et al., 2002; Pannu et al., 2006).

TGF- β is secreted in the ECM in an inactive form and requires local activation to be biologically effective. It is frequently related to fibrotic diseases (Nakerakanti and Trojanowska, 2012). SSc patients show upregulation of thrombospondins 1 and 2 in dermal SSc fibroblasts, detailing one of the mechanisms locally activating TGF- β (Avouac et al., 2011). Other studies showed a significant elevation of other local TGF- β activators such as α v β 5 integrins (Asano et al., 2005).

Likewise, complex mechanisms have been discovered which transmit membrane ligand binding to activation of nuclear factors. SMADs 3/4 or blocking nuclear factors SMAD7 all show the degree and complexity of TGF- β regulation (Zhang et al., 1996; Nakao et al., 1997a,b; Hayashi et al., 1997).

TGF- β and other growth factors can also induce their profibrotic effects in fibroblasts via SMAD-independent pathways such as c-Abl and CTGF. c-Abl is a non-receptor tyrosine kinase which stimulates TGF- β and PDGF. c-Abl is inhibited by imatinib and its congeners; this activity seems to be part of its potential in treating SSc (Plattner et al., 1999; Daniels et al., 2004; Bhattacharyya et al., 2009).

CTGF is a matrix protein that connects the cells to the ECM. It is part of the CCN family and is induced by

TGF- β , ET-1, hypoxia, shear stress, and biomechanical deformation (Gao and Brigstock, 2003; Leask and Abraham, 2006). CTGF has a clear direct profibrotic effect by inducing collagen gene expression in lung fibroblasts through a SMAD-independent pathway (Ponticos et al., 2009).

PDGF is another agent that plays a role in the pathogenicity of SSc. It is a mitogen and chemotactic factor with mitogenic and chemotactic effects on connective tissue cells (Seppä et al., 1982). PDGF is produced by smooth muscle cells, fibroblasts, EC, macrophages, in addition to platelets (Varga and Abraham, 2007). The fibroblasts from SSc skin lesions showed overexpression of PDGFR- α , leading to increased cell proliferation and transdifferentiation to myofibroblasts (Liu and Zhang, 2012).

A relatively newly described pathogenetic pathway involves the Wnt pathway and β -catenin. The Wnt family of signaling proteins regulates gene expression after cell surface receptor stimulation. Downstream of the Wnt signaling pathway is β -catenin which transmits the regulatory signals from the cytoplasm to the nucleus (Logan and Nusse, 2004). High β -catenin levels were found in the nucleus of SSc fibroblasts and these concentrations were directly profibrotic in SSc after exposure to increased expression of Wnt-1 and Wnt-10b (Beyer et al., 2012).

CONCLUDING REMARKS AND FUTURE PROSPECTS

Despite the number of studies on scleroderma/SSc and a great deal of progress, we are still far from a clear picture of the pathogenesis of disease. The interactions between different genetic, environmental, and molecular factors, at many levels, are behind the pathological complexity and phenotypical heterogeneity of scleroderma/SSc. Studies over many years helped uncover various mechanisms that may play a part in the development of SSc and that point to targets for new treatment strategies. This plethora of pathways and mechanisms, as their place and importance is dissected, should lead to better therapy.

Overall SSc is a combined disease which is initiated by endothelial damage and amplified by autoimmune response. One could say it is an autoimmune disease but this is just a simplification; on the other hand, one could approach treatment by considering immune suppressing medications and get a good response.

INTRODUCTION

In 1983, a discrete syndrome was described by Graham Hughes in which lupus patients with antiphospholipid antibodies were prone to arterial/venous thrombosis, recurrent abortions, neurological manifestations, and occasional thrombocytopenia (Hughes, 1983). In the following years the Hughes' syndrome was delineated as a systemic disease that can affect both children and adults and can present as a primary disorder or as secondary to other autoimmune disease (Shoenfeld et al., 2009). The definition of this classical autoimmune syndrome has greatly advanced from the original reports and classification criteria for antiphospholipid syndrome (APS) formulated in Sapporo, Japan, in 1998 to the current ones published in 2006 (Miyakis et al., 2006; Cervera and Ra, 2008) (Table 34.1). For determination of APS at least one classical clinical criterion (i.e., vascular thrombosis or pregnancy morbidity) and one serological criterion (i.e., the persistence presence of anti-cardiolipin or anti-B2GPI or

lupus anticoagulant) has to be met (Giannakopoulos and Krilis 2013).

Antiphospholipid antibodies (aPL) can be detected in up to 5–6% of normal healthy subjects and in 30–40% of SLE patients (Biggioggero and Meroni, 2010). Secondary APS is estimated to appear in 10–15% of systemic lupus erythematosus (SLE) patients, and less in other autoimmune diseases, whereas the prevalence of primary APS is yet unknown (Di Prima et al., 2011).

aPL appearing in healthy subjects are usually detected transiently and at low levels. They tend to appear in older individuals and in association with infections, vaccinations, malignancies, and exposure to certain drugs. Remarkably, such aPL are frequently clinically insignificant (Shoenfeld et al., 2008a; Biggioggero and Meroni, 2010). In contrast patients with Antiphospholipid Syndrome (APS), either primary or secondary, typically present with persistent (more than 12 weeks), high-level aPL sero-positivity and significant related morbidity and mortality (Cervera et al., 2009).

TABLE 34.1 Summary of the Sydney Consensus Statement on Investigational Classification Criteria for APS^a.

Anti-phospholipids antibody syndrome is present if at least one of the clinical criteria and one of the laboratory criteria that follow are met:

Clinical criteria

1. Vascular thromboses: One or more documented episodes of arterial, venous, or small vessel thrombosis—other than superficial venous thrombosis—in any tissue or organ. Thrombosis must be confirmed by objective validated criteria. For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.
2. Pregnancy morbidity:
 - a. One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, or
 - b. One or more premature births of a morphologically normal neonate before the 34th week of gestation because of: (i) eclampsia or severe pre-eclampsia defined according to standard definitions, or (ii) recognized features of placental insufficiency, or
 - c. Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded.

Laboratory criteria

1. Lupus anticoagulant (LA) present in plasma, on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Haemostasis (Scientific Subcommittee on LAs/phospholipid-dependent antibodies).
2. Anticardiolipin antibody (aCL) of IgG and/or IgM isotype in serum or plasma, present in medium or high level (i.e., >40 GPL or MPL, or >the 99th percentile), on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA.
3. Anti-b2-glycoprotein-I antibody of IgG and/or IgM isotype in serum or plasma (in level >the 99th percentile), present on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA, according to recommended procedures.

^aMiyakis et al. (2006).

In the largest survey of APS patients conducted by the Euro-Phospholipid Group (Cervera et al., 2009), 1000 APS patients, with a mean age of 42 ± 14 years at study entry were followed for a 5-year period. Among these, 20% developed recurrent thrombosis despite appropriate therapy, and 7.4% receiving oral anticoagulants presented with hemorrhage. In this cohort 5.3% of patients died within the follow-up period mostly due to bacterial infection, myocardial infarction, or stroke.

THE CLINICAL SPECTRUM OF ANTIPHOSPHOLIPID SYNDROME

APS is usually diagnosed following obstetric or thrombotic morbidity. Nonetheless the clinical spectrum of APS is considered nowadays to be wider and includes systemic and organ-specific symptoms induced by both thrombotic and immune-mediated mechanisms (Shoenfeld, 2007; Marai et al., 2004).

Obstetric APS

Obstetric complications are a hallmark of APS including mainly recurrent miscarriages and preterm deliveries. Early recurrent miscarriage (<10 weeks of gestation) occurs in about 1% of the general obstetric population of which 15% are associated with APS. Fetal loss (≥ 10 weeks of gestation) is less common and more strongly associated with the presence of aPL (Di Prima et al., 2011). Women with high-level aPL and a history of previous fetal loss have up to 80% risk of current pregnancy loss if not

treated (Galarza-Maldonado et al., 2012). In addition neonatal adverse outcomes as prematurity, intrauterine growth restriction, or rare fetal/neonatal thrombosis have been frequently described in patients with APS as well as maternal hypertensive disorders such as preeclampsia/eclampsia and HELLP syndrome (i.e., hemolytic anemia, elevated liver enzymes, and low platelet counts). Treatment of obstetric APS is still controversial and requires a multidisciplinary approach (Andreoli et al., 2012). The goals of such an approach are to improve maternal and fetal–neonatal outcomes by keeping to a minimum the risks recognized by both APS and its recommended therapy (Bramham et al., 2010; Galarza-Maldonado et al., 2012).

Thrombotic APS

Venous and/or arterial thrombosis are distinctive characteristic of APS (Taraborelli et al., 2012), and vessels in any site and of any size may be involved (Saponjski et al., 2011). Deep vein thromboses, pulmonary embolism, and strokes are the most commonly reported. Such thrombotic events are the main cause of morbidity and mortality in APS, and they tend to recur particularly in untreated patients (Taraborelli et al., 2012). The confirmation of thrombosis by an objective method is a requirement of the Sapporo criteria, nowadays performed by a diversity of invasive and noninvasive methods such as angiography, ultrasound, computed tomography (i.e., 64-multi-slice computed tomographic angiography), and others (Saponjski et al., 2011). Histopathology may also be utilized to confirm the diagnosis of APS-associated

thrombosis once there is no evidence of inflammation in the vessel wall (Taraborelli et al., 2012).

Neurological APS

Neurological manifestations were detailed in the original description of APS and have since remained a main cause for morbidity and mortality among patients affected by this syndrome (Hughes, 1983). Central venous thrombosis, i.e., stroke and transient ischemic attack are the most common and are the only manifestations included in APS criteria (Appenzeller et al., 2012). APS-related strokes often occur in young patients and have a tendency to recur without an adequate therapy (Andreoli et al., 2012). In addition to local thrombosis mediated by aPL, vascular heart disease may become a source of emboli and related cerebrovascular events (Andreoli et al., 2012). Yet, in the last 30 years aPL positivity has been correlated with a wide variety of neurological expressions including headache, cognitive dysfunction, psychosis, depression, dementia, migraine, convulsions, chorea, transverse myelitis, Guillain-Barré syndrome and a multiple sclerosis-like illness (Shoenfeld et al., 2004; Cimaz et al., 2006; Rodrigues et al., 2010). Additionally, APS should be considered in all unexplained cases of retinal arterial and venous thromboses, as well as in cases of unusual ocular inflammations, particularly in young individuals (Arnsion et al., 2010). APS-related ocular symptoms reflect both anterior and posterior pole involvement and include blurring of vision, dry eye sensation, amaurosis fugax, decreased visual acuity, diplopia, orbital and ocular pain, visual field defects, photophobia, scotoma, floaters, photopsia, and others.

Hematologic APS

Thrombocytopenia occurs in 20–40% of APS patients (Cervera et al., 2011b) and is associated with systemic involvement (Krause et al., 2005a). It is usually moderate, with platelet counts greater than 50K, rarely associated with major bleeding episodes, and does not require therapeutic intervention. Platelet reduction may be due to their destruction by autoantibodies or via their consumption following activation and aggregation (George et al., 1999). Some groups have reported anti-platelet glycoprotein antibodies which strongly correlate with thrombocytopenia whereas others observed that aPL bind directly to activated platelets via b2-glycoprotein-I thereby promoting platelet activation and aggregation (Krause et al., 2005a). Autoimmune hemolytic anemia is less frequent, reported in 6–10% of APS patients (Taraborelli et al., 2012). A significant association between the presence of aPL and a positive Coombs test as well as the co-occurrence of both autoimmune thrombocytopenia and

hemolytic anemia (named Evans syndrome) has been described (Rottem et al., 2006; Cervera et al., 2011b). Lymphopenia and neutropenia are well-recognized features of SLE, and therefore found more commonly in patients with APS associated with SLE.

Dermatologic APS

Skin manifestations are noted in 49% of APS patients and are the presenting signs in 30–40% of cases (Frances et al., 2005). The most frequent is livedo reticularis, a red or bluish alteration of the skin with a net-like pattern attributed to blood stasis in capillaries and venules (Toubi et al., 2005). The pathophysiology of livedo reticularis is not well characterized, but the relationship with arterial thrombosis such as Sneddon's syndrome suggests a possible role for an interaction of aPL with the endothelial cell or other cellular element in blood vessels (Taraborelli et al., 2012). Cutaneous necrosis is observed in 5.5% of patients with APS and the most commonly involved sites are the upper and lower extremities, helices of ears, cheeks, trunk, and forehead. These lesions may appear in the post-phlebotic state (following a thrombosis) or caused by a circumscribed skin necrosis. The latter may be confirmed by a biopsy demonstrating non-inflammatory thrombosis of dermal vessels without evidence of vasculitis. Cutaneous digital gangrene, with preceding ischemic symptoms, has also been observed in up to 7.5% of patients with APS. Many non-specific skin lesions of which some resemble vasculitis (pseudovasculitis) including red macules, purpura, cyanotic lesions on the hands and feet, ecchymoses, and painful skin nodules as well as primary anetoderma have also been reported.

Cardiac APS

The heart is one of the target organs in APS. Valve abnormalities, vegetations, and/or thickening, termed Libman-Sacks endocarditis, are the most common manifestations described in 30 to 50% of patients (Cervera et al., 2011a; Ziporen et al., 1996). Of note valve damage is more frequent in patients with secondary APS, is highly associated with the presence of aPL (Nesher et al., 1997), and coexists with neurological manifestations (Krause et al., 2005b). Myocardial infarction is diagnosed in 5.5% of patients with APS and is also significantly associated with the presence of aPL (Cervera et al., 2011a). Interestingly, in APS patients, acute myocardial infarction can occur in the absence of coronary artery lesions, especially in premenopausal women (Taraborelli et al., 2012). As a consequence of either valvular disease, myocardial infarction and secondary pulmonary hypertension, left ventricular systolic and diastolic dysfunction have both been reported. Taking it all together, echocardiographic

follow-up is recommended for all APS patients (Cervera et al., 2011a).

Pulmonary APS

Pulmonary embolism and infarction constitute the most frequent pulmonary manifestation of APS. In the Europhospholipid cohort pulmonary embolism was the presenting manifestation in 9% of patients (Taraborelli et al., 2012). Leaving aside this classical thrombotic manifestation, other pulmonary expressions including pulmonary hypertension, acute respiratory distress syndrome, intra-alveolar hemorrhage, and fibrosing alveolitis have been described in the clinical spectrum of APS features (Stojanovich et al., 2012). Notably, the presence of aPL correlated with distinct pulmonary types of involvement, such as the link between aCL and pulmonary arterial thrombosis, adult respiratory distress syndrome, and fibrosing alveolitis (Stojanovich et al., 2012).

Renal APS

Anti-phospholipid-mediated thrombosis can affect different parts of the kidney depending on the type and size of the vessels. Large vessel involvement is usually in the form of thrombosis and/or stenosis that present as marked hypertension, renal dysfunction, and pain. In the case of occlusive lesions both *in situ* thrombosis and embolization from heart lesions can take place (Taraborelli et al., 2012). Involvement of smaller vessels is most commonly expressed as thrombotic microangiopathy or non-thrombotic glomerulopathies (Chaturvedi et al., 2011), clinically characterized by hypertension, renal failure, and/or proteinuria. Investigation in such cases should include a renal biopsy (Chaturvedi et al., 2011).

Catastrophic Antiphospholipid Syndrome

The term catastrophic antiphospholipid syndrome (CAPS) was first used in 1992 to define an accelerated form of APS resulting in multi-organ failure. Currently this most severe form of APS is present in less than 1% of APS patients and is defined by the clinical evidence of three or more organs affected within a short period of time. CAPS is commonly triggered by infection, trauma, surgery, pregnancy or others, and histologically multiple small vessels as well as some large vessels are concomitantly occluded (Erkan et al., 2010). In recent years following improved diagnosis and intervention, the mortality rate of CAPS decreased.

THE ANTIPHOSPHOLIPID ANTIBODIES

The aPL comprise more than 20 different autoantibodies, of which just three serve as diagnostic criteria for APS. The pathogenic effects of these antibodies are exerted through binding to various cells, including monocytes, endothelial cells, and trophoblasts, leading to the recruitment of cell surface receptors and subsequent perturbation of intracellular signaling pathways (Blank et al., 1991; Giannakopoulos and Krilis 2013). aPL target a variety of antigens including negatively charged phospholipids, phospholipid-binding proteins (particularly b2GPI and prothrombin) and factors related to hemostasis (De Groot et al., 2012). Notably, up to 5% of healthy individuals, lacking any APS features, demonstrate aPL seropositivity. In most of these cases aPL appear transiently, at low levels, following exposure to an environmental trigger, such as an infectious disease. Thus, aiming to improve the specificity of the Sapporo criteria the pathogenicity of criteria-relevant aPL was defined by three requisites (Table 34.1): (1) the detection of aPL on two or more occasions at least 12 weeks apart; (2) the presence of specific isotypes, namely IgG or IgM; and (3) the presence of aPL in medium to high levels (i.e., >40 GPL or MPL), or in levels above the 99th percentile for a specific population (Miyakis et al., 2006).

The pathogenicity of aPL is further supported by the observation that higher levels of aPL as well as the concomitant presence of the three criteria aPL (lupus anticoagulants, anti-cardiolipin, and anti-b2GPI) indicate a subgroup of high risk APS (Sciascia et al., 2011). Recently Pengo et al. (Pengo et al., 2010) analyzed data of 160 APS patients with “triple positive” sero-reactivity. At study entry, thrombosis was documented in 47%, arterial thromboembolism in 43%, pregnancy morbidity in 9.7%, and catastrophic antiphospholipid syndrome in 2.5% of patients. During 10 years of follow-up, 10 out of 160 patients died and 44.2% experienced another thrombotic event.

Another mandate of the APS criteria is the need for “standardized” laboratory assays to detect any one of the criteria-relevant aPL. The latter are detected by functional assay (lupus anticoagulant) or by solid phase immunoassay, anti-cardiolipin and anti-b2GPI (Biggioggero and Meroni, 2010). Although attempts at standardization of these tests have been conducted over the last three decades, there remain inconsistencies, inter-assay and inter-laboratory variations, as well as various issues regarding the interpretation of results. Hence, updated guidelines for lupus anticoagulants (LAC) testing (Martinuzzo et al., 2012) have been issued, followed by the formulation of a task force of scientists and pioneers in the field aiming to standardize and improve the solid phase assays (Pierangeli et al., 2011).

FIGURE 34.1 The plasma protein $\beta(2)$ -glycoprotein I (b2GPI) is a phospholipid binding protein. It is constructed of five domains (I–V) that can present in a circular non-active form or in an active, open J-shaped conformation, as presented in the figure. Each of the five homologous domains of b2GPI include approximately 60 amino acids, and certain peptides in each domain have been identified as autoantigens (three of which are detailed in this figure). Anti-b2GPI antibodies can form a complex with b2GPI and activate intracellular signaling only in its open conformation while cryptic epitopes are exposed. *With acknowledgment to Prof. Miri Blank (The Zabudovitch Center for Autoimmune Diseases, Israel).*

The b2GPI–Anti-b2GPI Complex in APS

The term “antiphospholipid syndrome” is actually confusing, as most pathogenic aPL are not directed against phospholipids but towards the plasma protein $\beta(2)$ -glycoprotein I (b2GPI). The latter is a phospholipid-binding protein, present either in a circulating form or bound to cells (De Groot et al., 2012). b2GPI participates in the innate immune responses (i.e., lipopolysaccharide scavenging and clearance of unwanted anionic micro-particles) and has anti-thrombotic properties. It is constructed of five domains that can present in a circular non-active form or in an open J-shaped conformation that can bind and activate intracellular signaling. The five homologous domains of b2GPI each include approximately 60 amino acids, and certain peptides in each domain have been identified as autoantigens (Figure 34.1). Domain V is located at the C terminus of the protein and contains a hydrophobic core surrounded by 14 positively charged residues that promote electrostatic interactions with negatively charged membrane components (Mahler et al., 2012). Anti-b2GPI antibodies can form a complex with b2GPI only in its open conformation (de Groot and Meijers, 2011). Moreover, this conformational change in b2GPI enables the exposure of cryptic epitopes and the formation of specific autoantibodies (de Laat et al., 2011).

The formation of b2GPI–anti-b2GPI complexes is closely linked with various manifestations of APS both in humans and in animal models of this autoimmune disease. Lately, the role of anti-b2GPI antibodies directed at different domains of b2GPI has become a focus of attention. Antibodies directed at domain I of b2GPI are associated with a higher risk of thrombosis and, to a lesser extent, pregnancy complications. In addition peptides derived from domain I of b2GPI were able to inhibit *in vivo* the pathogenicity of anti-b2GPI (Ioannou et al.,

2009; Mahler et al., 2012). Specific autoantibodies directed at other domains of b2GPI were less extensively studied. Nonetheless, the presence of an antibody directed at a peptide derived from domain III of b2GPI was found to be a significant predictor of recurrent spontaneous abortions (Shoenfeld et al., 2003). In contrast, reactivity to domains IV or V may be considered as “innocent” autoantibodies, as they were mainly identified in non-thrombotic conditions, such as healthy children born to mothers with autoimmune disease, and atopic children (Andreoli et al., 2011).

NON-CRITERIA APL ANTIBODIES

Only three aPL are considered among APS-relevant criteria, yet a number of “non-criteria” aPL have been linked with APS manifestations (Shoenfeld et al., 2008b). Likewise, in rare cases, a diagnosis of “sero-negative APS” was suggested.

aPL of the IGA Isotype

These are present in up to 40% of SLE patients with a higher rate in Afro-Caribbean individuals. Anti-cardiolipin antibodies of the IgA subtype were found to be thrombogenic in mice, whereas IgA directed at b2GPI were documented in a subgroup of sero-negative women with recurrent pregnancy losses. IgA class aPL were also an independent risk factor for cardiovascular mortality and thrombotic events in hemodialysis patients (Serrano et al., 2012) and SLE patients (Sweiss et al., 2010). Interestingly, unlike IgG directed at domains IV and V of $\beta(2)$ GPI, IgA antibodies that bind to these domains may contribute to thrombosis atherosclerosis (Iverson et al., 2006) and early pregnancy loss (Staub et al., 2006).

Low-level aPL

Another requisite for “criteria aPL” is the presence of levels above >40 GPL or MPL, as high levels confirm both specificity and a worse outcome (Simchen et al., 2011). Even so, lower levels may still be considered if they are above the 99 percentile, an index rarely known or taken into consideration by the treating physician. Besides, aPL levels may decrease during follow-up and if determined weeks or months following a suspected event may be below the required cut-off (Faricelli et al., 2008). Moreover, technical aspects may play a role while evaluating aPL levels. Vlachoyiannopoulos et al. (Vlachoyiannopoulos et al., 1998) reported low levels of aPL in six out of 22 APS patients depending to a certain extent on the method of detection, urea resistance, and reactivity directed at a complex of cardiolipin–b2GPI rather than at the distinct antigens.

During cell apoptosis, lysophospholipids are exposed on the cell surface and can become targets for antibodies. Consequently, aPL can be directed at a heterogeneous group of non-APS criteria antigens, and antigen complexes as phosphatidylethanolamine, phosphatidylserine, vimentin, annexin A5, prothrombin, phosphatidic acid, serine proteases, and more (Alessandri et al., 2011; Pierangeli et al., 2011).

Antiphosphatidylethanolamine (aPE) were found to be associated with fetal loss and venous thrombosis (Pierangeli et al., 2011). Sugi et al. (Sugi et al., 2004) reported the prevalence of aPE in patients with unexplained recurrent early or mid-to-late pregnancy losses. In this cohort different subtypes of aPE were observed in up to 19%, suggesting an association between these antibodies and pregnancy losses. In another study Sanmarco et al. (Sanmarco et al., 2007) evaluated the role of aPE in 270 patients with APS. These antibodies were present in 15% of patients and were associated with thrombosis (odds ratio (OR) 6; $p = 0.005$) especially in the absence of criteria-type aPL.

Antiphosphatidylserine (anti-PS) positivity was documented in women with recurrent pregnancy losses who were negative for aCL (Sater et al., 2012). Additionally, anti-PS can inhibit trophoblast development and invasion, and impede syncytiotrophoblast formation further supporting their pathogenic role (Blank and Shoenfeld, 2004).

Antiprothrombin antibodies (anti-PT) similarly to anti-b2GPI are the most common aPL detected by ELISA methods, as both PT and b2GPI are phospholipid-binding proteins. The coexistence of IgG anti-PT and lupus anticoagulants was found to be an essential risk factor for venous thromboembolism in patients with SLE (Nojima et al., 2001) and to play a role in the pathogenesis of thrombosis in APS (de Groot et al., 1998; von Landenberg et al., 2003; Haj-Yahia et al., 2003). Besides, anti-PT was linked to thrombosis and disease progression

in other conditions such as acute ischemic strokes in young women (Cojocaru et al., 2008), fetal death in women with previous uneventful pregnancies and seronegative aPL (Marozio et al., 2011), and more advanced primary biliary cirrhosis (Agmon-Levin et al., 2010).

Antibodies directed at the complex phosphatidylserine/prothrombin (aPS/PT) were reported to be markers of APS with a high degree of concordance to lupus anticoagulant activity (Hoxha et al., 2012; Vlasea et al., 2013). aPS/PT correlated in a cohort of 295 individuals with particular expressions of APS, namely venous thrombosis (OR 7.44; CI 3.97–13.92) and obstetric abnormalities (OR 2.37; CI 1.04–5.43), but not with arterial thrombosis. aPS/PT were also detected at high levels in patients with cutaneous polyarteritis nodosa (Kawakami et al., 2007) and localized scleroderma, especially among patients with generalized morphea (Hasegawa et al., 2006).

The seronegative APS definition has been suggested for patients with clinical manifestations indicative of APS but with persistently negative results utilizing assays to detect criteria aPL (Rodriguez-Garcia et al., 2012). Apparently these patients exhibit similar frequencies of thrombotic events and obstetric morbidity. Transient or false-negative aPL tests may explain some of these cases, as even today anti-b2GPI is routinely tested in only a small number of laboratories, and standardization of other criteria aPL is yet to be accomplished. In addition, non-criteria aPL are currently tested in only a few research laboratories (Cervera et al., 2012). Taking it all together one may consider testing for a broad profile of aPL may enable better definition of this subgroup of patients with APS-like disease.

THE MECHANISMS OF APL-MEDIATED DISEASE EXPRESSIONS

In the last three decades much effort has been devoted to clarify the pathogenic potential of aPL (Bakimer et al., 1992). Both vascular thrombosis and pregnancy loss are the classical clinical expression of the APS, therefore aPL pathogenicity was studied focusing on these clinical aspects. Notably, aPL-related vascular thrombosis can occur both on the arterial and the venous side, making this acquired procoagulant condition very peculiar in human disease. The first evidence of the aPL-related pathogenic potential was obtained through animals that carried aPL as part of their disease (i.e., lupus-like-prone mice), or alternatively naïve mice that were infused with antibodies or stimulated to produce their own aPL (Ziporen et al., 1997; Katzav et al., 2010). In a long series of studies different polyclonal and monoclonal aPL antibodies with various specificities were utilized inducing

pregnancy losses and enhancing the coagulation process. Probably in no other autoimmune disorders has there been so much evidence produced to show the pathogenicity *in vivo* of these autoantibodies. This body of evidence was pivotal in proving autoantibody-mediated damage, and at the same time prompted further *in vitro* studies aiming to define the cellular pathogenic effects of aPL. Originally both pregnancy loss and vascular occlusions were ascribed to the thrombogenic effect of aPL. Nowadays it is clear that placental thrombosis can be responsible for pregnancy failures, but at the same time it is accepted that aPL can exert a direct non-thrombotic effect on trophoblast cells (Di Simone et al., 2000) and other cells (Del Papa et al., 1995). Over the years, the concept of aPL itself has also been redefined. In fact, starting from the hypothesis that these autoantibodies were directed to phospholipids, we now know that in most cases they are directed to phospholipid-binding proteins (Giannakopoulos et al., 2011). Even if these antibodies are detected with different assays, the main target of the so-called aPL was identified as beta2-glycoprotein I (b2GPI), a phospholipid-binding protein. Almost all pathogenic effects of aPL have been shown using highly purified anti-b2GPI antibodies (Meroni et al., 2011). By reporting pathogenic effects of aPL, we will substantially refer to the effect of anti-b2GPI antibodies and anti-b2GPI–b2GPI complexes, unless otherwise specified.

Thrombotic Manifestations

aPL and The Coagulation Cascade

Several mechanisms have been described to explain the thrombophilic properties of aPL, generally related to their interaction with the coagulation and fibrinolysis systems or with cells involved in thrombus formation. These include b2GPI–anti–b2GPI complexes that were found to be localized to atherosclerotic plaques, mainly to oxidized low-density lipoprotein (LDL) (oxLDL), to induce autoimmune thrombogenesis (Matsuura et al., 2003), and to amplify thrombus size (Arad et al., 2011).

Activated protein C (APC) is a natural anticoagulant that interacts with factors Va and VIIIa impairing their procoagulant activity. In the presence of b2GPI–anti–b2GPI complexes, APC cannot exert its action possibly because it is unable to bind Va/VIIIa or, alternatively, the formed APC/Va/VIIIa complex is sterically impaired in its binding to a phospholipid surface (Vlachoyiannopoulos and Routsias, 2010). Antiphospholipid antibodies can also impair the anticoagulant function of antithrombin. This can occur because some of the targets such as thrombin or activated factor IX, when bound by aPL, are no longer available for antithrombin action (Chen et al., 2010). On the other hand, aPL can interfere with the fibrinolytic cascade.

Fibrin degradation, which allows thrombus remodeling and dissolution, is mediated by the active enzyme plasmin, is derived from the conversion of plasminogen, which is mediated by its activators, tissue-type plasminogen activator (tPA) and urokinase-type plasminogen activator (uPA), of which both are controlled by specific inhibitors (plasminogen activator inhibitors PAI-1 and PAI-2). In the presence of aPL, PAI-1 activity was reported as enhanced resulting in reduction of tPA and plasminogen activation. Apparently b2GPI protects tPA from the action of PAI-1, thereby promoting fibrinolysis; if b2GPI is bound by its specific antibodies, it cannot exert its protective action with the consequent prevalent action of the inhibitory effect of PAI-1 (Vlachoyiannopoulos and Routsias, 2010). Another impairment of fibrinolytic activity seems to be due to a possible direct binding of aPL to plasmin, followed by its inactivation (Yang et al., 2004). The data reported so far represent only some of the plausible mechanisms by which aPL interfere with the coagulation process, and recently another possible explanation has been formulated (Lambrianides et al., 2011). Many of the proteins involved in coagulation/fibrinolysis processes belong to the family of serine protease (SP) enzymes, such as APC, thrombin, plasmin, tPA, and others. These proteins share a high homology region at their catalytic domain. Most aPL recognize a conformational epitope that is shared by b2GPI molecule and the catalytic domain of SP. Therefore the presence of aPL can result in binding of SP molecules and impairment of their enzymatic activity, resulting in enhanced risk of thrombosis.

aPL Cellular Interactions

One of the most studied pathogenic effects of aPL deals with the interaction of antibodies with the cells involved in the coagulation process. This basically occurs through the recognition of b2GPI that has adhered to cell membranes. It is known that anti-b2GPI antibodies can upregulate adhesion molecules such as endothelial leukocyte adhesion molecule-1 (ELAM-1), vascular cell adhesion molecule-1 (VCAM-1), intracellular adhesion molecule-1 (ICAM-1), and tissue factor (TF), conditioning their expression on the cell surface. This process was described *in vitro* on monolayers of human umbilical vein endothelial cells (HUVEC) (Meroni et al., 1996) and its consequences were shown *in vivo* on CD1 mice infused with aPL: in fact in this model leukocytes were seen to adhere to vascular endothelium favoring clotting (Pierangeli et al., 1995). In the presence of aPL, HUVEC also significantly increase the production of some proinflammatory cytokines like IL-6 and IL-1 β . Therefore the consequence of the aPL effect on endothelium is the shift towards a proadhesive/procoagulant as well as proinflammatory phenotype.

These profound modifications are basically due to the presence of b2GPI on the endothelial surface. A number of possible receptors for b2GPI have been described on the endothelial cell surface. Heparin sulfate, annexin2 receptor, Toll-like receptors (TLR) 2 and 4, and apolipoprotein E receptor 2 were all shown to be involved in the thrombogenic mechanisms related to aPL using *in vitro* and *in vivo* models (Poulton et al., 2012). It was also observed that animals lacking one of these receptors are only partially resistant to the pathogenic potential of aPL, suggesting that they play a similar, probably redundant, role (Meroni et al., 2011). The binding of anti-b2GPI to its antigen on the endothelial surface should produce intracellular signaling, able to upregulate the cellular expression of adhesion molecules and TF. The signal can start from the receptors that are sensitive to the clustering of b2GPI that follows their specific antibody binding. Among receptors, those having a cytoplasmic tail, TLR 2 and 4 are most likely to be the favorite candidate. Several intracellular pathways have been described as activated, including nuclear factor κ B (NF κ B), p-38 mitogen-activated protein kinase (MAPK), myeloid differentiation primary response protein (MyD88), and tumor necrosis factor (TNF) receptor-associated factor 6 (TRAF6). The above reported mechanisms are well defined in endothelial cells, but they are also at least partially described in monocytes, platelets, and in other cells serving as a possible target of aPL-mediated damage (Meroni et al., 2011; Poulton et al., 2012). The thrombophilic effect of aPL was also investigated at platelet level. In subjects with aPL, platelet activation was proven by the increase of thromboxane B2 and the decrease in vascular prostacyclin. Receptors of b2GPI at the platelet surface seem to be the apolipoprotein E receptor 2 and the platelet glycoprotein Ib alpha chain (Cognasse et al., 2005; Urbanus et al., 2008). *In vitro* the pathogenic effect of affinity purified anti-b2GPI antibodies was shown as an increased aggregation and intracellular signaling activation of platelets in the presence of low doses of thrombin stimulation. In this respect, a recent study (Vlachoyiannopoulos and Routsias, 2010) has underlined the importance of platelet factor 4, a protein derived from platelet alpha granules and belonging to the chemokine family. Platelet factor 4 is secreted by platelets but can also bind to the platelet surface as well as anionic molecules and b2GPI, both in solid phase and in solution. Platelet factor 4 is able to gather two b2GPI molecules, so favoring an efficient antibody binding. Complexes containing platelet factor 4, dimerized b2GPI, and anti-b2GPI antibodies can induce an activated procoagulant phenotype in platelets. Notably, platelet factor 4 is expressed in different cells such as endothelial cells, monocytes, T cells, and dendritic cells suggesting that its capacity to dimerize b2GPI could favor immune system sensitization and the production of pathogenic anti-b2GPI antibodies.

Obstetric Manifestations

Although many different obstetric expressions of APS have been described, the most typical are mid-pregnancy losses, mainly related to defective placentation and intra-uterine growth restriction. Therefore the first pathogenic mechanism to be investigated was the presence of intraplacental thrombosis (Inbar et al., 1993; Levy et al., 1998). Indeed the above-described thrombophilic properties of aPL favor an increased thrombosis occurrence, particularly during pregnancy, that can work as a “second hit” since pregnancy *per se* is characterized by an increased thrombosis risk, even in the general population. A potent anticoagulant acting mainly, but not exclusively, on the trophoblast surface is annexin V that produces the so-called “protective shield,” by binding negatively charged phospholipids such as phosphatidylserine. The presence of annexin V at the intervillous surface was found to be significantly reduced in patients with APS, thus confirming that b2GPI–anti b2GPI complexes are able to displace *in vivo* annexin V from the cell surface as shown *in vitro* (Hunt et al., 2011). Furthermore, it is recognized that aPL can also directly interact with trophoblast during syncytium formation (Di Simone et al., 2000) when it expresses phosphatidylserine at its outer surface. As shown by *in vitro* experiments, b2GPI can bind to negatively charged phospholipids such as phosphatidylserine on the cell surface and become a target of circulating anti-b2GPI antibodies. The antibody binding impairs the trophoblast capacity to proliferate and differentiate, and produce human chorionic gonadotropin. These changes are the final consequence of the aPL-mediated modulation of trophoblasts occurring through several intracellular biological alterations including apoptosis. This process is likely to alter the early placentation *in vivo* and can be responsible for the first trimester pregnancy failures, while late failures are probably due to uteroplacental thrombosis (De Carolis et al., 2010).

Neurologic Manifestations

Stroke was one of the historical clinical manifestations included in the APS definition supporting the neurological involvement of the disease. In fact many neurological manifestations are observed in APS patients. However, while stroke is clearly related to vascular events, this is not clear for other problems like cognitive dysfunction, mood disorder, epilepsy and others, which also occur in APS. Starting from animal models (Appenzeller et al., 2012) in which immunoglobulins from APS patients were injected into the brain of mice, it was shown that aPL can bind to neuron in the hippocampus and the cerebral cortex (Caronti et al., 1998). Importantly, the treated animals also performed poorly in a test designed to explore their cognitive capacity, proving that antibodies binding to

brain cells can alter their functioning (Chapman et al., 1999). Obviously this model implies that aPL cross the blood–brain barrier, therefore requiring the coexistence of an infective-inflammatory state as a precipitating factor. However, it has been clinically observed that infective-inflammatory events can worsen the course of APS and therefore this interpretation is likely to represent a valid pathogenic mechanism. In addition, an increased prevalence of learning disabilities in children born to women with high aPL levels during pregnancy (Nacinovich et al., 2008) supports the role of aPL as mediator of brain damage. In fact, during uterine life, the absence of an effective blood–brain barrier allows maternal antibody (of the IgG isotype) to reach the fetus brain and cause impairment of its functioning as described in the animals studied.

The Complement System in APS

Complement is apparently involved in APS as antibodies cannot exert their pathogenic effect in animals that lack complement factors or receptors. This effect has been observed in both pregnancy loss (Holers et al., 2002) and in a thrombosis model (Fischetti et al., 2005). If the binding of aPL to their target cells (endothelial cells, trophoblasts) can activate complement, several activation molecules can be released. A recently described damage mechanism focused on C5a as a possible activator of neutrophils via its receptor on the cell surface (Girardi, 2010); according to this model the consequence of C5a binding to neutrophils is tissue factor production that can exert procoagulant and proinflammatory actions, and these can cause both thrombosis and fetal loss. Data observed in human disease are less clear. Decreased complement levels have been described in patients with APS (Oku et al., 2009) but are not always associated with pathological events (Reggia et al., 2012). Studying pregnancy in primary APS patients, we showed C3 and C4 levels to be significantly decreased compared with those found in the “normal” obstetrical population; however, we could not show a clearly related increased risk of pregnancy complications. Moreover, a prospective study of placentas from APS patients showed complement deposition without any relationship to pregnancy outcome or treatment (Tincani et al., 2010). Thus the role of complement activation in APS is yet to be elucidated.

TREATMENT OF APS

In contrast to the large body of evidence on the pathogenesis, mechanisms, and diagnosis of APS, there is still a gap in our knowledge on appropriate therapy for patients affected by this disease. The management of patients with

APS is currently directed to antithrombotic medications. Balancing an individual’s risk of thrombosis against the benefits and risks of antithrombotic therapies is crucial for optimizing management and preventing morbidity in patients with APS or aPL positive-asymptomatic ones. The international therapeutic guidelines recommend, for the secondary prevention of recurrent thrombosis, oral anticoagulation with warfarin indefinitely. However, these therapeutic guidelines lack answers for minority groups of patients such as (1) those who are appropriately anticoagulated but have recurrent thromboembolic phenomena or (2) those with prolonged clinically and serologically quiescent disease (Henriques et al., 2012). On the other hand many physicians recommend a daily low dose of aspirin for primary thrombosis prevention in asymptomatic individuals with persistent antiphospholipid antibodies. Although recent data question the effectiveness of aspirin (Puente et al., 2009) especially in patients with a high risk profile (“triple positive”) (Pengo et al., 2012), the combination of aspirin and anticoagulants throughout pregnancy and the postpartum period is beneficial for the prevention of APS-associated obstetric morbidity, though the dosage and length of postpartum therapy is still an issue of debate. With proper management including low dose aspirin and/or heparin, more than 70% of pregnant women with antiphospholipid syndrome will deliver a viable infant. The role of other therapies as statins, hydroxychloroquine, steroids, and intravenous immunoglobulin (IVIG) is yet to be established (Carp et al., 2005; Blank et al., 2007; Bramham et al., 2010; Galarza-Maldonado et al., 2012).

In cases of catastrophic APS, an aggressive therapy is highly recommended using anticoagulation, glucocorticoids, and plasma exchange and/or intravenous immunoglobulins (Puente et al., 2009). This combination was retrospectively assessed and found to be advantageous (Espinosa et al., 2011), noting that APS has been revealed as a complex syndrome with multiple pathophysiological mechanisms previously unknown. In this context, new therapeutic approaches have been defended and empirically tested, with potentially promising results (Puente et al., 2009). It is well accepted that additional vascular and thrombotic risk factors such as hypertension, smoking, hyperlipidemia, and others should be actively reduced in all patients (Tuthill and Khamashta, 2009; Ruffatti et al., 2011). The potential beneficial roles of statins and hydroxychloroquine for APS-associated clinical manifestations have to be established. B cell-directed therapies have been approved for the treatment of several autoimmune diseases, and their favorable clinical and serological effects have been evident both in human and murine models of APS (Khattri et al., 2012). Vitamin D, recently defined as an immune modulator, is commonly deficient in patients with SLE and APS and

deficiency was found to be associated with thrombotic manifestations and mechanisms in APS, suggesting a beneficial role for vitamin D supplementation (Agmon-Levin et al., 2011). Last but not least, though current options remain limited for the treatment of APS, the future holds much promise with the identification of multiple novel targets. These include new B cell depletion (i.e., anti-BAFF), new-generation anticoagulants, targeting components of the complement system, interfering with aPL cell-mediated activation of endothelial cells and platelets both at the cell surface level and intracellularly, and the novel concept of using a peptide-based approach to target subpopulations of aPL (Pericleous and Ioannou, 2010).

CONCLUSIONS AND FUTURE ASPECTS

APS is a systemic autoimmune disease, mediated by autoantibodies directed at phospholipids and phospholipid-binding proteins. Since its definition some 40 years ago, our understanding of the mechanisms underlining this disease has greatly improved. Nonetheless, much is yet to be accomplished regarding the definition of subgroups of APS patients, the accurate diagnosis and interpretation of criteria and non-criteria aPL, and the appropriate treatments for APS- and aPL-affected patients. These goals may be achieved by conducting well-designed, large-scale, multi-center clinical trials to explore and address the unmet needs of better, safer, and targeted management of APS.

INTRODUCTION

Sjögren's syndrome (SjS) is a chronic, systemic autoimmune disorder, encountered in about 0.5–1% of the general population, usually in middle-aged females (female/male ratio = 9:1). It is characterized by lymphocytic infiltration of exocrine (mainly salivary and lachrymal) glands and tissue destruction. SjS has a wide spectrum of clinical features ranging from sicca symptoms (dry mouth and dry eyes) to systemic manifestations. About 5–8% of patients develop non-Hodgkin lymphoma. SjS may occur either alone as a primary process (primary SjS) or in association with other autoimmune diseases such as systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), and systemic scleroderma (SSc).

B cell hyperactivity is considered as a disease hallmark as evidenced by the presence of hypergammaglobulinemia and serum autoantibodies, both specific and non-specific. These include—among others—antinuclear antibodies against ribonucleoproteic complexes Ro/SSA and La/SSB, rheumatoid factor (RF), and cryoglobulins (Routsias and Tzioufas, 2010).

Despite the unprecedented progress, SjS etiology remains unknown. Over the last decades several studies have shed light on the underlying pathogenetic mechanisms of SjS development. According to the current belief, the interplay of environmental factors (such as viruses, stress, or hormonal factors) with the host's specific

genetic background can lead to aberrant immune responses, chronic inflammation, destruction of the affected tissue, and ensuing ocular and oral dryness. Epithelium, the principal target of SjS, has been indicated to be an active participant rather than an innocent bystander (Moutsopoulos, 2007).

CLINICAL FEATURES

While local manifestations arising from salivary and lachrymal gland involvement are considered the typical SjS-related features, virtually any other organ system can be affected in the setting of SjS giving rise to systemic manifestations. Depending on the underlying pathophysiological mechanisms, SjS-related systemic manifestations can be largely classified into those related to secretory dysfunction and to those affecting other organs beyond exocrine glands, with the latter being further segregated into non-specific, those characterized by periepithelial infiltrates in parenchymal organs (kidney, lung, liver, endocrine organs), and finally those resulting from immunocomplexes deposition as a result of B cell hyperactivity (purpura, peripheral neuropathy, glomerulonephritis) (Skopouli et al., 2000; Malladi et al., 2012). The latter connotes a disease subset associated with increased risk for lymphoma development and high mortality rates. The majority of SjS patients display an indolent benign course and in the vast majority of patients, the glandular sicca features and serologic profile remains unchanged during disease course, while lymphoma and glomerulonephritis are late events (Skopouli et al., 2000; Ioannidis et al., 2002; Voulgarelis et al., 2012).

Local Manifestations (Salivary and Lachrymal Glands)

Mouth and eye dryness are the most characteristic features of SjS, manifested as difficulty with chewing or swallowing, sore mouth, and/or a sandy feeling or itchiness of the eyes. Dry mouth is often associated with increased incidence of oral infections and development of dental caries. Fungal infections can also be observed, manifested as pseudomembranous or erythematous mucosal lesions, fissured tongue, atrophy of filiform papillae, and angular cheilitis. Salivary flow rates measured for whole saliva or for separate secretions from each major salivary gland (with or without stimulation) reveal reduced salivary flow rates. Sialography discloses various degrees of sialectasis in the majority of patients. Scintigraphy, a functional assessment of salivary glands, provides poorly specific results (Adams et al., 2003). Ultrasonography, conventional magnetic resonance imaging and magnetic resonance sialography may provide useful, non-invasive diagnostic alternatives (Milic et al., 2012). Parotid gland

enlargement (PGE) is a relatively common manifestation of SjS. It is usually bilateral, firm to palpation, asymptomatic, and is considered as an adverse prognostic factor for lymphoma development.

Diminished tear secretion leads to chronic irritation and destruction of the corneal and bulbar conjunctival epithelium [keratoconjunctivitis sicca (KCS)]. Diagnosis of ocular involvement is based on measuring tear production and tear film stability using Schirmer's test (wetting on paper strip of less than 5 mm per 5 minutes) and tear break time, respectively, and on staining of the cornea using Rose Bengal or Lissamine green staining (Vitali et al., 2002). The latter reveals punctate or filamentary keratitis lesions, characteristics of KCS.

Systemic Manifestations (Beyond Salivary and Lachrymal Glands)

Musculoskeletal

More than half of SjS patients display musculoskeletal manifestations, the most common of which are non-erosive arthritis affecting the small joints and intermittent synovitis. Myalgias, fibromyalgia-like features, and chronic fatigue are also observed (Kassan and Moutsopoulos, 2004).

Raynaud's Phenomenon

Raynaud's phenomenon affects approximately 30–50% of primary SjS patients and often precedes sicca manifestations. The clinical picture of Raynaud's phenomenon is milder in SjS compared to other autoimmune disorders (Skopouli et al., 1990; Youinou et al., 1990; Garcia-Carrasco et al., 2002) and is associated with increased prevalence of extraglandular manifestations.

Respiratory Tract Involvement

Several manifestations of the respiratory tract have been described in the context of SjS. They are usually mild and include dry cough as a result of desiccation of tracheobronchial tree and more rarely dyspnea (xerotrachea/bronchitis sicca). A small airway obstructive pattern is usually detected by pulmonary function testing, possibly resulting from peribronchial and/or peribronchiolar mononuclear inflammation, which gives rise to a peribronchial thickening on high resolution computed tomography imaging ("dirty lung" appearance at chest X-ray). Interstitial involvement occurs less frequently and pleurisy is usually observed in SjS patients with associated lupus features (SLE-associated SjS) (Constantopoulos et al., 1984; Papiris et al., 1999, 2007; Manoussakis et al., 2004).

Gastrointestinal and Hepatobiliary Manifestations

Patients with SjS may complain of dysphagia as a result of esophageal dysmotility or of decreased saliva volume, both observed in SjS (Tsianos et al., 1985). Gastroesophageal and laryngopharyngeal reflux can also occur manifesting as unexplained hoarseness.

Primary biliary cirrhosis (PBC) is the commonest type of liver involvement occurring in SjS, in contrast to autoimmune hepatitis and primary sclerosing cholangitis, both extremely rare. Liver manifestations are usually mild and almost never the presenting manifestations of primary SjS. Liver dysfunction is evident in about 5–10% of such patients and is manifested by the elevation of cholestatic enzymes. In a substantial proportion of primary SjS patients with liver involvement, serum anti-mitochondrial (AMA) reactivity is observed (Skopouli et al., 1994). The latter antibodies are thought to be specific for the diagnosis of PBC. Pancreatic involvement has been previously described in the setting of SjS either as a result of secretory dysfunction or in the form of autoimmune pancreatitis. The latter might connote the presence of underlying IgG4-related disease and therefore should be carefully investigated, given the beneficial response to steroids (Ebert, 2012; Takahashi et al., 2012).

A recent study showed that PBC in the context of SjS remains clinically, serologically, and histologically stable, with ursodeoxycholic acid being the main therapeutic choice (Hatzis et al., 2008).

Renal Involvement

Two types of renal involvement have been described in the setting of primary SjS and include tubulointerstitial nephritis and glomerulonephritis. Interstitial nephritis is the most common renal manifestation usually encountered in young patients; it is usually subclinical and can be expressed as hypokalemia, low urine specific gravity, and alkaline urine pH (Goules et al., 2000). Distal renal tubular acidosis, which can be presented as nephrocalcinosis, can also occur (Moutsopoulos et al., 1991). An extended follow-up in a large number of SjS patients ($n = 715$) for 271.8 person-years revealed that around one-third of these patients had evidence of interstitial involvement and of those approximately two-thirds developed mild chronic renal impairment during follow-up (Goules et al., 2012).

On the other hand, glomerulonephritis is a rather rare renal SjS manifestation usually observed in the context of systemic vasculitis and often associated with hypocomplementemia and cryoglobulinemia conferring increased risk for lymphoproliferation and mortality (Goules et al., 2012). Immune deposits in renal biopsy reveal IgM and complement deposition (Moutsopoulos et al., 1978).

Vasculitis

Vasculitis is observed in about 15% of SjS patients, is usually observed many years after the diagnosis of SjS, and is associated with increased risk for lymphoma development and increased mortality. It usually affects small vessels and the skin is the most frequent site/organ affected. Skin involvement is usually manifested as palpable purpura and more rarely as urticarial lesions. Involvement of other organs, such as peripheral nerves, muscles, and kidneys, has been also described. According to histopathological findings, two types of SjS-associated vasculitis are recognized: leukocytoclastic vasculitis (infiltrates of polymorphonuclear cells) and lymphocytic vasculitis (lymphocyte and monocyte infiltrates). Cryoglobulins (type II, IgMk), high titers of rheumatoid factor, and antinuclear antibodies as well as increased levels of gammaglobulins, hypocomplementemia, and increased erythrocyte sedimentation rate are usually detected (Tsokos et al., 1987; Ramos-Casals et al., 2004).

Neuropsychiatric Involvement

The prevalence of peripheral neuropathy in SjS varies from 2 to 60% in different studies reflecting the heterogeneity of definition criteria and population characteristics. The most common types of peripheral nerve involvement in primary SjS are sensory, small fiber neuropathy (SFN), and sensorimotor neuropathy. Sensory neuropathies are expressed as distal symmetric sensory loss (glove-stocking distribution) or rarely as sensory ataxia. Small fiber neuropathy is manifested as painful and burning paresthesias and deserves particular attention since physical and electrophysiological examination are usually normal; diagnosis is undertaken by skin biopsy (Pavakis et al., 2011, 2012). On the other hand, sensorimotor neuropathies in primary SjS patients and particularly axonal sensorimotor polyneuropathy are associated with adverse prognostic factors for lymphoma development such as hypocomplementemia, cryoglobulinemia, and vasculitic lesions. Trigeminal neuropathy, usually unilateral, as well as sensorineural hearing loss usually at high frequencies have also been said to occur in some primary SjS patients (Boki et al., 2001).

Central nervous system involvement in primary SjS remains controversial. Hemiparesis, sensory deficits, seizures, movement disorders, cerebellar defects, neurogenic bladder, transverse myelopathy, and multiple sclerosis-like picture have been described in primary SjS patients. However, other investigators using strict criteria for the classification of primary SjS have not substantiated these observations (Alexander et al., 1981; Soliotis et al., 2004).

Psychopathological features and distinct personality traits such as neuroticism, psychoticism, and obsessiveness have been also described in primary SjS patients at a higher

frequency compared to healthy controls. Of interest, it has been shown that psychopathological manifestations in the setting of primary SjS are primarily dependent on pre-morbid personality characteristics and are associated with the presence of antibodies to specific neuropeptides (Karaiskos et al., 2010).

Endocrine Involvement

In patients with SjS, autoantibodies against organ-specific autoantigens of endocrine glands such as thyroid, adrenals, and ovaries have been previously documented at higher rates (in approximately one-fifth of patients) compared to healthy individuals. The presence of these autoantibodies indicates that the classical SjS autoimmune exocrinopathy may be associated with concomitant involvement of endocrine organs, also histopathologically characterized by the presence of lymphocytic periepithelial infiltrations and may eventually give rise to hormonal abnormalities including hypothyroidism, adrenal hyporesponsiveness, and premature ovarian failure (Euthymiopoulou et al., 2007; Mavragani et al., 2012a,b).

Lymphoproliferative Disease

Non-Hodgkin lymphoma (NHL) is encountered in about 5–8% of SjS patients and is usually of indolent course. The most common type is mucosa-associated lymphoid tissue (MALT) lymphomas followed by nodal marginal zone and diffuse large B cell lymphomas. In the majority of cases, lymphoma is located in minor and/or major salivary glands. However, other organs such as the stomach and the lungs can also be involved (Baimpa et al., 2009; Voulgarelis et al., 2012). Peripheral neuropathy, glomerulonephritis, lymphopenia, vasculitis/purpuric lesions, low C4 levels, cryoglobulinemia, and the presence of germinal centers in salivary gland biopsy are well-recognized adverse predictors for lymphoma development (Skopouli et al., 2000; Ioannidis et al., 2002; Theander et al., 2011).

Overlapping Autoimmune Entities

Given that earlier studies have shown that 5% of patients with long-standing RA present a clinically overt SjS, and subclinical sicca complaints can be affirmed by as many as 20% of such patients (Andonopoulos et al., 1987), the term “secondary SjS” has been introduced and mistakenly applied to connote sicca disorder that occurs together with any autoimmune disorder. However, this disregards the possibility for true overlapping entities. In this context, a recent study has revealed that patients with coexisting SLE and SjS appear to constitute a subgroup (9%) of SLE patients with distinct clinical, serological, pathologic, and immunogenetic features in whom SjS is expressed as an overlapping entity, which is largely similar to primary SjS

and usually precedes SLE (Manoussakis et al., 2004). Oral and/or ocular dryness are also observed in approximately 20% of patients with systemic sclerosis, often associated with fibrosis of the exocrine glands. In contrast, sicca manifestations associated with frank lymphocytic infiltrative lesions are extremely common (60%) in patients with limited systemic sclerosis (Drosos et al., 1988). Increased prevalence of autoimmune thyroid disease (ATD) and thyroid dysfunction has been previously reported in patients with primary SjS. Studies so far demonstrate rates of ATD ranging from 6 to 50% (Zeher et al., 2009; D'Arbonneau et al., 2003; Mavragani et al., 2009).

Diagnosis and Differential Diagnosis

Combined clinical, pathologic, and serologic assessment of patients can easily lead to the diagnosis. Recently, an international agreement was established for the definition of SjS, based on the “European American consensus group criteria,” which requires the presence of either focal lymphocytic infiltrates in minor salivary glands with a focus score of 1 or more, or anti-SSA/SSB autoantibodies (Box 35.1) (Vitali et al., 2002). Differential diagnosis should consider various medical conditions that may cause mucosa dryness with or without salivary gland enlargement, including adverse effects of drugs, infections, tumors, metabolic disorders, and irradiation. In particular, sarcoidosis, lipoproteinemias types II, IV, and V, chronic graft-versus-host disease, lymphomas, amyloidosis, and infection by human immunodeficiency virus and hepatitis C virus might be misinterpreted as SjS (Kassan and Moutsopoulos, 2004). IgG4-related sialadenitis, formerly known as Mikulicz disease, should also be considered in SjS differential diagnosis (Nocturne et al., 2011). Clinical, pathologic, and serologic features can be helpful for the differential diagnosis. In particular, the identification of serum autoantibodies to Ro/SSA or La/SSB proteins is a strong indication for primary SjS. In elderly individuals, mucosal dryness is frequently an age-related atrophic process. In the presence of sicca symptoms together with fibromyalgia features, the diagnosis of “dry eyes and mouth syndrome” should be considered when SjS classification criteria are not fulfilled (Mariette et al., 2003).

AUTOIMMUNE FEATURES AND PATHOGENIC MECHANISMS

Immunopathology

Cellular Populations—Cytokine Production

T Lymphocytes

The classical SjS histopathological picture is characterized by the presence of periductal lymphocytic infiltrates.

Analysis of cell composition of the mononuclear infiltrates in minor salivary gland (MSG) biopsy specimens allowed the identification of histopathological patterns associating with distinct clinical and serological features.

CD4⁺T rather than CD8⁺ lymphocytes have been previously considered as the main cellular populations in the lymphoepithelial SjS lesions; however, according to recent findings, the incidence of specific immunocytes is associated with the lesion severity, with CD4⁺Th2 lymphocytes predominating in mild and B cells along with Th1 cells in more advanced lesions (Mitsias et al., 2002; Katsifis et al., 2007; Christodoulou et al., 2010). Th17 cells, a newly identified subset of CD4⁺ lymphocytes, which secrete cytokines belonging to the interleukin (IL)-17 family, are also found to contribute to the immunopathological SjS lesion (Katsifis et al., 2009). IL-22, which can exhibit a protective or inflammatory role, has also been recently shown to be produced by Th17 and natural killer (NK) cells (Ciccia et al., 2012). Th follicular cells—another CD4⁺ subset—are the main producers of IL-21 which has been shown to promote B cell differentiation in plasma cells contributing to germinal center formation. Increased IL-21 serum levels in SjS patients in association with serum IgG1 levels in conjunction with heightened expression in the lymphocytic infiltrations of SjS MSGs imply a role for this cytokine in disease pathogenesis (Kang et al., 2011; Scofield, 2011). An emerging role for IL-7 in activation of T cells at the level of SjS salivary glands was recently suggested (Bikker et al., 2012).

Regulatory T lymphocytes (Tregs), the primary suppressive component of the immune system, have recently attracted particular attention in pathogenesis of autoimmunity. In the setting of primary SjS, Tregs are possibly attracted to the site of inflammation, since an inverse correlation of Treg numbers has been observed between the affected salivary gland and the periphery. While the frequency of Tregs seems to positively correlate initially with lesion severity, the mostly advanced SjS lesions are characterized by low Treg incidence. While in early and moderate infiltrations a compensatory control of Tregs in response to Th17 expansion seems to occur, in advanced SjS lesions Tregs may fail to control the immune-mediated tissue injury (Christodoulou et al., 2008).

B Lymphocytes

B cells in the lesion contain intracytoplasmic immunoglobulins with anti-Ro(SSA) and/or anti-La(SSB) reactivity (Tengner et al., 1998). Oligoclonal B lymphocytes and germinal center formation in salivary infiltrate might represent a predisposing factor for lymphoma (Pablos et al., 1994). Comparative studies of peripheral blood and parotid glands from primary SjS patients have indicated the depletion of CD27 expressing memory B cells from

the peripheral blood and accumulation and/or retention of this antigen-experienced B cells in the inflamed salivary gland tissue (Dorner et al., 2002; Youinou et al., 2010).

Macrophages/Dendritic Cells

Increased incidence of IL-18⁺ producing macrophages (MΦ) were found in advanced histopathological lesions in association with cryoglobulinemia, low C4 levels, and salivary gland enlargement, previously regarded as adverse prognostic factors for lymphoma development (Manoussakis et al., 2007).

Dendritic cells (DCs) seem to contribute to histopathological SjS lesion, with two types of DCs being recognized; myeloid DCs (mDCs) and plasmacytoid DCs (pDCs). In early SjS lesions, reduction of blood mDCs possibly due to the preferential trafficking of mDCs into salivary glands is a common event (Ozaki et al., 2010). pDCs, the professional type I interferon (IFN) producers, have also been detected in minor salivary gland biopsies from SjS patients. They are characterized by the presence of Toll-like receptor (TLR)-7 and -9 receptors (sensed by exogenous or endogenous nucleic acids) implying the presence of a viral or viral-like trigger at the level of salivary gland tissue (Figure 35.1). In an attempt to identify possible endogenous elements that may act through TLR or other mechanisms and activate IFN-I pathways, recent work identified the transposable CpG-rich elements belonging in the long interspersed nuclear elements (LINE; L1) family as potential inducers of type I IFN activation in salivary gland tissues (Mavragani and Crow, 2010).

Despite the fact that elevated IFN levels in autoimmune disorders was first reported over 30 years ago, it was during the last few years that activation of the type I IFN system in the generation of autoimmunity attracted particular interest (Hooks et al., 1979).

In accordance with previous observations in SLE and other autoimmune disorders, activation of type I IFN in SjS was evidenced by the upregulation of IFN-related genes—the so-called interferon signature—in peripheral blood mononuclear cell (PBMC) and MSG tissues from SjS patients, heightened type I IFN levels in serum derived from SjS patients, and disease associations with genes involved in activation of type I IFN pathway. Moreover, the IFN α -producing pDCs—the professional IFN α -producing cells—were detected in the salivary glands of SjS patients, but not in controls. While the initial triggers for type I IFN production in the setting of SjS remain elusive, exogenous, such as viral agents or endogenous signals, might account for pDC activation through ligation of TLR-dependent or -independent pathways (Vakaloglou and Mavragani, 2011). Of interest, according to the findings by Ittah et al., B cell activating factor (BAFF), a member of the tumor necrosis factor (TNF) family, was shown to be overproduced by salivary gland

Box 35.1 European American Consensus Group Criteria

1. Ocular symptoms (at least one present)
 - Persistent, troublesome dry eyes every day for longer than 3 months
 - Recurrent sensation of sand or gravel in the eyes
 - Use of a tear substitute more than three times a day
2. Oral symptoms (at least one present)
 - Feeling of dry mouth every day for at least 3 months
 - Recurrent feeling of swollen salivary glands as an adult
 - Need to drink liquids to aid in swallowing dry food
3. Objective evidence of dry eyes (at least one present)
 - Schirmer test ≤ 5 mm/5 mn
 - Van Bijsterveld score ≥ 4 (after lissamin test)
4. Objective evidence of salivary gland involvement (at least one present)
 - Salivary gland scintigraphy
 - Parotid sialography
 - Unstimulated salivary flow (≤ 1.5 mL per 15 min, ≤ 0.1 ml/min)
5. Histological features
 - Positive minor salivary gland biopsy sample (focus score ≥ 1 : this refers to a cluster of 50 or more lymphocytes per lobule when at least four lobules are assessed)
6. Autoantibodies
 - Presence of antibodies to SS-A (Ro) or to SS-B (La)
 - Classification of primary Sjögren's syndrome requires:
 - four of six criteria, including a positive minor salivary gland biopsy sample or antibody to SS-A/SS-B,
 - or three of the four objective criteria (criteria 3 to 6)
 - Classification of secondary Sjögren's syndrome requires an established connective tissue disease and one sicca symptom (criteria 1 or 2) plus any three of the four objective criteria (items 3, 4, 5).
 - Exclusions include previous radiotherapy to the head and neck, lymphoma, sarcoidosis, graft-versus-host disease, and infection with hepatitis C virus, or HIV, use of anticholinergic drugs.

epithelial cells (SGECs) upon stimulation with ssRNA in an IFN-I-dependent manner (Ittah et al., 2008).

The BAFF gene—located on chromosome 13q33.3—contains 6 exons and 5 introns and encodes a type II transmembrane protein of 285 amino acids in humans. A newly identified splice variant lacking the exon 4 named $\Delta 4$ BAFF has been found to act as a transcription factor for the paternal gene and to regulate innate immune and apoptosis pathways. Several single nucleotide polymorphisms of the BAFF gene have been previously described in the setting of SjS and SLE, with the rs9524828 T allele being found to associate with BAFF levels but not with disease susceptibility (Kawasaki et al., 2002; Nossent et al., 2008; Lahiri et al., 2008).

BAFF is mainly produced by cells of mononuclear lineage but also by other cell types including bone marrow cells, synoviocytes, astrocytes, and SjS salivary epithelial cells. The major receptors of BAFF include the transmembrane activator and calcium modulator ligand interactor (TACI), the B cell maturation antigen receptor (BCMA), and the BAFF receptor (BAFF-R) (Lahiri et al., 2012).

BAFF, which is crucial for the development and survival of B lymphocytes, has been found elevated in SjS serum in association with antibodies against ribonucleoproteins and B cell clonal expansion in the salivary glands and disease activity score (Nossent et al., 2008). Accordingly, BAFF-transgenic mice, which are characterized by T2 cell hyperplasia in exocrine glands and increased numbers of mature B cells, manifest an SLE-like disease, while in advanced age they develop an SjS-resembling phenotype (Mackay et al., 1999; Groom

et al., 2002; Quartuccio et al., 2012). Taken together, activation of type I IFN with subsequent BAFF induction represents a model bridging innate immune mechanisms with B cell hyperactivity, a hallmark of SjS.

Epithelial Cells

Given that the typical histopathological lesion in affected tissues (salivary, bronchial, cholangial, kidney) in the context of primary SjS is characterized by lymphocytic infiltrates that surround and sometimes invade the epithelium, the term “autoimmune epithelitis” has been proposed identifying the epithelium as an important player in the SjS pathogenesis (Moutsopoulos, 2007). Salivary gland epithelial cells exhibit a plethora of immunoreactive molecules including molecules facilitating antigen presentation (MHC-I and MHC-II), costimulation (CD40, B.7/CD80,PD-L1), cell adhesion (ICAM.1/CD54), and apoptosis-related molecules (Fas, FasL). Activated epithelia are also the source of several inflammatory cytokines (IL-1, -6, -8, TNF α , and adiponectin), chemokines, and BAFF-mediating lymphocyte recruitment and organization of germinal centers as well as activation and proliferation of B lymphocytes (Manoussakis and Kapsogeorgou, 2010; Tzioufas et al., 2012).

Additionally, recent studies demonstrated that SGECs express functional molecules of the innate immunity such as the Toll-like receptors (TLRs)-1, -2, -3, -4, -7, -9, as well as the CD91 receptor that mediates endocytosis and antigen presentation (Kawakami et al., 2007; Spachidou et al., 2007; Bourazopoulou et al., 2009). Hence, the SjS epithelial

FIGURE 35.1 Epitheliotropic viruses or endogenous nucleic acids might serve as initial triggers in type I interferon (IFN) production—genetically determined by IRF-5/STAT-4 polymorphisms—by plasmacytoid dendritic cells (pDCs) through activation of Toll-like receptor (TLR)-dependent or independent pathways. Once produced, type I IFN along with environmental stressors and hormonal alterations might lead to inappropriate epithelial activation through upregulation of several immunomodulatory molecules (costimulatory, adhesion, MHC-II, etc.), BAFF production, and apoptotic events which result to exposure of autoantigens such as Ro/SSA and La/SSB and generation of disease-specific anti-Ro/SSA and La/SSB autoantibodies. The latter, in conjunction with autoantigens, would form immune complexes which in turn further promote the activation of type I IFN pathways through triggering of pDCs or other IFN α producing cells. On the other hand, the activated epithelial cell, serving as an antigen presenting cell, can activate several CD4⁺ T cell subtypes, which promote B cell differentiation and survival possibly through IL-17 and IL-21 secretion. IFN α perpetuates the autoimmune response through several immunomodulatory actions, including upregulation of chemotactic molecules and further recruitment of inflammatory cells, accumulation of helper and/or inducer memory T and B cells, B cell activation, autoantibody production, and ultimately tissue destruction with simultaneous B cell monoclonal expansion.

cell can act as an antigen-presenting cell to T lymphocytes since it intrinsically provides antigen-presenting and costimulatory molecules, contributes to the generation of the inflammatory microenvironment (expression of inflammatory cytokines), and can recruit, through lymphoattractant chemokines (CXCL13, CXCL21), B and T lymphocytes providing survival signals for the B lymphocytes under the effect of BAFF (Tzioufas et al., 2012) (Figure 35.1).

Proangiogenic factors shown to be produced by SGEs upon stimulation with SjS autoantibodies together with increased expression of neuropilin-1 in SjS SGEs (a co-receptor for members of the VEGF family) provide a potential mechanism for the enhanced angiogenesis shown in SjS salivary gland tissues (Sisto et al., 2012a,b). Proangiogenic factors such as VEGF and IL-8 have also been recently shown to be induced by SGEs upon stimulation of histamine receptor 4 by T cell- and dendritic cell-derived histamine at the level of salivary gland (Stegaev et al., 2012).

Apoptosis has been considered as one of the characteristic features of the SjS salivary gland epithelium. It has

been well documented that both SGEs and salivary gland tissues from SjS patients demonstrate increased *in situ* expression of pro-apoptotic molecules such as Fas, FasL, and Bax protein. The same is applied for the cultured non-neoplastic SGEs. Apoptosis mediated through Fas/FasL pathway is dependent on IFN γ which was found to reduce the survival of SGEs in a dose- and time-dependent manner (Abu-Helu et al., 2001; Manoussakis and Kapsogeorgou, 2007). The CD40 molecule, which is also upregulated by IFN γ , has been found to sensitize SGEs to apoptosis mediated by the Fas/FasL system possibly through downregulation of the anti-apoptotic protein cFLIP. The latter, and other anti-apoptotic molecules such as Bcl-2, are constitutively expressed by SGEs and are thought to act as defensive and tissue-repair mechanisms in an attempt to compensate for the increased rate of apoptosis observed in SjS (Abu-Helu et al., 2001; Dimitriou et al., 2002; Ping et al., 2005). Recent data support the role of B cells in inducing SGE apoptosis through protein kinase C delta activation (Varin et al., 2012). Apoptosis represents a central mechanism of tolerance

break through membrane expression or release of modified autoantigens (apoptopes), which subsequently can trigger an inflammatory immune response at the level of SjS salivary gland tissue. Identification of apoptopes, which are defined as epitopes on the surface of apoptotic cells by B cell epitope mapping techniques, appear as a promising novel diagnostic marker for both SjS and SLE. For instance, several La apoptopes react with the majority of sera from mothers of infants with congenital heart block and a Ro60 apoptope is specific for a subgroup of SLE patients characterized by isolated anti-Ro60 responses (Reed et al., 2007, 2008, 2010).

Another mechanism of autoantigen presentation to the immune system is mediated by small membrane vesicles (30–100 nm) of endosomal origin, the so-called exosomes. These are released by various cell types and represent a mechanism of intercellular communication and cellular material transportation. It is believed that they are able to relocate antigens to APCs or to T lymphocytes. Study from our group has shown that exosomes can be released from cultured SGEs and contain (among others) Ro, La, and Sm autoantigens, the most well-recognized antigenic targets in SjS and SLE (Kapsogeorgou et al., 2005).

Autoantibodies

From an immunological point of view, B cell activation is the hallmark of the syndrome resulting in hypergammaglobulinemia, cryoglobulinemia, and autoantibody production. The latter includes the presence of increased titers of antinuclear antibodies and rheumatoid factor as well as reactivities against the ribonucleoprotein complexes Ro/SSA and La/SSB. Antibodies against a-fodrin—an organ-specific cytoskeletal autoantigen—initially purified by salivary glands of a murine SjS mouse model have been also detected in almost all sera from patients with primary SjS (Haneji et al., 1997; Witte et al., 2000, 2003). However, subsequent reports failed to demonstrate their superiority in terms of specificity and sensitivity in comparison to anti-Ro/SSA and anti-La/SSB testing (Ruiz-Tiscar et al., 2005; Loch et al., 2008). As a result their use in clinical practice is quite limited. Hypergammaglobulinemia has been associated with cutaneous vasculitis, articular, pulmonary or renal involvement and cryoglobulinemia with B cell lymphoma development and increased mortality rates (Skopouli et al., 2000; Ioannidis et al., 2002). Antibodies directed against Ro/SSA and La/SSB antigens are detected in approximately 60% and 30% of SjS patients, respectively, and have been previously shown to be associated with earlier disease onset, longer disease duration, parotid gland enlargement, higher frequency of extraglandular manifestations, more intense lymphocytic infiltration of the minor salivary glands, other B cell activation markers,

as well as the presence of HLADR2 and DR3. While RNA immunoprecipitation has been considered as the reference method for detection of these autoantibodies, counterimmunoelectrophoresis demonstrates increased reliability with high levels of sensitivity and specificity. Commercially available enzyme-linked immunosorbent assay (ELISA) kits are now widely used in clinical practice (Manoussakis et al., 1993; Mavragani et al., 2000; Tzioufas et al., 2002; Hernandez-Molina et al., 2011). On the other hand, anticentromere (ACA) antibodies occur in 3.7% of SjS patients designating the presence of an intermediate scleroderma-like phenotype. The ACA⁺ SjS subgroup demonstrates a higher prevalence of Raynaud's phenomenon and dysphagia but lower rates of dry eyes, hypergammaglobulinemia, anti-Ro/SSA, and anti-La/SSB antibodies compared to ACA⁻ SjS patients. Furthermore, compared to age–sex matched counterparts with systemic sclerosis, the ACA⁺ SjS subset shares a less aggressive phenotype with fewer occurrences of telangiectasias, puffy fingers, sclerodactyly, Raynaud's phenomenon, digital ulcers, and gastroesophageal reflux, which rarely evolves in full blown scleroderma (Bournia et al., 2010).

Features related to the presence of peri-epithelial lesions of parenchymal organs such as the liver and the kidney have been associated with autoantibodies against mitochondrial and carbonic anhydrase, respectively (Hatzis et al., 2008; Bournia et al., 2010). The majority of AMA⁺ primary SjS patients (5%) demonstrated lesions compatible with primary biliary cirrhosis in their liver biopsies and tended to experience slow progression in clinical, biochemical, and histological terms. Anti-carbonic anhydrase II antibody has been described in a number of patients with SjS and associated with distal renal tubular acidosis (Takemoto et al., 2005). Additionally, we have recently identified a subset of primary SjS (approximately 17% of patients) characterized by the presence of antibodies against 21-hydroxylase—a major adrenal autoantigen—which was associated with adrenal gland hyporesponsiveness and the presence of B cell activating cytokines at the level of salivary gland tissue (Mavragani et al., 2012b).

Finally, antibodies to cyclic citrullinated peptides have been previously detected in a small percentage of sera from primary SjS patients in association with the presence of synovitis, and their presence might connote progression to inflammatory arthritis (Gottenberg et al., 2005; Atzeni et al., 2008; Haga et al., 2011; Ryu et al., 2012).

ETIOPATHOGENESIS

Genetics

Multiple immunogenetic studies, familial clustering, and the increased frequency of certain major histocompatibility complex (MHC)-II alleles strongly indicate the genetic

predisposition of SjS. Studies from different countries and ethnic groups have revealed an increased frequency of several HLA DR alleles. Various HLA class II alleles may have an important role in the regulation of immune responses against Ro/SSA and La/SSB ribonucleoproteins, with DR15 being associated with anti-Ro/SSA antibodies alone, and DR3 with both anti-Ro/SSA and anti-La/SSB antibodies (Mann and Moutsopoulos, 1983; Harley et al., 1986; Gottenberg et al., 2003; Cruz-Tapias et al., 2012).

Over the last years, the potential role of single nucleotide polymorphisms (SNPs) outside the HLA locus was supported by data derived from case–control association studies. Polymorphisms of the interferon regulating factor-5 (IRF5) gene, implicated in the activation of type I IFN pathway and the signal transducer and activator of transcription 4 (STAT4) gene—a transcription factor involved in Th1 and Th17 response promoting the secretion of IFN γ —seem to confer increased disease susceptibility. Of interest, the concomitant presence of IRF5 and STAT4 SNPs appears to have an additive effect in the susceptibility for SjS (Miceli-Richard et al., 2007, 2009; Nordmark et al., 2009). Polymorphisms of the genes involved in B cell differentiation and activation as well as of lymphotoxin α /lymphotoxin β /TNF locus—previously found to be upregulated in SjS salivary tissues and implicated in lymphoid tissue formation—have been also found to increase disease risk (Nordmark et al., 2011; Bolstad et al., 2012).

Epigenetics

Growing evidence is highly suggestive of the contributory role of epigenetic mechanisms such as microRNAs in pathogenesis of autoimmunity. The emerging role of these non-coding RNAs, which regulate gene expression as a potential disease biomarker, was explored in recent studies (Alevizos et al., 2011; Kapsogeorgou et al., 2011). Mir146a, previously shown to regulate innate immune responses was found to be upregulated in PBMCs from SjS patients (Kapsogeorgou et al., 2011; Pauley et al., 2011). Deep sequencing of small RNAs from SjS patients revealed the presence of previously unidentified microRNAs with high disease specificity. Further functional studies are required to delineate the role of miRNAs in the induction of autoimmune processes in the setting of SjS (Tandon et al., 2012).

Methylation mechanisms have been postulated as major epigenetic regulators with implications in the pathogenesis of autoimmunity and cancer. At the level of salivary gland biopsies, overexpression of several enzymes of the methylation machinery have been found to be strongly correlated with the mRNA expression of L1 retroelements, implying the presence of a compensatory defensive mechanism against aberrant overexpression of endogenous threats against immune homeostasis (Mavragani and

Crow, 2010). No alterations of the methylation status of the IRF5 promoter in the setting of SS have been detected (Gestermann et al., 2012).

Environmental Factors

Viruses

Viruses have been long suspected for the induction of SjS, since transient or persistent infection of epithelial cells by a putative virus may be an initiating event for autoimmune reactions. Research has been focused on various types of viruses, including cytomegalovirus, Epstein–Barr virus, human herpes virus type-6, HTLV-1, retroviruses, HCV virus, and enteroviruses; however, results have been inconclusive (Triantafyllopoulou and Moutsopoulos, 2007; Lee et al., 2012). Of interest, Epstein–Barr virus-encoded small RNA (EBER) derived from EBV infected cells in complex with the SjS-related autoantigen La/SSB can trigger type I IFN production through TL3 activation (Iwakiri et al., 2009). Endogenous viral elements have also been proposed as potential contributors in disease pathogenesis.

Stress

Stressful life events prior to disease onset in conjunction with a lack of adequate coping strategies have been previously indicated as SjS triggers (Karaiskos et al., 2009).

Hormonal Factors

Female predominance together with disease onset around menopause supports a role of hormonal factors in SjS. Estrogen deficiency in mice with a healthy background has been previously found to induce SjS-like autoimmune exocrinopathy and increased apoptosis, both resolved after estrogen administration; overexpression of the retinoblastoma-associated protein 48 (RbAp48) specific for estrogen deficiency-dependent apoptosis in the exocrine glands has been shown to account for these phenomena (Ishimaru et al., 2003, 2008). The contribution of estrogen deficiency in the generation of autoimmune responses was also shown in another mouse model lacking aromatase; deficiency of the latter which catalyzes the production of estrogens by androgens led to development of severe—SjS reminiscent—autoimmune lymphocytic exocrinopathy (Shim et al., 2004).

Estrogens have been previously shown to exert immunomodulatory actions in normal SGECs by inhibiting the IFN- γ -induced ICAM-1 expression, an adhesion molecule denoting cellular activation. Recent findings support estrogen unresponsiveness of SjS-SGECs as a potential contributor of intrinsic epithelial activation observed in SjS (Tsinti et al., 2009; Manoussakis et al., 2012).

Androgen deficiency has been additionally implicated in SjS induction. Reduced salivary gland tissue levels of dehydrotestosterone (DHT)—the active form of testosterone—were previously described in SjS patients. This might be due either to low systemic DHEA levels—the main source of DHT in females—or to defective intracrine DHT production, both observed in SjS patients. DHT has been previously suggested as an apoptosis inhibitor of salivary epithelial cells. Therefore, lack of androgen leads to unopposed induction of estrogen deficiency-dependent apoptosis in menopausal SjS patients accounting for the aberrant immune responses (Porola et al., 2008; Spaan et al., 2009; Kontinen et al., 2012).

EXOCRINE GLAND DYSFUNCTION

Despite the original belief that sicca manifestations result from exocrine gland destruction due to local lymphocytic infiltration, a growing body of evidence supports the presence of additional operative mechanisms in the alteration of glandular homeostasis (Hayashi, 2011).

Apoptosis

Several SjS animal models revealed the occurrence of hyposalivation related to apoptotic death of acinar cell events prior to lymphocytic infiltration, implying that cell death pathways might be the primary triggering events in initiation of the autoimmune process (Humphreys-Beher et al., 1998). Innate stimuli, such as TL3-ligands and IFN α itself together with other proinflammatory cytokines have been previously suggested to activate apoptotic pathways and salivary dysfunction (Deshmukh et al., 2009; Manoussakis et al., 2010).

Neurotransmission

Salivary gland secretory processes are under autonomic parasympathetic control through interaction of acetylcholine with muscarinic receptors, mainly M1 and M3 in the salivary glands. Antibodies to muscarinic receptors, proinflammatory cytokines such as TNF α , IL1 α , and IL-1 β , impaired neurotransmitter responsiveness, and destructions of neural innervations have been proposed as possible culprits (Pedersen et al., 2000; Gordon et al., 2001; Zoukhri and Kublin, 2002; Jin et al., 2012). Alterations of other neuropeptides, such as VIP and NPY, have been also observed in SjS (Santavirta et al., 1997).

Aquaporins

Optimal salivary secretion requires the presence of functionally adequate water channels, termed aquaporins. Abnormal distribution and expression of aquaporin 5 in

SjS-SGECs has been previously proposed as a contributor in the observed hyposalivation, even in the absence of intense inflammation (Steinfeld et al., 2001).

Structural Abnormalities

Tight Junctions

Changes in tight junctions protein levels with ensuing alterations in tissue integrity at the level of salivary SjS glands, possibly under the influence of locally produced cytokines, have been previously implicated in SjS-related salivary gland dysfunction (Baker et al., 2008; Ewert et al., 2010).

Basal Membrane

Disorganization of the basal membrane in labial salivary gland acini and ducts has been attributed to altered expression of laminin/laminin receptor and collagen IV levels possibly under the effect of local cytokine milieu, allowing the invasion of T-cytotoxic lymphocytes (Defilippi et al., 1992; McArthur et al., 1993; Molina et al., 2006). Additional data support alterations in laminin levels as a result of androgen deprivation known to occur in SjS, leading to abnormal remodeling though inhibition of differentiation of intercalated duct progenitors to acinar cells (Porola et al., 2010).

THERAPY

Treatment of SjS is directed to provide symptomatic relief and to recognize and treat disease complications in a timely fashion. In particular, patients with adverse prognostic factors should be regularly followed for early identification of lymphoproliferation. For KCS, the application of eye lubricants is the mainstay of treatment. Diuretics, antidepressants, and histamines may worsen lachrymal and salivary hypofunction and should be used with caution. Patients with residual glandular function may benefit from the oral administration of the muscarinic M3 receptor agonists pilcarpine (Vivino et al., 1999) and cevimeline (Petroni et al., 2002). Corticosteroid containing ophthalmic solutions should be avoided as they may induce corneal lesions or promote infections. Dental treatment with fluoride retards damage of teeth surfaces. For tender salivary gland enlargement local application of moist heat and non-steroidal anti-inflammatory drugs may be helpful. Bacterial infection as well as lymphoma should always be considered. Vaginal lubricants may be used to treat vaginal dryness and dyspareunia. The decision for systemic therapeutic intervention remains empirical and is based on the severity of extraglandular manifestations. Non-steroidal anti-inflammatory drugs and/or hydroxychloroquine may be administered for arthralgias/myalgias and methotrexate for persistent arthritis. Despite encouraging initial results the oral

administration of natural human IFN α has shown questionable efficacy (Cummins et al., 2003). Also, studies with anti-TNF agents, infliximab and etanercept, did not show any efficacy in primary SjS possibly due to augmentation of the already activated type I interferon–BAFF pathway (Mariette et al., 2004; Mavragani et al., 2007). Patients with overt distal renal tubular acidosis may be orally treated with sodium bicarbonate to avoid nephrocalcinosis. For Raynaud's phenomenon avoidance of cold exposure, emotional stress, and smoking should be recommended. Leukocytoclastic vasculitis does not require specific therapy. Corticosteroids are mainly employed for severe extraglandular manifestations. Aggressive treatment with cytotoxic drugs carries an increased risk for lymphoma development and should be reserved for threatening systemic manifestations. The treatment of malignant lymphoma in SjS patients is based on histological type and extent. The implication of ongoing B cell activation in the pathophysiology of SjS suggests targeted anti-B cell therapies as a major therapeutic strategy (Mavragani et al., 2006; Voulgarelis et al., 2012).

Finally, the contribution of patient-based associations such as the Sjögren's Syndrome Foundation in the management of SjS is of paramount importance, through patient/family education, coping strategies enhancement, and increase of public awareness of the disease burden.

FUTURE PROSPECTS

Despite the intense research efforts worldwide, the initiating events which lead to break of tolerance and eventually to local immune injury at the level of exocrine glands remain obscure. Given the recent identification of the LINE-1 endogenous retroviral-like elements at the level of SjS salivary glands in strong correlation with local IFN α levels, elucidation of the epigenetic mechanisms underlying their inappropriate overexpression seems a logical next step. Additionally, careful characterization of various SjS clinical phenotypes and association with distinct molecular signatures would allow the designation of tailored therapies. Comorbidities in the setting of SjS have not been adequately addressed so far and would be a field of further clinical research. Finally, elucidation of underlying mechanisms of lymphomagenesis in the setting of SjS would enhance our understanding of transition between benign autoimmunity and malignant transformation eventually allowing the development of preventive strategies for high risk individuals.

INTRODUCTION

The joints are a target organ of many systemic autoimmune diseases, but in rheumatoid arthritis (RA) they are the preponderant and mostly sole evident focus of attack, with a large propensity to become destroyed. The pain and damage it elicits underlie the significant disability that can strike the patients and may lead to a wheelchair- or bed-ridden state. Thus, RA impairs all aspects of quality of life, including ability to work, and the consequences of the burden of the disease to the individual and society are enormous. For all these reasons, a better understanding of the pathogenesis of RA to develop new therapeutic agents interfering ideally with all pivotal events in all patients, or finding and abrogating the cause (or causes) of the disease, constitute a major task.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

The *epidemiology* of RA is quite well characterized. RA is the most common chronic inflammatory joint disease, affecting 0.5–1% of the populations in the industrialized world and women more frequently than men (2–3:1) (Silman and Pearson, 2002; Helmick et al., 2008; Eriksson et al., 2013). However, in certain Native American (Eriksson et al., 2013) populations the prevalence is much higher (Helmick et al., 2008). The causes of the disease are unknown; however, several pieces of indirect evidence sug-

gest that environmental factors play an important role: (1) RA has already at the time of its description been regarded as a disease of the poor (Landre-Beauvais, 1800) and lower levels of education and upbringing under adverse socioeconomic conditions are afflicted with a more severe course of RA and/or a higher baseline inflammatory state (Callahan and Pincus, 1997; Uhlig et al., 1999; Packard et al., 2011); (2) smoking may increase the risk and possibly also the severity of RA and is associated with increased tumor necrosis factor (TNF) and autoantibody production which in turn is related to genetic factors characteristic of RA (Silman et al., 1996; Symmons et al., 1997; Uhlig et al., 1999; Mathey et al., 2002; Glossop et al., 2006); although these associations have not been confirmed in all populations (Klareskog et al., 2011; Vesperini et al., 2013); (3) the microbiome appears to play an important role in experimental forms of arthritis (Yoshitomi et al., 2005; Abdollahi-Roodsaz et al., 2008; Wu et al., 2010) and it is conceivable that this is also the case in man, especially given the increased prevalence of periodontitis in RA and its association with particular bacteria, such as *Porphyromonas gingivalis*, a bacterium that produces peptidyl-arginine deiminase (PADI), the enzyme responsible for citrullination (see below) (Wegner et al., 2010; Scher et al., 2012). Beyond these aspects, hormonal factors may also play a role in the development of RA (Silman and Pearson, 2002).

The main *clinical characteristics* of RA are pain and swelling of the joints. The 2010 ACR/EULAR classification

criteria (Aletaha et al., 2010), which are mainly used for clinical trial purposes but can also support the diagnostic process, require the presence of clinical synovitis (i.e., swelling due to synovial involvement) in at least one joint. The more joints that are affected (swollen or painful), the easier the patient can fulfill the criteria. Joints involved are primarily those of the wrists, fingers, toes, and knees (Smolen et al., 1995), but also many other joints can be affected, although some joints, such as the distal interphalangeal joints (DIPs), are usually spared. Affected joints are not only painful upon motion and visibly swollen (Figure 36.1A) or upon clinical examination, but also tender to mild pressure and stiff for many hours after rest, such as in the morning. RA synovitis leads to subchondral bone erosions and damage to cartilage and thus to the totality of the pathology of RA which can culminate in completely destroyed joints, as seen clinically (Figure 36.1A, lower photographs) and upon imaging, especially by radiography (Figure 36.1B).

AUTOIMMUNE FEATURES

The immunologic hallmark of RA is the presence of autoantibodies in the circulation (and also in the synovial fluid). Indeed, the presence of autoantibodies constitutes an important aspect of the new ACR-EULAR classification criteria of RA and contributes two points out of a maximum of 10 if detectable and even three points if at high levels (Aletaha et al., 2010).

The first autoantibody ever described in RA was *rheumatoid factor* (RF) (Waalder, 1939), subsequently recognized to be a family of autoantibodies directed against the Fc portion of immunoglobulin (Ig) G. In clinical routine, IgM-RF is most commonly determined, but RFs can be of any isotype, and next to IgM-RF, IgG-RF and IgA-RF are frequently seen. The latter has been found to be predictive for the development of RA and is associated with worse prognosis (Houssien et al., 1997; Rantapaa-Dahlqvist et al., 2003; Nell et al., 2005). Also, IgM-RF precedes the occurrence of RA and, especially at high levels (≥ 50 IU/ml), it is associated with significant joint damage (Nielen et al., 2004; Nell et al., 2005; Aletaha et al., 2012). Moreover, the risk of developing RA for RF positive individuals in the general population may be up to 26-fold increased (Nielsen et al., 2012). This suggests an involvement of RF in the pathways to inflammation and especially joint destruction which could be a consequence of immune complex formation and subsequent Fc receptor binding, complement activation, and consequential increase in levels of inflammatory cytokines (Winchester et al., 1970; Schur et al., 1975; Mallya et al., 1982). RF are not specific for RA but can occur in other disorders, such as systemic autoimmune rheumatic diseases (SARDs) or chronic infections (Elagib et al., 1999; Bassyouni et al., 2009; Lima et al., 2013); when occurring

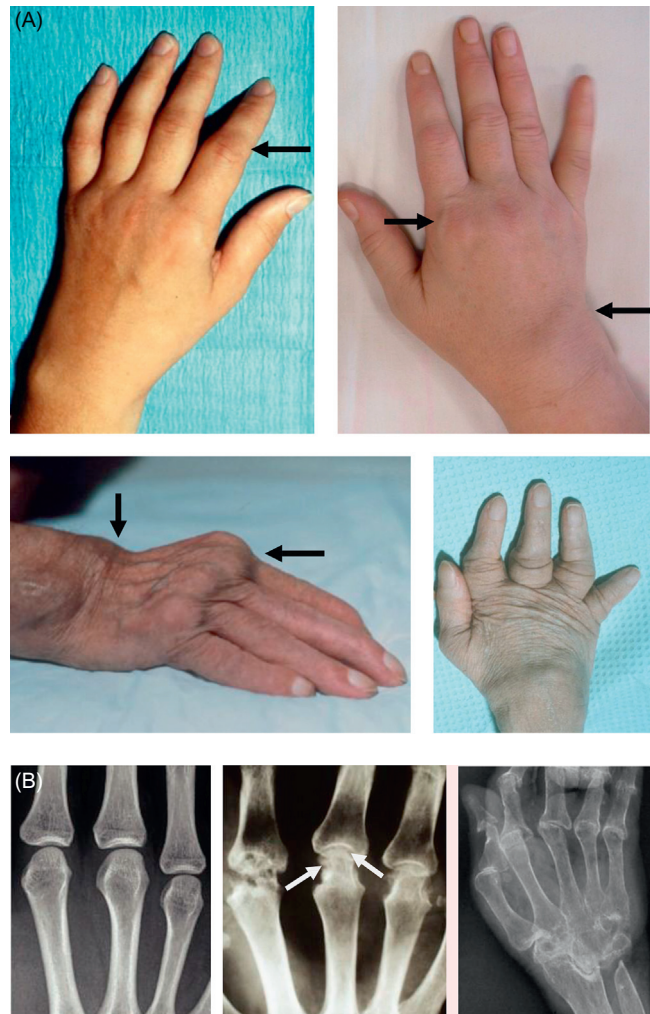

FIGURE 36.1 A. Hands of patients with RA. In the upper left image showing early RA, swelling is visible especially at the level of the proximal interphalangeal joints (arrow); in the upper right image, showing more established RA, swelling is visible at the level of the wrist, but also metacarpophalangeal joints (arrows). In the lower left image showing long-standing RA, joint damage has led to subluxation of the metacarpophalangeal joints and one can also find massive carpal joint damage (arrows). The lower right image shows a case of mutilation in virtually all joints of the hand. B. Evolution of X-ray changes from early arthritis without visible changes to severely destructive disease (bony erosions and cartilage damage seen indirectly as narrowed joint space, arrows) and ultimately mutilating disease.

in the course of acute infections, such as Epstein–Barr virus infection, they are usually of low level and transient (Halbert and Anken 1982). RF occur in up to 5% of healthy individuals, with the highest frequency in elderly people, although this has recently been disputed (Nielsen et al., 2012). The physiologic role of RFs may be to enhance immune complex clearance by amplifying complement binding and increasing immune complex size and to eliminate modified IgG (Grabar, 1975; van Snick

et al., 1978). RF are found in up to 80% of RA patients and, as indicated before, a pathogenic role of RF must be assumed. RF can be produced locally by B cells infiltrating the synovial membrane (Jasin 1985; Wernick et al., 1985; Kraan et al., 1999). The observation that RF have undergone somatic mutations and isotype switching (Williams et al., 1999) suggests that RF production in RA is T cell driven. On the other hand, some RF, and especially IgM-RF, may be highly conserved and coming from a B cell population producing natural autoantibodies (Chen et al., 1986; Martin et al., 1992; Hayakawa et al., 1999), suggesting that IgM-RF may not be derived from long-lived plasma cells. In line with the latter, RF levels change quite rapidly with changes in disease activity and decrease with effective therapy (Bohler et al., 2013).

Another very important autoantibody in RA is directed against *citrullinated peptides*. Originally described as anti-keratin antibodies and anti-perinuclear factor (Nienhuis and Mandema, 1964; Young et al., 1979; Aho et al., 1993b), the autoantibody was subsequently characterized as reactive with citrullinated peptides (Schellekens et al., 1998; Girbal-Neuhauser et al., 1999). Citrulline is an amino acid derived from deimination of arginine by PADI. A large number of proteins can undergo this post-translational modification, including fibrin, vimentin, alpha enolase, and collagen; some of these are used in ELISAs for the purposes of autoantibody testing, including a synthetic, not naturally occurring cyclic citrullinated peptide (CCP). The anti-citrullinated-protein antibodies (ACPA) have been suggested to be more predictive of RA, associated with a bad outcome and more specific for RA than RF. However, with increasing numbers of studies, an increasing number of diseases in which ACPA are present are reported, including chronic infections and other rheumatic diseases (Takasaki et al., 2004; Vossenaar ER et al., 2004; Candia et al., 2006; Bassyouni et al., 2009; Lima and Santiago 2010; Du Toit et al., 2011; Singh et al., 2011; Lima et al., 2013). Thus, while ACPA are somewhat more specific for RA than RF, they are neither pathognomonic nor of truly high specificity; this has also been accounted for in the ACR-EULAR classification criteria for RA (Aletaha et al., 2010), where both specificities are regarded as equivalent. Importantly, ACPA and RF overlap in over 90% of the patients and it has been suggested that RA is particularly severe when both specificities are present (Rantapaa-Dahlqvist et al., 2003). Interestingly, recent evidence suggests that RF and ACPA are independently associated with the progression of joint damage (De Rycke et al., 2004) and that RF may even be more strongly associated with disease activity than ACPA (Smolen et al., 2012), and it will have to be seen if this also translates into a lower effect of ACPA than RF on joint damage upon more detailed evaluation. In contrast to RF, ACPA levels do not rapidly change

with changes of disease activity or effective therapy (De Rycke et al., 2005; Bohler et al., 2013). While ACPA positivity has been reported to be associated with the shared epitope (see below) and suggested to be elicited by smoking by virtue of activation of PADI in the respiratory tract (Klareskog et al., 2006), these data stem from particular European sites and have not been uniformly confirmed in other cohorts of patients (Lee et al., 2007; Xue et al., 2008). Overall, determining ACPA is a valuable addition to the diagnostic armamentarium, but it may be sufficient to do this primarily in RF negative patients (National Collaborating Centre for Chronic Conditions, 2009). In general, autoantibody testing for RA should only be done when clinical synovitis is present in at least one joint. Interestingly, ACPA appear to precede RA for even longer periods of time than RF (Nielen et al., 2004; Brink et al., 2013); this indicates that once pre-RA becomes a recognized entity due to evidence for the efficacy of preventive therapy, ACPA testing may be an important screening method. At present, however, it appears that a significant proportion (~3%) of healthy individuals are ACPA or RF positive and, therefore, further studies to define “pre-RA” are needed (Jimenez-Boj et al., 2012).

As citrullination constitutes a post-translational protein modification, the potential autoantigenic nature of other post-translationally modified proteins was tested and, indeed, it appears that autoantibodies to carbamylated proteins also exist (anti-CarP) which are predictive of RA (Shi et al., 2013).

A variety of *other autoantibodies* can also be found in RA, confirming the broad autoimmune nature of the disease. Among these are autoantibodies to nuclear antigens, especially the heterogeneous nuclear ribonucleoprotein (hnRNP) A2 (anti-RA33) which occurs in 30–40% of RA patients, has some differential-diagnostic potential especially in RF/ACPA negative patients, and appears to be associated with a more benign form of RA (Steiner et al., 1992; Nell et al., 2003). Moreover, anti-RA33 can also precede the development of RA (Aho et al., 1993a), although this occurs closer to the time of disease onset than ACPA and RF. Anti-collagen antibodies are yet another interesting autoantibody subset, but their role appears more important in experimental models of RA (Trentham et al., 1977) than in the human disease (Steffen, 1970), although collagen might play some autoantigenic role in the context of its citrullination (Burkhardt et al., 2005).

The observation of the appearance of various autoantibodies prior to the onset of RA is similar to findings in other autoimmune diseases, such as type 1 diabetes and systemic lupus erythematosus (Arbuckle et al., 2003; Pietropaolo et al., 2012). This suggests that the activation of the autoimmune response occurs long before clinical

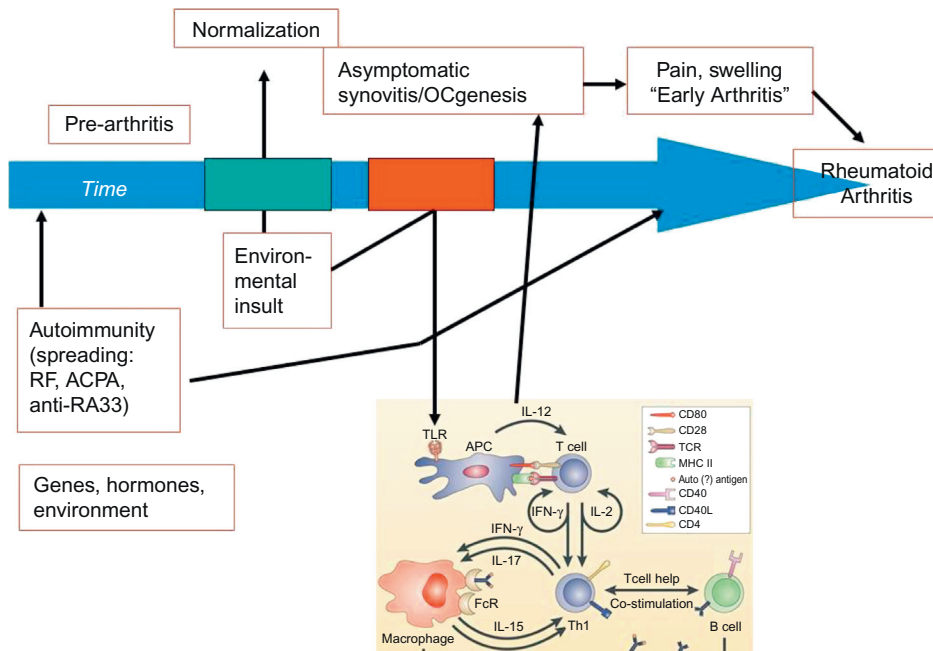

FIGURE 36.2 A Putative Concept of Pre-arthritis and Its Evolution to Full-blown Rheumatoid Arthritis. A host–environment interaction (with the microbiome?) could trigger the evolution of a non-pathogenic autoimmune response which, in contrast to many similar reactions, in a genetically predisposed host may persist. Another environmental insult leads to expansion (spreading) of the autoimmune response without any clinical consequence. At some point, one of such recurring environmental insults with a potentially arthrotropic agent could trigger an asymptomatic synovitis which, in the presence of autoantibodies, could ultimately become clinically manifest and due to an overwhelming cytokine response also trigger osteoclastogenesis (OCgenesis) and thus the full RA picture.

manifestations become apparent and that the evolution of disease is a multistep process which initially involves a trigger eliciting autoimmunity and a second trigger activating the disease pathology in the presence of a particular autoreactivity (Smolen et al., 2006). A depiction of a possible pathway from pre-arthritis to full-blown RA is shown in Figure 36.2.

T cell-mediated autoimmunity in RA has been described for collagen and hnRNPA2 (Trentham et al., 1978; Fritsch et al., 2002), but not for IgG-Fc or citrullinated peptides. Whether cellular immunity to autoantigens is of pathogenetic importance is hitherto unknown. Clearly, the presence of autoantibodies is the major autoimmune characteristic of RA.

GENETIC FEATURES

One of the major indications for a genetic predisposition to a disease is its increased familial occurrence. While in RA the prevalence in the general population is 0.5–1%, it rises to 2–4% in siblings and about 15% in identical twins (Silman et al., 1993; Seldin et al., 1999); however, a quantitative genetic analysis of two European populations showed a consistent heritability of RA in the order of ~60% (MacGregor et al., 2000).

The earliest observation that a particular gene may predispose to RA came from Stastny's seminal work describing the presence of human leucocyte antigen (HLA)-DRw4 in 70% of RA patients compared with 28% of controls (Stastny, 1978). The association with this major histocompatibility complex (MHC) class II

gene, located on chromosome 6p21, was subsequently numerous confirmed to constitute the most important genetic contribution to susceptibility for the disease. It was ultimately observed that in RA patients of various ethnic backgrounds the HLA-DRB1 alleles are frequently different, but each encodes a common sequence of amino acids at position 70–74 of the HLA-DRβ chain (QKRR or similar, such as QRRAA or RRRRAA) within the third hypervariable region of the HLA-DRB1 molecule (Gregersen et al., 1987), a region pivotally important for peptide binding. Thus, the risk contribution apparently comes from presentation of potentially arthritogenic antigens. The respective alleles include HLA-DRB1*0401, *0404, *0405, *0408; HLA-DRB1*0101, *0102; HLA-DRB1*1001; and HLA-DRB1*1402 which occur at different frequencies in different populations, but together are present in about 80% of RA patients. The overall odds ratio (OR) is about 3 with the biggest risk conveyed by HLA-DRB1*0401 and *0404, and especially strongly with homozygosity of the shared epitope (OR of ~30). There are also protective alleles, such as HLA-DRB1*0402. However, since HLA accounts for only about one-third of the total genetic risk in RA (Deighton et al., 1989), non-MHC genes must also contribute to susceptibility.

One of the non-MHC genes found to be associated with RA is protein tyrosine phosphatase, non-receptor type 22 (lymphoid) gene (*PTPN22*) on chromosome 1p13. A single nucleotide polymorphism (SNP) in this gene is the culprit, occurring in 14% of RA patients and 9% of controls (OR ~1.7) (Begovich et al., 2004). This

phosphatase, which is expressed in hematopoietic cells, inhibits T cell receptor signal transduction and the 620W variant is associated with reduced CD4T cell activation.

SNPs in the complement component 5 (*C5*)/tumor necrosis factor receptor-associated factor 1 (*TRAF1*) region at chromosome 9q33 have likewise been found to be associated with RA (Plenge et al., 2007). Complement genes, indeed, are interesting candidates given the potential involvement of complement activation in RA pathogenesis discussed previously and below. TRAF1, on the other hand, codes for a protein which acts as a negative regulator of signaling via TNF receptors (TNFR) 1 and 2, and in light of the apparent pivotal involvement of TNF in the pathogenesis of RA (see below), there is some logic behind this association. However, it is not clear at present which of these genes is primarily associated with RA or if the association may not even be with an adjacent gene. The OR is about 1.3.

Other proteins involved in signaling are the signal transducers and activators of transcription (STATs). STATs are activated by Janus kinases (Jaks) and recently the first Jak inhibitor was approved for the treatment of RA in the USA (Burmester et al., 2013). Indeed, a variant allele of *STAT4*, located on chromosome 2q, was found associated with RA (Remmers et al., 2007). *STAT4* protein mediates signaling of various cytokines, such as IL-12, IL-23, and type I interferons. The variant allele was found in 27% of patients and 22% of controls, OR ~1.3. Homozygosity of the allele was associated with a 60% increased risk of RA.

Other genetic risk factors include polymorphisms in the *CD40* and the tumor necrosis factor, alpha-induced protein 3 (*TNFAIP3*) genes (Li and Begovich, 2009).

Thus, a variety of genetic associations have been found in RA. Importantly, some of these, such as the MHC genes, are primarily related to autoantibody positive RA, indicating that immune response genes contribute their effects indeed via particular immune responses (Mattey et al., 2002; van der Helm-van Mil et al., 2006). Gene–environment interactions have been postulated in terms of genetic susceptibility in smokers to develop ACPA and RA (Klareskog et al., 2011), but have not been generally confirmed (Lee et al., 2007); thus, more information is clearly needed.

IN VIVO MODELS

Based on Koch's postulate that a causal agent must be sufficient and necessary to cause infectious disease (Koch, 1890), Witebsky et al. formulated postulates for autoimmune diseases: an autoantigen should be necessary and sufficient to cause an autoimmune disease in experimental models (Witebsky et al., 1957); in other words, the demonstration of an autoimmune nature of a disease

requires the recognition of a particular autoantigen to which antibodies or cells are autoreactive and which elicits a similar disease in an experimental model. To date, the only such autoantigen in RA is collagen, hypothesized to be the culprit several decades ago by Steffen (Steffen, 1970); collagen-specific autoantibodies and autoreactive cells exist (Menzel et al., 1975; Trentham et al., 1978; Smolen et al., 1980) and type II collagen (CII) elicits a chronic, destructive arthritis (Trentham et al., 1977). This collagen-induced arthritis (CIA) meanwhile, one of the classic RA models, depends on both the activation of T cells and the production of arthritogenic autoantibodies, but the disease itself can also only be transferred with anti-CII antibodies (Holmdahl et al., 2002). However, current views do not suggest a major role for this reactivity in eliciting human RA, and interestingly, this model responds better to IL-1- than TNF-blockade, contrasting human RA (Joosten et al., 2008). Not only CII but also other cartilage antigens, such as proteoglycan, can be used to induce experimental arthritis (Glant et al., 1987, 1998), but their role in human RA is not established.

Other autoantigens used to develop experimental models, to which autoantibodies and partly cellular immune responses exist in RA, and which are even widely used diagnostically, are immunoglobulin G (targeted by rheumatoid factors), several citrullinated proteins including fibrinogen, vimentin, alpha enolase, and collagen (targeted by ACPA), and heterogeneous nuclear ribonucleoprotein A2 (hnRNP-A2; targeted by anti-RA33 antibodies (Steiner et al., 1992). However, none of them elicit a chronic destructive arthritis upon immunization. At most, ACPA can be detected in occasional experimental approaches, such as a study on collagen-induced arthritis (Kuhn et al., 2006), although other studies reported negative observations in this respect. Further, immunization with hnRNP-A2 can aggravate arthritis in TNF overexpressing mice (Hayer et al., 2005).

Several adjuvants can induce arthritis, in particular Freund's adjuvant ("adjuvant arthritis") and pristane, a mineral oil ("pristane-induced arthritis"); while they allow one to study certain aspects of the pathways to arthritis, they do not appear to be appropriate models for human RA (Holmdahl et al., 2001), although being free of known autoantigens, they support the involvement of environmental factors in the generation of arthritis.

That any type of immune complexes can induce arthritis has been shown by Dumonde and Glynn (Dumonde and Glynn, 1962). A particular form of an immune complex arthritis has been more recently described in the form of the KRN mouse model, originally developed to study diabetes; these mice express a transgenic T cell receptor (TCR) recognizing glucose-6-phosphoisomerase (G6PI), a ubiquitous cytoplasmic protein which is also present on the surface of articular cartilage. The ensuing

autoantibodies, which by themselves can induce disease upon serum transfer, form intraarticular immune complexes followed by a severe inflammatory and destructive response, and expectedly the system is complement and mast cell dependent (Matsumoto et al., 2002). Interestingly, G6PI is not recognized as being an important autoantigen in man, but nonetheless this model confirms the role of immune complexes in chronic arthritis and especially the serum transfer model can be used to investigate the role of the innate immune system selectively. Also another model involves the TCR, namely the SKG model which is based on a spontaneous mutation of ZAP70, an important TCR signaling adaptor molecule. These mice develop a severe arthritis upon immunization with adjuvants. Of note, many of these animal models do not occur under germ-free conditions and different commensal agents can activate individual forms of experimental arthritis in hosts with particular genetic backgrounds (Wu et al., 2010), further suggesting the important involvement of the environment in the induction and maintenance of chronic arthritis (Scheinecker and Smolen, 2011; Scher and Abramson, 2011).

A number of “non-immune” models of RA also exist. The most widely used is a model in which a human TNF transgene is expressed in mice. These hTNFtg animals not only overexpress TNF but also develop a severely inflammatory and highly destructive polyarthritis (Figure 36.3A) (Keffer et al., 1991). This model has served particularly well in studies devoted to the development of bone and cartilage damage in arthritis (Redlich et al., 2002; Korb-Pap et al., 2012). Yet another example of the role of cytokine hyperactivity and consequential joint inflammation and damage is provided upon deficiency of IL-1 receptor antagonist (IL-1ra) (Horai et al., 2000), although as mentioned before IL-1 inhibition has little effect in human RA.

Thus, a variety of experimental models exist which can mimic parts of the spectrum of RA allowing studies of many aspects of pathways to arthritis and joint destruction. Some of these models even appear to fulfill Witebsky’s postulate; alas, the role of the respective autoantigen(s) in human RA is not confirmed.

PATHOLOGIC EFFECTOR MECHANISMS

The detailed mechanisms leading to the expression of the disease are still insufficiently known. Figure 36.4 depicts current views on the pathways to synovitis and joint damage in RA, showing a schematic representation of the events (Smolen et al., 2007) as well as histologic and immunohistochemical characteristics of the RA synovial membrane. It is assumed that an autoantigen or hitherto unrecognized foreign antigen is taken up by antigen presenting cells (APC), prototypically dendritic cells (DCs),

leading to activation of the innate immune system (including type I interferon and IL-6 production) as well as to that of T cells (and thus also the adaptive immune response) via respective antigen presentation and costimulation. The involvement of the shared epitope (see above) suggests that either particularly arthritogenic peptides bind with high affinity to these but not other MHC molecules or that an arthritogenic T cell repertoire is selected via the shared epitope. These activated T cells, formerly thought to be Th1 (gamma interferon producing) cells, are now believed to belong mainly to the Th17 family (IL-17 producing) (Korn et al., 2009) and to be insufficiently controlled by regulatory T cells (Chavele and Ehrenstein, 2011); they in turn activate macrophages and provide B cell help. These events presumably occur partly centrally and partly within the synovial membrane into which the cells have migrated. Activated macrophages secrete proinflammatory cytokines. Activated RA B cells and their progeny produce autoantibodies which, after forming immune complexes, bind to Fc- and complement-receptors and thus increase macrophage cytokine production (Aringer and Smolen, 2012). In parallel, fibroblast-like synovial cells (FLS) become activated and also produce inflammatory mediators (Lee and Firestein 2003). Indeed, FLS may play a particularly important role, since (1) mesenchymal overexpression of TNF is sufficient to drive all aspects of destructive arthritis (Keffer et al., 1991; Bluml et al., 2010), and (2) these cells may “travel” through the bloodstream from one joint to other joints, thus spreading arthritis (Lefevre et al., 2009). Taken together, all these events lead to synovial inflammation. The inflammatory reaction is a consequence of the activation of proinflammatory cytokines (TNF, IL-6, and IL-1); based on results of clinical trials, therapies targeting TNF and IL-6 appear to play predominant roles, while that of IL-1 appears to be minor. Subsequently other mediators of inflammation, such as various chemokines, metalloproteinases, and small molecules (like prostaglandins) are induced and increase the inflammatory reaction which clinically manifests in swelling and pain as discussed above.

By whichever way the detailed events evolve (i.e., whether the innate immune reactivity, T or B cell activation are dominant), the mechanisms ultimately lead to an influx of inflammatory cells into the synovial membrane; the inflamed synovial membrane transforms into an autonomous “semimalignant” tissue (pannus) leading to destruction of bone (erosions) and cartilage. Indeed, the major feature distinguishing RA from other inflammatory joint diseases is the high propensity for joint destruction.

Cartilage damage appears to arise primarily via direct action of metalloproteinases secreted within the joint on cartilage matrix and/or via the activation of chondrocytes by cytokines and subsequent matrix degradation;

FIGURE 36.3 A. Arthritis in mice overexpressing human TNF. Note the significant inflammatory response and the dramatic destruction due to subchondral invasion of the bone by the pannus tissue. B. Bone damage is elicited by osteoclasts differentiating within the synovial membrane. The small dark blue (tartrate-resistant acid phosphatase [TRAP] positive) cells are osteoclast precursors.

attachment of the synovial membrane to cartilage appears to play an important role in these respects (Korb-Pap et al., 2012).

Bone destruction is mediated by osteoclasts activated within the synovial membrane at sites adjacent to bone (Figure 36.3B) (Gravallese et al., 1998; Redlich et al., 2002). While osteoclast differentiation and activation is pivotally dependent on receptor activator of $\text{NF-}\kappa\text{B}$ (RANK) and its ligand (RANKL), proinflammatory cytokines enhance the generation and activity of osteoclasts (Lam et al., 2000; Teitelbaum, 2000). The much stronger destructive nature of RA compared with other inflammatory joint diseases may be explained by the higher load of cytokines like TNF and IL-6 (Partsch et al., 1997) which in turn are likely to be a consequence of the presence of autoantibodies and immune complexes in the joint (Zvaifler, 1974). Indeed, the presence of RF is related to joint damage via association with higher disease activity and also independently of disease activity (Aletaha et al., 2012).

With all due recognition of deliberations on pathogenic pathways based on experimental models or *ex vivo*

and *in vitro* studies of patient cells, tissues or body fluids, ultimately the validation of the involvement of specific pathways must come from the efficacy of therapies targeting a presumed pathogenetic principle (sort of reverse Witebsky postulate). Today, TNF and IL-6 blockade and also inhibition of T cell costimulation and B lymphocyte depletion are all approved RA therapeutics, thus validating these targets as importantly involved (although also eliciting new questions; see below). However, the fact that all these agents lead to similar clinical results, that their efficacy is not increased in patients who have failed one of the other targeted therapies, and combinations of these biological hitherto do not apparently increase efficacy although they do mostly increase serious adverse event rates, suggest that all these cells and molecules have a single major final pathway in common; this bottleneck appears to be the proinflammatory cytokine system (Smolen and Aletaha, 2013).

Still some questions arise in this respect: (1) if T cells do play a major role as suggested by the efficacy of costimulation inhibition, why is anti-CD4 therapy not effective (van der Lubbe et al., 1995)? (2) If B cells play a major role, why are several B cell directed therapies ineffective (Bluml et al., 2013)? (3) With so many similarities regarding the effects of the three major proinflammatory cytokines: TNF, IL-1, and IL-6, why is IL-1 inhibition so much less efficacious than TNF and IL-6 inhibition (Singh et al., 2009)? And, most importantly, (4) what determines the arthrotropism of the disease? Do particular antigens of the joint (cartilage components?) elicit the disease? Is it influx into the joint, with its permissive anatomical structures lacking efficient basement membranes, of non-specific bacterial products that is of decisive nature (Toivanen, 2001)? Resolving these questions will allow better insights into the pathways leading to RA, but they simply attest that proof of concept can only come from the clinic and not from theoretical considerations or experimental models.

AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

As discussed in the section on autoimmunity, the most important autoantibodies in RA are RF and ACPA. They are both important components in classification criteria and therefore of diagnostic help (Aletaha et al., 2010). Their sensitivity and specificity for the diagnosis of RA is similar (sensitivity about 50–60%, specificity about 85–95%) (Mjaavatten et al., 2010; Neogi et al., 2010; Nicaise-Roland et al., 2013). Both of these autoantibodies fluctuate with disease activity and effective therapy, although RF appears to do so to a much greater extent (Bohler et al., 2013); indeed, RF can become negative (seroconversion) with long-standing remission which is

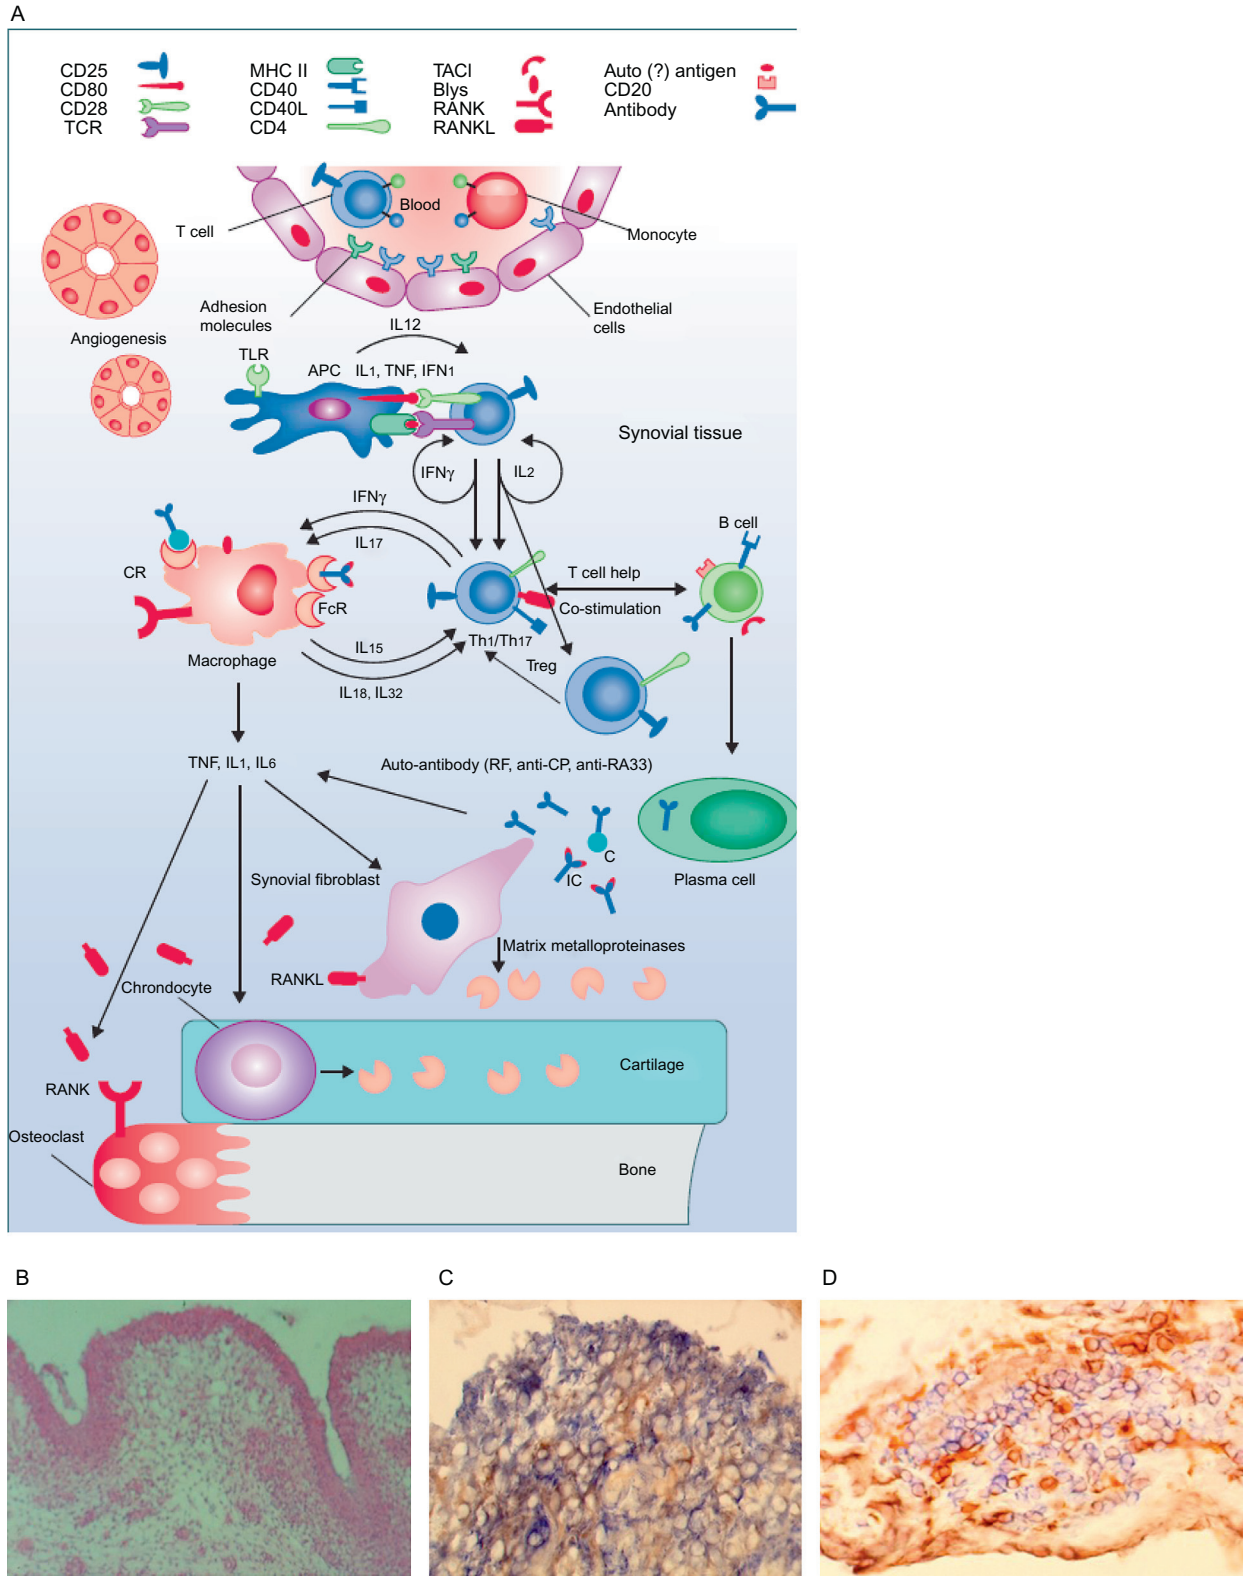

FIGURE 36.4 A. A schematic representation of the pathogenesis of RA (Smolen et al., 2007). B. Hematoxylin-eosin stain of an RA synovial membrane section showing hyperplasia of the lining layer, hypercellularity in the sublining and hypervascularity. C. TNF expression (brown) in type A (monocyte-like, blue) and type B (fibroblast-like, unstained) synovial lining cells. D. Activated T cells in synovial membrane (CD3 in brown, HLA-DR in blue).

not known for ACPA. ACPA can be tested for using several different citrullinated antigens: fibrinogen, vimentin, filaggrin, collagen type II, enolase, or a cyclic peptide. These autoantibodies differ only slightly in terms of time of appearance and frequency (Brink et al., 2013; Nicaise-Roland et al., 2013).

Another autoantibody specificity which can be of diagnostic help is anti-RA33, especially if RF and ACPA are negative (Nell et al., 2005).

All these autoantibodies can also be present in a variety of other diseases, especially other autoimmune disorders and infectious diseases, and also notably so for ACPA (Abdel Fattah et al., 2009; Bassyouni et al., 2009; Lima and Santiago 2010; Singh et al., 2011; Gokhan et al., 2013). They can also be present in healthy people and it has previously been suggested that RF positivity increases with age, but this was not seen in more recent series (Nielsen et al., 2012). Therefore, only in the right clinical setting RF and ACPA can be regarded as marker autoantibodies of the disease and as having a high weighting in the classification criteria for RA (Aletaha et al., 2010).

Of particular importance, the presence of autoantibodies can partly inform in advance on response to therapy. Thus, B cell targeted therapy with rituximab is more efficacious in RF and/or ACPA positive than negative patients (Chatzidionysiou et al., 2011). This is conceptually sound, since rituximab eliminates CD20 positive B cells and levels of these autoantibodies decrease with effective therapy. This observation appears to be specific for rituximab, since therapies targeted against cytokines or T cell costimulation do not appear to be differently effective in seropositive and seronegative patients.

CONCLUDING REMARKS—FUTURE PROSPECTS

Rheumatoid arthritis is the prototypic autoimmune joint disease. Autoreactivity, in association with a genetic predisposition, appears to play a major role in pathways to RA and the presence of autoantibodies is associated with joint damage and thus of prognostic in addition to diagnostic value. The observations that autoimmunity precedes clinical disease onset by many years and that the presence of RF in otherwise healthy individuals may increase the risk for developing RA more than 20-fold, implies that there is a pre-arthritis phase. This suggests that in the future, long before the onset of disease, preventive measures might be taken for people at risk (see Chapters 77–79). Thus, the autoimmune response may at some early point in time serve as guidance toward novel therapeutic approaches. Further, the causes of RA are still unknown: which (environmental?) provocation elicits RA? And how then does the autoimmune reaction ensue?

These questions will hopefully also find resolution over the next decade.

Finally, for patients with established disease, it is currently unknown to which therapies they will respond in the best way, ideally by attaining remission. It is conceivable that biomarkers, which may include the autoimmune reactivity pattern, will help in this regard. Thus, there is hope for the future that we may be able to predict not only people at high risk of developing RA, but also those likely to experience optimal therapeutic responsiveness.

ACKNOWLEDGMENT

The studies providing the basis for this chapter were partly supported by EU grants BT-Cure and EuroTEAM.

Juvenile idiopathic arthritis (JIA) is not a disease, but an exclusion diagnosis that gathers together all forms of arthritis that begin before the age of 16 years, persist for more than 6 weeks, and are of unknown origin (Ravelli and Martini, 2007; Prakken et al., 2011). This heterogeneous group of chronic arthritides has been classified on clinical and laboratory grounds to try to identify homogeneous, mutually exclusive categories suitable for etiopathogenic studies. The more recent classification is the one proposed by the International League of Associations for Rheumatology (ILAR) (Petty et al., 2004) (Table 37.1). This classification has, however, been recently challenged and suggestions for reconsidering some aspects of classification and nomenclature, as we will discuss, have been proposed (Martini, 2003, 2012).

EPIDEMIOLOGY

JIA as a whole is the most common chronic rheumatic condition in childhood and an important cause of short- and long-term disability. Studies in Western populations have reported an incidence and a prevalence varying from 2 to 20 and from 16 to 150 per 100,000, respectively (Ravelli and Martini, 2007).

CLINICAL FEATURES

The group of diseases gathered under the umbrella term of JIA encompasses several different forms of chronic arthritis that, in the absence of etiologic clues, have been classified according to clinical criteria.

Systemic Arthritis

Systemic arthritis is considered the equivalent of “adult-onset Still’s disease” and accounts for 10 to 15% of children with JIA. It is characterized by prominent systemic features, such as high spiking fever, an evanescent, non-fixed, erythematous rash that characteristically occurs with fever peaks, hepatomegaly or splenomegaly, generalized lymphadenopathy, and serositis. Myalgias and abdominal pain may be intense during fever peaks. Arthritis is more often symmetrical and polyarticular; it may be absent at onset and develop during disease course. Laboratory investigations show leukocytosis (with neutrophilia), thrombocytosis and very high erythrocyte sedimentation rate (ESR) and C-reactive protein concentration. A microcytic anemia is common.

About 5 to 8% of children with systemic JIA develop a life-threatening complication, named macrophage

TABLE 37.1 Frequency, Age at Onset, and Sex Distribution of the International League of Associations for Rheumatology (ILAR) Categories of Juvenile Idiopathic Arthritis. The Different Categories are Defined According to the Symptoms Presented during the First 6 Months of Disease

| | Frequency ^a | Onset Age | Sex Ratio |
|--|------------------------|---|-----------|
| Systemic arthritis | 4–17% | Throughout childhood | F = M |
| Oligoarthritis | 27–56% | Early childhood; peak at 2–3 years | F >>> M |
| Rheumatoid factor-positive polyarthritis | 2–7% | Late childhood or adolescence | F >> M |
| Rheumatoid factor-negative polyarthritis | 11–28% | Biphasic distribution, early at 2–4 years and later peak at 6–12 years | F >> M |
| Enthesitis-related arthritis | 3–11% | Late childhood or adolescence | M >> F |
| Psoriatic arthritis | 2–11% | Biphasic distribution; early peak at 2–4 years and later peak at 9–11 years | F > M |
| Undifferentiated arthritis | 11–21% | | |

^aPercentage of all juvenile idiopathic arthritis cases.

activation syndrome (MAS) (Ravelli et al., 2012). The syndrome is a form of reactive hemophagocytic lymphohistiocytosis and is characterized by the sudden onset of sustained fever, pancytopenia, hepatosplenomegaly, liver insufficiency, coagulopathy with hemorrhagic manifestations, and neurological symptoms. Laboratory features include elevated triglycerides, low sodium levels, and markedly increased ferritin concentrations. The demonstration of active phagocytosis of hematopoietic cells by macrophage in the bone marrow is common. Early recognition and treatment of MAS before the development of severe multisystem involvement is crucial for the prognosis.

Systemic JIA (sJIA) probably does not represent a disease but rather a syndrome, the common endpoint of several different diseases all causing a marked and persistent activation of the innate immune system (Martini, 2012). The potential heterogeneity of this condition is suggested by the exquisite sensitivity to IL-1 blockade presented by a subset of patients (see below) as well as by differences in clinical course.

Indeed, in about half of patients the disease is mainly characterized by the systemic features while the arthritis usually remits when systemic features are controlled. In the other half of patients the disease follows an unremitting course; systemic symptoms may eventually resolve, leaving chronic arthritis as the major long-term problem. There are, moreover, patients who present the same systemic features observed in sJIA but never develop arthritis, and therefore cannot by definition be classified as sJIA. Currently this subgroup of patients lacks any taxonomic definition. The super-imposable systemic clinical and laboratory features suggest that they have a disease strongly related to sJIA despite the lack of arthritis. This

type of patient is indeed included in the definition of adult onset Still's disease, where the presence of arthritis is not required for diagnosis. It has been suggested to include these patients in the sJIA disease category (Martini, 2012) but, given the absence of arthritis, the term sJIA should be changed; a possible new name could be Still's disease, by analogy with the adult counterpart, adult onset Still's disease.

Rheumatoid Factor-Positive Polyarthritis

This rare (5% of patients with JIA) subgroup is the childhood equivalent of adult rheumatoid factor (RF)-positive rheumatoid arthritis; in fact, it is the only form of JIA with positive antibodies to cyclic citrullinated peptides. As in adults it is a chronic, erosive disease.

Enthesitis-Related Arthritis

This represents a form of undifferentiated spondyloarthropathy. The most common sites of enthesitis are the calcaneal insertions of the Achilles tendon and of the plantar fascia and the tarsal area. Arthritis is usually oligoarticular and affects mainly the lower limbs. Most patients are human leukocyte antigen (HLA)-B27 positive. The disease can be mild and remitting but a variable proportion of patients, who are impossible to identify at disease onset, develop the involvement of sacroiliac joints during disease course. Indeed, all the different forms of adult spondyloarthropathies can be observed in children; the major difference is the much higher proportion of undifferentiated spondyloarthropathies in childhood. The discrepancy in terminology between children and adults has been a source of

confusion and it has been suggested to abandon the term enthesitis-related arthritis, which could suggest the existence of a form peculiar to childhood, and to use, with the prefix juvenile, the same terminology used to define the adult forms of spondyloarthropathies (Martini, 2012).

Oligoarthritis

Oligoarthritis is defined by the involvement of four or fewer joints during the first 6 months of disease. In Western countries the large majority of patients belongs to a quite well-defined disease entity observed only in children and characterized by an asymmetric arthritis, involving mainly large joints, an early onset (before 6 years of age), a female predilection, a high frequency of positive antinuclear antibodies (ANA), a high risk of developing chronic iridocyclitis, and consistent HLA associations. The current ILAR classification distinguishes two categories of oligoarthritis: one, often with a good long-term prognosis, in which the disease remains confined to four or fewer joints (persistent oligoarthritis) and one in which arthritis extends to more than four joints after the first 6 months of disease (extended oligoarthritis). It has, however, been shown that ANA-positive patients with persistent or with extended oligoarthritis share the same characteristics, strongly suggesting that they represent the same disease and just differ in the spread of arthritis (Ravelli et al., 2005).

A peculiar feature is a chronic, asymptomatic, nongranulomatous, anterior uveitis affecting the iris and the ciliary body (iridocyclitis) that can cause severe visual impairment and affects about 30% of patients. The onset is insidious and very often entirely asymptomatic in contrast with the painful, acute uveitis that can be observed in enthesitis-related arthritis. One or both eyes may be involved. Most children who develop uveitis do it within 5 to 7 years from the onset of arthritis. The course of uveitis may be relapsing or chronic and does not parallel the clinical course of arthritis. ANA positivity represents a strong risk factor for developing uveitis. Since uveitis is asymptomatic, children with ANA-positive JIA should be screened at least every 3 months by slit-lamp examination.

Rheumatoid Factor-Negative Polyarthritis

This is defined by the involvement of five or more joints during the first 6 months of disease and is an heterogeneous JIA category. At least two separate subsets can be identified: one, characterized by a symmetric synovitis of large and small joints, onset in school age, and negative ANA, is similar to adult-onset RF-negative rheumatoid arthritis; the other resembles oligoarthritis, except by definition for the number of joints affected in the first 6 months of disease. The similarities between this second subset and early-onset oligoarthritis led to the hypothesis

that they represent the same disease, the former representing a rapid arthritis spread in the latter (Martini, 2003). This view has been confirmed by the demonstration that those features (early age at onset, asymmetric arthritis, female predominance, ANA positivity, elevated incidence of chronic iridocyclitis) that characterize ANA-positive oligoarthritis are also present in ANA-positive, RF-negative polyarthritis, but not in ANA-negative, RF-negative polyarthritis or in ANA-negative oligoarthritis (Ravelli et al., 2005, 2011). Moreover, ANA-positive, RF-negative polyarthritis is seldom observed in those countries in which ANA-positive oligoarthritis is rare (Martini, 2003).

Of note, Barnes and co-workers (Barnes et al., 2010), studying gene expression in oligoarticular and polyarticular JIA, found that patients with early-onset arthritis (≤ 6 years) are characterized by a B cell signature independently from the number of joints involved; moreover, high resolution HLA class I and class II typing has also shown similarities between early-onset oligoarticular and polyarticular JIA (Hollenbach et al., 2010).

Psoriatic Arthritis

This is another inadequately defined JIA category. If Vancouver criteria (presence of arthritis and psoriasis or some psoriatic features) (Southwood et al., 1989) are used to define psoriatic arthritis two populations of patients are identified: (1) one that represents, as adult psoriatic arthritis, a form of spondyloarthropathy; (2) a second form that shares the same above-mentioned characteristics of ANA-positive, early onset oligoarthritis (Martini, 2003; Stoll et al., 2006). So the association of psoriasis with arthritis seems to lead to the identification of two different subsets of patients, one that is similar to adult psoriatic arthritis and the other that overlaps with ANA-positive, early onset oligoarthritis (Martini, 2003; Ravelli et al., 2011). The ILAR classification criteria for psoriatic arthritis, in which patients with enthesitis are by definition excluded, limit the identification of those patients that have a form of psoriatic arthritis similar to that observed in adults (Stoll et al., 2008).

Undifferentiated Arthritis

Undifferentiated arthritis does not represent a separate subset, but a category in which by definition patients that do not fulfill inclusion criteria of any of the categories, or fit criteria for more than one category, are included.

Perspectives

The ILAR classification has represented a step forward in the understanding of JIA. However, recent acquisitions call for a further refinement in order to better identify

clinically homogeneous entities suitable for etiopathogenic studies.

In particular, in our opinion there is now enough evidence that some patients with ANA-positive, early-onset arthritis, a well-defined entity observed only in childhood, are in the current ILAR classification wrongly included in the RF-negative polyarthritis and in the psoriatic arthritis categories. It would be therefore advisable to group all these patients together in a new category of ANA-positive, early onset arthritis independently from the number of joints involved or the presence of psoriasis (Martini, 2012). Once these patients are removed, the RF-negative polyarthritis and the psoriatic arthritis categories would presumably mainly be represented by patients with the same clinical characteristics observed in adults.

Further advances in classification will come from immunologic, genomic, and proteomic studies in the various JIA categories as well as from differences in the response to biological agents that, by targeting specific molecules, represent a precious opportunity of “reverse translation” (from the bed to the bench side) as it has been with the inhibition of interleukin (IL)-1 in sJIA.

ETIOLOGY AND PATHOGENESIS

As discussed above, it is now clear that in children, as in adults, there are several completely different diseases which are all responsible for chronic arthritis and that are gathered under the umbrella term of JIA. With the exception of early-onset, ANA-positive arthritis, which is specific to childhood, they appear to represent the childhood counterpart of diseases also observed in adults. Therefore, in order to avoid overlaps with other chapters only those immunological aspects that belong to systemic JIA, which is far more common in children, and to early-onset ANA-positive arthritis, which occurs only in children, will be discussed in detail. For the other diseases, there are no relevant, specific immunological findings characteristic of childhood-onset forms.

Systemic Juvenile Idiopathic Arthritis

Systemic JIA (sJIA) is etiopathogenically different from all the other forms of JIA (Mellins et al., 2011). The systemic features, the marked inflammatory response, the lack of sex bias, peak age at onset, association with autoantibodies or HLA antigens are all consistent with what is observed in autoinflammatory diseases. Also, the sensitivity to treatment is different and provides evidence for a different etiopathogenesis. Indeed, methotrexate or antitumor necrosis factor (TNF) agents are less effective than in the other JIA categories, while anti-IL-6 or anti-IL-1 drugs are of impressive efficacy.

Genetics

sJIA is much more frequent in children than in adults (adult-onset Still’s disease). This can suggest a role for some widely diffused infectious agents that are encountered early in life or represent the effect of a strong genetic predisposing background. The disease is considered multifactorial and multigenic although it is not known if genetic predisposition is due to the combinations of common genetic variants each providing a small contribution to inherited susceptibility or to high-penetrance rare mutations that only account for a few cases each.

Some genetic polymorphisms, particularly of cytokine genes, have been associated with sJIA (Table 37.2). A genome-wide association study is currently under way.

Consistently with the supposed autoinflammatory nature of sJIA gene expression, studies on peripheral blood mononuclear cells (PBMCs) have shown an upregulation of genes associated with the activation of monocyte/macrophage lineage and a downregulation of the gene networks involving natural killer (NK) cells, T cells, and major histocompatibility complex (MHC) antigen-related biological processes (Pascual et al., 2005; Allantaz et al., 2007; Fall et al., 2007; Ogilvie et al., 2007; Barnes et al., 2009).

Proinflammatory Mediators

Laboratory observations, as well as the therapeutic efficacy of cytokine inhibitors have provided clear evidence for a major pathogenic role of phagocyte-derived cytokines and in particular of IL-6 and IL-1.

Interleukin-6

The role of IL-6 in the pathogenesis of sJIA appears to be pivotal. Circulating levels of IL-6 are markedly elevated, increase during the peak of fever, and correlate with the extent and severity of joint involvement and with platelet counts (De Benedetti et al., 1991). Synovial fluid levels of IL-6 are also markedly increased and significantly higher than those observed in patients with polyarticular and oligoarticular JIA or in adult patients with rheumatoid arthritis (De Benedetti et al., 1997a). Moreover, in sJIA patients huge quantities of IL-6 circulate bound to the soluble receptor; this bound IL-6 seems biologically active since it correlates much better with the level of C-reactive protein than free circulating IL-6 (De Benedetti et al., 1994). At variance with findings in adult RA, anemia in sJIA is microcytic and characterized by a marked defect in iron supply for erythropoiesis, while growth of erythroid colonies is normal and erythropoietin production is appropriate (Cazzola et al., 1996). These findings are consistent with the effect of IL-6 on the bone marrow. Indeed, IL-6 stimulates both hypoxia-induced erythropoietin production and erythroid progenitor proliferation and,

by increasing ferritin expression and hepatic uptake of serum iron, causes a reticuloendothelial iron block. Moreover, IL-6 dramatically induces the liver production of hepcidin, a peptide that inhibits iron absorption in the small intestine and the release of recycled iron from the

macrophages (Nemeth et al., 2004). This can well explain the oral iron malabsorption that has been observed in patients with sJIA (Martini et al., 1994).

Growth impairment is a well-known feature of sJIA since its first description and IL-6-transgenic mice with

high circulating levels of IL-6 since birth show a decreased rate of growth, attaining 50–60% of the size of their wild-type littermates (De Benedetti et al., 1997b). Moreover, similar to patients with sJIA, IL-6-transgenic mice have normal growth hormone production but low levels of insulin-like growth factor 1 (IGF-1) and IGF binding protein 3 (IGFBP-3) (De Benedetti et al., 2001).

All these findings led to the hypothesis that sJIA is an IL-6- and not a TNF-driven disease (De Benedetti and Martini, 1998). This hypothesis was supported 10 years later by the double-blind controlled study with a withdrawal design that showed the marked efficacy of tocilizumab, a monoclonal antibody against the IL-6 soluble receptor (sIL-6R) which is essential for signal transduction (Yokota et al., 2008). These brilliant therapeutic results have been recently confirmed by a double-blind, placebo-controlled confirmatory study (De Benedetti et al., 2012).

Interleukin-1

The most compelling evidence for the important role of IL-1 in the pathogenesis of sJIA came from the quite serendipitous finding of the marked therapeutic efficacy of anakinra, an IL-1 inhibitor which is the recombinant version of the naturally occurring soluble IL-1 receptor antagonist (IL-1 Ra) (Verbsky and White, 2004; Pascual et al., 2005). The role of IL-1 is not in contrast with that of IL-6 since IL-1 is upstream to IL-6. It was also shown that serum from patients with active sJIA can induce the transcription of various IL-1-related genes (Pascual et al., 2005). However, gene expression studies mentioned above did not usually show increased expression of IL-1 β . Interestingly, serum levels of myeloid-related proteins (MRPs) 8 and 14 (which are secreted by activated neutrophils and monocytes) are very high during active disease, and MRP-14 in serum of patients with sJIA has been shown to be a strong inducer of IL-1 expression in phagocytes (Frosch et al., 2009). Moreover, MRP8/14 serum concentrations have been reported to correlate closely with response to drug treatment and disease activity and might therefore also be useful in monitoring treatment of individual patients with sJIA (Holzinger et al., 2012).

Of note, it has been shown that the response to anakinra can identify two different populations of patients with sJIA (Gattorno et al., 2008). One (accounting for about 40% of patients) shows a dramatic response to IL-1 blockade (similar to that observed in cryopyrin-associated autoinflammatory syndromes) leading to complete normalization of clinical as well as laboratory features in a few days. The other is resistant to treatment or shows an intermediate response; often in this second group of patients systemic features respond well to therapy while synovitis persists although it can improve. At variance with cryopyrinopathies both groups of patients do not secrete higher amounts of IL-1 with respect to controls (Gattorno et al., 2008).

Only minor differences were observed when serum levels of 30 different cytokines and other soluble molecules were analyzed: patients with a brilliant response had higher serum levels of IL-9 and lower serum levels of granulocyte colony-stimulating factor. The main differences observed were in the number of active joints and in neutrophil count; patients with fewer joints affected or with higher neutrophil count had a higher probability of responding to anti-IL-1 therapy. Thus sJIA can be stratified in two subgroups based on responsiveness to IL-1 inhibition. The group with a bright response could represent a separate entity in which the autoinflammatory component has the leading pathogenic role and in which therefore monocytes and neutrophils, rather than lymphocytes, are the predominant effector cells. The other group, characterized by the presence of an important synovitis, seems to have, in addition, a relevant autoimmune component.

A controlled trial has also supported the efficacy of anakinra in sJIA (Quartier et al., 2011). Of interest in this trial is a “*de novo*” type I IFN signature (which is not a feature of untreated sJIA) which was observed in the majority of anakinra-treated patients regardless of the clinical response.

Recently, it has been suggested, in a retrospective study, that a precocious treatment with anakinra could prevent the subsequent appearance of refractory arthritis in the large majority of patients (Nigrovic et al., 2011). This hypothesis, however, needs to be confirmed in prospective randomized trials.

More recently a monoclonal antibody against IL-1 β (canakinumab) has been used in the treatment of sJIA. A first dose-finding phase I/II trial has defined the correct dosage (Ruperto et al., 2012) which has been used in a subsequent phase III trial. The results have confirmed the efficacy of IL-1 inhibition in sJIA (Ruperto et al., 2012).

Interleukin-18

Systemic JIA as well as adult-onset Still’s disease are characterized by very high levels of circulating IL-18 (Kawashima et al., 2001; Maeno et al., 2002). Of note, IL-18 is a member of the IL-1 cytokine superfamily, is stored as precursor protein, and, upon activation, is cleaved by caspase-1 in a manner similar to that of IL-1 to yield the active cytokine. It seems that in sJIA as well as during macrophage activation syndrome (see below) IL-18 and other proinflammatory cytokines (IFN- γ , IL-6, TNF) are mainly produced by resident macrophages (bone marrow and liver) (Maeno et al., 2004; Billiau et al., 2005). A reversible defect in phosphorylation of IL-18 receptor has been reported in patients with sJIA (de Jager et al., 2009).

Macrophage Activation Syndrome

It remains substantially a mystery why sJIA is so strongly associated with MAS. Of note MAS is seldom observed

in autoinflammatory diseases. It is unclear if this complication characterizes a distinct subset of the disease. Interestingly, activated macrophages or frank hemophagocytic cells have been found in 53% of patients with sJIA who underwent bone marrow aspiration, suggesting that subclinical MAS may be present in half of the patients (Behrens et al., 2007).

As mentioned above, MAS bears a strong resemblance to a group of histiocytic disorders collectively known as hemophagocytic lymphohistiocytosis (HLH) (Janka, 2012). Two types of HLH are recognized. The primary or familial (FHLH) forms are secondary to genetic deficiency in cytolytic pathway proteins. The secondary or reactive (ReHLH) forms are associated with an identifiable infectious episode or are secondary to an autoimmune condition or to a neoplastic or a metabolic disorder.

To date, all the described genetic defects associated with HLH appear to be related to one another in the pathway of granule-mediated cytotoxicity with the lack of perforin being the most common. These genetic defects interrupt the mechanisms responsible for triggered apoptosis (mediated by cytotoxic cells on the target cell) or activation-induced apoptosis (putative suicide of activated T cell). A hallmark of HLH is therefore an impaired or absent function of NK and cytotoxic T cells. In patients with FHLH, NK cell numbers are normal and the functional defect is usually persistent; patients with ReHLH may have low NK cell numbers but NK cell number and function usually reverts to normal after treatment. Two pathogenic hypotheses have been proposed. One is an inability of cytotoxic cells to clear virally infected cells with persistent antigen stimulation, leading to activation and proliferation of T cells with escalating cytokine production and macrophage activation. The second is a failure to provide appropriate apoptotic signals for removal of APC and stimulated lymphocytes that continuously secrete IFN- γ , γ , and GM-CSF, potent activators of macrophages that secrete massive amounts of proinflammatory cytokines. HLH symptoms can be explained by the high concentration of inflammatory cytokines and by organ infiltration by lymphocytes and histiocytes. Fever is induced by IL-1 and IL-6 and pancytopenia is the consequence of high levels of TNF and interferon (IFN)- γ rather than of hemophagocytosis. TNF inhibits lipoprotein lipase leading to elevated triglycerides. Activated macrophages secrete ferritin and plasminogen activator which results in high plasmin levels and hyperfibrinolysis. Hepatosplenomegaly, increased liver enzymes, and neurological symptoms are the consequence of organ infiltration by activated lymphocytes and histiocytes. Activated lymphocytes and macrophages are respectively the source for high concentrations of circulating sIL-2 Ra and sCD163.

The best experimental model of HLH is perforin-deficient mouse in which CD 8 T cells produce large amounts of IFN- γ . The etiopathogenesis of MAS remains

unknown. Immunologic abnormalities, similar to those seen in HLH (poor NK cell cytolytic activity often associated with abnormal levels of perforin expression) but reversible have been reported (Ravelli et al., 2012). However, in many instances of sJIA/MAS, no such defects in cytotoxic cell function have been identified. This suggests that MAS represents an end-stage clinical syndrome that can be elicited by different mechanisms. In this respect other murine models of MAS have been recently reported.

It has been shown that repeated stimulation of toll-like receptor (TLR)9 produces an HLH/MAS-like syndrome on a normal genetic background, without exogenous antigen (Behrens et al., 2011). Like in perforin-deficient mice the syndrome depends on the presence of IFN- γ ; however, IFN- γ is arising from different sources than CD 8 T cells, including dendritic cells and NK cells. This model shows that MAS can develop during persistent innate immune activation independently from defects in cytotoxic cell function.

Treatment of IL-6-transgenic mice with TLR ligands led to elevated levels of IL-1 β , TNF, IL-6, and IL-18 and an increased fatality rate with features (high ferritin and decreased platelet and neutrophil count) similar to those observed in MAS (Strippoli et al., 2012).

Oligoarticular Juvenile Idiopathic Arthritis

As mentioned above, in Western countries most children with oligoarthritis have a definite disease, specific to childhood and characterized by an asymmetric arthritis, involving mainly large joints, an early onset (before 6 years of age), a female predilection, a high frequency of positive ANAs, and a high risk of developing chronic iridocyclitis. The homogeneity of this form of arthritis is also witnessed by consistent associations with HLA antigens. Positive associations include HLA-A2, HLA-DRB1*11 (a subtype of HLA-DR5), and HLA-DRB1*08. On the contrary, HLA-DRB1*04 and HLA-DRB1*07 have been found to be significantly decreased (Pralhad and Glass, 2008). HLA associations support an autoimmune pathogenesis and the early onset suggests that the disease could be elicited by a very common infectious agent that can be encountered early in life. In this respect evidence has been provided that T cells from patients with early-onset ANA-positive oligoarticular JIA are sensitized against epitopes that are shared between the disease-associated HLA antigens and proteins present on Epstein–Barr virus and other herpes viruses (Massa et al., 2002); herpes viruses represent a group of infectious agents to which the vast majority of children have already been exposed by 6 years of age.

ANA have been found to react against different chromatin constituents and against the DEK nuclear protein, a putative oncoprotein; however, none of these molecular targets has been found to be specific to oligoarticular JIA.

The reasons why chronic anterior uveitis is so strongly associated with the disease remain unknown.

The inflammatory synovitis observed in JIA is similar to that of adult rheumatoid arthritis. The synovium shows hyperplasia of the lining layer and infiltration of the sublining layer with mononuclear cells including T cells, B cells, macrophages, dendritic, and plasma cells. The T cell infiltrates are composed predominantly of Th-1 skewed, CD4⁺ cells, expressing an activated memory phenotype. The inflammatory process leads to pannus formation with cartilage and bone erosions mediated by degradative enzymes such as metallo-proteinases (Ravelli and Martini, 2007).

As mentioned above, a B cell signature has been shown to characterize patients with early-onset arthritis (Barnes et al., 2010). Moreover, lymphoid aggregates and plasma cell infiltration have been found more frequently in patients with circulating ANA (Gregorio et al., 2007). These observations suggest that B cells can play a role in early-onset ANA-positive arthritis. Corcione et al. found an expansion of activated switch memory B cells and of IgG-secreting plasma blasts in the SF of oligoarticular JIA patients. Memory B cells belonged to either the CD27⁺ or the CD27⁻ subsets and expressed CD86, suggesting their involvement in antigen presentation to T cells (Corcione et al., 2009). Another study (Morbach et al., 2011), involving mainly patients with oligoarticular disease, has also confirmed that activated immunoglobulin class-switched CD27⁺ and CD27⁻ memory B cells accumulate in the joints further suggesting that B cells play an antibody-independent immunopathologic role in oligoarthritis.

Cosmi et al. (Cosmi et al., 2011) have studied Th17 cells in children with oligoarticular JIA. They showed that synovial fluid T cells could switch easily from a Th17 phenotype to a mixed Th1/Th17 phenotype, and, then, to a Th1 phenotype; the switch was linked to the presence of IL-12 in the synovial fluid. This study is in line with the findings of another study performed in JIA patients which showed that synovial fluid Th17 cells “convert” to Th17/1 in the presence of low TGFβ and high IL-12 levels, whereas Th1 cells cannot convert to Th17 (Nistala et al., 2010).

Within the joint, an inverse relationship between IL-17⁺ T cells and FoxP3⁺ regulatory T (Treg) cells has been found (Nistala et al., 2008). In JIA, Tregs from the peripheral blood as well as from the inflamed joints are fully functional. Nevertheless, Treg-mediated suppression of cell proliferation and cytokine production by effector cells from the site of inflammation have been shown to be severely impaired (Haufe et al., 2011; Wehrens et al., 2011). This resistance to suppression has been shown to be secondary to the activation of protein kinase B (PKB)/c-akt in inflammatory effector cells since inhibition of this kinase restores responsiveness to suppression (Wehrens et al., 2011).

The fact that in oligoarticular JIA, joint involvement can remain limited to four or fewer joints (oligoarticular

persistent) or can extend to affect five or more joints after the first 6 months of disease (oligoarticular extended) provides an opportunity, in a rather homogeneous context, to study factors that are associated with disease extension.

IL-17⁺ T cell numbers were found to be higher in patients with extended oligoarthritis as compared with patients with persistent oligoarthritis (Nistala et al., 2008). The ratio between SF regulatory and activated effector CD4 cells was found to be higher in patients with persistent oligoarticular disease with respect to those in whom the disease extended to affect five or more joints (Ruprecht et al., 2005). Hunter et al. sampled patients with recent-onset oligoarticular JIA and looked at potential differences in synovial fluid cells between patients with persistent or extended disease. Synovial CCL5 levels were higher and SF CD4:CD8 ratio was lower in children whose disease extended to a more severe phenotype. Gene expression profiling revealed increased levels of genes associated with inflammation and macrophage differentiation in patients with extended disease and of genes associated with immune regulation in patients with persistent oligoarticular disease (Hunter et al., 2010). Finnegan et al. studied the immunohistochemical features of the synovial membrane in early untreated, newly diagnosed JIA in relation with disease outcome at 2 years. CD4 expression and B cell infiltrates was significantly higher and vascularization more pronounced in patients in whom arthritis extended to involve more joints with respect to those with persistent oligoarthritis (Finnegan et al., 2011).

The fact that persistent oligoarticular JIA is self-limiting, and in about half of all cases even self-remitting, suggests an endogenous regulation. Heat shock proteins (HSPs) are endogenous proteins that are expressed upon cellular stress and are able to modulate immune responses. HSPs are highly present at sites of inflammation, like the inflamed joints of JIA patients (Boog et al., 1992). Studies have shown in JIA the presence of antigen-specific T cells against peptides derived from two types of HSPs, HSP60 and DnaJ (Kamphuis et al., 2005; Massa et al., 2007). T cell recognition of self-peptides or of peptides with a high degree of homology with self was associated with immune mechanisms with regulatory function, including the presence of T cells with the regulatory functional phenotype. These responses are significantly augmented in patients with persistent oligoarticular JIA, which again suggests a direct role in modulation of autoimmune inflammation. The identification of HSP tolerogenic peptides could have therapeutic implications in the future.

TREATMENT

The last decade has witnessed a dramatic improvement in JIA treatment. This has been due not only to the

availability of the new potent biological agents but also to the implementation by the Food and Drug Administration (FDA) and the European Medicines Agency (EMA) of the so-called “pediatric rule.” According to this rule, an industry that wishes to register a new treatment for a given disease in adults has to also conduct studies in children if there is a pediatric counterpart of the illness. Pediatric rheumatology was able to take a quick advantage from this rule thanks to the existence of two very large networks that have worked in a highly integrated fashion, the Pediatric Rheumatology Collaborative Study Group (PRCSG) in North America and the Paediatric Rheumatology International Trial Organization (PRINTO) in Europe and the rest of the world (Ruperto and Martini, 2004).

The widespread use of intra-articular triamcinolone hexacetonide joint injections has played an important role in preventing deformities secondary to joint contractures. Patients who do not respond to non-steroidal anti-inflammatory agents and intra-articular steroid injections are treated with methotrexate (MTX) whose maximally effective dose has been established in a randomized trial (Ruperto et al., 2004). Although a trial has shown the efficacy of leflunomide in polyarticular JIA (Silverman et al., 2005), the experience with this drug in children is still scarce.

In patients who do not respond adequately to MTX the efficacy of several anti-TNF agents (Lovell et al., 2000, 2008) as well as of abatacept (Ruperto et al., 2008) has been demonstrated in RCTs in polyarticular course JIA while a phase III controlled trial with tocilizumab has just been completed. Patients with systemic JIA are initially treated with prednisone. Systemic JIA has been shown to be less sensitive to MTX and anti-TNF agents. In those patients who are steroid dependent, anti-IL-6 and anti-IL-1 treatments, as mentioned above, have shown a dramatic efficacy. The treatment of MAS relies on high dose steroids and cyclosporine.

The safety profile of biological agents appears to be good. The initial concern raised by the FDA that treatment with anti-TNF agents could be associated with an increased rate of malignancy (Diak et al., 2010) has not been confirmed by retrospective studies that have on the contrary suggested that JIA itself and not anti-TNF therapy is associated (as adult RA) with a small increased risk of neoplasia (Beukelman et al., 2012).

In iridocyclitis, early diagnosis is very important for the success of therapy. The initial approach consists of glucocorticoid eye drops with mydriatics. In patients resistant disease systemic steroids are required. If disease remains controlled, methotrexate, cyclosporine, anti-TNF antibodies, and abatacept have been anecdotally reported to be effective.

DEFINITION, EPIDEMIOLOGY, CLINICAL MANIFESTATIONS, AND TREATMENT

The spondyloarthritis (SpA) diseases comprise ankylosing spondylitis (AS), reactive arthritis (ReA), arthritis/spondylitis with inflammatory bowel disease (IBD), and arthritis/spondylitis with psoriasis. The main links between each of these is the association with human leukocyte antigen (HLA)-B27, similar clinical symptoms such as inflammatory back pain, and similar patterns of peripheral joint involvement with an asymmetric arthritis predominantly of the lower limbs, and the possible occurrence of sacroiliitis, spondylitis, enthesitis, and uveitis. Most striking is the direct relationship between the prevalence of SpA and the prevalence of HLA-B27 in the general population. This strong correlation suggests that the environmental or genetic factors that are necessary in addition to HLA-B27 to get SpA must be ubiquitous (Braun and Sieper, 2003).

Ankylosing spondylitis is regarded as the SpA with the most severe outcome. Its prevalence has been estimated to be between 0.2 and 0.9% and the disease normally starts in the second decade of life. The male-to-female ratio has more recently been estimated to be around 2:1. HLA-B27 is found to be positive in 90–95%

of patients, and IBD, psoriasis, or preceding ReA can be found in about 10% of AS patients. Back pain is the leading clinical symptom in these patients, which is characterized by morning stiffness and improvement by exercise. The disease starts in 90% or more cases with a sacroiliitis. Further in the course of the disease the whole spine can be affected with spondylitis, spondylodiscitis, and arthritis of the small intervertebral joints. As a reaction to the inflammation, ankylosis occurs, which can involve the whole spine. Relapsing uveitis, peripheral asymmetric arthritis predominantly of the lower limbs, and enthesitis are the most frequent extraspinal manifestations. Diagnosis is made by a combination of clinical symptoms (such as inflammatory back pain or limitation of spinal mobility) and the demonstration of radiologic sacroiliitis, according to the modified New York criteria (van der Linden et al., 1984). More recently, we have proposed an approach on how to make an early diagnosis before evidence of radiologic sacroiliitis by combining clinical, laboratory, and imaging parameters such as magnetic resonance imaging (MRI) (Rudwaleit et al., 2004). A new approach to an earlier diagnosis is also mandatory because of the major delay of 5–7 years between the occurrence of the first symptoms and making the diagnosis.

In the last decades, only non-steroidal anti-inflammatory drugs (NSAIDs) were used, together with physiotherapy, as an effective treatment. Rather surprisingly, disease-modifying antirheumatic drugs (DMARDs) and corticosteroids, which are highly effective in other chronic inflammatory diseases such as rheumatoid arthritis, only show an effect in patients with predominant peripheral arthritis. On this background, the finding that blockers of tumor necrosis factor (TNF) are highly effective means a breakthrough in the treatment of this disease (Braun and Sieper, 2004; van der Heijde et al., 2005; Inman et al., 2008). At least 50% of active AS patients refractory to treatment with NSAIDs show a 50% or more improvement when treated either with the monoclonal anti-TNF- α antibody infliximab (Braun and Brandt 2003; van der Heijde et al., 2005) or the soluble TNF-receptor construct etanercept (Davis et al., 2003).

Reactive Arthritis

ReA occurs after a preceding infection of the urogenital tract with *Chlamydia trachomatis* or of the gut with enterobacteriae such as *Yersinia*, *Salmonella*, *Campylobacter jejuni*, or *Shigella*, usually after a few days and up to 4–6 weeks (Sieper et al., 2000). Between 30 and 60% of patients with ReA are positive for HLA-B27; arthritis occurs in approximately 4% of the general population, but in about 25% of HLA-B27⁺ individuals after one of these infections. The arthritis is normally an oligoarthritis, predominantly of the lower limbs, but in about 20% this will manifest as a polyarthritis. Other manifestations can be an enthesitis, conjunctivitis/uveitis, or inflammatory back pain. Usually, the patients recover in 3–6 months; however, up to 20% can run a chronic course longer than 12 months. Bacterial antigen and, in the case of *Chlamydia*, also DNA and RNA have been detected in the joint, indicating that bacterial antigens persist in the joint and drive the local immune response. For making a diagnosis of ReA, a combination of clinical manifestations (preceding infection, typical pattern of arthritis) and laboratory evidence of previous or present bacterial infection is necessary (Sieper et al., 2002). While antibiotic treatment of urogenital tract infection with antibiotics prevents the occurrence of arthritis, this is not the case for bacterial enteritis. Once an arthritis is established, long-term antimicrobial monotherapy does not seem to influence the arthritis (Sieper et al., 2000). However, as recently shown, improvement of chronic *Chlamydia*-induced arthritis can be achieved after prolonged, 6-month combination antimicrobial therapy, suggesting that antibiotic monotherapy is inefficient in eradication of ReA-inducing microbes (Carter et al., 2010).

Arthritis with IBD

In approximately 10–20% of patients with IBD, this often occurs concurrently with gut inflammation. The arthritis is often a transient peripheral arthritis of the lower limbs. About 5% of IBD patients, mostly those who are HLA-B27⁺, will develop spondyloarthropathy. The frequency of HLA-B27 among patients with peripheral arthritis is only slightly elevated, but is present among 50–70% of patients with IBD and SpA. Treatment should primarily be directed against the gut inflammation.

Psoriatic Arthritis

Up to 50% of patients with psoriasis and arthritis show a clinical picture compatible with SpA, such as oligoarthritis of the lower limbs and/or spinal inflammation. Among these patients, HLA-B27 is positive in approximately 25% (peripheral arthritis) to 60% (spinal manifestations). Treatment is similar to that for other forms of SpA.

THE ROLE OF HLA-B27 IN THE PATHOGENESIS OF SPONDYLOARTHRITIS

Arthritogenic Peptide Hypothesis

The susceptibility to AS has been estimated to be more than 90% genetically determined, and so it has been suggested that there is a rather ubiquitous environmental factor. The most relevant genetic risk factor is HLA-B27 (Brewerton et al., 1973; Schlosstein et al., 1973). The association of HLA-B27 with SpA is the highest known major histocompatibility complex (MHC) association for human diseases (with a couple of very rare exceptions; see Chapter 75) and is the most relevant single factor for the pathogenesis of SpA. There are now considerable data from epidemiologic studies and transgenic animals to indicate a direct effect of HLA-B27, rather than that of a closely linked gene, in disease pathogenesis. It is also clear now that one copy of HLA-B27 (heterozygosity) is sufficient for the disease. Besides HLA-B27, other MHC genes such as HLA-B60 and HLA-DR1 seem to be associated, but are of minor importance. However, although MHC is the major susceptibility locus, it has been suggested that it contributes only approximately 36% to the overall genetic risk (Brown et al., 2002).

Since the main function of HLA class I molecules is to present peptide antigens to cytotoxic T cells, the antigen-presenting properties of HLA-B27 could be crucial in the pathogenesis of spondyloarthritides leading to the so-called arthritogenic peptide hypothesis (Kuon and Sieper, 2003). Thus, some HLA-B27 subtypes, due to their unique amino acid residues, can bind specific arthritogenic peptide, and so become recognized by CD8⁺

T cells. Furthermore, in response to these bacterial peptides, autoreactive T cells recognizing antigens with sufficient structural similarity between bacteria and self might become activated by self-peptides that are present particularly in spinal joints (Figure 38.1). Major support for this hypothesis comes from studies in humans showing the differential association of some of the HLA-B27 subtypes with AS. While B*2705, B*2702, B*2704, and B*2707 are strongly associated with the disease, the HLA-B27 subtypes B*2709 in whites and B*2706 in Southeast Asians are not at all or only rarely associated. Most interestingly, B*2709 differs from the disease-associated B*2705 by only one amino acid substitution, the exchange of Asp116 to His116. B*2706 differs by only two amino acid substitutions from the disease-associated B*2704 by exchange of His114 to Asp114 and Asp116 to Tyr116 (Khan, 2000). In studies on patients, both bacteria-specific and autoreactive CD8⁺ T cells have been demonstrated in AS and ReA. Recently, a synovial CD8⁺ T cell response to a peptide from *Yersinia* heat shock protein 60 in patients with *Yersinia*-induced ReA and also an HLA-B27-restricted CD8⁺ T cell response to peptides derived from several chlamydial proteins in patients with *Chlamydia*-induced ReA have been described (Kuon and Sieper, 2003). In the latter study, there was a novel approach in searching the whole chlamydial proteome to identify peptides which stimulate CD8⁺ T cells from patients in an HLA-B27 restricted manner. Recently, there was a report of a CD8⁺ T cell response to an Epstein–Barr virus (EBV) epitope derived from the LMP2 protein, and to a sequence-related self-peptide from the autoantigen vasoactive intestinal peptide (VIP) receptor 1

(Fiorillo et al., 2000). However, the exact identity of a potentially arthritogenic peptide has yet to be determined. An oligoclonal expansion of T cells has also been demonstrated for CD4⁺ and CD8⁺ T cells in AS and for CD8⁺ T cells in ReA. Synovial T cells derived from different HLA-B27⁺ patients suffering from ReA and triggered by different bacteria revealed an astonishingly high homology of T cell receptors (May et al., 2002). These results led to the suggestion that similar antigens are recognized by these oligoclonally expanded CD8⁺ T cells.

Misfolded HLA-B27 Hypothesis

Beside the “classical” arthritogenic peptide theory, other hypotheses have emerged. One interesting concept, the HLA-B27 misfolding and unfolded protein response (UPR) hypothesis, states that HLA-B27 itself is directly involved in the pathologic process of SpA. That is, HLA-B27 can be misfolded, which might have implications for pathogenesis (Colbert, 2004). The misfolding is suggested to be due to a particular feature of the HLA-B27 molecule: e.g., newly synthesized HLA-B*2705 seems to fold and associate with β 2-microglobulin more slowly compared with other MHC class I molecules. Allen et al. (1999) reported that as a consequence of HLA-B27 misfolding, free HLA-B27 heavy chains can form abnormal heavy-chain homodimers. This homodimer formation could be facilitated by unpaired free cysteine residues at position 67 (Cys67) of the HLA-B27 heavy chain α 1 helix. Using fluorescence-tagged tetramers of HLA-B27*05 homodimers, Kollnberger et al. (2002) showed that they bind to cell surface natural killer (NK) inhibitory receptors, KIR3DL1 and KIR3DL2, and to leukocyte immunoglobulin-like receptor B2 (LILRB2) which is expressed on dendritic cells, monocytes, and macrophages. In HLA-B27⁺ SpA patients, KIR3DL2⁺ NK cells and CD4⁺ T cells are expanded in peripheral blood, compared with HLA-B27⁻ SpA, rheumatoid arthritis, and other control patients and NK cells of these patients show higher level of cytotoxicity and CD4⁺ T cells produce IL-17 (Chan et al., 2005). It is suggested that binding of HLA-B27 heavy-chain homodimers to killer cell Ig-like receptor (KIR) and leukocyte Ig-like receptor (LILR) could promote inflammation by enhancing survival of NK and T cells and by influencing differentiation of LILR-expressing antigen-presenting cells (Kollnberger and Bowness, 2009).

Moreover, Mear et al. (1999) observed that HLA-B*2705 in cell lines showed a fraction of heavy chains undergoing degradation within the endoplasmic reticulum. These render the cells susceptible to the unfolded protein response (UPR) which is associated with the upregulation of interleukin (IL)-23, the main inducing factor for IL-17-producing T cells. The IL-23/IL-17 axis

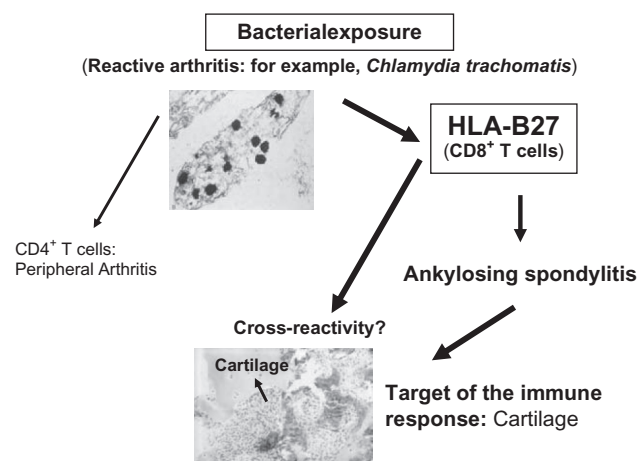

FIGURE 38.1 Hypothesis1 how bacterial exposure induces a peripheral arthritis, probably via a CD4⁺ T cell response. However, axial manifestations might be mediated by CD8⁺ T cells because of the high association with HLA-B27. The cartilage might become the primary target of the immune response through cross-reactivity with bacterial antigens.

is intriguing because IL-23 receptor polymorphisms have been shown to be associated with SpA, psoriasis, and Crohn's disease (Consortium WTC-CCaA-A-AS, 2007). Hence, the HLA-B27 misfolding and unfolded protein response hypothesis postulates a role for CD4⁺ T and NK cells in the pathogenesis of AS and other SpA. This hypothesis is also supported by the fact that disease development and severity is unimpaired in HLA-B27 transgenic rats that lack functional CD8⁺ T cells (Taurog et al., 2009). Similar results have been observed in cell transfer and depletion experiments (Breban et al., 1996; May et al., 2003) which challenge the arthritogenic peptide hypothesis.

THE ROLE OF NON-MHC GENES IN SPONDYLOARTHRITIS

Only a small proportion of HLA-B27 carriers develop AS (1–5% in most series) which cannot be explained by HLA-B27 subtypes. As we know from independent twin studies that the heritability of susceptibility to AS is more than 90% (Brown et al., 1997; Petersen et al., 2006), it is likely that other genes contribute to the susceptibility. Genome-wide association studies performed in recent years have identified definite associations of AS with the non-MHC genes *ERAP1* and *IL23R*, and with gene deserts 2p15 and 21q22 (Wellcome Trust Case-Control Consortium, 2007; Austrolo-Anglo-American Spondyloarthritis Consortium, 2010, 2011). Furthermore, strong evidence to support an association with AS has been demonstrated for the genes *IL-1R2*, *ANTXR2*, *TNFSF15*, *TNFR1*, *STAT3*, and a region on chromosome 16q including the gene *TRADD* (Wellcome Trust Case-Control Consortium, 2007; Austrolo-Anglo-American Spondyloarthritis Consortium 2010, 2011; Pointon et al., 2009; Zinovieva et al., 2009; Danoy et al., 2009).

The *ERAP1* gene encodes the enzyme endoplasmic reticulum aminopeptidase 1, which is involved in trimming of peptides in the endoplasmic reticulum prior to HLA class I presentation and it may be involved in trimming of cytokine receptors as well. The *ERAP1* polymorphisms only affect the AS risk in HLA-B27-positive individuals suggesting that HLA-B27 operates through a mechanism involving aberrant processing of antigenic peptides (Wellcome Trust Case-Control Consortium, 2007; Austrolo-Anglo-American Spondyloarthritis Consortium, 2010, 2011).

The association of *IL-23R* with AS was confirmed in several studies and *IL-23R* was also found to be associated with IBD and psoriasis (Wellcome Trust Case-Control Consortium, 2007; Austrolo-Anglo-American Spondyloarthritis Consortium, 2010). IL-23 signals through the IL-23 receptor. IL-17-producing T cells express IL-23R, and IL-23 plays an important role in

sustaining Th17 cell responses *in vivo*. Although one study showed loss of micro-RNA-dependent regulation of one IBD-associated IL-23R variant resulting in enhanced protein production, no enhanced IL-23 levels have been found so far in AS (Zwiers et al., 2012). Thus, it is still uncertain whether the disease-associated variants of the *IL-23R* cause gain or loss of function. Also *STAT3*, which encodes a downstream signaling molecule of the IL-23 receptor, was found to be associated with Crohn's disease and also has a suggestive association with AS (Barrett et al., 2008; Danoy et al., 2009). Thus, the genetic association of *IL-23R* and *STAT3* with AS definitively suggests an impact of the IL-23/Th17 axis in pathogenesis of AS.

The association of the gene deserts 2p15 and 21q22 with AS was identified and confirmed by the TASC genome-wide association study (Austrolo-Anglo-American Spondyloarthritis Consortium, 2010). Gene deserts are lengthy regions without known genes. Therefore, these regions might contain regulatory elements, as yet unidentified genes, or regions which are involved in epigenetic gene regulation.

Apart from these confirmed genetic associations, several other genes, such as *ANTXR2*, *IL-1R2*, *TNFSF15*, *TNFR1*, and *TRADD*, show suggestive associations with AS (Pointon et al., 2009; Austrolo-Anglo-American Spondyloarthritis Consortium, 2010).

In earlier studies, two promoter polymorphisms of the TNF- α gene at positions -308 (308.1 and 308.2) and -238 (238.1 and 238.2) have been investigated in AS. The 308.2 genotype was found significantly less frequently in AS than in controls. In some studies 308.2 was associated with higher transcriptional activity (Hoehler et al., 1998). Thus, there is some evidence that TNF- α genotypes that may be associated with a low TNF- α production are present in a higher percentage in patients with ReA or AS.

Also, in earlier studies, which investigated the association of TNF- α microsatellites, an association of ReA with a TNF- α 6 allele has been described; this allele has previously been associated with a low TNF- α secretion. Since, in this study from Finland, TNF- α 6 was also associated with HLA-B27, the association of TNF- α 6 with ReA was thought to be secondary to B27.

In another study, analyzing IL-10 gene polymorphism in ReA, a significant decrease in the promoter alleles G12 and G10 was found in the ReA group compared with HLA-B27⁺ controls, indicating that these alleles might have a protective effect against the occurrence of ReA (Kaluza et al., 2001). Although it is not yet clear whether these alleles are associated with a higher production of IL-10, these data suggest that the relative increase of IL-10 found in ReA might be, at least partially, genetically determined.

BACTERIAL TRIGGER AND AUTOIMMUNITY IN THE PATHOGENESIS OF THE SPONDYLOARTHRITIDES

Exposure of the immune system to bacteria seems to be an important initial triggering event for AS. The best evidence for this comes from ReA, which is usually triggered by a genitourinary infection with *C. trachomatis* or an enteritis due to certain Gram-negative enterobacteria, such as *Shigella*, *Salmonella*, *Yersinia*, or *Campylobacter*. The demonstration of microbial antigens within the synovium suggests that ReA may be related to the persistence of microbial antigens at the sites of inflammatory arthritis (Granfors et al., 1989). Approximately 20–40% of HLA-B27⁺ ReA patients develop the full clinical picture of AS after 10–20 years (Leirisalo-Repo, 1998). Although clinically diagnosed ReA arthritis precedes AS only in less than 10%, this figure may be much higher because many of the gut or urogenital infections preceding the clinical manifestation of ReA can be asymptomatic. The central role of bacteria in the pathogenesis of SpA is further supported by the relationship between Crohn's disease, HLA-B27 positivity, and the occurrence of AS: in one study, in 13 out of 24 (54%) HLA-B27⁺ patients with Crohn's disease, AS could also be diagnosed, but only in 5 out of the 189 (2.6%) patients who were HLA-B27⁻ (Purmann et al., 1988). In the case of Crohn's disease, the leakage in the gut mucosa, as a consequence of the related inflammation, presumably allows an interaction of the immune system with the normal gut bacteria. It has also become clear that in about 50% of patients with so-called idiopathic AS, macroscopic or microscopic mucosal chronic lesions resembling Crohn's disease can be detected in the gut by colonoscopy (Mielants et al., 1988).

Finally, there is also evidence for the importance of B27–bacteria interaction from animal models. HLA-B27 transgenic rats develop features of ReA, including gut inflammation, peripheral arthritis, and psoriasiform skin and nail changes. The importance of environmental factors is emphasized by the observation that many of these features, including gut inflammation and arthritis, do not develop in HLA-B27 transgenic rats born and bred in a germ-free environment. Germ-free animals rapidly develop inflammatory disease on removal from the sterile environment. This can be partially prevented by treatment with antibiotics (Taurog et al., 1999).

Therefore, AS can probably be regarded as the long-term outcome for patients most of whom are HLA-B27⁺ and who have been exposed to ReA-associated bacteria, bacteria in the gut, or other as yet unidentified bacteria.

Bacteria appear to play a crucial role as an initial event for the pathogenesis of AS; however, there is no

clear evidence that they are also directly responsible for the immunopathology in AS. Although bacterial antigens are found in the joints of ReA patients, no such antigens have been found so far in sacroiliac joints (Braun et al., 1997). Therefore, AS might rather be the result of bacteria-induced autoimmunity. Particularly in the light of the strong association with MHC, research has concentrated in the past on the role of T cells in SpA. Currently, there is no evidence for any role for the humoral immune response in the pathogenesis of SpA.

CYTOKINES IN THE PATHOGENESIS OF REACTIVE ARTHRITIS

As it has been shown that bacteria persist *in vivo* in patients with ReA, most likely in the joint in the case of *Chlamydia* and in the gut mucosa or lymph nodes of the gut in the case of the enterobacteriae, the following questions arise: (1) why do these bacteria persist in some patients but not in others; and (2) why do some patients (although the minority) develop a chronic course of their arthritis. The ReA-associated bacteria are obligate (such as *Chlamydia*) or facultative intracellular bacteria. T-helper 1 (Th1) cytokines such as TNF- α and interferon- γ (IFN- γ) are crucial for an effective elimination of these bacteria, while Th2 cytokines such as IL-4 or anti-inflammatory cytokines such as IL-10 might inhibit an effective elimination. We and others showed that there is a relative deficiency of Th1 cytokines in ReA, especially of TNF- α but also of IFN- γ , both locally in synovial fluid and synovial membrane and systemically in peripheral blood (Yin et al., 1997; Braun et al., 1999). Furthermore, we could demonstrate a correlation between a low TNF- α production in peripheral blood and a longer duration of arthritic symptoms (Braun et al., 1999). Thus, a relative lack of Th1 cytokines appears to be relevant for the occurrence and persistence of ReA, probably mediated by a persistence of bacteria. IL-10 has received increasing interest recently as a potentially immunosuppressive cytokine. While upregulation of such a cytokine would be wanted in autoimmune diseases such as rheumatoid arthritis, we could show that it is relatively upregulated in ReA, and thus that it might contribute to bacterial persistence in ReA, possibly by downregulation of the Th1 cytokines, IFN- γ and TNF- α (Yin et al., 1999b). Persistence of bacterial antigens disseminated to the joints might cause aberrant inflammation at these sites which are also exposed to mechanical stress. Alternatively, persistence of antigens might cause pathological priming of T cells cross-reacting to autologous antigens.

CYTOKINES IN THE PATHOGENESIS OF ANKYLOSING SPONDYLITIS

Data are scarce on cytokines in AS. We measured by flow cytometry cytokine-positive CD4⁺ and CD8⁺ T cells derived from peripheral blood after mitogenic *in vitro* stimulation (Rudwaleit et al., 2001). Patients with AS had a significantly lower percentage of IFN- γ ⁺ or TNF- α ⁺ CD4⁺ T cells compared with HLA-B27⁻ controls, while the results for an HLA-B27⁺ healthy control group were intermediate between the two groups. For IL-10⁺ T cells, we found a significant increase in the CD8⁺ T cell subpopulation from HLA-B27⁺ AS patients compared with B27⁺ and B27⁻ controls, but this did not pertain for the CD4⁺ subpopulation. This relative (small) lack of Th1 cytokines in the peripheral blood of AS patients is in contrast to the presence of abundant TNF- α in biopsies taken from the sacroiliac joint from AS patients (Braun et al., 1995) and the very strong therapeutic response to treatment with TNF blockers in AS (Braun and Sieper, 2004), suggesting that TNF- α and possibly also IFN- γ are important in the pathogenesis of AS and other SpA. This discrepancy is not easy to explain, but cytokines in peripheral blood might not accurately reflect the situation at the local site of inflammation. Furthermore, cytokines produced by innate immune cells might be of even greater impact on the pathogenesis of AS than cytokine production by adaptive immune cells. This is suggested by studies analyzing IL-17 expression within inflamed peripheral joints, where both mononuclear and polymorphonuclear synovial cell infiltrates were found to express IL-17 (Moran et al., 2011). Also in involved facet joints of AS patients increased numbers of IL-17-producing cells, primarily of myeloid origin, were found (Appel et al., 2011).

According to the misfolding hypothesis, accumulation of misfolded proteins within the endoplasmic reticulum triggers a conserved intracellular stress response that decreases protein production, enhances folding capacity of the endoplasmic reticulum, and promotes induction of gene expression. Stimulation of innate cells such as macrophages with pharmacological inducers of the unfolded protein response results in enhanced LPS-elicited production of inflammatory cytokines, in particular IFN- β and IL-23 (Smith et al., 2008). A recent study shows that peripheral blood-derived macrophages from AS patients produced strikingly higher levels of IL-23 in response to stimulation with lipopolysaccharide, even in the absence of induction by UPR (Zeng et al., 2011). This, together with the association of AS with the *IL-23R* gene, and evidence for the unrestrained signal transduction by a disease-associated variant, suggests that IL-23 production by innate immune cells might be instrumental in the pathogenesis of ankylosing spondylitis.

WHAT IS THE IMMUNE TARGET IN ANKYLOSING SPONDYLITIS?

Exposure to bacterial antigens is thought to drive AS (see above). However, since evidence for bacterial antigen in inflamed joints of the axial skeleton of AS patients is lacking, the target of the immune response in AS is still unclear. Studies using MRI have shown that the most relevant inflammatory site in SpA is an osteitis occurring at the bone/cartilage interface (McGonagle et al., 1999). This finding has been supplemented by histologic investigations in SpA from the sacroiliac joint and other structures where, especially in the early phases, mononuclear cells invade and seem to erode the cartilage at different sites (Bollow et al., 2000). Such findings have suggested that the cartilage is the primary target of the immune response in SpA (Maksymowych, 2000).

The aggrecan G1 domain has been implicated as one source of a possible T cell autoantigen in AS and similar rheumatic diseases, based both on results from animal models and on studies in patients. A specific CD4⁺ T cell response to peptides derived from the G1 domain of aggrecan was found in animal models and also in patients with AS. Here, in 60% of patients, a CD4⁺ response against the whole G1 protein and against a set of overlapping peptides derived from this G1 protein was evident (Zou et al., 2003).

Because of the type of tissue-specific damage in AS, other extracellular matrix proteins apart from aggrecan, derived from human cartilage and enthesis, could also be targets of an autoimmune response. Recently, a CD8⁺ T cell response to a nonameric peptide from collagen type VI was detected in the synovial fluid from patients with AS (Atagunduz et al., 2005). Further work is in progress and will, therefore, have to focus on T cell responses against cartilage-derived antigens.

INFLAMMATION AND BONE FORMATION

A hallmark of ankylosing spondylitis is the occurrence of aberrant bone formation leading to ankylosis of joints, like the sacroiliac joints, and the formation of syndesmophytes within the spine. The factors driving this process of new bone formation in AS are not clear. Experimental models suggest that the wingless (wnt) pathway which controls osteoblastogenesis and skeletal development during embryogenesis can also control aberrant bone formation. Several members of the wnt protein family bind a receptor complex on the surface of mesenchymal cells facilitating dephosphorylation of the intracellular protein beta-catenin which then can translocate into the nucleus and bind to target genes. Activation of mesenchymal cells by wnt agonists promotes osteoblastogenesis, which is inhibited by antagonists (Miller, 2002). Inhibition of

dickkopf-1 (DKK-1), which is a natural antagonist of this pathway, can reverse an erosive–destructive arthritis into a bone forming pattern of arthritis (Diarra et al., 2007). Modulation of this pathway does not change the inflammatory phenotype of arthritis suggesting that bone formation might be rather independent from inflammatory mediators. In AS, patients with progression of bone formation have reduced serum levels of wnt antagonists such as sclerostin and functional DKK-1, suggesting that the wnt pathway plays a major role in bone formation in AS (Appel et al., 2009; Heiland et al., 2012). Of note, 2-year evaluations of progression of syndesmophyte growth in patients treated with a TNF blocker did not show reduction in bone formation (van der Heijde et al., 2008a,b, 2009). This also suggests that bone formation is not controlled by inflammatory mediators like TNF- α . Further studies are required to understand more fully the complex control of this process of aberrant bone formation in AS.

CONCLUDING REMARKS—FUTURE PROSPECTS

The spondyloarthritis, in particular ankylosing spondylitis, are among the most interesting of the rheumatic diseases. New treatment options, utilizing biologic therapy, have greatly improved the outcome of disease. However, the contribution of genes, in particular of HLA-B27, to the disease is still a matter of research. Furthermore, the interplay between immune cells and mesenchymal-derived cells facilitating bone formation is another important aspect which is just being recognized and which has a great potential for new therapeutic targets.

DEFINING AUTOIMMUNE MYOPATHIES

The autoimmune myopathies are an uncommon group of disorders, unified by autoimmune damage of skeletal muscle (Mammen, 2011). The process may occur as a distinct named disease (e.g., polymyositis (PM), dermatomyositis (DM), immune-mediated necrotizing myopathy (IMNM)), or as a feature of other systemic autoimmune diseases (e.g., systemic lupus erythematosus or scleroderma). While skeletal muscle is a primary target in the autoimmune myopathies, there are frequently other tissues that may also be affected, including skin (in DM), lung, cardiac muscle, and synovial joints. Although inclusion body myositis (IBM) has features which might reflect autoimmunity (including recently described autoantibodies), the pathology of this entity and the poor response to the types of immunosuppressive therapies which characteristically are highly effective in PM and DM suggest that this entity is distinct, and we have not considered it further in this chapter.

CLINICAL AND PATHOLOGICAL DESCRIPTIONS OF DIFFERENT PHENOTYPES, INCLUDING IMNM

Like most autoimmune rheumatic diseases, the autoimmune myopathies are quite heterogeneous in their clinical presentation. These diseases are frequently characterized by the subacute onset of painless weakness, predominantly affecting proximal muscles in a symmetrical way (Robinson and Reed, 2011; Christopher-Stine et al., 2012, Miller, 2012). In some cases, there may be involvement of striated muscle of the nasopharynx and upper esophagus, with nasal regurgitation, weakness of phonation, tendency to aspiration, and difficulty swallowing. In severe cases, weakness of the respiratory muscles can occur, but this is infrequent. Muscle involvement is characterized by the leaking of various muscle enzymes, including creatine kinase (CK), and aspartyl and alaninyl transaminases (AST and ALT, which are often incorrectly interpreted as arising from liver), as well as aldolase A. Additionally, the

inflammatory myopathies are characterized by an irritable myopathy on electromyography.

Involvement of tissues other than skeletal muscle is also frequent, and may be accompanied by systemic inflammatory symptoms (malaise, fever). Skin involvement is a prominent feature in DM, with the pattern and type of skin involvement often being diagnostic features. Typical skin manifestations include (1) the characteristic heliotrope rash on the face around the eyelids; (2) Gottron's papules, inflammatory scaly papules limited to the dorsal aspect of the metacarpophalangeal and proximal interphalangeal joints; (3) a violaceous eruption involving the shawl area, the chest, the flanks, and the thighs; and (4) skin ulcers and palmar papules, which occur in a distinct subpopulation of patients with DM (Chaisson et al., 2012). Importantly, the small joints of the hands may be affected by a rheumatoid arthritis-like inflammatory synovitis; this is particularly evident in patients with the dermatopulmonary syndromes described below. Involvement of the lung is not infrequent in patients with autoimmune myopathies, with an estimated 20–65% of patients having evidence of interstitial lung disease (Labirua and Lundberg, 2010; Danoff and Casciola-Rosen, 2011).

A distinct form of IMNM associated with exposure to statins has recently been described (Christopher-Stine et al., 2010; Mammen et al., 2011). While statins are frequently associated with myalgias, which can sometimes necessitate cessation of the drug, muscle pathology is generally self-limiting, and stopping the drug results in complete resolution of the muscle process. A distinct subtype of this process presents with features of a severe autoimmune myopathy in the setting of statin exposure, where resolution does not follow cessation of statin therapy. Patients with this statin-induced IMNM have proximal muscle weakness, very high serum CK levels, irritable changes on EMG, and a prominent necrotizing myopathy on biopsy (Christopher-Stine et al., 2010; Grable-Posposito et al., 2010; Mammen et al., 2011).

CHARACTERISTIC PATHOLOGY, BUT SIGNIFICANT OVERLAP BETWEEN PHENOTYPES

Distinct pathological hallmarks of the different immune-mediated myopathies have been described. While PM is characterized by intrafascicular inflammation and regeneration (with evidence of lymphocytes surrounding morphologically normal muscle cells), the classic pattern of DM shows perifascicular atrophy and regeneration, associated with striking perivascular inflammation. In contrast, there is only a limited inflammatory infiltrate in IMNM. Although necrotic muscle cells are found in both

PM and DM, they are highly enriched in IMNM. There is an increasing appreciation that the pathological pattern in any specific patient is often less distinct, with features of the different entities present in mixed combinations (Pestronk, 2011).

It is noteworthy that biopsies reflect a single moment in time, capturing a highly dynamic and integrated homeostatic system. In the case of the autoimmune myopathies, this system includes normal, damaged, and repairing muscle cells, and various inflammatory cell subsets. Prominent among the infiltrating cells are cytotoxic lymphocytes and cells of the monocyte–macrophage and dendritic cell lineages. These different cells are not isolated, but, rather, are components of a highly interactive and reinforcing system. Indeed, the different clinical and pathological phenotypes likely represent new meta-stable states, reflecting a balance between pathways of damage and repair (see below).

EPIDEMIOLOGICAL CLUES INTO MECHANISM

The epidemiology of human disease can provide important insights into underlying mechanisms. In myositis, combining epidemiological associations with the specificity of the immunological response has been particularly instructive. For example, the recent recognition that patients with IMNM associated with statin exposure (see above) have high titer autoantibodies against HMG CoA reductase has highlighted the importance of environmental exposures in initiating autoimmunity to specific, ubiquitously expressed autoantigens, while driving injury relatively focused on skeletal muscle (Christopher-Stine et al., 2010; Mammen et al., 2011).

The association of myositis and cancer has the potential to provide similar insights into pathogenesis, but is significantly more complex for numerous reasons, including presentation of cancer either before or after myositis diagnosis, as well as effects of immunosuppressive therapy. Nevertheless, the nature of this association provides an important framework for understanding pathogenesis of spontaneous disease. The initial clinical observation that myositis and cancer are associated stimulated numerous studies over the past five decades to define the nature and kinetics of this association (Sigurgeirsson et al., 1992). Although the strength of the association of cancer with DM is higher than that with PM, there is now definitive evidence that cancer is associated with both phenotypes (Hill et al., 2001). Interestingly, the overall risk and frequency, as well as the types of cancers associated with myositis, differ between PM and DM. In one large study, cancer was found in 32% of DM patients, but in 15% of PM patients (Hill et al., 2001). Overall, the elevated risk

of cancer in DM has been noted in various studies to be 3–6-fold over controls for DM, but increased only 1.3–2.0-fold in PM (Chow et al., 1995; Buchbinder et al., 2001; Hill et al., 2001; Stockton et al., 2001). In DM, the highest risk was observed for adenocarcinomas, although any tumor type could be associated (Hill et al., 2001). The most frequent cancers associated with DM include ovarian, lung, prostate, pancreatic, stomach, and colorectal cancers. Non-Hodgkin's lymphomas are also enriched in DM. PM has been associated with an increased risk of non-Hodgkin's lymphoma, and lung and bladder cancers.

Multiple studies have demonstrated a striking temporal clustering of cancer and myositis in both phenotypes, with most cancers occurring within ± 2 years of the myositis diagnosis. Indeed, standardized incidence ratios (SIRs) appear highest in the first year after diagnosis of myositis, and decrease thereafter (Stockton et al., 2001). This temporal clustering would not be expected to occur if the cancers are the result of immunosuppression, suggesting that cancer and autoimmunity might be mechanistically related (see below). Although the incidence of cancer is increased in patients with myositis, it is noteworthy that 70–85% of DM and PM patients never develop a cancer. The reason for a cancer association in only a minority of myositis patients remains unclear at this time.

SPECIFIC AUTOANTIBODIES ARE STRONGLY ASSOCIATED WITH PHENOTYPE, MAKING THEM USEFUL PROBES OF DISEASE MECHANISM

While the clinical damage in autoimmune myopathies is focused on skeletal muscle and related tissues, the described targets of the immune response in these diseases are not muscle specific (Suber et al., 2008; Casciola-Rosen and Mammen, 2012). Rather, they are expressed ubiquitously, raising important questions about the mechanisms of the tissue-specific focus of the immune response. Importantly, however, there is striking association of specific autoantibodies with distinct clinical phenotypes, suggesting that the targeting of specific molecules by the immune system might (1) participate in generating the unique phenotype or (2) that the specific immune response is stimulated by a unique series of tissue events which make that specific antigen available to drive the immune response.

A key fact remains unknown regarding the kinetics of autoimmune myopathy evolution: does the immune response to myositis-specific autoantigens precede or coincide with the onset of clinical symptoms? For most autoimmune diseases where this has been studied (e.g., systemic lupus erythematosus, rheumatoid arthritis, and type I diabetes mellitus), evidence of autoimmunity

precedes clinical symptoms by several years (Baekkeskov et al., 1984; Arbuckle et al., 2003; Eisenbarth, 2003; Nielen et al., 2004; van der Helm-van Mil et al., 2005; Majka et al., 2008). For the autoimmune myopathies, no systematic data are yet available, but there have been cases where autoantibodies to histidyl tRNA synthetase preceded clinical myositis (Miller et al., 1990), suggesting that generation of the immune response may precede the establishment of the clinical phenotype.

Myositis-Specific Autoantibodies

The autoantibodies elaborated in patients with myositis recognize a family of autoantigens which have important, conserved functions in general cellular processes, and are apparently ubiquitously expressed. Prominent among these functions are protein translation (e.g., amino acyl tRNA synthetases, signal recognition particle; Mathews and Bernstein, 1983; Reeves et al., 1986), gene expression (e.g., components of the nucleosome remodeling and deacetylation complex (NuRD); Targoff and Reichlin, 1985), DNA repair machinery (e.g., double strand break and mismatch repair machinery; Casciola-Rosen et al., 1995, 2001; Suwa et al., 1996), and the exosome complex. Additionally, several autoantigens (e.g., Ro52 and MDA5) are induced by type 1 interferons (Rhodes et al., 2002; Sato et al., 2009).

Several observations about the autoantibodies in myositis are notable. With the exception of Ro52 (TRIM 21), patients generally target a single autoantigen. For example, patients with antibodies against an aminoacyl tRNA synthetase recognize only one of the multiple molecules which could be targeted in this family. Similarly, patients with antibodies against the Mi-2 component of the NuRD complex do not recognize autoantigens in the other functional families. Ro52 is an interferon-inducible antigen which is frequently targeted in myositis, and is almost always targeted in association with an autoantigen from a different protein family. For example, >50% of patients with antibodies recognizing an aminoacyl tRNA synthetase also have antibodies against Ro52. Ro52 is also frequently targeted together with antigens in other groups (Rutjes et al., 1997).

Autoantibodies in myositis have a striking association with phenotype (see Table 39.1). For example, antibodies recognizing aminoacyl tRNA synthetases are frequently associated with the “synthetase syndrome,” a clinical syndrome with relatively mild myositis, Raynaud's phenomenon, inflammatory arthritis of the small joints of the hands (mechanic's hands), and interstitial lung disease of variable severity (Friedman et al., 1996). Antibodies to the signal recognition particle are associated with a particularly severe form of necrotizing myopathy, with cardiac

TABLE 39.1 Association of Myositis-specific Autoantibodies with Disease Subsets

| Autoantibody | Disease subset |
|---|---|
| Anti-synthetases (anti-Jo-1, PL-7, PL-12, EJ, OJ, KS, Ha, Zo) | Anti-synthetase syndrome with polymyositis or dermatomyositis |
| Anti-Mi2 Anti-melanoma differentiation-associated protein (anti-MDA5, anti-CADM140) Anti-transcription intermediary factor 1 γ (anti-p155) Anti-nuclear matrix protein 2 (anti-NXP2, anti-MJ) Anti-SUMO-1 activating enzyme 1 (anti-SAE1) | Dermatomyositis |
| Anti-signal recognition particle (SRP) Anti-3-hydroxy-3-methylglutaryl coenzyme A (anti-HMGCR) | Necrotizing myopathy |

involvement. While antibodies to Mi-2 tend to be associated with the characteristic DM skin rash (including heliotrope and trunkal rash), antibodies to MDA5 have been associated with a distinct dermatopulmonary syndrome, with mild or no myositis, and mild to severe interstitial lung disease, as well as unique dermatological features (including gum pain, palmar papules, and ulceration) (Fiorentino et al., 2011; Chaisson et al., 2012). Numerous additional phenotypic features associated with the different antibodies have been described, and these are summarized in several excellent recent reviews (Mammen, 2011; Betteridge et al., 2011; Casciola-Rosen and Mammen, 2012).

An interesting feature of many of the autoantigens targeted in myositis is their striking susceptibility to cleavage by the cytotoxic lymphocyte granule protease, granzyme B (GrB) (Casciola-Rosen et al., 1999). While GrB is a fastidious protease which cleaves a minority of proteins across the proteome, it efficiently cleaves the majority of myositis autoantigens. This unusual enrichment of GrB substrates among myositis autoantigens, together with the demonstrated activity of cytotoxic cells against muscle cells in myositis patients, possibly identifies an important amplification loop in this group of diseases (see below).

New studies suggest that the autoantibodies found in myositis patients with cancer may be distinct from those found in patients where cancer does not appear. Thus, recent studies suggest that antibodies to TIF1 γ (TRIM33) may be enriched in DM patients with cancer, while cancer is very uncommon in patients with Mi-2 or aminoacyl tRNA synthetases (Hoshino et al., 2010; Fujimoto et al., 2012; Trallero-Araguas et al., 2012).

Since the majority of myositis autoantigens function in pathways of general relevance to cellular function and homeostasis, it has therefore been widely assumed that these autoantigens are ubiquitously expressed. Experiments to directly address expression of autoantigens in normal and

affected target tissues have only recently been attempted. These have shown that myositis autoantigens are expressed at very low levels in normal muscle, but are robustly expressed in myositis muscle, with the highest levels of autoantigen expression being found in regenerating muscle cells (Casciola-Rosen et al., 2005). This restriction of high level autoantigen expression to cells repairing muscle injury strongly suggests that normal muscle is unlikely to be the source of antigen to initiate and drive autoimmunity to these molecules in myositis, and focuses attention on other antigen sources (including cancer and repairing muscle cells) as more relevant in this regard (see model below).

Important insights have emerged from studies addressing myositis autoantigen expression in normal tissues and the relevant myositis-associated cancers. These demonstrated that myositis autoantigen expression in normal tissues is very low, but is elevated in multiple malignancies, including lung and breast (Casciola-Rosen et al., 2005). It is possible that high level autoantigen expression in the tumor can induce an immune response which cross-reacts with muscle cells. In patients with a malignancy, this reflects an effective anti-cancer response, or perhaps selection of this immune target via distinct mechanisms.

HMG CoA Reductase Autoantibodies in Statin-Associated Immune-Mediated Necrotizing Myopathy

Statin treatment is very frequent in the population, with an estimated 25 million users worldwide. Muscle-related complications related to statin therapy are widely recognized, with a spectrum from self-limited myalgias to statin-associated rhabdomyolysis (Franc et al., 2003; Graham et al., 2004; Bruckert et al., 2005). The vast majority of these cases resolve fully after stopping the statin. However, in a small group of patients, statin exposure appears to induce a self-sustaining, immune-mediated myopathy which persists despite statin discontinuation. In a recent series of

studies, a novel autoantibody specificity recognizing an autoantigen migrating as a doublet of 100k/200k bands was defined in a group of immunosuppression-responsive patients with a necrotizing myopathy and very high CK levels (Christopher-Stine et al., 2010).

Interestingly, the majority of patients in that study were statin exposed. Since the target of statins is a 100 kDa protein called hydroxymethylglutaryl CoA reductase (HMGCR), the key enzyme in the *de novo* cholesterol synthesis pathway, the association with statin exposure provided an important clue for identifying the autoantigen targeted in this syndrome. While HMGCR levels are low in most cells, they are dramatically upregulated by statin exposure (Goldstein and Brown, 1990). Antibodies from INNM patients recognized higher levels of the 100k/200k antigen in statin-treated cells, leading Mammen et al. to demonstrate that the intracellular C-terminal domain containing the HMGCR active site is indeed the target of these autoantibodies (Christopher-Stine et al., 2010; Mammen et al., 2011).

As has been noted with other myositis autoantigens, high level expression of HMGCR was detected in regenerating muscle cells in biopsies of patients with HMGCR antibodies (Casciola-Rosen et al., 2005; Mammen et al., 2011). This suggests that ongoing immune effector pathways are focused onto cells attempting to repair muscle injury, thereby creating a feedforward cycle of damage and repair (Casciola-Rosen et al., 2005). The patients with HMGCR antibodies did not have the genetic polymorphism in the anion transporter frequently associated with statin myopathy, suggesting a novel mechanism underlying the targeting of this molecule in this patient subgroup. Since the majority of patients exposed to statins do not generate immune responses to HMGCR (Mammen et al., 2012b), Mammen and colleagues examined whether there might be any MHC associations with the HMGCR subgroup. Indeed, he showed a striking association of HMGCR antibodies with HLA class II DRB1*11:01 (Mammen et al., 2012a). The magnitude of this association is one of the largest described to date, suggesting that the immune response to HMGCR might be restricted by this HLA molecule, and that patients with this HLA molecule might be particularly susceptible to this syndrome.

MECHANISMS OF DISEASE

Autoimmune myopathies represent a chronic, self-sustaining process, characterized by inflammation, muscle damage, and muscle repair. While the mechanisms of disease are likely heterogeneous in different individuals, with distinct pathways playing different relative roles in different patients, recent data enable the proposal of a unifying model which incorporates the essential features

of the disease spectrum described above. This model will include the following components: (1) the important association of malignancy with myositis as a potential initiating force; (2) the enhanced expression of myositis autoantigens in regenerating muscle cells to focus propagation on muscle; and (3) the modification of autoantigen expression or structure by immune effector pathways to generate a self-sustaining phenotype. Each of these components is discussed in detail below (see Figure 39.1).

The Association of Malignancy with Myositis: Insights into Disease Initiation

In 10–20% of myositis patients who also have cancer, the two processes cluster together temporally (Chow et al., 1995; Hill et al., 2001). This kinetic clustering suggests strongly that the two processes are mechanistically related. While there are numerous potential explanations behind the connection, the observation that cancer can both precede and follow the diagnosis of myositis is important, as it reinforces that cancer is not emerging exclusively due to immunosuppressive therapy once myositis is diagnosed. The short interval separating the two diagnoses, and the occurrence of cancers in tissues often unaffected in myositis, also makes it unlikely that the inflammatory microenvironment enhances transformation and cancer growth. The available data are consistent with a mechanism in which shared antigen expression patterns in cancers and regenerating muscle cells may explain numerous features of the disease, including the kinetics noted above. In this model, natural anti-cancer immunity (including CD4 T cell and cytotoxic lymphocyte responses) develops in response to an incipient cancer.

Enhanced Expression of Myositis Autoantigens in Regenerating Muscle Cells to Focus Propagation on Muscle

The evidence showing that myositis antigens are expressed at high levels in cancers and also in myositis tissue, where robust expression is noted in regenerating muscle cells, suggests a possible mechanism whereby an initial anti-cancer immune response targeting one of the myositis autoantigens becomes secondarily focused on injured muscle, thus beginning the propagation of a self-sustaining cycle at that site (Casciola-Rosen et al., 2005). The reasons for the unusual restriction of immune responses in myositis to such a limited group of antigens remains uncertain, but may reflect the ability of only a very limited group of molecules to participate in a feedforward cycle (due to the need to both respond to and stimulate an additional immune response—see below). It is possible that anti-cancer immune responses directed even

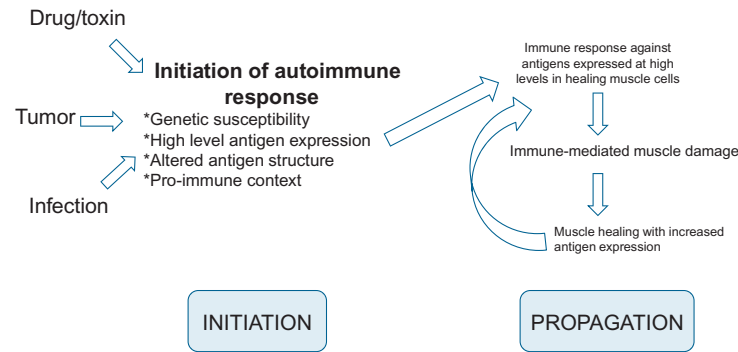

FIGURE 39.1 The Role of Autoimmunity in Myositis. Myositis arises when an immune response against myositis-specific autoantigens is initiated. The initiation phase may be separated spatially and temporally from propagation events, which are focused on muscle. In the absence of a stimulus inducing muscle injury and repair, it is possible that the autoimmune response may remain silent. In the case of cancer-associated myositis, it is possible that an unrelated muscle injury is the second hit which focuses the anti-cancer immune response onto repairing muscle, and propagates the injury there. In statin-induced necrotizing myopathy, the site of immunization with HMGR may be muscle. The autoantigens targeted are characterized by their shared expression patterns in immunizing tissue and regenerating muscle, and by their susceptibility to modification by immune effector pathways.

at myositis antigens might be silent, since the number of regenerating cells in unperturbed muscle is very low. Very few cells in normal muscle are therefore susceptible to immune injury focused on these “regenerating cell” antigens. In the setting of a second insult which damages muscle (strenuous exercise, drugs, viral infection), the pre-formed anti-cancer immune response could respond to antigens now expressed in regenerating muscle cells. When these cells are damaged, a self-sustaining damage-healing cycle is generated, driven by immune-mediated cytolysis and the need to continually provide additional precursors to accomplish tissue repair. This model explains several additional features of the disease, including the patchy nature of pathology, the inexact kinetic relationships between cancer and myositis, and the antigen expression patterns.

Modification of Autoantigen Expression or Structure by Immune Effector Pathways to Generate a Self-Sustaining Phenotype

A central feature of any feed-forward loop is that the activity of one component augments the amplitude of the other, which in turn augments the first. Several immune effector pathways (discussed below) are highly represented in myositis muscle. These dramatically influence antigen expression and structure, and may play important roles in driving ongoing immune responses.

Several prominent myositis autoantigens (MDA5 and Ro52) are strongly interferon regulated, and interferon signatures are prominent in the muscle (PM and DM) and skin (DM) in myositis patients. Additionally, cells with the capacity to secrete large amounts of both type I (from plasmacytoid (p)DCs) and type II interferons (from

activated CD8 T cells) are enriched in DM and PM muscle (Goebels et al., 1996; Greenberg et al., 2005). This capacity of effector pathways to augment antigen expression, and thus create additional targets for cytolytic damage and additional interferon secretion, may be important pathogenically, and might be particularly amenable to therapeutic manipulation.

A second potential intersection of the immune effector and antigen arms centers on the susceptibility of most myositis autoantigens to cleavage by GrB (Casciola-Rosen et al., 1999). It is noteworthy that expression of this protease is highly restricted to the cytolytic effector arm of the innate and adaptive immune systems (Darrach and Rosen, 2010). Furthermore, since GrB has a unique specificity among proteases, most antigens will not have been cleaved by GrB during development of tolerance. The potential for GrB-mediated cleavage to generate fragments that have not been tolerized would provide another feed-forward loop to contribute to driving myositis. In such a model, immune effector pathways generate forms of antigens not previously seen and tolerized by the immune system, thus driving the immune response, which further drives antigen generation. Multiple studies suggest that such effects are likely to be driven at the level of CD4 T cells, but this remains to be demonstrated directly.

THERAPEUTIC INSIGHTS

The therapy of myositis currently focuses entirely on modification of the immune side of the pathogenic cycle. Since myositis is a rare autoimmune phenotype, there is little randomized trial-derived data about the efficacy of specific agents, but clinical experience suggests efficacy with multiple immunosuppressive agents. As with all unfocused immunosuppressive strategies, the major limitations are

infectious side effects. Because autoantigen expression in cells which are repairing tissue injury may be an important partner in driving the ongoing immune response and tissue damage in myositis, it is possible that focusing attention on modifying pathways of antigen expression in the target cell may be an effective strategy. If cancer is an important driver of the initial immune response, perhaps early anti-cancer treatment strategies might be of benefit.

CONCLUDING REMARKS

Although the autoimmune myopathies are uncommon, their interesting presentations and associations provide unique insights into the mechanisms of human autoimmunity, which are potentially of broad relevance, and may be of importance therapeutically. The highly focused immune response on a limited number of antigens which function in pathways of general relevance is of great interest. The association of myositis with cancer, and the shared antigen expression patterns between cancer and regenerating muscle cells, may be of importance in disease propagation. The participation of multiple interacting pathways in augmenting the amplitude of response of other partners may be critical in generating a self-sustaining feed-forward loop which characterizes these diseases, and may provide novel therapeutic opportunities. Of particular importance are the reinforcing interactions between immune effector pathways, antigen, and the target tissue.

AUTOIMMUNE THYROIDITIS

Historic Background

The clinical features of myxedema, the end stage of autoimmune thyroiditis (AT), defined in 1874 by Gull, and Murray, in Newcastle-upon-Tyne, was the first to give thyroid extract as treatment in 1891. The characteristic lymphocytic infiltration (struma lymphomatosa) was first noted by Hashimoto in 1912. Proof that AT was due to loss of self-tolerance came from [Rose and Witebsky \(1956\)](#) who showed that rabbits immunized with homologous thyroid extract and adjuvant developed a thyroid lymphocytic infiltrate and thyroglobulin (TG) antibodies. The latter were detected in Hashimoto's thyroiditis during the same year by Roitt and Doniach.

Clinical, Pathologic, and Epidemiologic Features

Several types of AT have been described ([Table 40.1](#)). Two in particular, goitrous (Hashimoto's) thyroiditis and atrophic thyroiditis (primary myxedema), result in hypothyroidism ([Pearce et al., 2003](#)). The goiter in Hashimoto's thyroiditis is usually firm and painless, with an irregular surface. Patients are often euthyroid at presentation but serum thyroid stimulating hormone (TSH) levels can be elevated even if thyroxine (T4) levels are within the reference range, representing subclinical thyroid failure. Primary myxedema is typically identified when hypothyroidism is apparent clinically and biochemically.

Autoimmunity accounts for over 90% of non-iatrogenic hypothyroidism in iodine-sufficient countries. Women are

TABLE 40.1 Types of Autoimmune Thyroiditis

| Type | Course | Features |
|---|--|---|
| Goitrous (Hashimoto's) thyroiditis | Chronic: leads to hypothyroidism | Goiter: moderate to extensive thyroiditis lymphocytic infiltration and variable fibrosis |
| Atrophic thyroiditis (primary myxedema) | Chronic hypothyroidism | Atrophy: fibrosis and variable lymphocytic infiltrate |
| Juvenile thyroiditis | Chronic but may remit | Small goiter with moderate lymphocytic infiltrate |
| Postpartum thyroiditis | Transient thyrotoxicosis and/or hypothyroidism 3–6 months after delivery | Small goiter with some lymphocytic infiltrate |
| Silent thyroiditis | Transient thyrotoxicosis and/or hypothyroidism | Small goiter with some lymphocytic infiltrate |
| Focal thyroiditis | Progressive in some patients | Occurs in 20–40% thyroid specimens at autopsy: associated with thyroid carcinoma |

5–10 times more likely to be affected, with a peak incidence at 50–60 years of age. The prevalence of autoimmune thyroiditis in the general Caucasian population is 0.5 per 1000 (but only half this in black people), whereas thyroid autoantibodies can be found in up to 20%, reflecting the presence of focal thyroiditis (Eaton et al., 2010).

Pathological changes in AT range from mild focal thyroiditis to extensive lymphocytic infiltration and scarring (Figure 40.1). In Hashimoto's thyroiditis there is a dense infiltration by lymphocytes, plasma cells, and macrophages, and germinal center formation. Thyroid follicles are progressively destroyed and, in the process, the cells undergo hyperplasia and oxyphil metaplasia to become Hürthle cells. In rare cases there are concurrent changes of Graves' disease, so-called hashitoxicosis. There is a variable degree of fibrosis and, when this is extensive, the picture may resemble primary myxedema, in which the gland is atrophic and there is extensive fibrosis with loss of normal lobular architecture and minimal or modest lymphocytic infiltration. Patients with high serum IgG4 levels and increased IgG4-positive plasma cells in the thyroid have more stromal fibrosis, lymphoplasmacytic infiltration, and hypothyroidism (Kakudo et al., 2011). The histology in postpartum and silent thyroiditis resembles Hashimoto's thyroiditis.

Autoimmune Features

Autoantibodies

Circulating autoantibodies against TG and thyroid peroxidase (TPO) are found, often at very high levels, in most patients with AT. These antibodies are common, albeit at low levels, in association with focal thyroiditis.

Thyroglobulin Antibodies

TG is a 660-kDa homodimeric glycoprotein secreted by thyroid follicular cells (TFC) and stored in the luminal

FIGURE 40.1 Pathology of Autoimmune Hypothyroidism. (A) Hashimoto's thyroiditis showing germinal center formation; (B) primary myxedema with extensive fibrosis. (Original magnification: $\times 100$.) Photos courtesy of Dr. Judith Channer, Northern General Hospital, Sheffield.

colloid. At 4–8 hormonogenic sites, iodinated tyrosine residues couple to form T4 or triiodothyronine (T3). The iodination state of TG alters its immunogenicity in animals

and in man (Saboori et al., 1999). There are two major and one minor antibody epitopes on each 330-kDa subunit, and the wide spacing of these prevents IgG cross-linking and therefore complement fixation. The restriction of the response to three epitopes is only relative, as TG antibodies recognize an increasing number of determinants as their titer rises and somatic hypermutation occurs (McIntosh et al., 1998). Antibody reactivity is predominantly in the IgG1 and IgG4 subclasses but not light chain restricted.

Thyroid Peroxidase Antibodies

TPO is a 100–105-kDa apical membrane protein responsible for tyrosine iodination and coupling in the formation of thyroid hormones. Molecular characterization of this autoantigen has been reviewed extensively (McLachlan and Rapoport, 2007). Antibodies to TPO have a similar IgG subclass distribution to TG, but are kappa light chain restricted (McIntosh et al., 1998). Eighty percent of TPO antibodies recognize an immunodominant region involving overlapping, conformational epitopes in two extracellular domains: specific patterns of TPO autoantibody recognition are stable in an individual and genetically transmitted in AT families (Jaume et al., 1999). *In vitro*, TPO can bind C4 complement component, which may contribute to the susceptibility of TFC to destruction (Blanchin et al., 2003).

Other Autoantibodies

TSH-receptor (TSH-R) blocking antibodies are found in around 20% of patients with AT (Weetman and McGregor, 1994). They contribute significantly to hypothyroidism in some patients but there is no close correlation with the presence or absence of a goiter (Feingold et al., 2009). Other thyroid-specific autoantibodies recognize a poorly characterized second (i.e., non-TG) colloid antigen, the Na⁺/I⁻ transporter and pendrin, but any importance of these in pathogenesis is unknown (Ajjan et al., 2000; Yoshida et al., 2009). Autoantibodies against T4 and T3 occur in 15–35% of patients with autoimmune thyroiditis. AT occurs in association with many other autoimmune disorders (Boelaert et al., 2010) and the respective autoantibodies may help in diagnosing these associated conditions.

T Cell Responses

A major site of autoreactivity is within the thyroid itself, although autoimmune responses can also be detected within the draining lymph nodes and bone marrow (Weetman et al., 1984). Recruitment of lymphocytes to the thyroid requires upregulation, on endothelial cells, of various adhesion molecules and selectins, and the infiltrating lymphocytes express the reciprocal adhesion molecules, including CD11a, CD18, CD29, CD49a, and CD49e (Marazuela, 1999). The local infiltrate produces an array of chemokines

which aid homing, including CXCL12, CXCL13, and CCL22, particularly when lymphoid follicles are present, and the TFC contribute to the chemokine pool, exacerbating the autoimmune process (Liu et al., 2008). Most phenotyping and functional studies on T cells have used the readily sampled peripheral blood: this source may reflect poorly (if at all) the responses within the autoimmune target.

Studies of T Cell Phenotypes

The number of circulating human leukocyte antigen (HLA)-DR⁺ (activated) T cells is elevated and CD8⁺ T cells are reduced, but only in active thyroiditis (Iwatani et al., 1992). CD4⁺ T cells predominate in the thyroid infiltrate and many of these are activated (Aichinger et al., 1985). The majority of T cells express the αβ receptor and no obvious bias in T cell receptor usage is apparent (McIntosh et al., 1997). Although a pauciclonal T cell response seems likely in early AT, by the time of clinical presentation there is spreading of the immune response to produce a polyclonal T cell response, directed against an array of autoantigens and epitopes.

Functional Studies

Weak T cell proliferative responses against TG and TPO are found in many patients and can be enhanced by interleukin (IL)-2 supplementation (Butscher et al., 2001). To identify T cell epitopes for TPO, circulating T cells from patients with autoimmune thyroiditis have been stimulated with overlapping synthetic peptides (Tandon et al., 1991). No dominant epitope has been identified; instead there is considerable heterogeneity both within and between individual patients. A T cell epitope on TG has been identified as a strong and specific binder to the micro histocompatibility complex (MHC) class II disease susceptibility HLA-DRβ1-Arg74 molecule, and this stimulates T cells from both mice and humans with AT (Menconi et al., 2010). Such an epitope could initiate an immune response that then spreads to involve other autoantigens, and fits with observations in an animal model of AT that self-tolerance may be broken first for TG and subsequently for TPO (Chen et al., 2010). Migration inhibition factor-based assays have been used in attempts to identify a defect in thyroid antigen-specific suppressor T cells in AT (Volpé, 1988; Martin and Davies, 1992) but no consistent results have been produced and there is no evidence in man yet to implicate a defect in CD4⁺ CD25⁺ T regulatory cells. Indeed such cells are abundant in the thyroid infiltrate and appear unable to suppress the autoimmune process (Marazuela et al., 2006).

Reverse transcription of cytokine mRNA and cDNA amplification has revealed a mixed Th1 and Th2 response in Hashimoto's thyroiditis (Ajjan et al., 1996). The demonstration of MHC class II expression on TFC in Hashimoto's thyroiditis and Graves' disease gave rise to the concept that

such “aberrant” expression could initiate or perpetuate the autoimmune response by converting the TFC into antigen presenting cells (Bottazzo et al., 1983). However, class II expression is restricted to TFC adjacent to T cells producing interferon (IFN)- γ (Hamilton et al., 1991) and only this cytokine is capable of initiating class II expression *in vitro*. MHC class II expression is found on TFC in experimental autoimmune thyroiditis (EAT) induced by neonatal thymectomy (see below) but always follows the appearance of a lymphocytic infiltrate. TFC do not express costimulatory molecules even after cytokine exposure (Marelli-Berg et al., 1997). Together these results indicate that TFC are unlikely to initiate the autoimmune response.

T cell lines and clones derived from the thyroids of patients can be activated by class II-expressing TFC (Londei et al., 1985). Such T cells are likely to have been previously activated by classic antigen presenting cells and are no longer dependent on B7 costimulation (Marelli-Berg et al., 1997). Anergy can be induced in B7-dependent, naïve T cells by class II-positive TFC and this type of peripheral tolerance may be important in regulating autoreactive T cells within the normal thyroid. In established AT, however, T cells are resistant to tolerance induction (Dayan et al., 1993) and class II-expressing TFC may then help to perpetuate the autoimmune response. TFC may participate in the autoimmune process in other ways besides MHC class II expression, through the expression of other immunologically active molecules such as CD40 and CD56.

in other family members and the association of thyroiditis with other endocrinopathies as part of the type 2 autoimmune polyglandular syndrome. Twin studies show a 0.55 concordance rate in monozygotic but not dizygotic twins, and similar findings have been reported for the aggregation of thyroid autoantibodies in euthyroid twins of individuals with AT (Brix et al., 2000, 2004).

As with most autoimmune disorders, associations with HLA alleles have been extensively investigated, producing conflicting results (Tomer and Davies, 2003). Initially it appeared that primary myxedema and Hashimoto’s thyroiditis in Caucasians had distinct associations with HLA-DR3 and -DR5 respectively, but subsequent studies have shown that Hashimoto’s thyroiditis is associated with HLA-DR3 and to a lesser extent -DR4. Postpartum thyroiditis has a weak association with HLA-DR5.

Polymorphisms in *CTLA-4* confer a relative risk of around 2 (Kotsa et al., 1997; Ueda et al., 2003). Genome scanning methods have suggested a number of possible susceptibility loci but these have not been reproduced in larger patient sets (Taylor et al., 2006). The existence of many genes with individual small effects, gene–gene interactions and subset effects may explain why it has been more difficult to show the effects of individual genes in patient populations than would be expected from the twin data on genetic susceptibility (Tomer, 2010). Around 45% of Turner’s syndrome patients have TPO antibodies and a third become hypothyroid (Mortensen et al., 2009).

Genetic Features

The role of genetic factors in AT (Figure 40.2) is suggested by the frequent presence of thyroid autoantibodies

Environmental Influences

The female preponderance of AT may be due to the influence of sex steroids, although skewed X chromosome

FIGURE 40.2 Genetic Associations in Autoimmune Thyroid Disease. HLA class I and II polymorphisms on the antigen presenting cell (APC) interact with presentation of the polymorphic thyroid antigens TSH-R and thyroglobulin (Tg). The binding of CTLA4 and CD28 with CD80/CD86 (B7), IL-2 signaling via CD25 and *PTPN22*-encoded LYP signaling all regulate T cell activation. From Zeitlin et al. (2008), with permission.

inactivation may be a further factor. Certainly in EAT, estrogens or progesterone exacerbate thyroiditis and this is reversed by testosterone (Okayasu et al., 1981; Ansar-Ahmed et al., 1983), while use of exogenous estrogens lowers the risk of developing TPO antibodies in genetically predisposed individuals (Strieder et al., 2003). Pregnancy ameliorates AT but there is an exacerbation in the year after delivery, reflected by a rise in TPO antibody levels. In some women with a previously mild thyroiditis the enhanced autoimmune response is sufficient to cause biochemical or clinical thyroid dysfunction, and this is termed postpartum thyroiditis (Muller et al., 2001). These changes may be related to the fluctuations in regulatory factors operating to maintain fetal tolerance during pregnancy (Weetman, 2010). Although usually a transient phenomenon, around a quarter of such women develop permanent hypothyroidism within 10 years, so that pregnancy is a risk factor which precipitates clinical disease in predisposed subjects. Fetal microchimerism may play a pathogenic role via intrathyroidal chimeric cells breaking immunological tolerance, and such a possibility is supported by the increase in the prevalence of high titer TPO antibodies with advancing parity (Greer et al., 2011).

A strong influence of exogenous environmental factors is suggested by epidemiological data, such as the 10-fold rise in AT prevalence over three decades in Italy (Benvenaga and Trimarchi, 2008). There is no convincing evidence for a direct role of infection in etiology (Tomer and Davies, 1993) although thyroid autoantibodies can appear transiently after subacute viral thyroiditis (Iitaka et al., 1998). AT is more prevalent in areas of increased prosperity and hygiene, compatible with the “hygiene hypothesis” which suggests that exposure to microbial antigens may skew the immune response to protect against autoimmunity (Kondrashova et al., 2008). Indirect evidence for dietary iodine-induced injury is provided by studies of iodine-deficient regions, and an increase in thyroid autoantibodies and lymphocytic thyroiditis shortly after iodine supplementation has generally been reported. As well as causing thyroid injury through the generation of reactive oxygen metabolites (Bagchi et al., 1995), iodine enhances the immunogenicity of TG (Barin et al., 2005).

Anthracene derivatives and other chemicals induce EAT in the Buffalo strain rat, whereas smoking is associated with a decrease in AT (Effraimidis et al., 2009). Administration of lithium may exacerbate autoimmune thyroiditis both immunologically and biochemically, but the adverse effect of the cytokine IFN- α and other antineoplastic drugs on autoimmune thyroid dysfunction is more striking (Hamnvik et al., 2011). Radioactive fallout from the Chernobyl nuclear disaster led to an increase in the prevalence of thyroid autoantibodies in exposed children, with a small overall increase in the prevalence of AT 14–16 years later (Ostroumova et al., 2009).

In Vivo Models

AT can be induced experimentally in animals, and also occurs spontaneously, with features most closely resembling Hashimoto’s thyroiditis.

Immunization-Induced Thyroiditis

In mice and rats the strength of the autoimmune response to immunization with TG in adjuvant is strain dependent. Murine EAT susceptibility (as shown by the severity of lymphocytic thyroiditis) is governed by the class II I-A subregion of the H-2 MHC (Vladutiu and Rose, 1971). H-2^{k,s} strains may even develop EAT with syngeneic TG immunization alone, demonstrating that untolerized autoreactive T cells exist in normal animals, in which they are usually under active regulation (EiRehewy et al., 1981). The influence of I-E is strain dependent, but less clear. MHC class I K and D alleles also influence susceptibility, presumably by determining the strength of effector cytotoxic T cell interaction with the thyroid cell target. Transgenic mice expressing HLA-DR3 but not HLA-DR2 develop EAT after TG immunization, confirming a role for this HLA specificity in thyroiditis (Kong et al., 1996).

Female animals have worse EAT than males and this is dependent on sex hormones, estrogen excess worsening thyroiditis, and testosterone ameliorating it (Okayasu et al., 1981). Another important influence in mice is the level of circulating TG, which can induce T regulatory cells (Kong et al., 2009). The thyroiditis after immunization consists of CD4⁺ and CD8⁺ T cells and macrophages, with only a small percentage of B cells. Disease can be transferred by T cells but not by TG antibodies and the critical effector cells are CD8⁺ cytotoxic T cells which require specific CD4⁺ T cells for their induction (Creemers et al., 1983). Immunization with the immunodominant T cell epitope of murine TPO will also induce EAT (Ng and Kung, 2006).

Experimental Autoimmune Thyroiditis Resulting from Immune Modulation

Neonatal thymectomy in certain strains of mice or rats, or thymectomy plus sublethal irradiation in certain strains of rats, results in severe EAT (Penhale et al., 1973; Kojima et al., 1976), as well as other autoimmune endocrinopathies. From these initial observations came the understanding of the crucial role of CD4⁺, CD25⁺ immunoregulatory T cells in preventing autoimmunity (Sakaguchi et al., 2001). Other maneuvers affecting T cells, such as treatment of neonatal mice with cyclosporin A or T cell depletion and reconstitution, can induce EAT (Sakaguchi and Sakaguchi, 1989). Depletion of CD7/CD28 in knockout mice also prevents generation of CD4⁺, CD25⁺ regulatory cells and results in EAT

(Sempowski et al., 2004). The induction of EAT by T cell modulation elegantly demonstrates the presence of thyroid-reactive T cells in the normal newborn repertoire. These CD4⁺ T cells may be destined for deletion after birth but there is now strong evidence for incomplete tolerance and active suppression even later.

In addition to MHC and non-MHC genes, environmental factors play an important role in susceptibility. Rats raised under specific pathogen-free conditions until weaning are resistant to EAT following thymectomy and irradiation, but transfer of normal gut microflora results in EAT in the germ-free animals (Penhale and Young, 1988). It is unclear whether radiation-induced damage to the intestine is involved in this effect of gut microflora.

Spontaneous Autoimmune Thyroiditis

Several species develop spontaneous thyroiditis. Lymphocytic infiltration of the thyroid and TG antibodies occur in around 60% of diabetic and 10% of nondiabetic BB rats but diabetes-prone sublimes have a range of prevalence, from 100% in the NB line to 5% in the BE line, suggesting that diabetes is not tightly linked genetically to EAT (Crisa et al., 1992). The Buffalo strain rat has a low spontaneous incidence of thyroiditis, reaching a maximum of 25% in old, multiparous females (Noble et al., 1976). Non-obese diabetic (NOD) mice infrequently develop thyroiditis but this trait is greatly enhanced by deficiency of the chemokine receptor CCR7, possibly related to the roles of CCR7 in negative selection of autoreactive T cells in the thymus and T regulatory cell control (Martin et al., 2009). Expression of TGFβ by thyroid cells in NOD mice inhibits the development of thyroiditis by generating an increase in thyroidal T regulatory cells (Yu et al., 2010).

Spontaneous autoimmune thyroiditis in the OS chicken is the closest animal model of Hashimoto's thyroiditis. The birds were originally bred from a White Leghorn flock of Cornell strain chickens for phenotypic features of hypothyroidism. Over time, the factors influencing disease development have changed: the importance of MHC genes and sex has diminished and the main genetic determinants in current OS chickens govern target organ susceptibility, T cell hyperreactivity, and corticosteroid responses (Wick et al., 2006). Unlike other models, OS chickens develop severe hypothyroidism as well as a lymphocytic thyroiditis and TG antibodies, and require T4 supplementation to thrive. The disease is T cell-dependent as thymectomy at birth prevents disease, although later thymectomy exacerbates thyroiditis, presumably by altering the balance of T cell-mediated regulation.

Pathologic Effector Mechanisms

Several antibody- and cell-mediated mechanisms contribute to thyroid injury in autoimmune hypothyroidism, and

differences in the relative importance of each may determine some of the clinical and pathological variants described above (Figure 40.3).

Antibody-Mediated Injury

Immune complexes are deposited in the basement membrane around the thyroid follicles in Hashimoto's thyroiditis (Pfaltz and Hedinger, 1986) and terminal complement complexes are also present at this location indicating the formation of membrane attack complexes (Weetman et al., 1989). TFC are relatively resistant to lysis, through enhanced expression multiple regulators of complement activation, especially CD59, in response to cytokines derived from the infiltrating lymphocytes and macrophages (Tandon et al., 1994). After sublethal complement attack, TFC are less able to respond to TSH stimulation and also release cytokines (IL-1, IL-6), prostaglandin E₂ and reactive oxygen metabolites, which may have proinflammatory effects (Weetman et al., 1992). TPO antibodies are generally assumed to be the major mediators of complement fixation and activation within the thyroid and may also provoke damage by antibody-dependent cell-mediated cytotoxicity (Rebuffat et al., 2008). Cytokines like IL-1 may be critical in dissociating the junctional complex and thus allowing access of autoantibodies to apically-expressed TPO and other such antigens (Nilsson et al., 1998), in turn implying a secondary role for these antibodies in pathogenesis and explaining why neonates born to mothers with TPO antibodies have normal thyroid function.

Thyroid autoantibodies can also alter target cell function. TSH-R blocking antibodies have a clearly defined importance, as their placental transfer causes transient neonatal hypothyroidism (Matsuura et al., 1980). Although such antibodies have very similar characteristics to TSH-R stimulating antibodies, study of monoclonal antibodies has started to show subtle differences in binding and such approaches should allow a better understanding of their pathogenic action (Sanders et al., 2010). Although they appear to be particularly associated with atrophic thyroiditis in Asian patients (Arikawa et al., 1985), TSH-R blocking antibodies occur in both goitrous and atrophic thyroiditis in Caucasians (Kraiem et al., 1987).

T Cell-Mediated Injury

Despite the strong lead provided by studies in EAT, there is only modest direct evidence that T cell-mediated injury is important in autoimmune hypothyroidism. Two groups have derived CD8⁺ T cell clones and lines from patients with Hashimoto's thyroiditis which lyse autologous TFC in an MHC class I-restricted fashion (MacKenzie et al., 1987; Sugihara et al., 1995). The autoantigen specificity of these T cells has not been elucidated. Indirect evidence

FIGURE 40.3 Mechanisms of Thyroid Destruction in Autoimmune Hypothyroidism. From *Weetman (2002)*, with permission.

for the importance of cytotoxic T cells in pathogenesis is provided by the demonstration of frequent perforin-containing T cells in the intrathyroidal CD8⁺ T cell population in Hashimoto's thyroiditis (*Wu et al., 1994*). In addition, TFC in Hashimoto's thyroiditis express adhesion molecules such as CD54 in response to cytokines and these increase the potential for T cell binding, thereby enhancing cytotoxicity (*Weetman et al., 1990*). T cells may also provoke thyroid dysfunction by the release of cytokines. There is an increase in intrathyroidal Th17 lymphocytes and enhanced synthesis of Th17 cytokines in AT, implying a role for these proinflammatory cells in pathogenesis (*Figuerola-Vega et al., 2010*). Hürthle cell formation results from overexpression of immunoproteasome subunits secondary to chronic inflammation (*Kimura et al., 2009*).

Attention has also focused on the expression of death receptor-mediated apoptosis as a major pathway for TFC destruction, based on the finding of both Fas (CD95) and Fas ligand (CD95L) on TFC in Hashimoto's thyroiditis (*Giordano et al., 1997*). Fas expression by TFC was upregulated by IL-1 β , leading to the suggestion that cytokines could induce cytotoxicity through this pathway by suicide or fratricide as Fas interacted with FasL. Moreover, it has been proposed that FasL on TFC induces apoptosis in the infiltrating lymphocytes, suggesting that a T cell-mediated cytotoxic mechanism for thyroid destruction is less

important than autocrine/paracrine Fas–FasL interaction (*Stassi et al., 1999*). Other interpretations have been put on the role of such apoptosis, not least because of the possible role of other decoy death receptors and regulators of apoptosis signaling and these multiple complex pathways may explain why induction of apoptosis in AT results in the destruction of thyroid cells, while apoptosis in the GD leads to damage of thyroid-infiltrating lymphocytes (*Wang and Baker, 2007*).

Autoantibodies as Potential Immunological Markers

The diagnosis of autoimmune hypothyroidism is usually straightforward, patients having biochemical evidence of hypothyroidism plus TG and/or TPO antibodies which can easily be measured by passive hemagglutination or immunoassays. An abnormal thyroid ultrasound pattern is also highly predictive of AT (*Raber et al., 2002*). Fine needle aspiration biopsy is used in difficult cases, especially to exclude an associated lymphoma.

Treatment and Outcome

It is difficult to imagine a more straightforward treatment than T4 replacement and future attempts at immunomodulation seem unlikely (*Roberts and Ladenson, 2004*). In

around 10% of patients there may be a spontaneous remission 4–8 years after starting T4, and this is associated with the disappearance of TSH-R blocking antibodies (Takasu et al., 1992). However, the permanence of such remissions has not been established and remission in other patients has not been associated with changes in TSH-R blocking antibody levels (Cho et al., 1995).

Concluding Remarks—Future Prospects

Considerable progress in understanding the pathogenesis of AT has been made in the half century since the first demonstration of EAT and the realization that a similar process accounts for Hashimoto's thyroiditis. A major future goal is the identification of the earliest T cell responses, as these may be restricted to single T cell clones, recognizing restricted epitopes on a single inciting autoantigen, and have a particular cytokine bias. Additional work is also needed to determine the exact genetic basis for AT and to clarify the relationships between these disorders and Graves' disease, which are associated together in families and sometimes in the same individual. Finally, despite three decades of research, determining the exact role for T cell-mediated, thyroid-specific immunoregulation in preventing AT remains complex. There is no doubt that T regulatory cells are important but so far the mechanisms which control thyroid-specific T cells that have escaped central tolerance in human AT are elusive and not yet able to be exploited therapeutically.

GRAVES' DISEASE

Historic Background

Caleb Parry first described this disorder in 1825 but it was Robert Graves whose name became attached to the disease through his report of four cases published in 1835. Basedow was the first to highlight the association with exophthalmos in 1840. Originally believed to have a cardiac and then neurological origin, the role of the thyroid in Graves' disease became established in the 1890s as thyroidectomy for apparently coincidental goiter improved the other manifestations. The cause remained obscure until Adams and Purves (1956) showed that the serum from Graves' patients contained a long-acting thyroid stimulator which was distinct from TSH: working separately, Kriss and McKenzie went on to show this stimulator was an IgG.

Clinical, Pathologic, and Epidemiologic Features

Although it shares many immunological features with AT, it is the production of TSH-R stimulating antibodies which characterizes Graves' disease (Brent, 2008). It is the most common cause of hyperthyroidism, accounting for 60–80% of cases. The prevalence is around 4 per

FIGURE 40.4 Eye signs in a patient with thyroid-associated ophthalmopathy showing exophthalmos, scleral injection, and periorbital edema.

FIGURE 40.5 Pathology of Graves' disease showing columnar and folded thyroid epithelium, small new follicles, and active colloid resorption, with "scalloping" of the colloid. A lymphocytic infiltrate is not prominent in this specimen. (Original magnification: $\times 100$.) Photo courtesy of Dr. Judith Channer, Northern General Hospital, Sheffield.

1000, with a 5- to 10-fold higher frequency in women (Eaton et al., 2010). Over 70% of patients with Graves' disease have thyroid-associated ophthalmopathy (TAO), which can be revealed by scanning techniques showing enlarged extraocular muscles (Bahn, 2010). Clinically obvious eye disease is apparent in around 50% of patients (Figure 40.4). TAO is not exclusive to Graves' disease, as around 5% of patients have AT and another 5% have little evidence of thyroid dysfunction. Thyroid dermopathy (or pretibial myxedema, reflecting the usual site for this complication) occurs in only 1–5% of patients, who typically also have marked TAO (Schwartz et al., 2002).

In the untreated state there is both hypertrophy and hyperplasia of the thyroid follicles; the epithelium becomes columnar and folded into the follicular lumen, new small follicles form, and there is little colloid (Figure 40.5). A variable degree of lymphocytic infiltration occurs and

germinal centers may form. Antithyroid drugs diminish the lymphocytic infiltrate and the epithelium reverts to a normal appearance. Lymphoid hyperplasia may occur in the lymph nodes, thymus, and spleen, but reverses with antithyroid drugs.

Autoimmune Features

Autoantibodies

Thyroglobulin and TPO autoantibodies occur in up to 80% of patients. TSH-R stimulating antibodies (TSAb) can be detected in over 95% of patients with current assays. The TSH-R consists of a 398 amino acid extracellular domain with a series of leucine-rich repeats and a hinge region, a 266 amino acid transmembrane spanning domain with seven hydrophobic regions, and an 83 amino acid intracellular domain (Rapoport and McLachlan, 2007). The receptor undergoes complex post-translational processing at the hinge region to form two subunits linked by a disulfide bond. TFC shed the A subunit, which binds TSAb more strongly than the holoreceptor, and this may be critical in affinity maturation of the B cell autoimmune response (Mizutori et al., 2009). TSAb-induced activation of the TSH-R typically causes a rise in cAMP but TSH-R antibodies may also cause activation of other intracellular signaling pathways and these may relate to the whether such antibodies act as blockers of TSH-R activation or have no signaling (neutral) activity (Michalek et al., 2009).

The original bioassay method measured release of radioiodine from preloaded thyroid glands after injection of serum or IgG into intact animals and this activity was termed long-acting thyroid stimulator or LATS (Adams and Purves, 1956). Other early assays measured cAMP release from primary TFC cultures or thyroid cell lines (such as FRTL-5): more recently TSH-R-transfected eukaryotic cells have been utilized (Ajjan and Weetman, 2008). A separate type of assay measures displacement of TSH from solubilized or recombinant TSH-R by TSH-R antibodies in a radiolabeled or chemiluminescent format; these antibodies are called TSH-binding inhibiting immunoglobulins or TBII. Current TBII assays have a sensitivity and specificity which exceeds 95% but measure both TSAb and TSH-R blocking antibodies (which inhibit TSH-induced cAMP release). Therefore the level of TBII gives no direct information on functional activity but in practice these assays are very useful when interpreted in the clinical context (Costagliola et al., 1999). Unlike TG and TPO autoantibodies, TSAb are IgG₁ subclass restricted and are often λ light chain restricted (Zakarija, 1983), suggesting a pauciclonal origin for TSAb in some patients.

The majority of TSH-R B cell epitopes appear to be conformational and overlap with the binding site for TSH (Rapoport and McLachlan, 2007). Heterogeneity between patients in their antibody binding sites is apparent, for

instance by using chimeric TSH/LH hormone receptors, and mutated receptors have revealed that a component of the epitope for TSH-R stimulating antibodies is on the N terminus, whereas epitopes for blocking antibodies are more diverse (Schwarz-Lauer et al., 2002). Further details on the epitope binding of TSH-R antibodies is emerging from studies of cloned monoclonal antibodies crystallized with the receptor extracellular domain, which show that a single blocking antibody binds to different regions of the leucine-rich repeat domain and more towards the N terminal than a single stimulating antibody or TSH (Sanders et al., 2011). Clearly many different monoclonal antibodies from separate patients will be required to have a more general understanding of epitope binding in relation to antibody function.

T Cell Responses

Many studies have found a reduction in circulating CD8⁺ T cells and an increase in HLA-DR⁺ T cells in active Graves' disease (Weetman and McGregor, 1994). Intrathyroidal T cells are CD4⁺ and CD8⁺ in varying proportions (Jansson et al., 1984). Similar homing mechanisms to AT account for this localization (Marazuela, 1999). Using overlapping TSH-R peptides covering the extracellular domain, a heterogeneous response was obtained using circulating or intrathyroidal T cells in proliferation assays, with multiple peptides stimulating different patients' cells (Tandon et al., 1992). There is no distinct Th1 or Th2 pattern of response by the stage of disease that specimens are available for study (Watson et al., 1994; Okumura et al., 1999). Cytokines such as IL-1, IL-6, IL-8, and IL-10 are strongly expressed, with some cytokines being in part derived from the TFC themselves. As in AT, there are plentiful T regulatory cells in the thyroid in Graves' disease, apparently without the ability to halt disease (Marazuela et al., 2006). This T regulatory cell defect may be the result of both impaired plasmacytoid dendritic cell function and elevated levels of thyroid hormone (Mao et al., 2011).

Genetic Features

Monozygotic twins are around 20–30% concordant for Graves' disease, at least 10-fold higher than for dizygotic twins (Brix et al., 1998). A consistent but weak association exists between the serologically defined specificity HLA-DR3 and Graves' disease in Caucasians, with a relative risk of around 2–3 (Tomer and Davies, 2003). The relative weakness of the contribution of HLA genes is underlined by the low concordance (7%) for Graves' disease in HLA-identical siblings (Stenszky et al., 1985). A number of candidate gene polymorphisms (encoding immune receptors, immunoglobulins, and cytokines) have been tested for associations with Graves' disease with inconsistent results

(Figure 40.2). Polymorphisms in *CTLA-4* confer a relative risk of around 2–3 (Yanagawa et al., 1995) and polymorphism in other genes affecting B and T cell responses, *PTPN22*, *CD25*, *FCRL3*, and *CD226*, have also been associated with Graves' disease (Zeitlin et al., 2008; Tomer, 2010). The sharing of these genetic associations with many other autoimmune diseases probably accounts for the frequent concurrence of other autoimmune diseases with Graves' disease and AT.

Polymorphisms in the *TSH-R* gene confers susceptibility to Graves' disease but not autoimmune hypothyroidism, and may be an important factor in determining which members of families with a predisposition to develop thyroid autoimmunity actually get Graves' disease (Brand et al., 2009). Genome scanning methods have revealed other possible loci linked to Graves' disease (Tomer and Davies, 2003) but these have not been replicated in larger studies (Taylor et al., 2006). An impressive recent genome-wide scan of thousands of Chinese individuals with Graves' disease confirmed susceptibility loci in the major histocompatibility complex, *TSHR*, *CTLA4*, and *FCRL3*, and identified two new loci; the *RNASET2-FGFR1OP-CCR6* region at 6q27 and an intergenic region at 4p14 (Chu et al., 2011).

Environmental Influences

Women are predisposed to Graves' disease and, as with AT, parity increases the risk by around 10% (Jørgensen et al., 2011). Retrospective studies have shown a significantly higher number of adverse, major life events during the year preceding the recognition of Graves' disease when patients are compared to matched controls (Winsa et al., 1991; Prummel et al., 2004). Presumably this effect of stress operates through the interactions between the nervous, endocrine, and immune systems. A high iodine intake increases the risk of developing an autoimmune response against the thyroid, the type being determined by genetic factors. However, in an animal model of Graves' disease produced by immunizing NOD mice with adenovirus expressing the TSH-R A subunit, increased iodine intake increased the severity of thyroiditis but not hyperthyroidism, suggesting a dichotomy in these two autoimmune responses (McLachlan et al., 2005).

Evidence for a role of infections is circumstantial (Tomer and Davies, 1993). It remains possible that a variety of infections could precipitate Graves' disease either specifically by molecular mimicry, or modulation of TFC behavior, or non-specifically, by enhancing any ongoing immune responses. Such non-specific enhancement, presumably mediated by cytokines, would explain the association between attacks of allergic rhinitis and recurrence of Graves' disease (Hidaka et al., 1993).

Smoking is strongly associated with the development of ophthalmopathy and weakly with the development of Graves' disease, although negatively associated with the presence of TG and TPO antibodies in Graves' patients (Bartalena et al., 1995; Hou et al., 2011). Cytokine treatment is sometimes complicated by the development of Graves' disease, although this is less frequent than AT (Hamnvik et al., 2011). Perhaps the most striking example of Graves' disease caused by an obvious external agent is its appearance during the period of immune reconstitution following alemtuzumab or highly active antiretroviral treatments (Weetman, 2009). This type of response may be the result of alteration levels of T regulatory cells as the lymphocyte population is recovering.

In Vivo Models

There is still no entirely satisfactory animal model of Graves' disease. All are induced rather than spontaneous, and the likely absence of Graves' disease even in great apes suggests that there is something unique about the susceptibility factors for Graves' disease in man (Nagayama, 2007; McLachlan et al., 2011). In the first attempts to produce an animal model, immunization of BALB/c mice with the extracellular domain of TSH-R and adjuvant containing *Bordetella pertussis* induced TSH-R blocking but not stimulating antibodies and a severe thyroiditis (Costagliola et al., 1994), while genetic immunization with TSH-R cDNA produced thyroiditis but without TSAb production (Costagliola et al., 1998). Immunizing AKR/N mice with fibroblasts double transfected with human TSH-R and haploidentical MHC class II genes led to hyperthyroidism caused by TSAb, although without thyroiditis (Yamaguchi et al., 1997). A variant of this model used the hamster and Chinese hamster ovary (CHO) cells expressing TSH-R, resulting in TSAb production and a focal thyroiditis (Ando et al., 2003).

More recently, immunization experiments with adenovirus encoding the TSH-R, especially the A subunit alone, have been successful in producing a high frequency of disease in mice (Chen et al., 2004). Such immunization in transgenic mice expressing human TSH-R A subunit has provided an insight into the role for T regulatory cells in determining the disease outcome; depletion of these cells led to thyroiditis, hypothyroidism, and spreading of the autoimmune response from TSH-R to involve TPO and TG (McLachlan and Rapoport, 2007). This model has also been used to show that pre-treatment with the TSH-R A subunit can deviate the immune response from pathogenic epitopes to the production of neutral TSH-R antibodies (Misharin et al., 2009).

Reproducing ophthalmopathy has proved even more challenging. Transfer of TSH-R primed T cells appeared

to offer a possible model but these results have not been replicated, possibly due to changing environmental factors (Baker et al., 2005). Recently, genetic immunization by electroporation with the TSH-R A-subunit has been shown to lead to the production of antibodies against the IGF-1 receptor, a possible autoantigen in ophthalmopathy, and orbital fibrosis, in addition to TSAb and thyroiditis (Zhao et al., 2011). This is not a consistent response in all animals but it is the closest so far to the development of a successful animal model.

Pathologic Effector Mechanisms

Clearly the main effector mechanism in Graves' disease is the production of TSAb (Figure 40.6). However, the circulating levels of TSAb do not correlate closely with the level of thyroid hormones or the clinical severity of disease because of a variable, concurrent response against other autoantigens and, in some patients, production of TSH-R blocking antibodies, which reduce the effects of TSAb. Women with the highest levels of TSAb who

FIGURE 40.6 Pathogenesis of Graves' Disease. Hyperthyroidism is the result of TSH-R activation by thyroid stimulating antibodies. The intrathyroidal inflammatory response is enhanced by cytokines, some of which are derived from the thyroid cells themselves: antithyroid drugs interfere with this step in the pathway. Thyroid cells produce other molecules such as CD54, CD40, and HLA class II which help perpetuate the autoimmune response. From Weetman (2000), with permission.

become pregnant give birth to babies with transient neonatal thyrotoxicosis.

Autoantibodies as Potential Immunological Markers

TG and TPO antibodies provide readily available evidence for Graves' disease; although not specific, their presence in a patient with hyperthyroidism strongly suggests the diagnosis. These antibodies are present in 20–30% of cases 5–7 years before diagnosis (Hutfless et al., 2011). TSAbs are not generally measured because present bioassays are laborious. TBII estimation is a commercially available surrogate and is useful in confirming the diagnosis of Graves' disease in the absence of clinical evidence such as ophthalmopathy. TSAbs or TBII levels have been investigated as predictive markers for the success of antithyroid drug treatment in Graves' disease. Although patients with the highest levels tend to relapse the most, the results are insufficiently accurate for clinical use (Ajjan and Weetman, 2008). The most important indication for TSAbs assay in Graves' disease is in women with known Graves' disease during pregnancy to predict the risk of neonatal thyrotoxicosis (Endocrine Society et al., 2007).

Treatment and Outcome

Treatment consists of antithyroid drugs (carbimazole, methimazole, or propylthiouracil), radioiodine, or thyroidectomy (Bahn et al., 2011). Around 40% of patients treated with antithyroid drugs achieve a permanent remission. These drugs ameliorate EAT and TSAbs levels fall during treatment due to a decrease in the expression of proinflammatory molecules by TFC (Weetman et al., 1992). Relapse after antithyroid drugs is particularly likely in younger patients with severe hyperthyroidism or a large goiter, and those who smoke or have evidence of a strong Th2 response (Komiya et al., 2001). Radioiodine treatment is followed by a striking rise in TSH-R and other thyroid autoantibodies at 3–6 months whereas TSH-R antibody levels gradually fall in most but not all patients over the year following subtotal thyroidectomy (Laurberg et al., 2008). Complete ablation of thyroid tissue results in the disappearance of all thyroid autoantibodies, confirming the need for these autoantigens to maintain antibody production (Chiovato et al., 2003).

Thyroid-Associated Ophthalmopathy and Dermopathy

These complications of Graves' disease are most likely due to an autoimmune response which stimulates fibroblasts localized within the extraocular muscle or dermis, causing glycosaminoglycan release and edema, and accompanied by

FIGURE 40.7 Photomicrograph of an extraocular muscle from a patient with thyroid-associated ophthalmopathy. There is an extensive lymphocytic infiltrate and edema; the muscle fibers are intact. (Original magnification: $\times 200$.)

fat expansion (Naik et al., 2010). The extraocular muscles and dermis are infiltrated by activated T cells and local cytokine production (IFN- γ , IL-1, and tumor necrosis factor (TNF) can be demonstrated: these cytokines stimulate glycosaminoglycan synthesis by fibroblasts *in vitro* (Figures 40.7 and 40.8). The target of the autoimmune response appears to be the TSH-R which is expressed on a subset of fibroblasts, but the response may be enhanced by antibodies against the IGF-1 receptor (Wiersinga, 2011). Treatment of TAO usually consists of supportive measures or corticosteroids and in many the condition spontaneously becomes stable or regresses (Stiebel-Kalish et al., 2009).

Concluding Remarks—Future Prospects

Graves' disease shares many features with AT, and what determines the type of disorder is a critical issue. Apart from *TSH-R* polymorphism, genetic susceptibility factors have proven relatively non-specific, and more detailed analysis should reveal specific genotypes for Graves' disease. Future studies will clarify the relative importance of stress, iodine intake, smoking, and other environmental factors, as well as how these interact with each other and with genetic factors. It will be particularly important to study mechanisms at the earliest possible stage of disease so that an initiating rather than an enhancing role for these factors can be assessed. Experiments of nature, such as the appearance of Graves' disease after immunological treatments, may provide fresh insights into regulatory mechanisms and the early phase of disease.

The development of a robust animal model, especially one incorporating TAO, would be invaluable in clarifying the role of TSH-R as an autoantigen in TAO and its relationship to the IGF-1 receptor and other putative orbital antigens. Our current therapies for Graves' disease are

FIGURE 40.8 Pathogenic Mechanisms in Thyroid-Associated Ophthalmopathy. The inflammatory infiltrate in the orbit releases a variety of cytokines that stimulate orbital fibroblasts to secrete glycosaminoglycans (GAGs), which trap water and lead to edema; later fibroblast activation leads to fibrosis. A subset of orbital fibroblasts differentiates into adipocytes as a result of cytokine signaling, leading to fat expansion within the orbit. From Weetman (2001), with permission.

effective but not ideal, with many patients having recurrences or exchanging hyperthyroidism for permanent hypothyroidism. Pathogenesis-based treatment offers considerable potential advantages, but will need to be specific and innocuous: the recent description of a small molecular antagonist of TSAb suggests one possible approach (Neumann et al., 2011). An immunologically-directed strategy is even more appealing in TAO for which current treatment remains unsatisfactory.

INTRODUCTION

Autoimmune (type 1) diabetes (which will be referred to in this chapter as autoimmune diabetes mellitus: AI-DM) is a disease of undetermined etiology and mode of inheritance, in which genetically predisposed individuals are exposed to a group of putative environmental exposures that trigger an aggressive and selective autoimmune response against beta cells. Our understanding of this type of diabetes has improved through years of research along with several alterations in nomenclature (Table 41.1).

AI-DM is a multi-stage disease characterized by a complex and prolonged autoimmune prodrome (pre-diabetes phase) that develops over months to years (Figure 41.1). Several autoimmune markers circulate the peripheral blood and are readily detectable during the prodrome. However, it is only near the end of stage III (Figure 41.1), when the beta cells' secretory reserves are lost, that signs of dysglycemia and eventually hyperglycemia become evident. At this point, the only possible measure to take is to restore euglycemia and its subsequent metabolic disturbance through provision of exogenous insulin. More attention and research needs to be directed to both stage II and the pre-diabetes autoimmune stage III aiming at properly identifying determinants of autoimmune response in order to improve the diagnosis and classification of autoimmune diabetes. Primary prevention should be approached in stage II. However, the only possible cure for this form of diabetes is to halt or reverse the

autoimmune response through prevention or intervention measures rather than just replacing the insulin deficiency.

CLINICAL AND PATHOLOGIC FEATURES

The clinical onset of AI-DM follows after a prodromal phase of beta cell autoimmunity that is not associated with any symptoms (Figure 41.1). The diagnosis of diabetes is based on blood glucose level determinations according to combined recommendations of the World Health Organization (WHO) and the American Diabetes Association (ADA, 2013) (Table 41.2). The loss of beta cells varies with age. Young children have lost proportionally more beta cells compared to teenagers, young adults, and adults. The clinical onset is therefore not only a function of a reduced beta cell mass but also of insulin resistance. Young age at onset patients may show classic symptoms such as weight loss, thirst, frequent urination, and hunger. Adult subjects may develop diabetes symptoms that would be consistent with type 2 diabetes (T2D). It is not until beta cell autoantibodies are measured that AI-DM is properly classified. The so-called latent autoimmune diabetes in the adult (LADA) may represent 5–10% of all diabetes diagnosed above 35 years of age (Leslie et al., 2008). LADA is a useful clinical classification that requires the analysis of autoantibodies against the 65K variant of glutamic acid decarboxylase

TABLE 41.1 Variants of Diabetes Mellitus and Nomenclature Used to Describe Autoimmune (Type 1) Diabetes

| Nomenclature/Acronym | Period | Basis of Classification |
|---|------------|---|
| Juvenile diabetes | until 1970 | Classification by age |
| Insulin-dependent diabetes (IDDM) | until 1980 | Classification by treatment method |
| Type 1 diabetes | ongoing | Classification by clinical features |
| Latent autoimmune diabetes in adults (LADA) | ongoing | Classification by GAD65A positivity in adult T2DM |
| Latent autoimmune diabetes in the young (LADY) | ongoing | Classification by GAD65A positivity in young T2DM |
| Slowly progressive insulin-dependent diabetes mellitus (SPIDDM) | ongoing | Classification by clinical features |
| Autoimmune diabetes mellitus (AI-DM) | Proposed | Classification by immunogenetics |

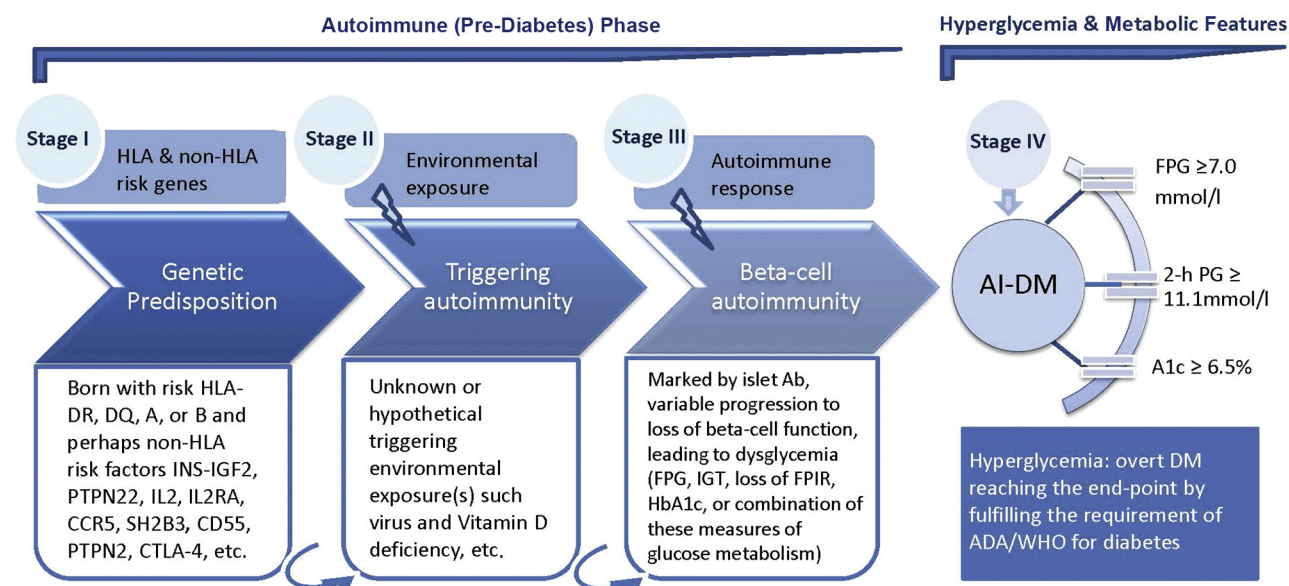

FIGURE 41.1 Stages of Autoimmune Diabetes Mellitus (AI-DM). The preclinical prodrome, which may last several months up to years, represented by three overlapping stages. Stage I represents genetic predisposition, which interacts with putative environmental factors to trigger autoimmune response in stage II. During stage III, islet autoimmunity is initiated and propagated, marked by detectable islet autoantibodies. During stages I–III, prediction, primary, and secondary prevention trials may be initiated to halt autoimmunity and progression to DM. Stage IV represents the final stage of clinical diabetes marked by metabolic consequences of insulin deficiency.

(GAD65A) as it identifies AI-DM that will require treatment with insulin within 5 years of the diagnosis of diabetes (Leslie et al., 2008). The pancreatic islet beta cells are specifically destroyed in the AI-DM. Replacement therapy with insulin is therefore introduced immediately in children and young adults diagnosed with diabetes along with symptoms of thirst, weight loss, and frequent urination. In LADA, insulin therapy will be needed after about 5 years when all other treatment approaches have failed. Insulin therapy is not a cure in AI-DM but a replacement therapy. Currently, there is no alternative to insulin replacement therapy and the many thousands of patients diagnosed each year throughout the world will all be dependent on daily insulin treatment for the rest of their lives.

Historically, the involvement of immune cells in AI-DM was described when inflammatory cell infiltrates, fibrosis, and atrophy of the islets were demonstrated in postmortem pancreatic tissues obtained from some children who died soon following diagnosis (Gepts, 1965). The pathological feature of AI-DM is the conspicuous loss of the pancreatic islet beta cells (Pipeleers et al., 2008). An infiltration of mononuclear cells in islets is often but not always observed (In't Veld, 2011). Insulinitis (≥ 2 mononuclear immune cells per islets) appears as a late manifestation and is observed primarily in multiple autoantibody positive subjects prior to clinical diagnosis (In't Veld et al., 2007). Quantitative immunocytochemistry reveals a specific loss of beta cells and that the neighboring cells producing glucagon, somatostatin, pancreatic

polypeptide, or ghrelin are not affected. In subjects with insulinitis, the islets of Langerhans may be infiltrated by T and B lymphocytes as well as monocytes and dendritic cells supporting a state of chronic inflammation (Eizirik et al., 2009). In some insulinitis-positive islets it has been possible to demonstrate markers of inflammation along with viral antigens (Foulis et al., 1991; Foulis, 2008). The known insulinitis characteristics are derived from specimens that mostly reflect an advanced stage of the disease or more extensive form of it when obtained from post-mortem autopsies. Little is understood about early stages of propagation of autoimmune pathologic features in the prolonged pre-diabetes phase. T lymphocytes, especially the CD4⁺ and CD8⁺ cell subsets, dominate the insulinitis (Pinkse et al., 2005), compared to B lymphocytes, and may be found in larger populations in the islets (Kent et al., 2005). Therefore, the infiltration of pancreatic islets by inflammatory cells, beta cell destruction and the resulting insulinitis is a multi-step process, which may vary widely in duration and intensity before diabetes becomes clinically manifest. Furthermore, in recent-onset AI-DM, residual beta cell function was temporarily preserved through the use of monoclonal antibodies targeting CD3 on T lymphocytes (Herold et al., 2002), CD20 on B lymphocytes (Pescovitz et al., 2009), or drugs such as cyclosporine targeting monocyte/macrophage populations (Bougneres et al., 1988). These observations in addition to the significant role of cellular immunological pathway, predominantly CD8⁺ lymphocytes, suggest that AI-DM is primarily a cell-mediated autoimmune disease (Notkins

and Lernmark, 2001; Willcox et al., 2009). However, in the absence of specific cellular assays, stage III is defined by islet autoantibodies (Figure 41.1). The islet autoantibodies therefore represent predictive markers of an ongoing autoimmune response, yet their exact role in beta cell destruction remains to be clarified.

EPIDEMIOLOGIC FEATURES

The epidemiology of stage III AI-DM (Figure 41.1) is essentially unknown. Studies such as DIPP, BABYDIAB (Schenker et al., 1999), DAISY (Rewers et al., 1996), and DiPiS (Larsson et al., 2005) have screened newborns for AI-DM high risk human leukocyte antigen (HLA). There are four standardized tests for diabetes-relevant autoantibodies: against insulin, glutamic acid decarboxylase (GAD65), islet antigen-2 (IA-2), and the zinc transporter 8 (ZnT8) (Pietropaolo et al., 2012). All have been used to follow high HLA risk children longitudinally. Children with low risk HLA genotypes are yet to be followed. Persistent autoantibody positivity (more than 3 months) would detect AI-DM stage III. However, its epidemiology remains unknown as there is a paucity of studies screening, e.g., schoolchildren (Schlosser et al., 2002).

It is generally accepted that up to 10% of all diabetes in different age groups are classifiable as type 1 or autoimmune (ADA, 2013). In obese patients, it may sometimes be difficult to discriminate between AI-DM and T2D especially in adolescents and young adults (Pozzilli et al., 2011) and shared pathways in such patients may be

present (Libman and Becker, 2003). The occurrence of AI-DM varies according to ethnic heritage and geographical locations where high-incidence regions are seen in populations of European descent especially Scandinavia (Karvonen et al., 2000). Recent estimates suggest that the annual rise in incidence of AI-DM among children under 15 years is 3% (2–5%) worldwide including low prevalence populations (IDF, 2011). AI-DM constitutes more than 85% of diabetes phenotypes in patients under 20 years in most populations (Vandewalle et al., 1997; Craig et al., 2006; Thunander et al., 2008) but it may also show a second peak between 50 and 65 years (Lorenzen et al., 1994). Nearly a quarter of patients become clinically evident during adulthood (Haller et al., 2005).

In younger patients, most AI-DM patients become clinically evident around or shortly after puberty (12–15 years in most countries), but it may be diagnosed as early as 9 months of age. This peak incidence around puberty (EURODIAB, 2000; Dabelea et al., 2007) is proposed to be related to spur of growth and upsurge metabolic demand. The highest rise in incidence was seen in younger individuals, especially preschool children indicating an increasing role of environmental factors (EURODIAB, 2000; Pundziute-Lycka et al., 2002; Berhan et al., 2011). Only 15% of newly diagnosed AI-DM patients have a first degree relative with the disease. Overall, AI-DM shows a slight male preference, which becomes evident after puberty up to 35 years (Pundziute-Lycka et al., 2002; Kyvik et al., 2004), a phenomenon that was partly linked to lack of the high risk HLA DQ2/8 genotype (Weets et al., 2004). Another significant indicator of environmental factors to the autoimmunity is the seasonal patterns of birth (Samuelsson et al., 1999; Mckinney, 2001; Willis et al., 2002; Kahn et al., 2009) and timing of diagnosis (Padaiga et al., 1999; Willis et al., 2002). The higher frequency of incident patients in colder months (Padaiga et al., 1999; Willis et al., 2002), and season of birth in spring (Mckinney, 2001) were correlated to exposure to cycles of viral infections (Knip et al., 2005) during early childhood and gestational life, respectively.

GENETIC FEATURES

AI-DM-associated genetic factors are essential yet not sufficient causal factors (Notkins and Lernmark, 2001). Among these there are more than 50 different loci on 12 chromosomes linked to AI-DM (Table 41.3). HLA class II alleles of the major histocompatibility complex (MHC) on chromosome 6p21 are the most important (Todd et al., 2007). The majority of implicated genes are essentially related to the immune response rather than predisposing to diabetes and metabolic derangements. Only few genes such as *INS* and *ERBB3* may modulate beta cell function through affecting insulin secretion and

metabolism. Other genes such as *TNFAIP3* are related to mechanisms of cell apoptosis (Todd et al., 2007; Concannon et al., 2009).

HLA Genetic Factors: The *DR-DQ* Alleles

The *HLA-DR-DQ* alleles are linked to susceptibility to AI-DM (Todd et al., 2007) and also several other autoimmune diseases such as celiac disease, multiple sclerosis, and rheumatoid arthritis, but some alleles provide protection from these diseases (Nerup et al., 1974; Owerbach et al., 1983). The AI-DM risk alleles may be found in up to 50% of the general population but only a smaller proportion develops the disease (Knip et al., 2005). The *DQ8* (A1*03:01-B1*03:02) and *DQ2* (A1*05:01-B1*02:01) haplotypes confer the strongest risk (Schranz and Lernmark, 1998; Erlich et al., 2008). These haplotypes share a linkage disequilibrium (LD) relationship with the DR4 (B1*04) and DR3 (B1*03), respectively (Hermann et al., 2004). Almost 90% of AI-DM patients diagnosed before 35 years of age carry one or both of these two haplotypes (Kockum et al., 1999; Komulainen et al., 1999; Graham et al., 2002). The *DR3-DQ2/DR4-DQ8* genotype may be detected in 30% of patients <15 years and up to 50% of autoantibody-positive children under 5 years (AI-DM stage III) but only 2.4% of the general population (Rewers et al., 1996; Thomson et al., 2007). A sibling who is *DR3-DQ2/DR4-DQ8* identical to a diabetic proband has almost 80% risk to develop islet autoantibodies and 60% for diabetes by the age of 15 years. The other main susceptibility genotypes are the homozygous *DR4-DQ8/DR4-DQ8* and *DR3-DQ2/DR3-DQ2* (Erlich et al., 2008).

It is frequently tested whether HLA class I genes confer risk for AI-DM independent of HLA class II (Noble et al., 2002; Aly et al., 2006; Nejentsev et al., 2007). The *HLA-A*24*, *A*02:01*, *A*03:02*, *A*01:01*, and also *B*39* were associated with a lower age of onset. The *A*02* allele was found to add to the class II risk haplotypes such *DR4-DQ8* (Fennessy et al., 1994), while others such as the (*B18 Ah 18.2*) haplotype may modulate the risk of *DR3-DQ2*. However, as HLA class I and II genes are in strong LD, it is problematic to prove independent contributions to AI-DM risk.

Non-HLA Genetic Factors

A larger group of non-MHC genes were implicated to contribute by up to half of the AI-DM genetic risk in families with AI-DM (Risch, 1989). As indicated in Table 41.3, the majority of these genes function through regulating autoimmune responses; however, the risk of each single gene is markedly less than HLA class II (Todd et al., 2007; Todd, 2010). The genetic marker of the candidate gene/region, its chromosome location, and

TABLE 41.3 The Significant HLA and Non-HLA Genes (Confirmed Associations Loci) Associated with Autoimmune Diabetes Mellitus, Listed by Relative Risks (RR) between Homozygous

After Todd (2010).

proposed function are all summarized in Table 41.3. The possible importance of the non-HLA genetic factors in relation to AI-DM stage II (Figure 41.1) is yet to be investigated. However, it cannot be excluded that the virus-response gene *IFIH1*, also known as MDA-5 and

INS controlling insulin gene expression in the thymus, may contribute. It will also be important to dissect to what extent the different non-HLA gene variants contribute to the variable rate of progression during AI-DM stage III.

AUTOIMMUNE FEATURES

The defining feature of AI-DM is islet (beta cell) autoimmunity (Notkins and Lernmark, 2001). The detection of islet autoantibodies in peripheral blood is currently considered as the earliest sign of AI-DM (Achenbach et al., 2005). The availability of standardized islet autoantibody tests may be used to distinguish AI-DM from other forms of diabetes (Table 41.2). Four major autoantigens have been identified in AI-DM along with a growing list of minor autoantigens (Hirai et al., 2008). Proinsulin is the exclusive beta cell-specific antigen (Pugliese et al., 2001) and insulin was described as a major target for the T lymphocyte attack especially in young children. GAD65 is specific for beta cells but is expressed in other cells as well (Karlsen et al., 1991). The IA-2 and the isoform IA-2 β are important antigens especially in carriers of the HLA-DQ8 haplotype (Delli et al., 2010). The development of persistent (>3 months) single or multiple (≥ 2) islet autoantibodies is thought to occur shortly following killing of beta cells but this seems to occur regardless of insulinitis (In't Veld et al., 2007). A larger group of minor autoantigens have also been proposed; however, the roles of T and B lymphocyte reactivity as well as autoantibodies against most of these autoantigens are not fully determined. Among these autoantigens are the secretory vesicle-associated proteins, chromogranin A, VAMP2 and NPY, HSP-60 and HSP-70, IGRP, Glima-38, and many others (for a detailed list see Wenzlau et al., 2008). It cannot be excluded that autoimmunity against these minor autoantigens reflects antigen and epitope spreading (Morran et al., 2008), meaning presentation of new antigen to inflammatory cells of the immune system leading to activation of new T lymphocytes.

The central role in autoimmune responses against islet autoantigens is related to the structural features of the HLA class II molecules and their interaction with T lymphocytes. Some of the HLA alleles coding these molecules may modify the timing, intensity, and rate of an autoimmune response and thereby affect the autoimmune feature of AI-DM. The *DQA* and *DQB* loci code for the alpha and beta subunits, the two chains of the HLA-DQ heterodimer molecules. These molecules are expressed on the cell surfaces of antigen presenting cells (APCs) and allow presentation of peptide antigens to T lymphocytes through the T lymphocyte antigen receptor (TCR). The binding of islet autoantigen peptides to HLA-DQ molecules was found to modulate the autoimmune response differentially (Eerligh et al., 2011). Binding insulin peptides to DQ8 molecules induced proinflammatory responses while binding to DQ6 molecules induced regulatory T lymphocyte responses (Eerligh et al., 2011). These differences may be related to structural differences in the DQ molecules and the affinity of these molecules to accommodate certain antigens and

thereby facilitate thymic recognition of such antigens as “self” or propagate proinflammatory response leading to activation of autoreactive T lymphocytes. Structural studies of autoantigen peptide binding to HLA-DQ2, 8, and 6.4 have suggested differences that may be related to features of AI-DM (Delli et al., 2012). It was proposed that the DQ2 heterodimer has the ability to bind multiple peptides due to a wider binding groove compared to DQ8 which is less accommodating (Lee et al., 2001; Suri et al., 2005). Structural differences between the risk-conferring alleles such as DQ8 and DQ2 and the protective allele DQ6 were suggested to modify their binding properties through modification of the volume and polarity of binding grooves (Jones et al., 2006). Similarly, HLA-DQ6.4, which is strongly associated with ZnT8 autoantibodies, showed an epitope binding pattern that would be consistent with a reduction in ZnT8 peptide presentation in the thymus. It has been speculated that a reduction in thymic presentation increases the risk for autoimmunity (Pugliese et al., 1997; Delli et al., 2012).

PATHOLOGIC EFFECTOR MECHANISMS

Triggering Autoimmunity

Normally, the HLA–autoantigen complex in the thymus presents weak and low affinity signals to T lymphocytes, which will be educated (positive selection) to identify self-antigen as “self.” If these signals were deficient or were too strong, these T lymphocytes will be deleted (negative selection) as part of central tolerance induction (Ohashi, 2003). In the periphery, T regulatory (Treg) cells help to maintain normal non-responsiveness to “self” antigens through eliminating autoreactive T lymphocytes that escape negative selection in the thymus by a process called “clonal deletion,” which is part of peripheral tolerance. In AI-DM, there is loss of the normal regulatory immune mechanisms, which assist in recognition of self-antigen (Morran et al., 2008). An imbalance between regulatory (Treg) and effector T lymphocytes has been described (Brusko et al., 2008), and the balance between regulatory CD4⁺CD25⁺ and CD4⁺ and CD8⁺ T lymphocytes is distorted (Brusko et al., 2008; Morran et al., 2008). The interaction between environmental and genetic factors (risk-conferring HLA alleles) may disrupt normal tolerance mechanisms and initiate or promote an aggressive autoimmune response. Many environmental factors, most importantly virus infections, have been incriminated in triggering such autoimmune response (Knip et al., 2005). It cannot be excluded that molecular mimicry may contribute. Coxsackievirus shares the sequence PEVKEK with GAD65 and it has been proposed that this type of molecular mimicry may explain the association between the virus and AI-DM (Atkinson et al., 1994). Direct viral

infection of beta cells may induce local inflammatory mechanisms, secretion of proinflammatory cytokines, and involvement of APCs. This activation may elicit autoimmune response and autoreactive T lymphocytes activation; however, it has been suggested that these T lymphocytes need to be provoked by molecular mechanisms before being able to propagate autoimmunity (von Herrath et al., 2003). Other mechanisms of triggering islet autoimmunity are yet to be elucidated.

APCs in Genetically Predisposed Subjects

The cellular pathway of the immune system plays a more significant role than the humoral pathway; the CD8⁺ autoreactive T lymphocytes are the most abundant (Pinkse et al., 2005) and the most active in beta cell destruction (Imagawa et al., 2001). It is proposed that following exposure to a putative antigen, the APCs residing in the islet process and present the autoantigen and drive CD4⁺ T lymphocyte activation through expression of surface markers (Gepts, 1965). These APCs, including macrophages, monocytes, and dendritic cells, also express immunological abnormalities (Jansen et al., 1995; Litherland et al., 1999; Plesner et al., 2002). Antigen presentation is facilitated by the HLA class II heterodimer molecules expressed on the surfaces of these cells. The presence of risk alleles such as DQB1*03:02 or predominantly non-risk alleles such as DQ6B1*06:02 determines the magnitude and pace of beta cell killing.

CD4⁺ cells drive and activate CD8⁺ cells in the regional lymph nodes through formation of complexes between the autoantigen and the TCR. Once activated these autoreactive T lymphocytes will invade islets and attack and destroy beta cells (Baekkeskov et al., 1990). This is possible as antigen presentation occurs directly on the cell surface of the beta cells with the help of HLA class I molecules. CD4⁺ may initiate direct killing of beta cells through secretion of proinflammatory mediators (Amrani et al., 2000; Plesner et al., 2002) or through inviting autoreactive CD8⁺ T lymphocytes. Activated T lymphocytes may also secrete inflammatory mediators such as cytokines, chemokines, and perforin, which are toxic to beta cells. Simultaneously, macrophages invading the islets produce proinflammatory cytokines (such as interferon (IFN)- γ , tumor necrosis factor (TNF)- α , and interleukin (IL)-1 β) and chemokines (Plesner et al., 2002) thereby recruiting additional T lymphocytes, macrophages, and dendritic cells. Cytokines are short polypeptides that serve as signaling mediators of inflammatory processes. The destruction of beta cells will expose intracellular “antigenic” component to APCs, which will further induce antigen presentation and T lymphocyte activation. This cycle of complex autoimmune interactions may be present for variable duration before the reserves of beta cells are severely diminished and hyperglycemia becomes inevitable. It is proposed

that the balance between the CD4⁺ T-helper (Th1) and the (Th2) pathways may also be distorted by various factors including infections and stress (Ernerudh et al., 2004). Whereas the cellular mechanisms of the Th2 pathway appear to conserve beta cells, cytokines of the Th1 pathways are the likely contributors to the inflammatory process in the islets as combinations of cytokines may be toxic to beta cells and enhance the immune reactions.

B lymphocytes can also act as APCs and may present putative islet autoantigen epitopes to CD4⁺ helper cells, which in turn invite CD8⁺ T lymphocytes from regional lymph nodes to invade the islets. The possible role of B lymphocytes in early AI-DM stage III and late stage IV has been understudied clearly demonstrated by the ability of the CD20 monoclonal antibody rituximab that was shown to delay the loss of endogenous insulin production following the clinical onset of AI-DM (Pescovitz et al., 2009). The Rituximab-treated AI-DM patients failed to mount an immune response to neoantigens including insulin, which may temporarily have reduced disease progression.

IN VIVO AND IN VITRO MODELS

Several animal species were studied as models for AI-DM, although their diabetes phenotype was found to differ from the human type. Nevertheless, research on these animals has yielded valuable guidance to human diabetes, where ethical issues or difficulties in obtaining human pancreatic samples may limit research. AI-DM-like syndromes develop spontaneously in the BB rat (Mordes et al., 2004), the LEW.1AR1-iddm rat (Jorns et al., 2010), and the Komada diabetes-prone (KDP) rats (Yokoi et al., 2003). All three strains of rat have features similar to human AI-DM; however, the cause (stage II, Figure 41.1) is mutations in different genes. Diabetes in all three rats is RT1.u, an ortholog of HLA-DQ2. None of the rats develop islet autoantibodies that predict AI-DM (stage III, Figure 41.1). The non-obese diabetes (NOD) mouse, which also develops diabetes with features comparable to human AI-DM, has been studied extensively (for reviews see Mathis et al., 2001; Thayer et al., 2010; Driver et al., 2011). The NOD mouse and its many congenic lines may be useful to dissect the genetic and pathogenic basis for T lymphocyte-mediated AI-DM. However, while sharing many similarities, it is becoming increasingly clear that there are not trivial but major differences in immunopathogenesis between humans and NOD mice. Combination therapy with rapamycin and IL-2 prevented NOD mouse diabetes (Rabinovitch et al., 2002) but accelerated the loss of residual beta cell function in newly diagnosed AI-DM patients (Long et al., 2012). Wild bank voles (*Myodes glareolus*) were reported to develop diabetes in laboratory captivity in association with

autoantibodies against GAD65, IA-2, and insulin in standardized radioligand-binding assays as well as antibodies to *in vitro* transcribed and translated Ljungan virus antigens. It was speculated that bank voles may have a possible zoonotic role as a reservoir and vector for a virus that may contribute to human AI-DM (Niklasson et al., 2003).

AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

Islet autoantibodies are an important indicator of progression to diabetes as well as the disease outcome (Harel and Shoefeld, 2006). The type and number of these autoantibodies signify the advancement of islet autoimmunity and therefore predict AI-DM not only in first degree relatives (FDR) (Verge et al., 1996) but also in subjects from the general population (Bingley et al., 1997). Islet cell autoantibodies have been standardized in international workshops since 1985 (Gleichmann and Bottazzo, 1987). A WHO standard assay for autoantibodies against GAD65 and IA-2 was established by the Immunology of Diabetes Workshops (IDW) (Mire-Sluis et al., 2000) and further developed by the Diabetes Autoantibody (DASP) and Islet Autoantibody Standardization Programs (IASP) (Torn et al., 2008; Schlosser et al., 2010; Lampasona et al., 2011). The inter-laboratory variation in analyzing autoantibodies to insulin, GAD65, IA-2, and ZnT8 has been reduced through the use of common standards in subsequent workshops.

Autoantibodies against all four autoantigens are used to follow children at increased genetic risk from birth to determine triggers of islet autoimmunity (stage II, Figure 41.1) (Hagopian et al., 2011; Ziegler et al., 2013), randomize subjects to secondary prevention trials (Yu et al., 2012) as well as to improve clinical classification (Delli et al., 2012). Interestingly, nearly half of all younger patients who were autoantibody negative at the time of diagnosis showed later sero-conversion (Hameed et al., 2011) indicating that islet autoantibodies may exist invariably in pre- and post- as well as at the time of diagnosis. Islet autoantibodies therefore remain robust markers of AI-DM and should prove useful to assist progress towards assays that better reflect environmental exposures (stage II, Figure 41.1) as well as sero-conversion (stage III, Figure 41.1).

The mechanisms that are responsible for the variable progression to clinical onset during stage III are poorly understood. Standardized islet autoantibody tests, primarily in first degree relatives but also in subjects from the general population, have proven useful to predict the clinical onset (Yu et al., 2012; Ziegler et al., 2013). Parallel testing for autoantibodies against GAD65 and IA-2 followed by insulin autoantibodies was found to

identify 50% of patients younger than 20 years and was associated with a 71% risk within 10 years (Bingley et al., 1999). In FDR at 20–39 years of age, this strategy conferred a 51% risk. Primary screening for anti-IA-2 and anti-GAD65 autoantibodies followed by testing for insulin autoantibodies conferred a 63% risk to develop diabetes. Further studies also including subjects from the general population such as in studies of children followed since birth because of increased genetic risk for AI-DM have been reported (Hagopian et al., 2011; Ziegler et al., 2013).

CONCLUDING REMARKS—FUTURE PROSPECTS

Our understanding of the etiology and pathogenesis of AI-DM is progressing rapidly through several major efforts. First, the sequencing of the human genome has made it possible to better define the genetic contribution to the risk of islet autoimmunity and diabetes (stage I, Figure 41.1). Further studies are needed to better understand the level of genetic propensity for AI-DM when moving between countries. Second, studies from birth may uncover triggers (stage II, Figure 41.1) that launch sero-conversion. Recent data that sero-conversion tends to occur during the first 3 years of life suggest that environmental exposures in early life may have a unique impact on children with increased genetic risk for islet autoimmunity and diabetes. Third, detection, characterization, and development of standardized autoantibody assays to islet autoantigens should prove useful to uncover part of the variable progress to the clinical onset of diabetes (stage III, Figure 41.1). At present, the larger the number of islet autoantibodies, the greater the risk for clinical onset. Fourth, a current challenge is therefore to remedy the paucity of cellular studies to better uncover the series of events that contribute to islet autoimmunity. It will also be a challenge to define the APC, T and B lymphocytes during the chronic stage III of islet autoimmunity and their contribution to the variable rate of beta cell destruction. Fifth, the more than 50 non-HLA genes should be scrutinized one by one to reveal their possible contribution to the variable progression. These non-HLA genetic factors may also represent potential drug targets for secondary prevention or intervention. The limited success in secondary prevention and intervention studies with immunosuppressive agents suggest that novel approaches perhaps in combination trials with islet autoantigens will be required to successfully halt progression to clinical onset or the loss of endogenous beta cell function that invariably takes place after the clinical diagnosis.

INTRODUCTION

Bartolomeo Eustachius was the first to describe the existence of the adrenals as “*de glandulis quae renibus incumbent*” in the *Opuscola Anatomica* published in Venice on 1563. Subsequently Casserius (1561–1616) validated the discovery, depicting and naming them as “*corpuscula reni incumbentia sive renes succenturiati*” (Hiatt and Hiatt, 1997).

In 1855, Thomas Addison first proved that the adrenals were vital organs when he described the symptoms and signs of patients with “anaemia. . . feebleness of the heart action. . . a peculiar change of colour in the skin occurring in connection with a diseased condition of the suprarenal capsules.”

He called this disorder “melasma suprarenale,” postulating that it might be due to abnormal lesions in the adrenal glands. In this first description from the autopsies of 11 patients, he found six cases with tuberculosis, three with malignancies, one with adrenal hemorrhage, and one with adrenal fibrosis of an unknown origin. In this case Addison reported: “The two adrenals together weighed 49 grains, they appeared exceedingly small and atrophied, so that the diseased condition did not result as usual from a deposit either of a strumous or malignant character, but appears to have been occasioned by an actual inflammation, that inflammation having destroyed the integrity of the organs, which finally led to their contraction and atrophy” (Addison, 1868). Probably, this last case was the first description of an autoimmune adrenalitis. In 1856, the adrenal insufficiency was named “Addison’s disease” by Trousseau.

ANATOMY AND PHYSIOLOGY OF THE ADRENALS

The adrenal glands develop from the mesenchyme—the outer part (cortex) from the mesoderm and the central part (medulla) from the neuroectoderm, which comprises part of the chromaffin system (Kannan, 1988). The cortex is divided into three layers. The *zona glomerulosa* (5–10% of the cortex) comprises discontinuous subcapsular aggregates of small cells, containing less cytoplasm than the other cortical cells; the middle zone or *fasciculata* (70% of the cortex) is formed by radial cords of large cells arranged in columns with abundant lipid-filled cytoplasm; the inner cortical zone or *zona reticularis* is composed of cells arranged in cords with compact, finely granular, eosinophilic cytoplasm (Figure 42.1A).

The adrenal cortex synthesizes three main groups of hormones (glucocorticoids, mineralocorticoids, and adrenal androgens) (Auchus and Miller, 2001). The homeostasis of glucocorticoids is regulated by a feedback mechanism through the hypothalamus by means of corticotropin-releasing hormone (CRH), the pituitary gland by ACTH, and the adrenal cortex by cortisol (Koch, 2004). The main steps in the synthesis of the adrenal cortex hormones and the enzymes involved are described in Figure 42.2.

By immunocytochemical techniques, the normal adrenal cortex shows the presence of many proteins (Thiebaux et al., 1987; Henzen-Logmans et al., 1988; Sasano et al.,

1989; Muscatelli et al., 1994; Fogt et al., 1998; Pelkey et al., 1998). Immunopositivity has been demonstrated for the class II major histocompatibility (MHC) complexes (found in 10–20% of the cortical cells) including the human antigen D-related leukocyte (HLA DR) (McNicol, 1986; Jackson et al., 1988) and interleukin-6 (Gonzalez-Hernandez et al., 1994), which is involved in the communication process between the immune and endocrine system. Using specific antibodies against the steroidogenic enzymes and cytochrome P450 (Sasano et al., 1994), it was demonstrated that cytochrome P450 is involved in the adrenal steroid biosynthesis process, while the AdBP/SF-1 transcription factor regulates the expression of the CYP genes (Orth and Kavacs, 1998).

EPIDEMIOLOGY OF ADDISON'S DISEASE AND AUTOIMMUNE ADRENALITIS

Addison's disease (AD) is a very rare disorder and formerly tuberculosis was the most frequent cause. Of the 11 cases of AD in 1855, six (55%) had tuberculosis and only one (9%) had an idiopathic fibrotic form—probably the first case of an autoimmune AD (AAD). For many years tuberculosis was the most frequent form of adrenal insufficiency. Guttman (1930) examined 566 autopsied patients with AD and found 70% with tuberculous adrenalitis. Dunlop (1963) reviewed 86 cases of AD and reported 79% with tuberculous adrenalitis. In the subsequent years the frequency of tuberculosis AD progressively decreased;

FIGURE 42.1 (A) Histopathology of the normal adrenal cortex showing the typical three layers. (B) Adrenal cortex from a patient with AAD showing atrophy of the cortex and a diffuse lymphocytic infiltration and, at top, a lymphoid follicle.

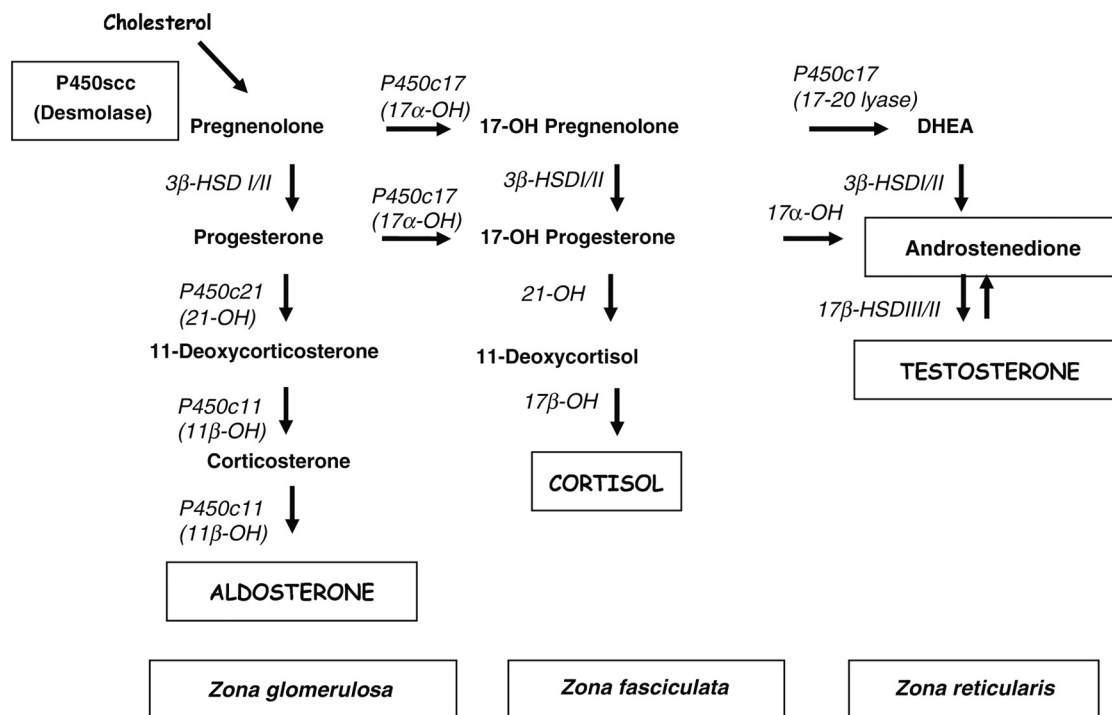

FIGURE 42.2 Main steps of the pathway of adrenal cortex hormone synthesis and the respective enzymes.

it was reported in London (Mason et al., 1968) in 31% and in Denmark (Nerup, 1974) in 17% of patients with AD. In the same years AAD progressively increased and has become the most frequent cause of AD. From 1974 to 2002, 1557 patients with AD were evaluated in various European studies, and the frequency of AAD ranged from 44.5 to 94% (Betterle et al., 2002).

In our experience, during the period 1968–2010, 633 patients with AD were collected and 524 (82.8%) were diagnosed with AAD, 57 (9.0%) with TBC-AD, 29 (4.6%) with genetic forms (G-AD), and 10 (1.6%) with adrenal cancer (C-AD); post-surgical AD (S-AD) was diagnosed in 6 (0.95%) patients, in 4 (0.63%) patients AD was caused by vascular disorders and in 3 (0.47%) AD resulted from infections affecting the adrenals, confirming that autoimmunity is by far the most frequent cause of AD in Italy (Betterle et al., 2013).

The general prevalence of AD is increasing; indeed, in London in 1968, Mason et al. found a prevalence of AD in 39 cases per million (Mason et al., 1968). In 1974 in Denmark, Nerup calculated a prevalence of 60 cases per million (Nerup, 1974), while in Coventry in 1997, Willis and Vince found a prevalence of 93 cases per million (Willis and Vince, 1997). In Nottingham in 1994, Kong and Jeffcoate reported a prevalence of 110 cases per million (Kong and jeffercoate, 1994), while in Italy Laureti et al. (1999) calculated 117 cases per million. Recently, the prevalence of AD was reported to be 144 cases per million in Norway with a calculated incidence, in the past decade, of

6.2 new cases per million per year (Erichsen et al., 2009b). The frequency of AD varies also in relation to different geographic areas: in New Zealand, Eason et al. (1982) calculated it to be 4.5 cases per million; in Japan it is five cases per million (Takayanagi et al., 2000); in the USA 50 cases per million (Jacobson et al., 1997); and in North Europe, more than 100 cases per million, as mentioned above (Kong and Jeffcoate, 1994; Laureti et al., 1999; Løvas and Husebye, 2002; Erichsen et al., 2009b). Despite the constant decrease of tuberculous forms of AD, the overall prevalence of AD has progressively increased and this may be due to the absolute increase of AAD.

AUTOIMMUNE ADDISON'S DISEASE (AAD)

AAD depends on a combination of genetic, environmental, and endogenous factors able to both induce a break of immune tolerance and initiate an autoimmune attack on the adrenal cortex, as for other autoimmune diseases (Kamradt and Mitchinson, 2001; Bratland and Husebye, 2011).

HISTOPATHOLOGY

Focal Lymphocytic Adrenitis

In 1933 Duff and Bernstein (1933) and in 1969 Kiaer and Rytter Norgaard (1969) described a focal adrenitis in patients without signs or symptoms of AD. Petri and Nerup (1971), studying two groups of patients (413 and

161 miscellaneous cases), reported the presence of very small numbers of lymphocytes in 15 and 18.6% of the adrenal glands, respectively. Subsequently, in up to half of the autopsied patients without AD, a focal accumulation of lymphocytes and plasma cells was demonstrated in the adrenal cortex, associated with chronic inflammatory diseases in the retroperitoneum (Fidler, 1977; Orth and Kavacs, 1998). The percentage of these infiltrates was similar to that reported in focal thyroiditis. In 1989, Hayashi et al. evaluated 174 cases at autopsy and demonstrated that mononuclear cell infiltration in the adrenal cortex increased with age, being present in about 7.4% of those aged over 49 years and 63% aged over 60 years. Immunohistochemical studies revealed that the infiltrating mononuclear cells were mainly composed of CD3⁺ T cells. The major proportion of CD3⁺ T cells express the CD4 phenotype, whereas CD8⁺ T cells were fewer. A proportion of the CD4⁺ T cells were activated (Hayashi et al., 1989). These findings indicate that the focal lymphocytic infiltration of the adrenal glands is not rare and may represent a latent adrenalitis, which, however, rarely reaches clinical expression since adrenal cortex antibodies and symptomatic AAD are extremely rare in the population.

A comprehensive investigation of the cellular and molecular components of the infiltrate has never been performed on the adrenal glands in patients with AAD so that the mechanisms by which the adrenal cortex is destroyed remain hypothetical (Bratland and Husebye, 2011).

Diffuse Lymphocytic Adrenalitis

The pathologic findings initially described by Addison (1855) as “idiopathic” are constantly present in the adrenal glands of patients affected by AAD. On macroscopic examination, both the adrenals are small (weight 1–2 g) and sometimes it is difficult to identify them in the retroperitoneal tissue. The capsule is fibrous, so that the adrenal glands are not detectable macroscopically and adrenal tissue is not detectable in multiple sections (Drury et al., 1979).

On microscopic examination, there is complete destruction of the three-layer architecture. The adrenal cortical cells are single, enlarged, or pleomorphic, with increased eosinophilia, depleted in lipids, or present as part of a cluster. Residual cortical nodules are seen as the disease progresses. The tissue is diffusely infiltrated by small lymphocytes, plasma cells, and macrophages (McNicol and Laidler, 1996). The histopathologic finding of infiltrating lymphocytes sometimes is associated with follicle formation and fibrosis (Figure 42.1B). The medulla in AAD remains normal. This pattern is present in patients with AAD, either isolated or associated in the

context of autoimmune polyendocrine syndromes (McIntyre Gass, 1962; Irvine and Barnes 1975; Betterle et al., 2002).

ANIMAL MODELS

Induced Immunity

Colover and Glynn (1958) reported isoimmunization in guinea pigs by injection of adrenal antigens and complete Freund’s adjuvant, with distinctive and “specific” lesions of the adrenals. Subsequently, many authors (Steiner et al., 1960; Barnett et al., 1963) reported examples of experimental autoimmune adrenalitis (EAA) in different species (rabbits, guinea pigs, rats, monkeys), including an antibody reaction in the guinea pigs and a lymphocytic infiltration in the rabbit adrenal tissue (Witebsky and Milgrom, 1962; Barnett et al., 1963). The adrenal lesions in rabbits were characterized by foci of lymphocytes and histiocytes, with a small number of plasma cells and eosinophils, and degenerative changes in adrenal cells. In 1968 Andrada et al. (1968) and in 1970 Werdelin and Witebsky (1970), EAA in a Lewis rat model was induced: adrenalitis occurred at day 7 after immunization. The histology was studied by autoradiographic tracing of H₃ thymidine and H₃ adenosine-labeled cells and demonstrated that adrenalitis was initiated with the appearance of a few specifically reactive lymphocytes, followed by an infiltration of mononuclear cells, mainly lymphocytes and plasma cells, throughout the adrenal cortex. Eosinophilia, cytoplasmic vacuolization, and a loss of nuclear definition were evident in cortical cells.

Using electron microscopy, Hoening et al. (1970) studied the inflammatory lesions in paraffin-embedded tissues; 5 days after immunization, lymphocytes were present in sinusoids and adrenal parenchyma where damage was in the vicinity of lymphocytes, with enlargement of intercellular spaces and ischemic areas with inflammatory cells and fibrin.

It was demonstrated by Fujii et al. (1992) that in mice, repeated immunizations caused a delayed type of hypersensitivity to adrenal antigens, and that transfer of adrenalitis from an affected to a healthy animal was not possible by serum but was possible using spleen cells, confirming previous reports (Levine and Wenk, 1968; Werdelin et al., 1971) in which the disease was passively transferred by immunocytes derived from lymph nodes.

Spontaneous Animal Models of AD

Spontaneous AD occurs in dogs (Harlton, 1976; Kaufman, 1984; Little et al., 1989; Kintzer and Peterson, 1994; Sadek and Schaer, 1996; Dunn and Herrtage, 1998) and cats (Kaufman, 1984; Peterson et al., 1989; Tasker et al., 1999; Stonehewer and Tasker, 2001) with

hypoadrenocorticism due to immune-mediated destruction of the adrenal glands. While biochemical laboratory data were reported, none of the authors described positivity for adrenal cortex autoantibodies, but only the presence of lymphocytic infiltration in the adrenal glands, at autopsy.

Beales et al. (2002) found the adrenal glands of a non-obese diabetic (NOD) mouse to contain a mononuclear cell infiltration in the adrenal cortex, but without signs of hypoadrenalism. Thus the NOD mouse was proposed as a spontaneous model suitable for investigating mechanisms involved in diffuse lymphocytic infiltration of the adrenal glands.

IMMUNOLOGIC STUDIES

Genetic Predisposition

As regards the genetic predisposition of AAD, it is important to remember that the majority of the studies were made in patients with isolated AAD or in the context of autoimmune polyglandular syndrome (APS) type 2. In these patients the correlation was primarily linked to class II HLA alleles in the major histocompatibility complex (MHC) (Myhre et al., 2002). Reports from several different populations have demonstrated that the risk of AAD is significantly increased in the presence of HLA-DRB1*03-DQA1*0501-DQB1*0201 (DR3/DQ2) and DRB1*0404-DQA1*0301-DQB1*0302 (DR4/4/DQ8). DRB1*0404 is much more frequent and indicates that peptides from 21-OH (21-hydroxylase) are well presented to autoreactive T lymphocytes in the presence of DR4/4. In addition to the above-mentioned alleles it has been demonstrated that HLA-B8 was significantly increased independently of DR3 (Bratland and Husebye, 2011). Furthermore, an association between AAD and the 5.1 allele of MHC class I chain-related A (MIC-A) has been demonstrated. Homozygosity for the 5.1 allele of MIC-A in the presence of high risk HLA genotype (DR3-DQ2/DR4/4-DQ8) may define subjects at very high risk of AAD. MIC-A is not involved in the antigen presentation but as a mediator of activating natural killer cells and T cytotoxic lymphocytes (Bratland and Husebye, 2011). A number of other genes outside the MHC complex have also been reported such as the cytotoxic T lymphocyte-associated protein-4 (CTLA-4), a key negative regulator in adaptive immunity, the MHC class II transactivator (MHC2TA), which regulates the expression of class II molecules, the tyrosine-protein phosphatase non-receptor type 22 (PTPN22), involved in the regulation of T cell receptor signaling, and the programmed death ligand 1 (PD-L1), an inhibitory molecule expressed on activated T cells. In addition to the above-mentioned genes AAD is associated with genes involved in the metabolism of vitamin D, with the gene encoding NACHT leucine-rich-repeat protein 1 (Bratland and Husebye, 2011).

Finally, it is important to remember that in patients with APS-1 where AAD is one of the major components, there is an association without HLA alleles but with mutations of the autoimmune regulator (AIRE) gene (Cervato et al., 2009; Bratland and Husebye, 2011). This gene is involved in the presentation of autoantigen to autoreactive T lymphocytes in order to induce tolerance, and the presence of the AIRE gene mutations with mutated proteins may inhibit the apoptosis of autoreactive T lymphocytes at the thymic level; these cells can migrate at the peripheral level where they can initiate an autoimmune aggression in a very young age in these patients.

Cellular Immunity

The early studies on AD, using the assay for migration inhibition factor, reported cell-mediated immunity in affected patients, with claims for organ-specific hypersensitivity (Nerup and Bendixen, 1969). Subsequent studies, by means of an intracutaneous test with adrenal extracts, showed a cutaneous delayed-type hypersensitivity reaction but no collateral evidence based on blast transformation experiments (Nerup et al., 1970). Other studies reported a decrease in suppressor T cell function (Verghese et al., 1980) and an increase in circulating Ia-positive T lymphocytes (Rabinowe et al., 1984), which indicated the involvement of cellular immunity. Initially, studies of cellular immunity in AAD were carried out (Freeman and Weetman, 1992) when a proliferative T cell response to an adrenal-specific protein fraction of 18–24 kDa molecular weight was described.

Recently, in order to identify the autoepitopes recognized by T lymphocytes, BALB/c and SJL inbred mouse strains were immunized with recombinant 21-OH. T lymphocytes of the immunized animals were stimulated by a peptide 342–361 of 21-OH. This region may be involved in the pathogenesis of AAD (Husebye et al., 2006).

Subsequently, it was demonstrated that patients with AAD have circulating 21-OH-specific T cells recognizing the amino acidic fragment 342–361 of 21-OH, who constitute a disease-specific epitope presented by HLA-DRB1*0404. Furthermore, cellular proliferation and secretion of interferon- γ in response to 21-OH was significantly higher in patients with AAD respect to controls (Bratland et al., 2009).

Humoral Immunity

Anderson et al. (1957), using a complement fixation test on a homogenate of adrenal cortex tissue, demonstrated that 2/8 (25%) of patients with idiopathic AD had antibodies (adrenal cortical antibodies—ACA). From 1957 to 1970, using this technique, ACA were cumulatively reported in 57/159 (36%) patients with idiopathic AD and in 2/23 (9%) of those with the tuberculous form, reviewed

FIGURE 42.3 Immunofluorescence pattern on normal human adrenal cortex given by serum of a patient with AAD. This serum reacted with the cytoplasm of cells in all three layers of the cortex, but shown here are only glomerulosa (A) and fasciculata (B).

by [Betterle \(2004\)](#). Subsequently, [Blizzard and Kyle \(1963\)](#), using indirect immunofluorescence (IIF) on animal or human adrenal gland sections, demonstrated that ACA are organ-specific antibodies which react with all three layers of the adrenal cortex, producing a homogeneous cytoplasmic staining pattern ([Figure 42.3](#)). Sometimes, there is reactivity against one or two of the three layers of the cortex ([Irvine and Barnes, 1975](#); [Sotsiu et al., 1980](#)). The autoantibodies also react with the surface of living cortical cells in culture ([Khoury et al., 1981](#)), indicating the existence of microsomal antigens on the surface of adrenal cells.

Between 1963 and 2002, IIF was used on human or animal adrenal tissues in 1637 patients with AAD and 267 with tuberculous AD, and ACA were detected in 61% and 6.7%, respectively, as reviewed by [Betterle \(2004\)](#).

The prevalence of ACA has varied considerably between different laboratories because of differences in the substrates used (animal or human), time of incubation, geographic or racial origins of individuals, gender, age of onset, duration of the disease, or whether other associated diseases were present ([Rees Smith and Furmaniak, 1995](#); [Betterle et al., 2002](#); [Nigam et al., 2003](#)). Other studies ([Kendall-Taylor et al., 1988](#); [Wulfraat et al., 1989](#)) have reported the presence of autoantibodies blocking the ACTH receptor in 90% of patients affected by AAD, but these data could not be confirmed ([Wardle et al., 1993](#)). Finally, autoantibodies to hydrocortisone were detected in patients with an Addison-like syndrome and AIDS ([Salim et al., 1988](#)).

In 1968, steroid-producing cell antibodies (StCA) were first described ([Anderson et al., 1968](#)) in males affected by AAD without gonadal failure ([Figure 42.4](#)). Subsequently, StCA were detected in 60–80% of the

FIGURE 42.4 Immunofluorescence pattern given by serum of a patient with AAD and premature ovarian failure. This serum reacted against adrenal cortex (A), follicular theca of the ovary (B), and Leydig cells of the testis (C), and reflects autoantibodies to steroid-producing cells (StCA).

patients affected by type 1 APS, in 25–40% of those with type 2 APS, and in 18% of those with isolated AAD ([Betterle et al., 2002, 2005](#); [Betterle, 2004](#)). The presence of these antibodies correlates with premature ovarian failure characterized by lymphocytic oophoritis ([Betterle et al., 1993](#); [Hoek et al., 1997](#); [Betterle and Volpato, 1998](#)).

Recent data demonstrated that in Norway 6.7% of females with AAD had premature ovarian failure ([Erichsen et al., 2009b](#)). Recent numbers from Italy confirm and extend revealing a frequency of 20% and that steroidogenic autoantibodies are not only highly correlated with the presence of premature ovarian failure, but also that there are predictive markers for future clinical manifestation ([Reato et al., 2011](#)).

Identification of 21-OH as Adrenal Antigen

With regard to the identification of adrenal autoantigens, in 1988 [Furmaniak et al.](#) described a specific 55 kDa protein in human adrenal microsomes which was reactive with the ACA ([Furmaniak et al., 1988](#)).

In 1992, two independent laboratories ([Baumann-Antczak et al., 1992](#); [Bednarek et al., 1992](#); [Winqvist et al., 1992](#)) demonstrated by means of purification of native 21-OH that this adrenal enzyme is a major antigen of adrenal cortical cells. Subsequently, this was confirmed in experiments with specific absorption with purified human 21-OH, using sera from six patients with different forms of AAD ([Morgan et al., 2000](#)).

21-OH is an adrenal-specific enzyme of the cytochrome P450 family and plays a key role in the synthesis of the cortical hormones ([Furmaniak et al., 1999](#); [Furmaniak and Rees Smith, 2002](#)). 21-OH is encoded by the CYP21B gene, whereas the CYP21A gene is inactive ([Wilson et al., 1995](#)). 21-OH catalyzes the conversion of

progesterone and 17-hydroxyprogesterone into 11-deoxycorticosterone and 11-deoxycortisol (see Figure 42.2). It is a 55 kDa microsomal protein containing a heme group, located in the active site of the C-terminal end of the molecule, which is important for autoantibody binding (Wedlock et al., 1993; Asawa et al., 1994) and in oxidation-reduction reactions (Picado-Leonard and Miller, 1987; Lin et al., 1994).

Analysis of autoantibody-binding sites on 21-OH indicated that the epitopes on 21-OH were conformational (Wedlock et al., 1993) and confirmed the participation of both the central and C-terminal parts of the molecule. These studies identified the presence of three different, short 5-, 6-, and 15-amino acid sequences in the C-terminal part of the 21-OH involved in the binding of antibodies to 21-OH (Chen et al., 1998). These observations are important in relation to effects of 21-OH antibodies on 21-OH enzyme activity. In fact, in studies *in vitro*, using sera positive for 21-OHAbs from patients with AAD, a dose-dependent blocking activity was identified (Furmaniak et al., 1994), although this is not usually evident *in vivo* (Boscaro et al., 1996).

Techniques for Identification of Autoantibodies to 21-OH

Following the discovery that 21-OH is the major adrenal cortex autoantigen, a specific and sensitive technique was described, by labeling the protein with ³⁵S-methionine in an *in vitro* transcription translation (TnT) system, and using a radioimmunoprecipitation assay (RIA), for the detection of antibodies (Colls et al., 1995; Falorni et al., 1995; Chen et al., 1996). Thereafter, because of certain limitations of this technique, a more convenient assay to measure 21-OHAbs was developed based on the use of ¹²⁵I-labeled recombinant human 21-OH and the precipitation of the immunocomplexes using solid-phase protein A (RIA) (Tanaka et al., 1997). Using these techniques, from 1995 to 2002, a group of 572 patients with AAD and 76 with tuberculosis were studied; 78% and 1.9%, respectively, were 21-OHAbs positive, reviewed by Betterle (2004).

In order to compare techniques for ACA and 21-OHAbs determinations, we studied 165 patients with AD, with different durations of disease, and found that 81% of those with AAD were positive by both techniques, whereas none with non-AAD was positive (Betterle et al., 1999). The prevalence varied in relation to both the clinical presentation (type 1 or 2 APS or isolated AAD) and the duration of the disease, being higher (100%) in patients with recent onset than in those with long-standing disease (79%) and in those with type 2 APS than in those with isolated AAD (Betterle et al., 2002). In these studies, results using IIF for ACA and RIA for 21-OHAbs were in good agreement.

Some discrepancies were reported by Falorni et al. (1997) and Betterle et al. (1999) on relationships between ACA measured using IIF and 21-OHAbs measured by RIA. For example, a few patient samples were positive for 21-OHAbs while negative for ACA and this may reflect greater sensitivity of 21-OHAbs IPA. In contrast a small number of sera were positive for ACA while negative for 21-OHAbs by RIA. This discrepancy may be related to serum reactivity with adrenal cortex antigens in the IIF that are distinct from 21-OH.

Recently, the first international standardization program for 21-OHAbs determination was carried out to compare the measurements from four different laboratories using different methods and an inter-laboratory concordance study (Falorni et al., 2011). This study has shown a very good agreement among the laboratories on reporting 21-OHAbs positive/negative samples. The sensitivity for AAD was greater than 80% in all four participating laboratories. However, the study highlighted the need to produce the international standard preparation to enable the harmonized expression of the results.

Subsequently, an International Standardization Program for 21-OHAbs measurements was organized by the EurAdrenal consortium, and 13 different laboratories across Europe and one from United States participated in this program and the results are under evaluation (Falorni et al., in preparation).

Identification of other Steroidogenic Autoantigens

With regard to steroidogenic autoantigens, in addition to 21-OH, Krohn et al. (1992) reported that screening of a human fetal adrenal cDNA expression library with sera from patients with APS type 1 identified a protein with high homology to 17 α -hydroxylase (17 α -OH) reacting also with a fragment of recombinant 17 α -OH expressed in bacteria. 17 α -OH, coded by a single gene on the human chromosome 10, showed 30% homology with 21-OH antigen.

Winqvist et al. (1992), using immunoblotting and immunoprecipitation studies, also observed a reactivity of sera from APS type 1 patients with a cytochrome P450 side chain cleavage enzyme (P450scc), a heme-binding protein coded by a single gene on human chromosome 15, that showed 20% homology with 21-OH sequence (Chung et al., 1986).

The binding sites of these two antigens and their enzyme activity have not been studied, even though Peterson and Krohn (1994) reported the presence of four distinct, reactive regions in the 17 α -OH molecule and an inhibiting effect *in vivo* of the P450sccAbs in the type 1 APS serum (Winqvist et al., 1993).

The 17 α -OHAbs and P450sccAbs are detectable by RIA, using recombinant human antigens, and are

correlated with StCA detected by IIF (Chen et al., 1996; Reato et al., 2011).

In addition to the main antigens mentioned above, other autoantigens have also been discovered. Winqvist et al. (1996) identified an autoantibody of 51 kDa, recognizing the aromatic L-amino acid decarboxylase (AADC) involved in the generation of serotonin and dopamine. AADC was reported in the sera of patients with type 1 APS in association with chronic hepatitis, vitiligo, and type 1 diabetes mellitus (Husebye et al., 1997).

Other authors (Ekwall et al., 1998; Dal Pra et al., 2004) reported the presence of autoantibodies against a 230 kDa enzyme, tryptophan hydroxylase (TPH), involved in the synthesis of serotonin, or against histidine decarboxylase (Skoldberg et al., 2003) in patients with type 1 APS, who have a gastrointestinal dysfunction (Scarpa et al., 2013).

Again, patients with type 1 APS and autoimmune hepatitis recognize the cytochromes P450 CYP1A2 and CYP2A6 as autoantigens (Clemente et al., 1997, 1998).

Subsequently, an autoantibody to SOX9 and SOX10 was reported in patients with type 1 APS and vitiligo (Hedstrand et al., 2001), and an antibody to tyrosine hydroxylase in those with alopecia areata (Hedstrand et al., 2000).

Some authors reported reactivities against other antigens: to 3 β -hydroxysteroid dehydrogenase (Arif et al., 1996), candidal antigens, heat shock protein 90, pyruvate kinase, and alcohol dehydrogenase, and in patients with AAD and chronic mucocutaneous candidiasis (Peterson et al., 1996). Two different studies (Song et al., 1994; Peterson et al., 1997) were unable to confirm the reactivity to other enzymes (11 α -hydroxylase, aromatase, adrenodoxin) in patients with AAD.

NATURAL HISTORY OF AAD

Apart from the patients with AAD, ACA can be detected in 0.2% of normal controls, in 4% of first-degree relatives of AAD patients, 4% of hospitalized patients, and 1.3% of patients with organ-specific autoimmune disease, with a much higher prevalence (2.5–20%) in premature ovarian failure or idiopathic hypoparathyroidism (Nerup, 1974; De Bellis et al., 1993; Betterle et al., 1997a,b).

AAD is a chronic disease with a long silent period marked by the presence of ACA. The natural history of the disease could entail five main phases: one potential, three subclinical, and one clinical (Betterle et al., 1988, 2002).

To recognize these different phases, it is necessary to basally measure levels of cortisol, ACTH, plasma renin activity (PRA), aldosterone, and cortisol 30 and 60 min after an intravenous injection of 250 μ g of cosyntropin (α 1-24-corticotropin) (ACTH test) (Stewart et al., 1988; Grinspoon and Biller, 1994).

Stage 0 is characterized by the presence of adrenal-specific autoantibodies and a normal adrenal cortical mass, in the absence of any detectable dysfunction of the adrenal glands by ACTH test, representing the “potential” phase of chronic adrenalitis. Subclinical stage 1 is characterized by an increase in PRA, together with normal/decreased levels of aldosterone (reduced production of mineralcorticoids); subclinical stage 2 by normal ACTH values with normal basal cortisol but a low cortisol peak (low reserve of glucocorticoids); subclinical stage 3 by an increase in ACTH and low level of basal cortisol, representing reduced glucocorticoid production. Stage 4, the clinical stage, is when the ACTH is significantly increased and the basal cortisol is very low (Table 42.1).

Stage 1 reveals that the *zona glomerulosa* of the adrenal glands is first affected by the autoimmune attack, or because of its greater sensitivity to diffuse lymphocyte infiltration, or because the other zones are protected by either locally produced high concentrations of corticosteroid hormones or the ability to self-regenerate (Betterle et al., 2002).

For the study of patients with ACA/21-OHAb, it was proposed to use also an ACTH test with a low dose (1 μ g) of ACTH (Laureti et al., 2000). It has been shown that this low-dose test has a diagnostic accuracy as high as that of the classical high-dose intravenous 250 μ g test but it remains unclear whether “low-dose” synacthen tests have better sensitivity for detecting adrenal failure than the standard test.

From 1983 to 2000, 236 ACA-positive patients were followed in 12 studies and 28% developed AAD, but the evolution varied greatly from 0 to 90% (Betterle, 2004; Betterle et al., 2005). The highest risk was found in children with respect to adults with high antibody titers and with the presence of DR1*0404 (Betterle et al., 1997a,b; Laureti et al., 1998; Yu et al., 1999).

Subsequently, in order to estimate risk of AAD, 100 ACA-positive patients (21 children and 79 adults) with autoimmune diseases but without clinical AAD followed up for a period of 19 years were reanalyzed; 31 of the seropositive patients developed clinical AAD. The overall cumulative risk of AAD in ACA/21-OHAb-positive patients was 47.5%, with an annual incidence of 4.9%.

In order to identify the real value of the various analyzed data we assessed a multivariate analysis, including clinical (gender and age), immunologic (type of preexisting autoimmune disease, titers of autoantibodies), genetic (HLA status), and functional status (normal or subclinical adrenal cortical function). This analysis demonstrated that the occurrence of AAD was significantly correlated to gender, adrenal cortex autoantibodies titers, adrenal cortex functional status, and type of autoimmune preexisting disease.

TABLE 42.1 ACTH Test: Stages of Adrenal Function in ACA-positive Patients

| Adrenocortical Function | Stage | Autoimmune AD | ACA/21-OHAb | Basal PRA | Basal Aldosterone | Basal ACTH | Basal Cortisol | Cortisol Response 60 min after ACTH i.v. | Clinical Manifestations |
|---|-------|---------------|-------------|-----------|-------------------|------------|----------------|--|-------------------------|
| Normal | 0 | Potential | + | Normal | Normal | Normal | Normal | Normal | Absent |
| Reduced production of mineralocorticoids | 1 | Subclinical | + | High | Normal or low | Normal | Normal | Normal | Absent |
| Reduced reserve of glucocorticoids | 2 | Subclinical | + | High | Low | Normal | Normal | Reduced | Absent |
| Reduced production of glucocorticoids | 3 | Subclinical | + | High | Low | High | Low | Absent | Absent |
| Important mineralocorticoids and glucocorticoids deficiency | 4 | Clinical | + | Very high | Very low | Very high | Very low | Absent | Present |

On the basis of these results the probability of developing AAD can now be estimated by a mathematical model. This evaluation yielded two practical outcomes: (1) individualization of the patients with different risk grades (low, medium, or high risk) in order to monitor them at different rates (every 6, 12, or 24 months); (2) selection of patients to begin an early substitutive therapy or in future an immuno-intervention trial treatment in order to prevent the development of the clinical disease (Coco et al., 2006).

DIAGNOSIS OF AAD

Clinical Manifestations

AAD has a long pre-clinical period and clinical features do not appear until 90% or more of the adrenal cortex is destroyed. The main clinical signs at onset are general malaise, fatigue, weakness (99%), anorexia, nausea and vomiting (90%), weight loss (97%), cutaneous and mucosal hyperpigmentation (Figure 42.5) caused by the enhanced stimulation of the skin MC1-receptor by ACTH and other pro-opiomelanocortin-related peptides (98%), and severe hypotension (87%). Other signs (abdominal pain, salt craving, diarrhea, constipation, syncope) have a variable frequency (34–39%) (Williams and Dluhy, 1998). In women a loss of axillary and pubic hair, dry skin, reduced libido, and an impairment of well-being also occur.

General Biochemical Indices

In AAD at diagnosis, the serum levels of sodium, chloride, and bicarbonate are reduced, while those of potassium are elevated. The hyponatremia (in 100% of patients) is due to loss of sodium in urine and increase in

FIGURE 42.5 Clinical Manifestations of AAD at Onset. (A) Hyperpigmentation of the skin, melanoses of the tongue, and exophthalmos as a sign of dehydration. (B) Male showing a melanoses of the tongue. (C) Hyperpigmentation of the nails.

both plasma vasopressin and angiotensin II which impair free water clearance; hyperkalemia (in 50–70%) is due to aldosterone deficiency, impaired glomerular filtration, and acidosis. From 10 to 20% of patients have a mild or moderate hypercalcemia, for unknown reasons (Williams and Dluhy, 1998). Anemia is present in 40–50%, and eosinophilia and lymphocytosis in 10–15% of the cases.

Hormonal Tests

The association between a morning (8 a.m.) immunometric determination of both plasma ACTH and basal cortisol levels differentiates cases of primary adrenal

failure from both a healthy status and other types of adrenal disease (Oelkers et al., 1992).

An increase in levels of ACTH (higher than 22.0 pmol/L) and decrease (below 165 nmol/L) in basal cortisol indicate primary adrenal failure. In the initial phases of AD, plasma renin activity increases above the normal range, and serum aldosterone is either subnormal or low to normal. In relation to differential diagnosis, in the case of secondary adrenal failure, levels of both ACTH and cortisol are low and, in general, aldosterone and plasma renin activity are normal. Dehydroepiandrosterone, which is the major precursor of sex steroid synthesis, is involved in the adrenal failure, causing a pronounced androgen deficiency in women, with the loss of both axillary and pubic hair, dry skin, reduced libido, and, frequently, an impairment in well-being (Arlt and Allolio, 2003).

In cases in which there are no clear clinical manifestations of AD, and/or in the presence of adrenal cortex antibodies, it may be necessary to perform an ACTH test (see above, Natural history of AAD). TSH levels are increased in 30% of patients, because of the lack of inhibiting effect of cortisol on TSH production or the presence of coexisting autoimmune hypothyroidism (Orth and Kavacs, 1998).

Recently, it has been demonstrated that the measurement of salivary and serum cortisol in the morning has a low sensitivity and specificity for detecting primary adrenal insufficiency (Raff, 2009).

Imaging

Computed tomography (CT) and nuclear magnetic resonance (NMR) show the adrenals with optimal resolution and clarity, and greatly facilitate the diagnosis and characterization of adrenal insufficiency. In patients with

FIGURE 42.6 Adrenal Imaging. CT of the adrenal glands of a patient with autoimmune Addison's disease at diagnosis. The adrenals are small (see arrows).

AAD, either isolated or as a component of APS syndromes, the adrenal glands appear bilaterally miniscule without calcifications (Doppman, 2001) (Figure 42.6).

Recently, the imaging of the adrenal glands was performed in 250 patients with AAD. Normal adrenal glands were found in 190 patients (76%), in 59 patients (23.6%) the adrenals were reduced in size/volume or undetectable, and only in the case of one patient (0.4%) was there a modest increase in adrenal volume. None of the examined adrenal glands showed calcifications. There were no differences in the adrenal imaging between different forms of AAD in the context of the various APS/MAS (Betterle et al., 2013).

DIFFERENT CLINICAL PRESENTATIONS OF AAD

Neufeld and Blizzard (1980) proposed the classification of autoimmune syndromes into four main groups, involving different endocrine glands, and named them “autoimmune polyglandular syndromes” (APS) (see Box 42.1). According to this classification, AAD can be associated with type 1 and 2 APS.

Box 42.1 Clinical Classification of APS According to Neufeld and Blizzard (1980) (modified).

- APS-1 Chronic candidiasis, chronic hypoparathyroidism, Addison's disease (*at least two diseases must be present*)
- APS-2 Addison's disease (*always present*) + thyroid autoimmune diseases and/or type 1 diabetes mellitus
- APS-3 Thyroid autoimmune diseases + other autoimmune diseases (*excluding Addison's disease and/or hypoparathyroidism*)
- APS-4 Combinations of other autoimmune diseases not included in previous classifications

Betterle and Presotto (2008), in a review of multiple autoimmune syndromes (MAS), proposed the existence of three different types of APS/MAS involving AAD (type 1 when associated with chronic candidiasis and/or chronic hypoparathyroidism; type 2 when associated with autoimmune thyroid diseases and/or type 1 diabetes mellitus; and type 4 when associated with other autoimmune diseases not included in the previous list). So, AAD can present in four main clinical forms: isolated or associated with type 1, 2, or 4 APS/MAS.

Association with other Autoimmune Disorders

Every patient with a diagnosis of AAD needs to be investigated for the family and personal clinical signs or symptoms of thyroid autoimmune diseases, gastric

TABLE 42.2 Four Different Clinical Presentations of Autoimmune Adrenalitis (Number of AAD patients = 524)

| Subgroups Frequency | APS-2 61.6% | APS-1 13.6% | APS-4 8% | Isolated 17.5% |
|--|-----------------------|------------------------|---------------------|---------------------|
| F/M | 2.3 | 2.1 | 1 | 0.6 |
| Adults/Children | 16 | 0.8 | 5,3 | 4 |
| Mean age (in years) at onset of AD | 34.6 | 15 | 32 | 32 |
| Range | 1–85 | 2–41 | 6–62 | 1–84 |
| Family history for autoimmune diseases | Frequent | Frequent | Frequent | Frequent |
| Family history for AAD | Rare | Frequent | Rare | Rare |
| Genetic | HLA-DR3 and/or DR4 | AIRE gene Mutations | HLA (?) | HLA(?) |
| Chr. candidiasis | Absent | 76% | Absent | Absent |
| Chr. hypoparathyroidism | Absent | 90% | Absent | Absent |
| Thyroid autoimmune dis. | 93.7% | 30% | Absent | Absent |
| Type 1 diabetes mellitus | 15.5% | 6% | Absent | Absent |
| Other autoimmune diseases (vitiligo, alopecia, autoimmune gastritis, pernicious anemia, celiac disease, myasthenia gravis, Sjögren's syndrome, Werlhof's syndrome, multiple sclerosis, etc.) | Until 43% | Until 57% | 100% | Absent |
| Ectodermal dystrophy | Absent | Present | Absent | Absent |
| Cancer | 5.3% | 9.9% | 2.6% | 4.3% |
| ACA or | 88% | 91% | 95% | 69% |
| 21-OHAb at onset of AD | 94% | 92% | 100% | 86% |
| Adrenals imaging | Normal/ atrophic | Normal/ atrophic | Normal/ atrophic | Normal/ atrophic |

autoimmune diseases, gonadal failure, type 1 diabetes, chronic hypoparathyroidism, chronic candidiasis, vitiligo, alopecia, autoimmune hepatitis, and other autoimmune diseases; in the absence of the clinical manifestations of these disorders it is also important to perform an organ- and non-organ-specific autoantibody screening because a proportion of patients with apparently isolated AAD can be positive for one or more autoantibodies and this can reveal the presence of a subclinical or a potential disease with a high risk of future clinical dysfunction. In 82–87% of the patients with AAD this approach allowed the identification of one or more clinical, subclinical, or latent autoimmune diseases (Erichsen et al., 2009) which represents the autoimmune disease with the highest prevalence in relation to other autoimmune diseases in the world.

In our experience, out of 524 patients with AAD, overall 432 (82.4%) were classified to APS/MAS; in particular 323 (61.6%) had APS/MAS-2, 71 (13.6%) had APS/MAS-1, 38 (7.2%) had APS/MAS-4, and only 92 (17.6%) had an isolated AAD (Betterle et al., 2013).

Every subtype of AAD had some common features (family history for autoimmune diseases, autoantibodies to adrenal cortex, adrenal imaging of normal or atrophy) and some different features (age at onset, F/M ratio, adults/children ratio, genetic predisposition, association with the minor autoimmune diseases, association with cancer). The typical profiles of the four different forms of AAD are summarized in [Table 42.2](#).

THERAPY

General Information

Life-saving therapy for patients with chronic adrenal insufficiency is two or three daily doses of a specific hormone replacement (Groves et al., 1988; Howlett, 1997; Williams and Dluhy, 1998; Arlt and Allolio, 2003b). Doses of 20–30 mg of hydrocortisone or 25–50 mg of cortisone acetate are required. The first dose is administered in the morning and the second in the afternoon, about 6–8 hours after the first, and the third at 6 pm or at least 4 hours before sleep. Substitutive glucocorticoid therapy is not taken with food. The dosage must be increased for obese individuals and those taking other drugs. Patients should be given relatively small doses to avert weight gain and osteoporosis.

ACTH cannot be used for the purposes of treatment surveillance, whereas a 24-hour urinary free-cortisol test has been advocated for monitoring of replacement therapy. However, urinary cortisol excretion shows considerable variability, because after oral administration and glucocorticoid absorption the cortisol-binding globulin is rapidly saturated with an increase of unutilized cortisol renal excretion (Arlt, 2009).

Some authors have proposed (Betterle et al., 2013). measurements of serum cortisol day curves to monitor replacement therapy but no agreement has been demonstrated between clinical assessment and cortisol levels (Arlt, 2009).

In order to mimic the physiological circadian bi-rhythm of cortisol, a once-daily dual-release hydrocortisone tablet was produced based on an immediate-release coating together with an extended-release core (Johannsson et al., 2009). The once-daily dual-release hydrocortisone tablet, compared to the conventional thrice-daily dose of conventional hydrocortisone tablets, produced a more circadian-based serum cortisol profile and reduced body weight, blood pressure, and improved glucose metabolism in patients with AD and concomitant diabetes mellitus (Johannsson et al., 2012).

Subcutaneous cortisol infusion is still an experimental treatment, but could be tested on selected patients not responding properly to regular peroral treatment (Løvås and Husebye, 2007).

Mineralocorticoid replacement is usually necessary and can be administered as a single daily dose of 0.05–0.2 mg of fludrocortisone or another aldosterone substitute. Patients should also receive an ample amount of sodium (3–4 g/daily), assessed by measurement of supine and erect blood pressure, serum electrolytes, and plasma renin activity levels (Williams and Dluhy, 1998). During the summer period, especially in Mediterranean or tropical climates, the doses of mineralocorticoids should be increased (Arlt, 2009). Complications are rare with this type of therapy. However, possible hypokalemia, hypertension, sodium retention, or heart disease should be monitored.

If essential hypertension develops in patients with mineralocorticoid replacement therapy, first, the dose may be slightly reduced; if the hypertension persists anti-hypertensive drugs need to be started (Arlt, 2009). DEHA (dehydroepiandrosterone) is the most important source of androgens in females; replacement therapy enhances well-being, mood, subjective health status, energy levels, and libido in women with adrenal insufficiency. For these reasons the therapy should be reserved for patients with significant impairment in well-being despite the optimized classical replacement therapy. Doses vary from 25 to 50 mg/day in a single dose in the morning (Arlt, 2009). The therapy remains optional because the drug is available only by ordering via the international pharmacy and the preparations are not pharmaceutically controlled (Arlt, 2009).

Steroid Replacement during Surgery, other Illness, Medical Procedures, Physical Activity, and Pregnancy

Patients with AD need to increase their steroid doses during surgery and medical procedures according to the stress induced.

In general, surgery, fever, gastrointestinal diseases, major dental procedures, and child delivery require

parenteral hydrocortisone followed by double oral doses being tapered to replacement doses over subsequent days.

Patients undergoing regular and time-limited physical activity do not generally need to make a dose adjustment. However, in case of intense or prolonged exercise an increase in hydrocortisone and salt intake may be necessary. However, there are no systematic studies of replacement therapy during strenuous physical activity.

Pregnancy is associated with a gradual but pronounced physiological increase in corticosteroid-binding globulin (CBG) and total serum cortisol. Free cortisol levels rise during the third trimester, and some pregnant patients have a small increase in hydrocortisone requirement (by 2.5 or 5 mg daily) during the third trimester. Serum progesterone has anti-mineralocorticoid effects and hence the fludrocortisone dose may need to be increased during late pregnancy. Plasma renin activity normally increases during pregnancy. During delivery a bolus dose of 100 mg hydrocortisone should be given, and repeated if necessary. The oral dose should be doubled for 24–48 hours post-partum (Husebye et al., 2012).

In any case, patients with AD should carry a medical identification card (or a bracelet), stating the current therapy and recommendations for emergency situations such as febrile illnesses, injury, vomiting, surgical interventions, dental extractions or pregnancies, when the intake of glucocorticoids must be doubled or tripled (Oelkers, 1996).

Adrenal Crisis

The risk of adrenal crisis is a possible life-threatening event in every Addisonian patient. The crisis can be due to unnecessary reduction of the glucocorticoid therapy or to lack of stress-related glucocorticoid dose adjustment by patients or medical practitioners. Generally, oral glucocorticoid therapy should be increased or doubled during infections with fever, or during any other major stress-producing event, and, in general, needs to be orally increased but parenterally injected in case of gastrointestinal infections with diarrhea, surgical procedures, delivery, vomiting, or major traumas (Arlt, 2009).

Mortality

Three Scandinavian studies have made a contribution to the rate of mortality of AD (Bergthorsdottir et al., 2006; Bensing et al., 2008; Erichsen et al., 2009a). The two registry studies from Sweden (Bergthorsdottir et al., 2006; Bensing et al., 2008) showed that the mortality was more than double that in the control population and particularly elevated in patients with APS type 1 with an odds ratio of 4.6. The causes of death were endocrine diseases and cancer (Bensing et al., 2008). It must be said that the two Swedish registries referred exclusively to hospitalized

patients, were not representative of the entire population of AD patients, and were both based on the codification of the disease without a definitive confirmation of the diagnosis. Potential assignment mistakes may have greatly influenced the outcome. More specifically, it is known that secondary adrenal insufficiency due to deficit of ACTH has an increased risk for mortality (Filipsson et al., 2006) also because of the concomitant deficit of other pituitary hormones and it is not certain that such patients have been excluded from the analysis.

A Norwegian case-control study did not report an overall increase in mortality, and also identified a subgroup of young males with doubled mortality rate, the causes of death being adrenal crisis, infections, and sudden death, while cardiovascular mortality was not increased (Erichsen et al., 2009a).

In an Italian study we examined the mortality in over 700 patients with AD followed up for a mean period of 15 years and demonstrated the existence of a normal survival rate in patients with autoimmune AD excluding those with APS type 1. Patients with APS type 1 revealed an increased mortality rate with respect to the general population matched for gender and age with the patients (Betterle et al., personal observation).

Osteoporosis

It is a constant concern that overtreatment with glucocorticoids may have negative health effects on bone mineral density. An increased incidence of osteoporosis has been reported in patients receiving daily replacement doses of 30 mg of hydrocortisone or higher, whereas replacement doses of 20–25 mg of hydrocortisone do not affect bone mineral density (Arlt, 2009).

Earlier studies have been hampered by low numbers of participants. In patients with AD a reduced bone mineral density (BMD) was reported along with polymorphisms in genes regulating steroid action influences BMD (Løvås et al., 2009). BMD revealed an inverse correlation to steroid dose, and was especially low in those taking synthetic potent glucocorticoids such as prednisolone. Despite reduced BMD, vertebral fractures were not more prevalent than in the background population. In contrast, a follow-up registry study from Sweden reported significantly increased frequencies of hip fractures in AD patients with an excess risk about 50% (Björnsdottir et al., 2011).

A recent study in 81 German patients who received low replacement doses of glucocorticoids found no reduction in BMD (Koetz et al., 2012). Thus, clinicians should aim to keep the glucocorticoid replacement dose as low as is compatible with normal well-being.

Patients with AAD should carry a medical identification card (or a bracelet), stating the current therapy; and

recommendations for emergency situations such as febrile illnesses, injury, vomiting, surgical interventions, dental extractions or pregnancies, when the intake of glucocorticoids must be doubled or tripled (Oelkers, 1996).

Based on a synthesis of the EurAdrenal research, and the views and experience of the consortium's investigators, we have attempted to provide European guidelines for diagnosis, treatment, and follow-up of patients with AD (Husebye et al., 2012).

ACKNOWLEDGMENTS

We would like to thank all those who have cooperated with us over the years regarding the study of the clinical, genetic, immunologic, morphologic, and endocrine aspects of AD.

This study was supported in part by a grant from the European Union Seventh Framework Programme, the Euradrenal project: Pathophysiology and Natural Course of Autoimmune Adrenal Failure in Europe. Grant Agreement No. 2008-201167 (EURADRENAL website: www.euradrenal.org/).

Autoimmune polyendocrinopathies can be divided into two distinct syndromes, autoimmune polyendocrine syndrome type 1 and type 2 (APS-1 and -2). The former is monogenic and caused by mutations in the autoimmune regulator (AIRE) gene, the latter is associated with certain major histocompatibility complex genotypes and a range of other genes. In both conditions a number of autoantibodies can be detected that correlate with clinical components. Clinically there are overlaps, but hypoparathyroidism and chronic mucocutaneous candidiasis are specific for APS-1. Recent years have provided remarkable progress in our knowledge about disease genes and immunopathology of APS, especially from studies of the AIRE-knockout mouse model. Assay of antibodies against tissue-specific enzymes, interferons, and interleukins can be used for both diagnostic purposes and to predict various disease components. However, the environmental triggers involved still remain elusive.

In this overview we summarize recent progress in the understanding of pathogenic mechanisms involved in APS-1 and APS-2, and in the corresponding animal models, and sum up similarities and differences in clinical presentation, diagnosis, and treatment.

HISTORICAL BACKGROUND

In 1855, Thomas Addison published observations linking the clinical features of “general languor and disability, feableness of the heart’s action” and hyperpigmentation of the skin to disease in the suprarenal capsules (adrenals) (Addison, 1855). This disorder has since been known as Addison’s disease (Wilks, 1862). Already in 1926 Schmidt (Schmidt, 1926) noticed the propensity for polyendocrinopathy by demonstrating lymphocytic infiltration in both the adrenal and thyroid glands (Schmidt syndrome, OMIM 269200); later, Carpenter (Carpenter et al., 1964) added insulin-dependent diabetes mellitus to this list. The first clinical reports on patients with Addison’s disease presenting with chronic candidal infection and hypoparathyroidism appeared in the 1950s (Hetzel and Robson, 1958), although Thorpe and Hanley had already reported a case with hypoparathyroidism and candidiasis in 1929 (Thorpe and Handley, 1929). In the 1960s several reports pointed to the clinical and genetic heterogeneity among patients with Addison’s disease (Blizzard and Gibbs, 1968; Spinner et al., 1968), proposing that, depending on the type of associated disorders, Addison’s disease could be part of two separate and distinct clinical syndromes: autoimmune polyglandular (polyendocrine) syndromes (APS) type 1 and type 2 (Neufeld et al., 1981).

CLINICAL PATHOLOGIC AND EPIDEMIOLOGIC FEATURES

APS-1 (OMIM 240300) has a broad spectrum of clinical manifestations (Table 43.1, Figure 43.1). The disease is also referred to as autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) or polyglandular autoimmune syndrome (PAS) type 1. The most frequent clinical entities include chronic mucocutaneous candidiasis, hypoparathyroidism, and Addison's disease. Usually, two of the three major components need to be present in order to make the diagnosis; however, the disease variability and delay in appearance of manifestations make the diagnosis difficult in many instances. Typically, APS-1 starts in childhood with chronic candidiasis as the first manifestation followed by hypoparathyroidism and Addison's disease, but there is a wide variety of phenotypes from serious to very mild disease, even within the same family (Perheentupa, 2002, 2006).

Candida infection appears in more chronic cases as white thrush on the tongue. Candidal esophagitis is often present and the infection may spread to nails and in some cases even to skin of the hands and face. Several cases of oral carcinoma have been reported, suggesting that oral candidiasis might be carcinogenic (Perheentupa, 2002). Chronic mucocutaneous candidiasis is associated with reduced numbers of Th17 cells and presence of autoantibodies against the Th17 cell mediators IL-17F, IL-17A, and IL-22 (Kisand et al., 2010; Puel et al., 2010).

Hypoparathyroidism is the most frequent and sometimes only endocrine component in APS-1. Gonadal insufficiency is very common in females (female/male ratio, 3:1) and manifests itself in the teenage years and early twenties (Reato et al., 2011). Other endocrinopathies in falling frequencies are type 1 diabetes, autoimmune thyroid disease, and hypophysitis. Many patients suffer from gastrointestinal autoimmunity, notably enteropathy with malabsorption, hepatitis, autoimmune

TABLE 43.1 Manifestations and Organ-Specific Autoantibodies in APS-1

| Main Disease Component | Autoantigen | Characteristics/Prevalence |
|--------------------------------|--|--|
| APS-1 | IFN- ω , IFN- α | Almost all patients are positive |
| Main triad | Hypoparathyroidism | 70–80%, childhood |
| | Addison's disease | 65–85%, childhood |
| | Candidiasis | 80–100%, childhood |
| Other endocrine manifestations | Ovarian failure | 60% |
| | Testicular failure | Adult prevalence up to 60% |
| | Autoimmune thyroid disease | ≈10%, relatively rare |
| | Type 1 diabetes | 0–25% |
| | Hypophysitis | Rare |
| Gastrointestinal | Malabsorption | Common, diarrhea, severe constipation, fatty stools |
| | Autoimmune gastritis | 10–30% |
| | Autoimmune hepatitis | 5–20%, childhood, severe sometimes fatal |
| Hematological | Exocrine pancreatitis | Rare |
| | Hypo/asplenia | 10–20%, risk of septicemia |
| | Hypergammaglobulinemia | 5% |
| | Pure red cell anemia | Rare |
| Nephrological | Mineralocorticoid excess with hypertension | Rare |
| | Interstitial nephritis | Rare |
| Lung | Bronchiolitis obliterans | Rare, can be fatal |
| Ectodermal | Keratoconjunctivitis | Prevalence approx. 10%, may result in blindness |
| | Alopecia | Common, prevalence 30–40% |
| | Vitiligo | Prevalence ≈20% |
| | Periodic rash with fever | Rare |
| | Squamous cell carcinoma | Associated with candidosis and smoking, can be fatal |
| | Enamel dysplasia | Prevalence 50–70% |
| | Muscular, neurological | Myopathy |

Abbreviations: AADC, aromatic L-amino acid decarboxylase; IFN- ω , interferon-omega; IA-2, islet antigen 2; IFN- α , interferon-alpha; NALP5, NACHT-LLR-PYD-containing domain 5; KCNRG, putative potassium channel regulatory protein; SOX9, sex determining region Y-box 9; TDRD6, tudor domain-containing 6; TG, thyroglobulin; TH, tyrosine hydroxylase; TPH, tryptophan hydroxylase; TPO, thyroperoxidase; TSGA10, testis-specific gene 10 protein.

FIGURE 43.1 Clinical manifestations of autoimmune polyendocrine syndrome type 1. A. Carpal spasm caused by hypocalcemia (Trousseau's sign; B. vitiligo (middle right); C. enamel hypoplasia with resultant wearing down of teeth. D. candida infection of the nail E. alopecia areata; F. candidiasis of the tongue. Photographs courtesy Martina M. Erichsen, Haukeland University Hospital.

gastritis with and without vitamin B12 and iron deficiencies, and exocrine pancreatitis. Many other disease associations have been reported in literature. APS-1 patients often display a number of organ-specific lesions affecting ectodermal structures, namely enamel dysplasia, vitiligo, alopecia, keratoconjunctivitis, and nail dystrophy. In addition, urticaria-like erythema and hyposplenism or splenic atrophy have been reported (Perheentupa, 2002, 2006), which render them susceptible to serious bacterial infections.

APS-2 is a genetically complex disease with a multifactorial etiology. The clinical onset usually occurs in adulthood, although it can start at any time during the lifespan. The classical definition of APS-2 (Neufeld et al.,

1981) comprises a combination of Addison's disease with autoimmune thyroid disease and/or type 1 diabetes. Probably any combinations of autoimmune disorders within the complex represent the same disorder with an inherited propensity to develop organ-specific autoimmunity (Schatz and Winter, 2002). Type 1 diabetes can develop before and after Addison's disease (Erichsen et al., 2009). In common with APS-1, manifestations such as vitiligo, alopecia, hypergonadotropic hypogonadism, and autoimmune gastritis with or without pernicious anemia are prevalent although less common and usually not present in childhood. The prevalence of APS-2 is estimated at up to 8 per 100,000 inhabitants (Erichsen et al., 2009) and first-degree relatives of patients with APS-2

are at high risk of autoimmune disorders (Michels and Eisenbarth, 2009). APS-2 affects in particular middle-aged Caucasian women with a male/female ratio of 1:2–3.

APS-3 was included in the original classification of autoimmune polyendocrine syndromes (Neufeld et al., 1981) to define the clinical entity of autoimmune thyroid disease and one or more other autoimmune diseases excluding Addison's disease. The genetic and etiological background of APS-3 is probably similar to that for APS-2. Sometimes, APS-4 is also mentioned as Addison's disease and other autoimmunity excluding autoimmune thyroid disease and type 1 diabetes. We here suggest for clarity that APS-4 is included in the group called APS-2.

AUTOIMMUNE FEATURES

Seminal evidence on the autoimmune pathogenesis in Addison's disease was provided by Anderson et al. (Anderson et al., 1957), who reported the presence of adrenocortical cell antibodies (ACC-Ab) in patients with Addison's disease, using complement fixation. The finding of these autoantibodies was later confirmed by immunofluorescence (Blizzard et al., 1962) revealing 50–90% positivity (Sotsiou et al., 1980; Betterle and Morlin, 2011). In addition to ACC-Ab, autoantibodies to the steroid producing cells (StC-Ab) can be present reacting with the theca interna and corpus luteum of ovary, interstitial cells of testis, and placental trophoblasts. These reactivities were later found to represent binding to steroidogenic P450 cytochrome enzymes. ACC-Ab was mainly associated with reactivity towards steroid 21-hydroxylase (P450c21 or CYP21) (Winqvist et al., 1992) expressed in the adrenal cortex, while StC-Ab was linked to reactivities against side chain cleavage enzyme (P450scc or CYP11A1) and steroid 17-alpha-hydroxylase (P450c17 or CYP17 expressed in both adrenals and gonads) (Krohn et al., 1992; Winqvist et al., 1993, 1995; Uibo et al., 1994; Brozzetti et al., 2010a; Reato et al., 2011).

Autoantibodies to several other organ-specific self antigens have been reported in APS-1 (Table 43.1). One group is decarboxylases and hydroxylases involved in neurotransmitter biosynthesis. Examples are autoantibodies against aromatic L-amino acid decarboxylase (AADC) correlated to type 2 autoimmune hepatitis (Husebye et al., 1997), tryptophan hydroxylase connected to autoimmune enteropathy (Ekwall et al., 1998), and tyrosine hydroxylases correlated to alopecia (Hedstrand et al., 2000). Patients also react with glutamic acid decarboxylase 2 (GAD2/GAD65) (Skoldberg et al., 2004; Soderbergh et al., 2004) and with GAD1/GAD67 (Tuomi et al., 1996). Recently, NACHT leucine-rich-repeat protein 5 (NALP5) has been identified as an autoantigen in hypoparathyroidism (Alimohammadi et al., 2008), and

potassium channel regulator KCNRG that is expressed only in the terminal bronchioli correlated with respiratory symptoms (Alimohammadi et al., 2009).

Autoantibodies to a new class of proteins were identified in 2006 when type 1 interferon (IFN) antibodies were found in virtually all patients with APS-1 (Meager et al., 2006). Autoantibodies to type 1 IFN, in particular to various isoforms of IFN- α and IFN- ω , are neutralizing, occur in extremely high titers up to 1 to 10⁶, are detected at very early stage of APS-1, and persist for decades. Such high frequencies of positivity renders assay of IFN- ω antibodies as a very useful tool to identify patients with APS-1 (Meloni et al., 2008; Oftedal et al., 2008). Finally, prevalent autoantibodies against interleukins IL-17A, IL-17F, and IL-22 were found with correlations to the presence of candidiasis (Kisand et al., 2010; Puel et al., 2010).

In APS-2, most of the patients have autoantibodies to P450c21, the major autoantigen of Addison's disease (Baumann-Antczak et al., 1992; Bednarek et al., 1992; Winqvist et al., 1992; Erichsen et al., 2009). Prevalences of P450c21 antibodies in European populations are in the range of 80–90% (Falorni et al., 2011). The P450c21 autoantibodies have been demonstrated by several methods including immunoblotting with recombinant protein expressed in bacteria, yeast, or mammalian cells or by immunoprecipitation with *in vitro* translated or luciferase-coupled protein (Burbelo et al., 2007). In approximately 15–20% of APS-2 female patients the autoantibodies to P450c17 and P450scc are detectable, which are the targets of the StC-Ab and correlate to the presence of ovarian failure (Hoek et al., 1997; Betterle et al., 2002; Soderbergh et al., 2004). APS-2 patients with type 1 diabetes frequently have autoantibodies to GAD65 and/or IA-2 protein, while anti-GAD65 does not correlate to type 1 diabetes in APS-1 patients; instead an association to malabsorption was seen (Soderbergh et al., 2004). Autoantibodies to thyroid peroxidase are common in patients with autoimmune thyroiditis (Erichsen et al., 2009).

GENETIC FEATURES

APS-1 is inherited in an autosomal recessive manner and occurs as a defect in the autoimmune regulator (*AIRE*) gene. The prevalence worldwide is very low and population dependent. The frequency is higher among certain populations such as Finns (1/25,000) (Aaltonen et al., 1994), Iranian Jews (1/9000) (Zlotogora and Shapiro, 1992), and Sardinians (1/14,400) (Rosatelli et al., 1998). The prevalence reported from Norway at 1/80,000 (Wolff et al., 2007) probably reflects the frequency in most countries.

AIRE, the gene mutated in APS-1, was identified by positional cloning on chromosome 21q22.3 (Finnish-German-Consortium, 1997; Nagamine et al., 1997). To

date more than 70 mutations have been found in *AIRE* gene (<http://www.hgmd.cf.ac.uk/ac/gene.php?gene=AIRE>). The mutations are spread throughout the coding region with two mutational hotspots. The most common mutation is amino acid arginine change to stop codon (R257X) in exon 6, which is found in 83% of the Finnish APS-1 chromosomes (Bjorses et al., 2000) but is also common in APS-1 patients of other ethnic origins (Scott et al., 1998). Another frequently occurring mutation is 967-979del13bp, which has been reported in patients from different populations (Wang et al., 1998; Pearce et al., 1998; Heino et al., 1999b; Myhre et al., 2002). Furthermore, R139X mutation is common among Sardinians (Rosatelli et al., 1998), R203X among Sicilians (Giordano et al., 2012), and Y85C among Iranian Jewish APS-1 patients (Pearce et al., 1998; Wang et al., 1998; Heino et al., 1999; Bjorses et al., 2000). Many *AIRE* mutations are nonsense mutations or deletion/insertions resulting in a truncated protein lacking SAND or PHD finger domains. Most of the missense mutations occur in the N-terminus of *AIRE*, a region responsible for the homodimerization and correct intracellular localization of the protein.

Despite considerable variation in the APS-1 phenotype, clear correlation of autoimmune disorders with genotype has not been found, although it is noted that among Iranian

Jews the Y85C mutation has much lower frequencies of candidiasis and Addison's disease than other cohorts (Zlotogora and Shapiro, 1992). Moreover, in a study of 160 Finnish patients with the three most prevalent mutations, candidiasis was found more often in patients with homozygous R139X and R257X mutations (i.e., truncating *AIRE* before SAND domain) than with homozygous 967-979del13bp mutation (Kisand et al., 2010; Kisand and Peterson, 2011).

APS-1 has no clear association with the genomic region of HLA, although some components of the disease seem to correlate with certain HLA alleles or haplotypes. For example, in one study, Addison's disease was found associated with HLA DRB1*03, alopecia with DRB1*04-DQB1*0302, and type 1 diabetes correlated negatively with DRB1*15-DQB1*0602 (Halonen et al., 2002). However, another study did not find association with HLA alleles (Gylling et al., 2003).

APS-2, in contrast to APS-1, is a genetically complex disease. As for most autoimmune diseases, APS-2 is strongly associated with the HLA gene locus in chromosome 6p21 (Table 43.2). Genetic studies have demonstrated a consistent association of APS-2 with HLA DRB1*0301 (DR3), DQA1*0501, and DQB1*02 (DQ2)

TABLE 43.2 APS-2-Associated HLA Alleles and Non-HLA Genes

| Genes | Details | Reference | |
|-------------------------------|---|---|--|
| MHC class II | DR3-DQ2 DR4 (0404)-DQ8 DQ5 | Antigen presentation; DR3/DR4(0404) heterozygotes have OR \approx 30 for AAD Protective; OR 0.4 for AAD | (Erichsen et al., 2009) (Erichsen et al., 2009) |
| MHC class I | HLA-B8 HLA-B15 (protective) | Antigen presentation, DR3-B8 haplotype associated with familial AAD Protective for progression to overt AAD | (Baker et al., 2010) (Baker et al., 2011) |
| Other genes in the MHC region | MICA5.1 P450c21 | Involved in NK and T cell activation, OR 18 for homozygotes with AAD Steroidogenic enzyme and main autoantigen in AAD; effect could be secondary due to LD | (Gambelunghe et al., 1999) (Peterson et al., 1995) |
| | Tumor necrosis factor | Inflammatory cytokine; effect could be secondary due to LD | (Partanen et al., 1994) |
| Non-MHC genes | CTLA4 PTPN22 NALP1 CLEC16A CIITA PD-L1 CYP27B1 FCRL3 | Involved in downregulation of T cell responses; A to G SNP at position 49; 3' untranslated region microsatellite Involved in T cell activation; AAD associated to the 1858 T allele and rare variants Involved in inflammatory responses; OR 1.15 for AAD C-type lectin of unknown function; OR 0.76 for AAD Govern MHC class II expression; OR 1.7 for AAD Downregulate cytokine production and T cell responses (CTLA4/CD28 family of costimulatory receptors); OR 1.33 for AAD 25-Hydroxyvitamin D3-1-alpha hydroxylase; OR 1.0–1.7 for AAD Immune regulatory; OR 1.6 for AAD | (Brozzetti et al., 2010b) (Blomhoff et al., 2004) (Skinningrud et al., 2008a); (Roycroft et al., 2009) (Magitta et al., 2009) (Skinningrud et al., 2008b) (Ghaderi et al., 2006) (Mitchell et al., 2009) (Lopez et al., 2004); (Jennings et al., 2005) (Owen et al., 2007) |

Abbreviations: AAD, autoimmune Addison's disease; CIITA, class II, major histocompatibility complex, transactivator; CLEC16A, C-type lectin domain family 16; CTLA4, cytotoxic T lymphocyte antigen 4; CYP27B1, 25-hydroxyvitamin D3-1-alpha hydroxylase; FCRL3, Fc receptor like 3; HLA, human leukocyte antigen; MHC, major histocompatibility complex; MICA5.1, major histocompatibility complex class I chain-related MIC-A polymorphisms in exon 5; NALP1, NACHT-LRR-PYD-containing protein 1; OR, odds ratio; PTPN22, protein tyrosine phosphatase, non-receptor type 22.

alleles, which are in strong linkage equilibrium with each other (MacLaren and Riley, 1986; Partanen et al., 1994; Falorni et al., 2008). The haplotype is associated with isolated disease components of APS-2, type 1 diabetes, Graves' disease, autoimmune hypothyroidism, and Addison's disease. Most of the studies have not elucidated which of these three alleles is the primary etiological genetic factor. Another haplotype, consisting of DRB1*04 (DR4) DQA1*0301 DQB1*0302 (DQ8), was also associated with type 1 diabetes and Addison's disease (Partanen et al., 1994). The increased risk of DR4 was attributed to DRB*0404 in Addison's disease, and not DR4*0401 in variance with type 1 diabetes (Gambelunghe et al., 2005; Erichsen et al., 2009; Falorni et al., 2008). Recently, these observations were extended revealing that the association was strongest for the DRB1 locus (Skiningsrud et al., 2010). Conditioning for DRB1 indicated independent effects of HLA-B and MICA5.1 (Falorni et al., 2008; Skiningsrud et al., 2010), a positive association to HLA-B8 (Baker et al., 2010) while HLA-B15 was not protective to the formation of P450c21 antibodies, but to the progression to overt disease (Baker et al., 2011). Conversely, the haplotypes DRB1*01 (DR1) DQA1*0101 DQB1*0501 (DQ5), DRB1*1301-DQB1*0603-DQA1*0103, DRB1*1302-DQB1*0604-DQA1*0102, and DRB1*07-DQB1*0201-DQA1*0201 were protective against Addison's disease (Erichsen et al., 2009). Alleles of other genes located in HLA region, such as TNF and P450c21, have been associated with APS-2 (Partanen et al., 1994; Peterson et al., 1995; Falorni et al., 2008) but these associations could be secondary to the strong linkage disequilibrium in the HLA region.

The cytotoxic T lymphocyte-associated protein 4 (*CTLA-4*) gene on chromosome 2q33 is associated with autoimmune endocrinopathies from different populations (Brozzetti et al., 2010b). In particular, the allelic variants of an A to G single nucleotide polymorphism at position 49 and microsatellite marker in the 3' untranslated region of the *CTLA-4* gene is associated with type 1 diabetes and thyroiditis in Italian, German, and British patients (Levin and Tomer, 2003). The *CTLA-4* association with Addison's disease and APS-2 with 3' untranslated region microsatellite was significantly increased among Italian and English patients and in a meta-analysis of European studies (Kemp et al., 1998; Brozzetti et al., 2010b). Recently, autoimmune disease susceptibility was mapped to a non-coding 6.1 kb 3' region of *CTLA-4* in autoimmune thyroid disease (Ueda et al., 2003), later reproduced in Addison's disease and APS-2 (Blomhoff et al., 2004). Even if the associated allelic variation was correlated with lower messenger RNA levels of the soluble alternative splice form of *CTLA-4* (Ueda et al., 2003), the mechanism by which

CTLA-4 confers susceptibility remains incompletely understood (Scalapino and Daikh, 2008).

Additionally, a number of other susceptibility genes have been characterized in Addison's disease and APS-2 (Table 43.2). The majority of these associations are to genes involved in immunity and inflammation, and none of the associations are specific for Addison's disease or APS-2. These include PTPN22 (Skiningsrud et al., 2008a; Roycroft et al., 2009), where both association to the 1858T allele and to rare variants were found; NALP1 that could be involved in inflammation (Magitta et al., 2009); the class II, major histocompatibility complex transactivator (CIITA) (Skiningsrud et al., 2008b Ghaderi et al., 2006), the programmed death ligand 1 (PD-L1) (Mitchell et al., 2009), and the lymphocyte cell surface molecule CD226. The genetic associations have recently been reviewed (Mitchell and Pearce, 2012).

An influence of *AIRE* gene polymorphisms in APS-2 or other major autoimmune diseases is possible. The *AIRE* gene was described as a susceptible locus for the predisposition to rheumatoid arthritis in the Japanese population (Terao et al., 2011), but neither *AIRE* mutations R257X and 967-979del13bp nor SNP analyses across the *AIRE* gene contributed to the susceptibility to type 1 diabetes, Graves' disease, autoimmune hepatitis, or Addison's disease (Nithiyananthan et al., 2000; Vaidya et al., 2000; Boe Meyer et al., 2001; Turunen et al., 2006; Wolff et al., 2008).

ENVIRONMENTAL FEATURES

The environmental factors involved in APS are less evident than genetic factors. A recent increase in the incidence of type 1 diabetes mellitus and other autoimmune endocrine diseases in most of the developed countries points to the novel environmental influences as the genetic background has largely remained unchanged. The role of environment has been best studied in patients with type 1 diabetes (see Chapter 41) in which analysis of twins shows that the genetic background cannot be the only reason for the disease (Hyttinen et al., 2003). National prosperity and good hygiene level seem to correlate in uncertain ways with type 1 diabetes (Patterson et al., 2001). The role of viral infections in polyendocrinopathies remains unclear. Recent studies on the interaction of the intestinal microbiome with the immune system provided interesting findings. One example is that segmented filamentous bacteria seems to induce the generation of Th17 cells involved in the early phases of the immune response and linked to autoimmunity (Ivanov et al., 2009). Thus, environmental factors could mediate their effect via the intestinal microbiome (see Chapter 23).

ANIMAL MODELS

AIRE-Deficient Mouse as a Model for APS-1

AIRE-deficient mice present the autoimmune features resembling the phenotype of APS-1 patients such as multi-organ lymphocytic infiltration and circulating autoantibodies (Anderson et al., 2002; Ramsey et al., 2002). Studies on Aire mouse have been critical in elucidation of APS-1 pathogenesis and thymic tolerance (for review see Mathis and Benoist, 2009). AIRE promotes the expression of self antigens in thymic medullary epithelial cells needed for efficient negative selection of autoreactive T cells (Liston et al., 2003; Anderson et al., 2005). AIRE is also involved in the presentation of self-proteins (Kuroda et al., 2005) as it enhances the capacity of mTECs to cross-present antigen to thymic dendritic cells (Koble and Kyewski, 2009; Hubert et al., 2011) and has been implicated in the differentiation of mTECs (Nishikawa et al., 2010; Wang et al., 2012) and migration of thymocytes (Laan et al., 2009). Although AIRE deficient mice have been central to understanding AIRE-function in thymic medullary epithelial cells, the mice are also at variance with APS-1 patients in several aspects. None of the AIRE-deficient mouse models displays any of the three main components of the APS-1, although autoimmunity towards liver, gastric mucosa, and ovaries is shared. Furthermore, they do not share autoantibody targets and the reduction of Tregs seen in humans (Kekalainen et al., 2007a).

Spontaneous Animal Models

Most studied spontaneous animal models for polyendocrine autoimmunity are bio-breeding (BB) rat and non-obese diabetes (NOD) mouse. The rodent models indicate that MHC genes are major genetic factors in disease development and that other non-MHC genes are also involved. BB rat and NOD mouse also have impaired regulation of immune responses including tolerance defects and abnormal function of regulatory T cells. The BB rat develops type 1 diabetes, which is clinically similar to the diabetes seen in humans. It has severe T cell lymphopenia which is strongly associated with diabetes development. The T cell lymphopenia is due to a single nucleotide deletion in the *Gimap5* gene (Hornum et al., 2002; MacMurray et al., 2002). The mononuclear infiltration into islets starts within first 3 weeks of age and the diabetes develops at 8–12 weeks. In addition to type 1 diabetes, BB rats frequently have lymphocytic infiltration in thyroid glands, for example in combination with distinct MHC alleles (Awata et al., 1995) or it can be potentiated by feeding rats with a high iodine diet (Allen et al., 1986). No evidence of lymphocytic infiltration to adrenal

gland has been observed, but autoantibodies to gastric parietal cells and smooth muscle have been reported (Crisa et al., 1992). Recently, significant interest in the studies of spontaneous canine models of autoimmunity has been triggered by the sequencing of the dog genome (Lindblad-Toh et al., 2005). A number of breeds such as the standard poodle and Portuguese water dog are susceptible to the development of Addison's disease (Klein and Peterson, 2010) and studies are under way to use these models as a way to find human susceptibility genes.

The NOD mouse is mostly studied as a model for type 1 diabetes (see Chapter 41). In addition to pancreatic beta cell destruction, NOD mice have, although to a lesser extent, autoimmunity to submandibular and lacrimal glands. The incidence of thyroiditis is low but similarly to the BB rat, high iodine in the diet has a triggering effect on development of thyroiditis (Many et al., 1996). Lymphocytic infiltration in the adrenal and parathyroid glands has been described in NOD mice (Beales et al., 2002). Insulinitis starts at an early age (4–5 weeks of age), reaching 70–90% by age of 9 weeks. Diabetes is more prevalent in females (80–90%) than in males (10–50%). The incidence of submandibular and lacrimal gland infiltration seems not to be secondary to insulinitis and is more prevalent in females. In addition, many transgenic, gene-targeted, and congenic variations of NOD mice have been developed with variable effects, for example CCR7 deficiency in NOD mice leads to severe inflammation in multiple tissues including thyroid, lung, stomach, intestine, uterus, and testis (Martin et al., 2009).

Thymectomy Animal Model

A well-studied mouse model for polyendocrinopathy is thymectomy at day 3 in the Balb/C strain, which leads to multi-organ autoimmunity characterized by gastritis, thyroiditis, oophoritis, and other infiltrations. The infiltrations are T cell predominant and the mice develop autoantibodies to affected tissues. Thymectomy-induced autoimmunity depends on time of thymectomy, i.e., between the 2nd and 5th day after birth (Bonomo et al., 1995). The lack of CD4⁺CD25⁺ regulatory T cells which migrate out of the thymus in the early neonatal period was proposed to cause autoimmunity, and injection of purified regulatory T cells into the thymectomized mice was used to prevent autoimmunity (Asano et al., 1996). However, in adult age the regulatory T cell numbers in thymectomized mice are restored and even become over-represented. More recent studies have shown that thymectomy causes lymphopenia in which development of autoimmune diabetes rather appears to be linked to effector and not to regulatory T cells (Gagnerault et al., 2009). Further implication of this model in endocrine

autoimmunity was demonstrated with NALP5 (MATER), an ovarian autoantigen in APS-1, which, when transgenically expressed in MHC class II cells in thymus and secondary lymphoid system, was sufficient to mediate a significant reduction in autoimmune oophoritis after thymectomy (Otsuka et al., 2011).

PATHOGENIC MECHANISMS

The endocrine glands in APS are gradually destroyed, resulting in atrophy, or parenchymal cells are replaced by fat cells (Perheentupa, 2002). Adrenalitis in APS patients appears to be diffuse, affecting all three layers of the cortex. As an indication of T cell-mediated autoimmunity, it mainly consists of lymphocytes but macrophages and plasma cells have also been detected (Carpenter et al., 1964; Muir et al., 1993). Treatment with immunosuppressive drugs, e.g., cyclosporin A, directed against T cells, produces temporary remission of the disease in APS-2 patients (Csaszar and Patakfalvi, 1992).

It has been difficult to characterize autoreactive T cells in APS patients, partly due to the lack of specific and sensitive methods, and to the fact that T cells in contrast to autoantibodies are sequestered in the specific tissue lesions and are thus difficult to access. Recently in several reports on analysis of autoreactive T cells targeting P450c21, Bratland and co-workers showed that CD4-positive T cells in patients with autoimmune Addison's disease proliferate when exposed to recombinant P450c21 (Bratland et al., 2009). Studies of various peptides of P450c21 revealed that the main reactivity was towards a peptide close to and overlapping with the substrate binding domain. Using a slightly different experimental approach, Rottembourg and co-workers identified C-terminal immunodominant peptides and a CD8-mediated immune response in autoimmune Addison's patients (Rottembourg et al., 2010). Autoantibodies have long been regarded as merely having a bystander role, yet they still could have an important role as amplifiers of the immune response towards the adrenal cortex. Increased serum levels of proinflammatory CXCL10 chemokine have been found in patients with isolated Addison's disease, APS-2 (Rotondi et al., 2005) and APS-1 (Kisand et al., 2008). The adrenocortical cell is likely to be an active participant in the autoimmune process as it can produce CXCL10 in response to interferon gamma (Rotondi et al., 2005; Rotondi et al., 2007) (for review see Bratland and Husebye, 2011).

Studies on peripheral blood subsets in APS-1 patients have had conflicting results. CD4⁺ T cell numbers and a proportion of memory or activated T cells have been reported to be increased or normal (Perniola et al., 2005; Tuovinen et al., 2009). Controversial results have been found on iNKT and monocyte cell numbers (Perniola

et al., 2008; Hong et al., 2009; Lindh et al., 2010). Reports on regulatory T cells have described lower numbers, impaired function, and decreased expression of FoxP3 (Kekalainen et al., 2007b). A recent study showed the accumulation of highly differentiated and oligoclonally activated effector-like CD8⁺ T cells with low expression of IL7R and lack of conventional naïve CD45RA CD8⁺ T cells (Laakso et al., 2011).

Autoimmunity in APS-1 has been postulated, based on studies in AIRE-deficient mice, to be a consequence of defective central tolerance to the autoantigens. The lack of AIRE expression in thymus may thus lead to a defect in clonal deletion of autoreactive T cells and ultimately to autoimmunity (Liston et al., 2003; Mathis and Benoist, 2009). However, direct data are lacking on clonal deletion in human APS-1 patients. The organs targeted in APS-1 patients are limited and the syndrome typically starts with chronic mucocutaneous candidiasis, followed by hypoparathyroidism and Addison's disease indicating above-mentioned phenotypic differences between human patients and AIRE mouse models. Whereas the candidiasis is associated with the early generation of anti-IL17 and IL-22 autoantibodies, the reason for the high prevalence of autoimmune hypoparathyroidism and Addison's disease remains unclear. The autoantibodies against type 1 IFN and Th17 cytokines in APS-1 have implications similar to those of thymoma patients where autoantibodies to type 1 IFN and other cytokines have also been found. An active autoimmunization process within the thymus tissue has been proposed to occur in both APS-1 and thymoma patients as both diseases are associated with thymus dysfunction (Meager et al., 2008; Kisand et al., 2011). According to this hypothesis the thymus in AIRE deficiency exports abnormal and already activated T cells capable of helping autoantibody production of B cells (Kisand and Peterson, 2011). The emerging idea of active autoimmunization in thymus, although needing validation, also points to the thymus as an important organ in protection against autoimmunity.

IMMUNOLOGIC MARKERS IN DIAGNOSIS

Autoantibodies are often diagnostic or even predictive markers for the clinical disease. The presence of high titer and persistent anti-IFN- α and IFN- ω autoantibodies in 100% of APS-1 patients provides an easier and more efficient way than AIRE mutation analysis to identify APS-1 patients. A similar test for anti-IL-17 or IL-22 autoantibodies in APS-1 could further confirm the diagnosis. These markers could be used for early detection of the disease pathogenesis as so far even samples collected before the age of 1 year appear seropositive for IFN- ω (Toth et al., 2010). In addition, autoantibodies to the steroidogenic enzymes (P450c21, P450c17, and P450scc) are significant

and specific markers for onset of Addison's disease. Antibodies against at least one of the three antigens are found in 84% of the patients with Addison's disease (Soderbergh et al., 2004; Brozzetti et al., 2010a). Furthermore, hypogonadism is well associated with the presence of autoantibodies to P450_{scc} protein. Autoantibodies to the IA-2 autoantigen, however, seem to have the strongest association with type 1 diabetes in APS-1 (Soderbergh et al., 2004). Autoantibody analyses in patients with APS-1 indicate serological markers for hepatitis (aromatic L-amino acid decarboxylase, cytochrome P450 1A2, or tryptophan hydroxylase), gastrointestinal dysfunction (tryptophan hydroxylase), and vitiligo (Hedstrand et al., 2001).

The vast majority (up to 80–90%) of patients with APS-2 have autoantibodies to P450_{c21} (Erichsen et al., 2009; Falorni et al., 2011). The titers of autoantibodies decrease to some extent as the disease progresses, and therefore the diagnostic value of the autoantibodies is highest at onset. The presence of anti-P450_{c21} antibodies in patients with autoimmune thyroid disease or type 1 diabetes, but without Addison's disease (Barker et al., 2005), would indicate risk for later development of overt Addison's disease, although the progression to overt Addison's disease may take years. Among relatives with organ-specific autoimmunity, individuals with normal adrenal function and P450_{c21} autoantibodies, about 15%, progressed to adrenal failure within 5 years (Coco et al., 2006).

TREATMENT AND OUTCOME

In patients with APS-1, anti-candidal drugs such as amphotericin B, ketoconazole, or fluconazole are used in the treatment of the candidiasis. Itraconazole has been reported to be effective for nail candidiasis; however, 4 to 6 months treatment is needed to eliminate the infection (Rautemaa et al., 2007, 2008a,b). Clinical follow-up of oral candidal infection is needed at least once or twice per year and, because of risk of cancer, attention should be paid to suppression of the oral infection; smokers are at particular risk. Replacement therapy with hormones has been efficiently used for Addison's disease and hypoparathyroidism. Patients with Addison's disease are treated with hydrocortisone at the smallest dose that relieves symptoms, usually 10 + 5 + 5 mg a day (the corresponding dose of cortisone acetate is 12.5 + 6.25 + 6.25 mg). Fludrocortisone is used to replace aldosterone. The therapy of hypoparathyroidism is aimed at maintaining normal calcium levels, and serum calcium and phosphate levels should be monitored regularly. Therapies are calciferol sterols (vitamin D hydroxylated forms, calcidiol, or calcitriol) and calcium salt preparations, preferably calcium carbonate, but

these, however, do not efficiently substitute for parathyroid hormone and are difficult to regulate. As the calcium levels may vary significantly over a short time, there are significant risks for both hypo- and hypercalcemia. Recently available recombinant parathyroid hormone may improve the treatment of the hypoparathyroidism in APS-1 patients, but is still experimental (Winer et al., 2012). The patients should receive advice and written information about the symptoms, complications, and risk elements of the disease. APS-1 may cause great psychosocial burden as the persistent risk of developing new disease components can be a source of continuous distress (Perheentupa, 2006).

CONCLUDING REMARKS—FUTURE PROSPECTS

Recent years have provided remarkable progress in our knowledge about the mechanisms of autoimmune polyendocrinopathies including a clear pathogenetic distinction between APS-1 and APS-2. The autoimmune reaction destroys with high precision the endocrine organs, which often express tissue-specific proteins. The identification of the autoantibody targets in APS has revealed that the autoantigens often belong to related protein families, raising the question of exactly how the immune system selects specific targets for autoimmune reactivity. Clinically, assay of autoantibodies can be used for diagnostic purposes. Presence of antibodies against IFN- ω and IFN- α is almost diagnostic for APS-1 if myasthenia gravis and thymoma have been ruled out. The pattern of autoantibodies is an early phenomenon, which correlates with organ manifestations and could therefore predict future disease, for instance oophoritis.

Much current research effort is put into the identification of genes involved in APS-2. Clearly, MHC genes have the dominant role, but whether an Addison-specific gene association exists is not yet clear. Environmental factors in APS-2 certainly remain to be clarified and deserve more attention. Although it is a monogenic disease, APS-1 also seems to be influenced by environmental, stochastic, and/or other genetic factors to account for the variety of clinical symptoms and disease expressions. The possibility that heterozygous deficiency of *AIRE* in combination with other genetic defects might contribute to the occurrence of autoimmunity is worthy of further investigation.

ACKNOWLEDGMENTS

The authors are grateful to Dr. Kai Kisand, Prof. Kai Krohn, and Prof. Annamari Ranki for fruitful discussions.

Pernicious anemia is the result of advanced autoimmune gastritis, which in its initial stages is an asymptomatic autoimmune disease. First reported by Addison in 1849, the link between the anemia and gastric degeneration was realized by Flint in 1860 and histologic evidence of the gastric atrophy was provided by Fenwick in 1870. In 1871, a fatal anemia was termed *perniciosa* by Biermer. Subacute combined degeneration was later applied to the posterolateral spinal cord lesions that can be associated with the anemia (Pearce, 2008). In 1926 Minot and Murphy discovered that feeding patients large meals of cooked liver led to a reticulocyte response and reversal of anemia, which earned them a Nobel Prize in 1934. At first, the causal connection between pernicious anemia and chronic gastritis was incomprehensible. Castle (Castle, 1953) showed that the anemia was a result of a combined deficiency of an “extrinsic factor” subsequently identified as vitamin B12 and present in the liver (Smith, 1948; Rickes et al., 1948), and an “intrinsic factor” (IF) in gastric juice (Highley et al., 1967). Oral treatment with extracts of hog stomach (Sharp, 1929; Sturgis and Isaacs, 1929; Renshaw, 1930) resulted in remission for several years (Wilkinson, 1949). However, relapses tended to occur and some cases became refractory to increasing amounts of the extract (Berlin et al., 1958a, b). This refractory state was due to a serum factor that

inhibited the effectiveness of intrinsic factor (Schwartz, 1958). Subsequently, sera from patients with pernicious anemia were shown to contain autoantibodies to intrinsic factor (Jeffries et al., 1962; Jacob and Schilling, 1966) and to gastric parietal cells (Irvine et al., 1962; Jeffries et al., 1962; Markson and Moore, 1962). However, little progress was made in understanding the pathology of the gastric lesion until a flexible biopsy tube was designed that permitted the taking of samples of the gastric mucosa for histologic examination (Wood et al., 1949).

Pernicious anemia was observed to cluster in families (McIntyre et al., 1959; Whittingham et al., 1969) and to coexist with autoimmune thyroid diseases (Tudhope and Wilson, 1960). These observations suggested a genetic component to the disorder, a suggestion further strengthened by an association with another endocrine autoimmune disease, type 1 diabetes mellitus (Ungar et al., 1968). The suggestion by Taylor (Taylor, 1959; Taylor and Morton, 1959) that the inhibitory substance to gastric intrinsic factor in the serum of patients with pernicious anemia was antibody and possibly autoantibody and the recognition that pernicious anemia fulfilled the markers of autoimmune disease put forward by Mackay and Burnet (Mackay and Burnet, 1963) led to its acceptance as an autoimmune disease of the stomach.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Autoimmune gastritis in the early stages is asymptomatic and demonstrable only by serologic detection of antibodies to gastric parietal cells. Pernicious anemia only manifests when stores of vitamin B12 are depleted and only 10–15% of patients with autoimmune gastritis develop pernicious anemia (Strickland and Mackay, 1973; Irvine et al., 1974) after a latent period of 20–30 years (Toh et al., 1997). Nonetheless, at an estimated prevalence of about 2% in Western adult populations at or over the age of 60 years, pernicious anemia represents the commonest cause of vitamin B12 deficiency (Carmel, 1996). Although “silent” until the end stage, the gastric lesion can be predicted years before clinical presentation by immunologic markers specific for gastric autoimmunity. Terminally, the gastritis results in deficiency of intrinsic factor, a protein that binds avidly to dietary vitamin B12 (Glass, 1963) and promotes its transport to the terminal ileum for absorption (Donaldson et al., 1967) by ileal cubulin receptors, a multifunctional endocytic receptor (Lindblom et al., 1999). Consequently, the gastritis is expressed clinically as vitamin B12 deficiency associated with megaloblastic anemia arising as a consequence of the requirement of the vitamin for DNA synthesis. The megaloblastic anemia is demonstrated by examination of blood and bone marrow (Chanarin, 1979) and is now readily controlled by vitamin B12 treatment (Carmel, 2008). Pernicious anemia usually results in low serum pepsinogen I levels and a low serum pepsinogen I/II ratio and increased serum gastrin levels which also can be diagnostically useful (Varis et al., 1979; Samloff et al., 1982; Carmel, 1988).

Pernicious anemia is uncommon before the age of 30. Reportedly more common in individuals of northern European descent, the disease has been reported in blacks and in Latin Americans (Carmel and Johnson, 1978). Patients with advanced pernicious anemia are usually

women of late middle age, who appear pale, tired, and depressed and may complain of a sore tongue and abdominal discomfort. Vitamin B12 deficiency can lead to neuropsychiatric syndromes such as sensory impairment, abnormal reflexes, motor impairment and spastic paraparesis, and possibly mental or psychiatric disturbances (Savage and Lindenbaum, 1995). Patients with pernicious anemia have also been reported to have a 3–5-fold higher risk of developing gastric cancer and a 13-fold increased risk of developing gastric carcinoids (Hsing et al., 1993; Fuchs and Mayer, 1995; Kokkola et al., 1998).

Strickland and Mackay (Strickland and Mackay, 1973) proposed a classification of gastritis based on histologic findings of the gastric mucosa, the presence of gastric parietal cell antibody, and serum levels of gastrin. Type A gastritis, the “pernicious anemia type,” is restricted to the fundus and body of the stomach. Early lesions are characterized by chronic inflammation in the submucosa that extends into the lamina propria of the mucosa between gastric glands with accompanying loss of gastric and zymogenic cells (Figure 44.1). In advanced disease, gastric atrophy is readily recognized macroscopically and microscopically (Figures 44.2 and 44.3). The wall of the fundus and body of the stomach becomes paper thin because the gastric glands are markedly reduced or absent. In particular, parietal cells and zymogenic (chief) cells are absent from the gastric mucosa and replaced by mucus-containing cells resembling those of the intestine (intestinal metaplasia) (Figure 44.3).

Type A gastritis is characterized by circulating antibodies to gastric parietal cells (Figure 44.4) that have subsequently been shown to be directed to the gastric H^+/K^+ ATPase (Burman et al., 1989; Goldkorn et al., 1989; Toh et al., 1990, 1997), achlorhydria, and high levels of serum gastrin secreted by the intact antral glands. Strickland and Mackay observed that five out of 30 patients with type A gastritis (16%) developed overt or latent pernicious anemia during a follow-up period of 3–24 years. Type A gastritis is also the gastritis characteristic of families in

FIGURE 44.1 The early lesion of autoimmune gastritis. (A) The normal mucosa of the body of the stomach showing gastric glands and the absence of a chronic inflammatory infiltrate in the lamina propria. (B) An early lesion of autoimmune gastritis showing a dense chronic inflammatory infiltrate in the gastric submucosa that extends into the lamina propria with the accompanying loss of gastric parietal and zymogenic cells. $\times 300$.

FIGURE 44.2 Macroscopic appearance of advanced autoimmune gastritis in a patient with pernicious anemia showing the extreme atrophy of the mucosa of the fundus and body of the stomach with loss of rugal folds contrasted with the healthy mucosa of the gastric antrum. Inset is the microscopic appearance of the mucosa.

FIGURE 44.3 Microscopic appearance of the gastric mucosa of advanced autoimmune gastritis showing a chronic inflammatory infiltrate in the gastric mucosa and the loss of parietal and zymogenic cells and replacement with mucus-containing cells.

FIGURE 44.4 Indirect immunofluorescent staining of gastric parietal cells in a mouse stomach reactive with serum from a patient with autoimmune gastritis.

whom pernicious anemia predominates (Varis, 1981; Kekki et al., 1983).

Type B gastritis, the nonpernicious anemia type, involves the antrum initially but can extend to the fundus and body of the stomach and shows incomplete failure of acid secretion and low levels of serum gastrin because of the antral gastritis. Type B gastritis is usually associated with *Helicobacter pylori* infection; type A is not (Fong et al., 1991).

Pernicious anemia in patients with the common variable type of immunodeficiency associated with low levels of serum immunoglobulins can be distinguished from classic pernicious anemia on this classification. This former type of pernicious anemia usually occurs in a younger age group, is histologically type B, is associated with a negative test for antibodies to gastric parietal cells and intrinsic factor, and shows a low level of serum gastrin (Twomey et al., 1969; Hughes et al., 1972; Cowling et al., 1974). Pernicious anemia in childhood is not associated with gastritis or achlorhydria and is the result of inadequate intrinsic factor production.

The evolution of gastric atrophy in most cases of pernicious anemia probably spans 20–30 years but this is difficult to assess in individual cases. The presence of gastric parietal cell antibody in the serum is predictive of autoimmune gastritis (Irvine et al., 1965; Serafini et al., 1970). Conversely, gastric parietal cell antibody is not observed when gastritis is due to diseases affecting the body of the stomach that are not autoimmune.

There are many reports of regeneration of gastric parietal cells, improvement in gastric function, and hematologic remission after treatment with corticosteroids (Doig et al., 1957; Gordin 1959; Ardeman and Chanarin, 1965; Jeffries et al., 1966; Rodbro et al., 1967; Strickland, 1969) or azathioprine (Jorge and Sanchez, 1973). This suggests that the gastric mucosa is the direct target of an autoimmune process that can be checked by immunosuppressive drugs. The observations also suggest that precursor stem cells capable of differentiating into parietal cells and zymogenic cells are present in stomachs of patients with autoimmune gastritis and that these are responsible for the regeneration of the differentiated cells when the destructive autoimmune process is controlled. The suggestion is supported by observations in experimental models of autoimmune gastritis where there is evidence of the persistence, and even expansion, of these precursor stem cells in gastric stomachs (see below). It is also of interest and relevance that reversal of recovery with degeneration of the gastric mucosa recurred once immunosuppressive treatment was halted (Wall et al., 1968). This highlights the persistence of autoreactive T cells that cause this disease, even in the face of immunosuppression.

Pernicious anemia associates predominantly with the autoimmune endocrinopathies and the antireceptor

autoimmune diseases. The associated diseases include Hashimoto's thyroiditis, insulin-dependent type 1 diabetes mellitus, primary Addison's disease, primary ovarian failure, primary hypoparathyroidism, premature graying of the hair, vitiligo, thyrotoxicosis, myasthenia gravis, and the Lambert–Eaton syndrome. These organ-specific “thyrogastric” autoimmune diseases may occur in the same patient with pernicious anemia but aggregate in “pernicious anemia families” (Ardeman et al., 1966; Wangel et al., 1968a; Whittingham et al., 1969).

AUTOIMMUNE FEATURES

Autoantibodies

Autoimmune gastritis is associated with autoantibodies to gastric parietal cells and to their secreted product, intrinsic factor. Like most autoantibodies, these autoantibodies are polyclonal but are predominantly of the IgG isotype (Serafini et al., 1970). IgA antibodies to gastric intrinsic factor have been demonstrated in gastric juice (Goldberg and Bluestone, 1970). Autoantibodies to gastric parietal cells are routinely detected by immunofluorescence (see Figure 44.4). These autoantibodies are directed toward both the catalytic 100 kDa α subunit and the 60–90 kDa glycoprotein β -subunit of the gastric H^+/K^+ ATPase (Figure 44.5) (Karlsson et al., 1988; Burman et al., 1989; Toh et al., 1990; Callaghan et al., 1993; Ma et al., 1994). The gastric H^+/K^+ ATPase is the enzyme responsible for acidification of gastric luminal contents (Forte et al., 1989; Rabon and Reuben, 1990; Prinz et al., 1992). It belongs to a family of ion-motive P-type ATPases and is most closely related to the ubiquitous Na^+/K^+ ATPase. The gastric H^+/K^+ ATPase is located on specialized secretory membranes of gastric parietal cells (DiBona et al., 1979; Callaghan et al., 1990; Toh et al., 1990; Pettitt et al., 1995). Parietal cell antibodies have been shown to deplete H^+/K^+ ATPase activity from parietal cell membranes *in vitro* (Burman et al., 1989). Antibody reactivity with the α subunit of the H^+/K^+ ATPase includes an epitope on the cytosolic side of the secretory membrane (Song et al., 1994). The H^+/K^+ ATPase β subunit extracellular domain has three disulfide bonds and is highly glycosylated and these structural features are required for binding of autoantibodies (Goldkorn et al., 1989; Callaghan et al., 1993).

Human intrinsic factor is a glycoprotein with a molecular mass of 44,000. Each molecule of intrinsic factor has the capacity to bind to one molecule of vitamin B12 (Chanarin, 1979). Two distinct antibody activities are detected by radioimmunoassay; one reacts with the

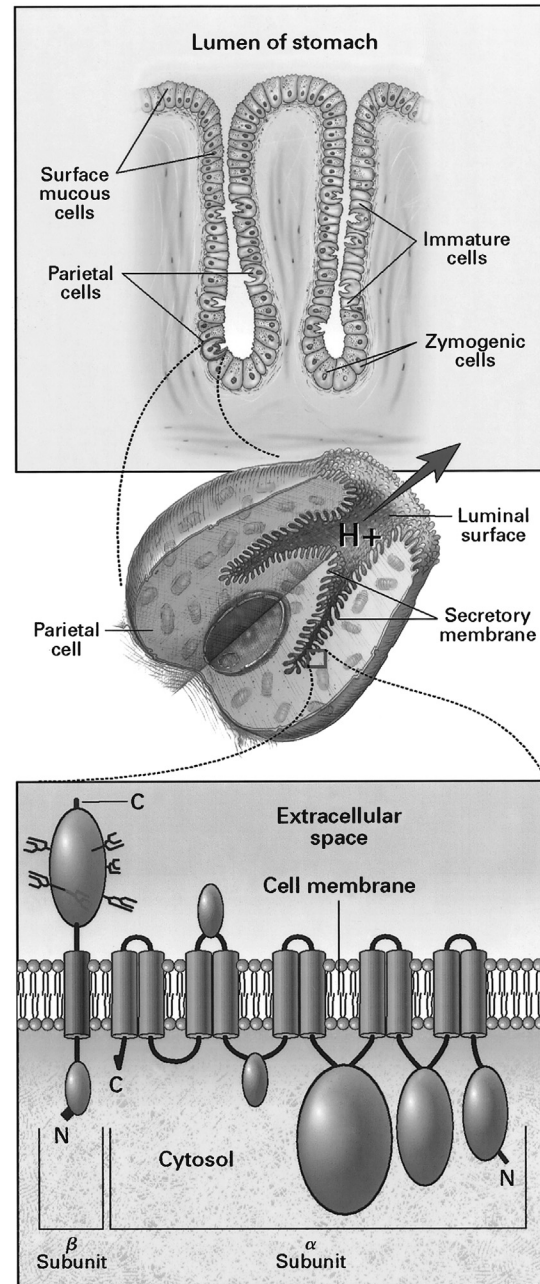

FIGURE 44.5 Gastric parietal cell H^+/K^+ ATPase as the target in autoimmune gastritis associated with pernicious anemia. Top panel represents a gastric gland showing location of parietal cells in relation to zymogenic cells, immature cells, and surface mucus cells. Middle panel represents a stimulated gastric parietal cell showing the lining membrane of the secretory canaliculus on which gastric H^+/K^+ ATPase is located. Bottom panel represents the catalytic α and the glycoprotein β subunits of the gastric H^+/K^+ ATPase showing their orientation in the membrane of the secretory canaliculus of the parietal cells. N denotes the N-terminal of protein and C the C-terminal of protein. Reproduced with kind permission of the *New England Journal of Medicine*.

binding site for vitamin B12 and blocks subsequent binding of intrinsic factor with free vitamin, and the other reacts with an antigenic determinant remote from this site (Samloff et al., 1968; Rothenberg et al., 1971).

T Cell Immunity

Studies of animal models suggest that CD4⁺ T cells mediate the gastric lesion (see below). In humans, a significant increase in CD4⁺ and CD8⁺ T cells and a six-fold increase in non-T cells (probably B cells) have been observed in the cellular infiltrate of stomachs of patients with pernicious anemia (Irvine et al., 1965; Kaye et al., 1983). Electron microscopy has shown that lymphocytes line up against the membranes of gastric parietal cells and zymogenic cells in the gastric mucosa. Phenotypic analysis of the peripheral blood T cells from patients with pernicious anemia have not shown any significant differences compared to age-matched controls (Vargas et al., 1995) although, in humans, no studies have been made on the gastric lymph nodes which are the sites appropriate for such studies.

A number of early studies suggested a T cell response to intrinsic factor and gastric extracts (Fisher et al., 1965, 1966; Tai and McGuigan, 1969; Rose et al., 1970; Fixa et al., 1972; Goldstone et al., 1973; MacCuish et al., 1974; Whittingham et al., 1975). However, the identification of the gastric H⁺/K⁺ ATPase as the major gastric autoantigen that was targeted by antibodies in humans and mice and T cells in mice led to the isolation of human H⁺/K⁺ ATPase-specific CD4⁺ T cell clones from the gastric mucosa of patients with autoimmune gastritis. The clones were shown to recognize a number of epitopes in the H⁺/K⁺ ATPase α and β subunits (Bergman et al., 2003) and were biased towards the production of IFN- γ and TNF- α although some also produced IL-4 and stimulated immunoglobulin production by B cells (D'elios et al., 2001). Most clones also displayed cytotoxic activity that was either perforin or Fas dependent.

Studies in mice have shown that a T cell immune response to the gastric H⁺/K⁺ ATPase is essential for the initiation and development of autoimmune gastritis. These observations include the resistance to autoimmune gastritis in mice expressing the H⁺/K⁺ ATPase β subunit in the thymus and mice deficient in the gastric H⁺/K⁺ ATPase, a high incidence of disease in mice with repertoires enriched in H⁺/K⁺ ATPase reactive T cells, and mice immunized with purified H⁺/K⁺ ATPase. Initial findings suggested that the H⁺/K⁺ ATPase β subunit may be the primary initiating autoantigen (Alderuccio et al., 1993). However, subsequent studies indicated that both subunits are targeted in disease and that the expression of the H⁺/K⁺ ATPase β subunit is required for presentation

of the α subunit to CD4⁺ T cells, which explained earlier findings on antigenic hierarchy (Allen et al., 2005).

The pathways that lead to immunological tolerance to the gastric H⁺/K⁺ ATPase have been extensively investigated. High avidity H⁺/K⁺ ATPase-specific T cells exit the thymus and the H⁺/K⁺ ATPase-specific T cells in the periphery represent the residue of a T cell repertoire that has been subjected to partial extrathymic deletion (Read et al., 2007). This depletion occurs following antigen-specific activation of H⁺/K⁺ ATPase-specific CD4⁺ T cells in the stomach-draining paragastric lymph node. Additional mechanisms of peripheral tolerance, mediated by dendritic cells and Foxp3⁺ regulatory T cells (Treg cells), play important roles in influencing the activation of self-reactive T cells that remain after clonal deletion (Scheinecker et al., 2002; Zwar et al., 2006; Dipaolo et al., 2007; Read et al., 2007; Hogan et al., 2008; Stummvoll et al., 2008). Therefore, protection from gastritis is mediated almost exclusively by tolerogenic mechanisms in the local tissue environment.

GENETIC FEATURES

Predisposition to pernicious anemia appears to be genetically determined, at least in part. Evidence for genetic factors influencing the expression of pernicious anemia includes clustering of this disease in families and with other autoimmune diseases as well as a racial predilection for northern Europeans. Pernicious anemia is rare among southern Europeans and earlier reports suggest that it is almost nonexistent among black and Asian people (Jayaratnam et al., 1967; Irvine et al., 1969). In keeping with ethnic differences, pernicious anemia is associated with phenotypic markers that are absent or occur with low frequency in these racial groups. These markers include blue eyes, fair skin, and blood group A (Callender et al., 1957). However, a more recent study by Carmel (1992) reported a higher prevalence in black people, particularly among black women.

There have been reports of a number of Caucasian families with a high frequency of pernicious anemia over several generations (Callender et al., 1957; Callender and Denborough, 1957; McIntyre et al., 1959; Doniach et al., 1965; Ardeman et al., 1966; Wangel et al., 1968a,b; Whittingham et al., 1969). A higher but not absolute concordance of pernicious anemia has been observed in monozygotic twins (Delva et al., 1965; Balcerzak et al., 1968). While associations with susceptibility to pernicious anemia and HLA molecules have been reported (Ungar et al., 1977), such findings were not substantiated in other studies (Whittingham et al., 1991).

Studies in mice have also substantiated the role of specific genes in predisposing to autoimmune gastritis. BALB/c mouse strains are highly susceptible to

autoimmune gastritis whereas C57BL/6 mice are very resistant (Kojima and Prehn, 1981; Silveira et al., 1999). To identify genes conferring susceptibility to the disease, linkage analysis was performed on (BALB/cCrSlc x C57BL/6)F2 mice. Two major genes on chromosome 4 that confer susceptibility to autoimmune gastritis, termed *Gasa1* and *Gasa2*, were identified (Silveira et al., 1999). Further analysis found *Gasa3* on chromosome 6, coincident with the MHC locus, and *Gasa4* on chromosome 17 as minor gastritis susceptibility genes (Silveira et al., 2001). Experimental evidence for the *Gasa1* and *Gasa2* loci was obtained using congenic mouse strains that also proved that *Gasa1* and *Gasa2* can act independently to cause full expression of susceptibility to autoimmune disease (Ang et al., 2007).

IN VIVO AND IN VITRO MODELS

Mice can readily develop high incidence of autoimmune gastritis, either spontaneously or after manipulation. Mouse models have proven to be a very reliable and robust model of autoimmune gastritis that shares key features with human disease including antigen and epitope commonality, cytokine secretion, and pathogenic mechanisms. As a result mouse autoimmune gastritis has been used extensively to investigate basic mechanisms of immune tolerance and the cellular and molecular basis for autoimmune disease.

Spontaneous gastritis has been reported in C3H/He mice with an incidence of about 20% (Alderuccio and Toh, 1998). A variety of organ-specific autoimmune diseases can be induced by lymphopenic conditions and the particular organ affected is determined by the genetic background of the mouse strain. BALB/c mice are the most susceptible mouse strain to lymphopenia-induced autoimmune gastritis whereas C57BL/6 mice are resistant to the induction of disease (Ahmed and Penhale, 1981; Kojima and Prehn, 1981). Thymectomy-induced autoimmune gastritis is historically one of the most commonly used gastritis models. BALB/c mice thymectomized at approximately day 3 after birth develop autoimmune gastritis at ~30–90%. Adult mice did not develop autoimmune gastritis followed by thymectomy unless the mice were treated with cyclophosphamide or irradiation (Ahmed and Penhale, 1981; Barrett et al., 1995). It was previously believed that induction of autoimmune gastritis by neonatal thymectomy was the result of a block in Treg cells being seeded into the periphery from the thymus; thus gastritogenic T cells were not suppressed (Asano et al., 1996). However, this proposal was not supported by findings that Treg cells are able to repopulate in the periphery after neonatal thymectomy and these Treg cells are fully suppressive *in vivo* (Asano et al., 1996; Dujardin et al., 2004; Ang et al., 2007; Samy et al., 2008).

Comparatively recently, it has been demonstrated that neonatal thymectomy results in a lymphopenic environment that promotes homeostatic proliferation of effector T cells, including expansion of gastritogenic T cell clones (Monteiro et al., 2008). Therefore, autoimmune gastritis induced by neonatal thymectomy is probably the result of a reduced Treg:effector T cell ratio that does not favor suppression by Treg cell, rather than the depletion of Treg cells *per se* or intrinsic defects of Treg cells.

Murine autoimmune gastritis can also be induced by immunization of adult BALB/c mice with purified gastric H⁺/K⁺ ATPase in complete Freund's adjuvant (Scarff et al., 1997). However, the disease induced is transient and is reversible after cessation of immunization, perhaps due to regeneration of parietal cells and zymogenic cells from the expanded stem cell population.

Autoimmune gastritis may occur as the result of the immune system being dominated by self-reactive T cells. T cell receptor (TCR) transgenic mouse lines that constitutively express H⁺/K⁺ ATPase-specific TCR on their T cells have been generated. A23 TCR transgenic mice contain CD4⁺ T cells that target residues 630–641 of the H⁺/K⁺ ATPase α subunit and display a Th1 phenotype (McHugh et al., 2001), whereas A51 TCR transgenic mice contain CD4⁺ T cells that target residues 889–899 of the H⁺/K⁺ ATPase α subunit and reveal a Th2 phenotype (Candon et al., 2004). Both A23 and A51 T cell clones were isolated from the paragastric lymph node of mice that developed autoimmune gastritis following neonatal thymectomy (Suri-Payer et al., 1999). A23 mice develop more severe autoimmune gastritis spontaneously with higher penetrance than in A51 mice due to difference in the availability of their respective autoantigenic epitopes (Levin et al., 2008). IE4 TCR transgenic mice were created using TCR genes isolated from a T cell hybridoma which was derived by immunization of a BALB/c mouse with residues 253–277 of the H⁺/K⁺ ATPase β subunit (Alderuccio et al., 2000; De Silva et al., 2001). Autoimmune gastritis only occurred in 20% of the mice, even though transgenic T cells in the periphery responded well to the antigenic peptide *in vitro*.

Constitutive expression of the cytokine granulocyte macrophage colony stimulating factor in the stomach induces autoimmune gastritis with very similar antigenic and pathological features to those of other models (Biondo et al., 2001). It is not clear which of the proinflammatory activities of granulocyte macrophage colony stimulating factor are responsible for disease initiation.

T cells from mice deficient in gastric H⁺/K⁺ ATPase autoantigens can induce autoimmune gastritis in sublethally irradiated mice, presumably due to the preponderance of H⁺/K⁺ ATPase-specific T cells that result from a lack of autoantigen-specific tolerance (Tu et al., 2011). This recent model is attractive for the study of many

aspects of organ-specific autoimmunity because of a high degree of consistency of disease severity, the use of polyclonal T cells, and a specific T cell response to a bone fide autoantigen (Figure 44.6). The cardinal features of mouse autoimmune gastritis are illustrated in this disease. The gastric mucosa becomes heavily infiltrated by mononuclear cells, parietal and zymogenic cells

are severely depleted, and there is overgrowth by immature cell types resulting in gastric hypertrophy visible at both microscopic and macroscopic levels (Figure 44.6A–D). The depletion of parietal cells leads to an increase in gastric pH (Figure 44.6E). High titer anti- H^+/K^+ ATPase autoantibodies develop within 4–6 weeks (Figure 44.6F, G).

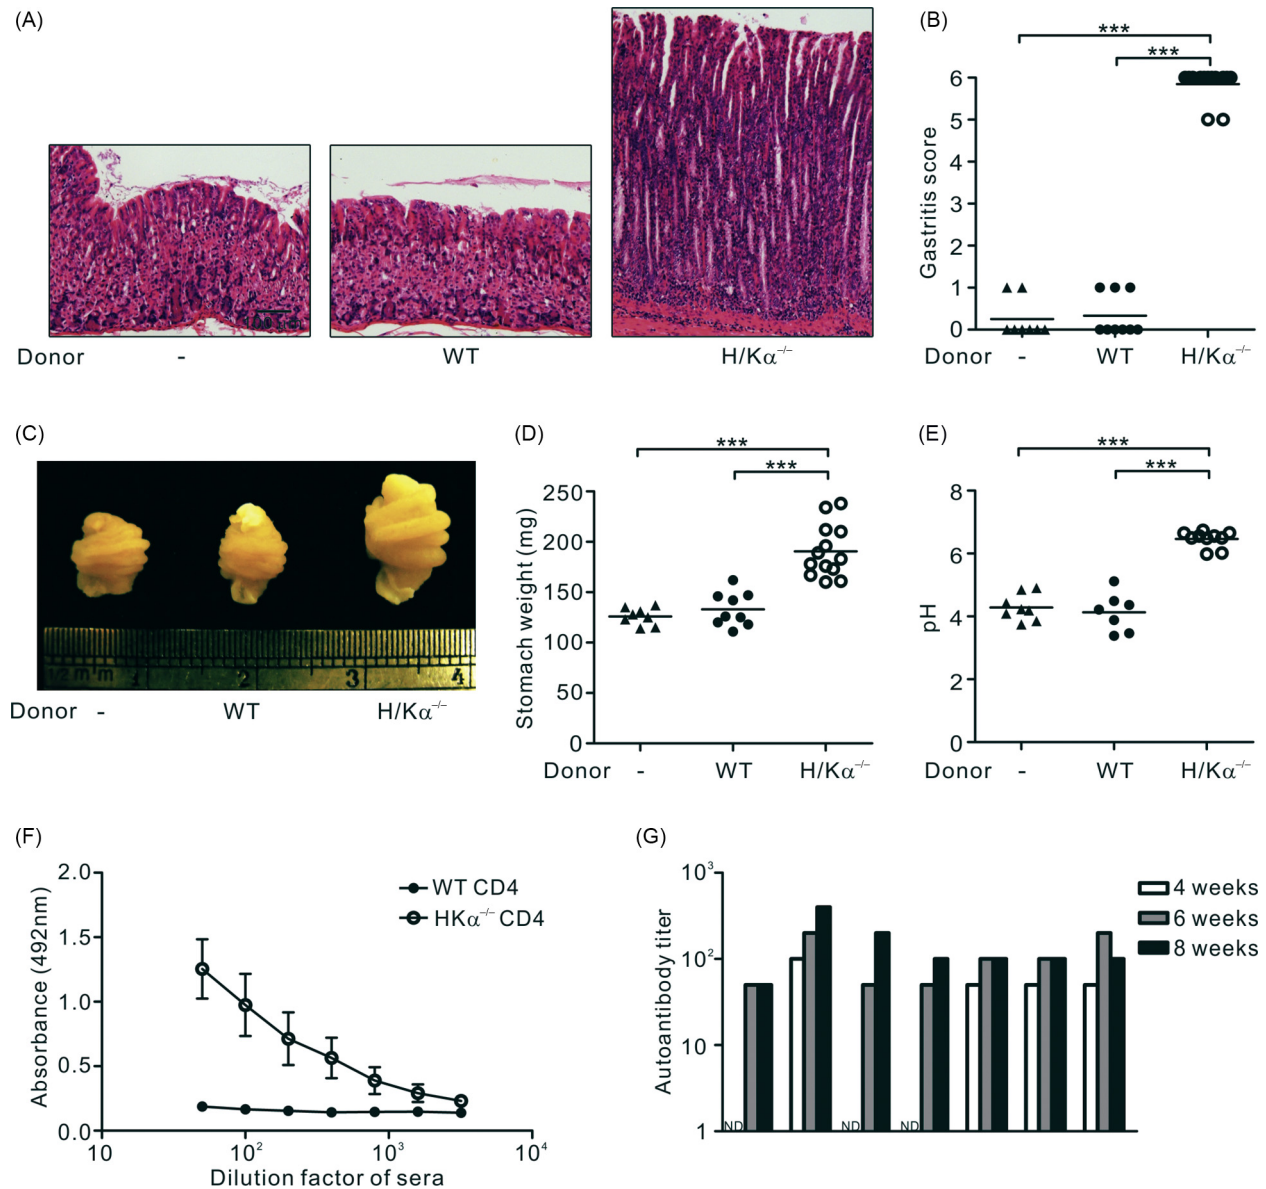

FIGURE 44.6 A mouse model of autoimmune gastritis. Irradiated wild-type mice that received 5×10^7 CD4⁺ T cells from either wild-type (WT) or H^+/K^+ ATPase α subunit-deficient mice ($H/K\alpha^{-/-}$), were killed 8 weeks after transfer and compared to non-manipulated mice (-). (A) Hematoxylin and eosin stained sections of stomachs. (B) Gastritis scores. (C) Macroscopic views of stomachs. (D) Stomach weights after stomach contents were removed. (E) Gastric pH. Mice were starved overnight and their stomachs were rinsed in 1 ml saline which was then collected and measured by a pH meter. (F) H^+/K^+ ATPase-specific autoantibodies in serum were detected by ELISA using serial two-fold dilutions of mouse sera, with a starting dilution factor of 50. (G) Gastric H^+/K^+ ATPase autoantibody levels in mice at various times after cell transfer. Serum samples were collected at the indicated time points from each mouse after transfer of CD4⁺ T cells from $H/K\alpha^{-/-}$ mice. Autoantibody titer was represented by the maximum dilution factor that had an absorbance reading above 50% maximum. ND = not detectable. Data pooled from four independent experiments. In (B), (D), and (E), each circle represents the data from one mouse. Mann–Whitney U test was used; bars, median and ***, $P < 0.001$.

PATHOLOGIC EFFECTOR MECHANISMS

Studies in mice have clearly indicated that autoimmune gastritis is initiated by CD4⁺ T cells. First, gastritis can be transferred to immunocompromised hosts by CD4⁺ T lymphocytes but not by sera from animals with autoimmune gastritis (reviewed by van Driel et al., 1984, 2005; Gleeson et al., 1996; Toh et al., 1997; van Driel and Ang, 2008). In addition, histopathologic features of gastritis occur in mice before the appearance of autoantibodies. The early gastric lesion is composed predominantly of CD4⁺ T cells and macrophages with production of a mix of Th1- and Th2-type cytokines but not interleukin-4, suggesting a key role for these cells and their cytokines in initiation of the disease (Martinelli et al., 1996; Katakai et al., 1998). Interferon- γ , probably produced by the Th1 cells, appears to be crucial for the induction of gastric lesion, as a single injection of antibodies to interferon- γ immediately following neonatal thymectomy prevents autoimmune gastritis (Barrett et al., 1996) and T cells from mice deficient in interferon- γ or interleukin-12 have a reduced pathogenicity in causing autoimmune gastritis (Suri-Payer and Cantor, 2001). CD8⁺ T cells do not seem to have a role in this disease since depletion of this T cell population by treatment with anti-CD8 antibody did not reduce the capacity of the remaining T cells to transfer disease (De Silva et al., 1998). Recent data suggest that interleukin-17 may play a role in assisting the development of severe late-stage autoimmune gastritis (Tu et al., 2012). B lymphocytes tend to accumulate in gastric lesions and aggregate in follicular-like structures and it is not known if they play a functional role at these sites (Martinelli et al., 1996).

There is evidence for various mechanisms whereby T cells could cause the lesion in the gastric mucosa including direct cytotoxicity and cytokine mediated disruption of developmental pathways in the stomach (Judd et al., 1999; Marshall et al., 2002; Kang et al., 2005).

As described above, CD4⁺ T cell clones specific for the gastric H⁺/K⁺ ATPase and with activities that support a pathogenic role have also been isolated from patients with pernicious anemia (D'elios et al., 2001).

AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

Autoimmune gastritis and pernicious anemia are typically associated with autoantibodies to parietal cells, directed to gastric H⁺/K⁺ ATPase and to intrinsic factor. For the diagnosis of pernicious anemia, intrinsic factor antibodies have a much higher disease specificity (>95%), albeit lower sensitivity (50–70%), than antibodies to gastric parietal cells. A recent study suggests that assaying autoantibodies to both intrinsic factor and the H⁺/K⁺

ATPase results in an increased specificity and sensitivity and would aid in selection of patients for follow-up gastroscopic procedures (Lahner et al., 2009). Since the Schilling test is no longer available as a diagnostic procedure, there has been increased dependence on intrinsic factor antibodies for diagnosis. Antibodies to the vitamin B12 binding site of intrinsic factor are demonstrable in serum of ~70% of patients and to a second site in ~50%. These frequencies are greater if gastric juice is assayed. There may be coexisting autoantibodies specific for the various other autoimmune diseases in the thyrogastric cluster. The incidence of these antibodies rises with increasing duration of disease, almost doubling after 10 years (Ungar et al., 1967).

Parietal cell antibodies to gastric H⁺/K⁺ ATPase are diagnostic of the underlying pathologic lesion of autoimmune gastritis, as gastric biopsies carried out in asymptomatic patients have revealed the presence of type A gastritis (Uibo et al., 1984). These antibodies are routinely detected by indirect immunofluorescence or, to gastric H⁺/K⁺ ATPase, by ELISA (Chuang et al., 1992; Lahner et al., 2009). Antibodies to gastric parietal cells can be demonstrated by serum reactivity with the cytoplasm of gastric parietal cells in unfixed, air-dried, and frozen sections of mouse stomach (see Figure 44.4). Mouse stomach is preferable to rat stomach because of a lower frequency of heterophile reactions (Muller et al., 1971) that could be misinterpreted as antibody to parietal cells. The antibodies are detected by immunofluorescence in ~90% of patients with pernicious anemia, with a prevalence of 2–5% in the general population, and in ~30% of patients with other thyrogastric autoimmune diseases, including type 1 diabetes mellitus (De Block et al., 2000, 2001a,b). The prevalence of gastric autoantibodies increases with age and correlate with rising serum gastrin levels (Jassel et al., 1999; De Block et al., 2001a). Parietal cell mass and hence the availability of autoantigens decreases as autoimmune gastritis progresses to pernicious anemia and this may explain the observation that the prevalence of autoantibodies decreases with progression (Davidson et al., 1989) and may also explain the lower antibody prevalence in one study of pernicious anemia (Carmel, 1992).

CONCLUDING REMARKS—FUTURE PROSPECTS

As one of the most common autoimmune diseases, autoimmune gastritis has been intensively investigated and a great deal has been discovered concerning its immunological pathogenesis. The availability of excellent animal models has meant that the identity of the gastric autoantigens is well defined, and the pathway that leads to

immunological tolerance in normal individuals is well understood. On the other hand, in common with most other autoimmune diseases, the reason why the immune system begins to react to gastric autoantigens to the detriment of patients is still not clear. While we know some level of detail of the genetics of autoimmune gastritis in mice, such data have not as yet been translated into the human setting. Environmental triggers for autoimmune gastritis are also unclear. While some data suggest a role for *Helicobacter* infection, this hypothesis is not supported by other epidemiological information.

From a clinical standpoint, pernicious anemia is now routinely treatable to prevent neurological complications of the disease by vitamin B12 replacement. However, this therapy does not cure the underlying cause of the disease, namely the decimation of the gastric mucosa by the autoimmune response, which increases the risk of gastric cancer. In mice, ectopic expression of the gastric autoantigen (Murphy et al., 2003) and treatment with Treg cells (Nguyen et al., 2011; Tu, Gleeson, and van Driel, unpublished) lead to long-term reversal of gastric lesions. Whether such treatments will become feasible or practical in humans remains to be seen.

DEFINITION AND CLASSIFICATION OF AUTOIMMUNE HYPOPHYSITIS

Autoimmune hypophysitis is a chronic inflammation of the pituitary gland that can be classified according to anatomic location, histopathology, or cause (Leporati et al., 2011).

Location distinguishes hypophysitis into adenohypophysitis, infundibulo-neurohypophysitis, or panhypophysitis depending on whether the clinical and radiological signs (and pathological findings if available) involve the anterior lobe, the posterior lobe and the stalk, or both structures.

Histopathology identifies two main forms of hypophysitis, lymphocytic and granulomatous, as well as xanthomatous, IgG4 plasmacytic, and necrotizing variants.

Etiology distinguishes primary and secondary hypophysitis. Primary hypophysitis refers to the cases that do not currently have an identifiable cause. It is the most common form of hypophysitis, has an autoimmune pathogenesis, and occurs in isolation or with other well-characterized autoimmune diseases. Secondary hypophysitis includes the cases where a clear etiological agent can be identified (for example, the administration of immunomodulatory drugs like CTLA-4 blocking antibody), the cases where the inflammation of the pituitary is considered a reaction to sellar diseases (Rathke's cleft cyst, craniopharyngioma, germinoma, and pituitary adenomas), and the cases where hypophysitis is part of a multiorgan systemic involvement (such as

Wegener's granulomatosis, tuberculosis, sarcoidosis, or syphilis).

In this chapter we will discuss predominantly primary hypophysitis and dedicate a section at the end for the hypophysitis secondary to CTLA-4 blockade.

HISTORICAL BACKGROUND

Autoimmune hypophysitis of the anterior lobe (lymphocytic adenohypophysitis, LAH) was first described in 1962 by Goudie and Pinkerton in Glasgow (Goudie and Pinkerton, 1962). The authors reported a 22-year-old woman who died 14 months after her second delivery, probably because of adrenal insufficiency. Two months before admission, the patient felt increasingly tired and noticed a neck enlargement; she then developed severe lower abdominal pain, radiating to the right iliac fossa, associated with vomiting and diarrhea. She was brought to the operating room for suspected appendicitis. Surgery revealed an acutely inflamed, gangrenous appendix that, however, had not ruptured. The appendix was removed but 8 hours later the patient went into peripheral circulatory shock and died. The autopsy revealed a firm, enlarged thyroid gland, infiltrated by lymphocytes, atrophic adrenal glands, and a small pituitary. Surprisingly for that time, the adenohypophysis was extensively infiltrated by lymphocytes and a few plasma cells, aggregating in some

areas into true lymphoid follicles. The neurohypophysis was normal. Noting the presence of Hashimoto's thyroiditis, a more extensively characterized autoimmune disease, the authors concluded their discussion by writing: "It seems reasonable to assume that the coexistence of Hashimoto's disease and the mononuclear cells infiltration of the anterior pituitary is not fortuitous. Both may be explained by the onset of autoimmune reaction to thyroid and pituitary antigens released during the puerperal involution of these glands." There is no doubt that Goudie and Pinkerton were the first to postulate the autoimmune nature of this condition, at a time when the field of autoimmunity had just begun. Earlier cases, however, are probably hidden in hospital archives or published without recognition of the disease (Duff and Bernstein, 1933; Rupp and Paschkis, 1953).

Autoimmune hypophysitis of the posterior lobe and infundibulum (lymphocytic infundibulo-neurohypophysitis, LINH) was first described in 1970 by Saito et al. in Tokyo (Saito et al., 1970). The authors reported on a 66-year-old asthmatic woman with 1-month history of severe dehydration who responded strikingly to the administration of pitressin. Two months after discharge, however, she developed a severe attack of bronchial asthma and died. Autopsy revealed a marked infiltration of the neurohypophysis and the infundibular stem with lymphocytes and plasma cells, aggregating in some areas in lymphoid follicles. The adenohypophysis was normal, except for vacuolar degeneration of the basophilic cells, likely due to the prolonged use of steroids for asthma.

Autoimmune hypophysitis involving both the anterior and posterior lobe (lymphocytic panhypophysitis, LPH) was first described histologically in 1991 by Nussbaum et al. in New York (Nussbaum et al., 1991). It was a 40-year-old male with a 3-month history of headache, impotence, polyuria and polydipsia, and a sellar mass abutting the optic chiasm. Transphenoidal surgery showed that the sella turcica was filled with whitish, fibrous tissue that was almost completely removed. Histology revealed extensive infiltration of the adenohypophysis and the neurohypophysis by lymphocytes, plasma cells, and histiocytes.

Hypophysitis secondary to blockade of CTLA-4 was first reported in 2003 by Phan et al. in Bethesda. The patient was a 54-year-old male with advanced melanoma metastatic to the lungs and brain who was treated with the CTLA-4 blocking antibody ipilimumab and vaccination with melanoma peptides (Phan et al., 2003).

EPIDEMIOLOGY AND BODY OF LITERATURE

Very limited data exist to estimate the incidence of autoimmune hypophysitis. Sautner and Fehn analyzed 2500 surgical pituitary specimens collected at Hamburg, Germany, from

1970 to 1996 and found six cases (0.24%) (Sautner et al., 1995; Fehn et al., 1998). Honegger et al. analyzed 2362 specimens collected from 1982 to 1995 in Erlagen, Germany, and found seven cases (0.3%) (Honegger et al., 1997). Leung et al. reported in Charlottesville, Virginia, 13 cases of autoimmune hypophysitis among 2000 patients who underwent transphenoidal surgery for pituitary mass lesions from 1992 to 2003 (0.65%) (Leung et al., 2004). Buxton and Robertson analyzed 619 consecutive pituitary surgeries performed over 15 years at Nottingham, UK, and found five cases (0.8%) (Buxton and Robertson, 2001). Considering that their hospital served a population of approximately 3 million and that all surgery for pituitary masses was dealt with there, the yearly incidence in Nottingham can be estimated to be one case in every 10 million people. This incidence is likely an underestimate of today's incidence, also considering that some cases of autoimmune hypophysitis go undiagnosed because of their indolent, subclinical course.

At the Department of Pathology of the Johns Hopkins Hospital we maintain a database of the papers published on hypophysitis, and pituitary autoimmunity in general, as well as of clinical characteristics of the featured patients (<http://pathology2.jhu.edu/hypophysitis>). A total of 837 papers have been published as of March 2013, featuring 3175 different authors and 12 languages. The top three publishing authors currently are Dr. P. Caturegli (25 articles, The Johns Hopkins University, Baltimore, MD), Dr. A. De Bellis (25 articles, Federico II University of Naples, Naples, Italy), and Dr. P. Crock (16 articles, The John Hunter's Children Hospital, New South Wales, Australia). Of the languages, 682 articles (82%) were in English, 61 (7%) were in Japanese, 26 (3%) in French, and the remaining 67 articles in nine other languages. The number of papers published per year on hypophysitis has increased significantly over time, reaching a peak of 60 in 2010 (Figure 45.1). The causes underlying this increase are multifactorial: in part they relate to the widespread introduction of non-invasive imaging techniques of the sella turcica (mainly MRI); in part to the expansion of the spectrum of pituitary autoimmunity, which now includes forms of hypophysitis that were not existing a few years ago: for example, the IgG4-related form of hypophysitis and the form secondary to blockade of CTLA-4; and in part to the increased awareness of hypophysitis in the medical community.

This body of literature described a total of 857 patients, 711 with primary hypophysitis, either biopsy proven ($n = 493$) or clinically suspected ($n = 218$), and 146 with secondary hypophysitis (Table 45.1). Patients have been reported in 42 of the 193 countries in the world, but most abundantly in Japan (27% of the patients) and the USA (19%) (Figure 45.2).

LAH is more common in women (F:M ratio of 4:1), who present at a younger age (35 ± 13) than men (49 ± 16). In approximately half of the women (49%),

FIGURE 45.1 Yearly trend of papers published on hypophysitis and pituitary autoimmunity.

LAH manifests during late pregnancy or early postpartum (Figure 45.3). A history of previous pregnancies does not increase the risk of developing LAH in subsequent pregnancies. This striking temporal association is one of the most interesting features of autoimmune hypophysitis, and, at the moment, remains unexplainable. LINH affects equally males and females (F:M ratio of 1:1), has a mean age at presentation of 39 (\pm 20) years, and is not associated with pregnancy. LPH is slightly more common in women (F:M ratio of 1.9), has similar age at presentation in both sexes (43 ± 17 years), and does not show association with pregnancy. Hypophysitis secondary to CTLA-4 blockade reflects the epidemiology of the underlying oncologic populations where the treatment is used. Most commonly these are patients with metastatic melanoma, but also renal cell carcinoma, non-small-cell lung cancer, prostate cancer, and pancreatic cancer. These patients, therefore, are mainly men (90%) and of older age (55 ± 10 years) than the patients with primary hypophysitis.

TABLE 45.1 Published Cases of Autoimmune Hypophysitis

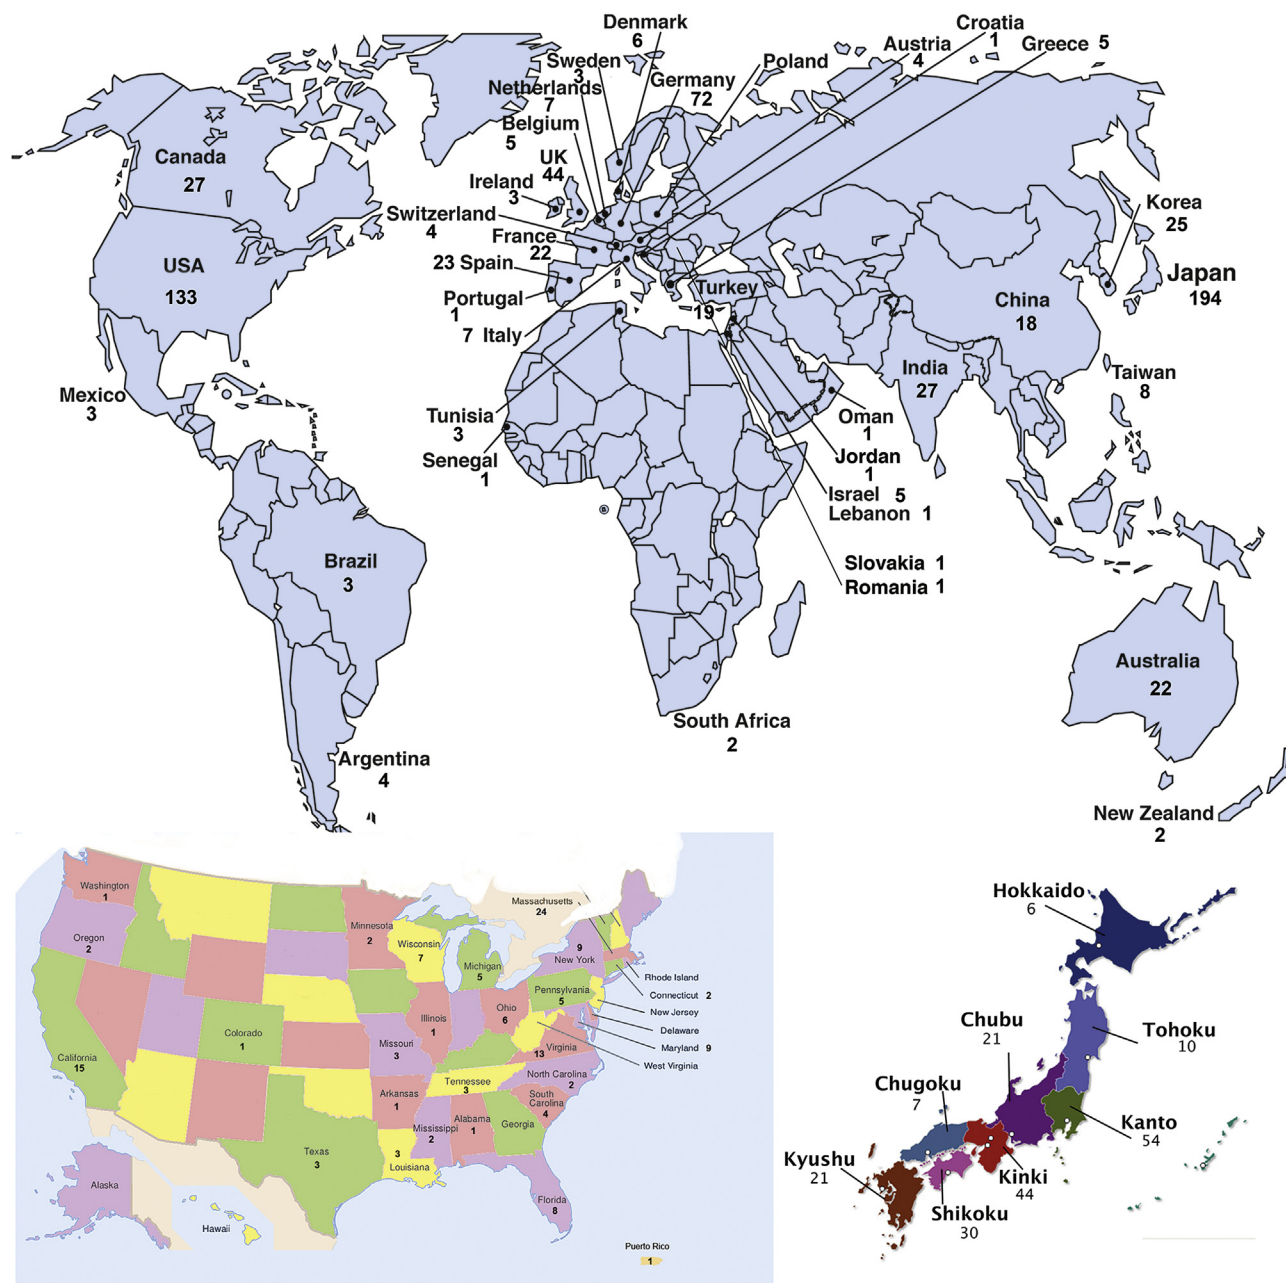

| Primary Hypophysitis (n = 711) | |
|--------------------------------------|------------|
| Biopsy-proven: | |
| Lymphocytic | 390 |
| Granulomatous | 59 |
| Xanthomatous | 17 |
| IgG4 plasmacytic | 6 |
| Necrotizing | 4 |
| Mixed lymphocytic and granulomatous | 15 |
| Mixed xanthomatous and granulomatous | 2 |
| Clinically suspected: | 218 |
| Secondary hypophysitis (n = 146) | |
| to CTLA-4 blockade treatment: | |
| Individual case reports | 18 |
| In clinical trials | 83 |
| to sellar lesions: | |
| Rathke’s cleft cyst | 15 |
| Germinoma | 14 |
| Pituitary adenoma | 10 |
| Craniopharyngioma | 4 |
| Pituitary lymphoma | 2 |
| TOTAL | 857 |

CLINICAL FEATURES

The clinical presentation of autoimmune hypophysitis includes four categories of symptoms.

The most common symptoms are those originating from compression of the sellar structures and usually appear suddenly. In fact, a pituitary gland that is infiltrated by autoreactive lymphocytes initially enlarges, forming a sellar mass that expands usually upward, impinging upon the optic chiasm and the dura mater or laterally to invade the cavernous sinus. Headache is the most common presenting symptom of hypophysitis. It is severe and often generalized. Visual disturbances are the next most common symptoms. They originate from compression of the optic chiasm and typically include defects in the temporal quadrants of the visual fields and occasionally deterioration of visual acuity. Encroachment of the cavernous sinus can cause diplopia and pupillary abnormalities from compression of the third, fourth, and sixth cranial nerves. Involvement of the branches of the trigeminal nerve can result in orbital pain or facial paresthesias.

The second most common symptoms are those originating from defective production of the anterior pituitary hormones, and usually present more insidiously. These defects are considered the direct consequence of the attack of the patient’s autoreactive lymphocytes onto the hormone-producing cells. The defects can be complete (panhypopituitarism) when all five adenohypophyseal axes (corticotroph, thyrotroph, gonadotroph growth hormone, and prolactin) are impaired, partial when more than one axis is involved, or isolated when only one axis is involved. The axis most commonly defective is the

FIGURE 45.3 Distribution of symptom appearance in relation to delivery (indicated as week 0).

TABLE 45.2 Distribution of Pituitary Hormone Defects in Patients with Hypophysitis

| | Secondary Decrease | Primary Decrease | Normal | Increase | Not Mentioned |
|-----------------------|--------------------|------------------|--------|----------|---------------|
| Adrenal axis | 53% | 2% | 27% | 0% | 18% |
| Thyroid axis | 45% | 6% | 29% | 2% | 15% |
| Gonadal axis | 43% | 1% | 30% | 0% | 26% |
| Prolactin | NA | 16% | 33% | 27% | 24% |
| Growth hormone | NA | 23% | 36% | 1% | 40% |
| Anti-diuretic hormone | NA | 28% | 20% | 0% | 25% |

NA = not applicable.

The third group of symptoms are those due to deficit of the posterior pituitary (polyuria and polydipsia), which can be attributed to direct immune destruction of the neurohypophysis and infundibulum, but also compression of these structure. Diabetes insipidus is the defining symptom of LINH, but it can also be observed in about a third of the patients who have defects in the anterior pituitary axes.

Last are the signs due to hyperprolactinemia (mainly amenorrhea/oligomenorrhea and galactorrhea), which occur in about a quarter of the patients.

These clinical features of autoimmune hypophysitis are indistinguishable from those caused by other non-hormone secreting masses arising in the sella turcica (Table 45.3). Thus, although *per se* rare, hypophysitis enters in the differential diagnosis of about 30 conditions, all characterized by the presence of a sellar mass. Currently, hypophysitis can only be diagnosed with certainty by pituitary biopsy. However, a pathological specimen is not always necessary since a presumptive diagnosis of hypophysitis can often be made on the basis of a combination of clinical and radiological features. Clinical features include the association with pregnancy or post-partum, the presence of other autoimmune conditions in the same patient (co-morbidity) or family (familial aggregation), and a relatively rapid development of hypopituitarism, which is often disproportionate to the size of the pituitary mass. MRI remains the most powerful tool currently available to aid in the differential diagnosis, and will be described in detail below.

PATHOLOGICAL FEATURES

Primary hypophysitis now comprises five pathological variants: lymphocytic, granulomatous, xanthomatous, IgG4 plasmacytic, and necrotizing (Table 45.1).

Lymphocytic hypophysitis, first reported by Goudie and Pinkerton in 1962, is the most common form of hypophysitis. It is characterized by the infiltration of the pituitary gland with lymphocytes (Figure 45.4A), sometimes aggregating into lymphoid follicles with germinal centers. Immunohistochemistry reveals a mixture of T and B lymphocytes (Gutenberg et al., 2005), without a dominant subset, as is seen in other autoimmune diseases. Additional hematopoietic cell types that are found in the infiltrate include plasma cells, eosinophils, macrophages, histiocytes and neutrophils, and mast cells (Vidal et al., 2002). Fibrosis is common and often severe, explaining the toughness and adherence the surgeon finds upon entering the sella turcica. Necrosis is rare and usually of modest and focal nature. Little is known of the mechanisms by which the infiltrate causes loss of function/destruction of the endocrine cells. Staining with reticulin usually shows that the delicate connective tissue framework is conserved (Figure 45.4B), whereas in pituitary adenomas it is destroyed.

Granulomatous hypophysitis was first described in 1917 by Simmonds (Simmonds, 1917). He analyzed 2000 pituitary glands at autopsy and found four cases not related to tuberculosis or syphilis, characterized by numerous scattered collections of multinucleated giant cells, histiocytes, and occasional granulomas surrounded by lymphocytes and plasma cells. The first ante-mortem patient was reported in 1980 (Taylon and Duff, 1980). The disease is rare, affects equally males and females, and can occur together with lymphocytic hypophysitis

TABLE 45.3 Classification of Sellar Masses, with Approximate Frequency Distribution

| Disease | % of all sellar masses |
|---|------------------------|
| Hormone-secreting pituitary adenomas | 55% |
| PRL-secreting adenoma | 42% |
| ACTH-secreting adenoma | 8% |
| GH-secreting adenoma | 5% |
| TSH-secreting adenoma | 0.25% |
| Non-hormone secreting sellar masses | 45% |
| Developmental lesions: | |
| Rathke's cleft cyst | 3.95% |
| Arachnoid cyst | 0.50% |
| Dermoid and epidermoid cysts | 0.40% |
| Vascular lesions: | |
| Pituitary apoplexy (caused by hemorrhagic necrosis) | 0.08% |
| Intrasellar aneurysm | 0.06% |
| Intrasellar angioma or hemangiopericytoma | 0.02% |
| Infectious lesions: | |
| Tuberculosis | 0.14% |
| Pituitary abscess | 0.13% |
| Fungal infections | 0.12% |
| Autoimmune and inflammatory lesions: | |
| Hypophysitis | 0.85% |
| Sphenoidal sinus mucocele | 0.13% |
| Sarcoidosis | 0.12% |
| Wegener's granulomatosis | 0.06% |
| Langerhans cell histiocytosis | 0.06% |
| Benign tumors: | |
| Non-functioning (null cell) pituitary adenoma | 32.0% |
| Craniopharyngioma | 2.00% |
| Chordoma | 1.30% |
| Meningioma | 1.00% |
| Glioma | 0.05% |
| Pituicytoma | 0.02% |
| Spindle cell oncocytoma | 0.02% |
| Malignant tumors: | |
| Metastasis (mainly from breast and lung cancer) | 1.20% |

(Continued)

TABLE 45.3 (Continued)

| Disease | % of all sellar masses |
|------------------------|------------------------|
| Germinoma | 0.24% |
| Lymphoma, plasmacytoma | 0.12% |
| Astrocytoma | 0.15% |
| Pituitary carcinoma | 0.02% |
| Teratoma | 0.02% |

(McKeel, 1983; Miyamoto et al., 1988; Madsen and Karluk, 2000), and has been recently reviewed by Hunn and colleagues (Hunn et al., 2013). It is significantly more common in women (F:M ratio of 4:1) and has a mean (\pm SD) age at presentation of 44 (\pm 15) years.

Xanthomatous hypophysitis, originally described by Folkerth in 1998 (Folkerth et al., 1998), features an infiltration of the pituitary with foamy histiocytes and lymphocytes. The histiocytes, also called xanthoma cells, have a cytosol loaded with lipids, which confer the characteristic foamy appearance. Cystic areas can be observed in the pathological specimen and also on the MRI images. The pathogenesis of xanthomatous hypophysitis remains unknown, with autoimmune, infectious, and localized endothelial dysfunctions as postulated etiologies. Xanthomatous hypophysitis is more common in women (12 of the 17 cases reported thus far, 70%), and impairs more frequently the gonadal axis.

IgG4 plasmacytic hypophysitis is the form of most recent description. It was first reported on clinical grounds in 2004 in a 66-year-old woman with multiple pseudotumors of salivary glands, pancreas, and retroperitoneum (van der Vliet and Perenboom, 2004), and then pathologically proven in 2007 in a 77-year-old man with blurred vision, hypogonadism, and a history of autoimmune pancreatitis and sclerosing cholangitis (Wong et al., 2007). This form is more common in men (13 of the 16 reported cases are men, 81%) and in advanced ages (mean age at presentation is 69 ± 6 years). It is characterized pathologically by a mononuclear infiltrate of the pituitary gland that is rich in IgG4-producing plasma cells. We suggested a number of 10 or more IgG4 producing plasma cells in a high-power microscopic field for establishing this diagnosis (Leporati et al., 2011). Other diagnostic criteria are the increased levels of IgG4 in the serum (> 140 mg/dl), and the association with IgG4-positive lesions in other organs. The disease responds extremely well to glucocorticoids and therefore a correct pre-operative diagnosis is crucial, since it can spare the patient an invasive pituitary surgery.

Necrotizing hypophysitis, first reported by Ahmed in 1993 (Ahmed et al., 1993), is the rarest form, with only five published cases, four biopsy proven (Ahmed et al., 1993; Gutenberg et al., 2012; Nater et al., 2012) and one clinically suspected (Ogawa, 1995). Patients present suddenly with severe headache and develop a long lasting hypopituitarism, features that, however, can also be seen with the other forms of hypophysitis, as well as with other non-hormone secreting sellar masses. Histologically, the pituitary appears destroyed by diffuse necrosis with surrounding lymphocytes, plasma cells, and a few eosinophils. MRI shows symmetric enlargement of the pituitary without signs of hemorrhage, and a thickened stalk, features that again are not specific enough to establish a diagnosis before surgery.

AUTOIMMUNE FEATURES

That autoimmune hypophysitis is indeed an autoimmune disease is indicated by the availability of animal models and by circumstantial evidence (Rose and Bona, 1993). The latter include the association with other diseases of known autoimmune nature, such as Hashimoto's thyroiditis (7% of the patients) and autoimmune polyglandular syndrome type 2 (2%), the improvement of symptoms upon usage of immunosuppressive drugs such as glucocorticoids, and the induction of the disease by drugs that promote immune activation like ipilimumab.

The autoantigen(s) recognized by the autoimmune attack await identification. Kobayashi's laboratory first described sera from patients with pituitary disorders that, when reacted with pituitary cytosolic extracts, recognized a 22 kDa protein (Yabe et al., 1995; Kikuchi et al., 2000), later identified by Takao et al. as growth hormone (Takao et al., 2001). Crock's laboratory subsequently reported that seven of 10 patients with biopsy-proven lymphocytic hypophysitis, and 12 of 22 patients with suspected hypophysitis, had a low titer antibody that recognized a 49 kDa cytosolic pituitary protein (Crock, 1998), later identified as alpha-enolase (O'Dwyer et al., 2002b). The authors concluded that alpha-enolase is the autoantigen targeted by the immune system in autoimmune hypophysitis and, considering its co-expression in the placenta, the basis to explain the strong association between autoimmune hypophysitis and pregnancy (O'Dwyer et al., 2002a). Antibodies recognizing alpha-enolase, however, have been reported in many other diseases, ranging from endometriosis to discoid lupus and Wegener's granulomatosis (Crock, 1998). In addition, Tanaka et al. have shown that the antibody is present in seven of 17 patients (41%) with autoimmune hypophysitis, but similarly in six of 13 (46%) patients with non-functioning pituitary adenoma, and in four of 17 (24%) patients with other pituitary diseases, making use of the alpha-enolase antibody inadequate as a diagnostic marker

of autoimmune hypophysitis (Tanaka et al., 2003). Finally, Nishiki et al. reported that five of 13 patients with LAH, and one of 12 patients with LINH, had antibodies that recognized 68, 49, and 43 kDa proteins in pituitary membrane extracts (Nishiki et al., 2001).

In addition to growth hormone and alpha-enolase, five candidate autoantigens have been reported in recent years: pituitary gland-specific factors 1a and 2 (Tanaka et al., 2002), secretogranin 2 (Bensing et al., 2007), chorionic somatomotropin hormone (Lupi et al., 2008), TPIT (Smith et al., 2012), and PIT-1 (Yamamoto et al., 2011). None of them, however, has yet proven to be pathogenic in animal models, useful in clinical practice, or confirmed by independent investigators.

Antibodies to pituitary antigens have been measured occasionally in the published patients (98 of 857, 11%), mainly by indirect immunofluorescence (Bottazzo et al., 1975) or Western blotting (Crock et al., 1993). They were found positive in a minority of patients, yielding an extremely poor sensitivity (37%) (Caturegli et al., 2005). They also seem to be not specific for autoimmune hypophysitis, since they have been described in type 1 diabetes (Mirakian et al., 1982), Hashimoto's thyroiditis (Kobayashi et al., 1988), Graves' disease (Hansen et al., 1989), and normal women during postpartum (Engelberth and Jezkova, 1965). This lack of sensitivity and specificity may have several explanations. For example, patients with autoimmune hypophysitis may come to medical attention long after the onset of disease and it is known that antibodies against endocrine glands disappear over the years (Figure 45.4).

FIGURE 45.4 Histopathology of primary lymphocytic hypophysitis. (A) Hematoxylin and eosin stain showing the infiltration of lymphocytes among the endocrine cells. (B) Reticulin stain showing the conservation of the connective tissue framework.

GENETIC AND ENVIRONMENTAL INFLUENCES

Insufficient data are available to establish associations between the genes that are classically thought to influence autoimmunity, such as the MHC locus and CTLA-4, and autoimmune hypophysitis. Also no environmental agent has been involved with primary hypophysitis, with the exception of four cases presenting after a viral infection of the meningi (Vanneste and Kamphorst, 1987; Honegger et al., 1997; Sandler et al., 1998; Matta et al., 2002).

ANIMAL MODELS

The first animal model for autoimmune hypophysitis was published in 1964 by Beutner and Witesbky. The authors immunized 16 rabbits with rabbit anterior pituitary extracts, emulsified in complete Freund's adjuvant, and were able to induce specific antibody responses but no pituitary pathology (Beutner et al., 1964). In 1967 Levine immunized rats with a single intra-cutaneous injection of rat pituitary tissue, emulsified in complete Freund's adjuvant (Levine, 1967), showing that 2–3 weeks after the injection, six of the 14 rats (43%) developed infiltration of the adenohypophysis with mononuclear cells, mainly lymphocytes, monocytes, and occasional epithelioid cells. A few posterior and intermediate lobes had minimal inflammation. Disease incidence could be increased to 75% (15 out of 20 rats) by addition of a second immunologic adjuvant, pertussis toxin. He subsequently showed that pituitary extracts from guinea pig were the most potent inducer of experimental autoimmune hypophysitis (six of six rat recipients), whereas human and cow extracts were poorly effective, and dog and rabbit extracts not effective at all (Levine, 1969). In 1970 Beck and Melvin (Beck and Melvin, 1970) induced experimental autoimmune hypophysitis in one rhesus monkey by injecting her multiple times, over the course of 3 years, with human placental extracts and human chorionic gonadotropin, both emulsified with Freund's adjuvant. Histology showed infiltration of the adenohypophysis with lymphocytes and scattered plasma cells; the neurohypophysis was normal.

In 1982 Klein induced lympho-plasmacytic infiltration of the anterior pituitary by injecting 12 rabbits (seven cases and five controls) three times, at 2-week intervals, with rabbit pituitary tissue, emulsified in complete Freund's adjuvant. Eight weeks (10 rabbits) or 16 weeks (two rabbits) after the first injection, five of the seven experimental rabbits showed focal infiltration of the adenohypophysis with lymphocytes, some plasma cells, and a few eosinophils and fibrosis. None of the five controls showed histological abnormalities. In 1992, Yoon et al. immunized over 100 hamsters by injecting intra-dermally three times, at 1-week intervals, recombinant rubella virus E1 and E2 glycoproteins. Three weeks after the first injection, specific antibodies against the

adenohypophysis were found in 95% of the hamsters. Eleven weeks after the first injection, a diffuse lymphocytic infiltration was found throughout the adenohypophysis. None of the hamsters that had received the control protein (nonglycosylated rubella nucleoprotein C) developed such lesions. The disease could be prevented by neonatal thymectomy, and could not be produced by passive transfer of the autoantibodies, thus indicating that T cells are critical for disease induction and that antibodies are more important as markers of disease, rather than as a pathogenic player (Yoon et al., 1992). Finally, Watanabe et al. in 2001 immunized 12 Lewis rats twice, at 1-week intervals, with rat pituitary extract emulsified in complete Freund's adjuvant. Three ($N = 6$) or 6 weeks ($N = 6$) after the first immunization, rats showed minimal lymphocytic infiltration in the adenohypophysis and developed antibodies directed against growth hormone, thyroid stimulating hormone, and luteinizing hormone (Watanabe et al., 2001). It is unclear, however, whether these hormones show that the initiating autoantigens are, rather, the natural response of the immune system to the injection of hormone-rich pituitary extracts.

A somewhat different experimental approach was taken by Stockinger's laboratory (De Jersey et al., 2002, 2004). The authors have made a transgenic mouse that expresses specifically in the anterior pituitary (as under transcriptional control of the growth hormone promoter) a nucleoprotein from the influenza virus, thus a foreign antigen. This influenza nucleoprotein contains a peptide that binds to the D^b allele of the mouse MHC locus, and is recognized by specific CD8 T cells. When the authors crossed the nucleoprotein transgenic mice to TCR transgenic mice that have CD8 T cells specific for that nucleoprotein, they observe growth hormone defect due to destruction of the growth hormone cells expressing the viral antigen. Although informative about accessibility and homing of CD8 T lymphocytes to the pituitary, this transgenic model is likely remote from the human disease where CD8 T lymphocytes are rarely seen in the infiltrate and somatotrophs are usually spared by the autoimmune attack.

In 2008 we published a comprehensive model of autoimmune hypophysitis. It is induced in SJL female mice by immunization with pituitary proteins emulsified in complete Freund's adjuvant (Tzou et al., 2008). The model mimics closely the human counterpart, featuring a female bias, a diffuse infiltration of the anterior lobe with a mixture of T and B lymphocytes, and panhypopituitarism. The model has provided useful insights into the human disease. It has shown that hypophysitis is characterized initially by an expansion of the pituitary gland but that later evolves into an atrophic structure that reflects the human empty sella condition (Lupi et al., 2011b). The model is being used to identify novel pituitary autoantigens with the intent of translating the findings to the human disease.

DIAGNOSIS

As indicated above, hypophysitis is a relatively rare condition but it enters in the differential diagnosis of other more common lesions, like the pituitary adenomas, and other masses arising in the sella turcica (classified in [Table 45.3](#)). All sellar masses share similar clinical and radiological findings, so that a diagnosis of certainty can only be achieved by examining under the microscope the pituitary tissue obtained from pituitary surgery. Clinical and immunological markers have, at the moment, low predictive values in establishing a differential diagnosis without pathology. Currently, the most powerful tool to differentiate autoimmune hypophysitis from other sellar mass is MRI. We have reviewed systematically the MRI features of the published patients with primary hypophysitis and identified a set of seven features that can orient the clinician toward a diagnosis of hypophysitis: pituitary volume, symmetry of the sellar mass, stalk diameter, status of the normal posterior pituitary bright spot, status of the mucosa lining the sphenoidal sinus, intensity of the signal after contrast, and heterogeneity of the signal after contrast ([Gutenberg et al., 2009](#)). Hypophysitis induces initially an enlargement of the pituitary gland, thus a measurable increased volume by MRI. This volume increase, however, rarely surpasses 6 mm³, as is instead more commonly seen in non-secreting pituitary adenomas. The increase in volume is also typically symmetric in hypophysitis, with the gland assuming a sort of pear-shaped appearance, whereas in adenomas the mass typically displaces the normal (non-tumorous) pituitary tissue. The stalk (or infundibulum) is composed of the median eminence of the hypothalamus, the infundibular stem that arises from it, and the pars tuberalis of the anterior hypophysis that surrounds the stem. The normal stalk has an average antero-posterior diameter (sagittal sections) of 3.25 mm at the level of the optic chiasm and 2.32 mm at the pituitary insertion ([Satogami et al., 2009](#)). In hypophysitis the stalk thickens above 4 mm, because the inflammation either involves directly the posterior pituitary or extends to it from the involved anterior pituitary. In coronal sections the normal stalk has a transverse diameter of 3.35 mm at the optic chiasm level and 2.16 mm at the pituitary insertion, and a uniform cylindrical appearance. In hypophysitis instead the thickened stalk assumes a V shape or round appearance ([Turcu et al., 2013](#)). The stalk is of normal size and shape in pituitary adenoma. On pre-contrast images, the anterior pituitary has a signal intensity that is approximately identical to that of the gray matter whereas the stalk is hyperintense. This hyperintensity, commonly known as posterior pituitary bright spot, is believed to reflect the high phospholipid content of the ADH and oxytocin neurosecretory granules. In hypophysitis the normal posterior pituitary bright spot is lost, whereas in adenomas it is conserved. After injection of the contrast, a pituitary gland affected by hypophysitis enhances the signal strongly (similarly to the

intensity of the cavernous sinus) and homogeneously, whereas in adenomas the enhancement is less intense and more heterogeneous. Finally, the mucosa lining the sphenoidal sinus is typically normal in hypophysitis whereas it is swollen in pituitary adenomas. None of these signs is individually specific enough to diagnose with certainty hypophysitis, but in aggregate the signs classified correctly 97% of the patients, with a sensitivity of 92% and a specificity of 99% ([Gutenberg et al., 2009](#)).

More recently, Nakata and colleagues described an additional MRI feature that was considered characteristic of hypophysitis and capable of distinguishing hypophysitis from adenoma with certainty: the presence in hypophysitis of a dark signal intensity area around the pituitary and in the cavernous sinus on T2-weighted images ([Nakata et al., 2010](#)).

TREATMENT

The treatment of autoimmune hypophysitis is, at the moment, only symptomatic and aimed at reducing the size of the pituitary mass and replacing the defective hormones.

Mass reduction treatment comprises lympholytic drugs (mainly glucocorticoids), surgery, and radiotherapy. The first line of treatment is typically the use of glucocorticoids to reduce the pituitary inflammation (reviewed in [Lupi et al., 2011a](#)). They are typically given in the form of high-dose prednisone or prednisolone that are then tapered over a period of weeks to months, depending on the clinical response. Some patients, however, do not respond to glucocorticoids or experience relapses after an initial improvement. In these instances, other immunosuppressive medications such as cyclosporine ([Ward et al., 1999](#)), methotrexate ([Tubridy et al., 2001](#)), azathioprine ([Lecube et al., 2003](#)), and rituximab ([Schreckinger et al., 2012](#)) have been reported with success.

Surgery has historically been the most used way to reduce the pituitary mass in patients with primary hypophysitis. It also has the advantage of providing a tissue sample for pathological examination, which establishes a diagnosis of certainty and also expands our understanding of the disease. Nowadays surgery is recommended for patients who have significant and progressive visual loss, for those who do not respond to the various options of medical treatment outlined above, and for those with intractable symptoms. Modern pituitary surgery is typically done through the endoscopic trans-sphenoidal approach, an approach that is relatively safe and effective. The goal of the surgery is to debulk the pituitary mass to relieve the compression of the cranial nerves or relieve the pressure responsible for headache. Excision of one-third to one-half of the pituitary mass is typically

sufficient, and there is no need to perform a total excision (Iuliano and Laws, 2011).

Stereotactic radiotherapy (Selch et al., 2003) and gamma knife radiosurgery (Ray et al., 2009) have been employed effectively in a few patients who failed medical and surgical treatments and experienced a disease recurrence.

Replacement of the defective pituitary hormones is the main form of long-term therapy in patients with hypophysitis. It is carried out similarly to the replacement performed for other causes of hypopituitarism. The hormones most commonly replaced are hydrocortisone for a defective corticotroph axis, thyroxine for the thyrotroph axis, desmopressin for the defective ACTH secretion, and testosterone or estradiol for a defective gonadotroph axis. The growth hormone axis, as indicated above, is not assessed systematically in patients with hypophysitis. However, a few adult patients have also had replacement recombinant growth hormone (Gachoud et al., 2002; Leung et al., 2004; Hindocha et al., 2013). Prolactin deficiency, if diagnosed and clinically significant, can be corrected with administration of recombinant prolactin (Powe et al., 2010).

OUTCOME

After a diagnosis of hypophysitis is made, either by pathology or on clinical grounds, there are five main outcomes. The majority of patients (68%) improve after the initial mass reductive treatment but the pituitary hormone deficiencies remain and require prolonged replacement. In some of these patients, a detailed imaging follow-up has shown that the pituitary gland becomes atrophic with time, yielding on the MRI the appearance of an empty sella (Karaca et al., 2009). In about a fifth of the patients (18%) the disease improves markedly after the initial mass reductive treatment and no further therapy is necessary. In a few patients (2%) the disease regresses spontaneously without any treatment. In a significant minority of patients (6%) the disease progresses and recurs despite medical and surgical attempts to contain it. In the remaining 6%, hypophysitis kills the patient, likely through the development of an irreversible adrenal insufficiency. These autopsy cases have been published sporadically but consistently throughout the years, the most recent one in 2009 (Gonzalez-Cuyar et al., 2009), reminding us that autoimmune hypophysitis can be fatal if unrecognized.

HYPOPHYSITIS SECONDARY TO CTLA-4 BLOCKADE

The introduction in the early 2000s of cancer drugs that act by blocking proteins expressed on immune cells has changed dramatically the significance of hypophysitis:

from being a rarity, it has now become a disease that most clinicians and practitioners involved in immunotherapy are familiar with. Ipilimumab (Yervoy™, Medarex, and Bristol-Myers Squibb) is one of the most used immunoregulatory drugs.

Ipilimumab is a fully human IgG1 monoclonal antibody that binds to cytotoxic T lymphocyte antigen 4 (CTLA-4). CTLA-4 is expressed on the surface of effector T cells a few hours after they become activated. It normally binds to B7 on antigen-presenting cells, initiating a negative cascade that ultimately results in T cell inhibition. Ipilimumab blocks the physiological binding of CTLA-4 to B7 and therefore prolongs T cell activation, inducing unrestrained immune responses against tumor cells but also against a variety of normal self-antigens. Ipilimumab was approved in 2011 by the FDA and the European Medicines Agency for the treatment of metastatic or unresectable melanoma, and is currently tested in several other types of cancer, including renal cell carcinoma, pancreatic cancer, prostate cancer, non-small cell lung cancer, and liver cancer. Patients undergo an induction course of ipilimumab consisting of one intravenous infusion every 3 weeks for a total of four infusions (Culver et al., 2011). The dose is usually 3 mg/kg and the price set by Bristol-Myers Squibb is \$30,000 per injection, which translates to a cost of \$120,000 for a course of therapy.

Patients treated with ipilimumab experience an array of autoimmune reactions collectively referred to as immune-related adverse events. As properly stated by Voskens et al., these adverse events represent “the price of tumor control” (Voskens et al., 2013). They occur in about 75% of the patients and are clinically significant (grade III or IV) in about 15% (Culver, 2011). The most common adverse events are dermatitis, enterocolitis, hepatitis, and hypophysitis, thus differing from adverse events typically reported with chemotherapy. It is unclear why hypophysitis, traditionally considered a rare autoimmune disease, is seen at increased frequency in cancer patients treated with ipilimumab. Approximately 50 clinical trials using CTLA-4 blocking antibodies have been published since 2003 (Culver, 2011). Of them, 20 reported hypophysitis as an adverse event (Table 45.4). These 20 trials included 2366 patients with advanced cancer, 83 of whom developed hypophysitis, for an average incidence of about 4%. Additional patients have been published as individual case studies.

Most patients with hypophysitis secondary to CTLA-4 blockade present with headache and symptoms from adeno-hypophyseal hormone deficiencies. As in primary hypophysitis, the most commonly involved axis is the corticotroph, but here the thyrotroph axis is as frequently involved as the corticotroph (almost 100% of the patients), and the gonadotroph is affected in about 85% of

TABLE 45.4 Clinical Trials using CTLA-4 Blocking Antibodies and Reporting Hypophysitis as a Side Effect

the male patients. As for primary hypophysitis, the growth hormone axis has not been assessed systematically. A recent case series of seven patients with metastatic melanoma treated with ipilimumab and developing secondary adrenal insufficiency, however, showed that three of five patients where the growth hormone axis was measured had low serum IGF-1. Prolactin and ADH are reported to be deficient only sporadically. In contrast to primary hypophysitis, visual disturbances are rare, likely related to the fact that the pituitary enlargement in ipilimumab patients is usually modest (Blansfield, 2005). MRI studies typically show a diffuse enlargement of the anterior pituitary, with conservation of the posterior

pituitary bright spot. All the cases reported thus far have been diagnosed on clinical and imaging grounds, therefore there is no information about the pathological lesions of hypophysitis secondary to CTLA-4 blockade.

The recommended treatment for grade 3 or 4 secondary hypophysitis is a course of high-dose glucocorticoids (like prednisone 50–60 mg/day), gradually tapered over a month to a physiological replacement dose (hydrocortisone 15–20 mg/day). It is unclear whether initial high doses are truly needed or if instead the patients could be started on physiological doses from the time of diagnosis. Thyroid hormone and sex steroids are then added as needed. No information about growth hormone replacement is

available. It is now considered not necessary to discontinue ipilimumab for the treatment of CTLA4-induced hypophysitis, although initial cases did. Pituitary deficits seem to persist after treatment and long-term hormonal replacement has to be anticipated for most patients.

CONCLUDING REMARKS—FUTURE PERSPECTIVES

Autoimmune hypophysitis is a rare but increasingly recognized disease that has exploded on the medical arena due to its association with cancer immunotherapies. Its spectrum continues to expand and increase in complexity. The field will advance when a reliable serological test that identifies the autoimmune nature of hypophysitis becomes available.

ACKNOWLEDGMENTS

We dedicate this chapter to the memory of Breanna, a patient with primary autoimmune hypophysitis who, after delivery of her daughter, developed inability to lactate and adrenal insufficiency that went unrecognized. Several months later she developed an acute adrenal crisis, and died on June 18, 2010.

HISTORICAL BACKGROUND

The earliest descriptions of autoimmune hemolytic anemia (AIHA) date from the 19th century, and the disease was one of the first shown to have an autoimmune pathology. Pioneering work by Donath and Landsteiner demonstrated that the destruction of red blood cells (RBC) was dependent on the absorption of hemolysins and complement from serum (Donath and Landsteiner, 1904). Further studies were impeded by the difficulty in distinguishing acquired from congenital hemolytic anemias, but an important advance was made using the antiglobulin, or Coombs', test, which detected RBC coated with autoantibodies by agglutinating them with antiserum to human globulin (Coombs et al., 1945; Boorman et al., 1946; Loutit and Mollison, 1946). Methods for measuring survival of circulating cells *in vivo* further demonstrated that RBC from patients with acquired hemolytic anemias were destroyed by a "random hemolytic process," rather than being "intrinsically defective" (Loutit and Mollison,

1946; Mollison, 1959). Together, these developments identified AIHA as a disease in which autoantibodies bind RBC and shorten their life span, affecting 1–3 per 100,000 of the population (Sokol et al., 1992; Petz and Garratty, 2004a).

CLASSIFICATION OF AIHA

AIHA can be classified both by the type of autoantibody and by the presence of underlying disease (Sokol et al., 1992; Petz and Garratty, 2004a) (Table 46.1). Pathogenic autoantibodies are divided into either cold (Petz, 2008) or warm (Packman, 2008) reactive, depending on the optimum temperature at which they bind RBC. Up to 7% of patients have "mixed" pathogenic autoantibodies of both types (Sokol et al., 1981, 1983, 1992). AIHA can also be described as primary, or idiopathic, in the absence of any associated condition, or as secondary if there is concurrent disease that may be considered causal or has shared etiology (Packman, 2008; Petz, 2008).

TABLE 46.1 Classification of AIHA by Antibody Type

| Classification by Autoantibody Type | | |
|--------------------------------------|--|---|
| | Cold Reactive | Warm Reactive |
| Optimum temperature for binding RBC | 4°C | 37°C |
| Predominant autoantibody class | IgM (cold agglutinin syndrome) IgG (paroxysmal cold hematuria) | IgG |
| Predominant site of hemolysis | Intravascular | Extravascular (spleen, liver) |
| Predominant mechanism of hemolysis | Complement lysis (membrane attack complex) | Phagocytosis via macrophage IgG Fc and complement receptors |
| Classification by Underlying Disease | | |
| Primary (idiopathic) | Secondary | |
| No underlying disease | Underlying disease (causal or shared etiology) Infection Other immune disease Neoplasia Drug induced | |

ANIMAL MODELS OF AIHA

Examples of AIHA in laboratory mice have proved valuable in understanding the pathogenesis of the disease. The New Zealand Black (NZB) mouse (Helyer and Howie, 1963; Barker et al., 1993b) develops AIHA spontaneously, and hemolysis can be recapitulated by transgenic expression of a monoclonal anti-RBC autoantibody derived from this strain (Murakami et al., 1992). AIHA is also one of the autoimmune pathologies arising in the non-obese diabetic (NOD) mouse (Baxter and Mandel, 1991), and from genetic modification to prevent expression of interleukin-2 (IL-2) (Hoyer et al., 2009). In addition to these spontaneous examples, the disease can be induced in healthy murine strains by repeated immunization with rat RBC (Playfair and Marshall-Clarke, 1973; Naysmith et al., 1981), or by infection of C3HeB/FeJ mice with the docile strain of lymphocytic choriomeningitis virus (LCMV) (Coutelier et al., 1994).

AIHA has also been described as a cause of anemia in the domestic dog (Barker et al., 1991), cat (Switzer and Jain, 1981), rabbit (Fox et al., 1971), horse (Mair et al., 1990), and ox (Dixon et al., 1978).

MECHANISMS OF RBC DESTRUCTION IN AIHA

AIHA is a classic example of type II hypersensitivity, with autoantibody-coated RBC removed from the circulation by phagocytes of the reticulo-endothelial system (RES), predominantly splenic macrophages, and/or lysis by complement fixation (Packman, 2008; Petz, 2008).

Anemia results if the hemolysis is insufficiently compensated for by increased RBC production.

Cold Reactive Antibodies

Cold reactive anti-RBC autoantibodies are responsible for 15–20% of human AIHA cases (Petz, 2008). They bind more strongly at 4°C than at higher temperatures, and the pathogenic effects of these antibodies depend more on their thermal amplitude than their titer. Cold autoagglutinins that bind RBC below 10–15°C can be demonstrated in the sera of most healthy individuals (Landsteiner and Levine, 1926). In contrast, cold autoantibodies active up to 30°C are associated with cold agglutinin syndrome (CAS) (Petz, 2008), since temperatures in the peripheral circulation can fall below this level. The antibody, usually IgM, causes intravascular hemolysis if it activates complement to form membrane attack complexes (MAC) (Engelfriet et al., 1981; Petz and Garratty, 2004b), overcoming protective regulators on the RBC such as CD35 (complement receptor 1 CR1), CD55 (decay-accelerating factor), and CD59 (protectin) (Nicholson-Weller et al., 1982; Krych-Goldberg and Atkinson, 2001; Ruiz-Argüelles and Llorente, 2007). RBC coated with C3b may also be temporarily sequestered by macrophages (Engelfriet et al., 1981). In some patients, cold IgM autoantibodies agglutinate RBC in extremities that become chilled, blocking small blood vessels and causing ischemia (Petz, 2008). CAS can be either transient, most frequently as a complication of mycoplasma infection (Costea et al., 1972), or chronic, typically associated with clonal lymphoproliferative disease (Berentsen et al., 2006).

Pathogenic cold reactive autoantibodies also include the Donath–Landsteiner (DL) hemolysins, which cause paroxysmal cold hemoglobinuria (PCH), a dramatic form of AIHA precipitated by chilling of the patient (Petz, 2008). These antibodies, which are IgG, bind RBC if the temperature falls below 37°C, then fix complement to trigger MAC formation and fulminant intravascular hemolysis when warmed again. PCH was commonly secondary to syphilis when first described in the late 19th century, but is now rare and typically follows childhood viral infections (Sokol et al., 1982, 1984, 1999).

Warm Reactive Antibodies

Warm autoantibodies are the commonest cause of AIHA and react as well, or more strongly, with RBC at 37°C than at lower temperatures (Sokol et al., 1992; Packman, 2008). Most are of the IgG class and cause extravascular hemolysis, predominantly by Fc receptor (Fc γ R)-mediated phagocytosis (Engelfriet et al., 1981; Petz and Garratty, 2004b; Packman, 2008). The complement regulators on the RBC membrane (Ruiz-Argüelles and Llorente, 2007) typically prevent MAC formation, but deposition of C3b and C3d is common and can strongly enhance opsonization (Kurlander et al., 1978) by interacting with specific receptors including CR1 and CR3 (Ross and Medof, 1985). Although blood monocytes and hepatic Kupffer cells also express appropriate sets of receptors, splenic macrophages are the main effectors of RBC destruction (Engelfriet et al., 1981; Petz and Garratty, 2004b; Packman, 2008). Some sensitized RBC may be only partially phagocytosed and released back into the circulation as spherocytes, which have a short half-life (Garratty, 1983).

Between 22% (Dausset and Colombani, 1959) and 81% (Pirosky, 1976) of warm AIHA cases have been reported to be secondary, varying with different interpretations of this classification. The most common associations are with other immune-based conditions, most notably ulcerative colitis, rheumatoid arthritis, and systemic lupus erythematosus (SLE), with neoplasia, particularly chronic lymphocytic leukemia (CLL), and with a variety of infectious diseases (Sokol et al., 1992; Petz and Garratty, 2004a).

Pathogenicity of Warm Reactive IgG Antibodies

Warm reactive IgG anti-RBC autoantibodies vary in their pathogenicity, exemplified by the finding of a positive direct agglutination test (DAT) in a small proportion (1 in 7–15,000) of healthy blood donors (Hernandez-Jodra et al., 1990; Win et al., 1997; Petz and Garratty, 2004b). The ability to cause hemolysis has been attributed to

multiple factors, including titer, subclass, affinity for autoantigen, patterns of heavy chain glycosylation, and also the activity of phagocytes responsible for clearance (Garratty, 1990; Sokol et al., 1992; Petz and Garratty, 2004b).

The amount of IgG blood group alloantibody coating RBC determines their rate of clearance in healthy subjects (Mollison and Hughes-Jones, 1967; Kelton et al., 1985), but it is less easy to demonstrate a similar relationship for autoantibodies in human AIHA (Rosse, 1971; Chaplin, 1990; Petz and Garratty, 2004b). Serial measurements from individual patients reveal some correlation of hemolysis with autoantibody titer, but many cross-sectional studies fail to do so, using either the DAT or more sensitive and quantitative flow cytometric or ELISA-based techniques to measure RBC-bound IgG (Van der Meulen et al., 1980; Garratty and Nance, 1990; Sokol et al., 1992; Petz and Garratty, 2004b). Autoantibody titer alone also appears to be an unreliable predictor of the severity of hemolysis in canine (Barker et al., 1992b) and murine AIHA (Naysmith et al., 1981; Shen et al., 2003).

The subclass of RBC autoantibody is a potentially important factor in its ability to cause hemolysis, by determining interactions with different types of Fc γ R and fixation of complement (Sokol et al., 1992; Petz and Garratty, 2004b). Comprehensive analyses of IgG subclass switch variants of monoclonal anti-RBC antibodies originally derived from NZB mice have established how differences in these Fc-associated effector functions can critically influence pathogenicity (Baudino et al., 2006), with affinity for autoantigen playing a less important role (Fossati-Jimack et al., 1999). In mice there are three activating Fc γ R types (Fc γ RI, Fc γ RIII, and Fc γ RIV), all of which are expressed on macrophages and can bind complexed IgG, while only Fc γ RI also has high affinity for monomeric IgG (Nimmerjahn and Ravetch, 2008). IgG_{2a} and IgG_{2b} autoantibody switch variants, each of which interacts efficiently with Fc γ RIII and activate complement, and mediate the most severe hemolysis *in vivo* (Baudino et al., 2006). Fc γ RIV makes an additional contribution to uptake by these isotypes, and IgG_{2a} also promotes clearance via Fc γ RI if it coats RBC at sufficient density to compete with free monomer in serum (Baudino et al., 2008). The next most pathogenic subclass is IgG₃, which activates complement but does not bind any Fc γ R, followed by the IgG₁ subclass that interacts only with Fc γ RIII and fails to fix complement. Overall, IgG_{2a} and IgG_{2b} autoantibodies are 20-fold more potent in causing hemolysis than IgG₁ (Baudino et al., 2006). Complement fixation by the murine autoantibodies does not lead to MAC formation, but CR-mediated erythrophagocytosis can be important if there is extensive opsonization of RBC by C3 associated with binding of high affinity IgG_{2b} or IgG₃ (da Silveira et al., 2002).

Compared with murine studies, the relationships between human RBC autoantibody subclass and hemolysis are less clear (Petz and Garratty, 2004b). Based on interactions with Fc γ R and complement, IgG₃ would be predicted to be the most pathogenic subclass, followed by IgG₁, with IgG₂ and IgG₄ relatively benign (Engelfriet et al., 1981; Petz and Garratty, 2004b; Sokol et al., 1992). However, in both patients with AIHA and healthy DAT-positive donors with no evidence of hemolysis, IgG₁ autoantibody predominates, and is the only isotype detected on RBC using agglutination-based techniques in up to 80% of each group (Garratty, 1989). Furthermore, IgG₃ can be detected by DAT not only in patients but also in normal blood donors, although RBC sensitization with IgG₄ alone may be restricted to healthy individuals (Garratty, 1989). Sensitive flow cytometric and ELISA methods (Sokol et al., 1990a; Garratty and Nance, 1990) have confirmed that increased levels of RBC-bound IgG₃ are not necessarily associated with disease, and suggest instead that autoantibodies of multiple IgG subclasses are common in AIHA, and that this diversity is important in promoting hemolysis via synergistic effects (Sokol et al., 1990a). The three families of human activating Fc γ R (Fc γ RI, Fc γ RIIa/Fc γ RIIc, and Fc γ RIIIa/Fc γ RIIIb) (Nimmerjahn and Ravetch, 2008) may each play a role in RBC uptake. As in mice, only Fc γ RI has high affinity for monomeric IgG, but may mediate erythrophagocytosis under conditions that allow RBC-bound IgG to compete with monomer in serum, particularly in the hemoconcentrated environment of the spleen (Kelton et al., 1985; Barker et al., 1992b). Although MAC formation rarely contributes to hemolysis in patients with warm antibodies, complement fixation appears to be an important determinant of disease (Petz and Garratty, 2004b). C3 can be detected by DAT in up to 50% of AIHA patients (Garratty, 1989) and is quantitatively associated with hemolysis (Freedman et al., 1982), reflecting synergy between Fc γ R and CR in RBC uptake (Sokol et al., 1992).

Changes in glycosylation of the CH2 domain of the IgG heavy chain may also influence interactions with Fc γ R and complement, with loss of either terminal sialic acid or galactose residues suggested to alter the pathogenicity of murine RBC autoantibody (Baudino et al., 2006). There is evidence in rheumatoid arthritis that IgG lacking galactose (G₀) can interact with mannose-binding protein, thereby fixing complement and triggering inflammation (Malhotra et al., 1995). However, in AIHA it seems likely that RBC autoantibody may be less hemolytic than G₀, since the loss of galactose reduces the affinity of IgG for Fc γ RIII (Hadley et al., 1995). Although G₀ RBC autoantibodies have been identified in some AIHA patients and in NZB mice, the

levels can vary widely over time in individuals and show no correlation with severity of disease (Barker et al., 1999a,b).

The final, important, factor determining the hemolytic potential of warm autoantibodies is the effectiveness of the RES in clearing sensitized RBC (Sokol et al., 1992; Petz and Garratty, 2004b). The ability of macrophages to phagocytose RBC can be enhanced by infections that upregulate Fc γ R expression (Atkinson and Frank, 1974; Coutelier et al., 2007), or compromised by saturation with immune complexes in AIHA secondary to SLE (Frank et al., 1979). Drugs such as corticosteroids can also inhibit phagocytosis by downregulating Fc γ R expression (Fries et al., 1983; Kelton, 1985). The cytokine milieu is a major influence on macrophage activation state, and the severity of NZB AIHA can be ameliorated by gene therapy to increase levels of circulating IL-4 (Youssef et al., 2005).

Additional Mechanisms of Hemolysis by Warm Antibodies

Although Fc γ R- and CR-mediated erythrophagocytosis of IgG coated RBC is the major cause of hemolysis in warm AIHA, there is evidence for other pathogenic mechanisms (Sokol et al., 1992; Petz and Garratty, 2004b).

In rare patients with warm AIHA, the main autoantibody class may be IgM or IgA, and not IgG. If warm IgM autoantibodies predominate, they can trigger MAC formation and fulminant intravascular hemolysis (Freedman et al., 1987). IgA autoantibodies may cause hemolysis by Fc-mediated uptake and cytotoxicity (Clark et al., 1984), or hemagglutination in the spleen (Baudino et al., 2007). More sensitive techniques than the DAT detect a higher prevalence of co-sensitization of IgG with low levels of IgM and/or IgA, and such coating of RBC with multiple antibody classes is associated with severe hemolysis, suggesting the importance of synergistic effects (Sokol et al., 1990b).

Another mechanism, which may be of particular relevance in patients with very low levels of RBC-bound IgG, is that splenic macrophages are instead “armed” with the autoantibody bound to Fc γ RI, allowing them to capture circulating RBC (Griffiths et al., 1994). Antibody dependent cell-mediated cytotoxicity may also play a role in hemolysis (Garratty, 1983; Griffiths et al., 1994), mediated not only by macrophages but also potentially by K cells (Urbaniak and Griess, 1980) or activated neutrophils (Engelfriet et al., 1981). In some patients, there is evidence that autoantibodies can interfere with erythropoiesis (Crosby and Rappaport, 1956) or RBC egress from the bone marrow (Conley et al., 1982), as well as causing hemolysis.

RBC Autoantigens

Many of the major RBC autoantigens in AIHA have been identified (Tables 46.2 and 46.3).

Serological studies have established that cold reactive RBC autoantibodies in healthy individuals, and pathogenic species with high thermal amplitude in CAS, are most commonly directed to the Ii blood group system of carbohydrate differentiation antigens (Berentsen and Tjønnfjord, 2012). On adult RBC, the I antigen predominates, while i is expressed at low levels. Antibodies from approximately 90% of CAS patients recognize the I antigen (Jenkins et al., 1960), with anti-i (Marsh and Jenkins, 1960) accounting for most of the remainder. Other, very rare specificities for autoantibodies in CAS include Pr (Dellagi et al., 1981). In PCH, anti-P autoantibodies are detected in at least 90% of patients (Sokol et al., 1999).

The most common targets in human warm AIHA, recognized in over 70% of cases, are the Rh proteins (Weiner and Voss, 1963; Barker et al., 1992a; Leddy et al., 1993), which also express important blood groups (Avent and Reid, 2000). Autoantibodies reactive against the glycoporphins, or against the RBC anion channel protein, Band 3, are produced in some patients (Victoria et al., 1990; Barker et al., 1992a; Leddy et al., 1993). The major canine RBC autoantigens are the glycoporphins,

with autoantibodies from some cases specific for Band 3 (Barker et al., 1991). In mice, Band 3 is the dominant autoantigen in NZB disease (Barker et al., 1993b; de Sá Oliveira et al., 1996) and in AIHA following LCMV infection (Mazza et al., 1997), and, together with glycoporphins, is also a target for autoantibodies induced by rat RBC (Barker et al., 1993a).

In addition to the autoantigens relevant to AIHA pathogenesis, RBC can also express cryptic determinants recognized by naturally occurring IgG autoantibodies. These include spectrin, the major component of the internal RBC cytoskeleton (Lutz and Wipf, 1982; Ballas, 1989; Barker et al., 1991, 1993a) and senescent red cell antigen (Alderman et al., 1981), which is exposed on Band 3 by aged RBC (Kay et al., 1990). The autoantibodies are thought to provide physiological mechanisms for disposing of damaged and effete RBC (Wiener et al., 1986; Pantaleo et al., 2008).

CLINICAL SIGNS OF AIHA

In both CAS (Petz, 2008) and warm AIHA (Packman, 2008), the predominant clinical features reflect the anemia, which most commonly causes lethargy and dyspnea. Signs include pallor and icterus, and massive hemolysis

TABLE 46.2 RBC Autoantigens in Human AIHA Caused by Cold Autoantibodies

| Form of AIHA | Common Autoantibody Specificity | Rare Autoantibody Specificity |
|---------------------------------|---------------------------------|-------------------------------|
| Cold agglutinin syndrome (CAS) | I (~90% patients) | i, Pr, A, B |
| Paroxysmal cold hematuria (PCH) | P (~90% patients) | i, p, HI, I |

TABLE 46.3 RBC Autoantigens in Human and Animal AIHA Caused by Warm Autoantibodies

| Species | B Cell Autoantigen (Dominant Antigen in Bold) | Th Cell Autoantigen Identified | Unprimed Autoreactive Th Cells in Health | Regulatory T Cell Response |
|---------------------------------|---|--------------------------------|--|--|
| Human AIHA | Rh proteins (~70% patients) Glycophorin A Band 3 | Rh proteins | Yes | IL-10 response to Rh protein epitopes |
| Canine AIHA | Glycophorins (~50% patients) Band 3 | Glycophorins | Yes | Not examined |
| Murine AIHA NZB mouse | Band 3 Band 4.1 (pr) Phosphatidylcholine (pr) | Band 3 | Not applicable | Weak IL-10 response to Band 3 |
| Induced by rat RBC | Band 3 (cr) Glycophorins (cr) | Band 3 | Yes | Recovery due to suppression by CD25 ⁺ cells |
| Induced by LCMV | Band 3 | Not examined | Yes | Not examined |

pr = polyreactive antibody, also binds nuclear antigens, e.g. histones; cr = cross reacts with rat RBC antigen. Modified from Barker et al. (2007).

may precipitate hemoglobinuria. In CAS there may also be cyanosis or even necrosis of the bodily extremities (Petz, 2008). AIHA due to DL antibodies is typified by recurrent bouts of anemia and hemoglobinuria precipitated by exposure to cold (Petz, 2008). In warm AIHA, splenomegaly or hepatomegaly can be associated with extravascular hemolysis (Packman, 2008). Where AIHA is secondary, the signs of the underlying disease may predominate.

LABORATORY DIAGNOSIS OF AIHA

In addition to anemia, most cases show evidence of erythroid regeneration, with a reticulocytosis (Packman, 2008; Petz, 2008). However, there can be a poor erythroid response (Liesveld et al., 1987), due to the physiological lag in increasing RBC production following acute hemolysis, or to autoimmune reactions inhibiting RBC regeneration (Conley et al., 1982), or to an underlying bone marrow disorder (Lefrere et al., 1986). Evidence of hemolysis can also be provided by increased bilirubin, aspartate transaminase, and lactate dehydrogenase levels. RBC autoagglutination or spherocytes may be seen in cold and warm AIHA, respectively.

Detection of RBC autoantibodies confirms the diagnosis of AIHA. The DAT has been the classic tool for measuring RBC-bound autoantibodies and complement (Petz and Garratty, 2004a). However, benign immunoproteins on the RBC surface can cause a positive DAT (Heddle et al., 1988; Huh et al., 1988), and the test also gives false-negative results in 3 to 11% of AIHA cases (Sokol et al., 1985, 1988; Petz and Garratty, 2004a). These limitations have led to more sensitive methods to detect RBC-bound immunoglobulins, including radioimmunoassay (Kaplan and Quimby, 1983), flow cytometry (Van der Meulen et al., 1980; Garratty and Nance, 1990), or ELISA (Sokol et al., 1985, 1988).

TREATMENT OF AIHA

Anemia in both cold and warm AIHA requires supportive care and, if life-threatening, transfusion (Packman, 2008; Petz, 2008).

Patients with pathogenic cold reactive autoantibodies should be protected from unnecessary exposure to low temperatures (Petz, 2008). Cases of secondary disease, for example CAS or PCH associated with infection, may be transient or resolve with treatment of the underlying condition. Corticosteroids or cytotoxic drugs have been used to treat CAS, but the response is frequently poor (Petz, 2008), and better results have been obtained by targeting B cells with the anti-CD20 monoclonal antibody rituximab (Berentsen et al., 2004).

Corticosteroids, such as prednisolone, are the most common therapy for warm AIHA and can be highly effective, although many patients relapse after withdrawal of these drugs (Packman, 2008). Corticosteroids can both downregulate macrophage Fc γ R to improve the survival of IgG-sensitized RBC (Fries et al., 1983) and reduce autoantibody production (Rosse, 1971; Sokol and Hewitt, 1985), but the rapid response they typically elicit suggests the importance of the former effect (Packman, 2008). Cytotoxic drugs such as cyclophosphamide or azathioprine may be used to suppress immune responsiveness, and splenectomy can also be considered to remove a major site of extravascular hemolysis (Packman, 2008; Crowther et al., 2011). Ablation of B cells with rituximab is now available as an effective treatment for AIHA that is refractory to conventional treatments (Zecca et al., 2003; Peñalver et al., 2010; Crowther et al., 2011).

ETIOLOGY OF AIHA AND PREDISPOSING FACTORS

It is clear that autoimmune diseases result from the interaction of multiple factors (Shoenfeld and Isenberg, 1989; Cho and Gregersen, 2011). Genetic background, gender, age, environmental factors such as infections, drugs, and neoplasia have all been implicated in the etiology of AIHA.

Genetic Predisposition

The possibility of a genetic predisposition to human AIHA was raised by rare reports of familial disease (Cordova et al., 1966; Pirofsky, 1968; Pollock et al., 1970; Lippman et al., 1982; Olanoff and Fudenberg, 1983). Particular human leucocyte antigen (HLA) haplotypes are the strongest genetic determinants of many autoimmune diseases (Shoenfeld and Schwartz, 1984; Caillat-Zucman, 2009; Cho and Gregersen, 2011; Lessard et al., 2012), and warm AIHA is positively associated with HLA-DR15, with approximately 60% of patients expressing this allele (Stott et al., 2002). Genome-wide association studies of other human autoimmune diseases reveal that large numbers of non-HLA genes further contribute to susceptibility (Cho and Gregersen, 2011; Lessard et al., 2012), and predisposition of the NZB mouse to AIHA has also been attributed to multiple loci (Chused et al., 1987; Lee et al., 2004; Scatizzi et al., 2012). The molecular bases of most such associations remain unknown. However, in common with other autoimmune-prone strains, the NZB mouse shares a promoter haplotype that is associated with reduced expression and function of the inhibitory Fc receptor Fc γ RIIb (Pritchard et al., 2000). The effects of the polymorphism on Fc γ RIIb expressed by macrophages and B cells are

enhanced phagocytosis of IgG opsonized RBC, and increased antibody responsiveness (Pritchard et al., 2000; Kikuchi et al., 2006).

Gender and Age

Unlike most other human autoimmune diseases (Talal and Ahmed, 1987), the incidence of AIHA is no higher in women than in men (Pirofsky, 1976; Sokol et al., 1981, 1992). AIHA becomes progressively more common with age (Sokol et al., 1981, 1992), perhaps reflecting defects in immune regulation (Tomer and Shoenfeld, 1988; Talor and Rose, 1991; Akbar and Fletcher, 2005).

Infectious Agents

Infectious agents are commonly implicated in provoking autoimmune disease in susceptible individuals (Shoenfeld and Isenberg, 1989), with almost 10% of human AIHA patients reported to have concurrent bacterial or viral conditions (Sokol et al., 1981, 1992), and RBC autoantibodies induced in mice by LCMV (Coutelier et al., 1994). Cross-reactivity between bacterial lipopolysaccharide and the blood group antigen I has been proposed to explain the high incidence of transient CAS which follows human *Mycoplasma pneumoniae* infection (Costea et al., 1972). The potential for mimicry to induce warm AIHA is exemplified by the disease that develops in mice following repeated injections of RBC expressing cross-reactive antigens from a closely related species, the rat (Playfair and Marshall-Clarke, 1973; Barker et al., 1993a). Studies of NZB mice also suggest that cross-reactivity between a microbe and a self-epitope can focus a predisposition to autoimmunity onto a particular target, even when not a primary or sufficient cause of disease (Hall et al., 2007). A second mechanism linking infection and AIHA is the ability of innate microbial stimuli and the cytokines they induce to activate antigen-presenting cells (APC) and therefore to enhance the immunogenicity of RBC autoantigens (Elson et al., 1995; Coutelier et al., 2007). Changes to the cytokine milieu resulting from infection, particularly IFN- γ production, can also enhance RBC phagocytosis by modulating both the subclass of autoantibody and the activation of macrophages (Atkinson and Frank, 1974; Coutelier et al., 2007). Finally, particular infectious agents associated with AIHA, such as Epstein–Barr virus, may directly infect and dysregulate immune cells (Bowman et al., 1974).

Drugs

Immune-mediated hemolytic anemias are a rare side effect of many drugs, including the penicillins, but in most cases the antibodies are not strictly autoreactive and

only bind RBC in the presence of the drug (Garratty, 2010). However, other examples such as α -methyl dopa can induce true RBC autoantibodies that may cause AIHA (Sokol et al., 1981), by perturbing immune regulation (Kirtland et al., 1980), or altering the antigenic structure of RBC (Owens et al., 1982).

Neoplasia

Up to 22% of human AIHA cases suffer from some form of concurrent neoplastic disease (Sokol et al., 1981, 1992). Many patients with CAS have a monoclonal RBC autoantibody associated with a clonal lymphoproliferative disorder (Silberstein et al., 1986), most frequently classified as lymphoplasmacytic lymphoma (Berentsen and Tjønnfjord, 2012). Warm AIHA, and autoimmune thrombocytopenia, are both closely associated with CLL. Over 10% of AIHA cases are also diagnosed with the condition (Sokol et al., 1992), and circulating leukocytes with an abnormal CLL-like phenotype can be detected in a further 19% of patients classified with apparent primary AIHA (Mittal et al., 2008). Conversely, up to 14% of CLL patients have AIHA or elevated levels of RBC-bound autoantibody (Dearden et al., 2008). One model to explain this association is that the large numbers of the malignant CLL cells present in the spleen drive an autoimmune response to circulating cells by acting as aberrant APC (Hall et al., 2005).

IMMUNE MECHANISMS UNDERLYING LOSS OF SELF TOLERANCE IN WARM AIHA

The study of specific pathogenic responses to RBC autoantigens has enabled mechanisms underlying the loss of self tolerance in warm AIHA to be characterized.

B Cells and Tolerance

Although RBC destruction is autoantibody mediated, it is not necessary to invoke a defect in B cell repertoire selection to explain the loss of tolerance in AIHA. Central tolerance of self-reactive B cells is incomplete in healthy individuals, since anti-RBC autoantibodies with a wide range of specificities can be induced to cause AIHA in murine strains that have no predisposition to spontaneous disease (Day et al., 1989; Barker et al., 1993a). Nevertheless, one model of AIHA, created by transgenic expression of an anti-RBC monoclonal autoantibody from NZB mice, does illustrate the potential for pathology to result from failure to censor autoreactive B cells (Murakami et al., 1992). The B cells producing monoclonal antibody are sequestered in the peritoneal cavity, and

survive to cause disease in only a proportion of mice, depending on whether they are deleted by contact with RBC (Murakami et al., 1992).

T Helper (Th) Cell and Tolerance

There is a long-standing belief that self tolerance in the T cell compartment is less secure than for B cells, and that, in health, antibody-mediated diseases such as AIHA are prevented due to lack of effective help (Naysmith et al., 1981; Elson and Barker, 2000). The vast majority of IgG responses are T dependent (Kelsoe, 1995), and the production of warm autoantibodies in AIHA appears to be no exception (Elson and Barker, 2000). NZB IgG autoantibody production *in vivo* is retarded by treatment with anti-CD4 monoclonal antibody (Oliveira et al., 1994), or by CD4 gene deletion (Chen et al., 1996), and splenic Th cells from NZB mice but not MHC-matched healthy strains, proliferate *in vitro* in response to the major murine RBC autoantigen, Band 3 (Perry et al., 1996; Shen et al., 1996). Furthermore, NZB disease is accelerated by immunization with an insoluble peptide bearing the dominant Th cell epitope from Band 3, and ameliorated by mucosal administration of a soluble analogue of this sequence (Shen et al., 2003). Other murine models are also Th dependent, since anti-CD4 mAb treated mice do not develop AIHA induced by LCMV (Coutelier et al., 1994), and T cell depletion prevents RBC autoantibody production in response to immunization with cross-reactive rat antigens (Naysmith et al., 1981). Findings in human AIHA are also consistent with the need for help. Rh autoantigen-specific effector Th cells that have been activated *in vivo* can be demonstrated in the peripheral blood and/or spleen from all patients with anti-Rh autoantibodies (Barker et al., 1997), but from very few healthy donors (Barker and Elson, 1994; Barker et al., 1997).

Warm AIHA in patients and NZB mice is associated with specific helper responses that are dominated by the Th1 subset, and inducing a corresponding Th2 bias can prevent or ameliorate NZB disease (Shen et al., 1996, 2003; Hall et al., 2002). Such a shift may be therapeutically beneficial partly because of the associated switch of the autoantibody to a less pathogenic isotype. Recent studies of human AIHA reveal that disease is also strongly associated with IL-17 responses to RBC, raising the possibility that Th17 cells may also provide help for autoreactive B cells to produce pathogenic IgG subclasses (Hall et al., 2012).

In common with B cells, it appears that potentially autoaggressive T cells can escape central tolerance as part of normal immune development, and that failure of peripheral mechanisms to control their activation results in AIHA. Healthy mice (Naysmith et al., 1981; Barker

et al., 1993a, 2002), dogs (Corato et al., 1997), and humans (Barker and Elson, 1994) all harbor naïve Th cells that can be stimulated to proliferate *in vitro* by RBC autoantigens. Comparison with AIHA patients demonstrates they differ, not in the presence or fine specificity of circulating RBC-specific autoreactive Th cells, but in the finding that these lymphocytes are activated *in vivo* (Barker and Elson, 1994; Barker et al., 1997). One possibility is that the surviving autoreactive Th cells are specific for RBC self-epitopes that are normally inefficiently processed and presented by APC from the intact antigen (Elson et al., 1995) and therefore unavailable to induce tolerance in the thymus. This model is supported by studies of human AIHA, where activated Th cells are specific for epitopes on the Rh protein autoantigens that are “cryptic” or sub-dominant (Hall et al., 1999). Such epitopes may be more efficiently presented and drive an autoaggressive Th response if APC are activated, for example by infection (Elson et al., 1995), or by the accumulation of aberrant APC types such as CLL cells (Hall et al., 2005).

It is now recognized that CD4⁺ regulatory T (Treg) cells are important mediators of peripheral self tolerance (Roncarolo et al., 2006; Sakaguchi et al., 2010; Shevach, 2011). AIHA induced by rat RBC immunization of mice provided an early example of such “infectious tolerance,” since the autoimmune response is transient and the mice become refractory to further induction of disease, with splenocytes transferred from recovered animals providing protection to naïve recipients (Playfair and Marshall-Clarke, 1973; Naysmith et al., 1981). Both the “adaptive” IL-10⁺ (Roncarolo et al., 2006) and “natural” CD25⁺FoxP3⁺ (Sakaguchi et al., 2010; Shevach, 2011) forms of Treg cell have been implicated in maintaining or restoring tolerance to RBC autoantigens. In murine AIHA induced by rat RBC, recovery is associated with protective CD25⁺ T cells (Mqadmi et al., 2005) and the development of AIHA in gene-deleted mice that lack IL-2 has been attributed to a deficiency of the “natural” Treg population (Hoyer et al., 2009). Treg cells specific for the target Rh autoantigens can be found in the peripheral blood or spleen of patients with AIHA, and are capable of inhibiting the Th1 effector responses *in vitro* by secretion of IL-10 (Hall et al., 2002). The Rh-specific Treg cells have been cloned and shown to mediate inhibitory activity only after stimulation by cognate antigen, and not in response to polyclonal activators, illustrating the importance of specificity in their function (Ward et al., 2008). Although able to secrete the “adaptive” inhibitory cytokine IL-10, these Treg cells also express the “natural” marker FoxP3, and the Th1 transcription factor T-bet, revealing plasticity between the different regulatory forms and effector subsets (Ward et al., 2008).

CONCLUDING REMARKS

In AIHA, many of the pathogenetic mechanisms by which autoantibodies can cause disease have been defined. The identification of major human and murine RBC autoantigens has also provided unique insights into the control of specific, pathogenic immune responses in both human and experimental animal disease. This work to understand how immunological tolerance is lost and can be restored holds out the prospect of more effective, specific therapies.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

General Features and Definitions

Immune thrombocytopenia (ITP) is an autoimmune acquired disease of adults and children characterized by transient or persistent thrombocytopenia resulting in a risk of bleeding. Antibody-mediated platelet destruction in the spleen has been the prevailing hypothesis to explain the pathogenesis of ITP; however, more and more data lend support to the notion that cell-mediated destruction of platelets as well as suppression of platelet production by autoantibodies and possibly T cells also contributes to an insufficient number of platelets (Cines et al., 2009).

Recent recommendations from an international working group defined that a platelet count less than 100 g/L is required for diagnosis and defined new categories of ITP based on disease duration. They proposed to avoid the term “acute ITP” and to use instead the term “newly diagnosed” for all patients at diagnosis, “persistent” for disease lasting between 3 and 12 months, and “chronic” if ITP lasts more than 12 months (Rodeghiero et al., 2009). ITP can be further characterized as being either primary or secondary to several associated disorders such as immunodeficiency diseases, autoimmune disorders, lymphoproliferative diseases, and certain infections. Finally, “severe” requires bleeding irrespective of the platelet count and “refractory” requires a failure to respond to splenectomy; the latter is not agreed upon for pediatric patients.

Diagnosis

Primary ITP remains a diagnosis of exclusion from both non-autoimmune causes of thrombocytopenia and secondary causes of ITP (Table 47.1). Distinguishing primary from secondary ITP and from, for example, inherited thrombocytopenia, is important because of different natural history and treatment.

TABLE 47.1 Differential Diagnosis of Primary ITP

| Non-Autoimmune Causes of Thrombocytopenia | |
|---|---|
| Pseudo-Thrombocytopenia | |
| Decrease of platelets production | Inherited thrombocytopenia: Bone marrow disorders (e.g., MDS, myelofibrosis) Folate or vitamin B12 deficiency Ethanol toxicity Certain viral infections |
| Decrease of platelets survival | Thrombotic thrombocytopenic purpura Disseminated intravascular coagulation Certain drugs Alloimmune thrombocytopenias (e.g., post-transfusion purpura) Cardiopulmonary bypass |
| Splenic sequestration | Portal hypertension Infiltrative diseases of the spleen |
| Dilutional Thrombocytopenia | |
| Secondary Causes of ITP | |
| Viral infections | HIV, HCV, EBV |
| Bacterial infection | <i>Helicobacter pylori</i> infection |
| Autoimmune diseases including | Systemic lupus erythematosus Autoimmune thyroiditis |
| Immunodeficiency disorders | CVID ALPS |
| Lymphoproliferative disorders | CLL Lymphoma |
| Vaccination | Measles-mumps-rubella vaccine |
| Drugs | |
| MDS, myelodysplastic syndrome; CVID, common variable immunodeficiency; ALPS, autoimmune lymphoproliferative syndrome; CLL, chronic lymphocyte leukemia. | |

Recommendations for the diagnosis of primary ITP in children and adults include a study of familial and patient history, a physical examination that should be normal aside from bleeding manifestations, and a complete blood count that should reveal isolated thrombocytopenia with normal white and red blood cell numbers. A peripheral blood smear is also mandatory (1) to exclude schistocytes or abnormalities in blood cell morphology that may suggest an underlying bone marrow (BM) disorder such as myelodysplastic syndrome or a congenital cause of thrombocytopenia and (2) to exclude hemolysis by absence of polychromasia if a reticulocyte count is not obtained. It is generally considered that a BM examination must be performed if a patient is older than 60 years, in case a bone marrow disorder is being considered, or in patients planning to undergo splenectomy (George et al., 1996). Detection of *Helicobacter pylori* (HP) infection has been proposed in adults preferably with the urea breath test or the stool antigen test (Stasi et al., 2009). Serologic evaluation for HIV and HCV infection should be performed. Other recommended tests are quantitative immunoglobulin level testing, direct antiglobulin test (DAT), and blood group Rh(D) typing (important if anti-D immunoglobulin is being considered). Several other tests such as antiplatelet antibody assays (glycoprotein-specific antibody testing), antiphospholipid antibodies, antinuclear antibodies, antithyroid antibody, thyroid function testing or viral PCR for parvovirus, EBV, and CMV have potential utility but are not systematically required for the differential diagnosis and management of ITP (Provan et al., 2010).

Epidemiology and Clinical Presentation in Children

Recent epidemiologic studies in childhood ITP demonstrated an incidence of four to five cases per 100,000 children under 15 years of age per year with a prevalence of males (Zeller et al., 2000, 2005; Kühne et al., 2001; Watts, 2004; Segal and Powe, 2006).

The peak age of presentation of ITP in children is between 5 and 6 years, with 70% of cases presenting between ages of 1 and 10 years (Kühne et al., 2003). Approximately two-thirds of children with ITP had a preceding febrile illness due to viral infections (including rubella, varicella, mumps, and EBV) or immunizations with measles-mumps-rubella vaccine (France et al., 2008).

Affected children generally have a good prognosis and the majority of patients had no or mild mucocutaneous bleeding at diagnosis (Neunert et al., 2008). Intracranial hemorrhage is the most severe complication of childhood ITP and the primary cause of death but its incidence is very

low, estimated at 0.125% to 0.5 childhood ITP (Lilleyman, 1994; Psaila et al., 2009).

Approximately 50–70% of children remit within 6 to 12 months (Kühne et al., 2003; Bennett and Tarantino, 2009), with improvement in others. Children who develop chronic ITP tend to be older, are more often female, and usually present with a higher platelet count while another predictor of chronic disease seems to be insidious onset of symptoms (Watts, 2004; Zeller et al., 2005).

Epidemiology and Clinical Presentation in Adults

Estimates of the incidence of adult ITP range from approximately 1.5 to 4 patients per 100,000 person-years depending on the threshold of platelet count used for the diagnosis. The incidence of ITP women is slightly higher compared to men, particularly in middle-aged adults. The disease incidence appears to increase with age with the absence of gender difference among older patients (Neylon et al., 2003; Schoonen et al., 2009). Mucocutaneous bleeding (petechiae, epistaxis, and gum bleeding) is the most common initial manifestation of ITP and the platelet count is predictive of more serious bleeding but not alone sufficient. Patients with platelet counts below $10 \times 10^9/L$ are at risk for severe bleeding, such as intracranial hemorrhage or other internal bleeding while intracranial hemorrhage is rare in patients with platelet counts above $20 \times 10^9/L$. Bleeding risk is higher in older patients and those with a prior history of bleeding. However, propensity to bleed remains markedly heterogeneous between patients and even between different times in the same patient. The risk of bleeding and fatal hemorrhage in adults with severe chronic ITP, defined as a platelet count of $30 \times 10^9/L$ at least 1 year after diagnosis, was analyzed by Cohen et al. using data from 17 adult case studies. They assessed the rate of fatal hemorrhage to be 0.0162 to 0.0389 cases per adult patient-year at risk and age-adjusted rates were 0.004, 0.012, and 0.130 cases per patient-year for age groups younger than 40, 40 to 60, and older than 60 years, respectively (Cohen et al., 2000). Michel et al. confirmed in a case–control study that ITP patients aged over 70 have an increased risk of bleeding and to a lesser extent a higher risk of some treatment-induced side effects (Michel et al., 2011). This greater risk of bleeding could be partially explained by the higher proportion of elderly patients taking anticoagulants or aspirin and also by the higher rate of comorbidities such as hypertension or renal failure. Adult patients with chronic ITP may have spontaneous, clinically significant (although not necessarily complete) remissions in 5–11% of cases (Neylon et al., 2003; Bizzoni et al., 2006).

AUTOIMMUNES FEATURES

Autoimmune Markers in Primary ITP

The 2010 international consensus report on the investigation and management of primary immune thrombocytopenia does not recommend researching systematically autoimmune markers. The panel considered that checking for the presence of antiphospholipid antibodies (aPLs), antinuclear antibodies (ANA), or antithyroid antibodies (ATA) does not belong to the basic evaluation but could be of potential utility in the management of certain ITP patients (Provan et al., 2010). We could, however, discuss the studies that support these conclusions.

Antiphospholipid Antibodies

Nearly half of ITP patients had either anticardiolipin antibodies (aCLs) and/or lupus anticoagulant (LA) at the time of diagnosis but the presence of these antibodies was not associated with sex, age, platelet count, or the severity of hemorrhages. The presence of aPLs does not appear to affect the response to ITP treatment (Stasi et al., 1994). Whether the presence of aPLs increases the incidence of thrombotic events is controversial (Diz-Kucukkaya, 2001). However, it seems that detection of LA emerged as a stronger risk factor for thrombosis than detection of aCLs (Diz-Kucukkaya, 2001). It seems reasonable to believe that patients with LA and ITP who have reached, after treatment, a normal platelet count may have a higher risk of developing thrombosis than the general population (Liebman and Stasi, 2007). The role of anti-beta2-GPI has not been well studied in ITP. One single study reported that significantly higher anti-beta2-GPI (IgG) mean concentrations occurred in chronic ITP cases compared with acute or control cases and that these increased IgG concentrations significantly correlated with steroid therapy resistance. But we do not know if anti-beta2-GPI may be a determinant cofactor for the developing risk of antiphospholipid syndrome or autoimmune diseases in ITP (El-Bostany et al., 2008).

Antinuclear Antibodies

ANA positivity is found in approximately 30% of adult and child patients with ITP but the detection of ANA positivity is insufficient to identify those patients with ITP who are at risk of developing systemic lupus erythematosus (SLE). Kurata et al. prospectively followed 66 adult patients with chronic ITP over 3 years. Twenty-nine of the 66 patients had a positive ANA, and throughout the period of follow-up none of these patients developed SLE (Kurata et al., 1994). However, ANA positivity may be an indicator of chronicity for childhood ITP as there is a

statistically significant difference in terms of ANA positivity between childhood acute and chronic ITP patients (Pratt et al., 2005; Altintas et al., 2007).

Antithyroid Antibodies

About 10% of ITP patients develop clinical hyperthyroidism during the follow-up (Liebman, 2007). It may also be useful to measure ATA and thyroid-stimulating hormone (TSH) at ITP diagnosis to identify a subclinical thyroid disease (Cheung and Liebman, 2009). Isolated ATA positivity is found in about 15% of childhood ITP (Pratt et al., 2005), but this is complicated because there is a 5–10% incidence of markers of thyroid disease (primarily ATA) in otherwise healthy young women. The literature is not clear about whether screening for ATA in ITP patients would identify a patient population at greater risk of developing a thyroid disease.

Evans Syndrome

Although we can find a positive direct antiglobulin test (DAT), without hemolytic anemia, in approximately 20% of patients with ITP (Aledort et al., 2004), its clinical significance is unknown. Evans syndrome (ES) is an autoimmune disorder defined by the simultaneous or sequential development of ITP and autoimmune hemolytic anemia (AIHA) with a positive DAT and/or immune neutropenia in the absence of known underlying etiology (Evans et al., 1951). The development of the second cytopenia may occur months to years after the first immune cytopenia and may delay diagnosis of Evans syndrome (Mathew et al., 1997). Michel et al. retrospectively analyzed the data from 68 ES adults. The mean age at time of first cytopenia was 52 years with 60% of women. Both cytopenias occurred simultaneously in 54.5% of cases. ES was considered as “primary” in 50% of cases but was associated with an underlying disorder in half of the cases, including mainly SLE, lymphoproliferative disorders, and common variable immunodeficiency (Michel et al., 2009). ES is characterized by recurrent episodes of relapse and remission of both ITP and AIHA. ITP episodes seem to be more frequent and harder to control than AIHA (Mathew et al., 1997). Long-term survival data are limited. Michel et al. found a mortality rate of 24% with a follow-up of 4.8 (Michel et al., 2009). Causes of death were mainly related to hemorrhage or sepsis (Norton and Roberts, 2006), although the paucity of large patient surveys and the lack of randomized-controlled trials make it difficult to make evidence-based recommendations about the optimal management of these patients. At best, the data suggest a role for corticosteroids +/- ivIg as first-line therapy in the acute setting. Cyclosporine seems to be the best second-line option for

most patients, with mycophenolate mofetil and then multi-agent therapy or rituximab.

ITP Secondary to Systemic Lupus Erythematosus

Immune thrombocytopenia is common in SLE as it occurs in 20–30% of patients during the course of the disease and may be the initial manifestation in 5%. Conversely, SLE develops in up to 5% of adult patients with ITP (Kurata et al., 1994). The risk factors to develop SLE include being older, female, having chronic ITP, and having high ANA titers (Hazzan et al., 2006). However, the ANA titer alone was not a significant predictor for the future development of SLE (Zimmerman and Ware, 1997).

Thrombocytopenia correlates with more severe disease with higher risk of damage involving heart and kidneys (Ziakas et al., 2006) and has a negative impact on the survival of lupus patients (Zhao et al., 2010). Platelet autoantibodies to platelet membrane antigens and non-specific binding of circulating immune complexes to platelet membrane, accelerating destruction by the mononuclear phagocytic system (McMillan, 1983), or the interaction of aCLs with the platelet membrane (Harris et al., 1985) are some of the mechanisms linking ITP and SLE.

ITP Secondary to Primary Immunodeficiencies

Autoimmune manifestations have increasingly been recognized as an important component of several forms of primary immunodeficiencies. We focus on four forms of PID in which autoimmune cytopenias are particularly common and may be the first manifestation of the disease: common variable immunodeficiency (CVID), autoimmune lymphoproliferative syndrome (ALPS), Wiskott–Aldrich syndrome/X-linked thrombocytopenia (WAS/XLT), and velocardiofacial (VCF)/DiGeorge syndrome.

Common Variable Immunodeficiency

Approximately one-quarter of patients with CVID develop autoimmune diseases, autoimmune cytopenias being the most common. Since ITP may precede the diagnosis of CVID, testing for immunoglobulin levels should be performed at diagnosis of ITP. Patients with CVID in association with autoimmune cytopenias seem in certain cases to have a “particular phenotype” with lower susceptibility to infection and higher susceptibility to autoimmune manifestations (Michel et al., 2004; Notarangelo, 2009). Treatment response generally seems similar to that of ITP without CVID but physicians should be aware of the increased infection risk associated with certain

treatments (e.g., splenectomy); the higher response rate to rituximab; and the occasional patient who responds completely to a short course of steroids, e.g., 1–3 months only to relapse again months to years later (Gobert et al., 2011). The recommended agents are a course of steroids (with particular attention to development of opportunistic infections which may require prophylaxis or treatment), ivIg especially at higher dose, i.e., 1 g/kg/infusion, and rituximab. After the latter and probably with steroids as well ivIg (400 mg/kg/infusion every 3–4 weeks) should be given to reduce the risk of infection.

Autoimmune Lymphoproliferative Syndrome

Autoimmune cytopenias affect over 70% of ALPS patients with a median first presentation age of 24 months. However, with increasing awareness of this condition, adults with autoimmune cytopenias are now being diagnosed more frequently (Deutsch et al., 2004) and testing for ALPS should therefore be considered in children and young adults with ES. Indeed, patients with ES frequently have other symptoms in addition to their autoimmune manifestations, which may include lymphadenopathy, hepatomegaly and splenomegaly, and these findings overlap with ALPS. Seif et al. tested 45 children with ES, measuring peripheral blood double-negative CD3+CD4–CD8– T cells (DNTs) and Fas-mediated apoptosis. ALPS was diagnosed in 47% of these patients (Seif et al., 2010). These data suggest that children with ES should be screened for ALPS. Screening is accomplished by finding an increased number of DNTs and can be confirmed functionally by *in vitro* assessment of Fas-mediated apoptosis and molecularly by finding a mutation in CD95 (Fas), which appears to be etiologic in 80–85% of patients. The pathogenesis seems to be a failure of apoptosis in autoreactive cells. Patients usually respond to immunosuppressive medications, including corticosteroids and IVIg but not as well as patients with isolated cytopenias. Splenectomy is relatively contraindicated in ALPS because of the risk of sepsis compounded, at least in children, by a lower rate of efficacy. Rituximab is highly effective but seems to create a lasting hypogammaglobulinemia for reasons not clear at this time so ideally one can avoid it in treatment. Mycophenolate mofetil may be effective in these patients as well.

Wiskott–Aldrich Syndrome/X-linked Thrombocytopenia

Wiskott–Aldrich syndrome (WAS) is an X-linked disease; affected boys exhibit microthrombocytopenia, variable degrees of eczema, combined immunodeficiency, and an increased risk for autoimmunity and lymphoid malignancies (Notarengelo et al., 2008). The disease is caused by mutations in the WAS gene, encoding the

WAS protein (WASp), a key cytoplasmic regulator of actin reorganization triggered by cell surface receptor signaling (Villa et al., 1995). The profound microthrombocytopenia seen in all individuals with WAS mutations (with the exception of a very small number of X-linked neutropenia patients) is the hallmark of the disease, and exact mechanisms underlying the thrombocytopenia of WAS/XLT patients remain incompletely defined, although WASp-deficient platelets undergo more rapid destruction than their wild-type counterparts. WAS^{-/-} mice having accelerated platelet turnover can be attributed not only to intrinsic platelet abnormalities but also in certain cases to immune-mediated mechanisms (Marathe et al., 2009).

Velocardiofacial/DiGeorge Syndrome

Velocardiofacial/DiGeorge syndrome is also known as chromosome 22q11.2 deletion syndrome, and occurs in approximately 1:4000 births. Many patients have a mild to moderate immune deficiency, and the majority of patients have a cardiac anomaly. Additional features include renal anomalies, eye anomalies, hypoparathyroidism, skeletal defects, and developmental delay (McDonald-McGinn and Sullivan, 2011). One secondary consequence of the immune deficiency is autoimmune diseases, seen in approximately 10% of patients. Juvenile idiopathic arthritis and hematologic autoimmune diseases are the most common disorders. ITP is the most common condition, occurring in 4% of patients, although platelet size and function are slightly aberrant in most patients with the deletion due to haploinsufficiency for GPIb β (Lawrence et al., 2005).

GENETICS FEATURES

Familial ITP

Family-based linkage studies are limited since familial cases of ITP are very rare. So, familial transmission of childhood “ITP” requires consideration of other genetic disorders with thrombocytopenia-like myosin heavy chain disorders (MYH9 gene), ALPS, and Wiscott–Aldrich syndrome/X-linked thrombocytopenia. In a retrospective registry analysis, Rischewski et al. found that 2.3% of 445 patients have a positive family history with a higher likelihood of patients with familial ITP presenting at an earlier age (Rischewski et al., 2006). When familial ITP occurs, it is most commonly not in first-degree relatives.

Genetic Markers of ITP

Clinical heterogeneity in ITP course, duration, and/or in drug responsiveness may prove to have genetic bases. Single nucleotide polymorphism (SNP) chip analysis and whole genome sequencing are technically feasible but

require an adequate sample size, which has been difficult to achieve in this disease. Numerous small studies have tried to demonstrate a consistent association between certain polymorphisms and ITP. Most of them, reported in the literature, affect B cell-associated genes (BAFF, Ig variable (v) gene), T cell-associated genes (CTLA4, PTPN22, SOX 13), Fc γ receptor-associated genes, cytokine-associated genes (TGF- β 1, IL-4, IL-6, IL-10, TNF- α , etc.), or antigen-associated genes (HLA, HPA) (Bergmann et al., 2010). Results of these studies are often of borderline statistical significance, perhaps because of small sample size or biological heterogeneity. It is currently thought that there are genetic contributions to ITP but this is such a multifactorial heterogeneous disease that it can be very difficult to tease out the genetic factors.

IN VIVO MODELS

Passive transfer models, in which injection of platelet-specific antibodies are given to induce or maintain a state of thrombocytopenia (Nieswandt et al., 2000; Samuelsson et al., 2001; Teeling, 2001), are the most common animal models for ITP. More recently a transplantation model was developed where in splenocytes from CD61 knockout mice immunized against CD61(+) platelets were transferred into severe combined immunodeficient CD61(+) mouse recipients (Chow et al., 2010). These models will undoubtedly play a significant role in the future research of human ITP, particularly related to understanding of the pathogenesis of the disorder and the development of novel therapeutics (see the report published by Semple et al., 2010).

PATHOLOGIC EFFECTOR MECHANISMS

In the past, a shorter platelet life span was consistently seen in ITP patients compared with the 8- to 10-day platelet survival duration in healthy controls (Heyns et al., 1986). Although historically thrombocytopenia in patients with chronic ITP was caused solely by autoantibody-induced platelet destruction it has become evident that suboptimal platelet production also plays a role.

Increased Platelet Destruction

Antibody-Mediated Platelet Destruction

Antiplatelet Antibody

In the early 1950s, Harrington et al. provided first evidence that ITP is caused by a plasma antiplatelet factor by demonstrating that infusion of plasma from ITP patients induced severe thrombocytopenia that persisted several days in non-ITP controls (Harrington et al., 1953). Subsequently, the immunoglobulin (Ig)G rich serum

fraction was found to be responsible for the antiplatelet activity by Fc γ -mediated platelet destruction in the reticuloendothelial system (Shulman et al., 1965). After several studies in the 1970s reporting nonspecific elevated platelet-associated IgG in around 90% of ITP (Dixon and Rosse, 1975; McMillan, 1981), antigen-specific assays have been developed to measure autoantibodies that recognize one or more platelet surface glycoproteins (GP). The first antigen identified was the GP IIb/IIIa complex (van Leeuwen et al., 1982). Antibodies that react with GP Ib/IX or GP Ia/IIa, among others, have since been identified, and the presence of antibodies against multiple antigens is not only possible but, in patients with chronic disease, seems relatively common (Kunicki and Newman, 1992; He et al., 1994).

Antigen-Presenting Cells (APCs)

Antibody-coated platelets bind to macrophages of the reticuloendothelial system through Fc γ receptors (Fc γ R) and are then internalized and degraded. Gamma camera imaging of ITP patients injected with ^{111}In -labeled autologous platelets revealed that destruction occurs primarily in the spleen and liver (Stratton et al., 1989). Antigen-presenting cells not only degrade GP IIb/IIIa, thereby amplifying the initial immune response, but also may generate cryptic epitopes from other platelet glycoproteins (Cines and Blanchette, 2002). The balance between the numbers of inhibitory receptors like Fc γ RIIB versus activating receptors like Fc γ RIIA and Fc γ RIIIA seems to have an important role in patients with ITP, with downregulation of the inhibitory receptor Fc γ RIIB (Asahi et al., 2008). Moreover, studies of SNP suggest that certain polymorphisms in the Fc γ RIIIA gene may be overrepresented in patients with ITP (Carcao et al., 2003) and individual Fc γ R may correlate with response to Fc γ R blockade therapy (Fujimoto et al., 2001). In particular, responses to anti-D appear to depend upon Fc γ RIIA (Cooper et al., 2004) and rituximab upon Fc γ RIIIA. Complement-induced lysis following antibody binding also plays a role in this process but the response of ITP patients to a monoclonal antibody against the Fc γ RIIIA receptor underlines the importance of the former mechanism (Clarkson et al., 1986).

CD4⁺Th Cells

CD4⁺Th cells are also implicated in antibody production as evidenced by the fact that antibodies are usually isotype switched and harbor somatic mutations. A well-known abnormality is the oligoclonal accumulation of CD4⁺Th cells in the peripheral blood of patients with ITP (Ware and Howard, 1993). Size analysis of cDNAs for the complementarity determining region 3 (CDR3) of the T cell receptor (TCR) β -variable region genes has

demonstrated the frequent use of VB3, 6, 10, and 13.1 to 14 genes (Shimomura et al., 1996). Presentation of platelet epitopes on the cell surface of activated APCs helped by costimulatory molecules (interaction between CD154 and CD40) and cytokines stimulate initiating CD4⁺Th clones and clones with additional specificities (Cines and Blanchette, 2002). T cells autoreactive to GP IIb/IIIa have been identified in ITP patients. GP IIb/IIIa-reactive T cells respond to chemically reduced and cryptic peptides of GP IIb/IIIa but not to native GP IIb/IIIa (Kuwana et al., 1998). Moreover the Th1/Th2 balance is well known to regulate the immune system under normal conditions, and is known to be impaired in many autoimmune diseases. Several studies have found evidence supporting a Th1 polarization of the immune response in ITP (Semple et al., 1996). An increased Th1/Th2 ratio has been observed in patients with active ITP (Wang et al., 2005). An increase of the Th1 cytokines, IL-2 and IFN- γ , have been shown in patients with ITP compared with controls as well as a suppression of Th2 cytokines, IL-4 and IL-5, in patients with active disease (Panitsas et al., 2004).

In ITP patients with active disease, CD4⁺CD25⁺ regulatory T cells (Tregs) are both reduced in number and defective in their suppressive capacity (Liu et al., 2007; Sakakura et al., 2007; Yu et al., 2008). Impaired function of Tregs could allow activation of autoreactive Th1 cells in ITP patients and might be responsible, upon remission, for the switch to the anti-inflammatory Th2 profile (Stasi et al., 2007).

Autoreactive B Cells

Quite separately, several studies have specified B cell clonality in patients with ITP on the basis of light chain restriction in anti-platelet autoantibodies (Stockelberg et al., 1995; McMillan et al., 2001; Roark et al., 2002). However, a more recent study found no evidence of B cell receptor clonality by a more sensitive method of spectratyping analysis (Toffoletti et al., 2008). Abnormal B cells and their factors play a role in the pathogenesis of ITP. B cell activating factor (BAFF), for example, belonging to the family of tumor necrosis factor (TNF) ligands, is critical for the maintenance of normal B cell development, homeostasis, autoreactivity, and T cell costimulation (Moisini and Davidson, 2009). In addition, BAFF augments Th1-associated inflammatory responses (Sutherland et al., 2005). The levels of plasma BAFF and BAFF mRNA are elevated in active ITP patients, whereas in patients in remission, normal levels of plasma BAFF and BAFF mRNA expression were observed. The high levels of BAFF in ITP have been shown to be responsible for promoting the survival of autoreactive CD19⁺ B cells and CD8⁺ T cells (Zhu et al., 2009).

T Cell-Mediated Cytotoxicity and NK Cell Activity

The absence of detectable autoantibody in a subset of ITP patients as well as the failure of some patients to respond to splenectomy suggests the presence of alternative platelet destruction mechanisms. Olsson et al. were the first to demonstrate that T lymphocytes from some patients with ITP lyse human platelets and they showed increased expression of cytotoxic genes such as tumor necrosis factor α , perforin, granzyme A, and granzyme B (Olsson et al., 2003). This study was confirmed more recently in a large clinical study (Wang et al., 2005). Furthermore, a novel mouse model of ITP was recently developed that also demonstrates platelet-specific CD8⁺ T cell immunity (Chow et al., 2010). Furthermore, genes from several members of the KIR receptor family that downregulate cytotoxic T lymphocytes were increased in patients in remission when compared with those with active ITP (Olsson et al., 2005). Similarly, an expansion of the CD56⁺CD3⁻ NK cell subsets has been reported in patients with active ITP (Garcia-Suarez et al., 1993).

Insufficient Platelet Production

Anomalies of Megakaryopoiesis

Autologous platelet survival studies showed that most ITP patients have normal or decreased platelet turnover, suggesting that platelet production in chronic ITP may also be impaired (Heyns et al., 1986; Ballem et al., 1987; Gernsheimer et al., 1989). Furthermore, early light microscopic observations of ITP bone marrow showed increased immature megakaryocytes with manifested degenerative changes in the nucleus and cytoplasm (Diggs and Hewlett, 1948). Various ultrastructural abnormalities of ITP megakaryocytes, including cytoplasmic vacuolization and distended demarcation membrane system, have also been described (Ridell and Branehög, 1976; Houwerzijl et al., 2004).

Serum Levels of Thrombopoietin (TPO)

TPO is a glycoprotein produced first and foremost in the liver and, to a lesser extent, in the kidney and bone marrow (Geddis et al., 2002; Kaushansky, 2005). It exerts biological effects on hematopoietic stem cells as well as megakaryocytes and platelets via its high-affinity receptors (c-Mpl) that bind and internalize the hormone receptor complex (Kuter and Rosenberg, 1995). Circulating TPO is mediated by an autoregulatory feedback loop. In thrombocytopenia, less TPO is bound to platelets and circulating levels increase, allowing binding to c-Mpl on megakaryocytes and hematopoietic stem cells, stimulating megakaryocyte development and platelet production (Li et al., 1999).

However, ITP patients demonstrate normal or only slightly increased level of TPO in contrast to the elevated levels found in patients with thrombocytopenia due to bone marrow failure (Mukai et al., 1996). This suggests that circulating TPO levels are regulated by all c-Mpl expressing cells of megakaryocyte lineage (Debili et al., 1995) and not primarily by the absolute number of circulating platelets. Because TPO could bind to the c-Mpl's increased megakaryocyte mass with subsequent internalization and degradation, the levels of TPO could be lower than expected in ITP (Kuter, 1996). This provides a rationale for the ability of supplemental TPO effect to increase platelet production.

Effect of Antiplatelet Antibodies on Megakaryocytopoiesis

As megakaryocytes also express GP IIb/III or GP Ib/IX on their surfaces during maturation (Vainchenker et al., 1982), the circulating autoantibodies could interfere with the megakaryocytes, provoke intramedullary megakaryocyte or platelet destruction, and hamper megakaryocyte maturation (McMillan et al., 1978). Chang et al. evaluated the effect of plasma from patients with childhood ITP on thrombopoietin-induced production of megakaryocytes from cord blood cells in liquid culture. They noted that plasma from ITP patients with detectable antiplatelet antibodies inhibits the *in vitro* production and maturation of megakaryocytes, whereas plasma from control subjects or ITP patients without demonstrable antibodies did not (Chang et al., 2003). These studies would imply that the number of megakaryocytes should be reduced in these patients but instead it has been repeatedly shown that the number of megakaryocytes is usually increased. This suggests that *in vivo* the megakaryocytes are made but then damaged such that they are in the marrow but relatively non-functional. T cell-mediated inhibition of megakaryocytopoiesis as well as increased apoptosis of megakaryocytes is also probably involved in the disturbance of platelet production but little studied (Figure 47.1).

Infection-related Thrombocytopenia

Mechanisms of platelet destruction in thrombocytopenia associated with lymphoproliferative disorders and collagen vascular diseases are similar to those in primary ITP, whereas infection-associated ITP occurs via various mechanisms as described below.

Molecular Mimicry

Molecular mimicry suggests that antigenic structures, such as those on infectious agents, resemble host self-antigenic structures and trigger anti-self reactivity. For example, it

has been reported that HIV, HCV, and the drug quinine stimulate a particular IgG antibody that reacts with a specific amino acid domain of the platelet GP IIIa (Zhang et al., 2009; Aster, 2009). Antibodies to both HIV and HCV destroy platelets by inducing platelet-generated reactive oxygen species via NADPH oxidase activation (Zhang et al., 2009). There is also strong evidence for an association between infection with HP and ITP, which may be related to molecular mimicry (Liebman and Stasi, 2007; Stasi et al., 2009). Platelets may be activated by binding of HP antibodies to platelet Fc γ IIA or through an interaction between HP-bound von Willebrand factor and platelet GPIB. Activation may promote platelet clearance and antigen presentation, which augments production of antibacterial antibodies (Cines et al., 2009).

Mechanisms other than Molecular Mimicry

Other mechanisms include accelerated platelet clearance due to immune complex disease (Karpatkin et al., 1995; Samuel et al., 1999). Alternatively, chronic infection may change the cytokine milieu, encourage loss of tolerance and stimulate B cells (Yun et al., 2005). Additional evidence exists for defective platelet production and direct infection of megakaryocytes resulting in megakaryocytic apoptosis. Several studies have postulated direct HIV cytopathic infection of the megakaryocyte as a mechanism for decreased platelet production (Sato et al., 2000; Sundell and Koka, 2006), as well as the binding to and possible infection of megakaryocytes by HCV (Bordin et al., 1995). Finally, advanced hepatic fibrosis (cirrhosis) in HCV may cause altered production of TPO and also portal hypertension with enlarged spleen. The latter may play a central role in the pathogenesis of thrombocytopenia in chronic viral hepatitis of any cause (Adinolfi et al., 2001).

AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

Direct tests for anti-GP IIb/IIIa and/or anti-GP Ib/IX have good specificity (78–93%), but very moderate sensitivity (49–66%) in prospective studies (Warner et al., 1999; McMillan, 2003). Indirect tests were only rarely positive. This low sensitivity of platelet antibody test may have several explanations including: (1) the population's heterogeneity in the different studies, (2) the platelet autoantibodies may be missed by current monoclonal-based assays that only detect antibodies with known specificity (typically, GP IIb/IIIa and GP Ib/IX), and (3) the circulating autoantibodies may be undetectable because of their sequestration in other tissues and/or cells (particularly megakaryocytes). The diagnosis of ITP (both primary and secondary) is generally accepted to be one of exclusion.

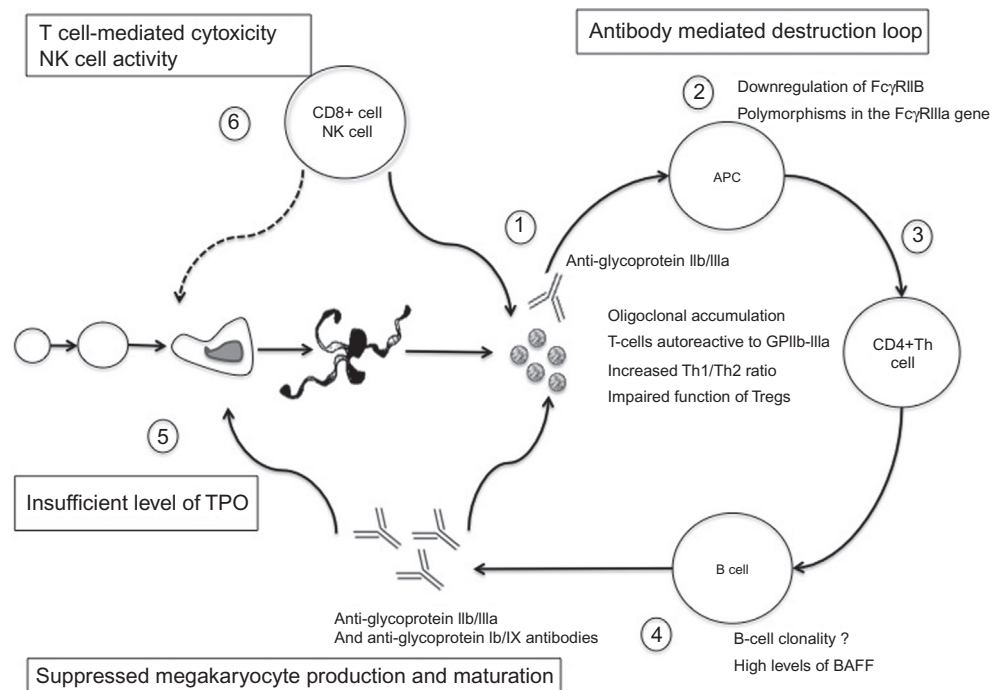

FIGURE 47.1 Central and peripheral pathogenesis of ITP. The factors that initiate autoantibody production are unknown. Here, glycoprotein IIb/IIIa is recognized by autoantibody, whereas antibodies that recognize the glycoprotein IIb/IX complex have not been generated at this stage (1). Antibody-coated platelets bind to antigen-presenting cells (macrophages or dendritic cells) through Fc γ receptors and are then internalized and degraded (2). Antigen-presenting cells not only degrade glycoprotein IIb/IIIa thereby amplifying the initial immune response, but also may generate cryptic epitopes from other platelet glycoproteins. Activated antigen-presenting cells express these novel peptides on the cell surface along with costimulatory help and the relevant cytokines that facilitate the proliferation of the initiating CD4-positive T cell clones (3). B cell immunoglobulin receptors that recognize additional platelet antigens are thereby also induced to proliferate and synthesize anti-glycoprotein IIb/IX antibodies in addition to amplifying the production of anti-glycoprotein IIb/IIIa antibodies (4). Antiplatelet autoantibodies may also induce decreased megakaryocyte production and suppressed megakaryocyte maturation, which is compounded by an insufficient level of TPO (5). Finally, cytotoxic T cells may exert cell-mediated lysis on megakaryocytes, as well as on platelets (6).

Although three prospective studies indicate that the detection of platelet autoantibodies has a high positive diagnostic value for ITP (Brighton et al., 1996; Warner et al., 1999; McMillan et al., 2003), the utility of platelet autoantibody assays in the clinical course of ITP is still a matter of debate and is not currently recommended (Provan et al., 2010). Nevertheless, several studies highlight the prognostic value of platelet autoantibody detection (Brighton et al., 1996; Berchtold and Wenger, 1993), such as Fabris et al., who demonstrate that ITP patients with platelet autoantibodies have a worse clinical course than patients without antibodies (Fabris et al., 2004). A recent study by Zeng et al. emphasizes that steroid (and IgIV) response depends on anti-GP IIb/IIIa vs. anti-GPIIb α antibodies (Zeng et al., 2012). The preliminary findings of this study suggest that the anti-GPIIb α and -GP IIb/IIIa status should be assessed in future clinical trials including corticosteroids in order to test its potential relevance in deciding future treatments.

CONCLUDING REMARKS—FUTURE PROSPECTS

ITP is a heterogeneous syndrome with a complex pathogenesis. Immune platelet destruction in ITP occurs by a complex process involving multiple components of the immune system. While new insights into the complex interplay involving humoral and cellular immunity have been provided, the triggering event for ITP, for the immune dysregulation, is still unknown. The mechanism of ITP involves insufficient platelet production and autoantibody-mediated platelet destruction. Some key points of ITP pathogenesis remain unresolved, including how interruption in the normal function of the immune system occurs. The success of the TPO receptor agonists suggests a fundamental concept, namely that platelet production by megakaryocytes is often sub-optimal and increasing it might compensate for autoantibody-mediated platelet destruction.

HISTORICAL BACKGROUND

In 1926, Charles Doan observed that sera from some patients agglutinated leukocytes from other individuals. This was the beginning of modern leukocyte immunology. The first report on autoimmune leucopenia was that of Franke (1940), who attributed the disorder to the “leukolysine” he found in a patient’s serum. Later, in 1948 Hickie reported a serum inhibitor of bacterial phagocytosis in a patient who had chronic agranulocytosis. Serum of this patient also neutralized the ability of normal leukocytes to prevent growth of bacterial colonies in a culture medium. “Leukocitidin” was reported by Wiard and Robbins (1952) in the serum of a pancytopenic patient. In this patient, the widespread leukophagocytosis observed at autopsy suggested that the patient had a severe autoimmune disorder. Dausset and Nenna (1952), Moeschlin and Wagner (1952), and Goudsmit and van Loghem (1953) then established an association between leucopenia and leukoagglutinins. Steffen and Schindler (1955) introduced the antiglobulin consumption test with which “incomplete” leukocyte autoantibodies could be demonstrated in sera of some neutropenic patients. Butler (1958) showed that infusion of plasma from neutropenic patients into normal recipients could cause leukopenia. Further progress in leukocyte immunology was the discovery that leukocyte antibodies develop as a result of pregnancy (Payne and Rolfs, 1958; van Rood et al., 1959). In 1960, Lalezari and

associates demonstrated that fetal–maternal neutrophil incompatibility might cause neonatal neutropenia, a condition analogous to erythroblastosis fetalis (Lalezari et al., 1960). This led to the discovery of NA and NB neutrophil-specific antigens involved in fetal–maternal incompatibility (Lalezari and Bernard 1966; Lalezari et al., 1971). The efforts of an international cooperative research, initiated in 1964, led to the discovery of human leukocyte antigens (HLAs), the antigens that are expressed on lymphocytes and many tissues and are markers for histocompatibility (Rodney and Lalezari, 2000). The finding of neutrophil-specific antigens suggested that other nucleated cells may also express “organ-specific” antigens. Autoimmune neutropenia was then established as a definable clinical entity when neutrophil-specific antigens were demonstrated to be a target in primary autoimmune neutropenias. More recently, the structure, genetics, and functions of neutrophil-specific antigens were determined and the finding that NA is a receptor for IgG was helpful in better understanding its clinical implications. Finally, the availability of colony-stimulating factors for treatment has had a major impact on the management of all neutropenias.

CLINICAL AND PATHOLOGIC FEATURES

The levels of blood cells in circulation are determined by the rate of their production and their destruction. Neutrophil

levels are also influenced by their large marginal pool. Neutropenia is defined by reduction of absolute neutrophil and band counts forms to below $1 \times 10^9/L$ in infants and to $1.5 \times 10^9/L$ in adults. Autoimmune neutropenias are probably as common as the more familiar autoimmune disorders of red cells and platelets, with clinical manifestations varying from being totally asymptomatic to severe forms complicated by overwhelming sepsis. Most patients develop intermittent mucocutaneous infections. Splenomegaly is an exception. Hematologically, the patients have selective neutropenia, while monocytes, eosinophils, and basophils are either normal or increased. Lymphocyte counts are normal or occasionally reduced. Platelets are normal, and in chronic forms hypergammaglobulinemia and a mild anemia, due to persistent infections, may exist. Bone marrow shows myeloid hyperplasia with a distinctly diminished number of mature cells, resembling “maturation arrest.” This is particularly relevant to cases when neutrophil-specific antigens are the targets of autoimmunity as these antigens develop after the myelocytic phase of maturation. Clinically, autoimmune neutropenia is divided into primary and secondary forms, the latter being associated with other immunological disorders. In primary forms, the diseases in children and adults are distinct.

AUTOIMMUNE NEUTROPENIA OF INFANCY

Since the first reports in which neutrophil-specific antigens were identified as the targets (Lalezari et al., 1975, 1986), many cases with similar features have been reported (McCullough et al., 1988; Bux et al., 1998). Autoimmune neutropenia of infancy (AINI) is characterized by a severe neutropenia diagnosed when infants are about 5–8 months old. Neutropenia is commonly associated with bacterial or fungal infections, and spontaneous recovery within 1–4 years is the rule. Diagnosis is made by demonstration of neutrophil-bound and circulating antineutrophil antibodies. The cause of AINI remains unclear. It was suggested that the disease represents a “physiologic state” in which strong autologous antigens provoke an immune response in infants in whom the immune regulatory system is underdeveloped (Lalezari et al., 1986). In AINI, the neutrophil counts are normal at birth probably because of immaturity of the immune system and inability to produce IgG antibodies. Later, with maturity of the immune regulatory system, autoantibody production is prevented. A long-term follow-up of AINI has confirmed that once recovered, the affected children remain immunologically normal. On rare occasions, some patients remain chronically and severely neutropenic. These patients may represent a wrong diagnosis or a subgroup of chronic autoimmune diseases seen in adults and adolescents.

PRIMARY AUTOIMMUNE NEUTROPENIA IN ADOLESCENTS AND ADULTS

Primary neutropenias in adolescents and adults are often chronic and debilitating with preponderance in females (reviewed by Shastri and Logue, 1993). Newborn infants from such mothers may develop a transient neutropenia due to transfer of the maternal autoantibodies across the placenta (Stefanini et al., 1958). Acute forms of autoimmune neutropenia are relatively rare and are self-limited. Little information is available on the specificities of the antibodies in adult forms. In a report by McCullough et al. (1988), the antibody had partial specificity for NA1. We documented NA1 specificity in a 73-year-old man who had acute neutropenia. The patient had a past history of sarcoidosis but had not received transfusion of blood or blood products. He acutely developed fever, severe pharyngitis, and gingivitis. His total leukocyte count was below $800/\mu l$ with absent neutrophils. Platelets were normal but he had a mild anemia. All other laboratory data were normal except for a positive test for antinuclear antibodies. Bone marrow was hyperplastic with absence of mature neutrophils. After 15 days of persistent severe neutropenia, treatment with prednisone was initiated and then discontinued after 3.5 months. Within 10 days after the start of treatment, the neutrophil count rose to $12,000/\mu l$ and remained normal. The blood sample obtained before prednisone treatment contained a strong agglutinating antibody that reacted with neutrophils from all 28 NA1-positive donors and none of the 12 NA1-negative donors. The blood samples obtained 3 and 6 months after recovery did not react with neutrophils from any of 30 donors tested. The patient’s neutrophils, obtained after recovery, were typed as NA1/NA2 and reacted strongly with the autologous sera obtained during the neutropenic phase, but not with the recovery samples. It is of interest that the target of the autoantibody was NA1 and not NA2, suggesting that NA1 may be more immunogenic than NA2. We also diagnosed a severe autoimmune neutropenia in a 12-year-old boy who was homozygous NA2 and had a high titer anti-NA2. The patient died of overwhelming sepsis.

NEUTROPHIL-SPECIFIC ANTIGENS IN PRIMARY AUTOIMMUNE NEUTROPENIAS

NA and rarely NB neutrophil-specific antigens are often the targets of autoantibodies in primary autoimmune neutropenias in early childhood. These antigens are anchored to the outer leaflet of the lipid bilayer of neutrophils via a glycosylphosphatidylinositol structure. NA has been determined to be the low-affinity receptor for IgG (Fc γ RIIb) (Ory et al., 1989) and its gene mapped to chromosome 1q22–24. The alleles of the NA are NA1,

NA2, and SH (Bux et al., 1997). Some rare individuals lack the Fc γ RIIIb gene and are called NA^{null} with a frequency between 0.1 and 0.8% (reviewed by Flesch et al., 1998). The NB antigen is expressed on CD177 glycoprotein (Stroncek et al., 2001) and its gene is located on chromosome 19 at 19q13.2 (Kissel et al., 2001). Recently, a glycoprotein called PRV-1 has been identified and has been shown to be overexpressed in polycythemia Vera and in some patients with essential thrombocytosis (Temerinac et al., 2000). Caruccio et al. (2004) have provided evidence that PRV-1, which belongs to the LY6/snake toxin gene and differs from NB1 in four nucleotides, is an allele of NB1, although the possibility of gene duplication has not been excluded.

The reason for involvement of neutrophil-specific antigens as the target of autoimmunity remains unclear. One possible explanation may be their strong immunogenicity. This would be similar to the strong immunogenicity of the Rh complex in the red blood cells, which are the main targets in fetal–maternal incompatibility as well as in autoimmune hemolytic anemias. An important aspect of the neutrophil-specific antigens, mainly the NA system that is most commonly targeted, is its physiological function as the IgG Fc γ RIIIb receptor. This receptor has a critical role in the removal and phagocytosis of opsonized bacteria, the NA2 allele being less effective than NA1 (Bredius et al., 1994). Neutrophils are crucial for host defense in the oral cavity, a reason for frequent oral infections in neutropenic patients. In studying *Porphyromonas gingivalis*, a bacterium that causes periodontitis, Kobayashi et al. (2000) and Fu et al. (2002) have demonstrated that individuals with NA2 phenotype are more susceptible to gingivitis and more resistant to treatment. These findings also suggest that in autoimmune neutropenias, patients with anti-NA1 may be more symptomatic than those with anti-NA2. Many children with AINI have been reported to have high levels of immune complexes (Lalezari et al., 1986). This may result from low absolute number of neutrophils in which the Fc γ II (CD32) receptors are responsible for clearance of immune complexes.

Secondary Autoimmune Neutropenias

Association of neutropenia with autoimmune hemolytic anemia or thrombocytopenia is not uncommon, as in Evans syndrome (Evans et al., 1951). A special combination, which we have designated “alternating autoimmune hemocytopenia,” is characterized by being multiphasic. Initially, cytopenia is limited to thrombocytopenia, neutropenia, or hemolytic anemia, and responds to treatment. After an interval, which may last from months to years, the autoimmune process recurs, this time involving another cell type. Alternation between neutropenia,

hemolytic anemia, and thrombocytopenia continues for several years, and eventually a combination prevails that is severe and resistant to treatment. Autoimmune neutropenia may be associated with hematological malignancies such as hairy cell leukemia and T-LGL (T cell large granular lymphocytic leukemia) (Loughran, 1985). T-LGL, a lymphoproliferative clonal disease of cytotoxic T cells, is associated with T cell receptor rearrangement (O’Keefe et al., 2004). Non-hematologic autoimmune disorders associated with neutropenia include systemic lupus erythematosus (SLE), Sjögren’s syndrome, Graves’ disease, rheumatoid arthritis, Felty’s syndrome, common variable immunodeficiency, and immune complex diseases (Breedceld et al., 1986).

Little is known about the target antigens in secondary immune neutropenias. The i and I antigens, the targets of red cell cold agglutinins, are also expressed on neutrophils and platelets, and high titer cold agglutinins cause neutropenia and thrombocytopenia (Lalezari and Murphy, 1967; Markenson et al., 1975). Antineutrophil cytoplasmic antigens also have been reported to be involved in some secondary autoimmune neutropenias (Hagen et al., 1993; Coppo et al., 2004).

DIFFERENTIAL DIAGNOSIS

Diagnosis of secondary neutropenias largely depends upon recognition of the underlying disease and awareness of their potential association with neutropenia. Positive diagnosis of autoimmune neutropenia and distinction from the genetic forms in infants is an important task for physicians and a crucial issue for the anxious parents. In mild and asymptomatic patients, a form of neutropenia known as “ethnic neutropenia” should be considered before other diagnoses are made. Ethnic neutropenias occur in individuals of African descent, Sephardic Jews, and Middle Eastern Arabs. The absence of neutropenia in siblings does not exclude this diagnosis. In infants, acute neutropenia occurs in association with viral and bacterial infections because of bone marrow suppression and its limited capacity to respond to demand. In mycoplasma pneumonia and infectious mononucleosis, cold-reacting antibodies are likely to be contributing factors to neutropenia. In chronic neutropenias in infants, AINI and neonatal neutropenia due to fetal–maternal incompatibility are the most common forms. Distinction can be made between these two entities by their starting differences: in alloimmune neonatal neutropenia, infants are neutropenic at birth and the antibodies are found in both the maternal and the newborn plasma whereas in AINI, neutrophil counts are normal at birth and the infants become neutropenic after several months; antibodies are found in the infant, not the maternal, blood.

The rare genetic forms of neutropenia that must be considered after transient and immunological forms are excluded include: cyclic hematopoiesis—a dominant, genetic disorder with 21-day cycles of severe and symptomatic neutropenia at nadir and sub-normal neutrophil counts at peak; cyclic neutropenia—caused by mutations in the ELA-2 gene that encodes for neutrophil elastase (Horwitz et al., 1999); and severe congenital neutropenias (SCN), also known as Kostmann's syndrome (Kostmann, 1956)—genetically heterogeneous disorders with 35–85% ELA-2 mutations (Dale et al., 2000), characterized by severe neutropenia and maturation arrest at promyelocyte level. Most cases arise sporadically with potentially lethal autosomal dominant mutations. Ten percent develop acute myelogenous leukemia with additional mutations at the G-CSF-receptor gene, monosomy 7, trisomy 21, and ras.

Details on other congenital forms that include Schwachman–Diamond syndrome, primary congenital immunodeficiency, Barth syndrome, cartilage hair hypoplasia, and Chediak–Higashi syndrome can be found in pediatrics literature.

Mechanisms of Cell Destruction

Most information on the mechanisms of neutrophil destruction in immunologic diseases is based on laboratory observations, but relevance to *in vivo* events has not yet been established. Neutrophils usually respond to their antibodies by agglutination, a reaction which, unlike red cells, is an active process requiring living cells. Neutrophils also aggregate in the presence of activated complement and adhere to endothelial cells (Jacob et al., 1980). Some neutrophil antibodies are known to activate the complement system, and thereby initiate complement-induced neutrophil aggregation. Thus, the *in vivo* neutrophil aggregation may be a mechanism for neutrophil removal in some autoimmune neutropenias. Boxer and Stossel (1974) have shown that neutrophils coated with auto- or alloantibodies can stimulate phagocytic cells. Leukophagocytosis is seen in the spleen of some patients with autoimmune neutropenia and indicates that this organ is a location for the clearance of opsonized neutrophils. However, using ¹¹¹In-labeling techniques, McCullough et al. (1988) have shown that neutrophils are not cleared at any selective site, but are removed by phagocytic cells distributed in many tissues. Cytotoxicity, either complement mediated or cell mediated, has been shown *in vitro* by dye exclusion test or by release of ⁵¹Cr. Inhibition of colony-forming unit (CFU)-C colonies by lymphocytes from neutropenic patients has been demonstrated in Felty's syndrome, rheumatoid disorders, and SLE. Neutrophils bind circulating immunoglobulins. This binding of immune complexes to Fc γ RII may not be

innocuous and lead to neutropenia, by complement activation, phagocytosis, or apoptosis (Gamberle et al., 1998). Also, binding of immune complexes to neutrophils causes their activation and adherence to endothelial cells. This would change neutrophil distribution and increase the marginal pool (Breedceld et al., 1986). Many patients with known immune complex diseases, however, are not neutropenic. Neutropenia in acquired immune deficiency syndrome (AIDS) may be due to myelosuppression or to immune complexes. A positive test for a high level of neutrophil-bound immunoglobulins is a common finding in AIDS patients. Many drugs cause dose-dependent neutropenia due to myelotoxicity and interference with protein synthesis and cell replication. Some drug-induced neutropenias are not dose related and are considered to be immunologic in nature. In rare cases, the antibodies or the suppressor cells are directed against progenitor cells, causing pure white cell aplasia (Levitt et al., 1983).

Finally, autoantibodies can alter neutrophil functions. The binding of anti-NA to the Fc receptor interferes with neutrophil phagocytic functions. The report by Kramer et al. (1980) exemplifies the inhibition of neutrophil motility by an IgG autoantibody, causing a non-neutropenic clinical condition indistinguishable from chronic neutropenic states. Thus, neutrophil dysfunction may explain the severity of clinical manifestations in cases where symptoms are disproportionate to the number of neutrophils.

LABORATORY DIAGNOSIS

Techniques available for detection of neutrophil antibodies have been summarized elsewhere (McCullough et al., 1988). In autoimmune neutropenia, as in other autoimmune diseases, direct examination of the target cells should be most relevant. Because of limitations in obtaining adequate numbers of neutrophils in neutropenic patients, however, it is often necessary to use indirect techniques. One exception may be the immunofluorescence (IF) test (Verheugt et al., 1977), which requires fewer cells. In this procedure, the use of specific antiglobulin reagents and flow cytometry allows determination of the class and subclass of antibodies. In the IF test, as it is used with a microscopic aid, neutrophils should be distinguished from the frequently present monocytes that strongly react with the labeled antiglobulin reagents. In addition, neutrophils of patients who receive granulocyte-colony-stimulating factor (G-CSF) treatment overexpress Fc receptors, leading to a nonspecific positive direct IF reaction. Pre-treatment of test neutrophils for 5 minutes with 1% paraformaldehyde in phosphate buffer (Verheugt et al., 1977) significantly reduces the non-specific binding of immunoglobulins and provides reliable results.

Among the indirect tests, the neutrophil agglutination reaction can be obtained only in the presence of EDTA, which prevents spontaneous neutrophil aggregation. Antibodies may be missed if the required incubation period is shortened. In the indirect agglutination test, the probability of detecting an antibody increases if the patients' plasmas are tested against a panel of cells selected from homozygous donors for the known antigens to produce stronger reactions. Testing for cytotoxic antibodies is less useful, because sera from many non-neutropenic, normal individuals produce a positive reaction, and the results can be considered positive only if high titers are obtained. Enthusiasm for tests based on opsonization and inhibition of phagocytosis is tempered by their complexity. Moreover, in some cases of alloimmune neonatal neutropenia, strong agglutinating antibodies have failed to cause neutrophil opsonization.

Unfortunately, unlike hemoglobin in hemolytic anemia, simple and reliable markers for *in vivo* neutrophil lysis are not available. For this purpose, measurement of the released neutrophil lysozyme (Boxer et al., 1975) has had limited clinical value. In conclusion, for diagnosis of autoimmune neutropenias, especially in the primary forms, a combination of agglutination and IF tests must be used. Another consideration, especially in AINI, is the fact that the tests are positive in early phases of disease, and that in late phases and prior to recovery, antibodies become undetectable.

TREATMENT

Introduction of CSFs has changed the outcome of all neutropenias, including autoimmune forms. Many patients with primary autoimmune neutropenia, especially children, tolerate the condition well and need antibiotics and other treatments only for the management of intercurrent infections.

The effectiveness of G-CSF is due to increased neutrophil production in the bone marrow and an increase in the expression of NA antigens. G-CSF also mobilizes neutrophils from the marginal pool. These effects may result in consumption of the antibodies by mass action. Included in these effects, the possibility of suppression of the lymphoid system cannot be excluded. The dose of G-CSF must be individualized. Most patients do not require more than two to three subcutaneous injections at $2.5 \pm 1 \mu\text{/kg}$. The treatment should be given only for control of complications and in preparation for surgical procedures. Another effective modality is intravenous administration of gammaglobulin, which temporarily reverses neutropenia (Bussel et al., 1988). Compared to hemolytic anemia and thrombocytopenia, splenectomy and steroids are not as effective. These differences may reflect pathophysiologic features unique to neutrophils, particularly

the multiplicity of mechanisms involved in their destruction. Steroids cannot be fully effective when phagocytosis by macrophages plays an essential role. Neutropenic patients often have chronic infection, which causes macrophage activation. Such activated macrophages are more destructive and less susceptible to inhibition by steroids. Despite these potential shortcomings, some severe cases may be resistant to G-CSF treatment and may require treatment with steroids.

PERSPECTIVES AND FUTURE DIRECTIONS

CSFs have become the treatment of choice for neutropenias with which most patients are treated, regardless of etiology. In addition, in view of the fact that few laboratories with expertise in neutrophil antibody detection are available, an increasing number of physicians avoid laboratory work-up. Consequently, availability of laboratory material for research has noticeably diminished. In the past three decades no new neutrophil-specific antigen has been discovered and the specificities of single antibody previously reported have not been confirmed. Nevertheless, the shift of research into molecular biology has led to much progress in our understanding of the molecular genetics of neutrophil antigens and their functions. The reason for the prominence of NA as the main target for autoimmunity remains a mystery, although we have attributed it to its high antigenicity. No explanation is available, however, as to why Fc γ RIIa (CD32), which like Fc γ RIIIb (CD16) is a diallelic antigen expressed on neutrophils, is not recognized as a target for autoimmunity.

More research is needed on the effects of anti-NB1 on NB1⁺ neutrophil functions, suggesting that autoantibodies may have consequences beyond obvious numerical reduction. At the clinical level, the role of regulatory T cells in the pathogenesis of autoimmune neutropenia of infancy needs to be investigated. If confirmed, this mechanism may prove to be a model for other transient autoimmune disorders in early childhood such as thrombocytopenia and hemolytic anemia. It would be most interesting to determine if similar disorders occur in non-hematological tissues. The target(s) of antibodies in secondary autoimmune neutropenias has not been fully identified, except for possible involvement of ANCAS in rare cases. To be determined also, is the possibility that neutrophil-specific antigens could be one of the targets in neutropenias associated with diseases such as SLE.

HISTORICAL BACKGROUND

The earliest case description of aplastic anemia in 1888 was by Dr. Paul Ehrlich (Ehrlich, 1888). He described a young woman who died following an abrupt illness characterized by severe anemia, bleeding, high fever, and a markedly hypocellular bone marrow. The term aplastic anemia was first introduced in 1904 by Chauffard. Until the early 1970s, most patients with severe aplastic anemia died within a year of diagnosis. The advent of allogeneic bone marrow transplantation (BMT) and immunosuppressive therapy markedly improved the outcome for these patients and prompted vigorous clinical and laboratory investigation. These studies have generated important insight into hematopoietic stem cell biology, immunology, and autoimmunity. Today, the majority of patients will survive this potentially fatal autoimmune disorder.

GENETIC FEATURES

Distinctive genetic abnormalities are more common with congenital bone marrow failure syndromes since most acquired aplastic anemia is autoimmune. Congenital aplastic anemia tends to present in the first decade of life and is often, but not always, associated with other physical anomalies. Fanconi anemia, the most common form of congenital bone marrow failure, predisposes to cancer and is frequently associated with other congenital

abnormalities (e.g., short stature, upper-limb anomalies, hypogonadism café-au-lai spots, etc. (Bagby, 2003). Dyskeratosis congenita (DKC) is another congenital bone marrow failure disorder that can be either X-linked recessive, autosomal dominant, or autosomal recessive (Dokal and Vulliamy, 2003). The X-linked recessive form results from mutations in a gene known as *DKC1* whose gene product, dyskerin, is important for stabilizing telomerase. The resulting telomerase deficiency leads to short telomeres, bone marrow failure, and premature aging. The autosomal dominant form of DKC results from *hTERT* gene mutations, the RNA component of telomerase. This chapter will focus on the acquired form of aplastic anemia. Genetic abnormalities are less well characterized in acquired aplastic anemia; however, there appears to be an underlying genetic predisposition to acquired aplastic anemia, as evidenced by the overrepresentation of HLA DR2 subtypes (Nimer et al., 1994).

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Aplastic anemia manifests as pancytopenia in conjunction with a hypocellular bone marrow (Brodsky and Jones, 2005). The disease may present abruptly (over days) or insidiously, over weeks to months. The most common clinical manifestations reflect the low blood counts and include dyspnea on exertion, fatigue, easy bruising,

TABLE 49.1 Aplastic anemia: diagnosis and definitions. Bone marrow cellularity must be <25% to diagnose aplastic anemia

| Peripheral blood counts | Nonsevere aplastic anemia (not meeting criteria for severe disease) | Severe aplastic anemia (any 2 of 3 criteria below) | Very severe aplastic anemia (meets criteria for severe disease and absolute neutrophils <200) |
|-------------------------|---|--|---|
| Absolute neutrophils | | < 500/ μ l | < 200/ μ l |
| Platelets | | < 20,000/ μ l | |
| Reticulocyte count | | < 1.0% corrected or < 60,000/ μ l | |

petechia, epistaxis, gingival bleeding, heavy menses, headaches, and fever. A complete blood count, leukocyte differential, reticulocyte count, and a bone marrow aspirate and biopsy are essential for diagnosis. Peripheral blood flow cytometry to detect GPI anchor deficient blood cells (Brodsky et al., 2000; Borowitz et al., 2010) as well as cytogenetics and fluorescent *in situ* hybridization (FISH) analysis should be performed on the bone marrow aspirate. Up to 70% of patients with acquired aplastic anemia have a detectable paroxysmal nocturnal hemoglobinuria (PNH) clone which essentially rules out inherited forms of aplastic anemia. Cytogenetic or FISH abnormalities are suggestive of a hypoplastic form of myelodysplasia. Patients under the age of 40 years should be screened for Fanconi anemia using the clastogenic agents diepoxybutane or mitomycin C (Bagby, 2003) and telomere lengths should be obtained on patients with a family history of bone marrow failure, premature graying, pulmonary fibrosis, or other stigmata of dyskeratosis congenita.

A hypocellular bone marrow is required for the diagnosis of aplastic anemia. However, some patients will have residual pockets of ongoing hematopoiesis; thus, an adequate biopsy (1–2 cm in length) is essential for establishing the diagnosis. Dyserythropoiesis is not uncommon in aplastic anemia, especially in cases with coincidental small to moderate PNH populations; however, a small percentage of myeloid blasts, or dysplastic features in the myeloid or megakaryocyte lineages, is more typical of hypoplastic myelodysplastic syndromes (MDS). CD34 is expressed on early hematopoietic progenitors and the number of CD34⁺ cells has also been used to help discriminate between aplastic anemia and hMDS. In aplastic anemia the percentage of cells expressing CD34 is usually less than 0.1%; in hMDS the CD34 count is either normal (0.5 to 1.0%) or elevated (Matsui et al., 2006).

As with other autoimmune diseases, there is a wide spectrum of disease severity in aplastic anemia. The prognosis in aplastic anemia is proportional to degree of peripheral blood cytopenias. Accordingly, aplastic anemia is classified as non-severe, severe, and very severe based

largely upon the degree of neutropenia (Table 49.1). Severe aplastic anemia (SAA) is defined as bone marrow cellularity of less than 25% and markedly decreased values of at least two of three hematopoietic lineages (neutrophil count <500/ μ l, platelet count <20,000/ μ l, and absolute reticulocyte count of <60,000/ μ l). Very severe aplastic anemia satisfies the above criteria except the neutrophil count is <200/ μ l, while non-severe aplastic anemia is characterized by a hypocellular bone marrow but with cytopenias that do not meet the criteria for severe disease. The 2-year mortality rate with supportive care alone for patients with SAA exceeds 50% (Camitta et al., 1979), with invasive fungal infections and overwhelming bacterial sepsis being the most frequent causes of death. Non-severe aplastic anemia is seldom life threatening and in many instances requires no therapy. Although some cases of non-severe aplastic anemia will progress, many will remain stable for years, and some may spontaneously improve.

Aplastic anemia has been associated with drugs, benzene exposure, insecticides, viruses, and other agents. However, over 80% of cases are classified as idiopathic. The disease most commonly affects children and young adults but may occur at any age. Precise estimates of the incidence of aplastic anemia are difficult due to the rarity of the disease and imprecision in establishing the diagnosis. The best estimates of incidence are case–control studies that report an incidence of two cases per million inhabitants in Europe (Kaufman et al., 1991) and Israel (Modan et al., 1975), but the incidence may be two- to three-fold higher in Southeast Asia (Issaragrisil et al., 1997a; Szklo et al., 1985). A population-based case–control study of aplastic anemia in Thailand found that drugs, the most commonly implicated etiology, explain only 5% of newly diagnosed cases (Issaragrisil et al., 1997b).

An intriguing association exists between seronegative hepatitis and aplastic anemia. The hepatitis/aplastic anemia syndrome accounts for 3–5% of newly diagnosed cases of aplastic anemia. The disease predominantly affects young males, with a precipitous onset of severe

pancytopenia occurring within 2 to 3 months after the onset of hepatitis (Brown et al., 1997; Locasciulli et al., 2010). Moreover, aplastic anemia has been reported to occur in up to 30% of patients following orthotopic liver transplantation for seronegative hepatitis (Tzakis et al., 1988; Cattral et al., 1994). The aplastic anemia in the hepatitis/aplastic anemia syndrome is autoimmune since most cases respond to immunosuppressive therapy (Locasciulli et al., 2010; Savage et al., 2007); however, it remains unclear whether the hepatitis results from an undiscovered virus or whether this too is autoimmune.

AUTOIMMUNE FEATURES AND PATHOGENIC MECHANISMS

Aplastic anemia was originally thought to result from a quantitative deficiency of hematopoietic stem cells precipitated by a direct toxic effect on stem cells. However, attempts to treat aplastic anemia by simple transfusion of bone marrow from an identical twin failed to reconstitute hematopoiesis in most patients. Retransplant in many of these patients following a high dose of a cyclophosphamide preparative regimen was successful, suggesting that the pathophysiology of aplastic anemia was more complicated (Champlin et al., 1984; Hinterberger et al., 1997). In the late 1960s, Mathé and colleagues were among the first to postulate an immune basis for aplastic anemia (Mathe et al., 1970). They performed BMT in patients with aplastic anemia using partially mismatched donors after administering anti-lymphocyte globulin as an immunosuppressive conditioning regimen. Although the patients failed to engraft, the investigators witnessed autologous recovery of hematopoiesis in some patients. This suggested that functional hematopoietic stem cells exist in aplastic anemia patients and that the immune system was somehow suppressing the growth and differentiation of hematopoietic stem cells. The response to immunosuppressive therapy was the first clear evidence that aplastic anemia was truly an autoimmune disease.

The first laboratory experiments implicating an autoimmune pathophysiology were co-culture experiments showing that T lymphocytes from aplastic anemia patients inhibited hematopoietic colony formation *in vitro* (Hoffman et al., 1977; Nissen et al., 1980). Since then, it has been shown that the immune destruction of hematopoietic stem cells in aplastic anemia is mediated by cytotoxic T cells and involves inhibitory Th1 cytokines and the Fas-dependent cell death pathway. The cytotoxic T cells are usually more conspicuous in the bone marrow than in the peripheral blood (Zoumbos et al., 1985; Maciejewski et al., 1994; Melenhorst et al., 1997b), and overproduce interferon- γ and tumor necrosis factor (TNF) (Nakao et al., 1992; Nistico and Young, 1994). TNF and

interferon- γ are direct inhibitors of hematopoiesis and appear to upregulate Fas expression on CD34⁺ cells (Maciejewski et al., 1995). Immortalized CD4⁺ and CD8⁺ T cell clones from some aplastic anemia patients have been shown to secrete Th1 cytokines and are capable of lysing autologous CD34 cells (Nakao et al., 1997; Zeng et al., 2001). Recently, evidence for a humoral autoimmune response in aplastic anemia has also been reported (Hirano et al., 2003; Feng et al., 2004).

Studies examining T cell diversity using complementarity-determining region (CDR3) spectratyping have further implicated the role of the immune system in aplastic anemia. Several groups have now found limited heterogeneity of the T cell receptor β chain (BV) in aplastic anemia, suggesting that there is oligoclonal or even clonal expansion of T cells in response to a specific antigen (Manz et al., 1997; Melenhorst et al., 1997a; Zeng et al., 2001).

ENVIRONMENTAL FEATURES

The medical literature is replete with reports of environmental exposures, most notably benzene and radiation, causing aplastic anemia. However, rigorous epidemiologic studies supporting an association between environmental toxins and aplastic anemia are lacking. A major confounder is that benzene, radiation, and other toxins also predispose to MDS and leukemia. Older literature was unlikely to have been able to distinguish different types of marrow failure, such as aplastic anemia, MDS, and hypoplastic leukemia, leading to an overestimation of the association between benzene and aplastic anemia. While the magnitude of the risk remains uncertain, benzene is probably not a major risk factor for aplastic anemia in countries with modern standards of industrial hygiene. A large case-control study in Thailand employing modern diagnostic and epidemiologic methods found that individuals of lower economic status and younger age are at greater risk than their counterparts in other countries following exposure to solvents, glues, and hepatitis A (likely a surrogate marker). Grain farmers were also found to have a higher risk of developing aplastic anemia (relative risk = 2.7) regardless of whether they used insecticides (Issaragrisil et al., 1997a). These same investigators noted marked differences in incidence between northern and southern rural regions of Thailand and among Bangkok suburbs implicating potential environmental factors in causing the disease (Issaragrisil et al., 1999).

ANIMAL MODELS

Animal models of bone marrow failure exist, but none of these models fully replicate the human disease-acquired aplastic anemia (Chen, 2005). Busulfan, benzene, and

FIGURE 49.1 Survival after allogeneic bone marrow transplantation for severe aplastic anemia. Data for HLA-identical siblings and related matched/mismatched transplants are from the International Bone Marrow Transplant Registry (IBMTR). Data for unrelated donor transplants are from the European Bone Marrow Transplant registry (EBMT), Fred Hutchinson Cancer Research Center, IBMTR, and the IMUST study group. Survival curves are not adjusted for varying patient, disease, and transplant regimen characteristics. *Reproduced with permission from the National Bone Marrow Donor Program.*

irradiation have all been used to establish models of marrow failure. All three of these agents lead to pancytopenia and a hypocellular marrow but the marrow failure is due to stem cell injury and damage to the microenvironment rather than autoimmune-mediated suppression of hematopoiesis. More recently, infusion of lymphocytes from congenic mice was used to model immune-mediated marrow failure; this model induces a hypocellular bone marrow and severe pancytopenia, but is not truly autoimmune (Chen et al., 2004).

THERAPY FOR APLASTIC ANEMIA

Definitive therapy for aplastic anemia includes bone marrow transplantation (BMT) or immunosuppressive therapy. A variety of immunosuppressive agents have been used, but antithymocyte globulin (ATG) and cyclosporin A (CSA) are the most commonly employed. Supportive care with blood transfusions and antibiotics is commonly required. Administration of hematopoietic growth factors has not been shown to improve survival in aplastic anemia.

Bone Marrow Transplantation (BMT)

BMT is the treatment of choice for young patients who have an HLA-matched sibling donor (Figure 49.1). Cyclophosphamide (50 mg/kg/day \times 4 days) with or without ATG, is most commonly used for conditioning before BMT. This regimen is non-myeloablative; however, the immunosuppression is sufficient to allow engraftment in most cases (May et al., 1993; Storb et al., 1997; Kahl et al., 2005). Alternative regimens using fludarabine, cyclophosphamide, and antithymocyte globulin are increasingly being used (Maury et al., 2009). Survival rates following matched sibling allogeneic BMT have steadily improved since the 1970s largely because of improved supportive care, improved human leukocyte antigen (HLA) typing, and better graft-versus-host-disease (GVHD) prophylaxis (Bacigalupo, 1999). Late BMT-related complications such as chronic GVHD occur

in up to one-third of patients, with many of these patients requiring long-term therapy for their GVHD (Storb et al., 2001). Patient age and the type of allograft (HLA-matched sibling, unrelated, or mismatched donors) are the most important factors influencing outcome. In patients under 30 years of age, the cure rate after HLA-matched sibling BMT ranges from 70 to 90% (Horowitz, 2000; Storb et al., 2001; Ades et al., 2004;). However, the risk of GVHD steadily increases with age, leading to reduced survival.

BMT from Unrelated Donors

BMT from HLA-matched unrelated donors (MUD) is usually reserved for patients who fail to respond to one or more courses of immunosuppressive therapy. The risk for transplant-related mortality and GVHD is almost twice that of BMT from matched sibling donors (Bacigalupo et al., 2000b). The best results have been reported in patients under 21 years of age with disease duration of less than 1 year (Margolis et al., 1996; Deeg et al., 2001, 2006). The International Bone Marrow Transplant Registry reported on the results of 318 alternative donor transplants between 1988 and 1998 (Passweg et al., 2006). Most patients in this series were young, heavily transfused, and of poor performance status. The probability of graft failure was 20% and the survival probability at 5 years was less than 40%. The Fred Hutchinson Cancer Research Center reported on the results of unrelated allogeneic bone marrow transplantation in SAA after conditioning with low-dose total body irradiation, high-dose cyclophosphamide, and ATG (Deeg et al., 2006). The median age was 19 years and with a median follow-up of 7 years. Overall survival was 61% for patients who received transplants from matched unrelated donors and 39% for patients receiving transplants from HLA mismatched unrelated donors; more than 70% of patients acquired acute GVHD and over 50% developed chronic GVHD. Nevertheless, improved typing, newer conditioning regimens, and better GVHD prophylaxis are leading to better survival, higher engraftment rates, and

less GVHD. The European group for Blood and Marrow Transplantation (EBMT) has been conditioning SAA patients for BMT with fludarabine, cyclophosphamide, and antithymocyte globulin (ATG) \pm total body irradiation (TBI). The EBMT has reported survival rates as high as 75% using this conditioning regimen (Bacigalupo et al., 2010). Survival is best in children and in patients who undergo BMT within 2 years of diagnosis.

IMMUNOSUPPRESSIVE THERAPY

Antithymocyte globulin (ATG) is produced by immunizing animals (horse or rabbit) against human thymocytes and kills human T cells through its cytolytic activity. Both horse (hATG) and rabbit (rATG) are approved for use in the United States. However, difficulty in maintaining quality control has led to the withdrawal of hATG in Europe. Cyclosporine (CSA) suppresses T cell function by inhibiting the expression of nuclear regulatory proteins. Both single agent ATG and single agent CSA (Maschan et al., 1999) can induce remissions in acquired aplastic anemia; however, the combination ATG/CSA leads to a higher response rate and a greater likelihood of achieving transfusion independence (Frickhofen et al., 1991; Marsh et al., 1999). A randomized controlled trial demonstrated that hATG/CSA is superior to rATG/CSA (Scheinberg et al., 2011). The combination of ATG/CSA leads to 5-year survival rates comparable to BMT, but most of these patients are not cured of their disease (Marsh et al., 1999). Response rates to hATG/CSA range between 60 and 80%, but in contrast to BMT, most patients do not acquire normal blood counts (Frickhofen et al., 2003; Rosenfeld et al., 2003). Another limitation of this approach is that many patients relapse, become dependent on cyclosporine, or develop secondary clonal disease such as PNH or MDS (Bacigalupo et al., 2000a; Rosenfeld et al., 2003). These late events often lead to substantial morbidity and mortality. The National Institutes of Health treated 122 patients (median age, 35 years) with the combination of ATG/CSA and methylprednisolone over a period of 8 years (Rosenfeld et al., 2003). The response rate was 58% and actuarial survival at 7 years was 55%; 13% of patients died within 3 months of treatment, most from fungal infections (Figure 49.2). The relapse rate for responders was 40% and 13 patients developed MDS. In an attempt to improve response rate and survival, and to decrease the relapse rate and secondary MDS that occurs after hATG/CSA, the NIH added mycophenolate (1 gram twice daily for 18 months) to the standard hATG/CSA regimen. This three-drug regimen resulted in a 62% response rate, but 37% of the responders relapsed (most while taking mycophenolate) and 9% progressed to either MDS or leukemia; thus, the addition of mycophenolate did not improve response or survival

(Scheinberg et al., 2006). Alemtuzumab is a highly immunosuppressive monoclonal antibody that binds to cell surface CD52, which is expressed primarily on B cells, T cells, and monocytes. Alemtuzumab has activity in treating SAA, but response rates in therapy naïve patients are less than 30% (Scheinberg et al., 2012).

HIGH-DOSE CYCLOPHOSPHAMIDE WITHOUT BMT

The first successful human allogeneic BMT, reported in 1972 by Thomas et al. in a patient with aplastic anemia, employed high-dose cyclophosphamide (Thomas et al., 1972), and this remains (often in conjunction with ATG) the most commonly employed conditioning regimen for aplastic anemia (Storb et al., 2001). Complete reconstitution of autologous hematopoiesis occurs in 10–15% of patients undergoing allogeneic BMT for aplastic anemia (Thomas et al., 1976; Sensenbrenner et al., 1977; Gmur et al., 1979). The EBMT reported that 10% of SAA patients experience autologous reconstitution following BMT using a cyclophosphamide + ATG conditioning regimen. Interestingly, 10-year survival (84%) in patients with autologous recovery was better than in patients who underwent engrafting (74%) (Piccin et al., 2010).

The unique pharmacology of cyclophosphamide explains the autologous hematopoietic recovery (Emadi et al., 2009). Cyclophosphamide is a prodrug that is converted to 4-hydroxycyclophosphamide and its tautomer aldophosphamide in the liver. These compounds diffuse into the cell and are converted to the active compound phosphoramidate mustard, or they are inactivated by aldehyde dehydrogenase to form the inert carboxyphosphamide. Lymphocytes have low levels of aldehyde dehydrogenase and are rapidly killed by high doses of cyclophosphamide; hematopoietic stem cells possess high levels of aldehyde dehydrogenase and are resistant to cyclophosphamide (Hilton, 1984; Jones et al., 1995). Thus, high-dose cyclophosphamide is highly immunosuppressive, but not myeloablative, allowing endogenous hematopoietic stem cells to reconstitute hematopoiesis (Figure 49.3). With this background, high-dose cyclophosphamide without BMT was used successfully in aplastic anemia patients who lacked appropriate donor (Brodsky et al., 1996, 2010; Tisdale et al., 2000; Jaime-Perez et al., 2001). The largest and most mature study with high-dose cyclophosphamide is from Johns Hopkins (Brodsky et al., 2010). These investigators treated 67 SAA patients with high-dose cyclophosphamide; 44 patients were treatment-naïve and 23 were refractory to one or more previous immunosuppressive regimens. At 10 years, the overall actuarial survival, response rate, and event-free survival was 88%, 71%, and 58%, respectively,

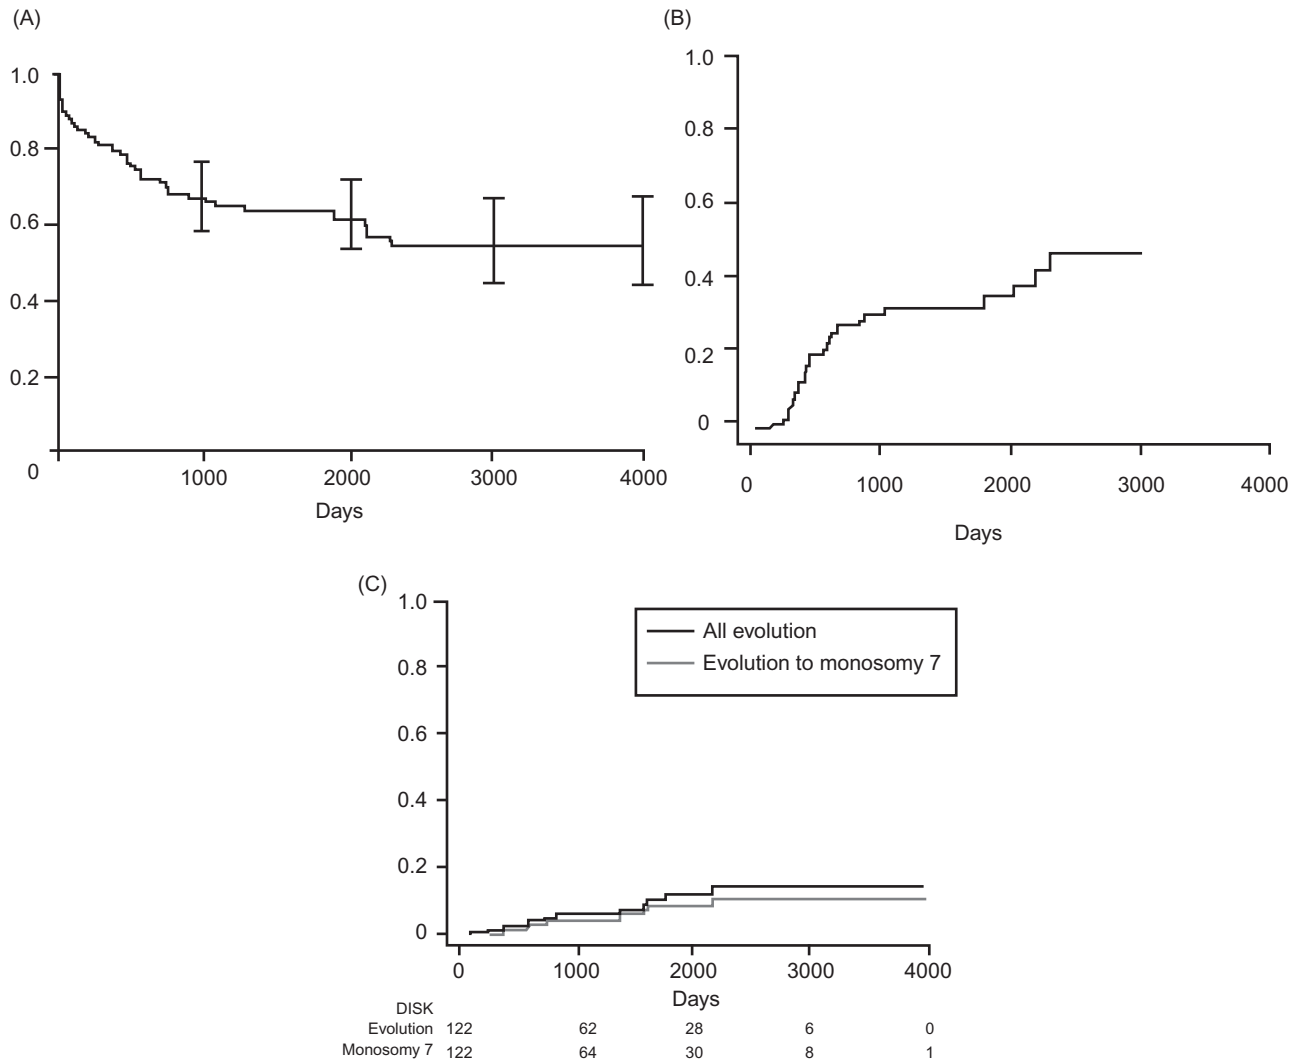

FIGURE 49.2 (A) Survival probability for 122 patients with severe aplastic anemia following treatment with antithymocyte globulin and cyclosporine. (B) Probability of relapse in 74 patients with aplastic anemia classified as responders at 3 months after treatment with antithymocyte globulin and cyclosporine. (C) Proportion of patients experiencing clonal evolution. *Reproduced from JAMA (Rosenfeld et al., 2003) with permission.*

FIGURE 49.3 Model depicting the pathophysiology of bone marrow failure in acquired aplastic anemia. Autoaggressive lymphocytes lyse CD34⁺ bone marrow progenitor cells but seem to spare more immature CD34⁺ cells known as high quality stem cells.

for the 44 treatment-naïve patients. Patients with refractory SAA fared less well; at 10 years, overall actuarial survival, response, and event-free survival rates were 62%, 48%, and 27%, respectively. For treatment-naïve

patients, the median time to a neutrophil count of $0.5 \times 10^9/L$ was 60 (range, 28–104) days; the median time to last platelet and red cell transfusion was 117 and 186 days, respectively. Relapse occurred in just two of the treatment-naïve patients, one of whom was retreated with high-dose cyclophosphamide into a second complete remission. Despite the high response rate and low risk of relapse and secondary clonal disease, many investigators are unwilling to accept the relatively long period of aplasia associated with this therapy (Figure 49.4).

APLASTIC ANEMIA AND CLONALITY

Survivors of aplastic anemia are at high risk of clonal progression following immunosuppressive therapy (Socie et al., 1993). PNH and MDS are the most common clonal

FIGURE 49.4 (A) Overall survival after high-dose cyclophosphamide therapy. Overall survival for 44 treatment-naïve patients (top line) and 23 patients refractory to prior immunosuppressive therapy (bottom line). $P = .03$ (log-rank test). (B) Failure-free survival after high-dose cyclophosphamide therapy. Failure-free survival for 44 treatment-naïve patients (top line) and 23 patients refractory to prior immunosuppressive therapy (bottom line). $P = .07$ (log-rank test). *Reproduced from Blood (Brodsky et al., 2010) with permission.*

disorders to evolve from aplastic anemia (Tichelli et al., 1988; de Planque et al., 1989). Even before the widespread use of immunosuppressive therapy, 5% of patients progressed to clonal hematopoiesis. This suggests that the increase in MDS and PNH following immunosuppressive therapy is not caused by the immunosuppression; rather, the increased survival following immunosuppressive therapy may allow time for these underlying clones to expand (Mukhina et al., 2001).

PNH results from the expansion of an abnormal hematopoietic stem cell that harbors a somatic mutation of the X-linked gene, termed *PIG-A* (Brodsky, 2008, 2009). The product of the *PIG-A* gene is required for glycosylphosphatidyinositol (GPI) anchor biosynthesis; consequently, PNH cells are deficient in GPI-anchored proteins. Several GPI-anchored proteins (CD59 and CD55) protect cells from complement-mediated destruction, and their absence explains the hemolytic anemia associated with PNH. It is unclear how the PNH stem cell and its progeny achieve clonal dominance in the setting of aplastic anemia, despite the fact that PNH cells are more vulnerable to complement-mediated destruction; however, it may relate to relative resistance to the autoimmune attack. Specifically, it has been suggested that PNH cells may be relatively resistant to an autoimmune attack because they are deficient in GPI-anchored ULBPs that serve as ligands for the NKG2D receptor found on natural killer cells and T cells (Hanaoka et al., 2006; Savage et al., 2009). Alternatively, it has been proposed that “second hit” mutations may also give the PNH clone a growth advantage (Inoue et al., 2006).

MDS also commonly arises in aplastic anemia patients treated with immunosuppressive therapy. In a retrospective review of children with severe aplastic anemia, 11 of 86 patients who received immunosuppressive therapy developed MDS (Ohara et al., 1997). Up to 15% of adult patients with aplastic anemia will also develop MDS following immunosuppressive therapy, with monosomy 7 being the most common chromosomal abnormality (Rosenfeld et al., 2003).

CONCLUDING REMARKS—FUTURE PROSPECTS

Aplastic anemia was originally thought to be due to a defect in hematopoietic stem cells or their microenvironment. It is now clear that most cases of acquired aplastic anemia are caused by autoreactive lymphocytes that target bone marrow stem/progenitor cells. With modern therapies, the 5-year survival rate for SAA exceeds 85%. BMT offers the best chance for cure, but its use is restricted by the relatively high morbidity and mortality in older patients and those who lack an HLA-matched sibling donor. Immunosuppressive therapy remains the standard of care for patients who are not suitable candidates for BMT. Remissions are achieved in up to 75% of patients, but the high rate of relapse and secondary clonal diseases limits the efficacy of immunosuppressive therapy. Unfortunately, the addition of newer immunosuppressive therapies (MMF, sirolimus, etc.) to ATG/CsA does not seem to improve response or decrease

the risk of relapse or clonal disease. High-dose cyclophosphamide therapy seems to produce higher quality remissions with fewer relapses, but this approach has not been widely adopted due to the prolonged period of aplasia. Currently, advances in mitigating graft failure and GVHD in the setting of alternative donor BMT appear to be outpacing the development of more effective IST therapies for SAA. Over the next 5 years, there is likely to be great use of unrelated and HLA-mismatched BMT to treat SAA, especially in patients who do not respond to or relapse after immunosuppressive therapy. The development of post-transplant CY to expand the donor pool and mitigate GVHD appears promising (Brodsky et al., 2008; Dezern et al., 2011).

INTRODUCTION—APOPTOSIS AND THE IMMUNE SYSTEM

In the immune system, lymphocyte homeostasis is controlled by cell proliferation and cell death. Maintaining lymphocyte homeostasis is important for the normal functioning of T cells, whose numbers must rapidly expand in response to pathogens, and which subsequently contract after pathogen clearance (Lenardo et al., 1999). A key mechanism by which an organism achieves this balancing act is through a form of programmed cell death called apoptosis, which has specific morphological and biochemical hallmarks (Galluzzi et al., 2007). The hallmarks include cell shrinkage, chromatin condensation, blebbing,

the formation of apoptotic bodies, and the activation of intracellular enzymes called caspases. Lymphocyte numbers can also be controlled by additional mechanisms such as programmed necrosis, which follows a set genetic pathway. In addition, stimulation of death receptors or T cell receptors can lead to a necrotic death when caspases have been inhibited and, therefore, it presumably serves as an auxiliary death mechanism for lymphocyte homeostasis (Han et al., 2011).

In lymphocytes, apoptosis can occur during the height of the immune response after cells enter late G1 or S phase of the cell cycle and become sensitive to signals generated by death receptors or after repetitive stimulation through antigenic receptors (Lenardo et al., 1999). Apoptosis also takes

FIGURE 50.1 Simplified scheme of immunoregulatory signaling pathways to immune cell apoptosis. Depicted are the proteins: Fas ligand, Fas receptor, Fas-associated death domain protein (FADD), caspase-8, and caspase-10, which have been found to be mutant in ALPS and related conditions. The Fas receptor and ligand have three-fold symmetry which contributes importantly to the dominant interfering effect of heterozygous mutations. The ovals represent “death domains” in the Fas receptor and FADD, the octagons represent “death effector domains” in FADD and in caspase-8 and -10 zymogens, and the rectangles and squares represent the large and small subunits of the processed caspase proteins, respectively. The precise stoichiometry of the intracellular signaling complex is more complicated based on microscopic and crystallographic studies. Depicted on the right is the death pathway triggered through the mitochondrion by lymphokine withdrawal-induced Bim protein which also leads to caspase activation and apoptosis. The induction/stabilization of Bim is blocked by activated Ras (Ras*) in RALD leading to an apoptosis defect in response to lymphokine withdrawal.

place during the waning of an immune response after antigen clearance in response to the withdrawal of trophic factors. Together these mechanisms serve to return lymphocyte numbers almost back to their original set point at rest. Lymphocytes that escape these apoptosis mechanisms persist as memory cells with specific phenotypes and functional capabilities. The importance of these mechanisms is illustrated by inherited defects in the FAS pathway of lymphocyte apoptosis (Figure 50.1), which cause a disorder called the autoimmune lymphoproliferative syndrome (ALPS). In ALPS, the abnormal accumulation of lymphocytes leads to enlarged secondary lymphoid organs. Lymphocytes that have abnormal specificities to autoantigens, or that have acquired further mutations, also persist, leading to the development of autoimmune disease, and in some cases the malignant outgrowth of cells. This chapter will focus on ALPS and related conditions associated with defective apoptosis.

CLINICAL AND PATHOLOGICAL FEATURES

Autoimmune Lymphoproliferative Syndrome

Autoimmune lymphoproliferative syndrome is characterized by nonmalignant lymphadenopathy, splenomegaly, and multilineage cytopenias secondary to sequestration

and autoimmune peripheral destruction (Sneller et al., 1997; Bidere et al., 2006). This is the first disease known to be caused by a primary defect in programmed cell death and is the first autoimmune disease with a defined genetic basis (Fisher et al., 1995; Rieux-Laucat et al., 1995). Though others had earlier described similar manifestations of chronic lymphadenopathy simulating malignant lymphoma, a molecular basis for the disease was identified as defective lymphocyte apoptosis secondary to heterozygous mutations in the *FAS* gene in 1995 (Canale and Smith, 1967; Fisher et al., 1995; Rieux-Laucat et al., 1995). Since then, other genetic defects associated with ALPS and related disorders have been identified in both extrinsic and intrinsic apoptotic pathways (Wu et al., 1996; Wang et al., 1999; Chun et al., 2002; Holzelova et al., 2004; Del-Rey et al., 2006; Bi et al., 2007; Oliveira et al., 2007; Bolze et al., 2010; Niemela et al., 2011).

ALPS patients have mutations in the FAS pathway of apoptosis (Figure 50.1). FAS is activated upon ligation by FAS ligand (FASL), a trimeric molecule bound to the cell surface or found in soluble form. The FAS–FASL interaction triggers a conformational change in the intracellular portion of FAS, resulting in the recruitment of the adapter molecule FADD, which in turn recruits caspase-8 and -10 to the signaling complex. In close proximity, these caspases

Box 50.1 Diagnostic Criteria for ALPS Based on International ALPS Workshop 2009.**Required Criteria**

1. Chronic (>6 months), nonmalignant, noninfectious lymphadenopathy and/or splenomegaly
2. Elevated CD3⁺TCR $\alpha\beta$ + CD4⁻CD8⁻ DNT cells (> 1.5% of total lymphocytes or >2.5% of CD3⁺ lymphocytes) in the setting of normal or elevated lymphocyte counts

Additional criteria**Primary**

1. Defective lymphocyte apoptosis in two separate assays
2. Somatic or germline pathogenic mutation in FAS, FASLG, or CASP10

Secondary

3. Elevated plasma sFASL levels (> 200 pg/ml), plasma IL-10 levels (> 20 pg/ml), serum or plasma vitamin B12 levels (> 1500 ng/L) or plasma IL-18 levels >500 pg/ml
4. Typical immunohistologic findings as reviewed by a hematopathologist
5. Autoimmune cytopenias (hemolytic anemia, thrombocytopenia, or neutropenia) with elevated IgG levels (polyclonal hypergammaglobulinemia)
6. Family history of a nonmalignant/noninfectious lymphoproliferation with or without autoimmunity

Definitive diagnosis: Both required criteria plus one primary accessory criterion.

Probable diagnosis: Both required criteria plus one secondary accessory criterion. Treat as ALPS until genetics can be done.

become activated, cleaving, in a typical signaling cascade, downstream effector caspases such as caspase-3 and -7. Upon activation, these caspases degrade several intracellular targets, leading to cell death. Mutations in all of these proteins (FAS, FASL, FADD, CASP8, and CASP10) are now known to cause ALPS or related disorders (Wu et al., 1996; Wang et al., 1999; Chun et al., 2002; Holzelova et al., 2004; Del-Rey et al., 2006; Bi et al., 2007; Oliveira et al., 2007; Bolze et al., 2010; Niemela et al., 2011). ALPS diagnostic criteria and molecular classification are shown in Box 50.1 and Table 50.1.

Clinical Presentation

ALPS usually presents in early childhood. However, this entity can be recognized in previously undiagnosed adult family members of patients following genetic counseling and testing of family members (Bidere et al., 2006; Neven et al., 2011). Most patients present with significant lymphadenopathy and splenomegaly before 3 years of age. The initial presentation of ALPS is often that of persistent lymphadenopathy and/or splenomegaly followed by an autoimmune disease such as immune thrombocytopenic purpura (ITP) or hemolytic anemia in an otherwise healthy child. Associated multilineage cytopenias due to autoantibodies and/or splenic sequestration can lead to mucocutaneous bleeding, pallor, icterus, and fatigue. Recurrent infections can also occur, mostly due to neutropenia and/or blockage of nasopharyngeal passages due to lymphadenopathy. Some patients also develop autoimmune

TABLE 50.1 ALPS Classification and Distribution of Different Categories of Patients Seen and Evaluated at National Institutes of Health Clinical Center as Part of our Current Cohort

| ALPS classification | Chronic LPD/ splenomegaly | Elevated $\alpha\beta$ DNTs | Apoptosis defect | % (no.) of ALPS cases (n = 257) |
|---|------------------------------|--------------------------------|---------------------|------------------------------------|
| ALPS-FAS (germline mutation) | + | + | + | 72 (185) |

diseases affecting other organs such as autoimmune hepatitis, glomerulonephritis, uveitis, and encephalomyelitis (Guillain–Barré syndrome). There may also be a family history of similar disorders, usually inherited in an autosomal dominant fashion with incomplete penetrance. A thorough review of a patient’s extended family for history of adenopathy, cytopenias, splenectomy, or lymphoma can provide information helpful in diagnosing ALPS.

Lymphadenopathy and hepatosplenomegaly seen in ALPS patients can often be remarkable, sometimes visibly distorting anatomic landmarks and clearly evident on CT or PET scans (Figure 50.2). Areas most commonly affected by lymphadenopathy are the neck, mediastinum, axillae, and inguinal and pelvic regions. Because of the propensity to malignant transformation of the expanded lymphocytes, ongoing lymphoma surveillance in these patients should include careful attention to the development of changes in lymph node size or appearance of new focal or generalized

lymphadenopathy and worsening splenomegaly associated with concomitant systemic symptoms such as fever, drenching night sweats, and weight loss (Rao and Oliveira, 2011).

Given that the clinical and laboratory features of ALPS can overlap with other common pediatric hematological disorders including sporadic acute ITP, Evans syndrome, and hematologic cancers, it is important for clinicians first to rule out other potentially more immediately life-threatening conditions (a short list of differential diagnose, is can be found in Box 50.2). Although rare, it is important to keep ALPS in the differential diagnosis for any child presenting with chronic non-malignant lymphadenopathy, particularly with a family history of a similar disease.

Laboratory Evaluation

Autoantibodies are frequently found in ALPS patients (Kwon et al., 2003). The most common autoantibodies occurring in ALPS patients are anti-erythrocyte antibodies detected by a Coombs direct antiglobulin test (DAT). Other common circulating autoantibodies include anti-platelet and anti-neutrophil antibodies. A complete blood count (CBC) with differential may demonstrate lymphocytosis, lymphopenia, reticulocytosis, thrombocytopenia, neutropenia, slight monocytosis, and/or eosinophilia. Polyclonal hypergammaglobulinemia is also a common feature in ALPS. In addition, a polyclonal expansion in the circulation and secondary lymphoid tissue of $CD3^+TCR\alpha\beta^+$ and $CD4^-CD8^-$ lymphocytes, henceforth referred to as the double negative T (DNT) cells, is highly characteristic of ALPS (Bleesing et al., 2001a, b). Double negative gamma-delta ($CD3^+TCR\gamma\delta^+$) T cells are not characteristic of this disease. Other abnormal laboratory findings that are commonly found in patients with ALPS include elevated serum levels of vitamin B12, IL-10, soluble FAS ligand, and IL-18 (Magerus-Chatinet et al.,

2009; Caminha et al., 2010). These serve as useful biomarkers of this disease, as discussed later in this chapter.

In patients with clinical and/or laboratory features consistent with a diagnosis of ALPS, molecular genetic testing of *FAS* (*TNFRSF6*), Fas ligand (*TNFSF6*), and caspase-10 genes (*CASP10*) should be obtained. Mutations of the *FAS* gene have been identified in the majority (74%) of patients with ALPS and most of these reside in the “death domain” encoded by exon 9 (Figures 50.1 and 50.4). This includes patients with either germline *FAS* mutations or somatic *FAS* mutations limited to the DNT cell compartment. We therefore recommend first testing for *FAS* mutations, followed by analysis of the other genes only when *FAS* gene analysis fails to reveal a causative mutation (Rao and Oliveira, 2011). This testing is important for two reasons. First, it is important to provide genetic counseling to the family and invite other family members for screening evaluations if the mutation is found. Second, the location of any specific gene mutation has been shown to be important in patient prognosis as certain mutation loci are associated with a higher risk of complications including lymphoma (Straus et al., 2001; Kuehn et al., 2011). Patients with a mutation of the intracellular domain of *FAS* have been shown to have a 14-fold increased risk of non-Hodgkin lymphoma and a 51-fold increased risk of developing Hodgkin lymphoma (Straus et al., 2001).

Lymph node biopsy also reveals findings virtually pathognomonic for ALPS. These findings include follicular hyperplasia and paracortical expansion with a mixed infiltrate containing the specific DNT cells noted by immunohistochemistry for CD3, CD4, and CD8 markers (Lim et al., 1998). This specific histological pattern can help distinguish ALPS from other benign and malignant lymphoproliferative disorders. Given the chronic fluctuating nature of their lymphadenopathy, patients with ALPS may have to undergo repeated lymph node biopsies to help rule out lymphoma if they develop systemic symptoms in addition to focal change of adenopathy. Testing lymph node tissue for clonality by means of immunoglobulin and TCR gene rearrangements as well as cytogenetic analysis for chromosomal aneuploidy is also useful for evaluating the diagnosis of lymphoma in ALPS patients.

Imaging Studies

Although imaging studies are not generally used to make a diagnosis of ALPS, once the diagnosis is established, it is useful to obtain baseline and periodic computed tomography (CT) scans. CT scans of the neck, chest, abdomen, and pelvis establish the location and extent of the patient’s lymphadenopathy and splenomegaly. Given the increased risk of lymphoma in patients with ALPS, surveillance with serial CT scans is an important part of the

chronic management of these patients. The degree of generalized lymphadenopathy can be documented longitudinally in a consistent fashion using the following guidelines during physical examinations: Grade: 1, few shotty nodes; 2, multiple 1–2 cm nodes; 3, multiple nodes, some >2 cm; 4, extensive visible adenopathy. Splenomegaly should also be clinically documented as a measure of its extent in the midclavicular line below the costal margin.

The use of positron emission tomography (PET) using 18-fluoro-2-deoxy-D-glucose (FDG) has become the standard in staging and follow-up evaluations of cancers including lymphomas. Whole body FDG-PET can be used to help differentiate chronic, benign lymphadenopathy in ALPS patients from ALPS-associated lymphomas, and its use decreases the number of lymph node biopsies these patients are required to endure (Rao et al., 2006). Lymph node biopsy may be indicated if sudden or dramatic change in a node is noted, particularly if these changes are associated with concerning constitutional symptoms such as weight loss, fever, or night sweats.

Treatment

Upon confirmation of a diagnosis of ALPS, patients should undergo counseling aimed at specifically addressing the risks associated with this condition. Most importantly, the increased risk of lymphomas and other malignancies should be discussed, and patients should be encouraged to seek further evaluation for any sudden fluctuations in lymph node or spleen size. In ALPS patients with intracellular *FAS* mutations, the risk of lymphoma should be particularly emphasized. Likewise, in asplenic ALPS patients, the infection risks, including opportunistic pneumococcal sepsis associated with asplenia (which may be compounded by lack of memory B cells and autoimmune neutropenia in these patients), should be stressed (Rao and Oliveira, 2011).

The massive lymphadenopathy often seen in children with ALPS may cause considerable anxiety for the patients and their families, which may lead clinicians to sympathetically treat these patients for cosmetic purposes alone. However, immunosuppressive drugs such as corticosteroids, azathioprine, cyclosporine, hydroxychloroquine, or mycophenolate mofetil do not consistently shrink lymph nodes and spleens of patients with ALPS, and treatment of these patients with such drugs for only cosmetic purposes is not indicated or desirable.

Spleen guards, made of fiberglass by an occupational therapist familiar with such devices, should be considered for ALPS patients with massive splenomegaly to help reduce the risk of traumatic splenic rupture. This is particularly important in those who are physically active (i.e., all toddlers) and/or patients involved in competitive

sports. Due to their increased risk of splenic rupture, patients with splenomegaly should be discouraged from participating in contact sports such as football or ice hockey.

All ALPS patients who are asplenic should be treated with long-term antibiotic prophylaxis against pneumococcal sepsis using penicillin V. ALPS patients frequently are unable to produce or maintain protective antibodies directed against polysaccharide antigens following vaccination due to defects in memory B cell function. Nevertheless, these patients should be vaccinated against encapsulated organisms such as pneumococcus, meningococcus, and *Haemophilus influenzae* type B (HiB). Patients who have undergone surgical splenectomy are encouraged to wear medical alert bracelets, necklaces, or wallet cards warning of their risk for sepsis.

An important aspect of caring for ALPS patients is the medical treatment of the chronic and refractory autoimmune multilineage cytopenias as these frequently cause substantial morbidity including low platelet counts resulting in mucocutaneous bleeding, and even mortality. Initial management for ALPS-related autoimmune cytopenias is similar to therapies used for sporadic cytopenias in other patient populations. For autoimmune hemolytic anemia (AIHA) or ITP, this includes the use of parenteral high dose methylprednisolone (5–30 mg/kg/day for 1–2 days) followed by oral prednisone (1–2 mg/kg/day) that is tapered slowly over months. High dose intravenous immunoglobulin (1–2 g/kg) may be considered for concomitant use with pulse dose steroids for severe AIHA. Some patients with autoimmune neutropenias who experience associated infection may be treated with low dose granulocyte colony stimulating factor (G-CSF 1–2 µg/kg administered SC two to three times per week). In patients with refractory autoimmune cytopenias requiring chronic steroid therapy, mycophenolate mofetil has been shown over the last 10 years to be an effective steroid-sparing agent that maintains adequate blood cell counts and reduces the need for other immunosuppressive agents or splenectomy (Rao et al., 2005; Rao and Oliveira, 2011; Teachey, 2012).

Finally, some ALPS patients with hypersplenism and associated cytopenias have shown significant improvement following treatment with sirolimus (Teachey et al., 2009; Teachey, 2012). While these results are very encouraging in terms of avoiding splenectomy, further studies of long-term outcomes are warranted before recommendations can be made regarding which patients would benefit most from this therapy. A suggested treatment algorithm for autoimmune cytopenias associated with ALPS is included (Figure 50.3). As with many chronic diseases with an onset in childhood, adolescence and early adulthood may provide the additional treatment challenge of poor compliance with prescribed medications.

Prognosis

The overall prognosis and outcome in most patients with ALPS is good, but the mortality and morbidity varies widely in patients depending on their disease severity. Many patients are expected to live a normal lifespan with few clinical complications. Some patients, however, develop life-threatening cytopenias, requiring hospitalizations, immunosuppressive therapy, blood transfusions, or splenectomy. Patients with mutations affecting the intracellular domain of the FAS protein have more severe disease and are at increased risk for Hodgkin lymphoma and non-Hodgkin lymphoma (Jackson et al., 1999; Neven et al., 2011). A large cohort of ALPS-FAS patients showed about a 6–10% incidence of lymphoma with a median age of presentation of 17 years (Straus et al., 2001). Lymphoma can be especially difficult to discern in the setting of persistent lymphadenopathy that is commonly found even in adult ALPS patients. However, ALPS-associated lymphomas appear to be as amenable to chemotherapy as sporadic lymphomas and should be managed as such.

Lymphadenopathy and splenomegaly associated with ALPS tends to become less prominent as patients grow older. This has been observed in mice with genetic deficiencies of Fas causing lymphoproliferation. It may be due to thymic involution that begins after puberty and a decrease in input of abnormal T lymphocytes. Perhaps related to this, though the reasons remain unclear, cytopenias in most patients with ALPS also improve with age. Nevertheless, stem cell transplantation has been successful in patients with ALPS and can be considered a treatment option for those with very severe, recalcitrant disease especially when a matched donor is available. Sibling donors should be screened and demonstrated to be free of mutations in the apoptosis pathway genes. The mortality of a matched unrelated donor-derived allogeneic bone marrow transplant continues to be too high to warrant the procedure in most patients with ALPS, as most of them have a near-normal life expectancy.

The major determinants of prognosis in patients diagnosed with ALPS include the severity of autoimmune disease (particularly autoimmune cytopenias) requiring chronic immunomodulatory therapy, hypersplenism, asplenia-related sepsis, and the development of lymphoma. Proper surveillance and education are vital to the prognosis of these patients.

ALPS-RELATED DISORDERS

Caspase-8 and FADD Deficiencies

Caspase-8 deficiency state (CEDS), due to an autosomal recessive mutation in the gene encoding caspase-8, was

Management Suggestions for ALPS Associated Chronic Refractory Cytopenia

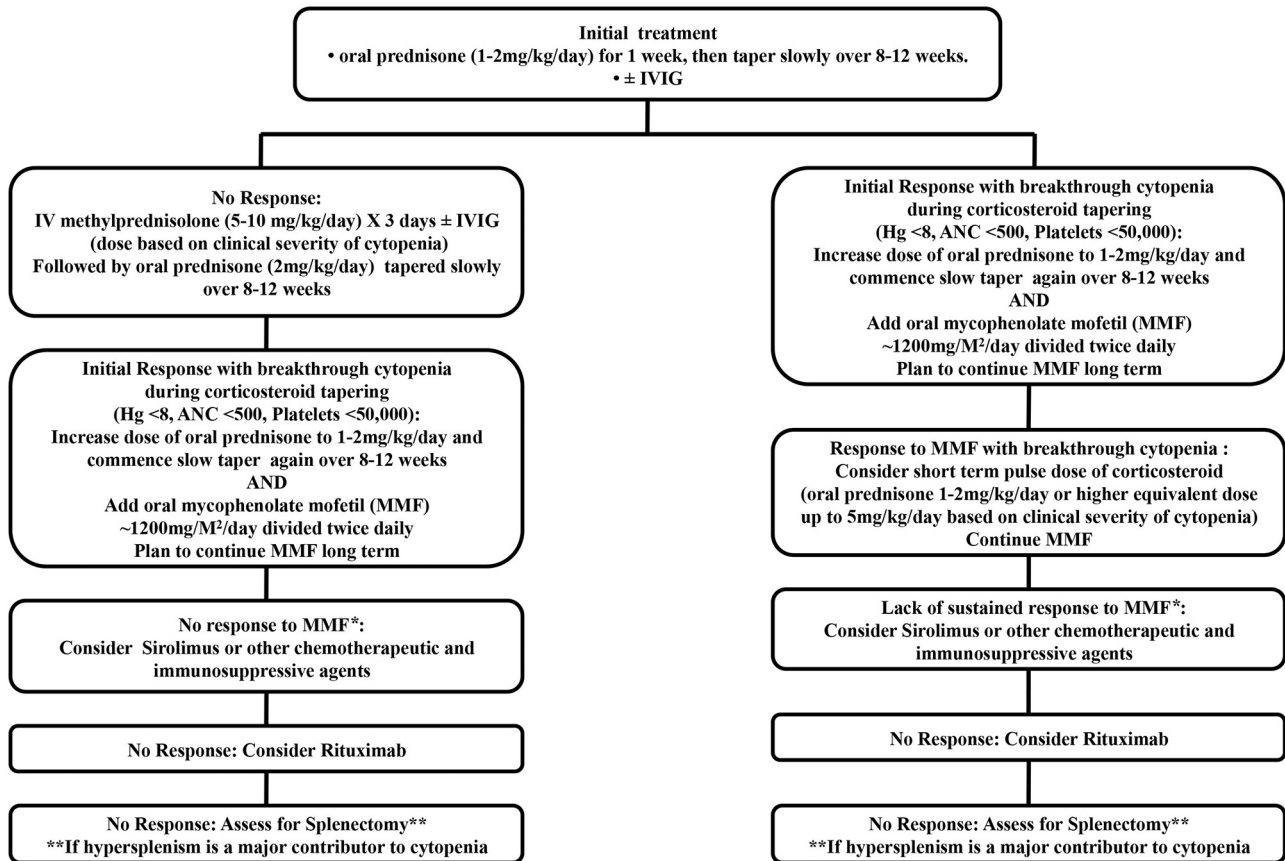

FIGURE 50.3 Treatment algorithms for ALPS-associated cytopenias. Note that paradigm comprises only suggested guidelines for managing ALPS patients with autoimmune multilineage cytopenias. G-CSF may be indicated for severe neutropenia associated with systemic infections. Chemotherapeutic and immunosuppressive agents including mycophenolate mofetil (MMF), sirolimus (rapamycin), vincristine, methotrexate, mercaptopurine, azathioprine, cyclosporine, and hydroxychloroquine can be considered as a steroid-sparing measure or to avoid/postpone splenectomy.

initially described in two siblings who had clinical features reminiscent of ALPS, with lymphadenopathy and splenomegaly, lymphocytosis but normal or barely elevated DNTs, defective lymphocyte apoptosis, and autoantibodies without autoimmune disease (Chun et al., 2002). However, the two patients also manifested concurrent immunodeficiency that is not typical of ALPS, with recurrent sinopulmonary and mucocutaneous herpes simplex virus infections, mild hypogammaglobulinemia, and poor pneumococcal antibodies. Recently, two more patients from the same extended family have been identified (S. Rosenzweig and J. Oliveira, unpublished results). These patients had immunodeficiency, with recurrent sinopulmonary infections, warts, molluscum contagiosum, poor pneumococcal antibodies, and normal DNTs. Besides their splenomegaly and lymphocytosis, they also had accumulation of lymphocytes in liver, lung, and brain. This is similar to the lymphocytic infiltration into parenchymal organs that develops in older mice lacking

caspase-8 within their T cells (Salmena and Hakem, 2005). Thus, CEDS in both humans and mice is characterized by a prominent combined immunodeficiency with pronounced lymphocyte accumulation and infiltration but minimal autoimmunity.

FADD assembles within the death-induced signaling complex (DISC), where it functions as an adapter molecule for apoptosis signaling. FADD can also associate with the CBM complex (but not the IKK α/β complex) upon antigen receptor stimulation, but it is also required for type I IFN antiviral immunity. Thus, FADD deficiency might be predicted to resemble CEDS. Indeed, four related patients with FADD deficiency due to autosomal recessive mutations were recently identified, who have an immunodeficiency phenotype (Bolze et al., 2010). The patients had invasive pneumococcal infections with functional hyposplenism, as well as repeated febrile episodes of encephalopathy with liver dysfunction that were associated with viral infections. However, unlike

CEDS, the viral susceptibility resulted from defective antiviral responses rather than effects on T cell proliferation. Furthermore, unlike CEDS or ALPS, none of the FADD-deficient patients had splenomegaly or lymphadenopathy. Nevertheless, one patient was demonstrated to have increased DNT cells, a lymphocyte apoptosis defect, elevated biomarkers that are usually associated with ALPS-FAS, and DAT autoantibodies without reported autoimmune disease. Taken together, FADD deficiency, like CEDS, clinically overlaps with ALPS but differs in featuring immunodeficiency prominently.

RAS-Associated Autoimmune Leukoproliferative Disorder

While studying patients with features of ALPS but without known gene mutations, in 2007 we discovered one subject with a somatic activating mutation in the gene *NRAS* (Oliveira et al., 2007). Although initially classified as ALPS, type IV, the patient had atypical features such as a history of significant leukocytosis early in life, persistent monocytosis, and a low level of $\alpha\beta$ -DNTs, which did not infiltrate lymph nodes. Later, additional patients with an ALPS-like disease were found to have heterozygote-dominant activating mutations in *NRAS* or *KRAS* which resemble the mutations that cause activation of oncogenic RAS in a wide variety of tumors. The disease was named RAS-associated autoimmune leukoproliferative disorder (RALD) (Oliveira et al., 2007; Niemela et al., 2011; Takagi et al., 2011).

RALD patients have several clinical and laboratory features that overlap with ALPS. They were diagnosed between 1 and 47 years of life and presented with a generally mild degree of peripheral lymphadenopathy. However, they manifested significant splenomegaly and autoimmunity including AIHA, ITP, and neutropenia. In some patients, a history of recurrent mild upper and lower respiratory tract infections could be elicited (Niemela et al., 2011). Unlike ALPS patients, patients with RALD had transient or persistent elevation in granulocytes and monocytes. Some RALD patients had a clinical and laboratory phenotype very similar to juvenile myelomonocytic leukemia (JMML) early in life, with marked hepatosplenomegaly and monocytosis. However, unlike patients with JMML, the relative or absolute monocytosis tends to improve spontaneously but never disappears.

Immunophenotyping in RALD reveals mild to no elevation in DNTs and an expansion of B cells. Total lymphocyte numbers are normal to modestly decreased. In contrast, absolute or relative monocytosis is noted in all patients. Autoantibodies are typically detected, including ANA and rheumatoid factor, as well as

anti-phospholipid, anti-cardiolipin, anti-platelet, anti-neutrophil, and/or anti-red cell antibodies (Oliveira et al., 2007; Niemela et al., 2011; Takagi et al., 2011). Unlike patients with ALPS, the biomarkers and *in vitro* FAS-induced apoptosis are also normal. By contrast, in RALD patients, the T cells are resistant to IL-2 withdrawal-induced cell death, pointing to a fundamentally different apoptotic defect in RALD (Oliveira et al., 2007; Niemela et al., 2011; Takagi et al., 2011). The histopathological findings include nonspecific polyclonal plasmacytosis with reactive secondary follicles, but without the typical paracortical expansion caused by DNT cells in ALPS. Given the small number of patients diagnosed to date, it is not known if these patients are at increased risk for hematological malignancy. In summary, RALD should be suspected in a patient with splenomegaly with or without lymphadenopathy, blood-cell directed autoimmunity, and relative or absolute monocytosis, in whom a malignancy or infection has been ruled out.

Genetic Features

There is marked genetic heterogeneity underlying the autoimmune lymphoproliferative syndromes. Strikingly, germline and somatic defects are seen in this patient population, complicating the molecular diagnosis in the clinical setting. We will discuss below each disorder separately.

AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME (ALPS)

Germline FAS Mutations

Around 74% of ALPS patients bear heterozygous germline mutations in the *FAS* (*TNFRSF6*) gene located on chromosome 10q24.1. Mutations can be found throughout the gene, either in coding regions or in splice sites, with the majority ($\approx 2/3$) affecting the intracellular death domain (DD) encoded by exon 9 (Figure 50.4). (All mutations found to date are in the ALPS database at <http://www.niaid.nih.gov/topics/ALPS/research/Pages/mutationDatabase.aspx>.) Essentially all mutations are transmitted in an autosomal dominant fashion and exert a dominant-negative effect. This effect is explained by the observation that incorporation of even a single mutant Fas chain in the trimeric receptor impairs function and that very few trimers, i.e., 1/8 or 1 out of 2^3 , will have exclusively wild-type subunits for heterozygous alleles encoding the trimeric receptor. Moreover, recent understanding of crystal structure of FAS protein and its oligomerization on the cell surface reveals it to be a complex structure that would make the calculations even less favorable for signaling since the mutant subunits would

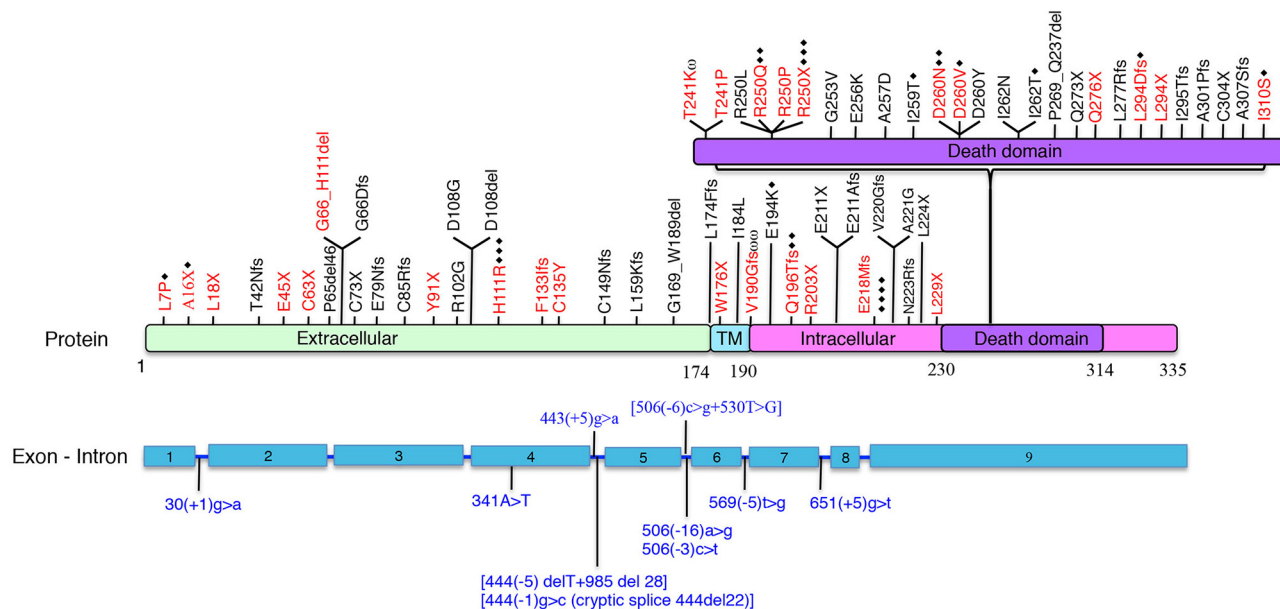

FIGURE 50.4 Schematic representation of FAS mutations in ALPS patient. Shown is the domain structure of the protein on the top (TM = transmembrane) with the amino acid position enumerated. The gene structure is shown below with the exons numbered as solid blue boxes and the introns as solid blue lines (not drawn to scale). Red text indicates mutations described in data in this chapter. Black text indicates additional known protein coding mutations. Blue text indicates complex mutations affecting the mRNA structure. Black diamonds represent the number of families with the same mutation. From *Kuehn et al. (2011)*.

abrogate function of even larger superstructures of Fas receptors (*Wang et al., 2010*). A few ALPS cases with aggressive disease phenotype in early childhood caused by homozygous germline mutations in *FAS* have also been reported.

There are important genotype–phenotype relationships in ALPS. Disease severity and penetrance are greatest for mutations affecting the *FAS* intracellular DD region, which disrupt the homotypic interactions required for FADD and initiator caspase recruitment into the death-inducing signaling complex. In contrast, mutations affecting the extracellular portions of the protein are commonly associated with *FAS* haploinsufficiency and manifest by milder clinical disease and lower penetrance (*Kuehn et al., 2011; Hsu et al., 2012*). More recently, it has been described that a group of ALPS patients with extracellular mutations that develop clinically important autoimmune disease present with somatic mutation in the second allele of *FAS* (*Magerus-Chatinet et al., 2011*). This association of germline and somatic mutations in the same gene is unique and sheds light onto the genetic mechanisms underlying disease severity in ALPS.

Somatic *FAS* Mutations

Curiously, the second most common genetic cause of ALPS is somatic mutations in *FAS* (*Holzelova et al., 2004; Dowdell et al., 2010*). These patients present with

mutations only in blood elements, affecting most DNT cells and a small proportion of CD4, CD8, CD20, and CD34 (progenitor) cells. Notably, these patients lacked apoptosis defects *in vitro*. The somatic event is thought to happen in a hematopoietic stem cell clone that expands by survival advantage. The clinical manifestations are similar to those in patients with germline *FAS* mutations. These patients do share the biomarkers of patients with germline *FAS* mutations and their diagnosis can be confirmed by sequencing *FAS* in a purified DNT cell population.

Additional Genetic Etiologies

A very small proportion of ALPS patients harbor mutations in the genes encoding for caspase-10 (*CASP10*) and *FAS* ligand (*FASL*). *CASP10* mutations have been found in 10 patients thus far. These mutations were heterozygous and cause defective apoptosis in lymphocytes and dendritic cells (*Wang et al., 1999*). The clinical phenotype was indistinguishable from that of patients with *FAS* mutations. A heterozygous mutation in Fas ligand (*FASLG, TNFSF6*) was originally reported for a patient with systemic lupus erythematosus (SLE) who had lymphadenopathy, splenomegaly, and defective lymphocyte apoptosis after TCR restimulation, but no apparent DNT expansion, and in another patient with ALPS (*Wu et al., 1996; Del-Rey et al., 2006*). Two other ALPS

FIGURE 50.5 RAS regulatory cycle. RAS GTPase proteins are turned “on” by loading with a guanosine-5′-triphosphate (GTP) molecule and “off” when it is hydrolyzed to guanosine-5′-diphosphate (GDP) with the release of a phosphate group. Ras proteins carry out effector functions, such as apoptosis inhibition, in the active, GTP bound form but not in the inactive, GDP bound form. The low intrinsic GTPase activity of RAS is increased over 300-fold upon interaction with GTPase activating proteins (GAP) which turn off the Ras protein. The exchange of GTP for GDP is accelerated by GTP exchange factors (GEF), which turns on the Ras protein. Most pathogenic mutations in KRAS or NRAS disrupt the interaction of RAS with GAPs and decrease the GTPase activity thereby keeping the Ras protein in an active state. This blocks apoptosis (see Figure 50.1) and can accentuate cell proliferation.

patients were also discovered who possessed homozygous *FASLG* mutations (Del-Rey et al., 2006). Finally, a subgroup of ALPS patients fulfills diagnostic criteria including increased circulating DNT cells in peripheral blood but lacks known mutations in the FAS pathway.

RAS-ASSOCIATED AUTOIMMUNE LEUKOPROLIFERATIVE DISORDER

All 12 patients with RAS-associated autoimmune leukoproliferative disorder (RALD) described so far harbor somatic, gain-of-function mutations in *KRAS* or *NRAS*, which are present only in blood cells. Somatic activating mutations in RAS are present in up to 30% of all human cancers. Germline RAS pathway mutations have been described as causing the related Costello (*HRAS*), Noonan (*PTPN11*, *KRAS*, *SOS1*, *NRAS*), and cardiofaciocutaneous syndromes (*KRAS*, *BRAF*, *MEK1*, and *MEK2*) (Zenker, 2011). The RAS mutations seen in RALD disrupt the interaction of RAS with the GTPase activating proteins (GAPs), significantly weakening the GTPase activity and allowing the protein to be in a permanent GTP-bound, “on” position (Figure 50.5). The consequences of this are discussed in the section below.

In Vivo and *In Vitro* Models of Disease

An important clue to the genetic etiology behind human ALPS was the unusual expansion of DNT cells which occurs in both germline and somatic Fas mutant patients (Sneller et al., 1992). Similar expansions were observed in the spontaneously arising lymphoproliferation (*lpr*) or

generalized lymphoproliferative disease (*gld*) mouse strains, which also develop lymphadenopathy, splenomegaly, hypergammaglobulinemia, autoantibodies, autoimmune disease, and lymphoma (Cohen and Eisenberg, 1991; Davidson et al., 1998). Unlike humans with ALPS who tend to have autoimmune cytopenias, autoimmune disease in their murine counterparts resembles systemic lupus erythematosus, with ANA and deposition of immune complexes leading to glomerulonephritis, arthritis, polyarteritis, sialoadenitis, and primary biliary cirrhosis. In *lpr* (and *lpr^{cs}*) mice, the genetic defect was mapped to the Fas gene that mediates apoptosis (Watanabe-Fukunaga et al., 1992). In the *gld* mice, the genetic defect was mapped to the Fas ligand gene that triggers apoptosis (Roths et al., 1984). In both cases, disease occurs in inbred strains of mice that are autosomal recessive for these specific loss-of-function mutations. This is consistent with a genetic “loss of function” or deficiency mechanism in the mice, which differs from the dominant interference that usually occurs in non-consanguineous humans who have heterozygous FAS or FASL mutations. No mouse models of ALPS resulting from somatic FAS mutations have been described. Also there are no mouse models of ALPS-CASPASE-10 because caspase-10 has no ortholog in the mouse.

The availability of mouse models has been helpful in elucidating disease pathogenesis. *In vitro* apoptosis assays performed on cells from patients, or in cells transfected with mutant FAS or FAS ligand molecules, clearly demonstrate defective apoptosis whenever the mutation is present (Fisher et al., 1995). However, even though the mutation and the degree to which it interferes with

apoptosis is the main factor contributing to disease, not all mutation-positive individuals exhibit disease (Sneller et al., 1997; Jackson et al., 1999). The variable penetrance argues for the additional contribution of genetic modifiers, which has been observed in mice. In *lpr* mice, the severity of autoimmune disease depends upon the inbred genetic background, with more severe disease seen in the MRL strain and less severe disease in other strains (Cohen and Eisenberg, 1991). Crosses of *lpr* mice on susceptible versus resistant backgrounds have been useful in identifying several loci that influence disease phenotype. An example of one such genetic modifier is osteopontin. Certain polymorphisms in osteopontin are associated with the development of glomerulonephritis in *lpr* mice (Miyazaki et al., 2005), or a variant of ALPS termed autoimmune lymphoproliferative disease (ALD) that lacks DNT expansion (Chiocchetti et al., 2004).

The ability to genetically manipulate mice has also facilitated other studies addressing key aspects of disease pathogenesis. For example, although DNT expansion is a defining criterion of ALPS, investigations on the provenance of these cells have been hampered by the inability to culture human or mouse DNT *in vitro*. However, mouse models suggest that DNT likely arise from senescent CD8 T cells that have lost their CD8 co-receptors (Koh et al., 1995; Merino et al., 1995). More recently, *in vivo* mouse models have also established that membrane bound but not soluble Fas ligand plays a physiological role in apoptosis induction (O'Reilly et al., 2009a), and that the normal apoptosis of antigen-presenting cells as well as T cells is crucial for establishing immune tolerance (Stranges et al., 2007). Finally, the use of mouse models has facilitated preclinical testing of potential therapies such as rapamycin that are now used to treat patients (Teachey et al., 2006, 2009). Thus, *lpr* mouse models provide a valuable complement to the clinical and laboratory investigation of ALPS.

Pathogenic Effector Mechanisms

ALPS

As described in previous sections, most ALPS patients have mutations affecting components of the FAS pathway of apoptosis. Given the crucial role of this pathway in the elimination of old, excessive, or damaged lymphocytes, the clinical consequences are predictable. The characteristic lymphadenopathy and splenomegaly are caused by local accumulation of DNT cells, which expand the paracortical areas of the lymph nodes and red pulp of the spleen. Additionally, there is marked plasmacytosis and follicular hyperplasia, also reflecting an active B cell population.

Although a hallmark of this disease, the role of the DNT cells in disease pathogenesis is important but not

well understood. They seem to be derived mostly from previously activated CD8 cells, and secrete large amounts of IL-10. It has been hypothesized that the high IL-10 levels may contribute to the survival and expansion of autoreactive B cell clones, resulting in antibody-mediated blood element autoimmunity. The finding that patients with somatic *FAS* mutations, which are detected mainly in DNT cells, have essentially identical clinical manifestations to patients with germline mutations reinforces the potentially key pathogenic role of these cells. However, 10–20% of B and T cells also carry the mutation, and may also participate in disease pathogenesis. Additionally, in murine models, *FAS* has a role in mediating B cell selection during a germinal center reaction, and it is not known if ALPS patients have a normally selected B cell repertoire. Regarding the increased risk for lymphoma, this can be explained by the known tumor suppressor role of *FAS*, coupled to the chronic activation state of B cells.

Lastly, it is interesting to note the lack of T cell-mediated vasculitis in ALPS patients, despite the important role of *FAS* for T cell apoptosis. Also, the range of autoantibody-mediated diseases is very narrow, affecting only blood cells, with absence of organ-specific autoimmune disease such as thyroiditis, adrenalitis, or pancreatic insulinitis. This points to a specific role of *FAS* or other as yet undefined modifier genes in controlling this specific aspect of immune tolerance.

RALD

The RAS genes (*NRAS*, *KRAS*, and *HRAS*) encode 21-kDa proteins that are members of the superfamily of small GTP-binding proteins, which have diverse intracellular signaling functions including control of cell proliferation, growth, and apoptosis. RAS activity differs when bound to GTP versus GDP (Figure 50.5). GTP-bound molecules are thought to be active signaling molecules and GDP-bound forms are thought to be inactive. The conversion from a GTP- to a GDP-bound state is catalyzed by a weak intrinsic GTPase activity, which is greatly enhanced upon interaction of RAS with GTPase activating proteins (GAPs) (de Vos et al., 1988). The *NRAS* and *KRAS* mutations seen in RALD patients are heterozygous and gain-of-function, such as p.G13D and p.G12V, similar to the ones described in tumors. These mutations disrupt the interaction of RAS with the GAPs, diminishing its GTPase activity by over 300-fold and locking the molecule in an “on” position (de Vos et al., 1988). This permanent activation state increases cell signaling through the RAS-ERK pathway, inducing the phosphorylation and destruction of the pro-apoptotic protein BIM (Ley et al., 2005; O'Reilly et al., 2009b). Consequently, the cells become resistant to certain kinds of apoptotic stimuli, such as growth-factor (IL-2)

FIGURE 50.6 The role of caspase-8 in the NF- κ B pathway during immune cell activation. Upon triggering of B cell, T cell, TLR, or NK receptors, a key transcriptional regulator, NF- κ B, is induced which activates a large transcriptional program that coordinates the immune response. The pathway proceeds through receptor activation of Src and Syk family proximal kinases and protein kinase C isoforms (PKC) that lead to the assembly of the CARMA1-BCL10-MALT1 (CBM) complex. The CBM complex binds to and activates the I- κ B kinase (IKK $\alpha/\beta/\gamma$) complex using caspase-8 as a bridge (Su et al., 2005). Once recruited to the CBM complex, IKK $\alpha/\beta/\gamma$ phosphorylates (P) the I- κ B α protein leading to its separation from NF- κ B, ubiquitinylation (Ub), and degradation, while NF- κ B translocates into the nucleus to activate the gene transcription program.

withdrawal, so that they can survive *in vitro* for long periods of time. Additionally, persistent ERK signaling decreases the intracellular levels of negative inhibitors of the cell cycle, namely p27^{kip1}, allowing for increased proliferation in the face of limiting IL-2 levels (Niemela et al., 2011). Interestingly, recent work has suggested that adequate RAS signaling is important for B cell selection, given the multiple antibody-mediated autoimmune manifestations seen in these patients with monocytosis (Limnander and Weiss, 2011; Limnander et al., 2011).

CEDS

The clinical phenotype of immunodeficiency coupled to lymphoproliferation can be explained by the dual role of caspase-8 in signaling for both apoptosis and lymphocyte activation. Upon FAS death receptor stimulation, caspase-8 is recruited into the death-inducing signaling complex (DISC) for apoptosis induction (Figure 50.1). By assembling with FAS through FADD adapter molecules, caspase-8 becomes enzymatically activated, is cleaved, and activates downstream caspases, thereby unleashing an enzymatic cascade that cleaves proteins for cell death. By contrast, upon immunoreceptor stimulation, caspase-8 assembles with the CARMA1-BCL10-MALT1 (CBM) and the IKK $\alpha\beta$ complexes (Figure 50.6) (Su et al., 2005). Oligomerization without cleavage weakly induces

caspase-8 enzymatic activity, but not full processing of the zymogen, which is required for the holocomplex to activate the gene transcription factor NF- κ B for lymphocyte activation. Thus, caspase-8 has a dual role in controlling cell activation and death.

BENTA Disease

In 1971, a form of non-malignant polyclonal B lymphocyte hyperproliferation was described in an infant that progressed in adulthood to B lymphoid chronic lymphocytic leukemia (B-CLL) (Darte et al., 1971; Snow et al., 2012). This disease, “B cell expansion with NF- κ B and T cell anergy” (BENTA) has been recently attributed to germline heterozygous missense mutations in the gene encoding CARD11/CARMA1, a scaffolding protein required for antigen receptor-induced NF- κ B activation in both B and T lymphocytes (Figure 50.6). Importantly, these are activating mutations that cause the CARD11 protein to spontaneously signal constitutive NF- κ B activation. It is notable that similar somatic gain-of-function CARD11 mutations have been reported to cause diffuse large cell B cell lymphoma, but the germline CARD11 mutations have only been associated with a single case of B-CLL thus far. BENTA disease patients manifest B cell activation and hyperproliferation especially IgM⁺ IgD⁺ CD19⁺, CD20⁺ B cells as well as CD10⁺ immature/transitional B cells with the relative

paucity of memory (CD27⁺) and class-switched B cells. Histological examination of spleen, lymph node, and appendix tissue showed dramatic follicular hyperplasia of B cells, containing numerous primary follicles with prominent mantles and marginal zones, but atrophic germinal centers (GCs). By contrast, the patient T cells are normal in number and distribution but markedly less functionally responsive to antigen receptor-induced activation. In apoptosis assays of T cells, Fas killing is normal, whereas RICD is mildly reduced, probably related to poor initial activation; for B cells Fas-induced apoptosis is low. B cell dysregulation in these patients can lead to autoantibodies, autoimmune cytopenias, and a positive anti-nuclear antibody. Although BENTA disease may resemble ALPS with B cell lymphoproliferation, autoantibodies, apoptosis abnormalities, mild increases in DNTs, and a propensity to lymphoid malignancy, the former can readily be distinguished by distinctive histopathology, B cell subset abnormalities, and decreased T cell function tests. Conversely, ALPS has been associated with a variety of histological types of lymphoma but not with B-CLL.

Disease Biomarkers

In recent years several biomarkers were observed to be abnormal in patients with ALPS (Magerus-Chatinet et al., 2009; Caminha et al., 2010). These include increased prototypal DNT cells, HLA-DR positive cells, and decreased memory B cells. Also, several reports described elevated serum levels of soluble FAS ligand, vitamin B12, IL-10, and IL-18. More recently, the diagnostic utility of all these markers was evaluated in a large cohort of 562 ALPS patients and their relatives, with or without FAS mutations. Although not clinically useful in isolation, the combination of these markers proved to be a powerful predictor of the presence of FAS mutations in patients with an ALPS clinical phenotype. Patients with a combination of DNT >4% and IL-10 >40 pg/ml or B12 >1500 ng/L or sFASL >300 pg/ml had a 97% chance of harboring a FAS mutation (Caminha et al., 2010). Conversely, patients with DNTs <2% and sFASL <200 pg/ml carried only a 1.7% chance of having a FAS mutation. These markers were also very sensitive in detecting patients with somatic FAS mutations (Dowdell et al., 2010). Thus, in the presence of elevated DNTs and B12 or sFASL, a negative genetic screening for germline FAS mutations should prompt an investigation for somatic mutations in the sorted DNT population. These biomarkers were incorporated into the recently modified ALPS diagnostic criteria (Oliveira et al., 2010).

CONCLUSION

Despite their rarity, the discovery of ALPS and related disorders and their underlying genetic defects has

provided valuable lessons about the role of these molecules in human immune homeostasis, tolerance and the prevention of autoimmunity, and tumor suppression. Despite these advances, about 20% of ALPS patients have yet-to-be-discovered genetic bases. The recent developments in high throughput genomics are likely to spur a new era of discoveries at an unprecedented pace.

INTRODUCTION

Immunologically mediated dysfunction of coagulation is observed secondary to a number of different autoimmune conditions but also occurs based on an isolated, specific autoimmune response to molecules of the coagulation system. The immune response directly or indirectly leads to an imbalance of hemostasis inducing hyper- or hypocoagulability.

Autoimmunity is found in primary and secondary—also called plasmatic—hemostasis. Primary hemostasis describes the initial reaction after injury of the endothelium of the blood vessel including the contraction of the blood vessel and exposure of tissue factor followed by the activation of platelets leading to the initial closure of the injury. In parallel, secondary hemostasis is initiated transforming the initial platelet clot into a stable fibrin clot. This clot is controlled by fibrinolysis. The classical schematic presentation of the coagulation cascade and the interplay of activation and inactivation are shown in [Figure 51.1](#) illustrating its complexity of regulation.

This chapter aims to provide a short but comprehensive overview of autoimmunity to various proteins involved in secondary hemostasis, summarizing different and independent autoimmune entities. Autoantibodies can be detected and quantified. They need to be distinguished from alloantibodies in patients with congenital bleeding disorders after substitution of plasma or plasma proteins, which are not covered in this chapter. Autoantibodies to platelets interfering with primary hemostasis are described in Chapter 47.

In general, autoimmunity to proteins of the coagulation cascade is a rare event; for some proteins, only individual cases have been described in the literature. Antibodies can be detected against such proteins and quantified. Such antibodies have been termed inhibitors historically. Therapeutic options have not yet been studied in controlled clinical trials. Thus information on therapeutic interventions provided in this chapter reflects individual reports or expert opinion based on cohort studies or case series.

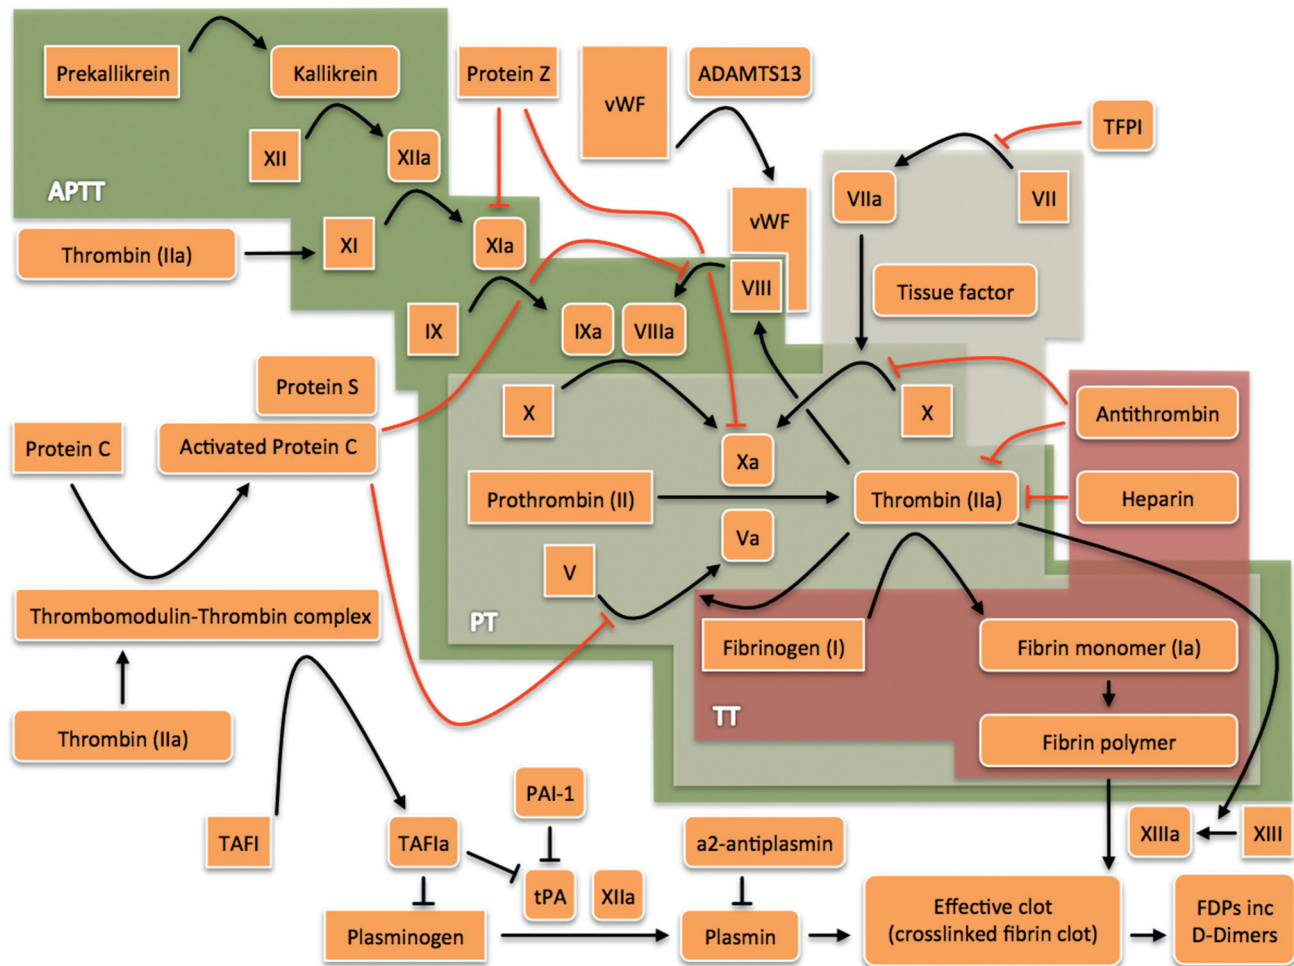

FIGURE 51.1 The coagulation cascade. The complexity of coagulation and the interplay of the different factors with regard to inhibition and activation are illustrated in the diagram. The classical scheme has been used to demonstrate the complexity of molecules and interaction. Although extremely rare, autoimmune inhibitors have been described against most coagulation factors. The factors influencing the different global tests aPTT, PT, and TT are shaded green, gray, and red, respectively.

PROCOAGULANT THROMBOTIC DISEASES

There are several autoimmune entities known to interfere with homeostasis of the coagulation system thereby leading to a procoagulant state; in particular the antiphospholipid syndrome (APS) interferes with many components of the coagulation cascade as discussed in Chapter 34. Except for APS and antibodies to ADAMTS13 (see below) only single case reports on autoantibodies to other proteins of the coagulation cascade leading to thrombosis have been published.

Lupus anticoagulants interfere with the protein C pathway and possibly block the inactivation of FVIIIa (Urbanus and de Laat, 2010; Saenz et al., 2011). Autoantibodies to protein C and protein S have been described whereas antibodies to protein S appear to be

the more clinically relevant. Both autoantibodies were found at higher frequencies in individuals with overt thrombosis compared to healthy controls. The presence of specific IgM but not IgG autoantibodies as determined by ELISA correlated with the clinical phenotype (Rossetto et al., 2009). Also, both antibodies have been associated with fetal growth restrictions and preeclampsia (Torricelli et al., 2009). Antibodies to protein S have been detected, for example, in Behçet disease associated with thrombosis in five cases (Guermazi et al., 1997; Lechner et al., 2011). Further, they were prevalent in a number of patients with acquired protein S deficiency, and in patients with activated protein C resistance in the absence of the FV Leiden mutation with or without underlying systemic lupus erythematosus (Sorice et al., 1996; Nojima et al., 2002a, 2009). Antibodies to protein S and clinically relevant thrombosis have also been detected in children

after infections, mainly varicella in several cases (Levin et al., 1995; Larakeb et al., 2009).

IgG and IgM autoantibodies to protein Z, which inactivates FXIa, have been detected in women with recurrent spontaneous miscarriages but not in healthy controls and were also associated with pregnancy complications, preeclampsia and fetal growth retardation (Gris et al., 2003; Erez et al., 2009; Sater et al., 2011). In a case–control study low protein Z levels and autoantibodies to protein Z were also found in patients with arterial or venous thrombosis (Pardos-Gea et al., 2008). The role of autoantibodies present in the antiphospholipid syndrome on the protein Z-mediated inactivation of FXa and on thrombosis is not clear (Forastiero et al., 2003; Sailer et al., 2008). Thrombotic complications also occur due to inhibitors to prothrombin (see below).

Autoimmune Inhibitors to ADAMTS13

Autoimmunity to ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif 13) causes the clinical picture of acquired thrombotic thrombocytopenic purpura (aTTP). Thrombotic events in terminal capillaries and arterioles are seen in aTTP. ADAMTS13 is a zinc protease, which cleaves the ultra large multimers of von Willebrand factor (vWF, see below) (Tsai, 1996; Furlan et al., 1997; Zheng et al., 2001; Fujikawa et al., 2001; Dong et al., 2002). Prior to the discovery of the enzyme itself the presence of ultra large multimers of vWF had already been demonstrated in aTTP patients (Moake et al., 1982). If not processed by ADAMTS13, the multimers rapidly form hyaline thrombi together with thrombocytes, mainly in the brain, kidney, adrenal gland, heart, pancreas, and spleen.

The incidence of aTTP is reported as 1.72 to 7 cases per million per year with women being affected twice as often as men. There is also a higher incidence and a more severe course seen in individuals of African descent (Torok et al., 1995; Miller et al., 2004; Terrell et al., 2005; Cataland et al., 2009). aTTP is mostly seen in adolescents and adults with a median age of 42 years (range 2–78) with a few pediatric cases being described (Scully et al., 2008; McDonald et al., 2010). aTTP can be seen in combination with underlying conditions including malignancies, drugs, infections, autoimmune diseases, primary immunodeficiency, after bone marrow transplantation, and pregnancy (Murrin and Murray, 2006; Scully et al., 2008; Yamada et al., 2011; Kawasaki et al., 2013). The combination of thrombocytopenia, hemolytic anemia, renal impairment, fever, and neurological symptoms has been described initially but the full pentad is present in fewer than half of all patients. The severe neurological symptoms are usually multifocal and often recurrent (Murrin and Murray, 2006). Typical but not

pathognomonic is the paradoxical combination of thrombosis and thrombocytopenia. Additional clinical findings include petechial bleedings. The full clinical picture depends on organs affected by microthrombosis. This includes affection of the heart with pathological levels of cardiac enzymes and an abnormal ECG. Differential diagnosis includes but is not limited to hereditary TTP, hemolytic uremic syndrome, disseminated intravascular coagulation, and other microangiopathies or combinations of the above. The diagnosis may be difficult as levels of ADAMTS13 are reduced in several conditions. In suspected aTTP, diagnosis requires a blood cell count, vWF indices including multimers, ADAMTS13 activity, and levels of antigen and antibodies. Different assays to determine the enzymatic activity are available. Von Willebrand antigen and activity appear higher in TTP. In the acute phase the large vWF multimers are lacking in the plasma but reappear in remission. The extent of depleted ultra large multimers correlates with the severity of hemolysis and thrombocytopenia. Fragmented erythrocytes, an elevated LDH and creatinine, depending on kidney involvement, are observed (Whitelock et al., 2004; Wu et al., 2006; Peyvandi et al., 2010; Lotta et al., 2011).

Antibodies mainly of the isotype IgG, but also IgA and IgM, are found in almost all patients with aTTP. Most antibodies are inhibitory, but, in 10–15% of patients with ADAMTS13 deficiency, non-inhibitory antibodies are found suggesting an increased clearance of the protease (Scheiflinger et al., 2003; Tsai et al., 2006; Shelat et al., 2006; Ferrari et al., 2007; Pos et al., 2011). Antibodies isolated from peripheral B cells and class-switched memory B cells show somatic hypermutations suggestive of a role for T cells (Luken et al., 2005). IgG to ADAMTS13 is also seen in random controls but to a much lesser extent compared to aTTP patients (Tsai et al., 2006). Specific autoantibodies mainly belong to the IgG4 subclass, but also IgG1, IgG2, and IgG3 have been identified (Ferrari et al., 2009). The correlation of the type of antibodies with the outcome is still being discussed: high levels of autoantibodies and in particular high levels of IgG4 and the combination of IgG1 and IgA have been associated with an unfavorable outcome. Antibodies decrease during successful treatment (Coppo et al., 2006; Ferrari et al., 2007; Scully et al., 2007). In a different study, levels of IgA, IgG1, and IgG3 correlated with disease severity in the acute phase. Detectability of IgG in remission was also associated with a higher relapse rate (Bettoni et al., 2012). In almost all patients, antibodies against the cysteine-rich and the spacer region were identified, followed by antibodies against the metalloprotease. The cysteine-rich region is required for the cleavage of vWF. Antibodies against all other domains have been detected at lower frequencies (Soejima et al.,

2003; Klaus et al., 2004; Luken et al., 2005; Zheng et al., 2010; Yamaguchi et al., 2011).

There are indications for a genetic predisposition for the development of anti-ADAMTS13 autoantibodies: in different cohorts the MHC class II alleles DRB1*11, DQB1*0301, DQB1*02:02, and DRB3* are found more frequently in patients with aTTP, while the DRB1*04 and DRB4 alleles appear to be protective (Coppo et al., 2010; Scully et al., 2010; Pos et al., 2011; John et al., 2012).

Timely diagnosis and adequate treatment are crucial. If untreated the mortality is around 90%. Initial treatment is unsuccessful in most patients, with a relapse rate of 30–60% over 10 years (Shumak et al., 1995; Tsai, 2006; Kremer Hovinga et al., 2010). The benefit of plasmapheresis and plasma transfusions compared to transfusions alone was shown in a randomized trial (Rock et al., 1991). The combination of plasma exchange and steroids induced remission of >90% (Ferrari et al., 2007). Reported immunosuppression was mainly based on corticosteroids alone, but combinations with cyclosporine have also been successfully used (Cataland et al., 2007). Treatment with rituximab was successful and associated with a faster time to remission and fewer relapses but with the limitation of a non-stated long-term follow-up (Foley et al., 2009; Ling et al., 2009; Ojeda-Urbe et al., 2010; Scully, 2012; Tun and Villani, 2012). Successful treatment with bortezomib was reported in a patient refractory to immunosuppression including rituximab (Shortt et al., 2013). The benefit of intravenous immunoglobulin (ivIg) is doubtful; single reports discuss the benefit of defibrotide (Pogliani et al., 2000). In patients with refractory aTTP, splenectomy has been performed successfully (Kremer Hovinga et al., 2004). Thrombocyte transfusions are contraindicated, being associated with a higher mortality. Novel therapies are currently being evaluated: novel gain of function mutants resistant to autoantibodies might add to the future options in the treatment of aTTP (Jian et al., 2012). The role of recombinant ADAMTS13 in the presence of autoantibodies remains to be determined.

ANTICOAGULANT (BLEEDING) DISEASES

Autoimmune inhibitors to proteins of the coagulation cascade can cause a severe bleeding phenotype so a rapid diagnosis in these rare conditions and appropriate treatment are often crucial to the outcome for the patient. Inhibitors should be suspected in patients with hemorrhages without a personal or family bleeding history, and without trauma or use of anticoagulants. The provided algorithm describes a summary of a potential and rational approach to investigate patients with unexpected and unexplained bleeding events or abnormal coagulation tests and suspected inhibitors (Figure 51.2). For each individual protein epidemiological, clinical, and immunological aspects of inhibitors are described below.

Autoimmune Antibody Inhibitors to Fibrinogen (Factor I) and Fibrin

The fibrin clot is the final product of the coagulation cascade. Fibrin is generated from fibrinogen after thrombin cleavage. The glycoprotein fibrinogen is a heterohexamer composed respectively of two α -, β -, and γ -chains. Autoantibodies to fibrin or fibrinogen are rare. They have been described in combination with different underlying conditions, in pregnancy, or as “idiopathic.” These conditions include other autoimmune disorders such as SLE or monoclonal gammopathies (Cohen et al., 1970; Coleman et al., 1972; Galanakis et al., 1978; Ruiz-Arguelles, 1988; Panzer and Thaler, 1993). Patients present with mild to severe bleeding symptoms. Antibodies to fibrin in pregnant women and newborns were not associated with a bleeding phenotype (Kondera-Anasz, 1998). More frequently cross-reactive antibodies occurred after exposure to bovine thrombin glue (see below; Chouhan et al., 1997).

Laboratory analysis reveals a prolonged TT, with both either normal or prolonged PT and aPTT. Fibrinogen levels may be normal or decreased. The TT is not corrected in mixing studies.

Antibodies against fibrinogen or fibrin usually belong to the IgG isotype; in a single report the subclasses IgG1 and IgG3 were detected (Galanakis et al., 1978). Most antibodies described interfere with the monomer formation and the release of fibrinopeptide A (Marciniak and Greenwood, 1979; Gris et al., 1992) or with the monomer polymerization (Ghosh et al., 1983). Two further cases have been described, with antibodies directed against the fibrinopeptide B also interfering with its release. These patients had no bleeding history, and a prolonged TT with a normal RT (Nawarawong et al., 1991; Llobet et al., 2007). The correlation of the clinical phenotype with the epitope location might reflect the different kinetics of thrombin cleavage for the two different fibrinopeptides and their distinct role in the three dimensional formation of the fibrin clot (Pechik et al., 2006).

The few published cases claim to show a spontaneous remission after the detection of an anti-idiotypic antibody (Ruiz-Arguelles, 1988), or report a normalization of clotting assays after treatment of the underlying disease (Panzer and Thaler, 1993). There are no treatment algorithms; an immunosuppressive or -modulatory therapy with corticosteroids or ivIg may be necessary in severe instances.

Autoimmune Inhibitors to Prothrombin (Factor II) and Thrombin

Thrombin plays a central role in coagulation by activating fibrinogen and also to some extent other proteins of the coagulation cascade. This leads to a thrombin burst by a positive feedback amplification. Thrombin also

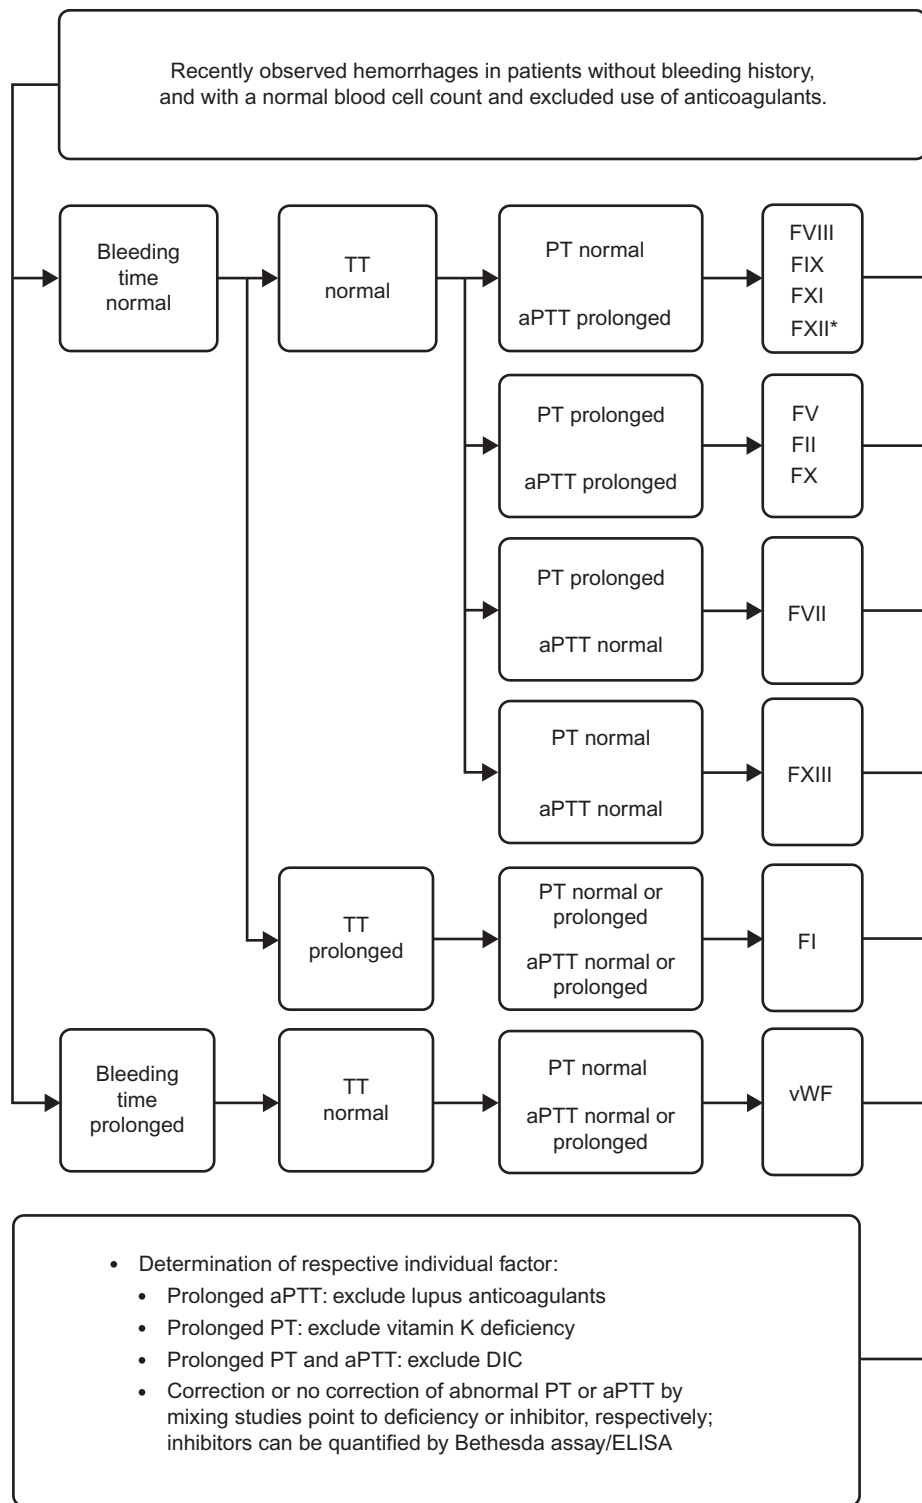

FIGURE 51.2 Possible guideline for the interpretation of coagulation tests for the diagnosis of factor inhibitors. TT: thrombin time, aPTT: activated partial thromboplastin time, PT: prothrombin time, vWF: von Willebrand factor, *: factor XII deficiency/inhibitors are not associated with a bleeding phenotype.

binds to thrombomodulin, which then activates protein C to control coagulation in a negative feedback loop. Thrombin is generated from prothrombin by activated factor X and its cofactor activated factor V. Prothrombin is a glycoprotein structurally including the gamma-

carboxyglutamic acid (Gla) domain, two kringle domains, and a C-terminal catalytic domain.

Antibodies to thrombin and prothrombin are rare and associated with bleeds of varying severity. Antibodies to prothrombin may also lead to a prothrombotic state

(Bertolaccini et al., 1998) as seen in patients with lupus anticoagulants (Roubey, 1998; Nojima et al., 2002b; Knobe et al., 2012; Chapter 34). Fatal cases have been described (La Spada et al., 1995). The occurrence of such antibodies has been described as “idiopathic” (La Spada et al., 1995; Knobe et al., 2012) or they may occur in association with gammopathies, liver cirrhosis, SLE, or infections including EBV (Barthels and Heimburger, 1985; Colwell et al., 1997; Bertolaccini et al., 1998; Atsumi et al., 2000).

More often antibodies to thrombin have been described during surgery after topical exposure to bovine thrombin, which is found in fibrin glues (Berruyer et al., 1993; Chouhan et al., 1997; Fastenau and McIntyre, 2000). In some patients there is no bleeding tendency. The prolonged TT may be also an *in vitro* effect of alloantibodies to bovine thrombin, which is used in the laboratory assay; when bovine thrombin is replaced in the assay by human thrombin, the TT is normalized due to lack of cross-reactivity of the antibodies with human thrombin (Stricker et al., 1988; Flaherty et al., 1989; Lawson et al., 1990; Berruyer et al., 1993). In some patients who do develop antibodies with cross-reactivity to human thrombin, the TT does not normalize when bovine thrombin is replaced in the assay by human thrombin (Lawson et al., 1990). In a prospective trial ($n = 150$), the outcome for patients with exposure to bovine glue was less favorable (Ortel et al., 2001), but the matter is still under discussion. A possible solution is the use of human recombinant thrombin, which has been shown to be less immunogenic in clinical trials (Ballard et al., 2010).

Coagulation assays show a markedly prolonged TT and a prolonged aPTT and PT without any correction in mixing studies. RT is normal. Thrombin levels and activity are reduced (Scully et al., 1982; Gabriel et al., 1987). Antibodies can also be detected by ELISA.

Antibodies to thrombin or prothrombin may be neutralizing or non-neutralizing, increasing the clearance of prothrombin (Bajaj et al., 1985). Isotypes IgG or IgM have been identified (Bertolaccini et al., 1998). Antibody directed to the catalytic center of thrombin (Sie et al., 1991) or the exosites of thrombin blocks the corresponding functions including the cleavage of fibrinogen (Arnaud et al., 1994; La Spada et al., 1995; Mollica et al., 2006). In a single patient antibodies were described that formed a complex with prothrombin leading to an interaction with antithrombin III and a direct inactivation without the conversion to thrombin (Madoiwa et al., 2001). The affinity of anticoagulant prothrombin antibodies appeared to be lower compared to the affinity of lupus anticoagulants (Bajaj et al., 1983; Field et al., 2001).

Establishment of normal hemostasis in the presence of inhibitors to prothrombin or thrombin can be challenging. The bypassing agents, activated factor VII (FVIIa) or activated prothrombin complex concentrate (aPCC), have

been used (Giovannini et al., 2004). Other therapies including plasmapheresis, fresh frozen plasma (FFP), immunosuppressives including corticosteroids, and ivIg have been applied (Scully et al., 1982). During therapy a hypercoagulant situation may occur with the need for anticoagulation. A timely diagnosis and treatment reduces morbidity and mortality.

Autoimmune Inhibitors to Factor V

Activated factor V (FV) represents an essential cofactor of the complex converting prothrombin to thrombin. FV is structurally related to FVIII in having the A1, A2, A3, B, C1, and C2 domains. After activation by thrombin the B domain is released and an A1-A2/A3-C1-C2 heterodimer is formed (Lollar, 2005). Most FV antibodies have been described after surgical procedures especially after exposure to bovine thrombin glue, which contains traces of bovine factor V (Zehnder and Leung, 1990; Berruyer et al., 1993; Spero, 1993; Muntean and Zenz, 1994; Chouhan et al., 1997). These alloantibodies cross-react with human FV. The occurrence of “true” autoantibodies to FV has been described as idiopathic, related to the use of β lactam or aminoglycoside antibiotics (Knobl and Lechner, 1998) or to surgery (even without the use of thrombin glue), or associated with autoimmune diseases including SLE, Hashimoto thyroiditis, primary biliary cirrhosis, rheumatoid arthritis, or with malignancies or infections (Shastri et al., 1999; Takahashi et al., 2003; Ang et al., 2009; Franchini and Lippi, 2011; Franchini et al., 2012). In a recent analysis of inhibitory antibodies to FV not associated with fibrin glue, 73 cases have been described with an estimated incidence of 0.09 (Singapore) to 0.23 (Australia) cases per million person-years. About two-thirds of the patients with autoantibodies show a bleeding phenotype with hemorrhages mainly at mucosal membranes including hematuria, and gastrointestinal and gingival bleeds but also intracranial or retroperitoneal hemorrhages. Hemorrhages seem to correlate with the FV levels and with the aPTT (Favaloro et al., 2004; Ang et al., 2009).

Coagulation assays show a prolonged PT and aPTT, while the TT is normal. Again, mixing experiments fail to correct the coagulation defects, in contrast to congenital FV deficiency or due to disseminated intravascular coagulation. FV antigen and activity are reduced. FV inhibitors are also quantified by the Bethesda assay.

Inhibitors belong to the isotypes IgG and IgA (Lane et al., 1978; Ortel et al., 1992; Takahashi et al., 2003). In a single publication an FV-specific IgG4 was described (Suehisa et al., 1995). The antibodies bind to the light chain of FV (A3-C1-C2) (Ortel et al., 1992). Interestingly, antibodies from patients showing a bleeding phenotype bind to the N-terminal part of C2 and inhibit the binding of FV to phospholipids, thereby interfering with the

formation of the prothrombinase complex (Ortel et al., 1998; Izumi et al., 2001). Platelet bound FV seems to be protected against most inhibitors but severe hemorrhages have been described in a patient with inhibitors against FV and platelet-associated FV (Nesheim et al., 1986; Ajzner et al., 2009). There are also non-inhibitory antibodies that increase the FV clearance. In addition to the anticoagulant nature of most FV inhibitors a single patient was identified with a FV inhibitor that mediated an activated protein C resistance and therefore led to a thrombophilic state instead of a bleeding phenotype (Kalafatis et al., 2002).

The focus of the initial therapy is the control of the acute hemorrhage. The use of platelets, fresh frozen plasma, activated prothrombin complex concentrate, and FVIIa have been described. FFP was often given prior to diagnosis and needs critical assessment due to the low content of FV. The use of aPCC and FVIIa seems more effective (Ang et al., 2009; Franchini et al., 2012). The need for eradication of FV inhibitors is discussed controversially since inhibitory antibodies can disappear spontaneously within several weeks (Knobl and Lechner, 1998). There was no statistical difference in inhibitor elimination according to whether the patients were treated or not (Ang et al., 2009). Nevertheless patients with bleeding symptoms showed benefit from eradication of the inhibitor. Several immunosuppressant approaches have been described including corticosteroids alone or in combination with immunosuppressants or rituximab. ivIg, immunoadsorption, or plasmapheresis have also been used (Jansen et al., 2001; de Raucourt et al., 2003).

Prevention seems feasible as at least half of the published cases with inhibitory antibodies to FV occurred after the use of bovine thrombin or fibrin glue and therefore appear to be preventable with using alternatives in the future (Streff and Ness, 2002; Ballard et al., 2010).

Autoimmune Inhibitors to Factor VII

Factor VII (FVII) is a serine protease composed of a gamma-carboxyglutamic acid (Gla) domain, two epidermal growth factor (EGF) domains, and a protease domain. FVII binds to tissue factor (TF) and is activated by thrombin, FXIa, FXII, and FXa. FVIIa is a heterodimeric assembly of the light chain (Gla and EGF domain) and the heavy chain (protease domain). The complex of TF and FVIIa activates FX and FIX (Vadivel and Bajaj, 2012). Acquired FVII deficiency is mainly due to vitamin K deficiency and rarely has an autoimmune pathology. Antibody-mediated FVII deficiency has been described in only eight case reports so far and with only indirect evidence for autoimmunity. These inhibitors have been described as idiopathic or in combination with malignancies, autoimmune disorders, HIV infection or after the administration of penicillin (Campbell et al., 1980; Delmer et al., 1989; Ndimbie et al., 1989; Weisdorf et al., 1989;

Mehta et al., 1992; de Raucourt et al., 1994; Brunod et al., 1998; Okajima and Ishii, 1999; Aguilar et al., 2003). The intensity of hemorrhages varied from mild to severe and life-threatening, presenting as hematomas, ecchymosis, gastrointestinal bleeds, hematuria, and intracranial hemorrhages (Delmer et al., 1989; Okajima and Ishii, 1999). Coagulation assays show an isolated prolonged PT with normal aPTT, TT, and bleeding time. FVII antigen and activity are decreased. Mixing studies do not correct the PT. The level of inhibitors can be determined by the Bethesda assay.

FVII inhibition is mediated by an IgG autoantibody belonging to the IgG1 subclass (Campbell et al., 1980; Weisdorf et al., 1989; Brunod et al., 1998). A direct inhibition of FVIIa interaction with tissue factor or phospholipids has been proposed: an autoantibody binds to the light chain with an epitope on or near the Gla domain in a Ca^{2+} -dependent manner. In addition, there are antibodies that increase clearance of FVII without inhibition *in vitro* (Weisdorf et al., 1989; Kamikubo et al., 2000).

The initial hemorrhage is controlled by administration of FFP, FVII, or FVIIa concentrates (Delmer et al., 1989; Mullighan et al., 2004). Tranexamic acid has also been used (Aguilar et al., 2003). The use of FVII concentrate has been associated with thrombotic events in patients with FVII inhibitors and underlying disease (Brunod et al., 1998). Eradication of inhibitory antibodies has been achieved by immunosuppression with corticosteroids plus azathioprine, ivIg, or plasma exchange (Delmer et al., 1989).

Autoimmune Inhibitors to Factor VIII

Properties of the Factor VIII Protein

The factor VIII (FVIII) protein includes the domains A1, A2, A3, B, C1, C2, and acidic spacers (Toole et al., 1984; Wood et al., 1984). This domain structure is shared between FV and FVIII. FVIII is produced in several tissues; hepatocytes are the main source of the protein. During processing FVIII is cleaved to form the heavy and the light chain, which include A1-A2-B and A3-C1-C2, respectively. The heavy and light chains form a non-covalent heterodimer, which is complexed to von Willebrand factor (vWF). Upon activation by thrombin, the B domain and the acidic a3 region are cleaved off and vWF dissociates. Activated FVIII (FVIIIa) interacts with the phospholipid membrane, FIXa, and the substrate FX, which form the tenase complex and activate FX (Lenting et al., 1998; Saenko et al., 2002).

Clinical Presentation

Despite its rarity, acquired autoimmune hemophilia A (aHA) is by far the most frequent anti-coagulant

autoimmune condition. A small number of studies and meta-analyses comprising 175 to 501 patients, and many case reports, have been published (Green and Lechner, 1981; Delgado et al., 2003; Collins et al., 2007). The reported incidence varies between 1.2 and 1.48 cases per million/year (Collins et al., 2004; Tay et al., 2009). Patients presenting with aHA show a biphasic age peak with postpartum women dominating in an early peak between 20 and 40 years (mean age: 33.9 years) and men dominating in the age peak above 60 years. Over all age groups, men appear to be slightly more often affected. The mean age at diagnosis is 73.9 to 78 years, depending on the cohort (Green and Lechner, 1981; Collins et al., 2007; Knoebl et al., 2012). A number of cases of aHA in children have also been described (Brodeur et al., 1980; Moraca and Ragni, 2002).

Clinically, greater than 90% of patients present with bleeds that occur spontaneously or after trauma and without a prior bleeding history. The majority of bleeds are severe, and, in contrast to congenital hemophilia A, bleeds comprise mainly large hematomas, ecchymoses, and soft tissue bleeds as well. Additionally many different clinical presentations have been reported including hematuria, gastrointestinal bleedings, intracranial hemorrhage, and hemothoraces. Around 6% of patients do not present with bleeding symptoms at the time of diagnosis. Diagnosis is often delayed and is associated with increased bleeding but without influence on the overall outcome (Micic et al., 2011; Fukushima et al., 2012; Knoebl et al., 2012; Rezaieyazdi et al., 2012; Webert, 2012). Similarly to inhibitory autoimmunity to other coagulation factors, aHA is associated with some underlying condition in about half of the cases. Among these are malignancies (11.8%) including solid tumors and hematological neoplasias, and autoimmune disorders (11.6%) including rheumatoid arthritis in one-third of the cases, and systemic lupus erythematosus. Postpartum antibody inhibitors comprised 7–15% of cases reported in cohorts (Green and Lechner, 1981; Delgado et al., 2003; Collins et al., 2007; Knoebl et al., 2012). Other conditions included exposure to certain drugs, surgery, infections, primary immunodeficiency, and dermatological conditions. Disease in the remaining half of cases with no concomitant condition was termed “idiopathic aHA” (Ozgur et al., 2007; Kim et al., 2008; Shetty et al., 2011; Reitter et al., 2011; Knoebl et al., 2012). A significant number of pregnancy-associated FVIII autoantibodies are present antepartum. Hemorrhages during birth have been observed and so diagnostic evaluation of the newborn is crucial due to placental transfer of IgG (Tengborn et al., 2012).

Mortality is between 7.9 and 31%; early mortality is related to bleeding and later mortality mainly to the underlying condition or complications of immunosuppression (Green and Lechner, 1981; Lottenberg and Kentro,

1987; Morrison et al., 1993; Hay et al., 1997; Bossi et al., 1998; Collins et al., 2007). Among the largest cohort studied at the end of the follow-up period, the survival of patients with postpartum inhibitors was 100% and, in those with concomitant autoimmune disease or malignancy, was 71% and 32%, respectively, and idiopathic aHA 58% (Collins et al., 2012).

Laboratory Results

Laboratory results reveal a prolonged aPTT, low FVIII antigen levels and activity, and normal PT or TT. Mixing studies do not correct the aPTT. Antibodies can be measured by ELISA and inhibitory antibodies by the Bethesda assay (Nijmegen modification). Bethesda units or residual FVIII activity do not correlate with the bleeding phenotype (Lindgren et al., 2002; Toschi and Baudo, 2010). Inhibitors may lead to type I and type II kinetics of FVIII inactivation with the latter being the dominant one albeit not inactivating FVIII completely. There are indications that type I inhibitory antibodies block the activation of FVIII by thrombin, whereas type II inhibitors block the binding to phospholipids resulting in different clinical phenotypes (Nogami et al., 2001; Matsumoto et al., 2012). The affinity of inhibitor reactivity with FVIII might also influence the type of kinetics observed.

Characteristics and Mode of Action of Anti-FVIII Antibodies

Inhibitory antibodies are mostly of the isotype IgG and subclasses IgG4 and IgG1; IgA and IgM inhibitors have been detected at low levels (Whelan et al., 2013). The IgG population is polyclonal. Dominant IgG4 responses are associated with higher inhibitor titers (Reding et al., 2002). Antibody epitopes are mainly found on the A2 and C2 domain of FVIII; the epitope distribution differs between aHA patients and patients with congenital hemophilia A (cHA) and inhibitors (Prescott et al., 1997; Scandella, 1999; Matsumoto et al., 2001). The anti-FVIII specific IgG subclasses and the epitopes recognized differ according to different clinical conditions; a dominance of the IgG4 subclass occurs in most conditions. In postpartum aHA FVIII-specific IgG1 and IgG3 were found more frequently than in patients with other concomitant conditions. In addition, postpartum anti-FVIII antibodies more often recognized the heavy chain especially the A1a1 domain (Lapalud, 2012). Antibodies can block the interaction of FVIII with different molecules of the coagulation cascade including vWF, phospholipids, thrombin, FIX, and FX by competition or steric hindrance. Proteolytic FVIII antibodies have also been described (Wootla et al., 2008; Mahendra and Padiolleau-Lefevre, 2012). In addition, there are indications that anti-FVIII

inhibitors with type II kinetics also inhibit the proteolysis of FVIIIa by activated protein C, and establish circulating immune complexes (Nogami et al., 2001). Recently the presence of hydrolyzing and activating FIX antibodies was described in aHA patients leading to thrombin generation in about a third of the patients (Wootla et al., 2011). Their clinical relevance is undetermined.

T Cell Epitopes in aHA

There are some T cell epitopes in the C2 domain of FVIII (amino acids 2291–2330) that are shared between aHA patients, cHA patients with inhibitors, and healthy individuals; there are additional epitopes including the region 2241–2290 only identified in aHA patients. In addition, distinct T cell epitopes on the A3 domain have been identified for patients with aHA that are not shared by patients with cHA and inhibitors (Reding et al., 2003, 2004).

Genetic Factors in aHA

In patients with aHA different polymorphisms in immune response genes occur more frequently than in healthy individuals: in regard to CTLA4 a higher frequency of the CTLA4 49 A/G polymorphism has been observed. Interestingly the G allele was found more frequently in patients with an underlying autoimmune disease. HLA class I haplotypes were not correlated with aHA disease, but for HLA class II haplotypes there was a higher frequency of DRB1*16 and DQB1*0502, and a lower frequency of DRB1*15 and DQB1*0602 in affected patients. These results do not align with HLA haplotypes seen in cHA patients with inhibitors. The influence of polymorphisms in the FVIII gene itself remains to be investigated (Pavlova et al., 2008, 2010; Tiede et al., 2010).

Treatment

The treatment of patients with aHA focuses initially on reestablishing hemostasis and, later on, the induction of tolerance. Despite being the most frequent autoimmune coagulopathy, treatment recommendations are based on expert opinion due to the lack of controlled trials. With modern aHA treatment, about 70% of patients receive bypassing agents including FVIIa and aPCC to control acute bleeds. In the largest cohort studied, FVIIa was used in more than half of the bleeds and aPCC in 20%. Both agents are equally effective overall but treatment success for each differed significantly for the individual patient. The residual patients were treated with FVIII products, desmopressin, and, historically, with porcine FVIII, which is currently unavailable. Treatment with bypassing agents was more effective than treatment with FVIII or desmopressin (Morrison et al., 1993; Kessler and Ludlam,

1993; Collins et al., 2007; Baudo et al., 2012). In about 4% of patients thromboembolic events occurred during treatment with bypassing products (Knoebel et al., 2012; Sumner et al., 2007). Around one-third of patients did not require any hemostatic treatment. For AHA patients requiring surgery a successful hemostatic management with aPCC was reported for five patients (Shetty et al., 2011). In cases with antepartum inhibitors, close monitoring of the newborn is required.

Immunosuppressive therapy is necessary to induce tolerance in most aHA patients. Various regimens based on corticosteroids, cytotoxic agents, rituximab, ivIG, plasmapheresis, immune adsorption, and protocols for induction of immune tolerance from cHA patients with inhibitors using high dose FVIII have been applied (Nemes and Pitlik, 2000; Wiestner et al., 2002; Freedman et al., 2003; Stasi et al., 2004; Collins et al., 2007, 2012; Tiede et al., 2009; Muzaffar et al., 2012; Barillari and Pasca, 2013; Zanon et al., 2013). Inhibitor eradication (complete remission) was achieved in about two-thirds of the patients. In the largest cohort of patients to date (EACH2, $n = 501$) most were treated with corticosteroids either alone (43%) or in combination with cyclophosphamide (25%) or with a rituximab-based regimen (15%), achieving complete remission in 58%, 80%, or 61%, respectively. Successfully treated patients who received a combination of corticosteroids and cyclophosphamide experienced more adverse events (41%), mainly infections, compared to the group treated with steroids alone (25%). The final outcome “alive and inhibitor free at last follow-up” was achieved by 67% of patients treated with steroids alone compared to 62% of patients treated with corticosteroids and cyclophosphamide (Collins et al., 2012). The modified-Bonn–Malmö protocol combining immune adsorption, immunosuppression, FVIII administration, and FVIIa to control acute bleeds achieved remission rates of >90% for non-malignancy associated AHA (Zeitler et al., 2012, 2013).

Treatment success appears to be associated with the nature of the underlying condition, a younger age, and a lower antibody level. Spontaneous remissions have also been described. Most patients with postpartum inhibitors achieved complete remission when treated with corticosteroids (Baudo and De Cataldo, 2003). There was no improvement in survival when treatment either with corticosteroids alone or in combination with cytotoxic agents was used. Among successfully treated patients, some 20% relapsed within a median of seven months (range 1–60 weeks). When complete remission was achieved life expectancy equaled that of non-affected individuals of the same age (Collins et al., 2007).

An international expert panel recommended anti-hemorrhagic treatment for aHA patients using FVIIa or aPCC for first line treatment. For eradication of inhibitory

antibodies a first line therapy with corticosteroids alone or in combination with cyclophosphamide is recommended. Protocols for induction of immune tolerance in cHA including immune adsorption are recommended in case of life-threatening bleedings. When hemostasis is controlled, anticoagulant prophylaxis needs to be considered (Huth-Kuhne et al., 2009). Prospective studies are currently examining treatment protocols. Also novel bypassing therapies are currently being developed such as recombinant porcine FVIII, FIX variants, and bi-specific antibodies (Kitazawa et al., 2012; Milanov et al., 2012; Kempton et al., 2012).

Autoimmune Inhibitors to Factor IX

Factor IX (FIX) is a serine protease structurally related to FVII and FX including a Gla-domain, two EGF-like domains, and a protease domain. FIX is activated by FXIa and FVIIa. FIXa forms, with FVIIIa, the tenase complex, which activates factor X (see above).

Autoimmune inhibitors of factor IX have been described only in single case reports (Roberts, 1970; Ozsoylu and Ozer, 1973; Largo et al., 1974; Reisner et al., 1977). The incidence is unknown. They have occurred mainly in elderly people, but sometimes in children (Miller et al., 1978; Mazzucconi et al., 1999; Jedidi et al., 2011). The condition was spontaneous or with various underlying diseases including hepatitis C (under therapy), autoimmune hepatitis, Sjögren syndrome, ITP, arteritis, and SLE (Castro et al., 1972; Torres et al., 1980; Carmassi et al., 2007; Campos-de-Magalhaes et al., 2011; Jedidi et al., 2011; Krishnamurthy et al., 2011). Three cases have been reported with inhibitors to both FVIII and FIX (Carmassi et al., 2007) and one with an inhibitor to FIX, FX, and prothrombin (Rochanda et al., 2012). Laboratory assessment reveals a prolonged aPTT while PT, TT, and bleeding time are normal. In mixing studies the aPTT does not correct. FIX inhibitors can be directly detected and quantified by the Bethesda assay.

With so few cases reported data are scarce on the nature of autoantibodies to FIX. Alloantibodies described in hemophilia B patients are mainly IgG and of the subclasses IgG1 and IgG4. The antibodies are mainly directed against the protease and the GLA domain, but also the EGF-like domain (Torres et al., 1980). In a single patient, in whom antibodies bound to FIX, FX, and prothrombin, the antibodies belonged to the IgG4 subclass and bound to a common motif on the Gla domain (Rochanda et al., 2012).

Acute bleeds were treated with FVIIa (Abshire and Kenet, 2008) accompanied by immunosuppression with prednisolone alone (Krishnamurthy et al., 2011), in combination with ivIg (Mazzucconi et al., 1999), or in addition with azathioprine (Carmassi et al., 2007).

Autoimmune Inhibitors to Factor X

Factor X (FX) also is a zymogen of a serine protease and is structurally related to FVII and FIX with an identical domain structure including the Gla, EGF, and protease domains. Upon activation by FVIIa and tissue factor or by the tenase complex composed of FVIIIa and FIXa, FXa cleaves prothrombin in the presence of FVa (prothrombinase complex) and phospholipids, so generating active thrombin. Antibody-mediated FX deficiency is extremely rare. Non-autoimmune acquired FX deficiency was described in the presence of amyloidosis and attributed to the adsorption of FX to amyloid fibrils (Mumford et al., 2000) and of malignancies including solid tumors and leukemias. Most cases of acquired inhibitory antibodies to FX have followed respiratory tract infections (Bayer et al., 1969; Hosker and Jewell, 1983; Currie et al., 1984; Mulhare et al., 1991); in a single childhood case the condition developed after extensive burns (Matsunaga and Shafer, 1996). Antibodies as inhibitors were identified only in recent cases. The clinical picture includes hematoma, ecchymosis, mucosal bleeds, hematuria, and also intracranial hemorrhages (Edgin et al., 1980; Lankiewicz and Bell, 1992; Smith et al., 1998; Rochanda et al., 2012). In laboratory findings PT and aPTT are prolonged while TT and bleeding time are normal. Inhibitors can be quantified by the Bethesda assay.

Anti-FX inhibitors belong to the IgG isotype. Several antibodies have been analyzed, and these bind to the light chain near or on the Gla domain. The antibody inhibited the activation of FX by the TF–FVIIa complex and by the tenase complex (Lankiewicz and Bell, 1992; Rao et al., 1994; Matsunaga and Shafer, 1996; Smith et al., 1998). Another report described an IgG4 antibody population recognizing an epitope in common with FII, FIX, and FX, and also an epitope on the Gla domain (Rochanda et al., 2012).

Treatment of acute bleeds in the presence of FX inhibitors is challenging due to the central role of FX in the coagulation cascade. The successful use of aPCC has been described, but has also been complicated by thromboembolic complications and cerebral infarctions (Henson et al., 1989; Mulhare et al., 1991; Smith et al., 1998). Transfusions of FFP have only been successful after plasma exchange followed by ivIg. Autoimmune inhibitors of FX are usually transient and treatment is not required, but corticosteroids or ivIg have been used in individual cases (Edgin et al., 1980; Matsunaga and Shafer, 1996).

Autoimmune Inhibitors to Factor XI

Factor XI (FXI) is also a zymogen of the serine protease that is activated by FXII or thrombin, or autocatalytically.

It is composed of four so-called apple domains in the heavy chain and a protease domain, and circulates as a homodimer. FXIa then activates FIX (Gailani and Smith, 2009). Autoimmune inhibitors to FXI are extremely rare and their incidence is unknown. Mostly, inhibitory antibodies to FXI have occurred with an underlying condition, including SLE, leukemias, autoimmune gastrointestinal diseases, psoriasis, or membranoproliferative glomerulonephritis (Rustgi et al., 1982; Vercellotti and Mosher, 1982; Goodrick et al., 1992; Kyriakou et al., 2002; Bortoli et al., 2009; McManus et al., 2012). Bleeding phenotypes due to FXI inhibitors differ; most are mild but a few have been life threatening (Reece et al., 1984; Bortoli et al., 2009).

In coagulation assays FXI inhibitors present with a prolongation of aPTT with a normal PT, TT, and bleeding time. Inhibitors are quantified by the Bethesda assay. The isotype of FXI inhibitors is IgG or IgM (Krieger et al., 1975). Antibodies that have developed in patients with congenital FXI deficiency are of the IgG1 or 3 subclass and are directed against the heavy chain of the molecule (De La Cadena et al., 1988). The mode of FXI inhibition has been identified as increased clearance of FXI by inhibitors or blocking of the activation of FXI (Krieger et al., 1975; Poon et al., 1984; McManus et al., 2012). No such data are available on autoimmune inhibitory antibodies to FXI.

The treatment of hemorrhages due to FXI inhibitors was based on FXI concentrate, FFP, PCC, and rFVIIa. Inhibitor eradication has been achieved either by immunosuppression with corticosteroids or by the immunosuppression used as part of the therapy of the underlying condition (Vercellotti and Mosher, 1982; Goodrick et al., 1992; Billon et al., 2001; Bern et al., 2005).

Autoimmune Inhibitors to Factor XII

Factor XII (FXII) is a monomeric zymogen of the serine protease FXIIa. FXII consists of a heavy chain including two fibronectin-type domains, two EGF-like domains, a kringle domain, and a proline-rich domain plus a light chain including the catalytic center. Polyphosphates on the surface of procoagulant thrombocytes (contact phase) pre-activate FXII, which is then activated by kallikrein. FXIIa then activates FXI and plasminogen. In addition to initiating the coagulation cascade, FXIIa starts the kallikrein–kinin system. FXII inhibitory antibodies have been described in association with particular autoimmune diseases, i.e., SLE, APS, and autoimmune hepatitis, with malignancies including lymphoma and gastric carcinoma, and with infections, particularly hepatitis B (Chalkiadakis et al., 1999; Jones et al., 2000; Davidson et al., 2005; Bertolaccini et al., 2007). The pathology of FXII inhibitors is still being discussed; they are not associated with

hemorrhages but possibly with a prothrombotic state (Aberg and Nilsson, 1972). In addition FXII inhibitors have been associated with pregnancy failure and fetal loss (Jones et al., 2001; D'Uva et al., 2005). Laboratory results show a very prolonged aPTT with a normal PT, TT, and bleeding time typically without any bleeding symptoms. Antibodies are detected by ELISA. For FXII inhibitors isotypes IgG or IgM have been identified (Jones et al., 2000; Davidson et al., 2005). In women with fetal loss most antibodies recognized the N-terminal portion of the heavy chain, which interacts with thrombocytes, whereas, in patients with APS, epitopes were identified in the catalytic domain and in the EGF-like domain (Harris et al., 2005; Inomo et al., 2008). Treatment is not required, but anticoagulation may be needed to prevent pregnancy failure.

Autoimmune Inhibitors to Factor XIII

Factor XIII (FXIII) is a tetramer composed of two A and two B domains; it is activated by thrombin and stabilizes the fibrin clot by cross-linking fibrin γ chains (Ariens et al., 2002). Autoantibodies to FXIII occur very rarely but are likely to be under-diagnosed. Some 50 individual cases have been described to date, some with underlying conditions including a monoclonal gammopathy (Luo et al., 2010) or another autoimmune disease including SLE (Ahmad et al., 1996; Lorand et al., 2002; Ajzner et al., 2009; Luo and Zhang, 2011). Antibodies to FXIII have also occurred following exposure to drugs including isoniazid (Otis et al., 1974; Shires et al., 1979; Krumdieck et al., 1991) and may develop spontaneously (Nijenhuis et al., 2004). Patients present clinically with recurrent hemorrhages of different intensity including mucosal or large soft-tissue hematomas, or with a life-threatening event such as intracranial hemorrhage (Daly et al., 1991; Lorand et al., 2002). The age of presented cases is usually between 60 and 70 years, but is wide considering all cases ranging from 10 to 87 years (Luo and Zhang, 2011). The laboratory findings reveal normal global coagulation tests like PTT, PT, bleeding time, and platelet counts. FXIII activity or levels are reduced and can be determined by chromogenic assays—ELISA for the FXIIIA or B subunits. The thromboelastogram reflects a reduced clot formation and increased fibrinolysis. Alternatively, a dissolved clot after treatment with 5M urea indicates a FXIII deficiency. Inhibitors to FXIII can be measured by mixing studies, and by ELISA to immobilized FXIII subunits. Antibodies are mainly directed against the active A domain of FXIII, and rarely against the B domain. Inhibitory antibodies block the activation by thrombin, catalysis, or the binding to fibrin or other substrates of FXIII depending on the cognate epitope (Nakamura et al., 1988; Fukue et al., 1992; Ahmad et al.,

1996; Lorand et al., 2002; Ajzner et al., 2009; Luo and Zhang, 2011).

Treatment is based on replacement therapy and immunosuppression. Despite the presence of antibodies, treatment of acute bleeds with FXIII concentrate, or with FFP (if concentrate was not available), has been successful. Treatment is mainly combined with immunosuppression with (methyl)prednisolone and/or cyclophosphamide (Tosetto et al., 1995; Ishida et al., 2010; Luo and Zhang, 2011; Hayashi et al., 2012). The use of ivIg or immune adsorption, cyclosporine, and FVIIa has also been described. Single patients have also been treated with rituximab (Gregory and Cooper, 2006; Ajzner et al., 2009).

Autoimmune Inhibitors to Von Willebrand Factor

Although von Willebrand factor (vWF) is not a classical coagulation factor, it plays a crucial role in primary as well as secondary hemostasis. This large glycoprotein includes the domains D', D1–4, A1–3, B, and C1–2. The protein binds to FVIII prolonging its half-life prior to activation, interacts with subendothelial layers after vascular injury, and promotes thrombocyte adhesion and aggregation. The vWF monomers assemble to multimers of different sizes up to 20,000 kDa. Ultra large multimers are cleaved by ADAMTS13 (see above) (Schnepenheim and Budde, 2008).

Acquired von Willebrand disease (avWD) is a rare condition with only a few hundred patients described; one report gave an incidence of 10% in a small, preselected cohort of patients with bleeding disorders (Mohri et al., 1998). Among patients with avWD, 10–30% express an autoantibody against vWF; their overall incidence has been estimated to be 0.04% (Kumar et al., 2003). The pathophysiology of avWD in most patients is not based on autoimmune effects but rather on conditions associated with a reduced production of vWF as seen in hypothyroidism, on an increased clearance due to attachment to tumor cells or paraneoplastic products, an increased mechanical clearance, or resulting from certain drugs (Veyradier et al., 2000). Thus avWS is associated with different underlying conditions, including hypothyroidism, lympho- or myeloproliferative disorders, solid tumors including Wilms' tumor, infections, and acquired or congenital heart defects. Drugs that may cause avWD include certain antibiotics, hydroethyl starch, and valproic acid. Autoimmune avWD has been described as idiopathic or with underlying autoimmune diseases, including SLE, or monoclonal gammopathies (Federici et al., 2000; Michiels et al., 2001; Will, 2006). Patients present with a spectrum of nil to severe bleeds, mainly ecchymoses but

also epistaxis, and gastrointestinal and mucosal bleeds (Mohri et al., 1998; Collins et al., 2008). avWD patients with inhibitors show a higher bleeding tendency than patients without inhibitors. Autoantibodies bind to the large or intermediate size multimers. They have been identified as mainly of the IgG isotype, but IgA and IgM isotypes have been described, depending on the underlying condition. IgG antibodies belong to the subclasses IgG1 and IgG4. Epitopes have been mapped to the A1 and the A3 domain with inhibition of collagen binding, and display binding to GP Ib and GP IIb/IIIa (van Genderen et al., 1994; Mohri et al., 1998).

Laboratory diagnosis of avWD and differentiation from congenital vWD can be often difficult. Analysis reveals a prolonged bleeding time, with normal PT and normal or prolonged aPTT. The vWF antigen, ristocetin cofactor, or collagen binding activity is reduced. Also, FVIII activity is often reduced. Large vWF multimers are often lacking. Anti-vWF antibodies can be detected. In a Bethesda-like assay several approaches have to be considered due to the large size of vWF and different epitope-related effect of the antibodies. A pharmacokinetic analysis might be useful as non-inhibitory antibodies that enhance clearance are not detected by the Bethesda assay (Mohri et al., 1998; Luboshitz et al., 2001; Siaka et al., 2003; Tiede et al., 2008).

The treatment of avWD is based on the therapy of the underlying condition. The use of desmopressin to release vWF, and the substitution of a vWF-containing FVIII concentrate or FFP have been described to successfully treat non-autoimmune avWD and to control acute bleeds. The response to FVIII/vWF concentrates or desmopressin is usually very poor when an inhibitory antibody is present. In severe uncontrollable bleeds, FVIIa has also been used successfully. Autoimmune avWD has successfully been treated with immunomodulation including the administration of immunoglobulins and immunosuppression with corticosteroids, plasma exchange, or immune adsorption (Collins et al., 2008; Sucker et al., 2009; Tiede et al., 2011).

Autoimmune Inhibitors to Further Proteins

In addition to autoimmune responses to proteins described above, one single case of an autoantibody to prekallikrein has been identified to date. An IgG1 and 4 polyclonal autoantibody population was detected in a single patient who presented with a prolonged aPTT without any symptoms of bleeding or thrombosis (Page et al., 1994).

CONCLUSIONS AND FUTURE PROSPECTS

Autoimmune inhibitors to coagulation factors are rare and highly diverse effectors, and remain as poorly understood

FIGURE 51.3 Severe soft tissue hemorrhage in a patient with acquired hemophilia A.

entities. Moreover, studies on the T lymphocyte component of these autoimmune reactions have been scarcely considered. In cases of bleeding in individuals without bleeding history, inhibitors to coagulation factors need to be assessed. The timely diagnosis and treatment of affected patients remains challenging. Further efforts are needed to understand the underlying pathology of autoimmunity leading to hemorrhages or thrombosis and to improve treatment outcome for affected individuals.

Understanding autoimmunity to individual proteins of the coagulation cascade may promote the understanding of autoimmunity in general. In contrast to many other autoimmune entities the autoantigens are well known and most of them well characterized. Additionally the same proteins are seen as autoantigens as well as alloantigens in patients with congenital bleeding disorders. This allows the comparison of allo- and autoimmune responses to the identical protein (Figure 51.3).

ACKNOWLEDGMENTS

The author would like to thank Stephan Schultze-Strasser, PhD and Manuela Krause, MD for assistance with or provision of figures, and Christine Heller, MD and Dirk Schwabe, MD for critical comments on the manuscript, and his family and the editors for support and patience.

HISTORICAL BACKGROUND

It is widely held that the earliest known reference of multiple sclerosis (MS) can be attributed to Scottish pathologist Robert Carswell (Murray, 2009). In his atlas, *Pathological Anatomy: Illustrations of the Elementary Forms of Disease (1838)*, Carswell described two patients affected by paralysis, both with lesions along the spinal cord and lower brain stem accompanied by atrophy. Carswell believed that the extensive paralysis the patients suffered was directly related to the impressive pathology he encountered (Behan, 1982). However compelling Carswell’s account was, it was not until 30 years later that MS was named by a French neurologist, Jean Martin Charcot. Charcot first described a comprehensive account of the features of MS in 1868 by correlating the clinical and pathological features of the illness in patients he examined both while they were alive and at autopsy. He noted the accumulation of inflammatory cells in a perivascular distribution, demyelination, and axonal sparing within the lesions or “plaques” in the brain and spinal cord white

matter of patients with intermittent episodes of neurologic dysfunction (Charcot, 1868a,b, 1877). This led to the term “*sclérose en plaques disséminées*,” or multiple sclerosis.

Over the last 100 years there have been many important historical milestones that have led to the fundamental understanding that MS is a multifocal inflammatory disease primarily affecting central nervous system (CNS) white matter resulting in progressive neurodegeneration in genetically susceptible hosts (recently reviewed in Nylander and Hafler, 2012). The hypothesis that MS is an autoimmune disease can be attributed to observations by Thomas Rivers at the Rockefeller Institute. In 1933 Rivers demonstrated that injection of rabbit brain and spinal cord into primates resulted in a demyelinating disease in mammals (Rivers et al., 1933). This disease, known as experimental autoimmune encephalomyelitis (EAE), is the result of immunization of CNS myelin and has served as an important animal model for multiple sclerosis.

In 1965, Schumacher et al. defined clinical diagnostic criteria based on the notion that MS is a disease disseminated in time and space throughout the CNS

(Schumacker et al., 1965). Such criteria continue to be utilized and revised today. Since then, the advent of magnetic resonance imaging and FDA approval of IFN- β 1b, among other therapeutic agents, have revolutionized how we examine and treat patients with MS (Young et al., 1981; Arnason, 1993). During the past 20 years, MS has evolved from a disease with no therapy to one with eight approved therapies in the USA to date. These major advances have established MS as a treatable neurological illness. Nonetheless, the development of more effective and safer treatments that can be used at the time of diagnosis for this potentially disabling illness is paramount, and predicated on a more thorough understanding of the underlying immunopathology. Advances in immunology and neurology have provided clinicians with powerful tools to better understand the underlying causes of MS, leading to new therapeutic advances. The future calls for extending the original observations of Carswell and Charcot by continuing to define the molecular pathology of MS in relation to growing knowledge surrounding immune-related pathology and DNA haplotype structure in addition to CNS and peripheral mRNA and protein expression, leading to the generation of a new series of disease-related hypotheses.

CLINICAL FEATURES

The signs and symptoms of MS are variable as the disease can affect anywhere within the CNS. Demyelinating lesions may develop at any site along myelinated CNS white matter tracts, and symptoms of MS therefore depend on the functions subserved by the pathways involved. Although the primary insult involves demyelination, edema, inflammation, gliosis, and axonal loss all contribute to the symptomatology of a lesion. The most common symptoms and signs involve alteration or loss of sensation due to involvement of spinothalamic or posterior column fibers, visual loss from optic neuritis, limb weakness and spasticity related to disruption of corticospinal tracts, tremors and incoordination of gait or limbs largely related to cerebellar or spinocerebellar fiber involvement, and abnormalities of cranial nerve function (such as double vision due to disturbance in conjugate eye movement) secondary to brainstem lesions (Noseworthy et al., 2000). Bowel, bladder, and sexual dysfunction occur in over two-thirds of patients at some time during the course of their illness (Betts et al., 1993; Mattson et al., 1995) largely due to disruption in spinal cord pathways. Fatigue, depression, and cognitive changes are common symptoms of elusive etiology that may significantly interfere with daily functioning and are now being recognized as significant contributors to disability (Whitlock and Siskind, 1980; Freal et al., 1984; Sadovnick et al., 1996). A correlation with progressive

brain atrophy, cognitive decline, and impairment on MRI has implicated axonal loss as the pathologic substrate of the cognitive deterioration in MS (Rao et al., 1989; Hohol et al., 1997; Amato et al., 2004).

While MS can have variability in clinical presentation and course of the illness, it can follow a number of rather predictable courses. MS may be divided into four clinical categories: clinically isolated syndromes (CIS), an early form of MS, relapsing–remitting multiple sclerosis (RRMS), which in a subgroup of patients becomes secondary progressive multiple sclerosis (SPMS), and primary progressive multiple sclerosis (PPMS).

CIS generally occur in young adults, and are defined by the presentation of a first episode of demyelination typically in the form of optic neuritis, cerebellar, or brainstem syndrome. During an episode, neurological symptoms develop over hours to several days, persist for days to several weeks and gradually dissipate (Miller et al., 2012). In order for such episodes of acute inflammatory CNS demyelinating events to be considered CIS, they must last for at least 24 hours with no more than 30 days between attacks (Polman et al., 2005). The resolution of symptoms appears to be due to the reduction of inflammation and edema at the site of the responsible lesion rather than to the reversal of demyelination, which may persist even in the absence of symptoms (McDonald et al., 2001). In a number of recent prospective studies, patients experiencing an initial episode suggestive of CNS demyelination and having MRI evidence indicating the presence of lesions either at the time of or within 3 months of the event is highly predictive for the development of relapses and thus clinically definite multiple sclerosis (CDMS). Without MRI lesions, the probability of developing MS is substantially less. More than half of those developing MS experienced the additional relapse within 1 year of their first episode (Achiron and Barak, 2000; Fisniku et al., 2008). Thus, it seems reasonable to label the first attack of what appears to be MS as CIS, explaining to patients that there is a high likelihood of developing multiple sclerosis (Rovira et al., 2009). This indicates to the patient there is a good understanding of the underlying problem, but the prognosis is not clear, allowing patients who never have another attack to be saved from carrying a diagnosis of MS (Miller et al., 2012).

If a patient with a CIS develops further episodes of relapses followed by a recovery with a stable course between relapses, patients are referred to as having RRMS. Early in the course of MS, patients often make complete recovery from relapses. As the disease goes on, the recovery from a relapse diminishes, which causes a patient to accrue disability. A relapsing–remitting onset is observed in 85–90% of patients, with relapses often lasting 4 weeks in duration. The outcome in patients with RRMS is variable; untreated, previous reports suggested that approximately 50% of all MS patients require the use

of a walking aid by 10 years after clinical onset (Weinshenker, 1994). The consequences on prognosis of newer treatment regimens are not completely delineated; however, many studies indicate improvement of disability status following continued treatment regimens (Bates, 2011). Increased attack frequency and poor recovery from attacks in the first years of clinical disease predict a more rapid deterioration (Confavreux and Vukusic, 2006).

Ultimately, approximately 40–50% of untreated relapsing–remitting patients stop having attacks and develop what may be a neurodegenerative progressive disease secondary to the chronic CNS inflammation, known as secondary-progressive multiple sclerosis (SPMS) (Confavreux et al., 2000). The evolution to this secondary progressive form of the disease is associated with significantly fewer gadolinium-enhanced lesions and a decrease in brain parenchymal volume (Khoury et al., 1994; Filippi et al., 1995; Weiner et al., 2000). Similarly, while earlier relapsing–remitting MS is sensitive to immunosuppression (Hohol et al., 1999), as times goes on, responsiveness to immunotherapy decreases and disappears in secondary progressive disease (Rieckmann et al., 2004). Thus, rather than conceiving of MS as first a relapsing–remitting and then a secondary progressive disease, it could be hypothesized that MS is a continuum where there are acute inflammatory events early on with secondary induction of a neurodegenerative process refractory to immunologic intervention. This hypothesis awaits experimental verification.

Primary progressive MS (PPMS) occurs in close to 15% of patients, and is characterized from the onset by the absence of acute attacks and instead involves a gradual clinical decline traditionally in the form of a progressive myelopathy (Miller and Leary, 2007). Patients may also present with a progressive cerebellar syndrome in the form of ataxia. Clinically, this form of the disease is associated with a lack of response to any form of immunotherapy. Researchers had therefore posited that PPMS may in fact be a different disease than RRMS.

In the absence of a specific immune-based assay, the diagnosis of MS continues to be predicated on the clinical history and neurological exam demonstrating multiple lesions disseminated in time and space within the CNS (McDonald et al., 2001). Although using McDonald's criteria the diagnosis of MS can be made solely on the basis of history of two relapses and objective findings on exam of two lesions disseminated in the CNS (periventricular, juxtacortical, infratentorial, or spinal cord), MRI of the neuroaxis is often sought to confirm the diagnosis or to rule out other mimics of the illness. The use of the MRI and other imaging modalities has had a major impact on early diagnosis by establishing newer criteria for the diagnosis of the disease as well as a means to determine prognosis and monitor disease course and response to therapy. T1-weighted scans generally provide appreciable contrast

between gray and white matter with water appearing darker and fat brighter. In T2-weighted scans fat is also differentiated from water; however, fat appears darker and water lighter in the image, making T2-weighted scans well suited for imaging edema since CSF appears lighter (Filippi and Agosta, 2009). As part of McDonald's criteria, new T1-weighted lesions or T2-weighted gadolinium enhancing lesions on follow-up MRI scans may serve as criteria for dissemination in space or time, thus allowing the diagnosis fulfilling the criteria of MS to be made with further confidence (Polman et al., 2011).

Imaging

MRI has gained a principal role in the assessment of MS because it allows clinicians to readily obtain an understanding of the pathophysiology of the lesions, CNS involvement, and ultimately the overall illness without invasive procedures. Currently, common MRI measures of disease burden include the quantification of brain lesions using T1- and T2-weighted images, gadolinium contrast, proton density, and fluid attenuated inversion recovery sequences. Each of these markers represents many possible histopathological correlates, including: demyelination, edema, axonal loss, matrix destruction, and inflammation (Filippi and Rocca, 2011). The lesions on MRI are often ovoid in shape, ranging from a few mm to more than 1 cm in size. Their location is crucial, considering that MS lesions have a high propensity to locate in the periventricular white matter, brainstem, and cerebellum. Additionally, MRI and pathological data suggest that evolution of MS lesions depends on whether they occur during early versus chronic phases of the disease course (Filippi et al., 2012).

Lesions on T2-weighted images are often clinically silent and correlate weakly with a patient's disability despite correlating well with the location on plaques in the CNS of postmortem MS patients (Newcombe et al., 1991). Hypointense lesions on T1-weighted images may be persistent or nonpersistent (Rovaris et al., 1999). Persistent hypointense T1-weighted lesions represent areas indicative of axonal loss and severe tissue destruction and correlate better than T2 lesion load with clinical severity of the disease (van Waesberghe et al., 1999). Multiple T2-weighted and/or gadolinium-enhancing lesions on initial MRI scans indicative of diffuse cortical lesions and atrophy also predict a more severe subsequent course related not only to physical disability but also to diminished cognitive outcome (Calabrese et al., 2009; Deloire et al., 2011). Nonpersistent hypointense lesions on T1-weighted images represent reversible edema due to abatement of inflammation. Post-contrast gadolinium enhancement of lesions on T1-weighted images represents acute disruption of the blood–brain barrier from inflammation. On average, disruption can last 3 weeks, but may range

anywhere from 2 to 6 weeks and is dependent on gadolinium dose, the characteristics and delay of image acquisition, and steroid treatment of acute attacks (Filippi, 2000).

Intermittent MRI imaging might underestimate severity of disease burden since weekly MRI scanning suggests that a significant proportion of MS lesions have very short-lived enhancement (Cotton et al., 2003). Brain and spinal cord atrophy may occur in MS and can represent loss of myelin, oligodendrocytes, and axons, in addition to contraction of astrocyte volume. Continued work in improving the use of various imaging modalities to more accurately characterize active disease is imperative in moving forward.

IMMUNOLOGICAL MARKERS IN DIAGNOSIS

CSF immunologic markers can function as adjuncts to clinical findings when considering the diagnosis of MS. The CSF of patients with MS typically shows normal glucose, a few lymphocytes (mostly T cells), normal to mildly elevated total protein, and oligoclonal immunoglobulin bands (OCBs). OCBs are uncovered when CSF from MS patients is electrophoresed. The cathode region reveals a number of discrete bands that represent excess antibody production by one or more clones of B cells. Such bands are not evident when CSF from healthy controls is electrophoresed. Often absent early in the disease, OCBs can eventually be detected in over 90% of patients with MS (Cruz et al., 1987; Mclean et al., 1990).

CSF OCBs have also been described in conditions such as subacute sclerosing panencephalomyelitis (SSPE) (Mattson et al., 1980), neurosyphilis (Pedersen et al., 1982), varicella zoster virus (VZV) infection (Vartdal et al., 1982), HIV infection (Skotzek et al., 1988), and in multisystem autoimmune diseases, cerebrovascular accidents, and up to 5% of normal individuals. Of note, OCBs are continuously present in MS regardless of disease activity, whereas they are transient in other conditions due to infection clearance (Link and Huang, 2006). Furthermore, OCBs have been reported to correlate with disease course and disability progression (Link and Huang, 2006; Mandrioli et al., 2008) and with the conversion to MS in patients with CIS and a negative MRI or an MRI with few lesions (Tintore et al., 2008). In diseases such as the viral encephalitides, OCBs commonly bind virus determinants, in contrast to MS, where the antigen against which the majority of bands are directed has not been identified to date (Olek, 2000).

Due to intrathecal synthesis from plasma cells, CSF immunoglobulin levels are also elevated in patients with MS. The immunoglobulins are mainly composed of IgG, with lesser amounts being IgM and IgA. Specifically, studies have delineated differences between IgG and IgM levels with the latter correlating more strongly with MS

disease course and IgG reflecting local B cell responses accompanying CNS inflammation. Nearly 90% of patients demonstrate elevated levels of CSF IgG production when the IgG index formula (spinal fluid IgG/spinal fluid albumin)/(serum IgG/serum albumin) is calculated. A spinal fluid IgG index greater than 0.58 implies that IgG are being synthesized in the CNS.

Apart from oligoclonal bands, numerous CSF markers have demonstrated specificity for the MS disease process. Several non-specific proteins may function as markers of disease process, including: tau protein and myelin basic protein (MBP), in addition to light and heavy neurofilament chains appearing during relapse and correlating with long-term functional outcome and the likelihood of conversion from CIS to RRMS (Graber and Dhib-Jalbut, 2011).

There are reports of serum and CSF anti-MBP, anti-MOG, and anti-PLP autoantibodies (Warren and Catz, 1994; Warren et al., 1994; Berger et al., 2003) in patients with MS. Such studies have been challenged due to the possibility of non-specific binding of low-affinity antibodies and observations that high-affinity antibodies against MOG epitopes are only present in a small proportion of patients (Menge et al., 2011). However, using sensitive solution phase assays, high-affinity autoantibodies to MBP and MOG can be detected in the serum and CSF of patients with acute disseminated encephalomyelitis and MS (O'Connor et al., 2003, 2005, 2007; Zhou et al., 2006). A recent study aiming to characterize intrathecal MOG antibodies in MS indicated that the rMOG index, a marker of intrathecal MOG antibody production, may provide complementary information to routine CSF testing in the diagnosis of MS (Klawiter et al., 2010). Moreover, anti-MOG autoantibodies can be eluted from the brain tissue of a subset of patients with MS (O'Connor et al., 2005). Such markers support the ongoing hypothesis of MS as a disease linked to immune dysfunction, ongoing inflammation, and tissue damage and repair. A serum autoantibody, neuromyelitis optica immunoglobulin (NMO-IgG), was identified in patients with neuromyelitis optica, an inflammatory demyelinating disease similar to, and considered by some to be a variant of, MS affecting the optic nerves and spinal cord, thereby highlighting the importance of the differential diagnosis between MS of NMO and NMO spectrum disorders. NMO and the associated autoantibody (NMO-IgG/anti-aquaporin 4) is discussed further in Chapter 57.

PATHOLOGY

Gross examination of MS brain tissue has largely been limited to autopsy specimens of individuals with long-standing disease. Such pathological examination reveals multiple sharply demarcated gray colored plaques in the CNS white matter with a predilection for the optic nerves and white matter tracts of the periventricular regions, brain stem, and spinal cord. The gray matter contains less myelin, and thus lesions in the gray matter are

less conspicuous on gross examination (Geurts et al., 2005). When examining the histological features of an MS lesion there exist three major components: inflammation, gliosis, and demyelination. The *inflammation* in lesions is composed of lymphocytes, monocytes, and macrophages whose proportions depend on the activity and age of the lesion (Frohman et al., 2006). The second component of a lesion occurs when reactive astrocytes and fibrillary gliosis are present in the lesion.

Demyelination is an important feature of the MS lesion. Although MS is described as a disease causing a loss of myelin, the notion of axonal loss has been suggested as the major cause of irreversible disability in patients with MS. Trapp et al. first reported that substantial axonal injuries with axonal transections are also abundant throughout active MS lesions, even in patients in early stages of the disease process (Trapp et al., 1998). Axonal reduction and acute damage have previously been correlated with demyelination and meningeal inflammation (Ferguson et al., 1997). Interestingly, differences in axonal loss exist among subsets of MS, with the least axonal loss being demonstrated in PPMS and the most pronounced in SPMS (Bitsch et al., 2000). Notably, there have been case reports of early RRMS presenting with inflammatory cortical demyelination prior to the appearance of white matter lesions, indicating possible inflammation being initiated at the subpial layer (Popescu et al., 2011). Recent work aimed at elucidating the pathogenesis of axonal damage and loss has implicated several mechanisms including: inflammatory secretions, Wallerian degeneration, disruption of axonal ion concentrations, loss of myelin-derived support, damage from nitric oxide and reactive oxygen species, energy failure from mitochondrial dysfunction, and Ca^{2+} accumulation (Smith and Lassmann, 2002; Dutta and Trapp, 2007; Dzedzic et al., 2010).

MS lesions can also be classified from a pathogenesis point of view into three types based on the age of the lesion: active, chronic active, and chronic inactive (Lassmann, 1998). Macrophages are most prominent in the center of the *active plaques* and are seen to contain myelin debris, while oligodendrocyte counts are reduced and generally present in lesions demonstrating signs of remyelination. Hypertrophic astrocytes and mild astroglial scarring are also characteristic of active lesions (Frohman et al., 2006). Lymphocytes may be found in normal appearing white matter beyond the margin of active demyelination (Prineas, 1975; Booss et al., 1983). The inflammatory cell profile of active lesions is characterized by perivascular infiltration of oligoclonal T cells (Wucherpfennig et al., 1992b) consisting predominantly of clonally expanded CD8^+ T cells in the plaque margins and perivascular cuffs, and to a lesser extent of CD4^+ cells invading the normal appearing white matter around the lesion (Traugott et al., 1983; Hauser et al., 1986;

Babbe et al., 2000). The inflammatory infiltrate may also include monocytes, occasional B cells, $\gamma\delta$ T cells, and rare plasma cells (Booss et al., 1983; Wucherpfennig et al., 1992a; Babbe et al., 2000). Remarkably, demyelination in acute lesions may be related to an antimyelin antibody-mediated mechanism in which normal myelin is coated with anti-MBP immunoglobulin or anti-MOG and phagocytosed in the presence of complement by local macrophages (Genain et al., 1999). *Chronic-active lesions* are sharply demarcated with perivascular cuffs of infiltrating cells, lipid- and myelin-laden macrophages, activated microglia, and hypertrophic astrocytes. These cells disappear from the center core suggesting the presence of ongoing inflammatory activity along the lesion edge. Within the hypocellular core there are naked axons embedded within a matrix of fibrous astrocytes, lipid-laden macrophages, a few infiltrating leukocytes, and no oligodendrocytes. The *chronic-inactive plaque* does not have macrophages at the border or center of the plaque. There is vast hypocellularity and no ongoing demyelination with histology demonstrating demyelinated axons with fibrillary gliosis (Raine, 1991).

EPIDEMIOLOGY OF MS

The prevalence rates of MS in North America range between 30 and 150/100,000. Based on a weighted mean of several studies, the average annual incidence of MS in the USA is 3.2/100,000 per year. The median age of onset of symptoms is 23–24 years of age, with a peak age of onset for women in the early twenties, and for men in the late twenties (Schumacker et al., 1965; Paty et al., 1994). As in most diseases classified as autoimmune, there is a clear female predominance in MS cases, with a 3:2 female to male ratio (Olek, 2000). Studies of MS incidence rates in migrants (Dean et al., 1976) and apparent epidemics of MS at geographical locations (Kurtzke et al., 1982), also discussed below, indicate a clear role for environmental factors.

Genetic Factors

Studies in twins (Mackay and Myriantopoulos, 1966; Williams et al., 1980; Heltberg and Holm, 1982; Ebers et al., 1986; Kinnunen et al., 1987; French Research Group on MS, 1992; Mumford et al., 1992) demonstrate shared genetic risk factors for MS. Most recently, work involving genome-wide association studies (GWAS) using single nucleotide polymorphisms (SNPs) from the haplotype map (HapMap) project have provided insights into the genetic associations involved in MS (Tishkoff and Verrelli, 2003; Frazer et al., 2007; Patsopoulos et al., 2011). While the risk of developing MS in the general population is 1/750, our early understanding of the genetic factors linked to MS has been derived from

epidemiological studies and disease concordance within family members or twins. Such studies have demonstrated that approximately 15–20% of patients have a family history of MS and when both parents are affected with MS, 9% of children develop the disease (Hogancamp et al., 1997; Sadovnick et al., 1997; Sadovnick, 2006). Twin studies have indicated that the monozygotic concordance rate is 30% versus the dizygotic rate of 5% (Holmes et al., 1967; Sadovnick et al., 1993). Nevertheless, large extended pedigrees are relatively uncommon.

The sequencing of the human genome and the generation of the HapMap has finally allowed the identification of the genetic architecture underlying risk for developing MS by GWAS (Tishkoff and Verrelli, 2003). GWAS have afforded an unbiased and widespread approach in scanning the whole genome and identifying haplotypes associated with risk of developing MS. They provide an alternative approach to classic linkage analysis and have greater statistical power to detect variants conferring a modest disease risk (Risch and Merikangas, 1996; Yang et al., 2005). These studies have provided convincing evidence that MS fits into the autoimmune disease category and is caused by common allelic variants each with only subtle but important variations on function.

In 2007, the first GWAS in MS clearly identified several gene regions. Subsequent GWAS and their corresponding meta-analyses identified 14 regions with genome-wide significance, several of which have been previously identified; these regions include CD58, CD40, CD6, IL-2RA, IL-7RA, EVI5, CLEC16A, TYK2 and TNF-RSF1A, IRF8, and STAT3, all of which are of interest due to their expression on regulatory T cells, and proinflammatory Th17 cells, both CD4⁺ subsets implicated in MS later described in detail (Wellcome Trust Case Control Consortium et al., 2007; Aulchenko et al., 2008; Comabella et al., 2008; Australia and New Zealand Multiple Sclerosis Genetics Consortium, 2009; Baranzini et al., 2009; De Jager et al., 2009b; Jakkula et al., 2010; Nischwitz et al., 2010; Sanna et al., 2010). Finally, a recent international GWAS collaboration aimed at analyzing over 9000 cases of MS succeeded in replicating many of the earlier findings in addition to highlighting 29 novel susceptibility loci, thereby identifying more than 50 regions of interest. Although each haplotype only represents a small influence on the risk of developing MS, together they account for approximately half of the genetic risk for MS (Sawcer et al., 2011) (Figure 52.1) As expected, these SNPs, upon being related to the known or likely function of nearby genes, are largely associated with lymphocyte function, providing further evidence of an immunopathogenesis of MS. A large meta-analysis with replication is now in progress.

One of the additional aims of GWAS has been to refine our understanding of the genetic risk associated with the

major histocompatibility complex (MHC) through looking more closely at HLA types at six loci (A, B, C, DQA1, DQB1, and DRB1) (Sawcer et al., 2011). Prior to GWAS, our understanding of the association and linkage of MS with respect to MHC was limited to alleles and haplotypes on chromosome 6p21. Recently, studies have successfully established HLA DRB*1501 as being the allele variant involved in MS as opposed to HLA DQA1 or DQB1 (Brynedal et al., 2007; Lincoln et al., 2009). Further work has implicated HLA-A2 as being negatively associated with MS, thereby potentially serving as a protective allele with consistent effects across cohorts.

Many of the alleles identified in MS are shared not only among other autoimmune diseases but also are strongly associated with immune pathways (Torkamani et al., 2008; Xavier and Rioux, 2008; International Multiple Sclerosis Genetics Consortium, 2009; Zhemakova et al., 2009). Given these genetic commonalities, it is therefore not surprising that MS and other autoimmune diseases share related defects in immune function and regulation. Recent work aimed at uncovering the intricacies of the relationships between autoimmune diseases has confirmed commonality across seven autoimmune diseases through identifying shared genes among some but not all of the diseases (Cotsapas et al., 2011). A model addressing the overarching interconnectivity of various autoimmune disease mechanisms is likely to be elucidated in the future. As MS is a complex disease, understanding which combinations of genes within the population confer the greatest risk of developing autoimmune disease is a central goal of present genetic research efforts.

Environmental Factors

Global maps of MS prevalence rates, constructed based on multiple descriptive epidemiological studies, reveal a non-random geographical distribution of the disease. A diminishing north to south gradient of MS prevalence was described in the Northern Hemisphere (Beebe et al., 1967; Kurtzke, 1977; Kurtzke et al., 1979; Hammond et al., 1987), with an opposite trend identified in the Southern Hemisphere (Hammond et al., 1988; Hogancamp et al., 1997; Kurtzke, 2000). Notably, there is a marked absence of MS cases directly near the equator. When taking continental differences into consideration, there is increased prevalence of MS with large dispersion in Western Europe and North America, both regions being highly populated by Caucasians, whereas areas in Central and Eastern Europe, Australia, and New Zealand have lower prevalence with the lowest prevalence occurring in Asia, the Middle East, and Africa. Such variation calls into question the possibility that ethnicity might be linked to the continental differences seen (Koch-Henriksen and Sorensen, 2010).

FIGURE 52.1 Regions of genome showing association to MS. Genome regions showing association with MS. Evidence for association from linear mixed model analysis of the discovery data (threshold at a $-\log_{10} P$ value of 12) is shown at left. Non-MHC regions containing associated SNPs are indicated in red and labeled with the rs number (green text for newly identified loci, black text for loci with strong evidence of association, and gray text for previously reported loci) and risk allele of the most significant SNP. Asterisks indicate that the locus contains a secondary SNP signal. (Continued)

The study of latitudinal differences has demonstrated only modest effect in Europe and North America, but none within Western Europe (Lauer, 1995; Weinshenker, 1996). The only clear trend of increased incidence can be attributed to the Southern Hemisphere where the majority of studies have come from New Zealand and Australia (Skegg et al., 1987; Mcleod et al., 1994). Descendants living New Zealand and Australia have a lower risk of MS than those descendants living in the UK. These studies are rather compelling because the populations in New Zealand and Australia are relatively homogeneous due to similar British ancestry. This general distribution likely reflects a combination of genetic and environmental influences particularly with respect to exposure to sunlight (Ebers, 2008).

Relatedly, environmental deficiencies have long been associated with MS, as indicated by the inverse correlation of the world prevalence of MS and environmental supply of vitamin D. Vitamin D may be supplied from the environment via sunlight exposure or via dietary intake of vitamin D3 (Vanamerongen et al., 2004; Ascherio et al., 2010). At higher latitudes, the exposure to sunlight is insufficient to produce vitamin D given the lower exposure to the sun in winter months. Vitamin D and its immunomodulatory effect has been established both in response to sunlight and in dietary vitamin D(3) intake (Smolders et al., 2008; Kragt et al., 2009). Subtle defects in vitamin D metabolism have suggested a possible genetic origin. Identification of a highly conserved vitamin D responsive element in the promoter region of the HLA-DRB*1501 haplotype has sparked ongoing debate as to whether HLA-DRB*1501 might be involved in the response to vitamin D particularly since studies suggest that the beneficial effect of vitamin D on MS may in fact be attenuated in those with the risk allele (Ramagopalan et al., 2009; Simon et al., 2011). Nevertheless, few genetic determinants have been identified.

Epstein–Barr virus (EBV) infection has been linked to MS risk since exposure to EBV is associated with 1.5 times greater risk of developing MS. Over 99% of individuals with MS have evidence of prior infection with EBV in comparison to 90% in humans overall (Bagert, 2009). However, the role of EBV in the development of MS is not known. EBV generally infects resting B lymphocytes transforming them into memory cells that survive long-term largely undetected by the immune system

(Thorley-Lawson and Gross, 2004). Interestingly, serostatus in individuals with MS has demonstrated elevated titers to EBV prior to the development of any neurologic sequelae (Thacker et al., 2006). It has been suggested that EBV may play a role in the pathogenesis of MS since postmortem analysis of brains from patients with MS have demonstrated diffuse EBV-association B cell dysregulation among the varying types of MS (Serafini et al., 2004). However, these results have been challenged due to the inability to unequivocally identify EBV infection in pathological tissues, particularly in respect to clinical scenarios unrelated to EBV-driven lymphomas or acute EBV infections. Such difficulties may be linked to differences in sensitivity and specificity of the detection methods utilized (Lassmann et al., 2011).

IMMUNE PATHOGENESIS

Until recently, there were discussions as to whether MS is a primary degenerative disease with secondary inflammation or an autoimmune disease with immune-mediated destruction of the CNS. The sharing of almost half of the allelic variants between MS and other autoimmune disorders from the GWAS has to a large extent provided convincing evidence for an autoimmune pathophysiology for the disease (Hafler, 2012). Our current understanding of MS strongly implicates involvement of the immune system and autoreactive proinflammatory T cells that are critical to the propagation of CNS tissue injury. Elucidating the mechanism of disease initiation and how it contributes to the transition from physiologic immunosurveillance to pathologic cascade continues to be an area of ongoing investigation. Our foundation is based on the understanding that peripherally activated cross-reactive T cells migrate into the CNS of genetically susceptible hosts and mount proinflammatory responses to myelin epitopes. Myelin-reactive T cells appear to be both increased in frequency and activation state in individuals with MS (Raddassi et al., 2011), suggesting a peripheral breach of tolerance to CNS antigen. However, the presence of autoreactive cells in the periphery is an insufficient explanation for the development of autoimmune disease given that myelin-reactive T cells can be found in the peripheral blood of both healthy individuals and patients with MS.

◀ Odds ratios (ORs; diamonds) and 95% confidence intervals (whiskers) are estimated from a meta-analysis of discovery and replication data (+ indicates estimates for previously known loci from discovery data only). Risk allele frequency estimates in the control populations are indicated by vertical bars (scale of 0 to 1, left to right). A candidate gene and the number of genes are reported for each region of association. Black dots indicate that the candidate gene is physically the nearest gene included in the GO immune system process term. “Tags functional SNP” indicates whether the most-significant SNP tags a SNP predicted to affect the function of the candidate gene. Where such an SNP exists, the gene is selected as the candidate gene; otherwise, the nearest gene is selected unless there are strong biological reasons for a different choice. The final column indicates whether SNPs are correlated ($r^2 > 0.1$) with SNPs associated with other autoimmune diseases. CeD, celiac disease; CrD, Crohn’s disease; PS, psoriasis; RA, rheumatoid arthritis; T1D, type 1 diabetes; UC, ulcerative colitis. *Reproduced with permission from Nature (Sawcer et al., 2011).*

T Cell Pathogenesis

Upon interaction of the T cell with the antigen-presenting cell (APC), the antigen-specific T cells proliferate and divide into subsets (see [Figure 52.2](#)). Of specific interest to MS are the Th1, Th2, Th17, and regulatory T cell subsets. T cells have been classified according to the cytokine profiles that they produce upon activation ([Abbas et al., 1996](#); [O'Garra, 1998](#); [O'Shea and Paul, 2010](#)). MHC class II restricted CD4⁺ T cells, producing IFN- γ , IL-2, lymphotoxin (LT), and TNF- α , have been defined as Th1 (inflammatory) cells, and have demonstrated pathogenicity in EAE models ([Leonard et al., 1995](#); [Segal et al., 1998](#);

[Severson and Hafler, 2010](#)). The Th1 cytokines activate macrophages for cellular immunity with the assistance of IgG₁ secreted by B cells. In contrast, CD4⁺ T cells producing IL-4, IL-5, IL-10, or IL-13 have been termed Th2 (anti-inflammatory) cells, and have demonstrated a protective role in EAE ([Khoury et al., 1992](#); [Owens et al., 1994](#); [Begolka et al., 1998](#); [Antel and Owens, 1999](#)). Th2 cytokines promote humoral immune responses alongside IgG₄. Th17 cells are thought to be proinflammatory in nature and secrete the cytokines IL-17A, IL-17F, IL-21, and IL-22, which have been strongly implicated in the pathogenesis of autoimmune diseases ([Harrington et al., 2005](#)). Regulatory T cells (Tregs) are a subset of T cells that are

FIGURE 52.2 Pathophysiology of MS. Defects in peripheral immune regulation lower the activation barrier for autoreactive T cells. (A) In normal homeostasis, APCs digest microbial antigens or self proteins and present them to naïve T cells in the context of costimulatory molecules. An appropriate cytokine milieu can drive differentiation of these naïve autoreactive T cells to a Th1 or Th17 cell phenotype; however, these potentially pathogenic T cells are not activated due to the actions of peripheral regulatory immune cell populations, such as FoxP3⁺ Tregs and Tr1 cells. Via the actions of co-inhibitory molecules and cytokines such as IL-10 and TGF- β , autoreactive T cells become anergic and autoimmune disease is prevented. Other mechanisms, such as thymic deletion and lack of costimulatory molecules on APCs, are also involved in controlling autoreactive T cells. (B) MS patients have defects in peripheral immune regulation, including higher expression of costimulatory molecules on APCs, lower CTLA-4 levels, and lower IL-10 production. Additionally, MS patients have an increased frequency of IFN- γ -secreting Tregs relative to healthy controls. Thus, the barrier for activation of autoreactive T cells is lowered for MS patients. Activated myelin-reactive T cells can then adhere to and extravasate across the choroid plexus and BBB, where they can initiate an inflammatory milieu that gives license to further waves of inflammation and eventual epitope spreading. *Reproduced with permission from the Journal of Clinical Investigation (Nylander and Hafler, 2012).*

involved in the regulation of the immune system, maintenance of tolerance to self-antigens, and surveillance of autoimmune disease. They can secrete a variety of cytokines including, TGF- β , IL-10, and IFN- γ in addition to utilizing FoxP3 as a transcription factor (Fontenot et al., 2003; Hori et al., 2003). Current work involving Tregs has linked this subset with immune dysregulation, a concept which will be discussed later.

Several lines of evidence support the hypothesis that Th1 cells may be pathogenic in MS. Th1 and Th2 cells express distinct profiles of chemokine receptors, including CXCR3/CCR5 and CCR3/CCR4, respectively (Bonecchi et al., 2009). An increased proportion of T cells from MS patients was shown to express the characteristic Th1 chemokine receptor pattern and MS plaques were found to express increased levels of the corresponding chemokine (Siveke and Hamann, 1998; Balashov et al., 1999; Sorensen et al., 1999). Analysis of cytokine mRNA in CSF from MS patients showed a bias towards Th1 cytokines (Blain et al., 1994). Immunohistochemical studies of MS plaques *in situ* have demonstrated the presence of the proinflammatory cytokines TNF- α and IL-12 (Hofman et al., 1989; Selmaj et al., 1991; Windhagen et al., 1995). Markedly, MBP-reactive T cells derived from patients with MS secrete cytokines that are more consistent with Th1-mediated response, whereas MBP-reactive T cells from healthy individuals are more likely to produce cytokines that characterize a Th2-mediated response (Crawford et al., 2004). Interventions that shift or deviate the cytokine responses away from a Th1 and towards a Th2 profile have been deemed favorable.

Despite the prior suggestion that Th1 cells are unique in driving the inflammatory response, recent work has characterized the putative role of proinflammatory Th17 cells in establishing the MS phenotype. Studies implicate pathogenic Th17 cells in gaining early access to the CNS (Steinman, 2007; Reboldi et al., 2009). Entry to the CNS is mediated via the choroid plexus, which, in addition to producing CSF, spans the blood–CSF barrier and facilitates immune surveillance. The Th17 mechanism implicates the CCR6/CCL20 axis in disease initiation as defined in the EAE model, with Th17 cells expressing CCR6 and choroid plexus endothelial cells expressing CCL20. In applying this information to human disease, it is likely that peripherally activated Th17 cells are able to bind to adhesion molecules and chemokine receptors expressed on the choroid plexus thereby migrating across the blood – CSF barrier and gaining access to circulating CSF. Dysregulated Th17 cells are subsequently able to access perivascular tissue, initiating a cascade of proinflammatory events. Th17 cells secrete IL-23, which, in EAE models, alongside the transcription factor ROR γ t, promotes production of GM-CSF. This induces a positive feedback loop where further secretion of IL-23 occurs

and is implicated in the encephalogenicity and incidence of axoglial damage (Codarri et al., 2011; El-Behi et al., 2011). In relating Th17 cells to the formation of perivascular infiltrates, it is possible that their secretion of IL-17 and IL-22 may increase blood–brain barrier permeability and thus facilitate the influx of immune cells, such as autoreactive Th17 cells, Th1 (IFN- γ secreting), $\gamma\delta$ T cells, cytotoxic CD8⁺ cells, B cells, and immunoglobulin-secreting plasma cells (Kebir et al., 2007). This leads to the possibility of a two-step process for initiation of MS, one in which Th17 cells prime the entrance of other dysregulated immune cells and therefore creating the appropriate inflammatory environment containing infiltrates of cells that result in downstream damage of the CNS (Nylander and Hafler, 2012).

Immune Dysregulation

In elaborating on the concept of immune dysregulation, GWAS have shed light on the likely involvement of allelic variants in disease states. A number of these variants involved genes for cytokine receptors and costimulatory molecules and have been associated with defects in Treg homeostasis. Costimulatory molecules have recently been found to function as negative regulators of the immune system. TIM-3 has been implicated in modulating Th1 and Th17 cytokine secretion and loss of TIM-3 functional T cell regulation has been established in MS patients (Koguchi et al., 2006; Yang et al., 2008; Hastings et al., 2009). GWAS studies have linked CD226 to MS risk (Hafler et al., 2009), and recent work has implicated the CD226/TIGIT axis in regulating human T cell function via a mechanism similar to that employed by CD28/CTLA4, in which binding to B7 induces coexpression of inhibitory and excitatory signals that modulate immune responses (Joller et al., 2011; Lozano et al., 2012). Costimulation between CD58/CD2 appears to be implicated in T cell receptor signaling, including activation of Tregs, and has been suggested to provide a protective effect for MS (De Jager et al., 2009a).

Recent studies have indicated that despite normal frequency of Tregs in MS patients, their suppressive ability is compromised and substantially decreased in response to autoreactive T cells in comparison to healthy individuals (Viglietta et al., 2004; Haas et al., 2005). Notably, Tregs have demonstrated great functional plasticity. Their ability to be reprogrammed suggests that Tregs may be able to function as a biomarker in MS (Nylander and Hafler, 2012). In the presence of IL-1 β and IL-6, Tregs are able to produce the inflammatory cytokine IL-17, further implicating this subset in autoimmune disease (Koenen et al., 2008; Ayyoub et al., 2009; Beriou et al., 2009). Moreover, the notion of Treg reprogramming has arisen due to the observation that patients with RRMS have the ability to produce IFN- γ -secreting

Tregs, thereby characterizing a Th1-type Treg effector phenotype. This finding was observed *in vitro* under IL-12 stimulation of Tregs and recapitulated in *ex vivo* Tregs derived from patients with untreated RRMS. This role of Th1–Treg effector cells was suggested by the use of IFN- β , a first-line therapy for RRMS, which has been shown to decrease IL-12 levels and normalize the ratio of IFN- γ ⁺Foxp3⁺ Tregs to that of healthy controls (Dominguez-Villar et al., 2011). Costimulatory molecules and regulatory T cell plasticity in MS undoubtedly provide fascinating clues into disease pathogenesis.

Autoantigens

Autoantigen-specific T cells have been identified both in healthy individuals and in patients with MS. Their entrance into the inflamed CNS environment is likely mediated by the immune mechanisms posited above, whereupon entering, the autoreactive T cells are able to subsequently contribute to myelin destruction and axonal damage in addition to secondary inflammation following activation by local antigen-presenting cells. Attention has been directed towards uncovering frequencies of autoantigen-specific T cell binding to myelin proteins including MOG, MBP, and proteolipid in addition to heat shock protein α B-crystallin and oligodendroglia-specific enzyme transaldolase in CD4⁺ cells isolated from MS patients (Banki et al., 1994; Greer and Pender, 2008). Anti-MOG has previously been isolated from postmortem CNS tissue in MS patients (O'Connor et al., 2005). In an assay based on self-assembly of radiolabeled MHC tetramers, it was demonstrated that such tetramers were more sensitive for MOG autoantibody detection. Nevertheless, MOG-specific autoantibodies were found more so in patients with acute disseminated encephalomyelitis, than in adults with MS (O'Connor et al., 2007). Likewise, the ability to detect and clone autoantigen-specific T cells from blood has allowed further quantification of MOG frequencies, work which demonstrated an increase in MOG-specific T cells in MS patients in comparison to healthy individuals (Raddassi et al., 2011).

Despite the inability to identify a putative role for environmental triggers, infectious factors, or microbial antigens in establishing MS risk, studies have suggested potential cross-reactivity between epitopes with microbial antigens. Finally, regardless of what antigen event initiates the self-reactive cascade, epitope spreading is likely to contribute to an array of activated immune cells that can respond to multiple antigens. Nevertheless, no single antigen has been clearly implicated in the pathogenesis of MS.

Meningeal Ectopic B Cell Follicles

Given the marked presence of OCBs and increased levels of IgG within the CSF of individuals diagnosed with MS

in addition to the ongoing debate underlying the increased incidence of EBV and its ability to prime the immune system in individuals with MS, the notion of B cell involvement has received great attention in playing a crucial role in MS pathogenesis. There appears to be great connectivity between the cell population in the CNS and CSF since clonally expanded B cells and plasmablast clones have been associated with the observed intrathecal immunoglobulin production (Lovato et al., 2011; Obermeier et al., 2011). Recently published work indicates that related B cell clones populate the meninges, leading to the hypothesis that these aggregate structures can be related to the B cell infiltrates found in MS lesions (Lovato et al., 2011). Likewise, ectopic lymphoid follicles, strongly resembling germinal centers, have been identified in the meninges of SPMS patients (Serafini et al., 2004). These follicles contain proliferating B cells, plasma cells, T cells, and dendritic cells with the corresponding diffuse meningeal inflammation being suggested to play a role in the manifestation of cerebral cortical gray matter pathology in MS. Follicles have been located more frequently in the deep sulci of the temporal cingulate, insula, and frontal cortex (Howell et al., 2011). Apart from being associated with cortical pathology, studies have implicated that meningeal B cell follicles can be associated with early onset of disease in patients with SPMS (Magliozzi et al., 2007). Overall, such humoral activation within ectopic lymph tissue and CSF has been postulated to play an imperative role in disease progression secondary to the ongoing persistence of antigens driving a constitutive inflammatory and humoral response.

TREATMENT

Therapeutic approaches in MS may be broadly divided into treatments that are symptomatic and/or supportive in nature, and treatments that are directed at the underlying pathophysiology of the disorder. There are currently nine agents approved by the United States Food and Drug Administration (FDA) (see Table 52.1 for comparison of FDA-approved therapies) as disease-modifying therapies (DMT). They are expensive, with 10-year disease-related costs averaging US\$467,712 for patients on a single disease modifying therapy (DMT) (Noyes et al., 2011). The vast majority of these DMTs have been studied in RRMS and CIS, and approved for such use, whereas the progressive forms of MS do not respond to immunotherapies. Their current use has marked a milestone for patient care. Understanding pharmacologic mechanisms of action in a number of MS DMTs has led to significant advancement in elucidating MS pathogenesis. The growing number of therapies being studied for the treatment of MS in addition to the advent of oral therapy indicates great promise for the future.

TABLE 52.1 FDA Approved Therapies for MS

| | Brand name | Indications | Results | Mechanism of action |
|--|---|---|--|--|
| IFN-β1a (IM weekly) | Avonex [®] | <ul style="list-style-type: none"> • Treatment of RRMS | <ul style="list-style-type: none"> • Reduction of relapses by one-third • Reduction of new MRI T2 lesions and the volume of enlarging T2 lesions • Reduction in the number and volume of Gd-enhancing lesions • Slowing of brain atrophy | <ul style="list-style-type: none"> • Acts on blood–brain barrier by interfering with T cell adhesion to the endothelium by binding VLA-4 on T cells or by inhibiting the T cell expression of MMP • Reduction in T cell activation by interfering with HLA class II and costimulatory molecules B7/CD28 and CD40: CD40L • Immune deviation of Th2 over Th1 cytokine profile • Normalizing ratio of IFN-γ⁺ Foxp3⁺ Tregs |
| IFN-β1a (SC three times weekly) | Rebif [®] | <ul style="list-style-type: none"> • Treatment of RRMS | <ul style="list-style-type: none"> • Same as IFN-β1a | <ul style="list-style-type: none"> • Same as IFN-β1a |
| IFN-β1b (SC every other day) | Betaseron [®] , Extavia [®] | <ul style="list-style-type: none"> • Treatment of RRMS | <ul style="list-style-type: none"> • Same as IFN-β1a | <ul style="list-style-type: none"> • Same as IFN-β1a |
| Glatiramer acetate (SC daily) | Copaxone [®] | <ul style="list-style-type: none"> • Treatment of RRMS | <ul style="list-style-type: none"> • Reduction of relapses by one-third • Reduction of 57% in the number and volume of Gd-enhancing lesions | <ul style="list-style-type: none"> • Induces cytokine shift from one that is proinflammatory to one that is anti-inflammatory and regulatory in nature |
| Natalizumab (IV monthly infusion) | Tysabri [®] | <ul style="list-style-type: none"> • Treatment of RRMS | <ul style="list-style-type: none"> • Reduced rate of relapse up to 68% and the development of new MRI lesions | <ul style="list-style-type: none"> • Monoclonal antibody that blocks alpha 4-integrin on surface T cells preventing them from crossing the blood–brain barrier |
| Mitoxantrone (IV infusions every 3 months) | Novantrone [®] | <ul style="list-style-type: none"> • Worsening forms of RRMS • SPMS | <ul style="list-style-type: none"> • Reduction in relapses by 67% • Slowed progression on EDSS, ambulation index and MRI disease activity | <ul style="list-style-type: none"> • Anti-neoplastic that intercalates DNA • Suppresses cellular and humoral immune response |
| Fingolimod (given orally once a day) | Gilenya [®] | <ul style="list-style-type: none"> • Treatment of RRMS | <ul style="list-style-type: none"> • Reduction of 54% in risk of relapse • Lower risk of disability progression by 30% | <ul style="list-style-type: none"> • S1P agonist, causing internalization of S1P₁ receptors on lymph-node T cells • Subsequent decrease in migration of activation lymphocytes into circulation |
| Teriflunomide (given orally once a day) | Aubagio [®] | <ul style="list-style-type: none"> • Treatment of RRMS | <ul style="list-style-type: none"> • Reduction of 36% in risk of relapse • Lower risk of disability progression by 31% | <ul style="list-style-type: none"> • Inhibits <i>de novo</i> nucleotide synthesis • Decreases T cell and B cell proliferation • Interrupts T cell and APC interactions • Subsequently possesses anti-inflammatory properties |
| BG-12, dimethyl fumarate (given orally twice a day) | Tecfidera [®] | <ul style="list-style-type: none"> • Treatment of RRMS | <ul style="list-style-type: none"> • Reduction of 49% in risk of relapse • Lower risk of disability progression by 38% | <ul style="list-style-type: none"> • Inhibits immune cells and molecules • Decreases myelin damage in the CNS • Exhibits anti-oxidant properties that may be protective against damage to the brain and spinal cord |

Interferons

Compared to placebo-treated RRMS controls, treatment with alternate-day subcutaneous injections of eight million units of IFN- β 1b (Betaseron[®]) was shown to decrease the primary efficacy outcome measure of frequency of relapses by 34% after 2 years (The IFNB Multiple Sclerosis Study Group, 1993). A significant decrease in the accumulation of MRI lesions was observed with treatment (Paty and Li, 1993) and 5-year follow-up data reported that disease progression in the

IFN- β 1b treated group was 35%, compared with 46% progression in the placebo group (IFNB Multiple Sclerosis Study Group, 1995). A 30% decrease in the annual exacerbation rate in the treated group was maintained. IFN- β 1a (Avonex[®], weekly IM injections), a glycosylated recombinant beta-interferon, was evaluated in a 2-year study of weekly intramuscular injections of six million units (30 μ g). The proportion of patients progressing by the end of the trial was 21.9% in the treated group compared to 34.9% in the placebo group. The annual exacerbation rate was decreased by 32% in the treated

group versus the placebo group. Treatment was also associated with a 40% reduction in mean MRI lesion load (Jacobs et al., 1995, 1996). Clinical and MRI benefit of IFN- β 1a (Rebif[®], subcutaneous, three times weekly) doses for up to 4 years was demonstrated in PRISMS-4, thereby suggesting that early treatment with IFN- β 1a was of increased benefit to patients with RRMS as compared with those treated later in disease course (PRISMS, 2001).

β -Interferon therapy utilizes recombinant forms of naturally occurring cytokines intrinsically possessing a wide range of properties. The mechanism of action involving β -interferons appears to be quite complex with the DMT exerting its effects on the pathophysiology of MS at several sites. Studies have suggested that β -interferons inhibit the migration of activated inflammatory cells across the blood–brain barrier (BBB) and into the CNS parenchyma through decreasing the function of the vascular cell adhesion molecule-1/very late activation antigen-4 cell adhesion axis (see Natalizumab (Tysabri[®]), below). IFN- β may potentially intercept inflammatory cell adhesion and subsequent migration across the BBB (Calabresi et al., 1997; Graber et al., 2005). The rapid effect of β -interferons on the gadolinium enhancing lesions of MS represents a biological marker of treatment response and establishes the BBB as an important site of action of β -interferon therapy (Stone et al., 1997).

Studies have also suggested that the β -interferons may exert their pharmacologic effects by shifting cytokines and immune cell profiles in MS patients towards one that is anti-inflammatory and protective (Brod et al., 1996). IFN- β has also demonstrated ability to upregulate expression of costimulatory molecules needed for antigen presentation (CD80, CD86, and CD40) on monocytes, thus decreasing the generation of autoreactive T cells and limiting T cell activation. As addressed earlier, IFN- β has been implicated in normalizing the ratio of IFN- γ ⁺Foxp3⁺ Tregs to that of healthy controls and in decreasing IL-12 levels, thereby potentially restoring the ability of Tregs to regulate immune cells (Dominguez-Villar et al., 2011).

Glatiramer Acetate (Copaxone[®])

Glatiramer acetate is the major noninterferon DMT used in the treatment of MS. Treatment with glatiramer acetate/copolymer 1 (Copaxone, GA, subcutaneous, daily) was associated with a 2-year relapse rate reduction of 29% compared to placebo control (Johnson et al., 1995). The clinical benefit of GA for relapse rate in comparison to placebo was sustained following an 11-month extension period utilizing the same study design (Johnson et al., 1998). Subsequent studies revealed a beneficial effect of GA in MRI with a 35% reduction in total gadolinium-enhancing lesions and 57% reduction in new gadolinium-enhancing lesions, with an overall decrease in T2 disease burden (Mancardi et al., 1998; Comi et al., 2001).

GA is a random sequence polypeptide of the four amino acids alanine (A), lysine (K), glutamate (E), and tyrosine (Y). As a sequence of amino acids, GA has been proposed to function as a T cell receptor antagonist to MBP/MHC at MBP-specific T cell receptors and operate as an altered peptide ligand to the MBP (Aharoni et al., 1999; Duda et al., 2000). Thus, research suggests that GA elicits its effect on the immune system by inducing deviation of cytokine production in response to MBP from Th1 cytokines to Th2 cytokines, a change that is characterized by increased secretion of anti-inflammatory cytokines, with prolonged GA treatment leading to a Th2 bias in MS patients (Miller et al., 1998; Duda et al., 2000; Gran et al., 2000; Neuhaus et al., 2000; Valenzuela et al., 2007;). Additionally, GA has been implicated in altering the cytokine profile to one that is more consistent with a regulatory population (Hong et al., 2005). Furthermore, increases in FoxP3⁺ expression in Tregs have been demonstrated following GA, also supporting theories that GA facilitates a regulatory population (Hong et al., 2005).

Natalizumab (Tysabri[®])

Natalizumab is a monoclonal antibody to the very late activation antigen (VLA-4), the α 4 β 7 integrin expressed on activated T cells and monocytes, and is the ligand for vascular cell adhesion molecule (VCAM) expressed on CNS endothelial cells. Natalizumab, by preventing adhesion of activated T cells to endothelial cells, has been able to decrease influx of potentially autoreactive T cells into perivascular tissue. Natalizumab-treated patients have developed cases of progressive multifocal leukoencephalopathy, a rare and fatal disease caused by JC virus and characterized by progressive inflammatory damage of CNS white matter. This prompted both its manufacturer and the FDA to review its utility in treating MS. Regardless, its clinical benefits have been deemed to outweigh the risks involved. Its use has been restricted to individuals with highly active disease. Two trials involving RRMS patients have demonstrated interesting clinical results. The AFFIRM study compared natalizumab alone to placebo and the SENTINEL study looked at adding natalizumab to ongoing IFN- β 1a therapy. The AFFIRM trial demonstrated a 42% reduced risk of sustained progression of disability, a 68% reduction in rate of clinical relapse at 1 year, and an 83% reduction in accumulation of new or enlarging hyperintense lesions over 2 years (Polman et al., 2006). Results of the SENTINEL trial were similar to those of AFFIRM with the exception of a 64% decreased risk of sustained disability progression with natalizumab (Calabresi et al., 2007; Hutchinson et al., 2009).

Mitoxantrone (Novantrone[®])

Mitoxantrone, a small molecule chemotherapeutic agent able to cross the blood–brain barrier, functions as a type II topoisomerase inhibitor, which disrupts DNA synthesis and DNA repair, both events which function in an immunosuppressant capacity thereby inhibiting T cell, B cell, and macrophage proliferation. Overall, this leads to enhanced T cell suppressor function, inhibition of B cell function and antibody production, decreased secretion of proinflammatory cytokines, and inhibition of macrophage-mediated myelin degradation (Fox, 2004). Mitoxantrone, administered intravenously, has been approved by the FDA as treatment for patients with worsening forms of MS including SPMS, worsening RRMS, and PRMS. The MIMS trial indicated a 44% reduction in time to first relapse; a 24% decrease in the expanded disability status scale, however, did not demonstrate a positive impact on MRI disease burden (Hartung et al., 2002; Krapf et al., 2005). Due to concerns related to increased incidence of systolic dysfunction and therapy-related acute leukemia, its use remains relatively limited (Marriott et al., 2010).

Fingolimod (Gilenya[®])

Fingolimod's pharmacologic activity is targeted towards lymphocyte migration out of lymph nodes. This action is highly dependent on the engagement of a G-protein-coupled receptor, S1P₁, present on the surface of the lymphocytes. Fingolimod is structurally similar to S1P and can function as an agonist by engaging four of the five known S1P receptors (S1P₁, S1P₃, S1P₄, S1P₅). This leads to a reduction in activated T cells that are able to exit the lymph node and subsequently cross the blood–brain barrier to exert their potential pathogenic effects on perivascular tissue (Schwab and Cyster, 2007; Pham et al., 2008). Studies have indicated the potential for S1P receptors to be present on other cells, including neurons, microglial cells, oligodendrocytes, and astrocytes, suggesting a putative role for fingolimod in influencing myelin repair, modulating survival of oligodendrocyte progenitor cells, and directing astrocyte migration and proliferation (Yamagata et al., 2003; Miron et al., 2008, 2010).

In September 2010 fingolimod became the first FDA-approved first-line oral agent for the treatment of MS. The FREEDOMS trial demonstrated, after 2 years, an overall 54% decreased risk of relapse in the group treated with fingolimod versus those taking placebo. The risk of disability progression was 30% lower in patients receiving the lower dose (0.5 mg) as opposed to placebo. With regard to MRI disease burden, those taking fingolimod presented with fewer new lesions and less brain tissue atrophy. The TRANSFORMS trial aimed at characterizing

the efficacy of fingolimod versus intramuscular IFN- β 1a (Avonex[®]). The group taking fingolimod had a 52% lower risk of having a relapse than those taking IFN- β 1a, with 82.5% of the fingolimod group and 70% of IFN- β 1a presenting with no relapses during the 1-year study period. Furthermore the group taking fingolimod had fewer signs of MRI disease burden. There was no difference among the groups in the risk of disease progression (Cohen et al., 2010). Although the arrival of fingolimod has been met with great enthusiasm, the lack of clarity surrounding long-term safety has led to caution as to its utility as a first-line agent.

Teriflunomide (Aubagio[®])

Teriflunomide is the active metabolite of leflunomide, an approved therapy for rheumatoid arthritis. It inhibits *de novo* pyrimidine nucleotide synthesis and therefore potentially decreases T cell and B cell proliferation (Hartung et al., 2010). Reports also indicate that teriflunomide may interrupt T cell and APC interactions in addition to possessing anti-inflammatory properties (Zeyda et al., 2005; Gold and Wolinsky, 2011). The TEMSO trial demonstrated a 31% reduction in annual relapse rate, a 21% reduction in disability progression, and a 76% reduction in number of new or enlarging T2 lesions on MRI in the higher dose cohort (O'Connor et al., 2011). Teriflunomide was approved by the FDA in September 2012 for patients with RRMS.

Dimethyl Fumarate, BG-12 (Tecfidera[®])

BG-12 is an oral formulation of fumaric acid, which is metabolized to monomethyl fumarate. It was approved a second-line agent in 2013. Other oral formulations of fumaric acid have previously been used to treat psoriasis. Both dimethyl fumarate and the active metabolite induce activation of the nuclear factor E2-related factor-2 pathway, which exerts neuroprotective effects and decreases myelin damage in the CNS (Kappos et al., 2008; Fontoura and Garren, 2010; Linker et al., 2011). Anti-inflammatory mechanisms have also been attributed to dimethyl fumarate (Gold, 2011). The DEFINE trial was completed in 2011. As a randomized, double-blind, placebo-controlled phase III study, patients with RRMS were assigned to receive either oral BG-12 at a dose of 240 mg twice or thrice daily, or placebo. The primary end-point was the proportion of patients who had a relapse 2 years later in addition to disability progression and MRI disease burden. The study demonstrated positive results with a significant reduction in relapse rate (27% with BG-12 twice daily and 26% with BG-12 thrice daily vs. 46% with placebo), in the rate of disability progression, in the number of new or enlarging T2 lesions, and in new gadolinium-enhancing

lesions (Gold et al., 2012). The CONFIRM trial was also completed in 2011. A phase III, randomized study, it aimed to ascertain the efficacy and safety of BG-12 at a dose of 240 twice or thrice daily in comparison to both placebo and glatiramer acetate in patients with RRMS. Similarly to the DEFINE trial, both BG-12 and glatiramer acetate significantly reduced relapse rates and MRI disease burden in relation to the placebo group (Fox et al., 2012). In early 2013, BG-12 was approved as a first-line therapy for adults with RRMS.

CONCLUDING REMARKS

Over the past decade, major strides have been made in our understanding of the immunopathogenesis underlying the development and course of MS, an autoimmune disease that predominantly impacts the CNS by way of white matter damage and demyelination of neurons thought to be primarily driven by T cell dysregulation, inflammation, and immune dysfunction. Nevertheless, our ever-growing fund of knowledge continues to inspire future directions. Novel insights are providing hints for future prospects related to early cortical demyelination, gray matter pathology, imaging, and B cell involvement in MS further establishing this disease as a multifocal entity. Overall, our increasing knowledge pertaining to MS continues to be multifactorial. The ability for clinicians and researchers to utilize our understanding of the immunopathogenesis in relation to known pharmacologic mechanisms, clinical findings, and imaging modalities will be paramount in taking the necessary steps towards eradicating MS.

Peripheral Neuropathies

Michael P.T. Lunn¹ and Kazim A. Sheikh²

¹National Hospital for Neurology and Neurosurgery, Queen Square, London, UK, ²University of Texas Medical School at Houston, TX, USA

Chapter Outline

| | | | |
|---|-----|--|-----|
| Introduction | 757 | Chronic Neuropathies: Chronic Inflammatory Demyelinating Polyradiculoneuropathy | 766 |
| Acute Neuropathies: The Guillain–Barré Syndrome | 757 | History | 766 |
| Historical Background | 757 | Epidemiology and Clinical Features | 766 |
| Epidemiology | 758 | Multifocal Motor Neuropathy with Conduction Block | 766 |
| Clinical Features and Subtypes of GBS | 758 | Multifocal-acquired Demyelinating Sensory and Motor Neuropathy (MADSAM) | 767 |
| Acute Inflammatory Demyelinating Polyradiculoneuropathy | 758 | Multifocal-acquired Sensory and Motor Neuropathy (MASAM) | 767 |
| Acute Motor Axonal Neuropathy | 758 | Paraproteinemic Demyelinating Peripheral Neuropathy | 767 |
| Acute Motor and Sensory Neuropathy | 759 | Autoimmune Features | 768 |
| Miller Fisher Syndrome | 759 | Immunogenetic Features | 768 |
| Autoimmune Features | 759 | Environmental Influences | 768 |
| Molecular Mimicry | 759 | Animal Models | 768 |
| Anti-ganglioside Antibodies in GBS Variants | 759 | Pathogenic Mechanisms | 769 |
| Gangliosides in Peripheral Nerve | 761 | Treatment and Outcome | 769 |
| Functional Effects of Antibodies | 761 | Concluding Remarks and Future Prospects | 770 |
| Environmental Effects | 762 | Acknowledgments | 770 |
| Animal Models of Disease | 763 | References | 770 |

INTRODUCTION

Autoimmunity is implicated in a small but important group of peripheral nerve diseases. These include the acute inflammatory neuropathies eponymously referred to as the Guillain–Barré (GBS) and Fisher syndromes, and the chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), both idiopathic and associated with a serum paraprotein. Substantial evidence exists for an autoimmune pathogenesis in GBS and its subtypes. Evidence is still gathering to support similar processes in the chronic inflammatory neuropathies including the demyelinating neuropathy associated with antibodies to myelin-associated glycoprotein (MAG). Although most current evidence supports an antibody-driven pathogenesis triggered by infection for GBS and Fisher syndrome,

T cell mechanisms predominate in CIDP and other cellular immune components are crucial effectors of disease. Experimental allergic neuritis (EAN), an inflammatory model of neuropathy, has been instructive in the detailed study of the pathogenesis of immune-mediated neuropathies and will be discussed.

ACUTE NEUROPATHIES: THE GUILLAIN–BARRÉ SYNDROME

Historical Background

Guillain, Barré, and Strohl described a rapidly evolving flaccid paralysis with areflexia and albuminocytological dissociation in the cerebrospinal fluid (CSF) in 1916

(Guillain et al., 1916). Early autopsies demonstrated both T cell inflammation and demyelination in peripheral nerves (Asbury et al., 1969; Haymaker and Kernohan, 1949) leading to the notion of GBS being a single pathophysiological entity synonymous with acute inflammatory demyelinating polyradiculoneuropathy (AIDP). AIDP is by far the most common variant of GBS in the developed world. Variants such as the Fisher syndrome (1956) (Fisher, 1956) and the axonal variants (1986) (Feasby et al., 1986), acute motor axonal neuropathy (AMAN) and acute motor and sensory axonal neuropathy (AMSAN) (Yuki et al., 1990; McKhann et al., 1991, 1993) are now part of a spectrum of disease with variable worldwide occurrence (see below and Box 53.1).

Epidemiology

Since the near eradication of poliomyelitis, GBS has become the commonest cause of acute flaccid neuromuscular paralysis in the world. The incidence of GBS is 0.81–1.89 per 100,000 (Hughes and Rees, 1997; Sejvar et al., 2011). The incidence increases steadily with advancing age (0.62 per 100,000 in 0–9 year olds and 2.99 per 100,000 in 80–89 year olds) and males are affected more than females by 1.25:1 (Hadden and Gregson, 2001; Sejvar et al., 2011). Case-control studies implicate infections as precipitating events (see later).

Severity may vary from mild with full recovery in 10% of patients only, to bedbound in 40%, to complete paralysis with ventilatory dependence in 20%. Death occurs in 3.5–12% of patients (Guillain-Barre Syndrome Study Group, 1985; Rees et al., 1998; Hughes and Cornblath, 2005).

Clinical Features and Subtypes of GBS

Acute Inflammatory Demyelinating Polyradiculoneuropathy

The diagnosis of GBS remains clinical. Electrophysiological studies patients help to subtype patients into diagnostic

categories. AIDP accounts for over 95% of patients with GBS in Europe and North America. Patients present with a rapidly evolving neuropathic (sensory-) motor paralysis, usually ascending, in two or more limbs over less than 4 weeks. The illness is monophasic. Most patients have numbness, tingling, or pain and many complain of bladder disturbance, facial weakness, or swallowing difficulty (Hughes, 1990). Autonomic disturbance is common with arrhythmia and fluctuating blood pressures. Tendon reflexes are absent or reduced. The CSF contains <50 leukocytes per μl (Asbury and Cornblath, 1990) and CSF protein is raised in 80% of cases. Antiganglioside antibodies may be detected in the serum (see below) by ELISA, often with thin layer chromatography confirmation, but novel solid phase multiplex and combinatorial ganglioside assays have emerged and are being increasingly used (Rinaldi et al., 2009). Electrophysiological studies typically show slowed motor conduction velocities, delayed F-waves, and preserved compound muscle action potential (CMAP) amplitudes consistent with demyelination, but conduction failure and axonal degeneration may complicate the picture.

Multifocal perivascular T cell infiltration with demyelination, typically patchy with involvement of proximal and terminal nerve segments, characterizes the pathology of AIDP (Asbury et al., 1969; Hall et al., 1992). Indications of blood–nerve barrier (BNB) breakdown and deposition of activated complement components can be seen in some but not all cases of AIDP (Hafer-Macko et al., 1996b). These observations raise the possibility that T cell- or antibody-mediated immune injury can predominate in an individual case, although the evidence is increasingly in favor of an antibody-driven process in humans.

Acute Motor Axonal Neuropathy

Acute motor axonal neuropathy (AMAN) is a pure motor variant of GBS seen most commonly in China, Japan, and Mexico (McKhann et al., 1991, 1993; Ogawara et al., 2000). Here it accounts for almost half of cases, but in Europe and North America it accounts for only 5–20% (Rees et al., 1995b; Visser et al., 1995), clinically probably nearer 5%. In China AMAN occurs in seasonal epidemics, affects more children (McKhann et al., 1991) and is strongly associated with *Campylobacter jejuni* infection. Sensory impairment is minimal and autonomic involvement less common. Electrophysiological studies are characterized by reduced CMAP amplitudes, absent F-waves with normal distal motor latencies and conduction velocity (Kuwabara et al., 2000) but many feel criteria of this sort misclassify AMAN as AIDP and the prevalence is higher (Uncini and Kuwabara, 2012). Sensory involvement is absent.

The pathology of axonal GBS has largely been described from AMAN cases in northern China. The

BOX 53.1 The Diversity of Guillain–Barré Variants

- Acute inflammatory demyelinating polyradiculoneuropathy (AIDP)
- Regional variants, e.g., pharyngo-cervical-brachial
- Acute motor axonal neuropathy (AMAN)
- Acute motor and sensory axonal neuropathy (AMSAN)
- (Miller) Fisher syndrome (ataxia, ophthalmoplegia, and areflexia)
- Acute panautonomic neuropathy
- Acute pure sensory neuropathy
- Acute motor conduction block neuropathy

pathological changes indicate an antibody-mediated immune attack directed preferentially against motor axons causing primary axonal degeneration in the absence of prominent T cell inflammation (Griffin et al., 1995, 1996a; Hafer-Macko et al., 1996a). Macrophages may be found in the periaxonal space suggesting that the antigen of interest is on the axolemma (Figure 53.1). Animal models of AMAN have disrupted nodal sodium channel clusters and detachment of paranodal myelin terminal loops. This would significantly reduce the safety factor for impulse transmission and might be responsible for the rapidly reversible conduction block frequently present in human AMAN (Yuki and Kuwabara, 2007). However, since in some patients little pathology is found (Griffin et al., 1996b) and in others recovery is too rapid for nerve fiber degeneration and regeneration (Ho et al., 1997; Kuwabara et al., 1998), axonal conduction failure and distal neuromuscular terminal failure must also make a prominent contribution to clinical weakness in AMAN.

Acute Motor and Sensory Neuropathy

Acute motor and sensory neuropathy (AMSAN) is a more severe form of AMAN with a more severe course, sensory involvement, and delayed recovery (Feasby et al., 1986; Griffin et al., 1995). Sensory as well as motor nerve roots are involved. The pathology is similar to that of AMAN.

Miller Fisher Syndrome

The Miller Fisher or Fisher Syndrome (FS) (Fisher, 1956) accounts for approximately 5% of GBS cases and comprises ophthalmoplegia, ataxia, and areflexia without limb weakness. In common usage facial and bulbar weakness have been included as part of the syndrome. Overlapping forms with AIDP are not uncommon. This syndrome is strongly associated with preceding *C. jejuni* infection and more than 90% of patients have antibodies to the ganglioside GQ1b that are almost certainly pathogenic (see below) (Mizoguchi, 1998; O'Hanlon et al., 2001). Anti-GQ1b antibodies are also found in GBS patients with ophthalmoplegia. The pathophysiological and structural basis of the clinical manifestations in FS are still not completely resolved, although complement has been shown to be important in models of disease (Willison et al., 2008).

Autoimmune Features

Molecular Mimicry

Molecular mimicry has been invoked as a mechanism in a variety of autoimmune diseases. AMAN and FS provide some of the best available evidence to support the hypothesis of molecular mimicry as a pathogenic mechanism

underlying post-infectious autoimmune disorders. AIDP may be very similar and as more evidence of complex ganglioside antigen associations emerges AIDP may be resolved into the same pathogenic category as AMAN and FS. AMAN and FS fulfill some of the Koch–Witebsky postulates supporting autoantibody as pathogenic (Witebsky et al., 1957; Rose and Bona, 1993). Anti-ganglioside antibodies can be demonstrated in patient serum. They have cognate antigens (gangliosides) enriched in peripheral nerve. It is possible to immunize animals (see below) with ganglioside antigens either purified or as whole bacteria to produce autoantibody and disease, albeit with difficulty. Transfer of antibody from patient/model animal to a normal subject can sometimes transfer disease. Furthermore mechanisms of antibody action are now starting to be understood.

Anti-ganglioside Antibodies in GBS Variants

Antibodies to ganglioside species are found in the serum of patients with GBS (both AMAN and AIDP). They are polyclonal, predominantly IgG, and generally complement-fixing IgG1 and IgG3 (Willison and Veitch, 1994; Ogino et al., 1995; Yuki et al., 1995; Ho et al., 1999). This implies class-switching usually with T cell help, both atypical of human anti-carbohydrate responses (see below). Antibodies to single gangliosides GM1, GM1(NeuGc), GM1b, GalNAc-GM1b, GD1a, GalNAc-GD1a, GD1b, 9-*O*-acetyl GD1b, GD3, GT1b, GQ1b, GQ1b α , LM1, galactocerebroside, and SGPG have been reported in more than 200 papers on inflammatory neuropathies (Willison and Yuki, 2002). Clinico-serological correlations between GBS subtypes and serum antibodies to putative ganglioside antigens have been drawn (Ho et al., 1999; Ogawara et al., 2000; Rees et al., 1995a). Antibodies to gangliosides GM1 and GD1a, implicated as the major target antigens in AMAN (Hadden et al., 1998; Ho et al., 1999), can be detected in 50–60% of AMAN patients in the Far East (Ho et al., 1999; Ogawara et al., 2000). Antibodies to GalNAc-GD1a and GM1b are found in motor predominant GBS in about 10–15% of cases (Ang et al., 1999; Yuki et al., 2000). Anti-GQ1b antibodies, frequently cross-reactive with structurally related gangliosides, are present in 80–90% of patients with FS (Willison et al., 1993; Yuki et al., 1993; Carpo et al., 1998). This correlation provides the strongest association between antibodies to a specific ganglioside and a clinical phenotype.

More recently the serendipitous identification of antibodies to complex gangliosides has led to a resurgence of interest in antibodies (Kusunoki's first reference) (Greenshields et al., 2009; Kusunoki and Kaida, 2011). Antibody activity to a ganglioside species can be enhanced or entirely abrogated by the close association of a second species of ganglioside presumably making a complex epitope. Antibodies to ganglioside complexes

FIGURE 53.1 Immunostained teased ventral root fibers from a case of AMAN 4 days after the onset of neurologic symptoms. (A–D) The complement activation product C3d was localized discretely at nodes of Ranvier (black arrows) of large myelinated motor fibers. The golden-brown immunoreaction product is at the nodes. (E–H) Many motor fibers had macrophages overlying, and extending processes into, the nodes of Ranvier (white arrows designate nodes of Ranvier). (E and F were immunostained with the macrophage marker HAM-56; G and H for HLA-DR [major histocompatibility locus class II]). Reprinted with permission of John Wiley & Sons Inc. from figure 1, p. 639 of *Hafer-Macko et al. (1996a)*.

may explain the lack of antibodies found in sera when only single ganglioside activities were sought, the difficulties of consistent identification of clinic-serological phenotypes, and the apparent inconsistency in spatial distribution of single gangliosides and antibody binding.

The serological studies have also identified associations of specific anti-ganglioside or -ganglioside complex antibodies with poor recovery (reviewed in [Lopez et al., 2010](#) and [Sheikh and Zhang, 2010](#)). These association studies imply that specific anti-ganglioside antibodies can

not only injure intact nerve fibers to induce neuropathy, but can also adversely affect recovery by either inducing more severe neuropathic disease or interfering with the nerve repair process required for recovery. Experimental studies with anti-ganglioside antibodies support the latter hypothesis (Lehmann et al., 2007; Lopez et al., 2010).

Gangliosides in Peripheral Nerve

Gangliosides are sialic acid containing glycolipids (see Figure 53.2), widely distributed in mammalian tissues, but enriched in the nervous system. GM1, GD1b, GD1a, and GT1b are most abundant. A simple hypothesis to explain the differences between GBS variants is based on the premise that target gangliosides have differential distribution in the PNS, but this hypothesis is being modified in response to the discovery of complex ganglioside epitopes. In relation to FS, GQ1b is relatively enriched in the oculomotor cranial nerves (Chiba et al., 1993, 1997) although anti-GQ1b antibodies may bind elsewhere (Goodyear et al., 1999). Although ganglioside immunolocalization studies are technically difficult, the AMAN-associated gangliosides GM1 and GD1a are localized at the nodes of Ranvier and in motor nerve terminals (Sheikh et al., 1999; Gong et al., 2002). Furthermore, preferential staining of motor nerve fibers has been demonstrated with monoclonal anti-GD1a antibodies in rats (Figure 53.3) and also with human anti-GD1a antibodies from a patient with AMAN (De Angelis et al., 2001). Distribution of ganglioside complexes *in vivo* will be even more difficult. Other factors such as variations in permeability of the blood–nerve barrier, density and accessibility of target gangliosides, and relationship to functional components of the axolemma such as ion channels, are likely to be relevant.

Functional Effects of Antibodies

Antibodies bind to nerves at nodes of Ranvier where gangliosides (especially GM1) and channels are enriched. Early studies indicated that anti-GM1 antibodies possibly blocked or altered channel function although the exact mechanism was unclear (Sheikh et al., 1999). Intraneural injection of GBS patient serum, purified immunoglobulin, or specific anti-ganglioside antibodies has produced mixed results (Saida et al., 1979; Winer et al., 1988; Sumner et al., 1992). Powerful models developed over the last 10 years have demonstrated clear binding of antibodies and complement to nodal structures, dissolution of the axonal cytoskeletal architecture, and disruption of nodal and paranodal channels (Susuki et al., 2007). The electrical effect of this is to destabilize the membrane resulting in trains of uncontrolled miniature end plate potentials identifiable in models.

An alternative site of attack is at the roots and motor nerve terminals (MNTs) where the blood–nerve barrier is

FIGURE 53.2 Some of the ganglioside species in peripheral nerve, potentially targets for neuropathy-associated antibodies. Note the similarity in structures between species, which allows for some cross-reactivity. Glc = glucose, Gal = galactose, GalNAc = N-acetylgalactosamine, NeuAc = Neuraminic (sialic) acid.

FIGURE 53.3 Unfixed fresh-frozen rat motor-sensory nerve root stained with a monospecific murine IgG anti-GD1a antibody. There is preferential strong staining of the motor axons of the ventral root (below) compared to the sensory axons of the adjacent dorsal root (above). Magnification $\times 320$.

relatively deficient. MNTs degenerate in AMAN (Ho et al., 1997) and are disturbed electrophysiologically in FS (Uncini and Lugaresi, 1999). In an *ex vivo* phrenic nerve–diaphragm preparation, Willison et al. showed that anti-GQ1b antibodies bind to nerve terminals, cause complement-dependent quantal acetylcholine (ACh) release resulting in neuromuscular blockade and a

calcium dependent disruption of the terminal bouton (Goodyear et al., 1999; Plomp et al., 1999; O'Hanlon et al., 2001). They have recently shown the same effect with anti-GD1a antibodies dependent upon GD1a antigen density (Goodfellow et al., 2005).

In a parallel series of patch-clamp experiments, IgG GQ1b, GD1a, GD1b, and GM1 antibodies have been shown to cause reversible complement independent pre- and post-synaptic blockade depending upon the antibody used (Buchwald et al., 2002).

The clinical, pathological, and electrical effects are almost entirely abrogated by the application of an inhibitor of the C5 component of complement (eculizumab) which results in failure of formation of the membrane attack complex (Halstead et al., 2008). This pathophysiological understanding and subsequent proof of concept in an animal model has led to the design of human trials.

Anti-ganglioside antibodies can inhibit neurite growth and growth cone extension in primary neuronal cultures consistent with the notion that these antibodies can adversely affect axon and nerve regeneration (Zhang et al., 2011b). Small GTPase RhoA is part of the downstream inhibitory intracellular signaling that mediates anti-ganglioside antibody-induced inhibition of axon growth (Zhang et al., 2011b). A recent study has shown that pleiotropic cytokine erythropoietin (EPO) with neurotrophic properties reverses the inhibitory effects of anti-ganglioside antibodies via EPO receptors and the Janus kinase 2/Signal transducer and activator of transcription 5 pathway (Zhang et al. 2011a).

Environmental Effects

Campylobacter jejuni is a Gram-negative, non-spore-forming enteropathogen and is one of the most common causes of bacterial gastroenteritis worldwide (Friedman et al., 2000; Oberhelman and Taylor, 2000) (see Figure 53.4). Infection with *C. jejuni* is found in 13–72% of patients with AMAN or GBS (Hughes and Rees, 1997; Hadden and Gregson, 2001) with an overall prevalence estimated around 30% (Moran et al., 2002). Only one in 1000 cases of *C. jejuni* infection is complicated by GBS. The exact characteristics of *C. jejuni* that determine whether GBS follows infection are still unclear. However, a relationship of GBS with a number of Penner serotypes is recognized (Prendergast and Moran, 2000). Penner serotyping distinguishes *C. jejuni* strains on the basis of strain-specific, heat-stable extractable capsular lipopoly- and lipooligosaccharides. Penner strains HS:19 (Rees et al., 1995b; Sheikh et al., 1998) and HS:41 (Goddard et al., 1997) are particular overrepresented in GBS and uncommon in patients with uncomplicated gastroenteritis.

The lipopolysaccharide (LPS) and lipooligosaccharide (LOS) of *C. jejuni* carry ganglioside-like moieties.

FIGURE 53.4 *Campylobacter jejuni*, a Gram-negative flagellated non-spore-forming enteropathogen, is one of the most common causes of bacterial gastroenteritis worldwide and is found in 13–72% of patients with AMAN or GBS.

Several studies have characterized these in GBS- and diarrhea-associated *C. jejuni* strains. GM1-, GD1a-, GalNAc-GD1a-, GM1b-, GT1a-, GD2-, GD3-, and GM2-like structures have all been identified (Aspinall et al., 1993; Yuki et al., 1994; Nachamkin et al., 2002). Although no GQ1b-like structure exists, antibody binding assays have shown the presence of GQ1b- and GT1a-cross-reactive moieties in *C. jejuni* LPS/LOSs (Yuki et al., 1994; Jacobs et al., 1995, 1997). It is these structures that are likely to provide the initial stimulus to auto-immune activation.

Upper respiratory tract infection or other febrile episodes caused by cytomegalovirus (CMV) (5–22%), Epstein–Barr virus (EBV) (2–10%), *Mycoplasma pneumoniae* (5%), and *Haemophilus influenzae* have all been identified as potentially causative (Hadden and Gregson, 2001). *H. influenzae* carries ganglioside-like moieties. Swine flu and rabies vaccinations have also been causatively implicated, but recent surveillance for an association with swine flu vaccination failed to demonstrate any conclusive link (Crawford et al., 2012).

Animal Models of Disease

Attempts to generate either IgG anti-ganglioside antibodies or neuropathy in animals by immunization with *C. jejuni* were for a long while either unforthcoming or not reproducible. Immunization of mice with *C. jejuni* LPSs/LOSs generates mainly low titer IgM antibodies (Wirguin et al., 1997; Goodyear et al., 1999) reflecting a high level of tolerance to self-gangliosides (Bowes et al., 2002). Tolerance to self-gangliosides can be overcome by immunization with gangliosides or *C. jejuni* LPSs conjugated to adjuvant in transgenic animals lacking complex gangliosides (Lunn et al., 2000) (see Figure 53.5). This model illustrates that where tolerance is circumvented, potentially pathogenic antibodies can be generated.

A sensory ataxic neuropathy with pathological changes in the nerve and the cord has been induced in rabbits by GD1b immunization and passive antibody transfer (Kusunoki et al., 1999). Immunization with mixed bovine brain gangliosides or GM1 alone produced an acute flaccid paralysis in rabbits reminiscent of human disease (Susuki et al., 2003). The implantation of a murine IgG antiGD1a secreting hybridoma into mice but not passive transfer of the same antibody led to an axonal neuropathy (Sheikh et al., 2004). Additional cytokine factors may be required to initiate the neuropathy.

The combined research in GBS models has clearly demonstrated that antibodies bind to ganglioside targets on the nerve, fix complement, destroy the nodal and cytoskeletal architecture through complement and calcium-dependent mechanisms, and result in electrophysiological instability and axonal dissolution (Willison et al., 2008).

A passive transfer animal model has been established to examine the effects of anti-ganglioside antibodies on peripheral nerve repair/axon regeneration (Lehmann et al., 2007). These passive transfer studies show that patient and experimental antibodies inhibit axon regeneration in a nerve crush model mimicking the regenerative response of degenerating/injured axons in GBS (Lehmann et al., 2007; Lopez et al., 2010). The impaired regenerative responses and ultrastructure of injured peripheral axons mimicked dystrophic and stalled growth cones typically seen after CNS injury. Such dystrophic/stalled growth cones can also be seen in nerve biopsy of GBS patients with poor recovery (Sheikh and Zhang, 2010). These observations support the notion that inhibition of axon regeneration is one mechanism of poor recovery in GBS patients with anti-ganglioside antibodies. Further, this antibody-induced nerve injury model was used to show beneficial proregenerative effects of EPO (Zhang et al., 2011a).

FIGURE 53.5 Mice lacking complex ganglioside species (*GalNAcT^{-/-}*) are able to class switch to complement fixing IgG production when immunized with keyhole limpet hemocyanin (KLH)-conjugated ganglioside. Figure shows serological responses of *GalNAcT^{-/-}* and wild-type mice immunized with GD1a-KLH or KLH alone. Sera collected at the indicated times were tested for IgG and IgM anti-GD1a antibody titers by ELISA. Open symbols, individual *GalNAcT^{-/-}* mice immunized with GD1a-KLH; filled symbols, individual wild-type mice immunized with GD1a-KLH; X, *GalNAcT^{-/-}* mouse immunized with unconjugated KLH. Titer values are presented as the greatest dilution resulting in a signal which exceeded 3 SD above the control mean. i.p., intraperitoneal; i.v. intravenous. Cellular Mechanisms

Comprehensive evidence of T cell involvement in GBS has not been so forthcoming despite the central role of T cells in the pathogenesis of experimental allergic neuritis (EAN). Studies of animal models and predominantly human AIDP have generated a complex multi-step pathogenesis for cellular involvement in the autoimmune neuropathies (see Figure 53.6).

Multifocal lymphocytic infiltration was established as the hallmark of the pathology of GBS in early post-mortem studies (Asbury et al., 1969) but it is not always seen (Cornblath et al., 1990; Honavar et al., 1991). Circulating activated T cells are found early in the course of GBS (Taylor and

FIGURE 53.6 Schematic illustration of the immune responses in the inflamed peripheral nervous system. Basic principles of the cellular immune responses: autoreactive T cells (T) recognize a specific autoantigen presented by major histocompatibility complex (MHC) class II molecules and the simultaneous delivery of costimulatory signals on the cell surface of antigen-presenting cells, such as macrophages (MΦ), in the systemic immune compartment. Activated T lymphocytes can cross the blood–nerve barrier (BNB) in order to enter the peripheral nervous system (PNS). Within the PNS, T cells activate macrophages that enhance phagocytic activity, production of cytokines, and the release of toxic mediators, such as nitric oxide (NO), matrix metalloproteinases (MMPs), and proinflammatory cytokines, propagating demyelination and axonal loss. The termination of the inflammatory response is mediated, in part, by macrophages by the induction of T cell apoptosis and the release of anti-inflammatory Th2/Th3 cytokines, such as interleukin-10 (IL-10) and transforming growth factor- β (TGF- β). Reprinted with permission from John Wiley & Sons Inc. from figure 1, p. 136 of Kieseier et al. (2004). Copyright © John Wiley & Sons Inc. 2004.

Hughes, 1989; Hartung and Toyka, 1990). $\alpha\beta$ T cells with CD4 and CD8 ratios in similar proportions to peripheral blood (Cornblath et al., 1990) are the predominant cells found in nerve. Restricted usage of V β genes, especially V β 15, suggests activation by a common antigen or superantigen (Khalili-Shirazi et al., 1997). Furthermore, $\gamma\delta$ T cells have also been found in, and isolated from, GBS-affected nerves (Khalili-Shirazi et al., 1998; Winer et al., 2002). $\gamma\delta$ T cells are capable of recognizing non-protein antigen and are thus candidates for responding to putative carbohydrate and ganglioside antigens (see above) (Bukowski et al., 1998). They proliferate *in vitro* in response to *C. jejuni* sonicates but require either $\alpha\beta$ T cells or IL-2/IL-15 to do so. Predominant use of V γ 8 δ 1 suggests activation of epithelially (possibly gut) resident $\gamma\delta$ T cells (Cooper et al., 2000). $\alpha\beta$ and $\gamma\delta$ T cells also probably provide the necessary help to

orchestrate class-switching of anti-ganglioside antibodies to IgG1 and IgG3.

Autoantigen in the systemic compartment is processed and presented by antigen-presenting cells. EAN can be initiated with neuritogenic epitopes of peripheral nerve proteins P0, P2, and PMP22 (Hughes et al., 1999) or by adoptive transfer of sensitized T cells. Disease severity depends upon the cell or antigen dosage (Hartung et al., 1996). Disease is dependent on the presence of T cells, their normal function (Holmdahl et al., 1985; Hartung et al., 1987; Jung et al., 1992), and normal function of the costimulatory partners B7.1/CD80 or B7.2/CD86 and CTLA4/CD28 (Kiefer et al., 2000; Zhu et al., 2001; Zehntner et al., 2003).

Lymphocyte activation is revealed by greater numbers of circulating T cells bearing activation markers and

increased concentrations of Th1 cytokines such as IFN- γ , IL-2, IL-2 receptor, and TNF- α (Taylor and Hughes, 1989; Hartung et al., 1991; Exley et al., 1994; Creange et al., 1996). Levels of TGF- β 1 are depressed (Creange et al., 1998). In EAN levels of IFN- γ , IL-1 β , IL-6, TNF- α , TNF- β , and IL-12 are raised during development of disease (Zhu et al., 1997).

Homing and migration of activated T cells to the peripheral nerve is modulated by E-selectin and mucins binding L-selectin and sialyl Lewis antigens (Hartung et al., 2002) and then VCAM-1 and ICAM-1, both upregulated early in GBS and EAN progression (Enders et al., 1998; Creange et al., 2001). Blockade of VCAM-1 or its ligand VLA-4/ α 4 β 1 integrin ameliorates EAN (Enders et al., 1998). Selectin and integrin released into the circulation may downregulate inflammation (Hartung et al., 1988). Chemokines assist in leukocyte recruitment localization and trafficking (Baggiolini, 1998; Campbell et al., 1998). The chemokine receptors CCR1, CCR2, CCR4, CCR5, and CXCR3 have been characterized in AIDP-affected nerves, differentially upregulated in infiltrating cell populations (Kieseier et al., 2002).

Diapedesis through the vascular endothelium and the basal lamina is facilitated by matrix metalloproteinases (MMPs). MMP-2, MMP-3, MMP-7, and especially MMP-9 have been implicated in the pathogenesis of EAN and GBS (Kieseier et al., 1998; Creange et al., 1999) and correlate with GBS severity.

Macrophages, both resident and recruited from the circulation (Hartung et al., 2002), remain the key component in perpetuating endoneurial inflammatory damage through the release of specific immune mediators. Under inflammatory conditions they continue to express antigen and induce Schwann cells to do so also (Gold et al., 1995). Depletion of macrophages abrogates the development of EAN, indicating their central role in the final common pathway of nerve damage. Activated macrophages target normal looking nerves and Schwann cells in EAN and AIDP (Hartung et al., 1996; Hughes et al., 1999) probably by antibody-targeted cellular cytotoxicity and complement-dependent mechanisms (Hafer-Macko et al., 1996a,b). Macrophage processes insinuate themselves between myelin lamellae and strip the myelin in AIDP (Hughes et al., 1999) or directly attack the axon in AMAN (see Figure 53.1) (Hafer-Macko et al., 1996a). In the endoneurium macrophages secrete a host of inflammatory mediators including MMPs, TNF- α , nitric oxide, eicosanoids, neutral proteases, lipases, and phospholipases, all contributing to nerve damage (Gregson and Hall, 1973; Redford et al., 1997; Smith et al., 1999).

Macrophages may also influence recovery from GBS. They direct T cell apoptosis reducing the ongoing response. During recovery, the T cell response shifts towards Th2 with rises in IL-4 in patients (Dahle et al., 1997) and

upregulation of TGF- β 1, IL-10, and cytolysin in models of disease (Kiefer et al., 1996). TGF- β 1 favors recovery (Vriesendorp et al., 1996; Zhu et al., 1997) and levels are correlated to severity of GBS (Creange et al., 1998).

A recent study (Mausberg et al., 2011) showed that EPO reduced disease severity and also shortened the recovery phase of EAN. The clinical improvement in this model correlated with decreased T cell inflammation within the peripheral nerve and produced less nerve fiber injury. In contrast, EPO increased the number of macrophages in the recovery phase of EAN. The beneficial effects of macrophages and the modulation of the immune system towards anti-inflammatory responses in the PNS was associated with upregulation of anti-inflammatory cytokine transforming growth factor (TGF)-beta.

Cellular and Humoral Immune Elements are Synergistic

Understanding of the pathomechanisms of the acute inflammatory neuropathies is incomplete. Neither antibodies nor T cells generate disease in isolation and immunization with any antigen induces responses in both cellular and humoral arms of the immune system. The apparent absence of T cells in some biopsies, and hence their possible non-necessity, is discussed above. Arguments against the early and significant involvement of antibodies include the absence of detectable anti-ganglioside antibodies, using current methodology, in a significant proportion of GBS (usually AIDP) cases, and the onset of adoptive transfer-EAN (AT-EAN) 4 days after transfer, before antibodies could be synthesized. However, recent advances have reduced the strength of these arguments. First, disease severity in AT-EAN is usually enhanced by co-transferring antibodies recognizing myelin or oligodendrocytes/Schwann cell epitopes (Spies et al., 1995), although this was not confirmed when pre-treatment AIDP GBS sera were co-administered to rats with mild EAN (Hadden et al., 2001). Gangliosides are not necessarily targeted by antibodies as single entities explaining why many sera were apparently negative for anti-ganglioside antibodies. Combinatorial epitopes made from adjacent but differing molecules that enhance or reduce antibody affinity *in vitro* and probably *in vivo* are recognized as targets (Kusunoki and Kaida, 2011).

Genetic Aspects of GBS

The role of host genetics in susceptibility to GBS is still in its infancy. No strong correlations have been established between disease susceptibility or GBS subtypes and host MHC class I or class II haplotypes in several studies (Magira et al., 2003; Geleijns et al., 2005a). The study of single nucleotide polymorphisms in genes for

various components of the immune response has not identified any significant contributors (Geleijns et al., 2005a, b). One Dutch study identified that GBS patients homozygous for the Fc γ receptor IIa-H131 had a higher chance of developing severe disease than patients with other genotypes (van der Pol et al., 2000). Polymorphisms in CD1 molecules which present ganglioside to T cells were associated with GBS in two studies but the largest study to date failed to confirm this (Kuijff et al., 2008). Meta-analysis focusing on TNF- α , CD1, and Fc γ R suggests that the TNF- α 308A allele may be a moderate risk factor for GBS (Wu et al., 2012), but this awaits confirmation in directed larger studies.

Treatment and Outcomes

The effectiveness of other immunotherapies for GBS is supported by good evidence (Hughes et al., 2003). Two to five sessions of plasma exchange (PEX) hastens recovery in non-ambulant patients preferably started within 2 weeks of disease onset (Raphael et al., 2012). Intravenous immunoglobulin (ivIg) is as effective as PEX and is still probably the intervention of choice (Hughes et al., 2012). The concern about possible contamination of ivIg with prions means that written informed consent is essential before administration although advances in ivIg purification technology and prion detection may reduce this concern. The drive to search for new, more effective, and safer therapies is stronger than ever.

A large randomized controlled trial, previous smaller trials, and a Cochrane meta-analysis (Hughes and van Doorn, 2012) have shown steroids to be at best ineffective, and in some cases harmful. There is no indication for their use in GBS.

Complement inhibitors such as eculizumab are effective in other complement-mediated conditions such as paroxysmal nocturnal hemoglobinuria, and possibly effective in multifocal motor neuropathy, and clinical trials in the treatment of GBS are planned. Immunoadsorption of pathogenic anti-ganglioside antibodies has been infrequently used (Willison et al., 2004). Preclinical studies in antibody and T cell-induced models of GBS suggest that EPO neuroprotection is a viable candidate drug to develop further for neuroprotection and enhancing nerve repair in patients with GBS (Zhang et al., 2011a).

CHRONIC NEUROPATHIES: CHRONIC INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is an acquired peripheral nervous system disease characterized by progressive or relapsing

proximal and distal weakness with or without sensory loss. There is good evidence to indicate that CIDP is autoimmune.

History

Osler recognized a chronic relapsing or progressive form of “multiple neuritis” in 1892. Austin described a slowly progressive or recurrent “steroid responsive polyneuropathy” (Austin, 1958) with histology indistinguishable from that seen in GBS. The term chronic inflammatory demyelinating polyradiculoneuropathy was coined in 1975 (Dyck et al., 1975).

Epidemiology and Clinical Features

The prevalence of CIDP is 1.25–7 per 100,000 (Lunn et al., 1998; Mygland and Monstad, 2001). Symmetrical sensory and motor deficits both proximal and distal reach their nadir over more than 8 weeks. The clinical course is commonly chronic and progressive particularly in untreated patients but some patients have a relapsing–remitting pattern of disease. Some case series have shown that up to 15% of patients with CIDP can start acutely with GBS-like onset (Dionne et al., 2010). Cranial nerve and the diaphragm are infrequently involved. CSF examination demonstrates albuminocytological dissociation with raised protein in more than 90% of cases (Bouchard et al., 1999) and the cell count is $<10 \text{ mm}^3$ unless complicated by human immunodeficiency virus (HIV). Electrophysiology typically demonstrates multifocal motor conduction slowing, temporal dispersion, and block with delayed or absent F-waves. Half of patients require treatment at any one time and 13% require long-term aid to walk (Lunn et al., 1999). In a single study, six of 21 patients were shown to have serum antibodies to the peripheral myelin protein P0 (Yan et al., 2001) but this remains unconfirmed. Morphological examination demonstrates macrophage-associated demyelination in nerve roots, plexuses, and nerve trunks with T cells in the endoneurium. The edema, Schwann cell proliferation, and inflammatory infiltrates testify to the ongoing inflammation. Axonal degeneration occurs in severe or late cases or in distal sensory nerve biopsies (Hadden and Hughes, 2003).

As with GBS, CIDP is heterogeneous and a number of subtypes or related conditions have emerged.

Multifocal Motor Neuropathy with Conduction Block

Multifocal motor neuropathy with conduction block (MMNCB) (Pestronk et al., 1988) is a rare but treatable condition sometimes misdiagnosed as motor neurone

disease. Wasting and weakness begin asymmetrically in the distribution of a motor nerve usually more distal than proximal, most commonly in the upper limb. Fasciculations and cramps occur. Males account for 70% of cases. Sensory symptoms are reported in 20% of patients. Depending upon assay methods, between 30 and 80% of patients have anti-GM1 antibodies in the serum (Sander and Latov, 2003), some as a paraprotein. Rarely anti-GD1a antibodies are described (Carpo et al., 1996). Electrophysiological studies demonstrate multifocal conduction blocks in two or more nerves with normal sensory conduction. Many studies demonstrate evidence of more widespread slowing or axonal degeneration.

The etiology of MMNCB remains unresolved, as it is seldom fatal and neuropathological material is seldom sought. Perivascular CIDP-like inflammation has been described in a motor nerve biopsy (Kaji et al., 1993), and there are minimal findings in sensory nerves (Corse et al., 1996). Inflammatory cellular infiltration and immunoglobulin deposition were described in the motor roots of an autopsy case (Oh et al., 1995). The therapeutic response to immunomodulation supports an autoimmune pathogenesis (Umaphathi et al., 2005).

Multifocal-acquired Demyelinating Sensory and Motor Neuropathy (MADSAM)

Lewis and Sumner described the entity now referred to as MADSAM in 1982 (Lewis et al., 1982). Electrophysiological examination demonstrates multifocal sensory and motor involvement with conduction block.

Multifocal-acquired Sensory and Motor Neuropathy (MASAM)

This group of patients has only been recently described (Alaadini et al., 2003). Anti-ganglioside antibodies are found in the serum of 48% and there is a beneficial response to immunomodulation. The nerve conduction studies do not suggest demyelination and are more consistent with axonal degeneration. These findings require confirmation.

Paraproteinemic Demyelinating Peripheral Neuropathy

Ten percent of patients with a peripheral neuropathy will have a paraprotein in the serum. Although this should initiate a search for a malignant source, such as multiple or solitary myeloma, most are monoclonal gammopathies of undetermined significance (MGUS). A number of MGUS-neuropathy syndromes are described.

The commonest is a progressive sensory ataxic neuropathy with unsteadiness and tremor associated with an IgM κ paraprotein that reacts with the HNK-1 epitope of the peripheral nerve antigen myelin-associated

glycoprotein (MAG). Up to 80% of patients with an IgM paraprotein and a demyelinating neuropathy have anti-MAG antibodies. Nerve conduction studies reveal motor conduction slowing, particularly distally (Cocito et al., 2001). Electron microscopic examination of myelin in sural nerve biopsies reveals characteristic widening of the intraperiod line not seen in other conditions (see Figure 53.7).

Neuropathies associated with IgG or IgA paraproteins are found in a diverse group of patients with axonal and demyelinating forms of disease. No consistent pathogenesis has yet emerged. The demyelinating cases have a similar therapeutic response to CIDP (Allen et al., 2007).

Chronic ataxic neuropathy with ophthalmoplegia, M-protein, and anti-disialosyl antibodies (CANOMAD) is a rare paraproteinemic syndrome rather like a chronic Fisher syndrome. Its pathogenesis is not yet resolved.

The POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes) is a rare condition associated with both osteosclerotic myeloma and Castleman's disease. The paraprotein required to make the diagnosis does not seem to participate in the pathogenesis as it is often still found after successful treatment. Furthermore, cytokines (especially IL-6 and IL-1 β) and vascular growth endothelial factor (VEGF) are implicated in causation (Laguery et al., 2004; Dispenzieri, 2012).

FIGURE 53.7 Widely spaced myelin. The normal myelin lamellae are tightly compacted and have a periodicity in electron microscope preparations of 12–15 nm. In the demyelinating neuropathy associated with IgM paraprotein that has activity against MAG (anti-MAG PDPN) the intraperiod line becomes split giving an overall periodicity of 30–40 nm. Note the suggestion of material within the widened spaces, possibly immunoglobulin M. Electron micrograph $\times 100,000$.

Autoimmune Features

Many of the features of autoimmunity displayed in the acute neuropathies are also seen in CIDP. Cellular and humoral responses are both important to the pathogenesis. Raised circulating levels of IL-2 and TNF- α correlate with disease activity (Misawa et al., 2001). A TH-17 response is active with raised levels of IL-17 detectable (Chi et al., 2010), and reduced levels of CD25/CD4 and FoxP3 cells indicate reduced Treg capacity (Chi et al., 2008). T lymphocyte migration into the endoneurium is facilitated by increased levels of chemokines, cell adhesion molecules, and MMPs (Previtali et al., 2001; Kieseier et al., 2004). Expression of the blood–nerve barrier constituents claudin-5 and ZO-1 is altered in CIDP perhaps contributing to increased BNB permeability (Kanda et al., 2004). Within the endoneurium T cells secrete IFN- γ , IL-2, and TNF- α (Mathey et al., 1999) and probably others, contributing to inflammatory upregulation of effectors such as macrophages, continued recruitment, and direct nerve damage. Expression of downregulatory cytokines IL-4, IL-10, and TGF- β is also found, and in CIDP expression of NGF, GDNF, LIF, and their receptors may contribute to nerve regeneration (Yamamoto et al., 2002). Clear evidence of Fas deficiency gives support to an inability to halt the ongoing response as effectively as in a monophasic disease (Comi et al., 2009).

Macrophage and Schwann cells in the endoneurium express the costimulatory molecules CD80 (B7-1) and CD86 (B7-2) and their cognate partners CTLA-4 and CD28 are found on endoneurial T cells (Hu et al., 2007).

Antibodies to the glycopeptides P0 and P2, and glycolipids and gangliosides LM1 and GD1b, and LM1 ganglioside complexes, have been described but remain unconfirmed, or difficult to confirm, in other studies (Yan et al., 2001; Sanvito et al., 2009; Nobile-Orazio et al., 2010). The involvement of antibodies in CIDP pathogenesis remains an open question.

Unlike GBS or CIDP, in the anti-MAG paraproteinemic demyelinating peripheral neuropathy (anti-MAG PDPN) there is evidence of only antibody-mediated immunity. There is no evidence of macrophage-associated demyelination, T cell infiltration into the endoneurium or upregulation of T cell costimulatory molecules. There is quite strong evidence that anti-MAG antibodies may fulfill the Koch–Witebsky postulates. Anti-MAG antibodies can be found in the serum of patients with characteristic clinical presentation. Myelin-associated glycoprotein is expressed at the Schmidt–Lantermann incisures, the paranodes, and on the periaxonal myelin (Gabriel et al., 1998). It displays the HNK-1 carbohydrate epitope shared by several other peripheral nerve antigens. Histological studies demonstrate IgM anti-MAG deposits on Schwann cells that co-

localize with MAG (Takatsu et al., 1985). Electron-dense material seen between widened lamellae is consistent with anti-MAG IgM insinuated between the layers (Mendell et al., 1985) (see Figure 53.7). Activated complement components have been described by some researchers (Monaco et al., 1990). The disruption of MAG functions and complement-mediated damage may result in alterations in the axonal neurofilament cytoskeleton (Lunn et al., 2002) and these in turn may lead to slowing of nerve conduction and axonal degeneration.

Immunogenetic Features

Restricted usage of T cell receptor (TCR) genes has been demonstrated in CIDP. The predominant TCR in CIDP is $\alpha\beta$ but $\gamma\delta$ T cells are found in the majority of nerve biopsy specimens (Winer et al., 2002), again implying a possible non-protein immune response. No clonality has been demonstrated in isolated T cells. However, significant numbers of highly Th1 inflammatory natural killer T cells identified by expression of V α 24J α Q invariant TCR chain are found (Illes et al., 2000).

A number of putative immunogenetic modifiers have been proposed. Polymorphisms in TAG-1 are not associated with treatment response or outcome (Pang et al., 2012) and no association has been found with CD1 in small studies (Uncini et al., 2011). Recently, studies to suggest that homozygous genotype for a low number of GA repeats in SH2D2A (Uncini et al., 2011) and defective AIRE-mediated central tolerance to P0 (Su et al., 2012a) may be implicated in disease, have been presented.

Environmental Influences

A preceding illness, infection, or vaccination has been identified in patients with CIDP in 32% in the 6 months and 16% in the 6 weeks preceding their illness. Others have found no convincing evidence of vaccination being a trigger (Pritchard et al., 2002). No specific provoking environmental events have so far been recognized for CIDP or the paraproteinemic peripheral neuropathies.

Animal Models

The pathogenesis of CIDP is not completely defined. Widely accepted animal models that recapitulate all the clinical aspects of CIDP are not available. However, recently developed spontaneous autoimmune polyneuropathy (SAP) models have provided useful insights into pathogenic mechanisms involved in inflammatory demyelinating nerve injury relevant to CIDP. SAP can be seen in transgenic mice expressing the major histocompatibility complex (MHC) class II IA^b molecule. This MHC

presents a single peptide, E α 52–68, in mice overexpressing interleukin (IL)-10 under the control of human *VMD2* promoter, and in non-obese diabetic (NOD) mice alongside modulations of the costimulatory molecule B7-2 (CD86) and the autoimmune regulator Aire. The subsequent pathogenic mechanisms in NOD mice are fairly well characterized. Elimination of B7-2 in NOD mice induces protection against diabetes mellitus in these animals but triggers the onset of a CIDP-like illness at 6–7 months of age that is almost 100% penetrant in female mice (Salomon et al., 2001; Ubogu et al., 2012). These mice develop a chronic progressive neuropathic disorder that has overlapping clinical, electrodiagnostic, and morphological features with CIDP (Ubogu et al., 2012). B7-2 knockout NOD mice point to the pathogenic role of costimulatory pathways such as B7-1/B7-2:CD28/CTLA-4 molecules in the development of SAP due to disruption of balance between pathogenic and regulatory T cells (Tregs) maintained by this pathway. Nerve injury in these animals is mediated by Th1 cells that are reactive against myelin P0, the most prominent PNS myelin protein (Bour-Jordan et al., 2005; Louvet et al., 2009). Sera from these animals also contain antibodies to P0, which may contribute to peripheral nerve injury (Kim et al., 2008; Su et al., 2012a).

The importance of the immunogenetic repertoire in the development of SAP is suggested by the absence of neuropathic disorder in B7-2 knockout mice on C57BL/6 or 129/Sv nonautoimmune mouse background (Salomon et al., 2001). How the immunogenetic repertoire contributes to the development of immune neuropathies was exemplified by the development of SAP in transgenic NOD mice with hypomorphic Aire gene function (NOD.Aire^{GW/+} mice) (Su et al., 2012a). Aire is critical to central tolerance. Aire functions by upregulating the ectopic expression of a variety of tissue-specific self-Ags in medullary thymic epithelial cells (mTECs) (Anderson et al., 2002) and increasing the probability of negative selection of antigen-specific high affinity (developing) thymocytes (Anderson et al., 2005). Interestingly, NOD.Aire^{GW/+} mice have increased immune cell and autoantibody reactivity toward P0 in the peripheral immune compartment (Su et al., 2012a). These observations support P0 being an Aire-regulated Ag in mTECs and that decreased P0 expression in mTECs is linked to the development of antigen-specific autoimmunity. Further, CD4⁺ T cells from NOD.Aire^{GW/+} mice are sufficient to transfer neuropathy and Th1 effector cells are dominant in the peripheral nerves in this model (Su et al., 2012a). The clinical relevance of these experimental findings was supported by the following observation. The patients with autoimmune polyendocrinopathy syndrome type 1 (APS1) have genetic mutations in Aire and develop multi-organ autoimmunity. Recently, a CIDP-like neuropathy was

recognized as a potential novel component of APS1 in two unrelated children in whom there were confirmed Aire mutations (Valenzise et al., 2009). These patients have evidence of defective tolerance to P0 and harbor anti-P0 antibodies in their sera (Su et al., 2012a). Overall, these studies show defective tolerance to P0 and antigen-specific dysregulated cellular and humoral immune responses in both Aire-deficient mice and APS-1 patients with CIDP-like neuropathy.

The relevance of myelin P0 as a potential antigenic target in CIDP remains contentious; however, Yan et al. demonstrated that 6/21 sera (28%) from patients with CIDP responsive to plasma exchange contained IgG anti-P0 antibodies. Four of these sera containing IgG anti-P0 antibodies produced conduction block and demyelination by passive transfer when the blood–nerve barrier was breached, either by direct injection or by preceding passive T cell transfer (Yan et al., 2000).

In anti-MAG PDPN passive transfer of antibodies results in complement-mediated demyelination in cats and rabbits (Hays et al., 1987; Willison et al., 1988) although the pathological features were not similar to those seen in human disease. Widened myelin lamellae, almost pathognomonic of the condition, were demonstrated after passive transfer to chicks (Tatum, 1993). Induction of high titer IgM antibodies cross-reactive with human MAG by immunization with the peripheral nerve glycolipid sulfated glucuronyl paragloboside (SGPG) has been achieved in rats, rabbits, and cats. However, no convincing neuropathy as a result has been demonstrated.

Pathogenic Mechanisms

The final common path of macrophage-mediated demyelination in CIDP is thought to be similar to that seen in GBS (see above).

Treatment and Outcome

Steroids, ivIg, plasma exchange, and immunosuppressive drugs have all been used in the treatment of CIDP. Plasma exchange and ivIg are both very potent (Eftimov et al., 2009; Mehndiratta and Hughes, 2012). There was no statistically significant difference between steroids and ivIg in an early comparative trial (Hughes et al., 2001), and even though steroid is cheaper in the short term, ivIg was the treatment of choice. More recent evidence suggests that steroids may have a disease modifying effect, driving patients into remission more frequently and effectively than ivIg (Nobile-Orazio et al., 2012). Interferon- β 1a was shown to be ineffective in otherwise treatment-resistant patients (Hadden et al., 1999). Campath-1H (alemtuzemab) and fingolimod, both designed to severely reduce circulating numbers of pathogenic T cells, are currently under trial. There is

inadequate evidence to properly assess anecdotally beneficial drugs such as azathioprine, ciclosporin, and mycophenolate mofetil.

In MMNCB a dramatic therapeutic response is sometimes seen to ivIg demonstrated in controlled trials, and cyclophosphamide may have a place in primary treatment (Umapathi et al., 2012). Many other agents including interferon- β 1a, rituximab, mycophenolate, azathioprine, and ciclosporin have been used with evidence for no effect for mycophenolate and only anecdotal evidence of partial benefit for the others (Umapathi et al., 2012). Plasma exchange has no effect and interestingly steroids often worsen the condition by an unknown mechanism. Predictors of favorable outcome are anti-GM1 antibodies, younger age, presence of conduction block, a normal CK, and less severe disease at outset (Hadden and Hughes, 2003). Despite treatment, conduction blocks are dynamic and weakness probably progresses slowly over time (Taylor et al., 2000).

In anti-MAG PDPN patients only need treatment for their neuropathy if it becomes severe and disabling. Randomized controlled evidence of benefit is available for ivIg in the short term (Lunn and Nobile-Orazio, 2012; Su et al., 2012a). Rituximab (an anti-CD20 monoclonal) was promising in case series but had disappointing benefit in RCTs (Lunn and Nobile-Orazio, 2012).

CONCLUDING REMARKS AND FUTURE PROSPECTS

The last decade has witnessed huge advances in the understanding of the pathogenesis of both acute and chronic inflammatory peripheral neuropathies. GBS and CIDP are heterogeneous clinical conditions in which humoral and cellular mechanisms conspire to cause disabling diseases. Although there are still innumerable advances to be made our greater understanding of pathomechanisms is inspiring trials of novel agents for treatment which will transform treatment in the next decade. Our understanding of disease with the emergence of further exciting discoveries will reduce significantly death and disability from GBS and CIDP.

INTRODUCTION

Over recent years, the recognition and ability to detect antibodies directed against receptors, ion channels, and relevant proteins within both the peripheral and the central nervous system has continued to evolve. Nevertheless, myasthenia gravis, and related autoimmune disorders of the neuromuscular junction, remains the paradigm, serving to highlight those features which help define an antibody-mediated disorder. The history of the discoveries in this archetypal autoimmune disease is summarized in [Table 54.1](#).

The Neuromuscular Junction

The neuromuscular junction (NMJ) consists of the presynaptic motor nerve terminal and the postsynaptic motor “end-plate.” At the NMJ, the distal motor axon loses its myelin sheath and expands to form the boutons of the presynaptic

nerve terminal. These contain mitochondria and the synaptic vesicles that store the acetylcholine (ACh). The vesicles are organized within specialized active zones, alongside voltage-gated calcium channels (VGCCs). In addition, voltage-gated potassium channels (VGKCs) are also present on the presynaptic nerve terminal ([Figure 54.1](#)).

The postsynaptic membrane is deeply infolded to create junctional folds. The crests of these, lying in close alignment to the presynaptic active zones, contain the highest density of acetylcholine receptors (AChRs). At the depths of the folds, there are relatively few AChRs, but an abundance of voltage-gated sodium channels (VGSCs). The clustering of the AChRs is critical for efficient neurotransmission. The development of the NMJ is dependent on a number of key proteins: agrin, rapsyn, muscle-specific kinase (MuSK), low density lipoprotein receptor-related protein 4 (Lrp4), and docking protein 7 (Dok-7) ([Singhal and Martin, 2011](#)) (see [Figure 54.1](#)).

TABLE 54.1 A History of Myasthenia Gravis Research

| Date | Key Observation | Reference |
|--------------|---|---------------------------------------|
| 1672 | Thomas Willis publishes what is arguably the first clinical description of MG | Willis (1672)* |
| 1895 | Jolly shows that the defect is at the neuromuscular junction | Jolly (1895)* |
| 1913 1939 | Thymectomy appears to produce clinical improvement in patients with thymoma or non-thymomatous MG | Sauerbruch (1913)* Blalock (1939)* |
| 1934 | Mary Walker demonstrates the effectiveness of cholinesterase inhibitors as treatment | Walker (1934) |
| 1960 | Simpson proposes that MG is caused by antibodies to an “endplate” protein | Simpson (1960) |
| 1962 | The snake toxin α -bungarotoxin can be used as a label for acetylcholine receptors at the neuromuscular junction | Chang and Lee (1963) |
| 1964 | Elmqvist and colleagues show that the miniature endplate potentials are reduced in MG | Elmqvist et al. (1964) |
| 1971 | Several groups begin to purify AChRs from electric organs of electric rays using affinity chromatography on neurotoxin columns | |
| 1973 | Immunization against purified electric ray AChR leads to an experimental autoimmune MG (EAMG) in rabbits | Patrick and Lindstrom (1973) |
| 1973 | Acetylcholine receptors are reduced in number at neuromuscular junctions, as determined by ^{125}I - α -bungarotoxin binding | Fambrough et al. (1973) |
| 1975 | MG can be passively transferred to mice by injection of patients' IgG | Toyka et al. (1975) |
| 1976 | MG patients have acetylcholine receptor antibodies as shown by radioimmunoprecipitation of ^{125}I - α -bungarotoxin-tagged AChRs | Lindstrom et al. (1976) |
| 1976–1978 | Plasma exchange produces striking clinical improvement in MG, which correlates inversely with AChR antibody levels | Newsom-Davis et al. (1978) |
| 1977 | IgG and complement are present at the neuromuscular junctions in MG patients and in mice with EAMG | Engel et al. (1977) |
| 1980 | MG can present with different HLA, thymic pathology, age at onset, and muscle antibodies | Compston et al. (1980) |
| 1981 | The MG thymus contains plasma cells making AChR antibody | Scadding et al. (1981) |
| 1977–present | Experimental autoimmune model used to determine pathogenic and immunological mechanisms | |
| 1984–present | Study of T cells from MG patients and their responses to AChR epitopes | |

*refer to Vincent, 2002 for further information.

The synaptic cleft between the pre- and postsynaptic membranes contains the basal lamina composed of collagen IV, heparan sulfate, and laminin. The enzyme acetylcholinesterase is anchored to the basal lamina through its collagen-like tail (ColQ).

AChR, MuSK, and Lrp4

The nicotinic AChR remains the major antigenic target in MG, followed by MuSK. Lrp4 is an antigen in rare cases of MG. The AChR is a pentameric ligand-gated ion channel that exists in adult and fetal isoforms. The adult form consists of two α -subunits and one each of the β -, δ -, and ϵ -subunits, with each subunit composed of a large extracellular domain, glycosylation sites, and four transmembrane

domains. In the fetal form, or after denervation, the ϵ -subunit is replaced by a γ -subunit. The AChR subunits are organized around a central ion channel (Figure 54.1). The two ACh binding sites are between the α - and ϵ - or γ -subunits, and the α - and δ -subunits. Both sites need to be occupied for the ion channel to be in the open state. The main immunogenic region (MIR) is a conformation-dependent region on the extracellular component of each of the α -subunits (Lindstrom, 2000).

MuSK is a receptor tyrosine kinase. The extracellular portion consists of four immunoglobulin-like domains and a cysteine-rich domain. The intracellular portion consists of a juxtamembrane domain, followed by a tyrosine kinase catalytic domain. MuSK is critical both for the development (DeChiara et al., 1996) and ongoing maintenance (Kong

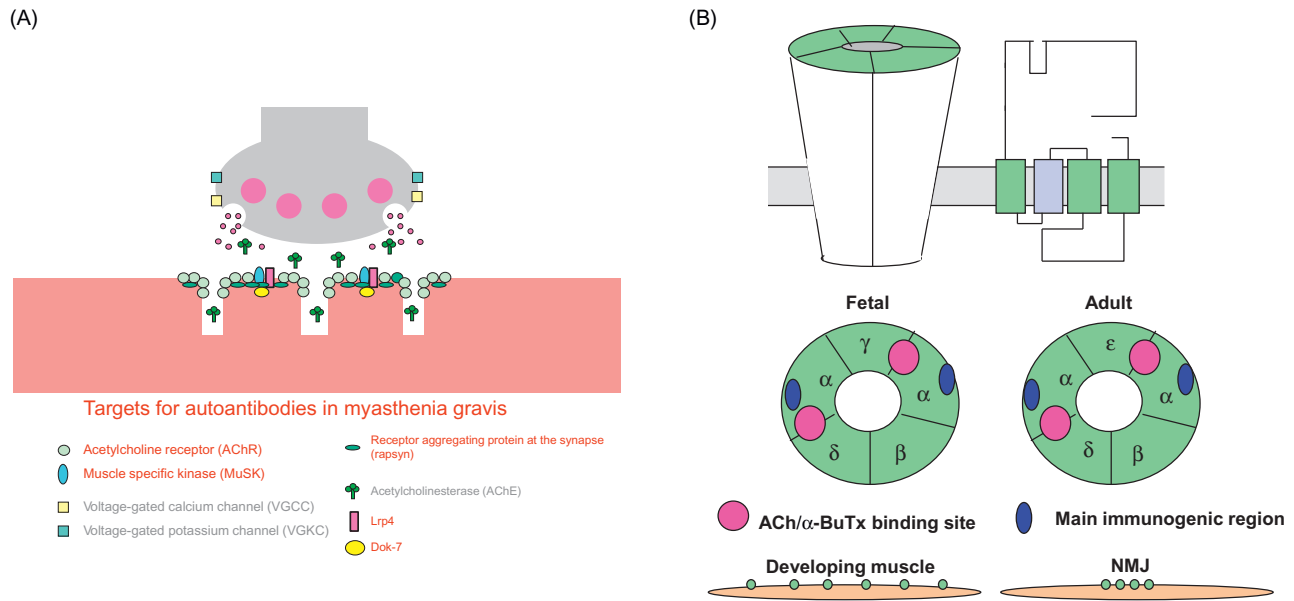

FIGURE 54.1 Ion channel targets for autoantibodies at the neuromuscular junction. (A) Neuromuscular transmission depends on the calcium-dependent release of vesicles of acetylcholine, ACh. ACh binds to the AChRs on the postsynaptic membrane resulting in a depolarization which, if it reaches a critical threshold, initiates an action potential in the muscle leading to contraction. ACh is immediately destroyed by acetylcholinesterase. AChRs, VGCCs, and VGKCs are all targets for antibody-mediated neurological diseases. Recently, the receptor tyrosine kinase MuSK has been found to be a target for antibodies in a proportion of patients with MG without AChR antibodies. (B) The acetylcholine receptor (AChR). The acetylcholine receptor is a transmembrane protein with $(\alpha)_2\beta\gamma\delta$ -subunits in the fetal form and $(\alpha)_2\beta\delta\varepsilon$ -subunits in the adult form. A high proportion of antibodies in MG bind to the main immunogenic regions that are on both the α -subunits. In addition, many patients' antibodies bind to the fetal-specific γ -subunit. In some cases antibodies that inhibit the function of the fetal form, selectively cross the placenta causing fetal muscle paralysis with severe and often fatal deformities.

et al., 2004) of the NMJ. The activation of MuSK requires N-agrin release from the presynaptic nerve. Agrin binds to the MuSK co-receptor, Lrp4, and this binds to and activates MuSK.

Neuromuscular Transmission

Neuromuscular transmission begins with propagation of the action potential into the motor nerve terminal. This depolarization causes opening of the VGCCs and the resulting calcium influx results in the fusion and release of ACh. The release of ACh is terminated by the closing of VGCCs, and the opening of the VGKCs with subsequent repolarization of the nerve terminal. ACh binding to the AChR results in opening of the AChR central ion pore and a localized depolarization of the motor endplate. If sufficient, this will cause the opening of the VGSCs and propagation of the action potential through the muscle fiber.

The amount of ACh released by a single vesicle is termed a quantum. The spontaneous release of a single quantum is responsible for the generation of a local depolarization, termed a miniature endplate potential (MEPP); a nerve impulse releases multiple vesicles leading to a greater depolarization, termed the endplate potential (EPP). It is possible to calculate the number of quanta

released, the quantal content (QC), from these parameters (Wood and Slater, 2001). An inherent safety factor exists in normal muscle, whereby more ACh is released than is required to reach the activation threshold for the opening of the VGSCs.

MYASTHENIA GRAVIS

Epidemiology

A recent meta-analysis of 55 published studies calculated a pooled incidence rate of 5.3 per million person-years (CI 4.4–6.1) and a pooled prevalence rate of 77.7 per million (CI 64–93) (Carr et al., 2010).

Etiology

In the majority of cases no single cause is identifiable. There is genetic predisposition, which most likely reflects the contribution of polymorphic MHC class I and II loci. Other possible genetic susceptibility markers include the AChR alpha subunit (Garchon et al., 1994; Giraud et al., 2007), IgG heavy and light chains (Dondi et al., 1994), Fc gamma receptor IIa (Amdahl et al., 2007), TAP (Hjelmstrom et al., 1997), CTLA4 (Wang et al., 2008), and PTPN22 (Provenzano et al., 2012). Molecular

TABLE 54.2 MG Patients Divided on the Basis of Antibody Status, Age at Onset, Thymic Pathology and HLA Association

| Subtype of MG | Age at Onset | Sex M:F | Typical Thymic Pathology | HLA Association | Associated Autoantibodies |
|--|--------------------|---------|--|----------------------|---|
| Early onset | <41 years | 1:3 | Thymitis | B8, DR3 | AChR. May have other tissue antibodies, e.g., thyroid |
| Thymoma associated | Mainly 40–60 years | 1:1 | Epithelial tumor containing many lymphocytes | No clear association | AChR. Titin and ryanodine receptor antibodies very common. Also cytokine antibodies |
| Late onset | >40 years | 1.5:1 | Normal or atrophied | B7, DR2 in males | AChR. Titin and ryanodine receptor antibodies common, particularly after age 60 years |
| AChR antibody negative MuSK antibody positive | 2–70 years | 1:3 | Normal or atrophied in most | Not known | MuSK. No other common antibodies |
| AChR antibody negative MuSK antibody negative | 1–80 years | 2:3 | Mild thymitis in some | Not known | Clustered AChR antibodies in some. Lrp4 in a small proportion. |

These subgroups are not appropriate in patients with purely ocular MG, and in other ethnic populations.

mimicry between AChR subunits and microbial proteins has been proposed as a possible initiating process, with autosensitization against muscle AChR occurring as a result of determinant spreading. Certain drugs, notably penicillamine, may also trigger the development of the condition in genetically susceptible individuals (Drosos et al., 1993).

General Aspects

Myasthenia gravis (MG) is an autoimmune disorder characterized by fatigable muscle weakness. It often involves the extraocular muscles at onset, causing diplopia and/or ptosis. If it remains confined to these muscles it is termed ocular MG. If other muscle groups are involved, often facial, axial, limb, bulbar, and respiratory muscles, it is termed generalized MG. Bulbar and respiratory involvement can be life threatening.

The diagnosis rests on a compatible clinical presentation, supported by serological confirmation (see below) and/or electromyographic evidence (with repetitive nerve stimulation and/or single fiber electromyography) of a defect in neurotransmission. MG is commonly associated with thymic abnormalities, notably thymic hyperplasia and thymoma, and appropriate imaging of the thymus is therefore recommended at presentation.

Symptomatic treatment includes the use of cholinesterase inhibitors, but the majority of cases will also require immunosuppressive agents including corticosteroids and steroid sparing agents (azathioprine, mycophenolate mofetil, methotrexate, and cyclosporine). Thymectomy is a therapeutic option in younger patients with detectable AChR antibodies. Intravenous

immunoglobulin and plasma exchange may be employed in severe, life-threatening, or refractory disease. Newer biological agents, such as the monoclonal anti-CD20 agent rituximab, have shown promise in refractory cases (Maddison et al., 2011). Most of these aspects are discussed in more detail below. The treatment modalities available for MG are more fully reviewed elsewhere (Vincent and Leite, 2005; Sanders and Evoli, 2010).

CLINICAL HETEROGENEITY

MG is not a single disease entity but can be classified into different groups. Defined serologically, it is possible to delineate five main subgroups of MG (see Table 54.2) that differ also by means of age of onset, HLA association thymic pathology (Compston et al., 1980), and presence of antibodies directed against non-AChR proteins. The latter group includes MuSK, Lrp4, and the striational muscle proteins titin and ryanodine receptor (RyR).

Early-onset AChR Antibody Positive MG (AChRab⁺ MG)

These patients present before the age of the 40 years, with a female predominance and an incidence that has remained relatively stable for many years. There is an association with HLA A1, B8, DR3, DR2, and DR52 among Northern Europeans (Compston et al., 1980; Janer et al., 1999; Hill et al., 1999) and HLA DPB1, DQB1, and DR9 among the Japanese (Horiki et al., 1994). Childhood onset AChRab⁺ MG is relatively rare in Northern Europeans, but more prevalent among oriental populations (Vincent et al., 2001).

Clinically the MG often involves extra-ocular muscles at onset before generalizing, although a proportion of cases will remain purely ocular. The early response to cholinesterase inhibitors is usually good, but the majority of patients will still require some form of immunosuppressive therapy. The thymus is typically hyperplastic and thymectomy is a therapeutic option in early-onset generalized AChRab⁺ MG, with current available evidence suggestive of benefit in over half of cases. Antibodies against titin and RyR are found in only a minority of cases.

Late-onset AChR Antibody Positive MG (AChRab⁺ MG)

By conventional definition these patients present after 40 years of age. There is a slight male predominance. Employing a registry to identify all individuals with positive AChR antibody levels, the age-specific incidence rises between 45 and 75 years, before rapidly falling (Vincent et al., 2003). There is a weak association with HLA B7, DR2 (Compston et al., 1980) and DR4, DQw8 (Carlsson et al., 1990).

Clinically these patients have a similar phenotype to the early-onset form, although ocular MG may be more common (Zivkovic et al., 2012). The overall response to immunosuppressive treatment is similar to that with early-onset disease, but a greater proportion of patients will encounter side effects, presumably due to co-morbid disease (Sanders and Evoli, 2010). The thymus is typically atrophic. The response to thymectomy is poorer, and it is not routinely offered to patients over 60 years of age.

Over half of these late-onset cases have detectable antibodies against titin and RyR (Buckley et al., 2001) while 25% have antibodies against the cytokines, interferon- α , or interleukin-12 (Meager et al., 2003). These antibodies are more prevalent in thymoma cases and some authors have speculated that late-onset MG may represent an immune response against occult thymomas that are subsequently destroyed (Marx et al., 2010).

Thymoma-Associated MG (Thymoma MG)

Thymomas are tumors derived from thymic epithelial cells, thereby distinguishing them from lymphoma, neuroendocrine, and germ cell tumors. They are conventionally classified by means of the WHO classification (A, AB, B, and C). A coexisting thymoma is identified in 10% of MG patients. It can occur at any age, but is most common among the 40–60 age group. There is no gender difference or consistent HLA association.

Clinically the myasthenia is generalized with detectable AChR antibodies, although ocular and seronegative cases have been reported (Maggi et al., 2008). The myasthenia may be more refractory to treatment than

other forms of MG (Sanders and Evoli, 2010). Following thymectomy, AChR antibody levels do not necessarily fall, without additional treatments, but in contrast to early-onset disease, the myasthenia rarely improves (Somnier, 1994).

Serum antibodies against striated muscle were recognized first in the 1960s. Their major targets are two intracellular proteins, titin and the ryanodine receptor (RyR), both of which are expressed in thymoma (Skeie et al., 1997; Mygland et al., 1995). These antibodies are typically observed in >90% of thymoma-associated MG cases, but there are no convincing data supporting their pathogenic role, and antibodies against the AChR are invariably identified. Neutralizing antibodies against interferon- α and interleukin-12 are observed in approximately 70% and 50% of cases, respectively (Buckley et al., 2001; Meager et al., 2003) (Chapter 76). These are useful markers for identification of recurrent disease.

MuSK Antibody-Positive MG (MuSKab⁺ MG)

These patients can present at any age, with a female predominance. There is significant worldwide variation, with a correlation with geographical latitude, suggesting potential environmental influences (Vincent et al., 2008). Despite the small numbers in individual studies, a significant association with HLA DR14 and DQ5 in a Dutch cohort (Niks et al., 2006) and DRB16 and DQB5 in an Italian cohort (Bartoccioni et al., 2009) has been identified.

Clinically, the phenotype can be different from AChRab⁺ MG with prominent ocular, bulbar, neck, and respiratory weakness (Evoli et al., 2003; Sanders et al., 2003). Muscle wasting and atrophy of the tongue and facial muscles may be evident both clinically and radiologically (Farrugia et al., 2006). The response to treatment can also differ with a comparatively poorer response (and occasionally intolerance) to cholinesterase inhibitors (Evoli et al., 2003; Pasnoor et al., 2010). A proportion can be refractory to conventional immunosuppressive treatment (Evoli et al., 2003). In such cases, plasma exchange is considered more effective than intravenous immunoglobulin (Pasnoor et al., 2010) but interestingly rituximab may be more effective in MuSK patients than in those with AChR antibodies (Maddison et al., 2011; Diaz-Manera et al., 2012). The therapeutic response to thymectomy remains uncertain (Evoli et al., 2008) and the thymus is typically normal or atrophic in direct comparison to that seen in AChRab⁺ MG (Leite et al., 2005) (Figure 54.2). To date, there is only a single case report of MuSKab⁺ MG associated with an underlying thymoma (Saka et al., 2005).

Neonatal MG

This is caused by passive transfer of maternal antibodies across the placenta. It may occur in up to 10% of female

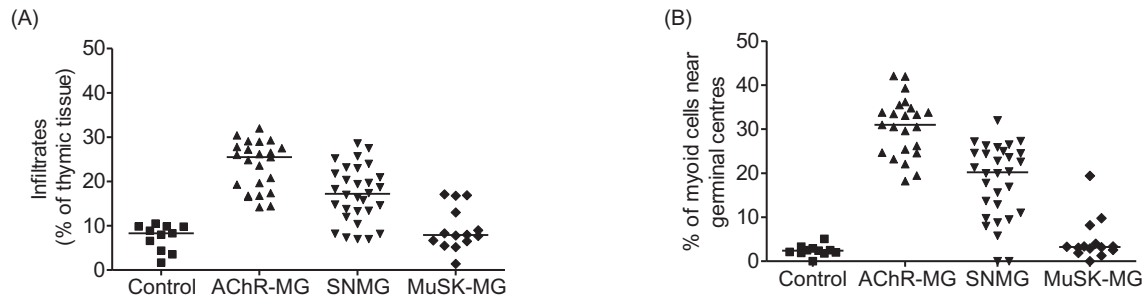

FIGURE 54.2 The thymus in different forms of myasthenia. (A) Patients with AChR antibodies typically have hyperplastic thymuses with large lymphocytic infiltrates, whereas those with MuSK antibodies do not. Patients without either antibody (seronegative, SNMG) may have lymphocytic infiltrates and a proportion of these patients have AChR antibodies identified only by cell-based assays (Leite et al., 2008). (B) myoid cells, which express AChRs on their surface, are found close to the germinal centers or even within them, particularly in patients with AChR antibodies. Data reproduced from Leite et al. (2007).

patients with AChR antibodies (Vincent et al., 2001). The affected newborn babies exhibit transient symptomatic weakness, requiring the use of cholinesterase inhibitors for a few weeks. Rarely, it can occur in women who are symptom free but have AChR antibodies. Arthrogryposis multiplex congenita is a condition where the newborn have multiple joint contractures as a consequence of absent fetal movement *in utero*. It can occur if there are high levels of maternal antibodies directed against the fetal isoform of the AChR (Barnes et al., 1995). An animal model where pregnant mice are injected with maternal plasma has been described (Jacobson et al., 1999b). There are also rare case reports of neonatal MG occurring in MuSK MG, with both transient (Niks et al., 2008) and more persistent disease (Behin et al., 2008) described.

ANTIBODIES IN MYASTHENIA

Serological Testing

AChR antibodies were first detected by means of a radio-immunoprecipitation assay (RIA) employing ^{125}I α -bungarotoxin, which binds strongly to AChRs, to label AChRs in detergent extracts of human muscle (Lindstrom et al., 1976). Modern RIAs employ AChRs extracted from muscle cell lines expressing mixtures of fetal and adult AChRs (Beeson et al., 1996). Directly radiolabeled recombinant MuSK are used for detection of MuSK antibodies (Matthews et al., 2004). Enzyme-linked immunosorbent assays are not as sensitive or as specific.

Cell-based assays (CBAs) use cells transfected with DNA(s) for the antigen of interest and expressed on the cell surface. Indirect immunofluorescence can then detect binding of patients' antibodies. This method is sensitive and, importantly, measures antibodies that only bind to extracellular determinants of the antigen (Leite et al., 2010). This was demonstrated in previously seronegative cases using cells transfected with AChR subunits and

with the scaffold protein rapsyn that clusters the AChRs (Leite et al., 2008). CBAs have also been developed to detect MuSK or Lrp4 antibodies (Leite et al., 2008; Higuchi et al., 2011).

In generalized MG, 85% have AChR antibodies and 0–10% have MuSK antibodies; up to 5% may only have clustered AChR antibodies, although there are few systematic studies at present. There are rare case reports of patients with both AChR and MuSK antibodies (Saulat et al., 2007; Rajakulendran et al., 2012). Lrp4 antibodies can be found in previously seronegative patients, but a number also have MuSK antibodies (Higuchi et al., 2011).

Other antibodies that have been reported in MG include those against the striational muscle proteins actin, myosin, and titin and the ryanodine receptor (RyR) (Aarli et al., 1998). Titin is required for muscle assembly and for its ongoing ability to contract and relax, while the RyR are calcium release channels required for muscle contraction. These antibodies are typically seen in thymoma and older non-thymoma cases. Antibodies against rapsyn have also been described (Agius et al. 1998), although these are not specific for MG. All of these antigens are intracellular proteins and the antibodies are unlikely to be pathogenic.

AChR Antibody Characteristics

AChR antibodies belong to variable IgG subclasses, although IgG1 and IgG3 predominate (Rodgaard et al., 1987; Vincent et al., 1987). A significant proportion of antibodies are directed against the MIR on α -subunits, although other sites (Whiting et al., 1986) and other AChR subunits (Jacobson et al., 1999a) can also be targets. These antibodies have a high affinity (around 100 pM) and are highly specific for the intact receptor with limited binding to recombinant polypeptides or denatured AChR subunits; the antibodies bind predominantly to the extracellular portion of the receptor.

Within an individual patient, disease activity correlates well with changes in antibody level, at least in the short term. Between patients, there is variation in the antibody specificity, isoelectric heterogeneity, and avidity for the AChR, and no clear correlation with disease activity is observed (Vincent et al., 1987).

Somatic mutations of the B lymphocyte Ig genes are necessary for the synthesis of these high affinity antibodies. Lower affinity AChR antibodies have been observed in monoclonal gammopathies using ELISA, but myasthenic symptoms are rarely encountered (Eng et al., 1987).

MuSK and Other Antibodies

MuSK antibodies may also belong to variable IgG subclasses, although IgG4 predominates (McConville et al., 2004). They bind to the Ig-like domains of MuSK and have a similar affinity to that of AChR antibodies (McConville et al., 2004). No clear relationship between MuSK antibody level and disease severity is seen across the patient cohorts but for an individual patient there is a reasonable correlation in the few studies done. By contrast, Lrp4 antibodies belong predominantly to the IgG1 subclass (Higuchi et al., 2011).

PATHOGENIC MECHANISMS

Evidence for Pathogenicity of AChR and MuSK Antibodies

Both AChR and MuSK antibodies are pathogenic, satisfying the strict criteria required for establishing causation in autoimmune disease (Rose and Bona, 1993). Both are directed against autoantigens that are highly relevant to a disorder of neurotransmission, and are highly specific for MG.

The main criteria in these diseases are the passive transfer of MG from man to animal (usually mice or rats) and the response to treatments that reduce antibody levels. Passive transfer models involve injection of IgG from MG patients into animals and lead either to objective weakness or at least to neurophysiological evidence of impaired neurotransmission. Plasma exchange dramatically reduces antibody levels within a few days, and leads to striking clinical improvement even in patients with long-standing disease. In addition, maternal–fetal transfer of the disease has been reported in both serological forms of MG.

Further *in vivo* evidence comes from replication of the human disease in animals that have been immunized with the relevant antigen, termed experimental autoimmune myasthenia gravis (EAMG). This active immunization

model has been used extensively to study the immunobiology of MG, as will be mentioned below.

AChR Antibody-Positive MG

AChR antibodies cause loss of AChRs through three principal mechanisms. These include complement-mediated destruction, cross-linking and accelerated degradation and functional blockade.

AChR antibodies belong predominantly to the complement fixing IgG1 and IgG3 subclasses (Vincent et al., 1987; Rodgaard et al., 1987). Activation of complement results in the generation of the membrane activation complex which is responsible for lysis and destruction of the postsynaptic membrane, loss of postsynaptic folding, and ultimately loss of AChR and related proteins. IgG colocalizing with activated complement is observed both in EAMG (Sahashi et al., 1978) and MG (Engel et al., 1977) muscle biopsies. The importance of complement in the pathogenesis of this form of MG comes from several lines of evidence. Depletion (Lennon et al., 1978), inhibition (Biesecker and Gomez, 1989), or blockade (Piddlesden et al., 1996) of complement all result in resistance to developing disease in EAMG. Further evidence is provided by the study of transgenic mice lacking components of the classical complement cascade (Tuzun et al., 2003) and complement regulators (Morgan et al., 2006).

AChR antibodies belonging to the IgG1, IgG2, and IgG3 subclasses are also able to divalently cross-link AChRs, increasing the rate of internalization and degradation of AChRs. This is termed antigenic modulation, and is observed in both MG (Drachman et al., 1978) and EAMG patients (Lindstrom and Einarson, 1979). It is most prominent when antibodies are directed against the MIR (Tzartos et al., 1991).

AChR antibodies have been shown to block the ACh binding sites of AChRs in cultured muscle cells (Howard et al., 1987) and even in human muscle biopsies *in vitro*. In EAMG they are capable of causing severe weakness, with little structural effect on the NMJ (Gomez and Richman, 1983). These blocking antibodies are often found at low levels, and while they may have a role to play in acute exacerbations, their effect is insignificant in the majority of patients.

Failure of neuromuscular transmission results from the loss of AChRs, with reduced MEPP and EPP amplitudes. The reduced EPP amplitude falls below the required threshold to initiate an action potential, leading to blocking of neurotransmission. There is partial compensation for this through an increase in the number of quanta of ACh released, which appears to be a compensatory mechanism in both MG and EAMG (Plomp et al., 1995).

MuSK Antibody-Positive MG

MuSK antibodies belong predominantly to the non-complement fixing IgG4 subclass (McConville et al., 2004). IgG4 antibodies are able to undergo Fab arm exchange to produce bispecific antibodies that do not cross-link identical antigens (van der Zee et al., 1986), and which therefore function monovalently (Schoorman et al., 1999). This suggests that the effector mechanisms are likely to be different from those in AChR-mediated disease. To date the only published human pathological study has demonstrated normal motor endplates, normal AChR numbers, and little evidence of complement deposition (Shiraishi et al., 2005). In contrast, both active immunization (Shigemoto et al., 2006; Viegas et al., 2012) and passive transfer (Cole et al., 2008; Viegas et al., 2012) models have demonstrated AChR loss in clinically affected animals, although complement deposition has not been observed and complement deficient mice remain susceptible to the disease (Mori et al., 2012). Nevertheless, both IgG4 and non-IgG4 MuSK antibodies can affect AChR clustering on myotubes in *in vitro* assays and the mechanisms of MuSK antibodies in general are not yet clear (Konecny et al., 2013).

MuSK has a critical role in the ongoing maintenance of the NMJ (Kong et al., 2004; Hesser et al., 2006). Combined pre- and postsynaptic morphological changes have been observed in animal models (Cole et al., 2008; Richman et al., 2012) and may explain the severe phenotype that is observed. There is also electrophysiological evidence of both pre- and postsynaptic defects (Klooster et al., 2012; Viegas et al., 2012) with failure of the presynaptic compensatory mechanism (Plomp et al., 1995) further impacting on underlying neurotransmission.

THE THYMUS AND CELLULAR IMMUNITY IN MG

Role of T Lymphocytes in MG

High affinity AChR antibodies are thought to be dependent on CD4⁺ T lymphocytes but as these are rarely observed in myasthenic muscle and almost never found at the neuromuscular junction, they are not thought to be effector cells in MG. Nevertheless their critical role in the autoimmune pathogenesis is demonstrated through several lines of evidence in both MG and EAMG. EAMG was first described following the immunization of rabbits with AChRs purified from the electric organ of *Torpedo californica* (Patrick and Lindstrom, 1973) and later reproduced in a number of other species. In the murine model there are both disease sensitive and resistant strains, related to their different H-2 alleles (Berman and Patrick, 1980).

AChR-specific CD4⁺ T lymphocytes occur in both the peripheral blood and thymuses of MG patients. They may

also be observed in healthy controls but the clinical improvement observed following their removal with anti-CD4 monoclonal antibodies (Ahlberg et al., 1994) and in HIV (Nath et al., 1990) supports a pathogenic role for these lymphocytes. These isolated CD4⁺ T lymphocytes may respond to stimulation with the intact AChRs, recombinant subunits, or AChR peptides (Conti-Fine et al., 1998; Wang et al., 1998) and T cell lines and clones propagated from MG patients will respond more vigorously to stimulation *in vitro* than those derived from healthy controls. The epitopes are most commonly found on the α -subunit of the AChR. In EAMG a dominant epitope within the α 146-162 activates MHC class II-restricted CD4⁺ T lymphocytes, leading to pathogenic antibody production (Christadoss et al., 2000). A clearly immunodominant epitope has not been identified reproducibly in a high proportion of MG patients, although an epsilon subunit epitope was identified in some (Hill et al., 1999). The TCR V β families show preferential expansion of the V β 4 and 6 among MG patients (Navaneetham et al., 1998) while mice lacking V β 6 respond poorly to immunization with AChR (Krcso et al., 1991).

Mice genetically deficient in functioning CD4⁺ T lymphocytes do not develop EAMG (Kaul et al., 1994) while severe combined immunodeficiency mice will only produce AChR antibodies and develop myasthenic symptoms if the human grafted cells contain CD4⁺ T lymphocytes (Wang et al., 1999).

CD4⁺ T lymphocytes and the cytokines they secrete will influence the type of autoimmune response generated in both MG and EAMG. Analysis of blood from MG patients has confirmed the presence of Th1 (IFN- γ ⁺), Th2 (IL-4⁺), Th17 (IL-17⁺), and Treg (Foxp⁺) cells (Li et al., 2008), but the role of these T lymphocyte subsets in the development of the disease is best examined using transgenic mice. IL-12 is essential for promoting development of Th1 cells and IL-12^{-/-} mice are resistant to the development of EAMG despite a significant antibody response (Karachunski et al., 2000). The role of IFN- γ remains unclear with conflicting reports of EAMG susceptibility (Balasa et al., 1997; Wang et al., 2007). IL-4 appears to be either neutral (Balasa et al., 1998) or confer a protective effect (Karachunski et al., 1999). There is an apparent increase in Th17 and decrease in Treg cells during development of EAMG in rats (Mu et al., 2009) and administration of Treg cells to myasthenic rats inhibited progression of EAMG (Aricha et al., 2008). Initial studies identified no change in Treg cell numbers in MG subjects compared with healthy controls (Huang et al., 2004) although a specific functional impairment in those Foxp3⁺ Treg cells (Balandina et al., 2005) was subsequently identified.

T cell activation requires the interaction of TCR/MHC peptide in addition to the interaction between CD28/CTLA4 on the T lymphocytes and CD80 (B7) on antigen-presenting cells (the CD28 – CD80 interaction). It also requires the

cross-linking of the CD40 ligand (CD40–CD40 L interaction). Using transgenic mice it has been demonstrated that both interactions are essential for the primary immune response (Shi et al., 1998) although their contribution to the secondary response is thought to be less prominent. Here the CD278 (inducible T cell costimulator) is thought to be important for the secondary response (Scott et al., 2004).

The Thymus and MG

The thymus is an epithelial organ that can be morphologically divided into a distinct cortex, medulla, and corticomedullary zone. The cortex contains densely packed immature lymphocytes alongside a sparse population of epithelial cells and bone marrow-derived macrophages. The medulla is less cellular containing more mature T lymphocytes, more prominent epithelial cells, dendritic cells, B lymphocytes, and rare myoid cells (Pearse, 2006). The thymus has a critical role in self-tolerance with a fine balance between the generation of protective T lymphocytes and deletion of autoreactive T lymphocytes required. Relevant autoantigens including the α -subunit of the AChR are expressed on medullary thymic epithelial cells (mTECs) under the control of the autoimmune regulator gene (AIRE) (Giraud et al., 2007). Central T cell tolerance relies on the close interaction between these mTECs and nearby dendritic cells and their effect on the T lymphocyte development and subsequent differentiation.

The thymus is thought to have a critical role in the development of early-onset AChR antibody-positive MG. The cortex is typically normal but the medulla contains lymphocytic infiltrates (Figure 54.2) and germinal centers with distinct areas of B lymphocyte proliferation, differentiation, somatic hypermutation, and immunoglobulin class switching. These B lymphocytes when cultured *in vitro* are capable of secreting anti-AChR antibodies spontaneously (Vincent et al., 1978; Scadding et al., 1981). It is therefore to be expected that antibody levels fall post-thymectomy (Vincent et al., 1983) but they seldom disappear.

Whether early-onset AChR antibody-positive MG begins in the thymus, or whether these changes are a reflection of a systemic process, remains unresolved. Individual AChR subunits are expressed on mTECs (Salmon et al., 1998), presumably as part of a self-tolerance mechanism and these are targeted by both autoantibodies (Safar et al., 1991) and complement (Leite et al., 2007). Native AChR is also expressed by the muscle-like myoid cells which, while comparatively rare, are more abundant in the hyperplastic thymus (Kirchner et al., 1986). The germinal centers appear to be focused around these myoid cells (Figure 54.2). Given that they lack MHC class II or costimulatory molecules they rely on the antigen-presenting dendritic cells to prime the CD4⁺ T lymphocytes. One proposed multi-step

hypothesis is that the mTECs first present epitopes from isolated AChR subunits to CD4⁺ T lymphocytes, evoking the production of early antibodies capable of attacking the thymic myoid cells which express the intact AChR. As the immune response continues to proliferate, germinal centers are formed which allow these antibodies to diversify allowing recognition of native AChRs (Willcox et al., 2008).

The thymus is typically involuted and atrophic in older patients. The aging thymus is gradually replaced with fat, although residual foci of mTECs may persist, and myoid cells are only rarely encountered. Histological analysis of thymus tissue from late-onset MG cases previously suggested no differences from normal controls (Myking et al., 1998). Nevertheless a more recent study looking at young and late-onset MG cases identified residual lymphocyte accumulation among the older cohort and no qualitative differences between the two groups (Ishii et al., 2007).

Thymomas are heterogeneous neoplasms of thymic epithelial cells with mixed cortical and medullary markers. They may develop from either early TEC progenitors or from more mature cortical or medullary TECs (Hasserjian et al., 2005). They are responsible for the generation of numerous maturing polyclonal T lymphocytes (thymocytes) capable of maturing into CD4⁺ or CD8⁺ T lymphocytes. The degree of thymopoiesis is known to vary according to the thymoma subtype (Nenninger et al., 1998). The B2 subtype is the most common type associated with MG (accounting for \approx 50% of cases) and contains an abundance of mature CD4⁺ T lymphocytes ready for export (Strobel et al., 2004). It should be noted that corticosteroids can deplete the immature T lymphocytes and thereby modify the histological subtype.

There are certain features in thymomas that are likely to promote inefficient self-tolerance including defective AIRE and MHC class II expression, an absence of myoid cells, and failure to generate Foxp3⁺ Treg cells as well as defective T lymphocyte signaling (Marx et al., 2010). Antigenic targets other than AChR are also recognized which is unsurprising given the wide range of systemic, hematological, endocrine, cutaneous, gastrointestinal, and renal disorders associated with thymoma (Marx et al., 2010).

Genetic aberrations and polymorphisms may also be identified in thymoma. These include HLA genes (notably loci at 6p21) which may affect MHC class II expression and non-MHC genes (including CTLA4 and PTPN22) which influence T cell receptor signaling.

LAMBERT–EATON MYASTHENIC SYNDROME

The Lambert–Eaton myasthenic syndrome (LEMS) is clinically and electrophysiologically distinct from MG.

Approximately 50% of LEMS cases are paraneoplastic, typically associated with small cell lung carcinoma (SCLC). There are certain features that make it possible to distinguish paraneoplastic and non-paraneoplastic forms.

Epidemiology and Etiology

LEMS is less common than MG, with an annual incidence of 0.48 per million in a Dutch study (Wirtz et al., 2003). The median age of onset is 60 years in both the paraneoplastic and non-paraneoplastic forms (O'Neill et al., 1988; Titulaer et al., 2011), although there is another smaller peak at 35 years in the non-paraneoplastic forms (Titulaer et al., 2011). There is a male predominance in the paraneoplastic form, and a slight female predominance in the non-paraneoplastic form. In the latter, similarly to early onset MG there is an association with HLA B8 and DR3.

Clinical Features

The cardinal clinical features of LEMS include muscle weakness, autonomic dysfunction, and areflexia. Typical findings include proximal muscle weakness that is more marked in the lower limbs. Ocular and bulbar symptoms may occur later in the disease course. The speed of progression is often more rapid in the paraneoplastic form (Titulaer et al., 2008). Autonomic involvement is seen in over 80% of cases. Commonly encountered symptoms include dry mouth, erectile dysfunction, and constipation. Micturition difficulties and orthostatic syncope are less common. In contrast to MG, the muscle strength in LEMS will improve after a period of maximal voluntary contraction.

Investigation and Treatment

Electromyography will confirm a disorder of neurotransmission, although a significant increase in the compound muscle action potential following a period of exercise or high frequency stimulation allows electrophysiological differentiation from MG. Serological confirmation involves detection of antibodies against the P/Q type voltage-gated calcium channels which are found in approximately 90% of LEMS cases, and are invariably present in paraneoplastic SCLC cases (see below).

To detect the antibodies, the P/Q type VGCCs are extracted from mammalian brain, labeled with ^{125}I ω -conotoxin which binds specifically to these VGCCs, and used in an RIA. In addition antibodies against N type (30–40%) and L type (25%) VGCCs may be present (Johnston et al., 1994; Motomura et al., 1997). Other antibodies which have been identified include those against

synaptotagmin (Takamori et al., 1995) and more recently against SOX-1 in 65% of paraneoplastic cases and around 5% of non-paraneoplastic cases (Sabater et al., 2008; Titulaer et al., 2009).

Symptomatic treatment requires 3,4-diaminopyridine. If additional treatment is required then corticosteroids and other immunosuppressive agents are used. Intravenous immunoglobulin, plasma exchange, and rituximab may be used in severe and refractory cases. Any underlying SCLC should be treated in the appropriate manner. Treatment options are reviewed in more detail in Titulaer et al. (2011).

Pathophysiology

The voltage-gated calcium channel complex contains several subunits but the α_1 -subunit is primarily responsible for the biochemical and electrophysiological functions of the protein. Similarly to the MIR on the α -subunit of the AChR there may be particularly immunogenic sequences; 50% of LEMS patients have antibodies against linker domains on the α_1 -subunit (Takamori et al., 1997).

Freeze fracture electron microscope studies of the presynaptic motor nerve terminal have demonstrated an ordered array of intramembranous particles. These are located close to the site of transmitter exocytosis. There is some evidence that VGCCs constitute at least some of the intramembranous particles in the active zone (Robitaille et al., 1990). LEMS patients have both a reduction in the total number of active zone particles and the number of particles per active zone (Nagel et al., 1988).

The evidence for the pathogenic nature of VGCCs comes from both clinical and experimental studies. Patients respond to plasma exchange (Newsom-Davis et al., 1982) and cases of maternal to fetal transfer of the disease have also been reported (Lecky, 2006). Passive transfer with LEMS plasma or IgG produces the same neurophysiological abnormalities in mice (Lang et al., 1983; Fukunaga et al., 1983), although no weakness was observed. Further studies confirmed the localization of IgG close to the presynaptic active zones (Fukuoka et al., 1987). Additionally, active immunization of rats with peptides from the α_1 -subunit led to mild weakness and compatible neurophysiological changes (Komai et al., 1999). Finally, mice with mutations in the P/Q type VGCC (CACNA1a) share some of the electrophysiological characteristics of LEMS (Kaja et al., 2007).

CONCLUSIONS AND FUTURE PROSPECTS

Historically, the classification of MG has been based on AChR antibody status, age of onset, and thymic pathology. MuSK antibodies were first recognized over a

decade ago, and while there was some initial skepticism about their relevance, it is now well established that they are pathogenic, satisfying all the necessary criteria for causation in autoimmune diseases. Defined serologically, this particular form of MG is typically more severe and more refractory to conventional immunosuppressive therapy. From an immunological perspective the predominance of the non-complement fixing IgG4 subclass contrasts with AChR antibody-mediated disease. The relative absence of complement as an effector mechanism may help explain the largely normal neuromuscular junctions that have been observed in human studies.

Over recent years further advances in serological assays for MG have been made. Alongside established radioimmunoprecipitation assays for detecting AChR and MuSK antibodies, cell-based assays have been developed that allowed us to first identify antibodies to clustered AChR, and then more recently Lrp4 antibodies. Over the next few years we need to confirm if these Lrp4 antibodies are pathogenic. Given that these antibodies are predominantly of the IgG1 subclass, we would anticipate that the role of complement may be more akin to that observed in AChR antibody-mediated MG.

Conventional treatment for MG relies on symptomatic treatment, oral immunosuppressive agents, and immunomodulatory treatment with intravenous immunoglobulin and plasma exchange. Newer biological agents, such as rituximab, have shown promise and may benefit those with refractory disease. We should soon learn the results of the international thymectomy study. In the future, our greater understanding of the immunology of MG may allow the development of more targeted immunotherapy. Potential drugs could include those directed against the complement cascade/membrane attack complex, B lymphocyte proliferation, relevant cytokines and their receptors, and lymphocyte adhesion and migration pathways.

HISTORICAL BACKGROUND

The concept that the eye harbors autoimmune-inducing or uveitogenic materials has been suggested by many since the beginning of the last century. It was the demonstration by Uhlenhuth (1903) of autoantibody production to the lens that pioneered investigation in this area. Several investigators used homogenates from the eye, which appeared to be capable of inducing an intraocular inflammatory response when injected into an animal eye. Noteworthy of mention are Wacker and Lipton (1968) and Faure 1980.

The presence of uveitogenic antigens in the human eye that are capable of inducing disease is a well-established concept, proposed as early as 1910 by Elschnig (Elschnig, 1910). Since then several antigens have been isolated that are capable of inducing ocular inflammatory disease similar to that seen in humans. Retinal S-antigen, or arrestin, was isolated and its immunologic properties partially characterized by Wacker et al. (1977). It is one of the most potent uveitogenic antigens defined to date. It causes an immune-mediated, bilateral inflammatory response in the eye, or experimental autoimmune uveitis (EAU), when injected in microgram quantities at a site far from the globe (Pfister et al., 1985). S-antigen and its clinical relevance in uveitis were widely studied in the 1980s by many investigators

(Nussenblatt et al., 1980a,b, 1983; Graham et al., 1981; Gregerson et al., 1981, 1983; Forrester and Borthwick, 1983). Several other uveitogenic antigens have since been identified, such as interphotoreceptor retinoid-binding protein (IRBP) (Hirose et al., 1986); recoverin (Gery et al., 1994); bovine melanin protein (Chan et al., 1994); rhodopsin (Schalken et al., 1989); phosducin (Lee et al., 1990); RPE 65 (Ham et al., 2002), and tyrosinase proteins (Yamaki et al., 2000).

These studies have broadened our understanding of the ocular immune response and allowed templates to be developed with which newer approaches to immunosuppression can be tested.

CLINICAL FEATURES

The uveal tract can be divided anatomically into the iris, ciliary body, and choroid (Figure 55.1). Uveitis is usually defined as any inflammation of the uveal tract. This inflammation may be an antigen-specific, immune-mediated response, or a nonspecific response, which can be elicited by infection, trauma, or surgery. In clinical practice, any inflammatory reaction involving the structures of the eye (see Figure 55.1) is considered to be uveitis.

Episcleritis is an inflammatory disease involving the tissue that lies superficial to the sclera. Scleritis is a

FIGURE 55.1 Key anatomic features of the eye.

FIGURE 55.2 Slit-lamp photograph of a patient with scleritis of presumed autoimmune etiology, having ruled out infectious etiologies. Arrow indicates dilated episcleral and scleral vessels.

painful and potentially sight-threatening inflammatory disease involving the sclera. Episcleritis is typically more acute and less severe than scleritis and it is often idiopathic; however, many of the diseases associated with scleritis have also been associated with episcleritis. Clinical examination evaluates for the presence of erythema and edema of the episclera or sclera as well as injection of the deep episcleral vessels (Figure 55.2). The inflamed sclera is usually characterized by a violaceous hue which can be graded in a standardized fashion (Sen et al., 2011). Many inflammatory systemic disorders are associated with scleritis, the most common being rheumatoid arthritis. Others include juvenile idiopathic arthritis (JIA), Reiter syndrome, Crohn's disease, ankylosing

FIGURE 55.3 Slit-lamp photograph of a patient with anterior uveitis with keratic precipitates. Arrow points to corneal endothelium with keratic precipitates.

spondylitis, ulcerative colitis, polymyositis, polyarteritis nodosa, systemic lupus erythematosus (SLE), Wegener's granulomatosis, sarcoidosis, Lyme disease, and Cogan syndrome. In up to 40% of cases no associated disease can be identified (Sainz de la Maza et al., 2012).

According to standardization of uveitis nomenclature (SUN) working group criteria (Jabs et al., 2005), uveitis can be classified based on anatomic location: anterior, intermediate, posterior, and panuveitis. *Anterior uveitis* describes a disease predominantly limited to the anterior segment. In the literature it is also called iritis, iridocyclitis, and anterior cyclitis. There are many inflammatory systemic diseases associated with anterior uveitis, including juvenile idiopathic arthritis, HLA-B27-associated diseases, Behcet's disease, and sarcoidosis. The corneal examination may reveal keratic precipitates (Figure 55.3), small aggregates of inflammatory cells which can be granulomatous or non-granulomatous in nature, which accumulate on the endothelial surface of the cornea. Examination of the anterior chamber via biomicroscopy will reveal the presence of inflammatory cells and increased protein (flare), resulting from spillover of inflammation from the iris and the ciliary body, graded in a standardized fashion (Nussenblatt and Whitcup, 2004; Jabs et al., 2005). An accumulation of leukocytes associated with fibrin, layered in the lower angle of the anterior chamber, is called a hypopyon (Figure 55.4), and is commonly associated with Behcet's disease and the HLA-B27-associated uveitides. Inflammation of the iris may cause synechiae (adhesions) between the iris and the lens capsule (Figure 55.5) or the cornea. It may also develop accumulations of inflammatory cells called nodules on the papillary margin, referred to as Koeppe nodules, or on

FIGURE 55.4 Slit-lamp photograph of a patient with ocular Behcet's disease and anterior uveitis, with a hypopyon. Arrow points to layer of inflammatory cells in the anterior chamber, the hypopyon.

FIGURE 55.5 Slit-lamp photograph of a patient with anterior uveitis, extensive posterior synechiae, and iris adhesions to the anterior lens capsule. Arrows show the areas of adhesions.

the iris surface, known as Busacca nodules, commonly seen with sarcoidosis and other granulomatous diseases.

Intermediate uveitis refers to uveitis where the vitreous is the major site of inflammation. Inflammation in the vitreous is characterized by increased cells and protein, vitreous haze (Nussenblatt et al., 1985; Jabs et al., 2005) or pars plana exudates. Retinal inflammation may cause cystoid macular edema and retinal vasculitis. There are specific systemic autoimmune diseases associated with this type of uveitis: multiple sclerosis, sarcoidosis, and Lyme disease. A common form of intermediate uveitis is referred to as pars planitis, which is by definition idiopathic. Syphilis and tuberculosis are common infectious etiologies of intermediate uveitis.

Posterior uveitis refers to inflammation affecting the posterior segment, particularly the retina and the choroid.

There are numerous autoimmune diseases that are associated with posterior uveitis: Behcet's disease, systemic lupus erythematosus, polyarteritis nodosa, Wegener's granulomatosis, sarcoidosis, syphilis, and Vogt–Koyanagi–Harada syndrome. There are also many infectious etiologies: ocular histoplasmosis, cytomegalovirus retinitis, acute retinal necrosis (varicella zoster virus, herpes simplex virus), toxoplasmosis, and immune-mediated local ocular disorders: sympathetic ophthalmia, birdshot retinochoroidopathy, and the “white-dot syndromes,” which can cause posterior uveitis. In addition, primary intraocular lymphoma can masquerade as an intermediate or posterior uveitis.

Finally, *panuveitis* is a term reserved for inflammation involving all segments of the eye and in which there is no predominant site of inflammation (Nussenblatt and Whitcup, 2004; Jabs et al., 2005). Typical systemic diseases associated with this form of uveitis are Behcet's disease, sarcoidosis, VKH syndrome, and syphilis.

PATHOLOGIC FEATURES

Uveitis can be classified as granulomatous or nongranulomatous. This is a clinical definition, based on the type of inflammatory cells infiltrating the ocular tissues, as seen by biomicroscopy. It is not based on histopathologic analysis. Biomicroscopy will reveal inflammatory precipitates throughout the eye. The most common type of corneal (keratic) precipitates is nongranulomatous, characterized by fine, white-colored lymphocytes, plasma cells, and pigment. Many etiologic factors may be responsible for this type of inflammation. Granulomatous inflammation forms large, greasy-appearing collections of lymphocytes, plasma cells, and giant cells, also called “mutton-fat” keratic precipitates. It can also cause iris nodules, vitreous inflammatory cells, called “snowballs,” and retinal vascular inflammation, called “candle wax drippings.” This clinical classification is an important diagnostic clue, because the etiologic agents associated with granulomatous uveitis form a fairly short list, including sarcoidosis, Vogt–Koyanagi–Harada syndrome, syphilis, tuberculosis, and toxoplasmosis.

EPIDEMIOLOGIC FEATURES

According to a study by Gritz and Wong (2004), the incidence of uveitis was 52/100,000 person-years and the period prevalence was 115/100,000 persons. It has been found that women have a higher prevalence than men, and the highest incidence and prevalence of disease are in those 65 years and older (Gritz and Wong, 2004), although the age group with the highest prevalence is still under debate. Rodriguez et al. (1996) analyzed their university/referral-based population and found 83% of cases

were non-infectious in etiology. There are many demographic features that offer important clues when evaluating a patient with uveitis such as age, sex, race, ethnic heritage, and geographic residence. Specific examples include juvenile idiopathic arthritis associated with chronic anterior uveitis seen in children under age 16. One half of the JIA patients in one study reportedly had chronic uveitis by the age of 6 (Key and Kimura, 1975). It is mostly seen in young females with pauciarticular arthritis and a positive antinuclear antibody (ANA) test (Cassidy et al., 1986). The uveitis associated with ankylosing spondylitis is typically a recurrent anterior uveitis seen in young men between the ages of 20 and 30 years (Brewerton et al., 1973). Sarcoidosis affects young adults aged 20–50 years and has a slightly increased prevalence in women. It can affect all races, but African Americans are 10 times more likely to be affected compared to white persons, and with chronic sarcoidosis they are more likely to develop ocular manifestations than are white persons (Jabs and Johns, 1986). Vogt–Koyanagi–Harada syndrome is a multisystem disorder, with ocular, central nervous system, cutaneous, and vestibular-auditory manifestations; the ocular manifestation is usually a severe, bilateral, granulomatous panuveitis. It is common in Japan and certain parts of Latin America (Sugiura, 1988). We have also noted a fairly high Native American ancestry among our patients. Finally, Behcet’s disease is a multisystem disorder with ocular involvement; it is especially common in the Far East and the Mediterranean basin (Ohno and Matsuda, 1986). The ocular disease may be an anterior and/or posterior uveitis, associated with retinal vasculitis (Figure 55.6).

AUTOIMMUNE FEATURES

Immunity in the eye is deviant and atypical. The eye’s ability to regulate local immune responses has been attributed to several factors. First, there are several immunosuppressive substances in the aqueous humor of the eye, such as α -melanocyte-stimulating hormone (α -MSH), vasoactive intestinal peptide (VIP), transforming-growth factor-beta (TGF- β), and macrophage-migration-inhibitory factor (MIF), which act to modulate ocular immune responses. Second, there are bone marrow-derived cells in the vascularized tissues of the eye that may capture antigens and present them to immune cells. Third, surface markers, such as CD95 ligand (Griffith et al., 1996; Ferguson and Griffith, 1997), CD46 (Bora et al., 1993), and CD59 are expressed in ocular parenchymal tissues; they directly inhibit effector T cell components of complement, thus saving the eye from tissue damage. Also, inside the eye, both the retina and anterior chamber have a well-structured vascular network with blood-ocular barriers that protect the eye from intruding macromolecules.

The ability to discriminate between self and non-self is used for elimination of autoreactive cells. Because the eye is considered to be an immunologically privileged organ, it is believed that expression of ocular autoantigens occurs exclusively within the intraocular environment (Gery and Streilein, 1994). A classic example of organ-specific autoimmune disease caused by autoantigens is sympathetic ophthalmia, a rare form of intraocular inflammation in which the fellow eye develops inflammation after penetrating injury of the opposite eye. The inflammation may develop as early as several days after

FIGURE 55.6 Fundus photograph with corresponding fluorescein angiogram of a patient with Behcet’s disease and retinal vasculitis. Arrow points to areas of macular retinitis.

the penetrating insult to decades later. Typically, it occurs in the first several weeks (4–12 weeks). It is speculated that the injury causes primary immunization to self-antigens. Although the target antigen is still unknown, an experimental animal model has been developed. In this model cutaneous immunization of animals with retinal antigens (arrestin, rhodopsin, interphotoreceptor retinoid-binding protein), retinal pigment epithelial-associated antigens, and melanocyte-associated tyrosinase results in an autoimmune uveitis, with features characteristic of sympathetic ophthalmia (Rao, 1997). Substantial evidence exists that autoimmune diseases may also be initiated or aggravated by infection. This happens presumably when nonspecific polyclonal activation of the immune system, either by virus or immunostimulatory agents such as Gram-negative bacterial cell wall components, overwhelms the normal regulatory mechanisms and permits “forbidden clones” of cells to proliferate and cause tissue damage. The molecular mimicry theory states that structural similarity between invading organisms and organ tissue components may lead to persistence of the inflammatory response even after the inciting agent has been quickly cleared. This has been postulated as a mechanism for uveitis. The primary amino acid sequence of hepatitis B virus DNA polymerase shows sequence homology to the retinal S-antigen. An experimental autoimmune uveitis was induced in Lewis rats using synthetic peptides (Singh et al., 1990). Lymph nodes cells from rats immunized with this synthetic peptide or peptide M in S-antigen showed a significant degree of cross-reaction. As a clinical corollary, some types of idiopathic posterior uveitis have been reported in association with hepatitis B virus vaccine (Brezin et al., 1995; Baglivo et al., 1996). However, no definitive etiologic link has been made via histopathology or immunohistochemistry.

HORMONAL INFLUENCES

Hormones play a significant role in immunomodulation, yet the exact mechanism is not understood. Certain hormones of pregnancy, such as progesterone, α -fetoprotein, α 2 pregnancy-associated globulin, and early pregnancy factor are thought to have immunomodulating properties (Anon, 1976; Chakraborty and Mandal, 1993; Harness et al., 2003). Other hormones, the levels of which increase during pregnancy, such as corticotrophin-releasing hormone, α -melanocyte stimulating hormone, estrogens, or altered estrogen/androgen ratios, are thought to be immunosuppressive (Lipton and Catania, 1997; Ilias and Mastorakos, 2003). We and other researches have reported that flares of uveitis decrease during pregnancy compared to the nonpregnant state (Rabiah and Vitale, 2003). Many women with chronic recurrent noninfectious uveitis report an association between flares and point in

the menstrual cycle. Further studies are needed to more definitively delineate hormonal influences on uveitis.

GENETIC FACTORS

Genetic factors play a significant role in the development of endogenous uveitis. The ability to respond to a specific immune stimulant is genetically determined. Genes for human leukocyte antigens (HLA) are clustered in major histocompatibility complex (MHC) proteins, located on the short arm of chromosome 6. They have been linked to various uveitic syndromes (Table 55.1).

Brewerton et al. (1973) were among the first to observe that a high percentage of white patients with ankylosing spondylitis showed HLA-B27 positivity. Khan et al. (1977) demonstrated that HLA-B7 was associated with ankylosing spondylitis in African Americans to a greater degree than HLA-B27. It is clear that HLA associations may be different for various ethnic groups. It is possible that different genes initiate responses that finally lead to a common pathway resulting in a particular disease. The reasons for association between HLA and diseases are unclear. It has been hypothesized that exogenous environmental factors may play a role in expression of a disease. For example, it has been suggested that Ia antigens are required for antigen presentation and initiation of the immune response; if Ia expression is inappropriate and other defects of immunosurveillance occur, it may result in a disease (Bottazzo et al., 1983).

Most researchers agree that mechanisms of the autoimmune disease of the eye are multifactorial, so several factors must be present to cause the disease, otherwise disease expression would be far more common. MHC plays an important role in determining disease susceptibility. Family studies in patients with uveitis show that susceptibility to particular types of idiopathic uveitis is possibly due to genetic background (Kimura and Hogan, 1963; Hogan et al., 1965; Giles and Tranton, 1980; Augsburger et al., 1981; Culbertson et al., 1983; Doft, 1983; Wetzig et al., 1988; Duinkerke-Eorela et al., 1990; Tejada et al., 1994; Lee, 1995). Genetic predisposition may determine the severity of the disease. A permissive MHC in a nonpermissive background will result in a mild disease or no disease at all (Caspi et al., 1992).

Single-nucleotide polymorphisms (SNPs) are genetic variations found normally in genes that mediate the immune response as opposed to those that control it. For example, one cytokine may have several SNP variations. Some SNPs may change the functioning of the protein. Population studies of disease groups versus controls are able to identify SNPs more commonly seen in disease groups and thus are associated with these particular autoimmune or neoplastic diseases (Shastry, 2002). A report of 102 patients with ocular Behcet’s disease, who were

TABLE 55.1 Association of Selected Ocular Disease with Human Leukocyte Antigens

| Human Leukocyte Antigen | Ocular Disease |
|-------------------------|---|
| HLA-A11 | Sympathetic ophthalmia |
| HLA-A24 | Tubulointerstitial nephritis—uveitis syndrome |
| HLA-A29 | Birdshot retinochoroidopathy |
| HLA-B5 | Adamantiades—Behcet's disease |
| HLA-B7 | Presumed ocular histoplasmosis |
| | Serpiginous retinochoroidopathy |
| | Acute posterior multifocal placoid epitheliopathy |
| | Ankylosing spondylitis |
| HLA-B8 | Acute anterior uveitis |
| HLA-B12 | Ocular cicatricial pemphigoid |
| HLA-B27 | Acute anterior uveitis |
| | Reiter syndrome |
| HLA-B51 | Adamantiades—Behcet's disease |
| HLA-DQw3 | Vogt—Koyanagi—Harada (VKH) syndrome |
| HLA-DR2 | Presumed ocular histoplasmosis |
| HLA-DR4 | Rheumatoid arthritis |
| | Vogt—Koyanagi—Harada (VKH) syndrome |
| | Relapsing polychondritis |
| HLA-DR6 | Tubulointerstitial nephritis—uveitis syndrome |
| HLA-DR15 | Intermediate uveitis |
| | Multiple sclerosis |
| HLA-DRB1 | Sarcoidosis |
| HLA-DRB1*0405 | Sympathetic ophthalmia |
| HLA-DRw53 | Vogt—Koyanagi—Harada (VKH) syndrome |

tested for a possible link between a specific tumor necrosis factor (TNF) SNP and the disease, found no TNF gene polymorphisms to be associated with the disease (Verity et al., 1999).

ANIMAL MODELS

Several species of mammals have been used to establish experimental autoimmune uveitis (EAU) models, including guinea pigs (Collins, 1949; Kalsow and Wacker, 1973),

rabbits (Wacker and Lipton, 1968), rats (Faure 1980; de Kozak et al., 1981; Gery and Nussenblatt, 1986), mice (Caspi et al., 1988), and primates (Nussenblatt et al., 1981). Currently, mice and rats are probably the two most commonly used animals for EAU studies due to the availability of inbred and other genetically-modified strains, such as gene knockout or transgenic animals. Typically, uveitogenic antigens such as S-antigen, interphotoreceptor retinoid-binding protein (IRBP), retinal pigment epithelium-specific 65 kDa protein (RPE65), or crude extract of retina/uvea are emulsified with complete Freund's adjuvant (CFA) and injected subcutaneously into the animals ("active immunization"). Coinjection of pertussis toxin intravenously or intraperitoneally has been routinely administered to achieve maximum EAU score. EAU can also be induced by adoptively transferring primary T cells from diseased animals with active EAU or uveitogenic cell lines to syngeneic normal recipients. EAU induced by adoptive transfer typically has a shortened clinical course because of the lack of an induction phase compared to the active immunization protocol.

It is noteworthy that despite the fact that both rat and mouse EAU models have been extensively used for studying molecular mechanisms of uveitis, the clinical manifestations of the two models differ. Murine EAU seems to be less acute than rat EAU, with a later onset and longer duration. In addition, pathologic changes in murine EAU primarily involve the posterior segment with little anterior segment involvement, while rat EAU usually manifests inflammation in both anterior and posterior segments (Gery and Nussenblatt, 1986; Caspi et al., 1988). Although it was shown that passive transfer of immune serum from humans induced ocular retinitis in guinea pigs (de Kozak et al., 1976) and there is evidence of involvement of humoral immunity in EAU (Faure 1980; Gery and Nussenblatt, 1986), humoral immune response-mediated uveitis animal models have not been widely reported or used.

PATHOGENIC MECHANISMS

The establishment of extensive studies using EAU models has greatly facilitated the understanding of autoimmune uveitis. Despite some evidence of the involvement of humoral immunity (Faure 1980; Gery and Nussenblatt, 1986), cellular immunity is primarily responsible for the disease (Nussenblatt et al., 1980a,b; Gery and Nussenblatt, 1986; Caspi et al., 1986; Nussenblatt, 1987). The majority of data support the notion that helper T cells (Th) are the key players in the molecular pathogenesis of EAU models (Caspi, 1999). While the Th1 subset has been shown to play the predominant role, accumulated data also point to a role of the Th2 subset (Caspi, 2002; Kim et al., 2002). In addition, the pertussis toxin, an adjuvant routinely administered to maximize induction of

EAU, has been shown to block the induction of EAU by adoptive transfer (Su et al., 2001) underscoring a delicate balance of the immune system in this disease setting. Although limited, some data have also suggested an important role of immunosuppressive T regulatory (Tregs) and/or cytokines in EAU. Tregs were shown to be reduced in patients with active disease compared with inactive disease (Yeh et al., 2009). Coadministration of interleukin (IL)-2 could potentiate induction of oral tolerance by IRBP, accompanied by increased levels of IL-10, IL-4, and TGF- β (Rizzo et al., 1994). Induced tolerance to S-antigen after intratesticular injection of S-antigen into the Lewis rat was shown to be associated with the induction of regulatory T cells capable of secreting immunosuppressive cytokines such as IL-4, IL-10, and TGF- β (Yotsukura et al., 1997). An immunosuppressive neuropeptide believed to be associated with immune privilege of the eye, α -melanocyte-stimulating hormone, was shown to induce CD4⁺CD25⁺ Tregs.

Besides T cells, other immune cells have also been investigated for their roles in the pathogenesis of EAU. For example, dendritic cells and macrophages have been shown to be important in EAU induction and tissue destruction (Jiang et al., 1999). In addition, natural killer (NK) cells and natural killer T (NKT) cells have also been implicated in the pathogenesis of EAU. One report suggested that NK cells might play a detrimental role in EAU (Kitaichi et al., 2002), while another study showed increased NK and NKT cells in association with interferon (IFN)- β amelioration of EAU (Suzuki et al., 2002). Nonetheless, the data point to potential roles for other cellular components of the immune system that could be critical in the pathogenesis of EAU.

Ocular Immune Responses

The ocular immune system is thought to have an innate set of mechanisms for “effector blockade” that protects the ocular tissue from the destructive effects of the secondary effector phase of the immune response arc. This blockade in the anterior chamber is known as anterior chamber-associated immune deviation (ACAID), where immunization by an anterior chamber injection in experimental animals results in an altered form of systemic immunity to that antigen (Streilein, 1993, 1997; Streilein-Stein and Streilein, 2002). The eye also has soluble and membrane-bound inhibitors, such as CD178 (FasL), which can induce apoptosis (Green and Ferguson, 2001). Additionally, the eye appears to have an immunosuppressive microenvironment of chemokines and cytokines (Granstein et al., 1990; Foxman et al., 2002). Finally, it is believed that a state of tolerance can be induced in the eye (Ferguson and Griffiths, 1997; Ferguson et al., 2002).

Tissue Destruction

During ocular inflammatory processes, there is an influx of T cells, B cells, macrophages, and polymorphonuclear leukocytes (PMNs) into the choroid, choriocapillaris, and retina. There is also local synthesis of cytokines by ocular tissue. These changes in the ocular milieu most likely contribute to the ocular tissue damage seen clinically and experimentally. The underlying pathogenesis depends on the disease process involved and thus will vary. Immunohistopathology in ocular sarcoidosis shows a predominance of lymphocytes and macrophages (Chan et al., 1987), while ocular Behcet’s disease revealed predominantly lymphocytic infiltration, with some B cells and plasma cells (George et al., 1997). These reports indicate that cell-mediated immunity may play a pivotal role, while others have reported humoral-mediated immunity and also the involvement of immune complex formation (Reinsh and Moyer, 1991).

Macrophages are reported to be important effector cells for retinal tissue destruction in the animal model (Forrester et al., 1998). However, the macrophage-mediated retinal tissue destruction is probably under the control of antigen-specific T cells and the cytokines that T cells release (Jiang et al., 1999). TNF- α is a well-known cytokine capable of tissue destruction either by direct tissue damage or by induction of apoptosis (Selmaj et al., 1991; Zheng et al., 1995), but other factors such as free radicals, e.g., nitric oxide, could also contribute to inflammation-induced retinal damage (Hoey et al., 1997).

IMMUNOLOGIC MARKERS

Recent advances have demonstrated that cytokines are equally important in the pathogenesis of noninfectious uveitis. The Th1 types of cytokines, such as IFN- γ , IL-2, TNF- α , and IL-12, are considered to be the primary factors in the pathogenesis of uveitis. In humans, IFN- γ and IL-2 were found to be elevated in ocular tissues with concomitant infiltrating T cells in uveitic patients (Hooks et al., 1988). IL-6 has been shown to be elevated in the aqueous humor of patients with noninfectious uveitis (Murray et al., 1990; Franks et al., 1992). Higher levels of TNF- α and IL-1 have also been demonstrated in both peripheral sera and aqueous humor samples (Palexas et al., 1992; Sakaguchi et al., 1998). Cytokine profile analysis of peripheral T cells from uveitic patients suggested that the intracellular level of IFN- γ was increased (Frassanito et al., 2003), but similar analysis of T cells derived from aqueous humor samples showed decreased IFN- γ compared to those from peripheral blood (Hill et al., 2005). Recent interest has surrounded the role of Th17/IL-17, which is believed to play a role in chronic

inflammation whereas Th1 drives the early pathogenic response (Hoyer et al., 2009).

Data derived from animal EAU studies, however, have provided more consistent insights into the molecular mechanisms of autoimmune uveitis. TNF- α was shown to be detrimental to the development of EAU (Nakamura et al., 1994; Dick et al., 1996; Robertson et al., 2003), while IL-10 and IL-12 were suggested to be protective to the development of EAU (Rizzo et al., 1998; Tarrant et al., 1999). Consistent with findings in humans, IFN- γ was also found in the ocular tissues of EAU animals, and correlated with the disease course (Charteris and Lightman, 1992). However, treatment with anti-IFN- γ antibody exacerbated EAU, while treatment with rIFN- γ ameliorated the diseases in a murine EAU model (Caspi et al., 1994), leading investigators to conclude that endogenous IFN- γ was protective for EAU. The same investigators also showed that IFN- γ gene deficient mice developed EAU similar to their wild-type littermates, suggesting that IFN- γ is not necessary for the development of EAU (Jones et al., 1997). To further complicate the issue, an independent study using IFN- γ transgenic rats showed that overexpression of IFN- γ resulted in more severe EAU (Egwuagu et al., 1999). These studies underscore the complexity of cytokine networks in the pathogenesis of EAU.

TREATMENT AND OUTCOMES

Corticosteroids have been the mainstay of therapy for ocular inflammatory disease since the early 1950s. Both systemic (oral, intravenous) and local (topical, periocular, intravitreal) formulations are available. In addition, steroid implants (fluocinolone acetonide (Retisert™) and dexamethasone (Ozurdex™)) have recently become popular choices as both adjuvant and monotherapy. They offer the benefit of sustained corticosteroid delivery to the eye while avoiding systemic complications (Larson et al., 2011).

Some diseases are steroid resistant and for others long-term steroid therapy carries the risk of developing unacceptable systemic side effects. For these patients other immunomodulatory agents need to be added as a steroid-sparing agent. Steroid-sparing agents include alkylating agents (cyclophosphamide, chlorambucil), antimetabolites (azathioprine, methotrexate, mycophenolate mofetil), cyclosporine, tacrolimus, rapamycin, antibodies, and monoclonal antibodies (daclizumab, etanercept, infliximab, adalimumab, rituximab).

Antibodies and monoclonal antibodies directed against various parts of the immune cascade represent the new era of immunomodulation through the ability to interfere with specific molecules or pathways based on our understanding of the inflammatory process (Heiligenhaus et al.,

2010; Larson et al., 2011). Daclizumab is a humanized anti-Tac monoclonal recombinant antibody. Tac is a subunit of the IL-2 receptor (IL-2R) high-affinity complex. Caspi et al. (1986) demonstrated the presence of high-affinity IL-2Rs in animal models of uveitis. It was used safely and effectively in the treatment of intermediate and posterior uveitis in adults and children, as well as active JIA-associated anterior uveitis (Yeh et al., 2008; Sen et al., 2009). However, it was pulled from the market in 2009 due to insufficient market demand (Smith et al., 2012).

TNF- α is found during the acute phase of experimental autoimmune uveoretinitis (Kim et al., 2001). Etanercept is a TNF fusion protein that binds to and inactivates TNF, while infliximab is a chimeric monoclonal antibody directed against TNF- α , and adalimumab is fully humanized monoclonal IgG1 antibody against TNF- α . Etanercept was found to be effective in some systemic diseases; however, a review of multiple case series showed new onset of uveitis in previously unaffected rheumatologic patients (Smith et al., 2012). As a result, etanercept is not used in uveitis. Infliximab has been demonstrated to be effective in several clinical studies in reducing ocular inflammation. Suhler et al. (2009) reported successful control of inflammation within 10 weeks of initiating treatment in approximately 75% of patients with refractory uveitides including idiopathic, sarcoidosis, Behcet's disease-associated uveitis, and bird-shot retinochoroidopathy. Adalimumab has also been effective for the treatment of several autoimmune diseases including rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, juvenile idiopathic arthritis, and Crohn's disease (Smith et al., 2012). Rituximab is a chimeric anti-CD20 monoclonal antibody which targets CD20, a surface antigen expressed on pre-B and mature B cells. It has demonstrated success in rheumatoid arthritis, systemic lupus erythematosus, and Wegener's-associated scleritis (Smith et al., 2012).

In our treatment approach cytotoxic agents are often used last, after corticosteroids, cyclosporine, and monoclonal antibodies, for sight-threatening intraocular inflammation. Other less widely used therapeutic modalities include intravenous immunoglobulin therapy, oral tolerance plasmapheresis, and IFN- α . In addition, nonsteroidal anti-inflammatory agents have been used for specific diseases; however, they have not been shown to be effective as a sole agent in the treatment of noninfectious uveitis.

In general, the following therapeutic guidelines can be used:

- Topical corticosteroids for anterior segment disease.
- Periocular corticosteroids for unilateral disease, the presence of intermediate or posterior complications, and in select childhood uveitis to avoid systemic complications of corticosteroids.

- Systemic immunosuppressive agents for bilateral, sight-threatening intermediate uveitis, posterior uveitis, or panuveitis. Biological immunomodulatory therapy for those who fail (or are intolerant of) standard immunosuppressive therapy.
- Consideration of corticosteroid implants for unilateral disease, contraindication or intolerance to standard agents, or multiple systemic comorbidities which limit the use of systemic immunosuppressive therapy.
- Reserving cytotoxic agents for therapeutic failures.
- For uveitis associated with infectious etiologies, specific agents are indicated, including antivirals and antitoxoplasmosis therapy.

CONCLUDING REMARKS AND FUTURE PROSPECTS

We have learned a great deal since the advent of steroids for uveitis in the early 1950s. Most therapies during the 20th century tended to be monotherapy, and combination therapy only began to be used more frequently during the 1990s. Concerns about the side effects of steroids, i.e., osteoporosis, came to the attention of treating physicians relatively early, as did the goals for therapy, including long-term approaches that reduced secondary effects. Because of this the use of local therapy, including intra-ocular therapy, whether by injection or a time-released device, has become more popular. So where will we be going in the 21st century? Some of the possibilities include pharmacogenetics study of variability in drug responses attributed to hereditary factors in different populations; pharmacogenomics determination and analysis of the genome and its products (RNA and proteins) as they relate to drug response; evaluation of patient genomes to identify which patients are the best candidates for a specific therapy; and finally, using cytokines or other biomarkers as a marker for inflammation, as potential therapeutic targets, and to determine the true level of immunologic quiescence in chronic uveitis.

INTRODUCTION

The hypothesis that a syndrome of sensorineural hearing loss (SNHL) often accompanied by vestibular symptoms might be of autoimmune origin was first proposed by McCabe (1979), who based his findings on clinical features, presence of abnormal immunological tests, and a positive response to immunosuppressive therapy. Since then, a number of syndromes characterized by SNHL with overlapping clinical features have been described and termed in different ways: autoimmune SNHL, immune-mediated inner ear disease (IMIED), idiopathic progressive bilateral SNHL, sudden SNHL, idiopathic SNHL, bilateral immune-mediated Ménière's disease, and autoimmune vestibulo-cochlear disorders (Rahman et al., 2001a), generating a great confusion in the identification of patients and in the evaluation of different studies. SNHL in adult patients remains idiopathic in the vast majority of cases (71%); known causes are viral infections (12.8%), inner ear abnormality (4.7%), trauma (4.2%), vascular or hematologic (2.8%), neoplastic (2.3%), and CNS abnormality (Chau et al., 2010). In a series of children with idiopathic SNHL, Berti et al. confirmed an autoimmune origin in the majority of the cases included in the study (manuscript submitted).

It is still debated whether we can define “autoimmune” in the majority of cases of SNHL without any apparent cause (Greco et al., 2011). Although most of the

authors in the field refer to these cases as “autoimmune inner ear disease (AIED)” or “autoimmune sensorineural hearing loss (ASHL)” (Solares et al., 2003; Mathews and Kumar, 2003), we and others (Stone and Francis, 2000; García-Berrocal et al., 2003) still prefer the definition of IMIED, since an autoimmune process cannot always be identified. Immune-mediated inner ear disease may be a process confined to the inner ear, and antibodies against a vast array of different molecular weight inner ear antigens may be found in a percentage of these patients; in this case the process can be identified as an organ-specific autoimmune disease. In other cases, IMIED is a feature of a systemic disorder such as primary vasculitides or of systemic autoimmune diseases. Indeed a systemic autoimmune disorder can be present in one-third of the patients with IMIED.

CLINICAL FEATURES

Immune-mediated inner ear disease is characterized by the presence of rapidly progressive, often bilateral SNHL, and frequently by vertigo, tinnitus, and a sense of aural fullness, sometimes indistinguishable from Ménière's disease at the beginning. Immune-mediated inner ear disease usually leads to irreversible damage within hours or days from the onset and involves both ears often asynchronously. Sometimes the disease shows an initial fluctuating

course of remissions and relapses typical of an autoimmune disease. Since the devastating sequelae of IMIED may be avoided with the early institution of aggressive immunosuppression, a prompt diagnosis represents a major goal for the clinician. Indeed the clinical manifestations are shared with entities of different etiologies such as vascular, toxic, metabolic, genetic, traumatic, and infective (Beyea et al., 2012; Massimo et al., 2012; Yariz et al., 2012; Abdelfatah et al., 2013; Gao et al., 2013; Lin et al., 2013). Therefore all the possible non-immune-mediated causes of SNHL need to be excluded. Overall, the incidence of SNHL has been estimated to range from five to 20 per 100,000 subjects per year (Chau et al., 2010).

Ménière's syndrome, characterized by hearing loss and episodes of vertigo, tinnitus, and aural fullness, may accompany several causes of inner ear inflammation, including IMIED. In the absence of an identifiable cause, usually viral, this syndrome is termed Ménière's disease, considered of autoimmune origin at least in 30–40% of the cases although the immunological mechanisms involved are not clear (Riente et al., 2004; Greco et al., 2012). Time course is the most important criterion to differentiate IMIED from Ménière's disease where hearing loss occurs over a long period of time, sometimes several years. Moreover, Ménière's disease is usually limited to one ear in the majority of the cases.

Due to the many different etiologies which can lead to SNHL and to the absence of specific diagnostic markers, García-Berrocal and Ramírez-Camacho (2002a) proposed the following criteria to correctly assess IMIED as a distinct entity:

1. Major criteria: bilateral involvement, presence of systemic autoimmune disease, positive antinuclear antibodies (ANA), reduced number of naïve T cells (CD4RA) and recovery of hearing >80%.
2. Minor criteria: unilateral involvement, young/middle-aged patient, often female, presence of antibodies against heat shock protein70 (HSP70) and good response to steroid therapy.

The suspicion of IMIED would be supported by the presence of three major criteria or two major and more than two minor criteria. The same authors (in 2003) used these criteria to characterize and evaluate the response to therapy of 69 patients with recent onset SNHL of different origin such as viral, vascular, immune mediated, and idiopathic. Patients with IMIED had the best and the earliest recovery rate of hearing after therapy, but also a higher rate of recurrence, typical of an autoimmune disorder. However, profound hearing loss (>90 dB) presents a low percentage of recoveries, regardless of the etiology. The criteria proposed by García-Berrocal et al. still need to be validated by different groups in a greater number of patients. In particular, we think that the presence not only

of ANA but also of other autoantibodies such as anticardiolipin antibodies, antithyroid antibodies, rheumatoid factor, or myeloperoxidase-antineutrophil cytoplasmic antibodies (Takagi et al., 2004; Toubi et al., 2004; Bachor et al., 2005) may suggest the presence of an autoimmune aggression of the inner ear. Moreover we believe that a positive therapeutic response to corticosteroid administration should be considered a major criterion for the diagnosis of IMIED (Ruckenstein, 2004; Gallo et al., 2013).

Due to the lack of a reliable diagnostic tests (Bovo et al., 2009), MRI–PET of the inner ear, in association with anti-HSP70 antibody determination, had been proposed as a useful technique for assessing IMIED (Mazlumzadeh et al., 2003).

However, the utility of the determination of anti-HSP70 antibodies is still unclear and they are no more frequent in Ménière's disease compared to healthy controls; moreover, the presence of such autoantibodies was not correlated with bilateral disease, activity, or stage of the disease (Hornibrook et al., 2011).

IMIED Associated with Systemic Autoimmune Diseases

Hearing loss, both sensorineural and conductive, has been reported in patients with rheumatoid arthritis (Raut et al., 2001; Ozcan et al., 2002; Salvinelli et al., 2004), with psoriatic arthritis (Giani et al., 2006), and with primary Sjögren's syndrome (Boki et al., 2001). Anticardiolipin antibodies have been found associated with the presence of SNHL in patients with Sjögren's syndrome (Tumiati et al., 1997; Tucci et al., 2005) and with systemic lupus erythematosus (SLE) (Naarendorp and Spiera, 1998; Green and Miller, 2001; Kastanioudakis et al., 2002; Batueca-Caletrio et al., 2013). Moreover SNHL can be present in patients with primary antiphospholipid syndrome (Vyse et al., 1994; Chapman et al., 2003). The histopathologic features of temporal bone described in subjects affected by SLE showed various degrees of hair cell loss and atrophy of the organ of Corti, marked cochlear inflammatory infiltrate or formation of fibrous tissue and new bone throughout the cochlea, and degeneration of the spiral ligament, findings very similar to the known features of IMIED (Sone et al., 1999).

Similarly, the histopathology in four patients with Sjögren's syndrome showed severe loss of intermediate cells of stria vascularis and immunoglobulin G deposition on the basement membrane of stria vascularis blood vessels. These pathologic changes are very similar to the inner ear histology found in a mouse model of Sjögren's syndrome (Calzada et al., 2012a).

Sensorineural hearing loss has also been reported in progressive systemic sclerosis (Kastanioudakis et al.,

2001) and in ulcerative colitis (Kumar et al., 2000). Granulomatous inner ear disease has been described in Crohn's disease (Dettmer et al., 2011).

Finally, Ménière's disease displays an elevated prevalence of systemic autoimmune diseases such as RA, SLE, and ankylosis spondylitis (Gazquez et al., 2011).

In conclusion, the presence of a systemic autoimmune disease needs always to be ruled out in SNHL (Mijovic et al., 2013).

IMIED Associated with Primary Vasculitides

Sensorineural hearing loss is often an early symptom of primary vasculitides, which usually affect both the middle and the inner ear. The best example is granulomatosis with polyangiitis, previously known as Wegener's granulomatosis (Kempf et al., 1989; Takagi et al., 2002), characterized by chronic otitis media leading to conductive hearing loss; SNHL is often associated and is related to vasculitis of the inner ear. Similar findings may be present in patients with relapsing polychondritis (Malard et al., 2002), characterized by vasculitis of the labyrinthine artery and inflammation of the cartilage within the inner ear. Sensorineural hearing loss has been described in polyarteritis nodosa (Tsunoda et al., 2001), microscopic polyangiitis (Koseki et al., 1997), Behcet's disease (Adler et al., 2002), and Kawasaki disease (Silva et al., 2002).

Cogan's Syndrome

Cogan's syndrome is a rare chronic inflammatory disease characterized by three main clinical features: vestibulo-auditory dysfunction, interstitial keratitis, and vasculitis (St. Clair and McCallum, 1999; Greco et al., 2013). It occurs primarily in children and young adults and was first described by Cogan in 1945. Systemic manifestations occur in approximately half of the cases (Van Doornum et al., 2001); fever and weight loss are associated with active vasculitis which can involve the aorta, aortic arch vessels, or medium vessels (Vollersten, 1990; Weissen-Plenz et al., 2010; Branislava et al., 2011). Central and peripheral nervous system abnormalities may be present in up to 50% of the subjects (Bicknell and Holland, 1978; Albayram et al., 2001).

Morbidity in Cogan's syndrome results from permanent hearing loss and from cardiovascular disease.

Inner ear pathology reveals endolymphatic hydrops, infiltration of the spiral ligament with lymphocytes and plasma cells, degeneration of the sensory receptors and supporting structures of the cochlea and vestibular apparatus, and demyelination and atrophy of the vestibular and cochlear branches of the eighth cranial nerve. In some cases extensive new bone formation can be observed.

The cause of the disease is unknown; upper respiratory tract infections may precede the onset of the disease, suggesting an infectious origin (Vollertsen et al., 1986). Autoimmunity has been implicated because of the presence of serum antibodies to a mixture of corneal antigens and inner ear extracts (Disher et al., 1997; Helmchen et al., 1999). In a few cases, anti-neutrophil cytoplasmic autoantibodies (ANCA) have been reported.

We have demonstrated that Cogan's syndrome is an autoimmune disease and that DEP1/CD148 is the pathogenetically relevant autoantigen (Lunardi et al., 2002). Using the peptide library approach (Puccetti and Lunardi, 2010), already applied to the study of systemic sclerosis (Lunardi et al., 2000), we identified a peptide recognized by the sera of all the patients. The peptide shares homology with autoantigens and with the major core protein lambda 1 (Bartlett and Joklik, 1988) of reovirus type III, which causes mild rhinitis and pharyngitis. Peptide-specific IgG antibodies isolated from patients' sera recognized the viral protein, suggesting a viral involvement in the pathogenesis of the disease, possibly through a molecular mimicry mechanism (Zhao et al., 1998).

The peptide showed homology with the high cell density enhanced protein tyrosine phosphatase-1 (DEP-1/CD148), which is highly expressed on both endothelial cells (Takahashi et al., 1999) and supporting cells of the inner ear (Kruger et al., 1999) and with connexin-26, a gap-junction protein expressed in the inner ear (Kikuchi et al., 2000). Affinity-purified antibodies against the peptide obtained from the patients recognized CD148 and connexin-26 in human cochlear extracts. DEP1/CD148 is a widespread cell-surface antigen and its distribution explains the clinical spectrum of Cogan's syndrome. Connexin-26 represents a major system of intercellular communication and its loss results in local intoxication of the Corti organ, leading to hearing loss; moreover mutations at the connexin-26 gene are responsible for the majority of congenital deafness. Connexin-26 shows homology with connexin-43 and connexin-50, gap-junction proteins present in corneal fibroblasts and epithelium and this homology may explain the eye involvement in the disease. Peptide-specific antibodies bind human cochlea by immunohistochemistry (Figure 56.1A, B).

To prove that these autoantibodies are pathogenic and that the identified autoantigen is relevant to Cogan's syndrome we induced the clinical features of the disease in animals (Balb/c mice and rabbits NZW) following either passive transfer of peptide-specific autoantibodies or active immunization with autoantigen peptides. The animal developed hearing loss as assessed by auditory brainstem responses evaluation (Figure 56.2).

We have so far tested many patients with Cogan's syndrome and with idiopathic SNHL for the presence of antibodies directed against the Cogan peptide, DEP-1/CD148,

FIGURE 56.1 Antibodies against the Cogan peptide bind human cochlea. Human cochlea immunostained with antibodies purified against an irrelevant peptide (negative control (A)) and with antibodies purified against the Cogan peptide (higher magnitude, (B)). FIGURE 56.2 Grand average of auditory brainstem responses (ABRs) obtained from the same six mice before (upper trace) and 1 week after (lower trace) the third injection of purified antibodies directed against the Cogan peptide. A higher stimulus intensity (80 versus 35 dB) was needed to obtain much smaller and delayed responses (lower trace), consistent with hearing loss. The traces shown were obtained with above-threshold stimuli in order to clearly identify the single components. The delay of waves II, III, and IV suggests an impaired transmission along the auditory pathway from the acoustic nerve to the midbrain. Data represent amplitude of the response in microvolts (μV) (vertical axis); time elapsed from stimulus in milliseconds (horizontal axis). The time of stimulus delivery (click) is coincident with the 0 of the horizontal axis; no pre-stimulus baseline is shown. Reprinted with permission from Elsevier; *The Lancet*, 2002, 360, 915–921.

reovirus, and connexin-26 peptides in order to define the specificity and the sensitivity of the test. We consider positive those patients who have at least two antibodies directed against the four peptides, and one of the

two positivities needs to be either anti-Cogan peptide or anti-DEP1/CD148 antibodies. Interestingly, antibodies against Cogan peptide and DEP1/CD148 have been found also in patients diagnosed as affected by autoimmune SNHL.

EVIDENCE OF AUTOIMMUNITY

Autoantibodies and autoreactive T cells have been implicated in the etiopathogenesis of idiopathic SNHL (Yehudai et al., 2006). Different antibodies directed either against inner ear-specific or widely distributed autoantigens have been described in patients with SNHL of unknown origin. Antibodies against type II and type IX collagens as well as against other autoantigens in patients with Ménière's disease and with IMIED have been reported (Yoo et al., 2002). The Kresge Hearing Research Institute-3 (KHRI-3) antibody binds to guinea pig inner ear supporting cell antigen which has been found to be homologous to the human choline transporter-like protein 2, expressed in the inner ear, making this protein a possible target for autoimmune aggression in IMIED (Nair et al., 2004). Anti-endothelial cell autoantibodies have been reported in some patients with SNHL and may represent a marker of vasculitis or vascular damage of inner ear which leads to leukocyte infiltration and local immunoglobulin production (Cadoni et al., 2002; Mathews and Kumar, 2003). The detection of antibodies against the myelin protein P0 (30 kDa) has given conflicting results (Passali et al., 2004; Pham et al., 2007). Besides

TABLE 56.1 Putative Autoantigen Targets in IMIED and Cogan's Syndrome

| | Molecular Weight | Ref. | Induces Hearing Loss in Animals | Ref. |
|-------------------------|------------------|---|---------------------------------|--------------------------|
| IMIED | | | | |
| Collagen type II | | Yoo et al. (2002) | No | Harris et al. (1986) |
| Collagen type IX | | Yoo et al. (2002) | ? | — |
| Myelin protein P0 | 30 kDa | Boulassel et al. (2001a) | No | Boulassel et al. (2001a) |
| Beta actin | 42 kDa | Boulassel et al. (2001a) | ? | — |
| HSP-70 | 68 kDa | Billings et al. (1995) Bloch et al. (1999) | No | Billings et al. (1998) |
| Cochlin | 58 kDa | Boulassel et al. (2001b) | Yes | Solares et al. (2004) |
| Beta tectorin | 43 kDa | Boulassel et al. (2001b) | Yes | Solares et al. (2004) |
| Beta tubulin | 55 kDa | Zhou et al. (2011a) | Yes | Zhou et al. (2011a) |
| CTL2 | 68–72 kDa | Kommareddi et al. (2009) | ? | — |
