Anticardiolipin assays may detect antibodies directed against oxidized lipids. The fatty acid chains of cardiolipin purified from natural sources are readily oxidizable, and some oxidation is likely under the conditions used in anticardiolipin ELISAs (Hörkkö et al., 1997). Some reports suggest a cross-reactivity between anticardiolipin antibodies and antibodies to oxidized lipoproteins (the latter are thought to play a role in the pathophysiology of atherosclerosis) (Hörkkö et al., 1996). However, β2GPI, binds covalently to certain oxidized phospholipids (Kobayashi et al., 2001) confounding this interpretation.

Cell Surface Proteins

Antiplatelet and anti-endothelial cell antibodies have been detected in patients with APS (Harris et al., 1985; Jouhikainen et al., 1990). The relationship of these autoantibodies to those detected in LA and anticardiolipin assays is not entirely clear. In some cases, antibody binding to endothelial cells (Del Papa, et al. 1995; Simantov et al., 1995) and to platelets (Shi et al., 1993) is dependent upon β2GPI, which may bind to these cells via membrane phospholipids; however, several cell surface receptors have been implicated, e.g., annexin A2 on endothelial cells (Ma et al.,

2000) and the apolipoprotein E receptor 2′ on platelets (Lutters et al., 2003).

Cellular Autoimmunity

Until recently relatively little was known about the cellular autoimmune response in APS. Initial reports on T-cell reactivity towards β2GPI differed significantly among research groups (Visvanathan and McNeil, 1999; Hattori et al., 2000; Ito et al., 2000). Subsequently, consistent data from Kuwana and colleagues suggest that β2GPI-reactive $CD4^+$ cells are present in both normal individuals and APS patients, but activated *in vivo* only the latter (Hattori et al., 2000; Kuwana, 2004). These cells preferentially recognize peptides that include amino acids 276–290 (which encompasses the major phospholipid-binding site) in the context of DR53 (Arai et al., 2001), and preferential usage of $V\beta7^+$ and $V\beta8^+$ T-cell receptors (Yoshida et al., 2002). Interestingly, antigen-presenting cells pulsed with phospholipid-bound β2GPI, but not with phospholipid or β2GPI alone, stimulated p276–290-specific $CD4^+$ T-cell lines generated from the APS patients (Kuwana et al., 2004). This continues to be an exciting area for future research.

GENETIC FEATURES

Familial occurrences of APS have been reported by several groups. Goel et al. studied seven families, in which 30 of 101 family members met diagnostic criteria for APS (Goel et al., 1999) . Segregation analysis strongly supported a genetic basis for the disease that was best explained by a dominant or co-dominant model. Interestingly, in these families APS was not linked with HLA genes.

At least a dozen studies have investigated the HLA associations of aPL and APS (Domenico et al., 2003). Data from these studies are briefly summarized in Table 30.1.

There are a number of polymorphisms of β2GPI, and several groups have investigated whether these are associated with anti-β2GPI antibodies and APS. The valine/

leucine polymorphism at position 247 has been the focus of several reports (Atsumi et al., 1999; Hirose et al., 1999; Camilleri et al., 2003; Prieto et al., 2003). An increased frequency of valine at this position was found in white patients with primary APS and anti-β2GPI antibodies (Atsumi et al., 1999). Hirose et al. studied this polymorphism in APS patients and healthy controls of various racial backgrounds (Hirose et al., 1999). Among controls, the valine allele and the valine/valine genotype were more common in white than in African-American or Asian patients. There were no significant differences in allele or genotype frequencies between white or African-American patients and racially matched controls. In contrast, the valine allele and valine/valine genotype were significantly more frequent among Asian APS patients with anti-β2GPI antibodies than among Asian controls. In a relatively small group of Mexican patients with primary APS, the valine allele and valine/valine genotype were associated with anti-β2GPI antibodies (Prieto et al., 2003). Another study, however, found no association of this polymorphism with aPL in a white patient population (Camilleri et al., 2003). Two polymorphisms in the fifth domain of β2GPI, at codons 306 and 316, affect phospholipid binding (Sanghera et al., 1997), and β2GPI from homozygotes with either mutation or the compound heterozygote does not bind to anionic phospholipids. Data on whether either of these polymorphisms offers protection against developing aPL and APS are equivocal (Gushiken et al. 1999; Kamboh et al. 1999).

ANIMAL MODELS

Animal models of APS are important tools for investigating the cellular basis of the autoimmune response, the contribution of genetic factors, and mechanisms by which aPL contribute to thrombosis and pregnancy loss (Radway-Bright et al., 1999).

The MRL/lpr and NZW × BXSB F1 strains of autoimmune mice are putative spontaneous models of APS (Smith et al. 1990; Hashimoto et al., 1992). Although MRL/lpr mice have antibodies detectable in anticardiolipin assays, the exact nature of these anticardiolipin antibodies is controversial. Stroke, decreased fecundity, and thrombocytopenia have been reported in these animals. NZW × BXSB F1 mice develop true anti-β2GPI autoantibodies (Monestier et al., 1996). In addition to features of lupus, these mice develop a degenerative coronary vasculopathy with myocardial infarction.

Induced animal models of APS include passive transfer of antibodies and various forms of active immunization. Passive transfer models evaluate the short-term effects of antibodies on coagulation and/or pregnancy in recipient animals. Pierangeli and colleagues have used this model extensively to examine the effects of a "pinch" injury to an isolated blood vessel on thrombus size and kinetics (Pierangeli et al., 1994), and to study leukocyte adhesion in the microvasculature (Pierangeli et al., 2001). Active immunization models can be divided into two groups based on the nature of the immunizing agent—APS-associated antigens and aPL. Experiments in which normal mice are immunized with APS-associated antigens generally confirm the observation that phospholipids themselves are poor antigens. In contrast, immunization with heterologous (human) β2GPI and an adjuvant induces an initial antibody to respond to the foreign protein. Over time tolerance is broken with the development of anti-murine β2GPI autoantibodies (Tincani et al., 2002). Mice immunized with human β2GPI develop clinical features of APS in approximate temporal association with the appearance of autoreactive anti-murine β2GPI antibodies (Blank et al., 1994). Immunization of mice with heterologous β2GPI bound to apoptotic cells, in the absence of adjuvant, also breaks tolerance (Levine et al., 1998). The second type of active immunization model has been developed by Shoenfeld and colleagues (Blank et al., 1991). This is an idiotype/anti-idiotype model in which mice immunized with an anti-cardiolipin (anti-β2GPI) antibody produce antibodies of the same specificity (an anti-anti-Id response). While this model may be useful for studying antibody effects, it is not known whether it is relevant to the immunopathogenesis of human APS.

PATHOGENIC MECHANISMS

It is widely hypothesized that aPL play a direct role in the pathogenesis of APS, contributing to hypercoagulability and possibly other mechanisms. This hypothesis is generally supported by the association of aPL titer with the risk of developing clinical manifestations of APS (Harris et al., 1986; Ginsburg et al., 1992), and by the passive-transfer animal models described above (Branch et al., 1990; Blank et al., 1991; Pierangeli et al., 1994; Radway-Bright et al., 1999). A wide variety of specific mechanisms of aPL-mediated hypercoagulability and pregnancy loss have been proposed.

Dysregulation of Hemostatic Reactions

Autoantibodies to β2GPI, prothrombin, and perhaps other phospholipid-binding plasma proteins may cross-link membrane-bound antigens leading to a very high avidity between the antibody–antigen complex and the vesicle or cell surface. This is the mechanism by which certain antibodies express LA activity *in vitro*. It is likely that similar high avidity interactions could also occur *in vivo*, leading to the dysregulation of phospholipid-dependent hemostatic reactions.

Inhibition of the Protein C Pathway

The protein C pathway is an important natural anticoagulant mechanism. Genetic abnormalities of this pathway (deficiencies of protein C and protein S, factor V_{Leiden}) are common causes of inherited thrombophilia. Antiphospholipid antibodies may inhibit phospholipid-dependent reactions of the protein C anticoagulant pathway: 1) the activation of protein C by thrombin bound to thrombomodulin; and/or 2) the inactivation of factors Va and VIIIa by activated protein C and its cofactors protein S and factor V (Comp et al., 1983; Cariou et al., 1988; Marciniak and Romond, 1989; Malia et al., 1990; Oosting et al., 1993; Izumi et al., 2002; Hwang et al., 2003). Anti-β2GPI autoantibodies may be involved. Autoantibodies directed against protein-C-pathway components, e.g., protein C and protein S, may also play a role (Oosting et al., 1993; Nojima et al., 2002). Some APS patients are reported to have decreased levels of protein S, although the data are equivocal (Ruiz-Argüelles et al., 1991; Bertolaccini et al., 2003; Song et al., 2000).

Displacement of Annexin A5

Rand and colleagues have suggested that annexin A5 bound to the luminal surface of vascular endothelial cells functions as a physiological anticoagulant, and that aPL (e.g., β2GPI/anti-β2GPI complexes) are procoagulant because they displace annexin A5 from the endothelial cell surface (Rand, 2002). Other data do not support this hypothesis (Lakasing et al., 1999; Bevers et al., 2000; Donohoe et al., 2000; Willems et al., 2000). Further, while annexin A5 may play an important thrombomodulatory role in the placental circulation (Krikun et al., 1994; Wang et al., 1999), at the present time there is little direct evidence that it functions as an anticoagulant throughout the systemic vasculature.

Inhibition of β2-Glycoprotein I

It has been suggested that β2GPI may function as an anticoagulant, although the phospholipid-binding properties of β2GPI (Harper et al., 1998) and studies of β2GPI-deficient individuals (Takeuchi et al., 2000) do not clearly support such a function. However, β2GPI may play such a role if recent observations that β2GPI binds to factor XI and is cleaved by plasmin are shown to be physiologically important. Anti-β2GPI antibodies could, in theory, interfere with these interactions.

Impaired Fibrinolysis

Impairment of fibrinolysis has been observed in patients with APS (Sanfelippo and Drayna, 1982; Killeen et al., 1987; Kolev et al., 2002) and anti-β2GPI antibodies have been implicated (Takeuchi et al., 2002; Yasuda et al., 2004).

Cellular Effects

Although the mechanisms listed above involve reactions on cell surface, activation or inhibition of cellular function is not primarily involved. There is growing evidence, however, that aPL may stimulate or activate various types of cells (monocytes, endothelial cells, platelets), leading to a procoagulant phenotype. Antiphospholipid antibodies may do this via cross-linking of antigens, such as β2GPI, bound to cell surface receptors.

Monocytes

Tissue factor (TF) is the major initiator of normal and pathologic coagulation and is not normally expressed by cells in contact with blood. A number of studies suggest that increased expression of TF on circulating blood monocytes is an important mechanism of hypercoagulability in APS (Cuadrado et al., 1997; Amengual et al., 1998; Dobado-Berrios et al., 1999; Zhou et al., 2004). Anti-β2GPI antibodies from patient sera and patient-derived monoclonal anti-β2GPI autoantibodies induce TF expression on normal blood monocytes *in vivo*, and TF expression is increased on monocytes from patients with IgG anticardiolipin antibodies and a history of thrombosis.

Endothelial Cells

Antiphospholipid antibodies may stimulate or increase the procoagulant activity of vascular endothelial cells via a number of mechanisms (Riboldi et al., 2003). Sera and IgG fractions from certain APS patients increase TF expression (Oosting et al., 1992a), the production of endothelin 1 (Atsumi et al., 1998), and the expression of the adhesion molecules E-selectin, VCAM-1, and ICAM-1 (Simantov et al., 1995; Del Papa et al., 1995). The latter effects are dependent on anti-β2GPI antibodies and β2GPI. Upregulation of adhesion molecules has been shown to mediate the thrombogenic effects of aPL in animal models (Pierangeli et al., 2001; Espinola et al., 2003).

Antiphospholipid syndrome autoantibodies may cause dysregulation of eicosanoid metabolism, inhibiting the production of endothelial cell prostacyclin (PGI_2), a potent vasodilator and platelet inhibitor (Carreras et al., 1996). Antiphospholipid antibodies may also affect platelet eicosanoids, as discussed below.

Platelets

Autoimmune thrombocytopenia is a manifestation of APS and thought to be due to the anti-platelet reactivity of

certain aPL. Potential target antigens that may be involved include β2GPI bound to platelet membranes or receptors (Shi et al., 1993), CD36, and several of the major platelet membrane glycoproteins (Rock et al., 1994; Macchi et al., 1997; Pelegri et al., 2003). Dysregulation of eicosanoids by aPL increases platelet thromboxane A_2 production (Martinuzzo et al., 1993; Forastiero et al., 1998). Anti-β2GPI autoantibodies are associated with increased levels of platelet-derived thromboxane urinary metabolites. Several studies demonstrate that aPL induce platelet aggregation (Wiener et al., 2001; Lutters et al., 2003). Monoclonal anti-β2GPI antibodies bind to platelets in a β2GPI-dependent fashion and lead to platelet activation in the presence of sub-threshold concentrations of weak agonists (Arvieux et al., 1993).

Pregnancy Loss

The proximate cause of fetal death in APS is probably hypoxia due to insufficient uteroplacental blood flow (Branch, 1994). Pathophysiological findings in the placenta of women with pregnancy loss include maternal spiral artery vasculopathy, placental infarction, chronic villitis, atherosis, decreased number of syncitio-vascular membranes, increased number of syncitial knots, and fetal thrombi (Magid et al., 1998; Ogishima et al., 2000; Locatelli et al., 2002; Sebire et al., 2002). Infarctions in the placenta may be associated with decreased amounts of annexin A5 on placental villi (Rand, 2002), although some investigators report normal amounts of annexin A5 are present (Donohoe et al., 2000; Lakasing et al., 1999).

Recently the work of Salmon and colleagues has highlighted the role of the complement activation in mediating pregnancy loss in a murine model of aPL-induced pregnancy loss (Salmon et al., 2003). Mice genetically deficient in complement components and mice treated with complement inhibitors were protected from fetal resorption (Holers et al., 2002; Girardi et al., 2003; Thurman et al., 2005). Heparin, a complement inhibitor as well as an anticoagulant, prevented fetal resorption, whereas fondaparinux and hirudin, anticoagulants that do not inhibit complement, did not (Girardi et al., 2004)

IMMUNOLOGIC MARKERS IN DIAGNOSIS

The two standard clinical laboratory tests for aPL are anticardiolipin ELISAs and LA. In general, both tests may need to be performed as the assays are discordant in up to 35% of APS patients (Petri, 1994). The presence of aPL should be confirmed by repeating positive tests in 6 to 8 weeks. The significance of transiently positive tests is unclear.

Tests are available for IgG, IgM, and IgA anticardiolipin antibodies. Although the strongest clinical associations are with IgG anticardiolipin antibodies, isolated IgM or IgA antibodies are also associated with APS. Anticardiolipin ELISAs are reasonably well-standardized, and positive reference standards for IgG, IgM, IgA isotypes are available (Harris et al., 1987; Harris, 1990; Tincani et al., 2001). Interlaboratory variation remains somewhat of a problem, however (Reber et al., 1995). Practically speaking, there is generally good agreement on most specimens, with most variability occurring with results that fall close to the upper limit of normal or in the low end of the positive range. Care should be taken in interpreting results in this range.

Anti-β2GPI ELISAs have been developed and are clinically available (Arvieux et al., 1991; Matsuura et al., 1994; Roubey et al., 1995). Compared with anticardiolipin assays, anti-β2GPI assays may be more specific for clinical manifestations of APS and may detect species-specific autoantibodies that recognize human β2GPI, but not bovine β2GPI (present in most anticardiolipin assays) (Arvieux et al., 1996). Currently, most experienced clinicians in this field consider the anti-β2GPI assay as a second-line test. It may provide useful information in situations where there is a high index of suspicion for APS and the standard aPL tests are negative. Additional interlaboratory standardization efforts and prospective clinical studies will help define the role of anti-β2GPI assays in clinical practice. Immunoassays for antiprothrombin antibodies are currently in development (Atsumi et al., 2000; Amengual et al., 2003).

The first step in LA testing is an appropriately sensitive screening test, e.g., lupus-activated partial thromboplastin time (aPTT), dilute Russell viper venom time, and the kaolin clotting time (Brandt et al., 1995a; 1995b). A routine aPTT is generally not adequate for LA screening. If the screening test is prolonged, confirmation of a positive LA requires 1) demonstration that prolongation of the screening test is due to an inhibitor rather than a factor deficiency (failure of the abnormal screening test to correct when patient plasma is mixed with normal plasma); and 2) demonstration of phospholipid-dependence (the inverse relationship of phospholipid concentration to prolongation of the coagulation test). Phospholipid-dependence may be demonstrated in an assay in which reduced phospholipid accentuates the anticoagulant activity, or an assay in which excess phospholipid neutralizes the anticoagulant activity (e.g., platelet-neutralization procedure, hexagonal-phase phospholipid-neutralization procedure).

Testing for antibodies to multiple phospholipids is generally not recommended (Bertolaccini et al., 1998). These panels of tests can be expensive, lack standardization, and have little proven diagnostic value. An exception might be antibodies to phosphatidylethanolamine. Clinical manifestations of APS have been reported in a number of patients with

anti-phosphatidylethanolamine antibodies in the absence of other aPL (Berard et al., 1996; Boffa et al., 1996). The test is not widely available or standardized, and is best considered as a research tool at this time.

TREATMENT AND OUTCOME

Thrombosis

Medium-to-high levels of aPL are associated with a substantial risk for thromboembolic disease. The relative risk of deep venous thrombosis, pulmonary embolism, or stroke is approximately 7–8 (Ginsburg et al., 1992). Patients with medium to high aPL levels and a history of arterial or venous thrombosis have a significant risk of recurrent thrombosis (Rosove and Brewer, 1992; Khamashta et al., 1995; Ruiz-Irastorza et al., 2002). After initial treatment with heparin followed by warfarin, long-term warfarin is recommended to prevent recurrent thrombotic events. Retrospective studies suggest that a relatively high level of anticoagulation, international normalized ratio (INR) of more than 3.0, is necessary. A recent randomized controlled trial, however, found that high-intensity warfarin (target INR 3.1–4.0) was not superior to moderate-intensity warfarin (target INR 2.0–3.0) (Crowther et al., 2003). Many experienced clinicians in the field now recommend the lower INR target. Lifelong anticoagulation may be necessary. The decision regarding long-term anticoagulation should be individualized, given the risks of warfarin, and various factors should be considered (age and reliability of the patient, level of aPL, the type of thrombotic event, temporal distance from the event). In certain patients with LA, these autoantibodies may interfere with accurate determination of the INR, requiring other tests to assess the level of anticoagulation (Della Valle et al., 1996; Moll and Ortel, 1997).

In general, immunosuppression is not thought to be effective in preventing thrombosis, and is not recommended. Anecdotally, rituximab has been tried in a few severe, refractory cases of APS with variable results.

Pregnancy Loss

Women with moderate-to-high levels of aPL and a history of one or more otherwise unexplained fetal deaths (>10 weeks gestation) or recurrent pre-embryonic or embryonic spontaneous abortions are candidates for treatment to prevent loss and morbidity in subsequent pregnancies. Currently, most experts recommend treatment with heparin and low-dose aspirin (Kutteh, 1996; Rai et al., 1997; Branch and Khamashta, 2003). Prednisone and aspirin appear to be equally efficacious, but prednisone is associated with a higher frequency of adverse side effects, including infection, pre-eclampsia, gestational diabetes, and osteonecrosis (Cowchock et al., 1992). With treatment, the chance of a successful pregnancy is 70–80%. Women with APS who are considering pregnancy should have preconception consultations with their obstetrician and rheumatologist and/or hematologist. Low-dose aspirin is often initiated (or continued) at this time. Treatment with heparin is begun as soon as pregnancy is diagnosed, usually at 5–7 weeks gestation. Either unfractionated or low-molecular-weight heparin (enoxaparin, dalteparin) may be used. For women without a history of thrombosis, a typical regimen is subcutaneous heparin, 5000–10,000 units every 12 hours, and aspirin, 75 or 81 mg daily. The low end of the heparin-dose range appears to be as efficacious as the high end (Kutteh and Ermel, 1996; Rai et al., 1997). For women with prior thrombosis, higher doses of heparin are recommended. Specific heparin regimens for prevention of APS-related pregnancy loss have recently been reviewed (Branch and Khamashta, 2003). Heparin is held at the time of delivery, and then reinstituted for 4–6 weeks after delivery, due to the risk of thrombosis in the postpartum period. Intravenous immunoglobulin (IVIg) therapy is an option if heparin and prednisone fail (Scott et al., 1988; Spinnato et al., 1995; Clark et al., 1999), although a small randomized controlled trial did not show an increased benefit of IVIG over heparin and aspirin (Branch et al., 2000). In a randomized trial of low-molecular-weight heparin and aspirin versus IVIG, the live birth rate was higher in the heparin/aspirin group (16/19 or 84% vs 12/21 or 57% for IVIG) but the difference did not reach statistical significance (Triolo et al., 2003). It is unclear whether women with low levels of aPL and recurrent pregnancy loss require treatment. A randomized controlled trial, in which a majority of subjects had low titer antibodies, observed successful pregnancy rates of 80–85% in patients receiving low-dose aspirin or placebo (Pattison et al., 2000).

Catastrophic APS

Due to the severe nature of catastrophic APS, most patients receive a combination of therapies, including anticoagulants, corticosteroids, plasmapheresis, cyclophosphamide, and IVIG (Asherson et al., 1998; Asherson et al., 2001). Anticoagulation appears to be particularly useful; survival was 62% in patients receiving anticoagulation versus 23% in those who were not anticoagulated (Asherson et al., 2001). In individual cases plasmapheresis (Neuwelt et al., 1997) and defibrotide (Burcoglu-O'Ral et al., 2002) have each been helpful.

Thrombocytopenia

Thrombocytopenia in APS is usually moderate and does not require treatment. Lower counts may require treatment with corticosteroids.

Asymptomatic Patients

Low-dose aspirin is generally recommended for asymptomatic patients with aPL but without a history of thrombosis (Erkan et al., 2001; 2002; Alarcon-Segovia et al., 2003). These patients are usually identified in three situations, i.e., patients with SLE found to have aPL on routine screening, women with a diagnosis of APS based on pregnancy loss or morbity, and LA^+ individuals discovered during coagulation screening. Hydroxychloroquine may help prevent thrombosis in patients with aPL and SLE (Petri et al., 1994; Erkan et al., 2002).

CONCLUDING REMARKS— FUTURE PROSPECTS

APS is an under-recognized autoimmune disease that accounts for a significant proportion of thromboembolic disease and recurrent pregnancy loss. Anticoagulation rather than immunosuppression is the current mainstay of therapy. Although effective in most cases, full anticoagulation carries a significant risk of adverse side effects. Future research characterizing the underlying autoimmune response, the spectrum of APS autoantibodies, and the relevant mechanisms of hypercoagulability will lead to the identification of novel therapeutic targets and approaches. These new approaches raise hope for safer and more effective treatment of APS.

CHAPTER

31

Sjögren Syndrome

MENELAOS N. MANOUSSAKIS AND HARALAMPOS M. MOUTSOPOULOS

Department of Pathophysiology, School of Medicine, National University of Athens, Greece.

Sjögren syndrome (SS) is an autoimmune disorder characterized by exocrine gland dysfunction and destruction, mainly the salivary and lachrymal glands, leading to dryness of mouth and eyes. Exocrinopathy is associated with dense lymphocytic infiltrates of glandular tissues and B-cell hyper-reactivity. Sjögren syndrome appears unique for two reasons. First, it has a broad clinical presentation, extending from local exocrinopathy to involvement of multiple organs; it may be found alone (primary SS) or in association with other autoimmune diseases (secondary SS). Although clinical, serologic and genetic features may distinguish primary from secondary SS, it remains unclear whether these entities are etiologically and pathogenically different. Second, it is a model disorder where a benign process can evolve into a lymphoid malignancy. Thus, the study of SS may provide insights into the pathogenesis of autoimmune disorders and lymphoid malignancy. Sjögren syndrome has been long regarded as an autoimmune disease, due to the presence of lymphoid infiltrates in the exocrine glands, the plethora of serum autoantibodies, the various hyperimmune clinical complications, as well as its frequent association with other autoimmune disorders.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Most SS patients have an indolent course. The initial manifestations can be nonspecific and usually antedate the full-blown development of the syndrome by a decade. In approximately one-third of primary SS patients mild extraglandular manifestations are present, whereas a small but significant number of patients develop lymphoid neoplasia.

Glandular Manifestations

Dryness of mouth (xerostomia) and eyes are the major glandular manifestations of SS. Patients variably complain of difficulty in chewing and swallowing, sore mouth, and/or a sandy feeling or itchiness in the eyes. The oral mucosa is dry, sticky, and erythematous, often with fungal overgrowth. The tongue appears with fissures and atrophy of the filiform papillae. Teeth show increased plaque formation, hypocalcification, and caries at the gingival margins. Diminished secretion of tears (aqueous layer) leads to chronic irritation and destruction of the corneal and bulbar conjunctival epithelium [keratoconjunctivitis sicca (KCS)]. Major sali-

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

vary gland enlargement, particularly of the parotid glands (Figure 31.1), occurs episodically or chronically in 25–65% of primary SS patients, but is uncommon among patients with secondary SS (Moutsopoulos et al., 1979).

Salivary flow rates measured for whole saliva or for separate secretions from each major salivary gland (with or without stimulation) reveal reduced salivary flow rates. Sialography reveals various degrees of sialectasis in the majority of patients. Scintigraphy, a functional assessment of salivary glands, appears unable to differentiate between SS patients and controls (Adams et al., 2003). Ultrasonography, conventional magnetic resonance imaging and magnetic resonance sialography may provide noninvasive diagnostic alternatives (Niemela et al., 2004).

Decreased tear secretion rate as measured by the Schirmer's test (wetting of the paper strip of less than 5 mm per 5 minutes), is an indication of diminished secretion but is not diagnostic for KCS (reviewed by Kincaid, 1987). Slit-lamp examination after Rose-Bengal staining reveals punctuate or filamentary keratitis lesions that are characteristic for KCS (Figure 31.2) (Kincaid, 1987). The tear breakup time (overly rapid breakup time) is used to evaluate tear film integrity labeled by a drop of fluorescein.

FIGURE 31.1 Firm, painless, nodular parotid gland enlargement in a 54-year old patient with primary Sjögren syndrome.

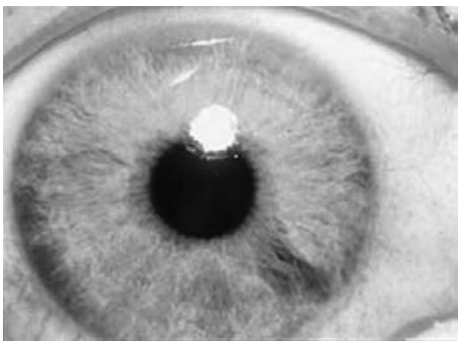

FIGURE 31.2 Staining of damaged corneal and conjunctival epithelia by Rose Bengal dye in a patient with primary Sjögren syndrome and keratoconjunctivitis sicca (KCS). See color plate section.

Extraglandular Manifestations

Patients with clinically extraglandular manifestations may complain of easy fatigue, general malaise, low-grade fever, and of myalgias and arthralgias.

Musculoskeletal Manifestations

Arthralgias, myalgias, morning stiffness, intermittent synovitis, and, infrequently, chronic symmetric polyarthritis may be encountered in primary SS patients. Polymyositis is rare.

Respiratory Tract Involvement

Various respiratory tract manifestations have been described in SS patients affecting the respiratory tract, the mediastinum, and the pleura. These are frequent but usually mild and of low clinical importance. Patients can present with dry cough secondary to dryness of the tracheobronchial mucosa (xerotrachea), dyspnea from small airway obstruction, and, very rarely, interstitial disease.

Gastrointestinal and Hepatobiliary Manifestations

Dysphagia, nausea, dyspepsia, and epigastric pain are seen. Biopsies of gastric mucosa show chronic atrophic gastritis and lymphocytic infiltrates. Liver involvement in primary SS patients is rare (5%) and subclinical, presenting with elevated liver enzymes and/or with antimitochondrial antibodies associated with stage I primary biliary cirrhosis (PBC). Sicca manifestations have been described in half of PBC patients (Trevino et al., 1987).

Urinary Tract Involvement

Less than 10% of SS patients manifest renal disease. Abnormal urine acidification test is found in one-fourth of the patients. Interstitial disease is found early in the disease and manifests with renal colici, hyposthenuria, and hypokalemic hyperchloremic renal tubular acidosis (type I). Immune complex glomerulonephritis (membranoproliferative or mesangial proliferative) is a late-disease manifestation and is associated with cryoglobulinemia and hypocomplementemia (Goules et al., 2000). Interstitial cystitis has been also described (Van de Merwe et al., 1993).

Vascular involvement

Raynaud phenomenon is seen in one-third of the patients with primary SS and precedes sicca manifestations (Skopouli et al., 1990). Small vessel hypersensitivity vas-

culitis and, rarely, polyarteritis nodosa-like vasculitis have been observed in primary SS patients (Alexander, 1987). Episodic palpable purpuric or petechial lesions of variable intensity in the lower extremities (dependent purpura) are common. Recurrent urticaria-like lesions, various maculopapular erythematous lesions, subcutaneous nodules, and skin ulcerations may be also seen. Cases of systemic vasculitis with visceral involvement affecting kidney, lung, and gastrointestinal tract have been described.

Neuropsychiatric involvement

Neurologic involvement occurs in approximately 10–20% of primary SS patients manifesting with peripheral sensory or sensory-motor polyneuropathy and/or mononeuritis multiplex. Carpal tunnel and other entrapment syndromes as well as sensory gangliopathy have also been described. Trigeminal and/or optic neuropathy has been observed. Sensorineural hearing loss is usually subclinical (Tumiati et al., 1997).

Hemiparesis, sensory deficits, seizures, movement disorders, cerebellar defects, neurogenic bladder, transverse myelopathy, and a multiple sclerosis-like picture have been described in SS patients (Alexander et al., 1994). However, other investigators using strict criteria for the classification of primary SS have not substantiated these observations (Soliotis et al., 2004). Sjögren syndrome patients often present various neuropsychiatric features, which may at least partly be attributed to dysregulation of the stress response (Johnson and Moutsopoulos, 1992). Anxiety, depressed mood, and personality structure disorders are frequently manifest and may necessitate therapeutic intervention.

Lymphoproliferative disease

In primary SS, malignant non-Hodgkin lymphomas (most often low-grade marginal-zone B-cell lymphoma) have been estimated to occur in approximately 4–8% of patients followed for approximately 8–10 years (Kassan et al., 1978; Kauppi et al., 1997; Voulgarelis et al., 1999) (Figure 31.3). This usually is seen in patients with low C4, mixed monoclonal cryoglobulinemia, and purpura (Skopouli et al., 2000). In most cases, the patients are in fairly good clinical performance status, at an early clinical stage, whereas extranodal localization is frequent (Table 31.1) (Voulgarelis et al., 1999). The survival is closely associated with the histologic grade of lymphoma.

Secondary Sjögren Syndrome and Overlapping Entities

Sicca manifestations can be found alone or in conjunction with several other autoimmune rheumatic diseases, such as RA, systemic lupus erythematosus (SLE) and systemic sclerosis. In addition, manifestations of SS have been described in patients with polymyositis, polyarteritis nodosa, PBC, mixed connective tissue disease, and myasthenia gravis (Moutsopoulos et al., 1980).

Approximately 5% of patients with rheumatoid arthritis (RA) present a clinically overt SS, while subclinical sicca complaints can be affirmed by as many as 20% of such patients. The diagnosis of RA usually precedes that of SS by

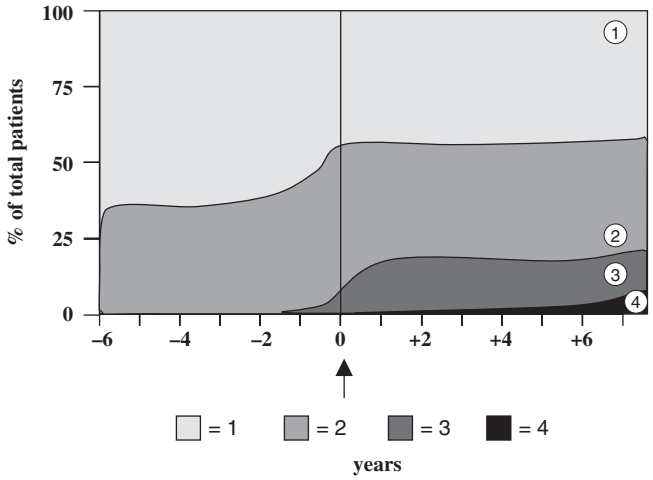

FIGURE 31.3 The clinical spectrum of primary Sjögren syndrome (SS) and disease evolution. Schematic representation of the proportion of the various subgroups of primary SS patients in different time points relatively to the time of diagnosis, as derived from a synthesis of published information. 1: patients with disease confined in the exocrine glands; 2: patients with extraglandular involvement without adverse prognostic signs (palpable purpura, low C4 complement levels and/or mixed monoclonal cryoglobulins); 3: patients with extraglandular involvement with adverse prognostic signs; 4: patients with extraglandular involvement and lymphoma development.

TABLE 31.1 Clinical characteristics of malignant non-Hodgkin's lymphoma in primary Sjögren syndrome patients

Features of lymphoma*	% positive
Clinical performance status:	
0–1	82
2–4	18
B symptoms	24
Localization:	
Nodal	63
Extranodal	81
Clinical stage:	
I/II	58
III/IV	42

*Performance status was graded (0–4 scale) at the time of lymphoma diagnosis using the Eastern Cooperative Oncology Group scale, whereas the Clinical Staging (I–V scale) was based on the Ann Arbor classification system (Voulgarellis et al., 1999). B symptoms: fever, night sweats, and weight loss.

many years (Moutsopoulos et al., 1979). Keratoconjunctivitis sicca is the predominant sicca manifestation of patients with RA and SS, whereas xerostomia, salivary gland enlargement, lymphadenopathy, renal involvement, and Raynaud phenomenon are uncommon.

Based on distinct clinical, serologic, and immunogenetic profiles of patients with SS alone and of those with SS associated with RA (Moutsopoulos et al., 1979; 1980), the terms "primary SS" and "secondary SS" were proposed for the former and the latter groups of patients, respectively (Moutsopoulos et al., 1979). During recent decades, the term "secondary SS" has generally been applied to connote sicca disorder that occurs together with any autoimmune disorder; however, this disregards the possibility for true overlapping entities. In this context, a recent study has revealed that patients with coexisting SLE and SS (SLE SS) appear to constitute a subgroup (9%) of SLE patients with distinct clinical, serologic, pathologic, and immunogenetic features, in whom SS is expressed as an overlapping entity, is largely similar to primary SS and usually precedes SLE (Manoussakis et al., 2004).

Oral and/or ocular dryness are also observed in approximately 20% of patients with systemic sclerosis (Medsger, 1987), often associated with fibrosis of the exocrine glands. In contrast, sicca manifestations associated with frank lymphocytic infiltrative lesions are extremely common (60%) in patients with limited systemic sclerosis (Drosos et al., 1991).

Pathologic Features

The histopathologic assessment of SS patients usually reveals focal or diffuse mononuclear infiltrations in one or more organs that are potentially progressive and likely contribute to the dysfunction of the affected organs. Destructive and degenerative lesions, such as diffuse acinar atrophy, duct dilation and fibrosis may be also present; however, the loss of secretory function of the exocrine glands is often disproportionate to the destruction encountered.

Salivary gland involvement is central in primary SS and, therefore, the pathologic study of the salivary gland tissues has been long applied for the diagnostic confirmation of SS (Daniels et al., 1987) and the focus of an extensive research of its pathogenesis. The pathologic assessment of labial salivary gland biopsy reveals chronic focal sialadenitis that typically consists of focal mononuclear aggregates (at least 50 lymphocytes and plasma cells), which are adjacent to and replace the normal acini (Daniels et al., 1987). Larger foci forming germinal centers may be found. Among several proposed histologic classifications, a focus score of more than 1 focus/4 mm^2 (with focus defined as an aggregate of 50 or more mononuclear cells) has been proposed as a specific measure for SS (Chisholm and Mason, 1968) and the best single classification criterion (Vitali et al., 1993). In a modification of this method, Greenspan and Daniels had considered scores from 1 to 12 foci/4 mm^2 and found a significant positive correlation between a higher score and larger foci (Greenspan et al., 1974, Daniels et al., 1987).

Clinical Course and Evolution of the Disease

The initial presentation of primary SS at diagnosis essentially determines its outcome (Figure 31.3) (Skopouli et al., 2000). In the vast majority of patients, the glandular sicca features and serologic profile remain unchanged during the disease course (Gannot et al., 2000; Skopouli et al., 2000). Ordinarily, lymphoma and glomerulonephritis are late events (Skopouli et al., 2000). Lymphoproliferative disease increases with patient follow-up (2.6% at 5 years and 3.9% at 10 years) and is predicted by the presence of palpable purpura and low complement levels at the first visit (Ioannidis et al., 2002). These manifestations appear to distinguish high-risk patients (type I) from patients with low risk (type II) (Ioannidis et al., 2002; Theander et al., 2004). The overall mortality of primary SS is not different from that of the general population, whereas mortality increases in high-risk patients (Martens et al., 1999; Skopouli et al., 2000; Pertovaara et al., 2001; Ioannidis et al., 2002; Theander et al., 2004).

Diagnosis and Differential Diagnosis

Combined clinical, pathologic, and serologic assessment of patients can easily lead to diagnosis. Differential diagnosis should consider various medical conditions that may cause dryness of the mucosae, with or without salivary gland enlargement, including adverse effects of drugs, infections, tumors, metabolic disorders, and irradiation. In particular, sarcoidosis (Drosos et al., 1989), lipoproteinemias (types II, IV, and V), chronic graft-versus-host disease, lymphomas, amyloidosis and infection by human immunodeficiency virus (HIV) (Itescu, 1991) and hepatitis C virus (HCV) (Haddad et al., 1992, Ramos-Casals et al., 2002) might be misinterpreted as SS. Clinical, pathologic, and serologic features can be helpful for the differentiation of these processes from genuine SS. In particular, the identification of serum autoantibodies to Ro(SSA) or La(SSB) proteins is a strong indication for primary SS (Table 31.2). In elderly individuals, mucosal dryness is frequently an age-related atrophic process (Drosos et al., 1988).

A prospective concerted action from 12 European countries resulted in the validated definition of the European criteria for SS (Vitali et al., 1993; 1996). Recently, the American-European Consensus Group has modified the criteria. Among others, the presence of histopathologic evidence of sialadenitis and of serum anti-Ro(SSA)/La(SSB) autoantibodies were introduced as obligatory classification criteria (Box 31.1) (Vitali et al., 2002). These criteria can be

TABLE 31.2 Differential diagnosis of primary Sjögren syndrome (SS) from sicca syndrome associated with infection by HIV or HCV or with sarcoidosis

	Primary SS	Sarcoidosis	HCV infection with sicca syndrome	HIV infection with sicca syndrome
Sex predilection	Female	No difference	No difference	Male
Age	Middle-age	Middle-age	All ages	Young
Serum autoantibodies to Ro(SSA) and La(SSB)	Frequently present	Absent	Absent	Absent
Predominant T-cell subset in lymphoid infiltrates	$CD4^+$	Non-caseating granuloma	$CD4^+$	$CD8^+$
HLA-association	DR3, DRw53, DQA1*0501	Unknown	Unknown	HLA-DR5
Diagnostic viral serologic test	None	None	HCV tests	HIV tests

HCV, hepatitis B virus; HIV, human immunodeficiency virus.

Box 31.1
The American-European Consensus Group classification criteria for Sjögren syndrome

I. Ocular symptoms: a positive response to at least one of the three following questions:
1. Have you had daily, persistent, troublesome dry eyes for more than 3 months?
2. Do you have a recurrent sensation of sand or gravel in the eyes?
3. Do you use tear substitutes more than three times a day?

II. Oral symptoms: a positive response to at least one of the three following questions:
1. Have you had a daily feeling of dry mouth for more than 3 months?
2. Have you had recurrently or persistently swollen salivary gland as an adult?
3. Do you frequently drink liquids to aid in swallowing dry food?

III. Ocular signs: objective evidence of ocular involvement defined as a positive result in at least one of the following two tests:
1. Schirmer's I test, performed without anesthesia (≤5 mm in 5 minutes) ¶
2. Rose-Bengal score or another ocular dye score (≥4 according to van Bijsterveld's scoring system)

IV. Histopathology

Presence of focal lymphocytic sialadenitis in minor salivary glands (obtained through normal-appearing mucosa), evaluated by an expert histopathologist with a focus score ≥1, defined as a number of lymphocytic foci which are adjacent to normal-appearing mucous acini and contain more than 50 lymphocytes per 4 mm^2 of glandular tissue.

V. Salivary gland involvement: objective evidence of salivary gland involvement defined as a positive result in at least one of the following three diagnostic tests:
1. Unstimulated salivary flow (≤1.5 mL in 15 minutes)
2. Parotid sialography showing the presence of diffuse sialectasias (punctate, cavitary or destructive pattern), without evidence of obstruction in the major ducts.
3. Salivary scintigraphy showing delayed uptake, reduced concentration and/or delayed excretion of tracer.

VI. Autoantibodies: presence in the serum of the following autoantibodies:

Antibodies to Ro(SSA) or La(SSB) or both

Rules for classification: In patients without any potentially associated disease the presence of any four of the six items is indicative of definitive primary SS. In patients with a potentially associated disease (for instance another connective tissue disease) item-1 or item-2 plus any two from items 3, 4, 5 is indicative of secondary SS.

Exclusion criteria: prior head and neck irradiation, pre-existing lymphoma, acquired immunodeficiency disease (AIDS), hepatitis C infection, sarcoidosis, graft-versus-host disease, sialoadenosis, use of neuroleptic, anti-depressant, anti-hypertensive or parasympatholytic drugs.

¶Test should be excluded from the criteria or not considered indicative for a diagnosis of SS in elderly subjects (older than 60 years).

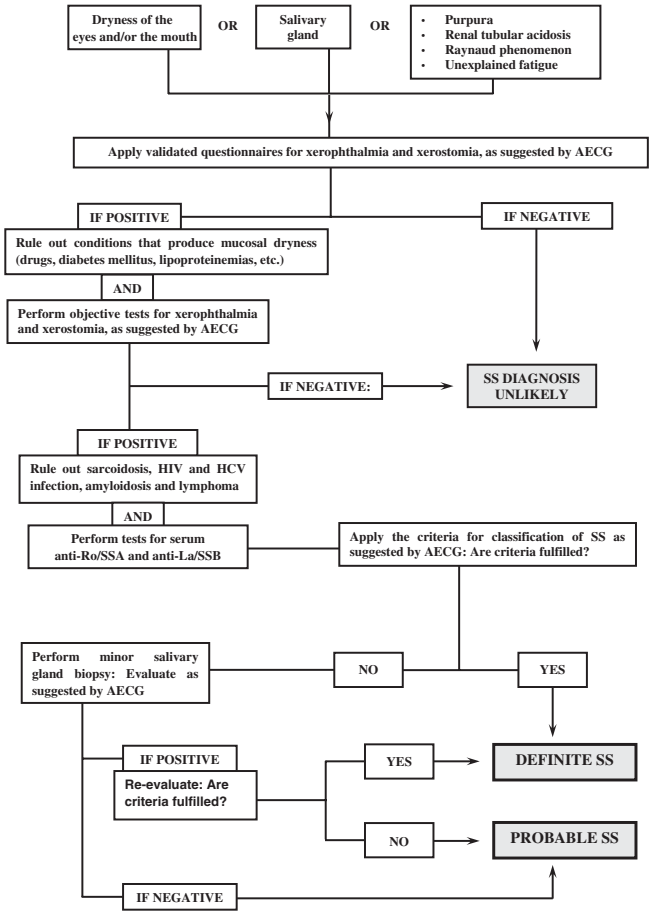

FIGURE 31.4 A practical algorithm for the assessment and diagnosis of Sjögren syndrome (SS) based on the sequential application of validated questionnaires and objective tests, as suggested by the American-European Consensus Group (AECG) criteria for the classification of SS (see Box 31.1). Adapted from Vitali et al. (2002).

also utilized to derive a practical algorithm for diagnosis (Figure 31.4).

Epidemiology

SS affects primarily women (women to men, 9:1), mainly in the fourth and fifth decades of life. However, reported cases include individuals of all ages, from children to elderly persons (Stiller et al., 2000). In different population studies, the overall prevalence of primary SS has been estimated to be approximately 3% (Jacobsson et al., 1989; Dafni et al., 1997).

AUTOIMMUNE FEATURES AND PATHOGENIC MECHANISMS

Humoral Autoimmune Features

Primary SS is one extraordinary example of disorders associated with polyclonal B-cell hyper-reactivity, as attested by profound hypergammaglobulinemia, multiple autoantibodies, and cryoglobulins (Harley, 1987). Organ-specific autoantibodies include those to antigens of salivary ducts, thyroid, gastric mucosa, erythrocytes, pancreas, prostate, and nerve cells. Non-organ-specific autoantibodies include antibodies to cellular antigens (Ro/SSA and La/SSB, histones, single-stranded DNA, α-fodrin) and rheumatoid factors.

Ro/SSA and La/SSB represent heterogeneous ribonucleoprotein complexes consisting of antigenic proteins (two main proteins of 52 kDa [Ro52] and 60 kDa [Ro60] for Ro/SSA and one protein of 48 kDa for La/SSB) associated with small cytoplasmic RNAs (hYRNAs) (Slobbe et al., 1991). The function of Ro/SSA hYRNA complexes remains largely unknown. The La/SSB protein has been suggested to participate in the transcription termination of RNA polymerase III and in the initiation of the translation of at least the poliovirus mRNA, whereas it is capable of melting DNA/RNA hybrids by virtue of its ATPase activity (Bachmann et al., 1990). Antibodies to Ro/SSA and La/SSB antigens frequently coexist in the serum of primary SS patients, and their detection has been recently included as a classification criterion for SS (St Clair, 1992; Vitali et al., 2002). Several mechanisms, including molecular mimicry with viral antigens or antigen-driven responses, have been proposed to explain the genesis of these autoantibodies in SS. Furthermore, these particular autoantibodies appear to represent a meaningful link between sicca syndrome that occurs in primary SS and in SS that coexists with SLE (Manoussakis et al., 2004). These findings are especially important not only for classification purposes but also because they strongly suggest a relationship between the biologic processes that generate these specific immunologic responses and the autoimmune sicca disorder itself.

By gel-precipitation assays, anti-Ro/SSA and anti-La/SSB antibodies are extremely uncommon in healthy individuals, whereas they are detected in approximately 38–60% and 25–40%, respectively, of primary SS patients. More sensitive techniques, such as enzyme-linked immunosorbent assay (ELISA), using purified or recombinant antigens, may reveal anti-Ro/SSA and anti-La/SSB in up to 95% and 87% of patients, respectively, but also in 10–15% of healthy controls. Of note, these autoantibody specificities are not specific for the primary syndrome and may be found also in 3–20% of patients with several other autoimmune diseases, usually in the presence of associated SS. Except for certain anti-La/SSB responses (Tzioufas et al., 2002), attempts to demonstrate linear immunodominant epitopes using small synthetic peptides have been inconclusive. In a recent study, autoimmune sera from patients with primary SS and SLE have been found to contain anti-idiotypic antibodies targeting a common anti-La/SSB idiotype that mask the anti-La/SSB response (Routsias et al., 2002). Interestingly, these anti-idiotypic antibodies can be detected using complementary peptides of La/SSB epitopes and hidden anti-La/SSB

antibodies can be released and detected using complementary epitope analogs (Routsias et al., 2002).

Viral infections or the induction of cellular stress by heat, UV light, serum starvation, and chemicals on cultured epithelial cells and keratinocytes has been shown to induce the translocation of Ro/SSA and La/SSB ribonucleoproteins to the cell surface (Rosen et al., 1995). Interestingly, abnormal translocation and localization to the outer membranes of the nuclear autoantigen La/SSB have also been observed in the conjunctival and salivary epithelial cells of SS patients (Yannopoulos et al., 1992; Price et al., 1994). Also, various autoantigenic ribonucleoproteins have been detected in the exosomal bodies normally released by cultured salivary gland epithelial cells (Kapsogeorgou et al., 2003).

Multiple other non-organ-specific autoantibodies have been described in primary SS patients, including anticentromere antibodies, antimitochondrial antibodies, antibodies to the U1nRNP ribonucleoprotein, antiphospholipid, anticytokeratin and antineutrophil antibodies. IgG present in the sera of SS patients has been found to bind to and activate cholinergic receptors present on rat parotid gland that were identified as M3-muscarinic receptors (Bachman et al., 1998) with possible inhibitory effect on parasympathetic neurotransmission (Waterman et al., 2000) (see Chapter 17). The detection of autoantibodies to the cytoskeletal protein α-fodrin was initially considered a specific diagnostic marker for SS (Haneji et al., 1997), but subsequent studies by ELISA gave a sensitivity of only 48% and a specificity less than that of anti-La (Zandbelt et al., 2004).

Cellular Autoimmune Features

Peripheral Blood Lymphocytes

The analysis of the absolute number of the total peripheral blood lymphocytes as well as T and B cells does not generally reveal significant differences compared with normal individuals. Recent comparative studies of peripheral blood and parotid glands from primary SS patients have indicated the depletion of CD27-expressing memory B cells from the peripheral blood and accumulation and/or retention of these antigen-experienced B cells in the inflamed salivary gland tissues (Dorner et al., 2002).

Tissue-Infiltrating Lymphocytes

The majority of infiltrating lymphocytes in the immunopathologic lesions of the exocrine glands are T cells, while B lymphocytes constitute approximately 20–25% of infiltrating cells. Most of the T lymphocytes (60–70%) bear the $CD4^+$ phenotype, the αβ T-cell receptor (TCR), and the CD45 Ro memory inducer marker. A relative predominance of certain TCR-Vβ (e.g., Vβ2 and Vβ13) and TCR-Vα (e.g., Vα2, Vα11.1, and Vα17.1) genes and a relatively limited junctional (Jβ-genes) usage has been reported, which possibly support an antigen-driven proliferation of T cells in the inflammatory lesions (Matsumoto et al., 1996).

Oligomonoclonal B-cell Expansion

Monoclonal light chains or immunoglobulins have been demonstrated in the serum and/or the urine of approximately 80–100% of patients with extraglandular involvement, compared with approximately 25–40% of patients with disease limited to the exocrine glands. In addition, approximately one-third of primary SS patients exhibit high serum levels of mixed monoclonal cryoglobulins (type II) that contain an IgMκ monoclonal rheumatoid factor. It appears that SS patients with polyclonal B-cell activation generate monoclonal B-cell processes very early in their disease course, and this monoclonality is most frequent in patients with extraglandular involvement, which, in fact, is associated with an increased risk for developing lymphoid malignancy (Kassan et al., 1978).

Monoclonal immunoglobulin gene rearrangements are also detected in the salivary glands and may antedate the development of non-Hodgkin lymphoma (Freimark et al., 1989). Recent studies have indicated that in primary SS patients there is no apparent major molecular abnormality in the generation of the IgV chain repertoire; however, there is biased usage of V(L) chain genes caused by selection and clonal expansion of B cells expressing particular V(L) genes, as well as accumulation of B cells bearing mutated V(L) gene rearrangements within the inflamed parotid glands (Dorner et al., 2002). In addition to the less aggressive oligoclonal B-cell expansion, other tumor-inciting events, such as Bcl-2 translocation appear essential for the development of SS-associated lymphoma (Pisa et al., 1991).

Cell Trafficking, Adhesion, and Activation of Infiltrating Cells

Glandular endothelium of SS patients likely represents the entry site for inflammatory cells. Vessels in the inflamed salivary glands of patients have been shown to express vascular cell adhesion molecule 1 (VCAM1, CD106), intercellular adhesion molecule 1 (ICAM1, CD54), as well as P- and E-selectins, whereas infiltrating mononuclear cells surrounding blood vessels express the counter-receptors lymphocyte function-associated antigen-1 (LFA1), α4- and α5-integrins, and CD44 (Aziz et al., 1996). In addition, high levels of the chemokine CXCL-13/BCA1 have been found on endothelial cells of patients, whereas its counter-receptor CXCR-5 is observed on B cells, a fact that possibly indicates the contribution of this chemokine to the establishment of germinal center-like structures of patients (Amft et al., 2001; Xanthou et al., 2001; Salomonsson et al., 2003).

Immunohistochemical and *in situ* hybridization studies have demonstrated the presence of the proinflammatory cytokines tumor necrosis factor (TNF) and interleukins 6

and 1β (IL-6I, L-1β) in the salivary gland biopsies of SS patients that localize to mononuclear cell infiltrates and epithelium (Oxholm et al., 1992; Fox et al., 1994; Boumba et al., 1995; Cauli et al., 1995; Ohyama et al., 1996). Both TNF and TNF-receptor are present in the inflammatory infiltrates, vascular endothelium, and ductal epithelium (Koski et al., 2001). Salivary gland $CD4^+$ T cells produce abundant IL-2, IL-2R, interferon-γ, IL-1a, and IL-10 mRNA, but minimal or no IL-4, IL-5, and IL-13, suggesting the relative predominance of a Th1 response in SS (Fox et al., 1994; Boumba et al., 1995; Ajjan et al., 1998). Recently, the infiltrating $CD68^+$ macrophages in the minor salivary gland biopsies of SS patients were shown to express high amounts of the proinflammatory cytokine IL-18 (Boiu-Zahiu et al., 2004).

The majority of T cells expresses activation molecules such as major histocompatibility complex (MHC) class II, LFA1, as well as other cell adhesion molecules (CD2/LFA2, CD58/LFA3, CD54/ICAM1, CD154/CD40L) (Skopouli et al., 1991; St. Clair et al., 1992, Kapsogeorgou et al., 2001a; Dimitriou et al., 2002a). Interestingly, infiltrating T lymphocytes have been shown to express large quantities of the serine protease granzyme-A and perforin, possibly involved in the salivary tissue destruction (Alpert et al., 1994; Polihronis et al., 1998; Xanthou et al., 1999).

The Role of Apoptosis (Programmed Cell Death)

Abnormalities in apoptotic pathways may be critically involved in the deterioration of immunologic tolerance, in altered homeostasis of tissue infiltrative processes, as well as in the presentation of autoantigens. Studies in murine models indicated that genetic abnormalities in programmed cell-death processes (mutations in the apoptosis-related proteins Fas(CD95) or Fas-ligand(CD95L) lead to the persistence of autoimmune T-cell clones. Importantly, the infection of exocrine glands of such mutant mice by epitheliotropic viruses may result in chronic inflammatory glandular lesions (Fleck et al., 2001). In SS patients, peripheral blood $CD4^+$ T lymphocytes have been shown to display accelerated *in vitro* apoptosis, enhanced expression of Fas and decreased expression of Bcl-2 (apoptosis inhibitor) proteins (Ichikawa et al., 1995; Ogawa et al., 1996). On the other hand, the salivary gland-infiltrating mononuclear cells express elevated levels of Fas(CD95), Fas-ligand and Bax (pro-apoptotic proteins) and Bcl-2 (apoptosis inhibitor) and rarely undergo apoptosis: a phenomenon referred to as "blocked apoptosis" (Kong et al., 1997; Polihronis et al., 1998; Ohlsson et al., 2001). In direct contrast, apoptosis appears to play a role in the destruction of glandular epithelial cells, since these cells display DNA-strand breaks; widespread and high expression of the apoptotic proteins Fas, Fas-ligand, and Bax; and downregulation of Bcl-2 (Kong et al., 1997; Polihronis et al., 1998), associated with caspase-3 activation (Jimenez et al., 2002). The expression of the negative regulator molecules CTLA-4 and PD-1 is also increased (Bolstad et al., 2003). Furthermore, using cultured non-neoplastic cell lines, salivary gland epithelial cells have been shown to be susceptible to Fas-mediated and Fas-unrelated apoptotic death after stimulation by interferon-γ (but not TNF or IL-1) (Abu-Helu et al., 2001). These findings indicate that epithelial cell apoptosis contributes to the glandular lesions of SS, either by the action of local infiltrating cytotoxic T cells or via intrinsic mechanisms, possibly prior to lymphocytic infiltration.

The apoptotic epithelial cell death possibly results in the release of autoantigens that are captured by antigen-presenting cells and presented to the immune cells, thus resulting in the perpetuation and the expansion of immune responses. Apoptosis may also represent a specialized mechanism whereby nuclear antigens may gain access to the immune system, leading to the induction of humoral responses to Ro/SSA and La/SSB ribonucleoproteins (Rosen et al., 1995). In fact, during early apoptosis, La/SSB autoantigen has been shown to redistribute diffusely to the cytoplasm, whereas both Ro/SSA and La/SSB autoantigens lead to surface apoptotic blebs and bodies (Ohlsson et al., 2002).

Implication of Glandular Epithelial Cells in Immunopathology

During the last decade, a new immunopathogenetic concept has emerged, placing the glandular or acinar epithelial cells at the center of the immunopathologic processes. Several lines of evidence indicate that the epithelia of SS display features of activation and participate in the induction and maintenance of the autoaggressive lymphocytic infiltrations that characterize the syndrome. In fact, the early lymphoepithelial lesions in primary SS have been demonstrated to begin around the ducts.

In salivary gland biopsies of SS patients, ductal and/or acinar SGEC display high levels of several immunoactive proteins, such as adhesion, presentation molecules that are known to mediate the lymphoid cell homing and the amplification of interactions between epithelial and immune cells. Epithelial cells adjacent to sites of intense inflammation display high levels of MHC class I and class II (DR) molecules (Lindahl et al., 1985), CD54/ICAM1, CD106/VCAM, and E-selectin adhesion molecules (St. Clair et al., 1992; Kapsogeorgou et al., 2001a; Tsunawaki et al., 2002), as well as CD80/B7.1 costimulatory molecules (Manoussakis et al, 1999; Tsunawaki et al., 2002; Fujihara et al., 1999). Also, high expression of CD54/ICAM1 has been detected in the periacinar myoepithelial cells of SS patients (Kapsogeorgou et al., 2001a).

Salivary epithelia have been also found to express increased levels of the proinflammatory cytokines IL-1,

IL-6, and TNF (Fox et al., 1994; Boumba et al., 1995) and of several T-cell-attracting and germinal-center-forming chemokines, including CCL3/MIP-1α, CCL4/MIP-1β, IL-8 and CCL5/RANTES (Cuello et al., 1998), STCP-1/MDC, CXCL-9/Mig, CXCL-10/IP-10, CXCL12/SDF-1, CCL17/TARC, CXCL13/BCA-1, and CCL19/ELC (Amft et al., 2001; Xanthou et al., 2001), whereas CXCR-4 (the counter-receptor for CXCL-12) and CXCR-3 (the receptor for CXCL-9 and CXCL-10) have been shown on periductally infiltrating T cells (Amft et al., 2001; Ogawa et al., 2002). Thus, the epithelial cells in the glandular lesions of SS, by virtue of aberrant expression of various immunoactive factors, are potentially capable of attracting lymphocytes and of promoting chronic inflammatory reactions. This fact is in agreement with the widespread involvement of epithelial tissues in primary SS patients that has been described as autoimmune epithelitis (Moutsopoulos, 1994).

The activated cell phenotype of glandular epithelial cells that is encountered *in situ* in SS patients may be solely due to the influence of factors produced locally by the infiltrating cells. On the other hand, their expression could also be a result of intrinsic cellular activation processes that may operate in patients' epithelia. Interestingly, the careful analysis of CD54/ICAM1 expression in salivary tissues of SS patients has revealed that the epithelial expression is observed throughout glandular tissues and is not confined in areas proximal to lymphoid infiltrates (Kapsogeorgou et al., 2001a). Such peculiar activation of epithelial cells was also previously recognized for the proto-oncogene c-myc expression (Skopouli et al., 1992).

The establishment and analysis of long-term cultured non-neoplastic SGEC obtained from minor salivary gland tissues (Dimitriou et al., 2002b) indicated that SGEC were capable of expressing various immunoactive molecules, including MHC class I and class II molecules, adhesion molecules, and functional CD80 (B7) and CD40 costimulatory molecules (Manoussakis et al, 1999; Kapsogeorgou et al., 2001a; 2001b; Dimitriou et al, 2002a; 2002b), and thus, are suitably equipped for the presentation of antigenic peptides and the transmittance of activation signals to T cells. The expression of functional CD80 (B7) costimulatory proteins deserves particular attention (Manoussakis et al, 1999; Kapsogeorgou et al., 2001b; Tsunawaki et al., 2002), since these proteins are typically expressed by classical antigen-presenting cells and are critical for the regulation of naïve T-cell activation. Notably, the (CD86) B7.2 molecules that are expressed by SGEC have been shown to display unique binding properties denoted by the functional interaction with CD28-receptor and reduced binding to the negative-regulator of immune responses CTLA-4 (Kapsogeorgou et al., 2001b).

Furthermore, parallel analyses of non-neoplastic SGEC cultures derived from SS patients and controls revealed the constitutive and stably higher expression of various immunoactive molecules in cells derived from SS patients, including MHC class I, costimulatory, adhesion, and apoptosis molecules (Manoussakis et al, 1999; Abu-Helu et al., 2001; Kapsogeorgou et al., 2001a; Dimitriou et al, 2002a; 2002b). This fact most likely indicates an intrinsic activation process taking place in the epithelia of patients. The nature of such intrinsic activation is presently unclear; however, the implication of an exogenous agent, such as an epitheliotropic virus remains a reasonable possibility (Figure 31.5).

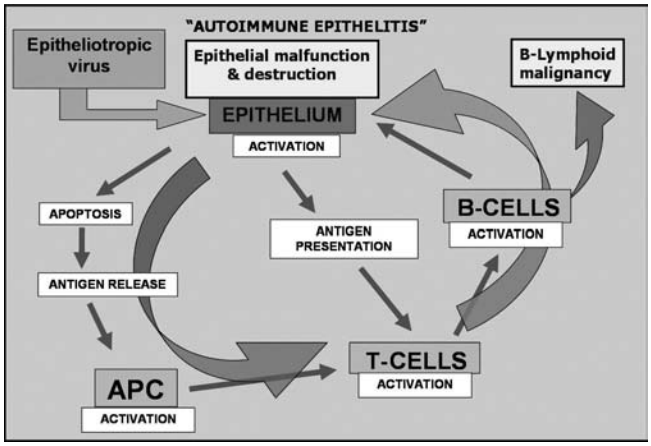

FIGURE 31.5 A schematic model for the pathogenesis of autoimmune epithelitis lesions in the salivary glands of Sjögren syndrome patients. An epitheliotropic virus and/or other intrinsic aberration(s) may initiate a constant degree of activation of epithelia and/or of apoptosis. During the course of recurring activation of salivary gland epithelial cells, persistent presentation of antigen(s) to T cells and salivary gland epithelial cell apoptosis, focal lymphocytic infiltrates, and the destruction of epithelia likely ensue. Salivary-gland epithelial cells, by virtue of aberrant expression of various immunoactive molecules, such as class I and class II MHC proteins, adhesion molecules, costimulatory proteins, proinflammatory cytokines, and chemokines, are likely able to attract lymphocytes and to induce the activation of T cells by typical antigen-presentation mechanisms. The cytokines (such as interferon-γ) that are produced by activated T cells may further trigger the antigen-presenting capacities of salivary-gland epithelial cells. In addition, epithelial apoptosis by direct cytotoxic and/or Fas-mediated mechanisms are also further induced. This leads to the release of epithelial constituents that are subsequently endocytosed and presented to T cells by professional antigen-presenting cells (APC), such as dendritic cells, that reside in the gland, thus further potentiating antigen-induced responses and chronic proliferation of T- and B-cells. The polyclonal activation of B lymphocytes is associated with the production of autoantibodies to epithelial cell constituents that may induce the dysfunction and/or the destruction of the glandular epithelia. Chronic B-lymphocyte stimulation may give rise to monoclonal B-cell processes and occasionally to frank malignant non-Hodgkin lymphoma.

GENETIC FEATURES

Multiple immunogenetic studies, familial clustering, and the increased frequency of certain MHC class II alleles strongly indicate the genetic predisposition of SS. Studies

from different countries and ethnic groups have revealed an increased frequency of several MHC HLA-DR alleles (DRB1 genes), including HLA-DR3, HLA-DR5, HLA-DRw11, HLA-DR8, and HLA-DRw53. Particular HLA class II alleles may have an important role in the regulation of the immune responses against the Ro/SSA and LA/SSB ribonucleoproteins. The generation of these autoantibodies has been correlated with heterozygosity for HLA-DQwl/DQw2 and particularly with the alleles DRB1*03, DQB1*02, DQA1*0501, DQB1*0201, as well as alleles comprising DQw6 (Harley et al., 1986; Reveille et al., 1991; Bolstad et al., 2001; Gottenberg et al., 2003). In addition, human recombinant Ro60 was recently shown to induce strong immunologic responses in transgenic mice carrying DR2, DR3, or DQ8 HLA genes, but not control HLA-DQ6 gene (Paisansinsup et al., 2002).

During recent years, the role of single-base-exchange polymorphisms of gene promoters or microsatellite regions of various immunologic molecules has been addressed in primary SS patients. Polymorphisms of transforming growth factor-β (TGF-β) and TNF have been shown to associate with the production of anti-La/SSB antibodies (Gottenberg et al., 2004). In addition, the genomic absence of the T-cell receptor Vβ7.2 gene in SS patients has been shown to associate with the presence of autoantibodies (Manavalan et al., 2004).

ENVIRONMENTAL INFLUENCES

A viral infection has been long suspected for the induction of SS, since transient or persistent infection of epithelial cells by a putative virus may be an initiating event for autoimmune reactions. Research has been focused on various types of viruses, including the herpesviruses (cytomegalovirus, Epstein–Barr virus, and human herpesvirus type-6), retroviruses, and the HCV virus; however, results have been inconclusive. Chronic lymphocytic sialadenitis is found in 14–50% of patients infected by HCV (Haddad et al., 1992); however, SS patients seldom show evidence of HCV infection. Type A retroviral particles have been identified in labial salivary gland extracts from patients with SS (Garry et al., 1990). Recently, based on the exclusive detection of viral genome sequences in minor salivary gland lesions of primary SS, the enterovirus coxsackie B virus arises as a possible candidate etiologic agent (Triantafylopoulou et al., 2004).

ANIMAL MODELS

Clinicopathologic features resembling human SS have been observed to develop in several animal species, either spontaneously or following experimental induction (Hoffman and Walker, 1987), including immunization with salivary gland extracts or tissues, graft-versus-host reactions, viral infections, as well as in TGF-β-knockout mice, HTLV1-transactivating factor-transgenic mice, and BAFF- (Groom et al., 2002).

The development of spontaneous sialodacryoadenitis-transgenic mice resembling primary SS has been reported in several inbred mouse strains, including the nonobese diabetic (NOD) mice, several murine lupus models (NZB, NZB/NZW, and MLR), the IQI/Jcl (Saegusa et al., 1994) and the NFS/sld mutant mice (Haneji et al., 1994). NOD mice, an inbred animal model for insulin-dependent diabetes, develop lymphocytic infiltrates of the salivary glands and antisalivary autoantibodies. In this strain, over 15 genetic loci have been associated with diabetes, insulitis and/or sialadenitis. Idd5 and Idd3 loci appear primarily to relate to the development of sialadenitis, whereas Idd1 appears protective (Brayer et al., 2000; Boulard et al., 2002; Cha et al., 2002). In addition, aberrant histomorphologic differentiation of submandibular glands has been observed (Cha et al., 2001). In these mice, the disruption of the ICA69 locus (a self-antigen expressed in brain, pancreas, salivary, and lacrimal glands) or immunotherapy against ICA69-specific T cells has been shown to ameliorate glandular disease (Winer et al., 2002).

TREATMENT

Treatment of SS patients is directed to provide symptomatic relief, to lessen mucosal dryness-induced damages, and to timely recognize and treat disease complications (Vlachoyiannopoulos and Moutsopoulos, 1997). In particular, patients with adverse prognostic factors should be regularly followed for disease complications.

For KCS, the application of eye lubricants as often as necessary is the mainstay of treatment. Diuretics, antidepressants, and antihistamines may worsen lachrymal and salivary hypofunction and should be used with caution. Patients with residual glandular function may benefit significantly from the oral administration of the muscarinic M3-receptor agonists pilocarpine (Vivino et al., 1999) and cevimeline (Petrone et al., 2002). Ordinary or closed glasses and soft contact lenses offer additional corneal protection. Corticosteroid-containing ophthalmic solutions should be avoided as they may induce corneal lesions or promote infections. Dental treatment with fluoride retards damage of teeth surfaces. For tender salivary gland enlargement, local application of moist heat and nonsteroidal anti-inflammatory drugs may be helpful. Bacterial infection as well as lymphoma should be always considered. Vaginal lubricants may be used to treat vaginal dryness and dyspareunia.

The decision for systemic therapeutic intervention remains largely empirical and is primarily based on the severity of extraglandular manifestations (Table 31.3).

TABLE 31.3 Classification of clinical manifestations and management of Sjögren syndrome according to the severity of systemic involvement

	Type I Debilitating but not life-threatening manifestations	Type II Potentially severe manifestations	Type III Severe or life-threatening manifestations
Chronic	Xerostomia Xerophthalmia Xerotrachea Dyspareunia Constitutive symptoms Raynaud phenomenon Thyroiditis	Distal tubular acidosis Tubulo-interstitial nephritis Bronchiolitis Diffuse interstitial lung disease High risk for lymphomatous transformation*	Progressive interstitial lung disease Lymphoma
Acute	Recurrent salivary gland enlargement Arthritis Purpura	Local infections	Visceral vasculitis Membranoproliferative glomerulonephritis Peripheral neuropathy Myositis CNS involvement Systemic infections
Clinical	Periodic follow-up	Regular follow-up	Frequent follow-up
Management	Conservative measures	Cautious medical intervention	Aggressive medical intervention

*Disease manifestations associated with high risk for lymphoma development (low C4 complement levels, and possibly purpura, persistent salivary gland enlargement, splenomegaly, lymphadenopathy and type II mixed monoclonal cryoglobulinemia).

Nonsteroidal anti-inflammatory drugs or hydroxychloroquine may be administered for arthralgias and myalgias and methotrexate for persistent arthritis. Despite encouraging initial results, the oral administration of natural human interferon-α has shown questionable efficacy (Cummins et al, 2003). Also, a recent study with the anti-TNF agent infliximab did not show any efficacy in primary SS (Mariette et al., 2004).

Patients with overt distal renal tubular acidosis may be orally treated with sodium bicarbonate to avoid nephrocalcinosis. For Raynaud phenomenon, avoidance of cold exposure, emotional stress, and smoking should be recommended and oral nifedipine may be tried. Leukocytoclastic vasculitis does not require specific therapy. Corticosteroids are mainly employed for severe extraglandular manifestations. Aggressive treatment with cytotoxic drugs carries an increased risk for lymphoma development and should be reserved for threatening systemic manifestations. Finally, the treatment of malignant lymphoma in SS patients is based on histology and extent, as for lymphoid neoplasias in general.

PERSPECTIVES ON IMMUNOPATHOGENESIS

Chronic immune system stimulation has a central role in the pathogenesis of SS, as illustrated by the extraordinary systemic immunologic hyper-reactivity and the lymphoplasmacytic infiltrates in affected organs. The further delineation of immune system functions such as memory, tolerance and suppression, the production and function of immunologic mediators, antigen presentation, apoptosis, and the effect of sexual, hormonal and neuroendocrine factors may further elucidate the pathogenesis of autoimmune disorders. Future immunologic studies of SS should address two major issues that may provide insight not only into the pathogenesis but also into specific treatment strategies. The first concerns the nature of processes that initiate and perpetuate the cellular and humoral autoreactive processes. The second involves how and to what extent these processes take part in the actual pathogenesis of the disorder. Although lymphocytic infiltrates characterize the lesions, it is still unclear to what extent these represent the primary cause of tissue destruction. Also, it is unknown whether epithelial tissues in SS patients are more vulnerable to autoaggressive attacks by the immune system, compared with healthy individuals. Glandular infiltrative lesions of SS may be actually perceived as idiomorphous chronic inflammatory reactions to antigens persistently expressed by epithelial cells. Such persistence may be due to repetitive exposure to antigenic substances and/or to the ineffective clearance of damaged cells by the immune system.

The anatomic proximity of salivary and lachrymal glands to mucosal surfaces and ports of antigen entry renders these tissues potentially accessible to various infectious agents and environmental antigens. In fact, salivary glands are sites that frequently harbor pathogenic viruses, and chronic infection of glandular tissues (e.g., by a slow pathogenic virus) has long been evoked to explain the pathogenesis of SS.

Such a process could induce various changes in infected epithelial cells, including aberrant function and differentiation, degeneration and altered survival, altered expression of various proteins and antigens, and enhanced antigen presentation capacities. Indeed, several lines of evidence indicate that the epithelial cells in the salivary and lacrimal glands, and probably elsewhere, are not simply the targets of activated immune cells but they actively participate in the genesis of lesions. These include the expression of various immunoactive substances and the widespread involvement of epithelial tissues.

Such "disseminated" epithelitis apparently arises as a direct response of immune cells to nonspecific inflammatory mediators secreted by local epithelial tissues and/or antigen-specific stimulation. Although not considered to be professional antigen-presenting cells, epithelial cells of certain tissues, such as those of the gastrointestinal tract, are capable of stimulating T cells in an antigen-specific manner, through the presentation of MHC-antigenic peptide complexes and expression of costimulatory molecules. In this context, glandular epithelial cells, initially affected and intrinsically activated by an environmental agent, may trigger a cascade of immune-mediated reactions, which in turn may incite chronic inflammatory and potentially injurious autoimmune reactions. The delineation of the antigenic specificity of tissue-infiltrating lymphocytes is of paramount importance for the understanding of SS. The precise appraisal of involvement of these cells in tissue injury, whether foreign-specific, cross-reactive, or truly autoreactive clones (e.g., Ro/SSA- or La/SSB-specific), may direct specific therapeutic interventions. Innate characteristics of SS patients, by and large directed by their genetic background, may also be determining factors for the induction and perpetuation of the disease. For instance, MHC class II molecules, by virtue of preferential binding and shaping of distinct peptides, influence specific T-cell activation and thus can be directly implicated in the generation of harmful immune responses. In addition, neuroendocrine factors, stress mediators, and sex hormones have been also recognized as active participants in immunological reactions. The elucidation of the role of such factors in the pathogenesis of autoimmune diseases is expected to improve our understanding. In this context, it should not escape attention that the exocrine glands are organs with one of the richest autonomic innervations, evolved to sense and to express emotional stresses.

CHAPTER

32

Rheumatoid Arthritis

SARAH MACKIE, MARK QUINN, AND PAUL EMERY

Academic Unit of Musculoskeletal Medicine, University of Leeds, Great George Street, Leeds, United Kingdom

Rheumatoid arthritis (RA) is a systemic inflammatory disorder characterized by symmetrical synovitis of peripheral joints and tendon sheaths. Without treatment there is progressive damage to soft tissue, cartilage, and bone, resulting in deformity and disability. Rheumatoid factor, an autoantibody that binds the constant region (Fc) of immunoglobulin, is usually present. Subcutaneous nodules and involvement of other organs may also occur.

Until the nineteenth century, there was no concept of RA as a disease entity. Descriptions of inflammatory arthritis date back to antiquity, but these contain insufficient detail to clearly differentiate RA from gout, except arguably in a few writings from Eastern cultures (Sturrock et al., 1977). Rheumatoid arthritis was first described in the medical literature by Landré-Beauvais in 1800, and was first named by Garrod in 1859. Paleopathologic evidence suggests that RA may have existed at least since the seventh century in Europe and for several millennia in North America (Aceves-Avila et al., 2001).

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Clinical studies utilize the classification of RA developed by the American College of Rheumatology (ACR), which is shown in Box 32.1 (Arnett et al., 1988). Because these tend to favor active RA, they may be modified for use in population studies (MacGregor et al., 1994). However, the ACR criteria are less useful in diagnosing RA of less than 12 weeks duration (Green et al., 1999). Assessments of disease severity include measures of joint inflammation (disease activity) and the rate of joint destruction. Predictors of future severe disease include the presence of rheumatoid factor (RF), the rapid appearance of erosions, shared-epitope positivity (discussed below), active disease at onset, extra-articular features, and poor functional status at disease onset.

Epidemiologic Features

The prevalence of RA is approximately 1% in the United States and Western Europe (Lawrence et al., 1998; Symmons et al., 2002). In some other populations, such as China, Japan and some black populations in rural South Africa, estimates of the prevalence are as low as 0.2–0.3%

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Box 32.1
The 1987 American Rheumatology Association criteria: at least four criteria must be fulfilled for classification as rheumatoid arthritis (RA)

1. Morning stiffness of joints—lasting at least 1 hour before maximal improvement for at least 6 weeks
2. Arthritis in 3 or more joint areas—soft tissue swelling or effusion in 3 or more joint areas simultaneously for at least 6 weeks
3. Arthritis of hand joints—swelling of wrist, metacarpophalangeal, or proximal interphalangeal joints for at least 6 weeks
4. Symmetric arthritis—simultaneous involvement of the same joint areas bilaterally for at least 6 weeks
5. Rheumatoid nodules—subcutaneous nodules over bony prominences, extensor surfaces, or in juxta-articular regions
6. Rheumatoid factor—detected by a method that is positive in <5% of normal controls
7. Radiographic changes—typical RA changes on hand and wrist radiographs, e.g., erosions, peri-articular osteopenia

Adapted from Arnett et al. (1988) ©Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley and Sons, Inc.

(Adejabo, 1995); while in certain Native American tribes, such as the Pima Yakima and Chippewa Indians, the prevalence is over 5% (Jacobsson and Pillemer, 1994). In most populations, RA is 2 to 3 times as common in women as in men, particularly in the premenopausal years.

Estimates of the incidence of RA in Westernized countries have shown a peak at 45–55 years of age for women and a continued increase up to 75 years for men (Wiles et al., 1999). However, the incidence of RA may be in decline over recent decades (Doran et al., 2002).

Clinical Features

Articular

The classical presentation of RA is that of a symmetrical inflammatory polyarthritis. The metacarpophalangeal joints, wrists, and metatarsophalangeal joints are most commonly involved at the onset, but any synovial joint may be affected. The inflammation primarily affects the synovial membrane—the lining of the joint; this is termed synovitis. The tendon sheath lining may also become inflamed. The inflammation causes the joints to become painful, swollen, and stiff after rest. As disease advances, progressive damage to bone and soft-tissues occurs, with consequent joint subluxation or deformity. Ulnar deviation and volar subluxation at the wrists and metacarpophalangeal joints are common. The fingers classically exhibit "swan neck" or "boutonniere" deformities. The cervical spine may also become involved.

Early radiographic signs of RA include soft-tissue swelling, peri-articular osteopenia, joint-space loss, and bony erosions. These erosions tend to appear at characteristic sites, such as the ulnar styloid and fifth metatarsophalangeal joints, and contribute to deformity. Serial radiographs are often used to monitor progression of RA, but ultrasound and magnetic resonance imaging are more sensitive in the detection of subclinical synovitis and early erosions. Such studies suggest that bone damage occurs in proportion to the level of synovitis but not in its absence (Conaghan et al., 2003).

TABLE 32.1 Extra-articular features of rheumatoid arthritis

System	Extra-articular features
Skin	Subcutaneous rheumatoid nodules
Lung	Fibrosing alveolitis Obliterative bronchiolitis Pleuritis Pleural nodules
Cardiac	Pericarditis/pericardial effusion Myocardial fibrosis
Eye	Scleritis Episcleritis Scleromalacia perforans Keratoconjunctivitis sicca
Bone	Osteoporosis
Hematologic	Felty syndrome
Neurologic	Peripheral nerve compression Peripheral sensory neuropathy Mononeuritis multiplex Cord compression Transverse myelitis

Extra-articular

Active RA may produce fatigue, low-grade fever, or weight loss. Extra-articular features, systemic vasculitis or amyloidosis, may be observed, particularly in late or severe RA (Table 32.1, Figures 32.1 and 32.2).

Prognosis

Most studies show that RA is associated with higher mortality, often due to respiratory disease, cardiovascular disease, and malignancy, including non-Hodgkin lymphoma and lung cancer (Mellemkjaer et al., 1996; Symmons et al., 1998). Early diagnosis and successful treatment of

FIGURE 32.1 Rheumatoid arthritis with nailfold vasculitis (see color plate section).

FIGURE 32.2 Rheumatoid nodule on extensor aspect of forearm (see color plate section).

inflammation with methotrexate are associated with better mortality rates (Symmons et al., 1998; Krause et al., 2000). Rheumatoid arthritis also carries an increased risk of infections and of osteoporosis.

Pathologic features

Normal Synovium

The synovial membrane lines the joint capsule. The lining layer (intima) is made up of cells called synoviocytes; lacking a basement membrane, it is supported directly by the subintima layer. The subintima contains loose connective tissue, blood vessels, lymphatics, and nerve endings. The synovial fluid lubricates and nourishes the adjacent cartilage.

Most synoviocytes are "fibroblast-like." These, also called type B synoviocytes, express adhesion molecules and synthesize constituents of the synovial fluid and the extracellular matrix. Others (type A synoviocytes) express macrophage markers and originate from bone marrow-derived monocytes. In this chapter, the terms "fibroblast" and "macrophage" are used as convenient terms for these two synoviocyte populations, but in RA these cells may take on altered properties such that exact correspondence with other fibroblasts and macrophages cannot be assumed.

Synovium in Rheumatoid Arthritis

In RA, synoviocytes of both types proliferate. The inflamed synovium also contains many new blood vessels, including specialized high endothelial venules that are formed early in RA, allowing leukocytes to move from the bloodstream into the tissues. Subintimal blood vessels are surrounded by $CD4^+$ T cells. The synovial membrane contains T and B lymphocytes and macrophages, sometimes in structures resembling lymphoid follicles or even germinal centers (Duke et al., 1982); synovial plasma cells produce autoantibodies. Neutrophils accumulate in synovial fluid, which becomes a fibrinous inflammatory exudate. Local release of matrix-degrading enzymes and inflammatory mediators promotes damage to adjacent cartilage (Zvaifler and Firestein, 1994).

In end-stage RA, fibrous scar tissue replaces most of the synovial cells and blood vessels. Ultimately the cartilage too is destroyed and the joint may fuse.

AUTOIMMUNE FEATURES

Evidence for the role of autoimmunity in RA is substantial, to the extent that it is sometimes regarded as a prototype autoimmune disease. The presence of RF and the association with other autoimmune diseases such as autoimmune hypothyroidism provided early support for this view. Strong evidence in support of an autoimmune basis for RA is provided by the observation that it may be ameliorated by immunomodulation by many different modalities, whether physiological (such as pregnancy), pathologic [RA tends to improve as $CD4^+$ counts decline with human immunodeficiency virus (HIV) infection], or pharmacologic (a wide variety of immunosuppressant drugs are used in treatments).

The role of humoral autoimmunity is supported by the presence of RF and other autoantibodies, discussed more fully below. Rheumatoid factor is produced in the synovium of affected joints, and its presence in the serum is related to adverse outcomes. Lately there has been much interest in antibodies against citrullinated epitopes, which are present in the joints of patients with RA. Commercial availability of serologic tests for these "anti-cyclic citrullinated peptide" (anti-CCP) antibodies has led to interesting data. Like RF, anti-CCP antibodies may antedate the development of clinical RA by several years (Nielen et al., 2004), and their presence predicts more aggressive disease. However, the corollary to this is that the presence of RF or anti-CCP does not appear necessary for the development of RA, nor is the presence of either or both sufficient to produce

disease. Yet the effectiveness of depletion of B-cell precursors in the treatment of RA, discussed below, is intriguing, since symptomatic response may correlate more closely with levels of RA-related autoantibody than with total immunoglobulin.

The role of T-cell-based autoimmunity is supported most strongly by the association with certain major histocompatibility complex type II (MHC II) haplotypes; although no single T-cell reactant appears unique to RA, certain self-antigens, such as BiP, are interesting (see section on B cells, below). Therapies directed against T cells, such as total lymphoid irradiation, cyclosporine, anti-CD4 therapy (Isaacs et al., 1997), and CTLA4-Ig (see below) tend to ameliorate RA. Research into new T-cell-directed therapies has already led to the introduction of drugs such as leflunomide into the clinical armamentarium.

Finally, diseases resembling RA may be produced experimentally in animals by various immunomodulatory strategies, as discussed below. These serve to illustrate the wide variety of immunologic mechanisms by which a similar clinical picture may be produced. By definition, this clinical picture must feature an inflammatory arthritis, and thus strategies directed primarily at inflammation, ranging in potency from nonsteroidal anti-inflammatory drugs (NSAIDs) to anti-tumor necrosis factor (TNF) therapies, are still among the most reliable strategies to relieve the symptoms of RA.

The concept of a self/non-self dichotomy in immunology has given way to more complex models in which innate and adaptive immunity interact with each other and with immunoregulatory mechanisms. It is difficult, therefore, to entirely separate autoimmune from inflammatory features, since innate immunity is so closely interwoven with both. Examples of such interactions will be given throughout the section dealing with pathogenic mechanisms.

GENETIC FEATURES

Twin studies in Finland and the UK suggest a genetic influence on the etiology of RA. Compared with a prevalence of 1% in the general population, a sibling or a dizygotic twin of a patient with RA has a 4% risk of developing RA, and monozygotic twin concordance is 15–20% (Aho et al., 1986). Epidemiologic data suggests that RA has a heritability of 50–60%, of which half may be attributed to the HLA genes (MacGregor et al., 2000).

HLA-DR4 is present in about 70% of North American and European white patients with RA, compared with a background prevalence of 28% in the non-RA population. In other populations, such as Israeli Jews, RA is associated with HLA-DR1.

The different RA-associated HLA-DR subtypes have in common a "shared epitope," a particular sequence of amino acids (residues 67–74: LLEQKRAA in HLA-DRB1*0401; LLEQRRAA in *0404, *0405, and *0101; and LLERRRAA in *1001) on the third hypervariable region of the HLA-DR β chain (Gregersen et al., 1987). Approximately 90% of Western Europeans with RA possess at least one HLA-DR carrying the shared epitope, and these patients have a higher risk of severe (seropositive, erosive, and extra-articular) disease (McDonagh et al., 1997). The prevalence of the shared epitope in RA is affected by the ethnicity of the background population, but the risk of severe disease given shared-epitope-positive RA seems similar in many populations (del Rincon et al., 2003). Other amino acid patterns in the 67–74 region of HLA may conversely be protective against RA (de Vries et al., 2002). A possible association between shared-epitope-negative RA and presence of the shared epitope in the mother of the RA patient has been explored in some studies (Harney et al., 2003).

No individual gene provides such a strong association with RA as the HLA region, necessitating larger population cohorts. Candidate gene approaches have yielded various associations in selected cohorts, but interesting results from high-throughput techniques in genomics are generating new hypotheses. The results of whole-genome linkage screens using DNA microsatellite data from sibling pairs affected by RA are also not always replicated in other cohorts (Eyre et al., 2004). Linkage analysis using single-nucleotide polymorphisms (SNPs) has yielded an association with the (*PADI4*) gene in Japanese RA (Suzuki et al., 2003), but this result has not been replicated in a UK population (Barton et al., 2004). An association with a missense polymorphism of a protein tyrosine phosphatase has also been identified in RA as in several other autoimmune diseases (Begovich et al., 2004).

ENVIRONMENTAL INFLUENCES

Disentangling genetic and environmental features is difficult. One approach taken is to compare the prevalence of RA exposed to different environmental conditions, but associations with factors such as urbanization and breastfeeding have not always been replicated in other studies. Smokers appear to have an increased risk of developing seropositive RA (Stolt et al., 2003), particularly if they are shared-epitope-positive (Padyukov et al., 2004). Evidence for the role of infection and the related "hygiene hypothesis" remains controversial (Carty et al., 2003).

ANIMAL MODELS

Autoimmune arthritis may be induced in animals by various methods: by immunization with cartilage components, by non-specific immune stimulation, by infectious

agents, or by genetic manipulation. None of these models exactly resembles human RA, but nevertheless may provide useful information relating to pathogenesis and treatment of autoimmune arthritis.

Most traditional models of autoimmune arthritis featurea stimulus to overcome normal immunologic tolerance to self-antigens, often by introducing immunostimulatory foreign material in close proximity to joint-related self-antigens. For example, collagen-induced arthritis (CIA) is induced by immunizing mice with rat type II collagen. This produces T cells directed against autologous cartilage antigens, causing a destructive synovitis. The disease can be transferred to an unaffected animal by T-cell transfer. A particular epitope of the rat collagen (peptide 256–270) was shown to be immunodominant in CIA (Malmstrom et al., 1996); glycosylation of this peptide was important (Corthay et al., 1998). Mice transgenic for RA-associated HLA molecules, which bind to the 261–273 peptide of type II collagen, are particularly susceptible to CIA (Andersson et al., 1998).

Transfer of monoclonal antibodies specific to native type II collagen into naïve mice, however, induces an acute form of arthritis that could be potentiated by lipopolysaccharide stimulation and displayed massive neutrophil infiltration (Nandakumar et al., 2003).

Streptococcal cell wall (SCW) arthritis is induced by intraperitoneal injection of SCW fragments in the Lewis rat. This produces a relapsing-remitting arthritis, the severity of which correlates with the level and persistence of SCW antigen within synovium. The arthritis is initially T-cell independent; it requires intact Toll-like receptor 2 (TLR-2) signaling (Joosten et al., 2003) and involves the alternative complement pathway. Later, T-cell-dependent mechanisms supervene (van den Broek, 1990).

Adjuvant-induced arthritis (AIA) in rats is produced by immunization with *Mycobacterium tuberculosis* in oil. The immunodominant epitope involved is the mycobacterial heat-shock protein (hsp) hsp65, which has a homolog in rats. AIA can also be induced in certain rat strains (presumably against self epitopes) by injecting adjuvant or pristane alone into the joint. In both AIA and pristane-induced arthritis, the oil is taken up by macrophages but is non-degradable, so that the macrophages are persistently activated and "primed" towards development of an autoreactive adaptive immune response. Interestingly, preimmunization with mycobacterial hsp65 or DNA coding a particular human hsp60 epitope (Quintana et al., 2003) protects rats not only against AIA but against various other experimental arthritides (including CIA and SCW arthritis); this protection appears to mediated by Th2 cytokine-secreting regulatory T cells (van Eden and Waksman, 2003), which normally compensate for the incomplete tolerance to self-hsp65 in Lewis rats (Durai et al., 2004).

Some animal models feature high levels of RF secretion, but the clinical manifestations often more closely resemble systemic lupus erythematosus (SLE) than RA. For example, the MRL/lpr mouse has a reduced expression of the Fas protein, involved in apoptosis, and produces high levels of RF in addition to SLE-type autoantibodies. Another example is the BAFF-overexpressing mouse; this cytokine influences peripheral B-cell numbers and may perhaps "rescue" autoreactive B cells from deletion (Lesley et al., 2004). The BAFF transgene produces an SLE-like syndrome featuring RF- and SLE-related autoantibodies such as antibodies against double-stranded DNA.

The K/BxN mouse, a non-derived mouse with a transgene T-cell receptor, develops a spontaneous destructive arthritis mediated by antibodies against glucose-6-phosphate isomerase (G6PI) (Kouskoff et al., 1996). Glucose-6-phosphate isomerase is a ubiquitous intracellular protein, but may also be found extracellularly over the cartilage surface of normal joints (Matsumoto et al., 2002). Production of these antibodies requires T cells and occurs only in lymph nodes that drain the affected joints (Mandik-Nayak et al., 2002). Transfer of anti-G6PI antibodies to healthy mice produces a transient arthritis that does not require the presence of B or T cells (Korganow et al., 1999). The antibodies cause disease via Fc receptors and complement (Ji et al., 2002), but localization of antibodies to the joint depends on mast cells, neutrophils, and Fc receptors (Wipke et al., 2004).

A different spontaneous T-cell dependent model of arthritis is produced by a mutation in ZAP-70, a T-cell signaling protein (Sakaguchi et al., 2003). Abnormal T-cell signaling produces alteration in T-cell selection in the thymus resulting in autoreactive T cells. Mice with the disease show elevated IgG-RF and antibodies to type II collagen but not to double-stranded DNA. The disease may be transferred by $CD4^+$ T cells into nude mice, but not by transfer of serum. ZAP-70 signaling is also suppressed in patients with RA, but this seems to be a consequence of the systemic inflammation rather than a gene mutation; it improves with successful treatment of RA.

Animal models demonstrate the wide variety of mechanisms that may produce a similar phenotype of autoimmune arthritis. For example, mechanisms of innate immunity may be the initiating trigger or the final effector mechanism; some autoantibodies are sufficient to cause arthritis, whereas others are not; and a pathogenic T-cell repertoire can be produced by means of a single transgenic T-cell receptor or by affecting T-cell signaling more globally. However, none of these animal models exactly resemble RA (many resembling psoriatic arthritis more closely), and treatments that work in animal models do not always translate well into clinical practice. Nevertheless, these approaches will continue to produce fascinating insights into autoimmunity and to generate hypotheses relevant to human disease.

PATHOGENIC MECHANISMS

Different mechanisms are likely to be responsible for initiation, perpetuation, and chronic inflammation (Thomas and Lipsky, 1996). The presence of autoantibodies and the HLA association suggest that the adaptive immune system is involved in RA. An exogenous or endogenous "danger" signal from the innate immune system may be necessary for an adaptive autoimmune response to develop (Matzinger, 2002). A failure of self tolerance may also implicate dysfunctional regulatory T cells or natural killer T (NKT) cells.

Cytokines are present in complex networks that may be self-reinforcing (Firestein and Zvaifler, 1990). Inflammation may be also perpetuated by the continued ingress of im-mune cells, due to signals from adhesion molecules and chemokines, and by the antigen-specific amplification inherent in adaptive immunity. Defective apoptosis of immune cells may also perpetuate inflammation, and the stromal environment may play a role in this (Salmon et al., 1997); the fibroblasts themselves also tend to proliferate rather than undergo apoptosis. Potential mechanisms by which cells in RA resist apoptosis include the apoptosis inhibitor, Fas-associated death domain-like interleukin-1β-converting enzyme-inhibitory protein (FLIP), in RA macrophages (Perlman et al., 2001), activation of NFκB, and overexpression of the signaling molecules Bcl-2 and Stat-3 (Liu and Pope, 2003), and of heat shock proteins such as hsp70 (Mosser et al., 1997).

Role of Shared Epitope

Given the location of the shared epitope on the class II HLA gene, its effect on susceptibility and severity of RA (see above) is likely to operate via an interaction with T cells. However, the exact mechanism of this remains unclear (Buckner and Nepom, 2002); broadly speaking, it may permit autoreactive T cells to escape peripheral or central tolerance. Some theoretical possibilities follow and are laid out in Table 32.2.

1. The MHC has a vital role in generating normal self-tolerance, and is involved in both central and peripheral mechanisms of this. One of the mechanisms of peripheral tolerance involves regulatory T cells. The shared epitope might be involved in a failure of regulatory T cells to keep autoreactivity in check.
2. The shared epitope may predispose to immunologic tolerance to an important pathogen-related peptide, causing an inadequate immune response and persistence of the pathogen, theoretically triggering the onset of RA. Epstein–Barr virus, for example, expresses a protein with amino-acid sequence homology to the shared epitope.
3. The shared epitope may predispose to presentation of a particular self peptide, triggering autoimmunity. However, the identity of such an "arthritogenic" self peptide is unclear, partly because of epitope spreading, whereby autoimmunity comes to involve progressively greater numbers of epitopes from the target organ. Some novel autoantibodies that are relatively specific for RA have lately been discovered, but the role of the shared epitope in producing T-cell help for the production of such autoantibodies remains undefined. One suggestion is that the shared epitope may cause imperfect intracellular antigen processing—for example, compared with non-RA associated HLA DR*04 alleles, the rheumatoid arthritis-associated HLA class II alleles DR*0401, *0404 and 0405 form relatively unstable DR-CLIP (class II associated Ii peptide) complexes, which may result in a tendency to present non-CLIP self peptides (Patil et al., 2001).
4. The shared epitope may predispose to presentation of a particular foreign peptide, which then cross-reacts with a self peptide. For example, the shared epitope may tend to present a peptide from dnaK (the 70 kDa heat shock protein of *Escherichia coli*), which has a natural ligand that has a QKRAA sequence; other sequences on dnaK have homology with sequences of type II collagen (Auger and Roudier, 1997).

TABLE 32.2 Possible mechanisms by which the shared epitope might confer susceptibility to rheumatoid arthritis

	Predisposition towards decreased immune reactivity	**Predisposition towards increased immune reactivity**
Immune response to endogenous (self) antigen	1. Impaired response of regulatory T cells that are necessary for maintaining peripheral tolerance to autoantigen	3. Shared epitope predisposes to presentation of self peptide, e.g., intracellular self peptide; *or* shared-epitope peptide sequence itself is immunogenic
Immune response to exogenous (foreign) antigen	2. Shared epitope predisposes to impaired defense against pathogen; pathogen persists and itself affects the immune system	4. Defense against pathogens is overexuberant, leading to cross-reactivity to self antigens by "molecular mimicry"

T Cells

There is substantial evidence for the role of T cells in RA. The strong association with HLA-DR and the shared epitope, the Th1 dominance in RA synovium, the evidence for both $CD4^+$ and $CD8^+$ T-cell activation in RA, and the involvement of T cells in many animal models are all supportive; the efficacy of T cell-directed therapies such as total lymphoid irradiation, thoracic duct drainage, cyclosporine, leflunomide, and costimulatory blockade provides further evidence.

The expression of early activation markers such as CD69 by synovial, but not peripheral blood, T cells suggests that T-cell activation occurs within the inflamed joint (Iannone et al., 1996). Activated RA T cells, via expression of CD154 (CD40), are capable of activating B cells and dendritic cells (MacDonald et al., 1997). Polyclonal T cells enter the joint in established RA, so that T-cell receptor repertoire studies have failed to consistently identify a particular pathogenic T-cell clone. The pathogenic autoantigen could be related to any of the targets of the RA-associated autoantibodies described below, and may not be the same in every individual. Mechanisms potentially involved in breaking tolerance have been discussed in the section above, and include molecular mimicry (perhaps by the effects of infection) and the appearance of new epitopes, or modification of existing epitopes, with ongoing inflammation or joint damage—citrullination of joint-related antigens, discussed below, provides a potential example of this.

The cytokine profile in RA is broadly Th1-like, but is rather atypical in that there are high levels of TNF-α and moderate levels of interferon-γ (IFN-γ), but minimal interleukin 2 (IL-2). T cells in RA exist in a state of partial activation, as shown by their markers (expression of IL-2 receptor is limited [Emery et al., 1988]), by functional tests *in vitro* (the autologous mixed lymphocyte response is impaired [Bergroth et al., 1989], as is the response to mitogens or recall antigens), and by anergy to tuberculin testing *in vivo* (Emery et al., 1984). $CD4^+$ T cells in RA are also atypical in that they possess some cytotoxic functions and receptors more usually associated with natural killer (NK) cells (Weyand et al., 2003). They have impaired ability to generate a clonal burst or to undergo activation-induced cell death or apoptosis (Salmon et al., 1997; Szodoray et al., 2003).

T-cell function seems to improve when RA is treated. Cytokines such as TNF-α (Cope, 2003) or IFN-β (Pilling et al., 1999), and oxidative stress can all alter T-cell function *in vitro*; defective thymic output of T cells has also been proposed as a primary cause (Weyand et al., 2003).

Regulatory T cells have a role in maintaining peripheral tolerance of autoantigens, and evidence from animal models suggests that they have the potential to suppress autoimmune disease (see above). Regulatory T cells operate by various mechanisms, including direct cell–cell contact and by secretion of cytokines such as TGF-β, causing "bystander suppression" of immune cells in the locality of the antigen recognized by the regulatory T cell. This is a rapidly-developing field of research. For example, RA synovium contains $CD25^+CD4^+$ T cells with the capability to inhibit responses of other T cells (Cao et al., 2003); it is as yet unclear what role these play in either promoting or limiting the autoimmunity of RA.

B Cells

The presence of RF was originally thought to be pathognomic of RA, and thus RA was originally conceptualized as an autoantibody-driven disease. Localization of immune complexes to the joint, and the presence of polyclonal B-cell activation in RA provide further evidence for a role for B cells. However, early studies showed that infusion of RF-containing serum into healthy volunteers did not elicit arthritis. Rheumatoid arthritis may occur in the absence of RF, although presence of RF correlates strongly with severity and extra-articular manifestations. Some autoantibodies, such as anti-G6PI, even appear to be correlated with severity and extra-articular manifestations but not with susceptibility to RA (van Gaalen et al., 2004a). Rheumatoid factor and anti-CCP antibodies may be detected in asymptomatic patients years before the development of clinical RA; 49% of RA patients were positive for either IgM-RF or anti-CCP on at least one occasion before the development of RA, compared with 1% and 0.6% respectively for patients who did not later develop RA (Nielen et al., 2004). These results suggest that these autoantibodies might have a role in pathogenesis of early RA, but demonstrate that their presence alone is not sufficient to elicit clinical disease. Evidence that would support a pathogenic role for an autoantibody in RA would include the demonstration of T cells reacting to the same antigen in RA, class switching, and affinity maturation. These have been described for various candidate autoantibodies, as will be seen below.

Beyond production of autoantibodies, B cells can also act as antigen presenting cells with or without costimulatory molecules to induce T-cell activation and expansion. B cells also produce a variety of cytokines, including lymphotoxin, IL-6, and IL-10 (Dorner and Burmester, 2003). They appear to play a role in formation of lymphoid organs and germinal centers and influence the activation and regulation of dendritic cells and effector T cells. It has been suggested that a similarity between the molecules expressed by synoviocytes to those expressed by follicular dendritic cells may promote B-cell persistence in RA synovium (Edwards and Cambridge, 1995).

Rheumatoid factor is produced by normal individuals, usually transiently, in response to events such as infection or vaccination; it preferentially binds IgG that is aggregated,

such as IgG bound in immune complexes; therefore, it may have a physiological role in modulating the effects of small immune complexes, or in stimulating RF B cells to present antigens contained in those immune complexes. The RF produced due to such stimuli is usually germline-encoded and of IgM isotype, but in RA there is evidence of class switching and affinity maturation, suggesting the involvement of RF-specific T-helper cells. A requirement for activation of TLRs of RF B cells (Leadbetter et al., 2002) may help explain why more immunoglobulin is produced in affected joints and draining lymph nodes. RF B cells can be triggered by T cells specific for a variety of foreign antigens (Roosnek and Lanzavecchia, 1991).

Various novel autoantibodies have recently been described in RA; many appear to be directed against "cryptic" antigens, those exposed in the context of cell stress or joint damage (Table 32.3).

Many of these autoantibodies recognize citrullinated autoantigens. For example, anti-filaggrin antibodies, antiperinuclear factor, antikeratin, and anti-Sa antibodies all recognize citrullinated epitopes. Citrullination tends to occur when inflammatory cells undergo apoptosis, activating the enzyme peptidyl arginine deiminase. Sera from different patients with RA react with different combinations of citrullinated antigens, such that no particular peptide is dominantly antigenic. An enzyme-linked immunosorbent assay (ELISA) detecting antibodies reacting to CCP is available for clinical use; epidemiologic studies have revealed an association with the shared epitope (van Gaalen et al., 2004b). This is interesting, since citrullinated peptides can be shown to fit into the P4 pocket of the shared epitope, but the homologous arginine peptides do not (Hill et al., 2003). B cells from the synovial fluid of anti-CCP-positive RA patients spontaneously produce anti-CCP antibodies, but B cells from the peripheral blood of these patients do not. This suggests antigen-driven maturation of CCP-specific B cells at the site of inflammation in RA (Reparon-Schuijt et al., 2001). Anti-Sa antibodies fall into at least two populations: one, recognizing 50 and 46 kDa antigenic determinants, is highly specific for RA and tends to be elevated during flares of disease; the other, recognizing the 68 kDa Sa antigen, is also observed in patients with SLE and tends to be seen in RA patients during remissions (Escalona et al., 2002).

The RA33 antigen, a shuttling protein involved in mRNA transport, is overexpressed in RA synovium; Th1-polarized T cells directed against RA33 have also been identified in RA (Fritsch et al., 2002). While anti-RA33 antibodies are described in RA, they are not specific for the disease, being also associated with multisystem autoimmune diseases.

BiP, a chaperone protein, migrates onto the cell surface under conditions of cell stress, and is overexpressed in RA synovium. Many patients with RA have T cells reactive to BiP (Blass et al., 2001).

Neutrophils

Neutrophils within RA synovium are involved in generating reactive oxygen species, and proinflammatory and chemoattractant molecules. They also produce vascular endothelial growth factor (VEGF) (Kasama et al., 2000). They express class II MHC, but not the costimulatory molecules CD80 and CD86 (Cross et al., 2003). Synovial fluid has an antiapoptotic effect on neutrophils (Ottonello et al., 2002).

Synoviocytes

As discussed above, macrophage-like synoviocytes are capable of antigen presentation whereas fibroblast-like synoviocytes in RA express high levels of proteases that degrade cartilage, and may exhibit properties similar to those of follicular dendritic cells.

Fibroblast-like synoviocytes in RA appear "transformed" in some respects (Zvaifler and Firestein, 1994). They produce high levels of TGF-β and platelet-derived growth factor (PDGF), perhaps stimulating their own growth in autocrine fashion, and evidence of monoclonal expansion in the pannus area may be observed (Imamura et al., 1998). Synoviocytes from subjects with RA co-implanted into

TABLE 32.3 Some novel autoantibodies in rheumatoid arthritis

Antibody	Antigen	Sensitivity (%)	Specificity (%)
Antikeratin	Filaggrin (citrullinated portion)	40	92–99
Anti-cyclic citrullinated peptides	Deiminated arginine in molecules such as filaggrin, fibrin	53	96
Anti-RA33	Heterogenous nuclear ribonucleoprotein A2	32	90–96 in absence of connective tissue disease
Anti-Sa	Unknown	42	98
Anti-p68	BiP (formerly known as grp78)	40	96

SCID mice adjacent to articular cartilage are capable of cartilage destruction that is independent of inflammatory cell infiltration; unlike conventionally "transformed" cells, however, their proliferative capacity is limited (Seemayer et al., 2003). The pathogenic significance of this is controversial, but RA synoviocytes can be shown to exhibit reduced apoptosis *in vivo* and are resistant to apoptotic signals mediated via CD95 (Fas) and TNF-α *in vitro*. Embryonic genes are expressed by synovial fibroblasts in RA (Sen et al., 2000).

Cytokines and Soluble Mediators

Many proinflammatory cytokines are produced in RA (Feldmann et al., 1996). They may form self-perpetuating networks; however, disease reactivates once treatment with IL-1 or TNF-α blockers is stopped, suggesting that cytokine networks are not the sole mechanism of disease persistence in RA. The following is limited to a brief overview of a complex field.

Most of the cytokines in RA synovium (Table 32.4) appear to derive from macrophages rather than from T cells; levels of T-cell products such as IFN-γ and IL-2 are relatively scanty (Firestein et al., 1990), although there is debate regarding whether the observed levels of IFN-γ are biologically significant. The cytokine profile displays a bias towards a Th1 type (Simon et al., 1994; Steiner et al., 1999), although this may vary according to the histologic features (Klimiuk et al., 1997).

In RA, IL-1 and TNF-α are principally produced by macrophages, and in smaller quantities by B cells, T cells, and (in the case of TNF-α) fibroblasts (Firestein et al., 1990). Injection of these cytokines into animal joints synergistically produces synovitis (Henderson and Pettipher, 1989). They have many actions, including stimulation of T cells, B cells, macrophages, and fibroblasts. IL-1 and TNF-α induce expression of chemokines and vascular adhesion molecules (ICAM1, E-selectin and VCAM), which enable recruitment of leucocytes including polyclonal memory T cells (Sedgwick et al., 2000). Both TNF-α and IL-1 induce expression of further IL-1, of many other cytokines, and of matrix- and tissue-degrading enzymes. Bone metabolism is also affected: Il-1 regulates production of osteoprotegerin (OPG); IL-1 and TNF-α cause osteo-

blasts to increase production of receptor activator of NFκB ligand (RANKL). Effects of RANKL include maturation of osteoclast precursors and bone resorption by mature osteoclasts.

Interleukin 6 is produced by a wide range of cells in RA, including fibroblasts under the influence of IL-1 and TNF-α. In combination with its soluble receptor, sIL-6R, IL-6 induces both B- and T-cell proliferation, and promotes differentiation of macrophages, osteoclasts and megakaryocytes. Interleukin 6 also stimulates production of acute phase proteins by the liver.

Interleukin 12, produced by dendritic cells and activated macrophages, increases production of IFN-γ by $CD4^+$ T cells and NK cells, biasing the cytokine response towards a Th1 pattern.

Interleukin 15 is a cytokine, produced primarily by macrophages, with structural similarities to IL-2. It is chemotactic for activated T cells and promotes the production of IL-1, TNF-α and IL-6 (McInnes et al., 1997).

Interleukin 17 is produced by a small number of T cells in RA synovium, but synergizes with IL-1 or TNF-α and is proinflammatory in its action on fibroblasts (Miossec, 2003).

Interleukin 18 shares a signal transduction pathway with IL-1, and is produced by macrophages and fibroblasts. In synergy with IL-15 and IL-12, it increases the production of TNF-α and IFN-γ (Liew et al., 2003).

Macrophage migration inhibitory factor (MIF) is a cytokine of unique structure with many proinflammatory effects, including upregulation of IL-1, TNF-α, prostaglandins, and matrix metalloproteinases (Morand et al., 2003). It induces proliferation of fibroblast-like synoviocytes via extracellular signal regulated protein kinase (ERK) mitogen-activated protein (MAP) kinase rather than NfκB (Lacey et al., 2003). Levels of synovial MIF are elevated in RA and correlate with disease activity.

In RA, there is inflammation despite compensatory upregulation of immunoregulatory cytokines and cytokine antagonists, such as IL-10, IL-13, TGF-β and IL-1Ra and the soluble TNF-α receptors. Interleukin 10, from synovial fibroblasts, inhibits production of proinflammatory cytokines by macrophages and may contribute to the low level of production of IL-2 and IFN-γ by synovial T cells. Transforming growth factor-β is profibrotic and chemotactic for monocytes. Interleukin 1Ra, produced by mature macrophages and by stimulated intrasynovial neutrophils, is a competitive antagonist of IL-1 at its receptor binding site.

Growth Factors

Growth factors upregulated in RA include PDGF and fibroblast growth factor (FGF), which may have autocrine effects, and VEGF, a major angiogenic factor.

Chemokines

Chemokines comprise four supergene families according to their cysteine residue structure: C-X-C, C-C, C, and C-X_3-C (Szekanecz et al., 2003).

Most chemokine ligands act on more than one chemokine receptor within each supergene family. The receptors are differentially expressed on various inflammatory cells (Katschke et al., 2001; Shadidi et al., 2003). Integrins and chemokine receptors may direct organ-specific lymphocyte homing; in RA, some of this specificity seems to be lost (Buckley, 2003).

The C-X-C family contains ligands such as IL-8 (CXCL8), which is produced in large quantities by macrophages and fibroblasts in RA synovium and has proinflammatory and proangiogenic effects; it influences leukocyte chemotaxis, adhesion molecule expression, cell–matrix interactions, and the respiratory burst of neutrophils. CXCL9 and 10 are also produced by RA synovium (Patel et al., 2001), and their receptor CXCR3 is expressed on almost all T cells infiltrating the joint in RA, but only a minority of circulating T cells in these patients (Qin et al., 1998). Another member of this family, SFD-1 (CXCL12) has its own receptor, CXCR4, is also proangiogenic and may play a role in retention of T cells within the RA synovium.

C-C chemokines such as MCP-1 (CCL2), MIP-1α (CCL3) and RANTES (CCL5) are all produced in large amounts by RA synoviocytes and have roles in chemotaxis and activation of macrophages and in promotion of angiogenesis. T cells infiltrating high endothelial venules in RA synovium bear the receptor CCR5 in addition to CXCR3 (Patel et al., 2001).

The C family includes lymphotactin (XCL1), which seems to play a role in T-cell chemotaxis in RA (Wang et al., 2004).

The C-X_3-C family has a sole member, fractalkine (CX3CL1), which has its own receptor, CX3CR1. Effects in RA may include monocyte chemotaxis and angiogenesis.

Complement

C4 depletion in synovial fluid is evidence of complement activation in RA (Ruddy and Austen, 1975; Konttinen et al., 1996). Complement's many roles may be relevant in RA pathogenesis, including neutrophil chemotaxis, opsonization, and local inflammation. Low levels of complement may be associated with serious extra-articular manifestations of RA, although the association is not sufficient to be clinically useful (Saraux et al., 2001).

Pro- and Anti-Angiogenic Factors

In RA, angiogenesis (neovascularization) occurs and may play a significant role in joint damage. In early RA, high

synovial vascularity on magnetic resonance imaging (MRI) or Doppler ultrasound correlates with increased joint erosions (Taylor, 2002). Angiogenesis is promoted by many factors, including VEGF, VCAM1, and E-selectin. Other stimulators of angiogenesis include angiogenin, the angiopoietins (Ang-1 and Ang-2), G-CSF, IL-8, TNF-α, FGF, epidermal growth factor (EGF), insulin-like growth factor (IGF) and TGF-β; inhibitors include IL-12, IFN-γ and tissue inhibitor of metalloproteinases (TIMP). The joint in RA is hypoxic compared with normal joints and this induces expression of HIF-1α; in addition to optimizing intracellular metabolism for hypoxic conditions, hypoxia inducible factor-1α (HIF-1α) regulates transcription of mediators such as VEGF. Production of VEGF is also induced in RA synovial T cells by cytokines TNF-α and IL-1. The same appears true of many other proangiogenic factors including αVβ3 integrin.

Adhesion Molecules

The intercellular adhesion molecule 1 (ICAM1), expressed widely in RA synovium and induced by TNF-α, IL-1 or IFN-γ, helps recruit lymphocytes, monocytes, and neutrophils.

The vascular cell adhesion molecule 1 (VCAM1) is expressed by the RA synovial intima and by activated endothelium. It is upregulated by IL-1, TNF-α, IFN-γ, and IL-4. It binds α4β1 integrin (found on lymphocytes and macrophages) and also α4β7 integrin, expressed by many synovial lymphocytes as well as those homing to gut lymphoid tissue.

Recognition of Pathogen-Associated Molecular Patterns

Pathogen-associated molecular patterns (PAMPs) are recognized by pattern-recognition receptors (PRRs), which play a key role in innate immunity in the recognition of pathogens or of cellular injury. Macrophage mannose receptors and scavenger receptors help mediate phagocytosis. Non-phagocytic immune cells may be directly activated by TLRs. TLR4 may be activated not only by bacterial lipopolysaccharide but also by hsp60, hsp70, and fibronectin, all present within the inflamed joint. In a serum transfer model, the intracellular effects of TLR4 and Il-1 activation were similar (Choe et al., 2003). TLR2 expression by fibroblasts is upregulated by inflammatory cytokines (Siebl et al., 2003) and its effects are mediated by nuclear factor-κB (NFκB).

Small amounts of bacterial mRNA may be detected in inflamed joints, mainly relating to commensal skin and gut organisms (Kempsell et al., 2000). These commensal organisms are unculturable and do not cause clinical evidence of joint sepsis.

Intracellular Signaling Pathways

The NFκB pathway is activated by a wide range of inflammatory and immune stimuli such as cytokines, TLR engagement, and cellular stress. NFκB is a transcription factor that, when released from inhibition by cytoplasmic IκB, translocates to the nucleus and induces transcription of many proinflammatory cytokines, such as TNF, IL-6 and IL-1β; enzymes, such as inducible nitric oxide synthase (iNOS) and cyclooxygenase 2 (COX-2); and adhesion molecules. NFκB also inhibits apoptotic cell death. The NFκB pathway thus appears to summate diverse immune signals and to be an important local regulator of inflammation. Expression of both NFκB, particularly in macrophage-like synoviocytes, and members of the activator protein 1 (AP-1) transcription factor family can be demonstrated in RA (Handel et al., 1995); they are synergistically activated by cytokines such as TNF-α and IL-1 (Granet et al., 2004). It is notable that steroids, which are among the most reliably effective drugs for RA, inhibit the NFκB and AP-1 pathways; various other drugs used for RA also inhibit NFκB. Specific inhibitors of NFκB dramatically ameliorate disease manifestations in mouse models of erosive inflammatory arthritis (Clohisy et al., 2003).

Rheumatoid arthritis synovium shows activation of the mitogen- and stress-activated protein kinase pathways: p38 MAP kinase, ERK, and c-Jun amino-terminal kinase (JNK) (Schett et al., 2000). Each of these pathways is predominant in a particular region of the synovial membrane. For example, the p38 pathway predominates in synovial endothelium and mediates angiogenesis, chemoattraction and vasodilatation; the JNK pathway mediates Th1 differentiation of T cells, and cytokine and MMP expression by mononuclear cells.

Pathogenesis of Bony Erosions

Recently, data has emerged that osteoclast recruitment, maturation, activation and osteolysis are regulated by RANKL in synergy with IL-1 and TNF-α (Romas et al., 2002a). RANKL is produced in RA by activated T cells and synovial fibroblasts. In rat AIA, T-cell activation leads to a RANKL-mediated increase in osteoclasts and bone loss (Kong et al., 1999). Knockout of RANKL, or administration of analogs of OPG, the soluble decoy receptor to RANK, blocks bone destruction in animal models (Romas et al., 2002b) while having little effect on cartilage damage (Pettit et al., 2001).

Enzymes Involved in Tissue Damage

Zinc-dependent metalloproteinases include matrix metalloproteinases (MMPs), transmembrane ADAMs (e.g., the TNF-α converting enzyme [TACE]) and soluble ADAMTS

such as the aggrecanases ADAMTS-4 and -5. Tissue inhibitors of metalloproteinases (TIMPs) inhibit many of these. Matrix metalloproteinase levels are increased in RA. These enzymes cleave matrix proteins, such as collagen and aggrecan, and may activate or inactivate various inflammatory mediators. It has been proposed that products of MMP activity may be immunogenic in themselves (Descamps et al., 2003). The TNF-α converting enzyme causes shedding from the cell membrane of TNF-α, soluble TNF receptors, and fractalkine. Serine and cysteine proteases, such as cathepsins, also contribute to degradation of the cartilage matrix.

Many key inflammatory mediators participate in pathways of tissue damage. For example, the inducible COX-2 is overexpressed in RA synovium, causing increased production of proinflammatory prostaglandins, including PGE2. Nitric oxide, which is involved in both cartilage and bone damage, is produced by iNOS. Reactive oxygen intermediates are generated by the respiratory burst of neutrophils and contribute to local tissue damage.

Neurotransmitters and Mechanical Stress

RA spares the joints on the side of a pre-existing hemiparesis (Thompson and Bywaters, 1961). This may be partly due to a proinflammatory effect of mechanical stress: cultured synovial fibroblasts produce heat shock proteins in response to shear stress (Schett et al., 1998), and joint areas subject to greater mechanical stress exhibit greater inflammation in RA (Tan et al., 2003). However, AIA in rats is less severe in limbs previously treated with the sympathetic blocker guanethidine, suggesting that sympathetic neurotransmitters or cotransmitters may also play a role in inflammation. Neuropeptides such as substance P, released locally on stimulation of sensory nerves, have proinflammatory effects; substance P has been shown to stimulate RA synoviocytes to proliferate via the neurokinin-1 receptor (Lotz et al., 1987). Antagonists of this receptor have shown promise in animal models but remain untested in RA.

Summary: Interaction of Pathogenic Mechanisms

With such a large number of interdependent factors involved in pathogenesis of RA, many different models of pathogenesis might be constructed. Most of these would involve predisposing factors such as the genetic background (including shared epitope) and the existing T-cell repertoire, which controls tolerance to autoantigens. For example, shared-epitope positivity may predispose to the development of anti-CCP antibodies, which are specific for RA and may precede clinical symptoms by some years. The trigger for disease initiation seems most likely to be a stimulus, such as infection or injury, which causes activation of innate immunity in the joint. This would activate local dendritic cells, fibroblast-like synoviocytes and macrophages. Dendritic cells would travel to the local lymph nodes and there present auto-antigen to T cells. T cells allow B cells to produce high-affinity, class-switched autoantibodies, perhaps initially in the local lymph node and later within the joint itself. Chemokines and adhesion molecules expressed by the affected joint would stimulate the ingress of T cells and other inflammatory cells, such as neutrophils. There the T cells would interact with dendritic cells and with macrophage- and fibroblast-like synoviocytes, eliciting production of pro-inflammatory cytokines, tissue-degrading enzymes and partial transformation of the synoviocytes into an erosive, proliferating pannus. Once established, autoimmune joint inflammation would become self-perpetuating by means of a number of factors, and spread to a characteristic distribution of joints, perhaps due to mechanical and neurogenic factors. Extra-articular features usually develop in the context of severe disease in the presence of high titer RF and are associated with other autoantibodies such as anti-G6PI; whether these directly cause the extra-articular features is unclear.

IMMUNOLOGIC MARKERS IN DIAGNOSIS

As yet no single immunologic marker is in itself diagnostic of RA, particularly in early disease when early treatment has the maximum potential to modify disease progression. However, in combination with careful clinical assessment and radiographic imaging studies, positive immunological tests may be extremely useful in increasing the certainty of the diagnosis of RA.

Rheumatoid factor is an autoantibody directed against the Fc region of IgG. An elevated RF is included in the ACR classification criteria for rheumatoid arthritis. Between 70% and 90% of patients with RA have RF, but levels may be lower in early RA. Rheumatoid factor may also be present in the normal elderly and in many other diseases, including Sjögren syndrome, SLE, and other rheumatological conditions, and in certain malignancies and chronic infections. Patients with RA who are positive for RF are classed as seropositive. A negative RF does not exclude RA and, in the presence of other defining criteria, the patients are classed as seronegative.

Rheumatoid factor can be any class of immunoglobulin but IgM-RF, IgA-RF, and IgG-RF are the most common. The RFs were traditionally detected by agglutination of sheep red cells, but more modern agglutination tests tend to use latex beads. Agglutination assays tend to favor the detection of IgM-RF. Quantitative analyzer-based nephelometric assays are now frequently used and results are standardized against a reference preparation; the results appear equiva-

lent to the latex test in diagnostic utility (Wolfe, 1998). These assays are reported to detect other classes of RF. Over 90% of patients with established RA have IgM-RF and a high titer increases the risk of severe, extra-articular, nodular disease particularly if IgG-RF and/or IgA-RF are also present. The combination of IgM-RF and IgA-RF appears highly specific for RA (Jonsson et al., 1998). A number of international external quality assurance schemes are available for total RF. Specific ELISAs for IgM-, IgG-, and IgA-RF are now widely available. These can be highly specific, but their performance depends on the quality of the detection system. There are no widely-used quality assurance schemes.

Several other autoantibodies have been described that appear to have greater specificity for RA. However, these assays were not convenient for widespread laboratory use. Antikeratin antibodies (AKA) can be detected using immunofluorescence to rat esophageal epithelium, antiperinuclear factor (APF) using immunofluorescence to the keratohyalin granules of human buccal mucosa epithelium, and antifilaggrin antibody (AFA) by immunoblot. Combinations of these assays increase sensitivity in diagnosis of RA (Ferraro-Peyret et al., 2002). It is now realized that these assays detect closely related autoantibodies. Both AKA and APF recognize filaggrin-related epitopes (Sebbag et al., 1995). The major target for AFA in RA synovium is deiminated (citrullinated) fibrin (Masson-Bessiere et al., 2001). Anti-Sa antibodies also recognize a similar epitope. Enzyme immunoassays were, therefore, developed for antibodies to a linear filaggrin peptide and subsequently to cyclic peptide variant of the deiminated filaggrin epitope (CCP). Second-generation ELISA-based anti-CCP kits are now available which appear to outperform the older assays in diagnosis of RA (Dubucquoi et al., 2004). Anti-CCP antibodies have specificity of 98% and sensitivity 68% in the diagnosis of established RA, and perform nearly as well in diagnosing early RA (Schellekens et al., 2000). In addition to their value in diagnosis, particularly in RF-negative patients, anti-CCP antibodies are also associated with aggressive disease and the development of radiologic erosions. Positive anti-CCP antibodies can predate clinical symptoms of RA by many years.

TREATMENT AND OUTCOME

Established Treatments

The treatment of patients with RA requires the collaboration of many healthcare professionals. First-line, symptomatic therapy is usually with NSAIDs, which relieve symptoms of inflammation but do not appear to alter the progression of disease or its prognosis. Some newer NSAIDs are more selective for the COX-2 isoenzyme and have been shown to have a lower incidence of gastrointestinal complications, but controversies remain over whether the COX-2 drugs may also increase the risk of thrombotic complications relative to standard NSAIDs.

The course of RA is characterized by episodic flares and remissions, superimposed on progressive damage to bones and joints. Most patients require long-term therapy to reduce the frequency and severity of flares: usually this requires immunomodulatory disease-modifying antirheumatic drugs (DMARDs), such as methotrexate, sulphasalazine or gold. In many cases, these are very effective (Pincus et al., 2002), but their onset of action is slow: they may take months to achieve their full effect. Leflunomide is the newest drug in this class and is more T-cell targeted. Much evidence suggests that early, aggressive therapy of RA matters more in the short and long term than which particular DMARD is chosen. The first DMARD used appears often to be the most effective (Aletaha and Smolen, 2002). However, although clinical parameters improve, radiographic progression may continue (Mulherin et al., 1996).

The modern treatment approach emphasizes early DMARD therapy to reduce long-term disability (Emery, 1994). However, a significant proportion of patients experience disease activity and progression of RA "resistant" to all traditional DMARDs. Systemic corticosteroids are effective in most patients, but serious adverse effects commonly occur if significant doses of steroid are continued long-term.

Biologic drugs are drugs designed to target particular steps in the pathogenesis of RA, either by mimicking endogenous molecules or administering monoclonal antibodies specific for an endogenous molecule. Currently, the principal class of biologics in clinical use is the anti-TNF class. The first of these was infliximab, a chimeric IgG1-type monoclonal antibody with murine variable domains. Infliximab binds soluble and membrane-bound TNF with high affinity, forming stable immune complexes and preventing TNF from binding to its receptor. These drugs may have dramatic efficacy, even in patients resistant to multiple conventional DMARDs, in rapidly reducing the inflammatory response and clinical disease activity, and retarding or even halting radiographic progression (Maini et al., 1999; Klareskog et al., 2004). Anti-TNF drugs have revolutionized clinical management of patients with RA, and have transformed expectations for the future from empirical immunosuppression to the hope of targeted, individualized therapies. Tumor necrosis factor-α has been conceptualized as a "dominant cytokine" in RA and it has been shown that blockade of the TNF-α pathway has benefit on many of the different characteristic aspects of RA, including synoviocyte proliferation, bony erosion, and angiogenesis (Table 32.5).

The anti-TNF drugs, however, have limitations. They are not universally efficacious, and an initial response may be lost after a period of treatment. Blockade of TNF-α is associated with an increased incidence of infections, including

TABLE 32.5 Anti-tumor necrosis factor (TNF) drugs currently licensed for treatment of rheumatoid arthritis

Anti-TNF drug	Structure	Administration	Action *in vitro*
Infliximab	Chimeric mouse/human IgG1, binding soluble and membrane-bound TNF-α	Intravenous	Binds soluble TNF-α, lyses cells carrying surface TNF-α
Etanercept	Fusion protein of Fc of IgG1 with p75 TNF-α receptor	Subcutaneous	Binds soluble TNF-α and lymphotoxin α
Adalimumab	As for infliximab but fully humanized	Subcutaneous	Similar to infliximab

encapsulated organisms. The drugs may cause a vasculitic syndrome, perhaps related to the commonly-observed induction of antinuclear antibodies or other autoantibodies. Problems with drug tolerability may range from non-specific infusion or injection site reactions to a frank anaphylacticoid reaction. Antichimeric antibodies develop in many patients receiving infliximab, but the clinical significance of this is unclear. There is not yet sufficient data to confirm or refute a theoretical association with malignancy. When anti-TNF drugs are given for established RA, efficacy is maintained only during the period of treatment; however, there is some emerging evidence to suggest that if given in early RA there may be a benefit lasting longer than the duration of treatment.

Anakinra, an IL-1Ra analog, is a biologic drug targeted at IL-1 mediated pathways. Although there is some evidence that it is moderately efficacious, perhaps particularly regarding bony erosions, of treatment benefit is relatively short-term and current clinical practice favors use of anti-TNF drugs in preference. Patients who do not respond to anti-TNF do not tend to respond to anakinra (Buch et al., 2004). Combination of anti-TNF drugs with anakinra does not seem to increase the benefit over treatment with anti-TNF alone, and is associated with an increased risk of infections (Genovese et al., 2004).

Other potential biologic targets will be discussed in the following section; their clinical utility currently remains largely unproven.

Experimental Drug Treatments

The success of anti-TNF therapy has stimulated much further interest in experimental therapies for RA. Some past, present and future directions of research are here briefly alluded to (see Chapter 76).

Intensive, Nonspecific Immunosuppression

Alemtuzumab (Campath-1H) is a monoclonal antibody directed against the lymphocytic antigen CD52, expressed on both B and T cells; it has some efficacy in RA, but this was only maintained in the short term (Schnitzer et al., 1997). High-dose chemotherapy and autologous bone marrow transplantation has been performed in some patients with severe RA resistant to conventional therapies; a temporary remission was achieved, but responsiveness to traditional DMARDs was often subsequently restored (Snowden et al., 2004).

T Cells

T-cell depletion is effective in RA but is too toxic to consider as a therapy. Anti-CD4 therapy produces some clinical response; this may relate to T-cell coating rather than to T-cell depletion (Mason et al., 2002).

A more subtle modulation of T-cell function is provided by costimulatory blockade. For an antigen-presenting cell to activate a T cell, rather than render it anergic or apoptotic, requires costimulation by CD80 or CD86. Once a T cell is fully activated, it expresses cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), which blocks CD80 or CD86 with very high avidity. Abatacept, a synthetic fusion protein of CTLA-4 with an immunoglobulin domain, is designed to mimic this signal and thereby block T-cell activation. This drug shows promising results in the treatment of RA in combination with methotrexate (Kremer et al., 2003).

Since regulatory T cells seem to be present in RA, another strategy might be to stimulate these cells, perhaps by means of molecules such as heat shock protein (Prakken et al., 2002).

Apoptosis

Induction of $CD4^+$ cell apoptosis using anti-CD95 (Fas) monoclonal antibody suppresses osteoclastogenesis in an animal model (Ogawa et al., 2003). Apoptosis of fibroblasts in RA synovium is mediated by the receptor TRAIL-R2, which represents a potential therapeutic target (Ichikawa et al., 2003).

Angiogenesis

Targeting angiogenesis in RA would be a novel approach since theoretically it would be less likely to predispose to infection or malignancy, although it could disrupt certain

other biologic processes such as fracture healing and fertility. Soluble VEGF receptor 1 is effective in CIA, and an anti-VEGF antibody has now been developed as a cancer treatment.

B Cells

Depletion of immature B cells using the anti-CD20 antibody rituximab appears efficacious in RA (Leandro et al., 2002); recent data demonstrate that response may be sustained up to 48 weeks (Edwards et al., 2004). Plasma cells and total levels of immunoglobulin are unaffected, but RA-specific autoantibodies are reduced. B-cell development may be targeted at a slightly later stage by targeting the B-cell survival factor BLyS, which is normally produced from monocytes. Antagonizing this, either by an anti-BLys monoclonal antibody or by giving TACI-Fc (a modified version of BLyS receptor), inhibits mature B-cell development and the ability of B cells to act as antigen presenting cells.

Cytokines, Chemokines, and Complement

With the success of anti-TNF therapies, attention has been directed to developing small-molecule TNF inhibitors, such as the PEGylated humanized anti-TNF fragment CDP870 (Choy et al., 2002a). Other strategies directed at TNF include inhibitors of TACE. It is hoped that a synthetic IL-1 binding molecule or IL-1 "trap," composed of human IgG1 Fc and the extracellular domain of the IL-1 receptor, will prove to be more potent than anakinra in RA.

Apart from anti-TNF and anti-IL-1 strategies, most targeted cytokine therapies, such as administration of recombinant human IL-4 or IL-10 (Smeets et al., 1999), have failed to demonstrate efficacy in RA. However, results of trials of anti-IL-6 receptor antibody are encouraging (Choy et al., 2002b; Nishimoto et al., 2004). Blockade of other cytokines such as IL-15 or IL-23 also shows promise.

It is hoped that blocking chemokine receptors may block leukocyte entry into affected joints. This has been demonstrated for CCR5 and CXCR2 in animal studies, and early clinical trials of CCR1 blockers show some promise (Haringman et al., 2003). A C5a antagonist has also been used with some success in animal models.

Other Targets

Many other therapeutic strategies might be described as more anti-inflammatory than immunologic in nature. Blockade of integrins or other adhesion molecules appears promising in animal models. Inhibitors of intracellular signaling molecules, such as NFκB and p38 MAP kinase, are theoretically attractive but must be made specific enough to avoid toxicity. Inhibiting osteoclasts reduces the rate of radiographic progression of RA, as shown by encouraging results with zolendronic acid. Strategies targeting the RANKL pathway also show promise. Matrix-degrading enzymes are another therapeutic target that has received some attention. However, the concern with therapeutic modalities that inhibit inflammation or other essential processes is that the treatment could cause toxicity by interfering with the physiological role of these processes. The hope of specific immunologic therapies is that, since RA is an autoimmune process, single or combination immunotherapies can act as a "master switch" that reverses the immunologic dysregulation that is presumed to drive the disease.

CONCLUDING REMARKS—FUTURE PROSPECTS

Rheumatoid arthritis is a rapidly-expanding field of knowledge. New animal models have challenged old conceptions of the disease. Developments in high-throughput techniques of genomics and proteomics promise further clues towards the pathogenesis of RA; further advances in our understanding of tolerance and immunoregulation will shed light on the key events leading to autoimmunity in RA. Attention will be directed also to the factors contributing to disease heterogeneity in RA. The advent of anti-TNF therapy has revolutionized the field and encouraged the development of further novel therapies. The characterization of specific autoantibodies and the efficacy of B-cell depletion has challenged paradigms of T-cell directed therapy in RA. Close cooperation between clinicians and scientists will continue to yield valuable insights as we move from an era of relentless disease progression in the face of nonspecific immunosuppression to a new era of early administration of individualized, probably combination therapies based on advances in our understanding of the pathogenesis of RA.

SPONDYLOARTHRITIDES

Definition, Epidemiology, Clinical Manifestations, and Treatment

The spondyloarthritis (SpA) diseases comprise ankylosing spondylitis (AS), reactive arthritis (ReA), arthritis/spondylitis with inflammatory bowel disease and arthritis/spondylitis with psoriasis. The main links between each of these is the association with HLA-B27, similar clinical symptoms such as inflammatory back pain, and similar patterns of peripheral joint involvement with an asymmetric arthritis predominantly of the lower limbs, and the possible occurrence of sacroiliitis, spondylitis, enthesitis, and uveitis. Most striking is the direct relationship between the prevalence of SpA and the prevalence of HLA-B27 in the general population. This strong correlation suggests that environmental or genetic factors that are necessary in addition to HLA-B27 to get SpA must be ubiquitous (Braun and Sieper, 2003).

Ankylosing spondylitis is regarded as the SpA with the most severe outcome. Its prevalence has been estimated to be between 0.2 and 0.9% and the disease normally starts in the second decade of life. The male-to-female ratio has more recently been estimated to be around 2 : 1. Back pain is the leading clinical symptom in these patients, which is characterized by morning stiffness and improvement by exercise. The disease starts in 90% or more cases with a sacroiliitis. Further in the course of the disease the whole spine can be affected with spondylitis, spondylodiscitis, and arthritis of the small intervertebral joints. As a reaction to the inflammation, ankylosis occurs, which can involve the whole spine. Relapsing uveitis, peripheral asymmetric arthritis predominantly of the lower limbs, and enthesitis are the most

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

frequent extraspinal manifestations. HLA-B27 is found to be positive in 90–95% of patients, and inflammatory bowel disease, psoriasis, or preceding reactive arthritis can be found in about 10% of AS patients.

Diagnosis is made by a combination of clinical symptoms (such as inflammatory back pain or limitation of spinal mobility) and the demonstration of radiologic sacroiliitis, according to the modified New York criteria (van der Linden et al., 1984). More recently, we have proposed an approach on how to make an early diagnosis before evidence of radiologic sacroiliitis by combining clinical, laboratory, and imaging parameters such as magnetic resonance imaging (MRI) (Rudwaleit et al., 2004). A new approach to an earlier diagnosis is also mandatory because of the major delay of 5–7 years between the occurrence of the first symptoms and making the diagnosis. In the last decades, only nonsteroidal anti-inflammatory drugs (NSAIDs) were used, together with physiotherapy, as an effective treatment. Rather surprisingly, disease-modifying antirheumatic drugs (DMARDs) and corticosteroids, which are highly effective in other chronic inflammatory diseases such as rheumatoid arthritis, show only a small or no effect in AS. On this background, the finding that blockers of tumor necrosis factor (TNF) such as infliximab and etanercept are highly effective means a breakthrough in the treatment of this disease (Braun and Sieper, 2004). At least 50% of active AS patients refractory to treatment with NSAIDs show a 50% or more improvement when treated either with the monoclonal anti-TNF-α antibody infliximab (Braun et al., 2002; van der Heijde et al., 2005) or the soluble TNF-receptor construct etanercept (Davis et al., 2003).

Reactive arthritis occurs after a preceding infection of the urogenital tract with *Chlamydia trachomatis* or of the gut with enterobacteriae such as *Yersinia*, *Salmonella*, *Campylobacter jejuni*, or *Shigella*, usually after a few days up to 4–6 weeks (Sieper et al., 2000). The arthritis is normally an oligoarthritis, predominantly of the lower limbs, but in about 20% this will manifest as a polyarthritis. Other manifestations can be an enthesitis, conjunctivitis/uveitis, or inflammatory back pain. Between 30 and 60% of these patients with ReA are positive for HLA-B27; arthritis occurs in approximately 4% of the general population, but in about 25% of HLA-B27$^+$ individuals after one of these infections. Usually, the patients recover in 3–6 months; however, up to 20% can run a chronic course longer than 12 months. Bacterial antigen and, in the case of *Chlamydia*, also DNA and RNA have been detected in the joint, indicating that bacterial antigens persist in the joint and drive the local immune response. For making a diagnosis of ReA, a combination of clinical manifestations (preceding infection, typical pattern of arthritis) and laboratory evidence of previous or present bacterial infection is necessary (Sieper et al., 2002). While antibiotic treatment of urogenital tract infection with antibiotics prevents the occurrence of arthritis, this is not the case for bacterial enteritis. Once an arthritis is established, long-term therapy with antibiotics does not seem to influence the arthritis, suggesting that either the antibiotics used are not effective enough or that the once-triggered hypersensitive immune response cannot be interrupted by antibiotics (Sieper et al., 2000).

Approximately 10–20% of patients with inflammatory bowel disease (IBD) exhibit an often transient peripheral arthritis, which often occurs concurrently with gut inflammation. The frequency of HLA-B27 is only slightly elevated among patients with peripheral arthritis, but is present among 50–70% of patients with IBD and AS. About 5% of IBD patient, mostly those who are HLA-B27$^+$, will develop AS. Treatment should primarily be directed against the gut inflammation. Up to 50% of patients with psoriatic arthritis show a clinical picture compatible with SpA, such as oligoarthritis of the lower limbs and/or spinal inflammation. Among these patients, HLA-B27 is positive in approximately 25% (peripheral arthritis) to 60% (spinal manifestations). Treatment is similar to that for other forms of SpA.

Bacterial Trigger and Autoimmunity in the Pathogenesis of the Spondyloarthritides

Central to the discussion about the pathogenesis of the SpA is the interaction between bacteria and HLA-B27 (Kuon and Sieper, 2003). The best evidence for this comes from ReA, which is triggered usually by a genitourinary infection with *C. trachomatis* or an enteritis due to certain gram-negative enterobacteria, such as *Shigella*, *Salmonella*, *Yersinia*, or *Campylobacter*. The demonstration of microbial antigens within the synovium suggests that ReA may be related to the persistence of microbial antigens at the sites of inflammatory arthritis. Approximately 20–40% of HLA-B27$^+$ ReA patients develop the full clinical picture of AS after 10–20 years (Leirisalo-Repo, 1998). Thus, exposure of the immune system to bacteria seems also to be an important initial triggering event for AS. Although clinically diagnosed ReA arthritis precedes AS only in less than 10%, this figure may be much higher because many of the gut or urogenital infections preceding the clinical manifestation of ReA can be asymptomatic. The central role of bacteria in the pathogenesis of SpA is further supported by the relationship between Crohn's disease, HLA-B27 positivity and the occurrence of AS: in one study, in 13 out of 24 (54%) HLA-B27$^+$ patients with Crohn's disease, AS could also be diagnosed, but only in 5 out of 189 (2.6%) such patients who were HLA-B27$^-$ (Purrmann et al., 1988). In the case of Crohn disease, the leakage in the gut mucosa, as a consequence of the related inflammation, presumably allows an interaction of the immune system with the normal gut bacteria. It has also become clear that in about 50% of patients with so-called idiopathic AS, macroscopic or microscopic

mucosal chronic lesions resembling Crohn disease can be detected in the gut by colonoscopy (Mielants et al., 1988).

Finally, there is also evidence for the importance of B27-bacteria interaction from animal models. HLA-B27 transgenic rats develop features of ReA, including gut inflammation, peripheral arthritis, and psoriasiform skin and nail changes. The importance of environmental factors is emphasized by the observation that many of these features, including gut inflammation and arthritis, do not develop in HLA-B27 transgenic rats born and bred in a germ-free environment. Germ-free animals rapidly develop inflammatory disease on removal from the sterile environment. This can be partially prevented by treatment with antibiotics (Taurog et al., 1999).

Therefore, AS can probably be regarded as the long-term outcome for patients most of whom are HLA-B27$^+$ and who have been exposed to ReA-associated bacteria, bacteria in the gut, or other as yet unidentified bacteria.

Although bacteria appear to play a crucial role as an initial event for the pathogenesis of AS, there is no evidence that they are also directly responsible for the immunopathology in AS. It seems to be unlikely that bacteria or bacterial antigens do persist in such diverse structures as the sacroiliac joint, the enthesis, and in the eye. Furthermore, biopsies from the sacroiliac joint were investigated for the presence of bacteria and have been proven to be negative (Braun et al., 1997). Therefore, the induction of autoimmunity by bacteria is the more likely event in AS. Especially in the light of the strong association with major histocompatibility complex (MHC), research has concentrated in the past on the role of T cells in SpA. Currently, there is no evidence for any role for the humoral immune response in the pathogenesis of SpA.

Cytokines in the Pathogenesis of Reactive Arthritis

As it has been shown that bacteria persist *in vivo* in patients with ReA, most likely in the joint in the case of *Chlamydia* and in the gut mucosa or lymph nodes of the gut in the case of the enterobacteria, the questions raised are 1) why do these bacteria persist in some patients but not in others; and 2) why do some patients (although the minority) develop chronic courses of their arthritis. The ReA-associated bacteria are obligate (such as *Chlamydia*) or facultative intracellular bacteria. T-helper 1 (Th1) cytokines such as TNF-α and interferon-γ (IFN-γ) are crucial for an effective elimination of these bacteria, while Th2 cytokines such as interleukin 4 (IL-4) or Th3 cytokines such as IL-10 might inhibit an effective elimination. We and others showed that there is a relative deficiency of Th1-cytokines in ReA, especially of TNF-α but also of IFN-γ, both locally in synovial fluid and synovial membrane and systemically in peripheral blood (Yin et al., 1997a; Braun et al., 1999). Furthermore, we could demonstrate a correlation between a low TNF-α production in peripheral blood and a longer duration of arthritic symptoms (Braun et al., 1999). Thus, a relative lack of Th1 cytokines appears to be relevant for the occurrence and persistence of ReA, probably mediated by a persistence of bacteria. If this assumption is correct, immunopathology would then be caused by a "hypersensitive" immune response against bacterial antigens.

IL-10 has received increasing interest recently as a potentially immunosuppressive cytokine. While upregulation of such a cytokine would be wanted in autoimmune diseases such as rheumatoid arthritis we could show that it is relatively upregulated in ReA, and thus that it might contribute to bacterial persistence in ReA, possibly by downregulation of the Th1 cytokines, IFN-γ and TNF-α (Yin et al., 1999b).

Cytokines in the Pathogenesis of Ankylosing Spondylitis

Data are few on cytokines in AS. We measured cytokine-positive CD4$^+$ and CD8$^+$ T cells derived from peripheral blood after mitogenic *in vitro* stimulation by flow cytometry (Rudwaleit et al., 2001). Patients with AS had a significantly lower percentage of IFN-γ$^-$ or TNF-α$^+$ CD4$^+$ T cells compared with HLA-B27$^-$ controls, while the results for a HLA-B27$^+$ healthy control group were intermediate between the two groups. For IL-10$^+$ T cells, we found a significant increase in the CD8$^+$ T-cell subpopulation from HLA-B27$^+$ AS patients compared with B27$^+$ and B27$^-$ controls, but this did not pertain for the CD4$^+$ subpopulation. This relative (small) lack of Th1 cytokines in the peripheral blood of AS patients is in contrast to the presence of abundant TNF-α in biopsies taken from the sacroiliac joint from AS patients (Braun et al., 1995) and the very strong therapeutic response to treatment with TNF-blockers in AS (Braun and Sieper, 2004), suggesting that TNF-α and possibly also IFN-γ are important in the pathogenesis of AS and other SpA. This discrepancy is not easy to explain, but measuring cytokines in peripheral blood might not accurately reflect the situation at the local site of inflammation.

Cytokine Gene Polymorphisms in Reactive Arthritis and Ankylosing Spondylitis

Cytokine genes have also been investigated as possible candidate genes (Sieper et al., 2000). Most data in SpA patients are currently available for TNF-α. Investigating TNF-α microsatellites, an association of ReA with a TNF-α6-allele has been described; this allele has previously been associated with a low TNF-α secretion. Since, in this study from Finland, TNF-α6 was also associated with HLA-B27, the association of TNF-α6 with ReA was thought to be

secondary to B27. Two promoter polymorphisms of the TNF-α gene at positions –308 (308.1 and 308.2) and –238 (238.1 and 238.2) have been investigated in AS. The 308.2 genotype was found significantly less frequently in AS than in controls. In some studies 308.2 was associated with higher transcriptional activity (Hoehler et al., 1998). Thus, there is some evidence that TNF-α genotypes that may be associated with a low TNF-α production are present in a higher percentage in patients with ReA or AS. However, clear proof of an association of these genotypes with low TNF-α production is lacking.

Looking for IL-10 gene polymorphism in another study, there was a significant decrease in the promoter alleles G12 and G10 in the ReA group compared with HLA-B27$^+$ controls, indicating that these alleles might have a protective effect against the occurrence of ReA (Kaluza et al., 2001). Although it is not yet clear whether these alleles are associated with a higher production of IL-10, these data suggest that the relative increase of IL-10 found in ReA might be, at least partially, genetically determined.

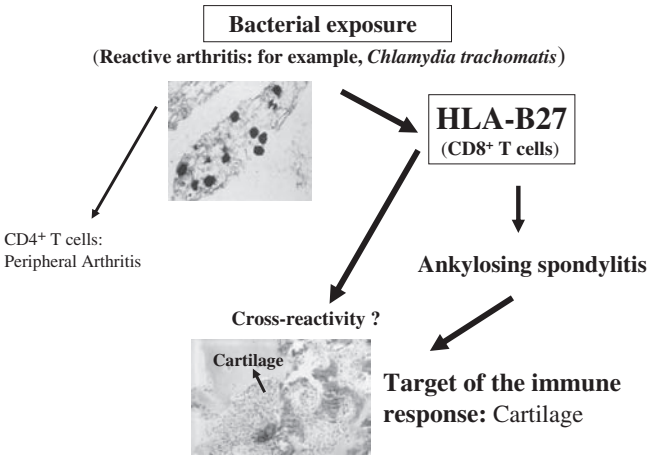

FIGURE 33.1 Hypothesis how bacterial exposure induces a peripheral arthritis, probably via a CD4$^+$ T cell response. However, axial manifestations might be mediated by CD8$^+$ T cells because of the high association with HLA-B27. The cartilage might become the primary target of the immune response through cross-reactivity with bacterial antigens.

The Role of HLA-B27 in the Pathogenesis of Spondyloarthritis

The association of HLA-B27 with SpA is the highest known MHC association for human diseases and the most relevant single factor for the pathogenesis of SpA. There are now considerable data from epidemiologic studies and transgenic animals to indicate a direct effect of HLA-B27, rather than that of a closely linked gene, in disease pathogenesis. It is also clear now that one copy of HLA-B27 (heterozygosity) is sufficient for the disease. The susceptibility to AS has been estimated to be more than 90% genetically determined, and so it has been suggested that there is a rather ubiquitous environmental factor. Besides HLA-B27, other MHC genes such as HLA-B60 and HLA-DR1 seem to be associated, but are of minor importance. However, although MHC is the major susceptibility locus, it has been suggested that it contributes only approximately 36% to the overall genetic risk (Brown et al., 2002).

Since the main function of HLA class I molecules is to present peptide antigens to cytotoxic T cells, the antigen-presenting properties of HLA-B27 could be crucial in the pathogenesis of spondyloarthritides leading to the so-called arthritogenic peptide hypothesis (Kuon and Sieper, 2003). Thus, some HLA-B27 subtypes, due to their unique amino-acid residues, can bind specific arthritogenic peptide, and so become recognized by CD8$^+$ T cells. Furthermore, in response to these bacterial peptides, autoreactive T cells recognizing antigens with sufficient structural similarity between bacteria and self, might become activated by self-peptides that are present particularly in spinal joints (Figure 33.1).

Major support for this hypothesis comes from studies in humans showing the differential association of some of the HLA-B27 subtypes with AS. While B*2705, B*2702, B*2704, and B*2707 are strongly associated with the disease, the HLA-B27 subtypes B*2709 in whites and B*2706 in Southeast Asians are not at all or only rarely associated. Most interestingly, B*2709 differs from the disease-associated B*2705 by only one amino acid substitution, the exchange of Asp116 to His116. B*2706 differs by only two amino acid substitutions from the disease-associated B*2704 by exchange of His114 to Asp114 and Asp116 to Tyr116 (Khan, 2000).

In studies on patients, both bacteria-specific and autoreactive CD8$^+$ T cells have been demonstrated in AS and ReA. Recently, a synovial CD8$^+$ T-cell response to a peptide from *Yersinia* heat shock protein 60 in patients with *Yersinia*-induced ReA and also an HLA-B27-restricted CD8$^+$ T-cell response to peptides derived from several chlamydial proteins in patients with *Chlamydia*-induced ReA have been described (Kuon and Sieper, 2003). In the latter study, there was a novel approach in searching the whole chlamydial proteome to identify peptides which stimulate CD8$^+$ T cells from patients in an HLA-B27 restricted manner. Recently, there was a report of a CD8$^+$ T-cell response to an Epstein–Barr virus (EBV) epitope derived from the LMP2 protein, and to a sequence-related self-peptide from the autoantigen vasoactive intestinal peptide (VIP) receptor 1 (Fiorillo et al., 2000). However, the exact identity of a potentially arthritogenic peptide has yet to be determined.

An oligoclonal expansion of T cells has also been demonstrated for CD4$^+$ and CD8$^+$ T cells in AS and for CD8$^+$ T cells in ReA. Synovial T cells derived from different

HLA-B27$^+$ patients suffering from ReA and triggered by different bacteria revealed an astonishingly high homology of T-cell receptors (May et al., 2002). These results led to the suggestion that similar antigens are recognized by these oligoclonally expanded CD8$^+$ T cells. This implies that under certain conditions a specific arthritogenic peptide might indeed be produced and presented to the host's immune system.

Beside the "classical" arthritogenic peptide theory, other hypotheses have emerged. One interesting concept, the HLA-B27 misfolding hypothesis states that HLA-B27 itself is directly involved in the pathologic process of SpA. That is, HLA-B27 can be misfolded, which might have implications for pathogenesis (Colbert, 2004). The misfolding is suggested to be due to a particular feature of the HLA-B27 molecule: e.g., newly synthesized HLA-B*2705 seems to fold and associate with β2-microglobulin more slowly compared with other MHC class I molecules. Allen et al. (1999) reported that as a consequence of HLA-B27 misfolding, free HLA-B27 heavy chains can form abnormal heavy-chain homodimers. This homodimer formation could be facilitated by unpaired free cysteine residues at position 67 (Cys67) of the HLA-B27 heavy chain α1 helix. Furthermore, Boyle et al. (2004) have proposed that these HLA-B27 homodimers might mimic MHC class II molecules, and they provided evidence that HLA-B27 can be recognized by CD4$^+$ instead of CD8$^+$ T cells (Boyle et al., 2001). Hence, they postulate a role for HLA-B27 reactive CD4$^+$ T cells in the pathogenesis of AS and other SpA. All in all, despite the high frequency of HLA-B27 in these diseases, its role in pathogenesis has not yet been clarified.

What is the Immune Target in Ankylosing Spondylitis?

If it is indeed unlikely that persistent bacterial infection drives the immunopathology in AS (see above), the question is the nature of the target of the immune response. Studies using MRI have shown that the most relevant inflammatory site in SpA is an osteitis occurring at the bone/cartilage interface (McGonagle et al., 1999). This finding has been supplemented by histologic investigations in SpA from the sacroiliac joint and other structures where, especially in the early phases, mononuclear cells invade and erode the cartilage at different sites (Bollow et al., 2000); such findings have suggested that the cartilage is the primary target of the immune response in SpA (Makymowych, 2000).

Aggrecan G1 domain has been implicated as one source of a possible T-cell autoantigen in AS and similar rheumatic diseases, based both on results from animal models and on studies in patients. A specific CD4$^+$ T-cell response to peptides derived from the G1 domain of aggrecan was found in animal models and also in patients with AS. Here, in 60% of patients, a CD4$^+$ response against the whole G1 protein and against a set of overlapping peptides derived from this G1 protein was evident (Zou et al., 2003).

Because of the type of tissue-specific damage in AS, other extracellular matrix proteins apart from aggrecan, derived from human cartilage and enthesis, could also be targets of an autoimmune response. Recently, a CD8$^+$ T-cell response to a nonameric peptide from collagen type VI was detected in the synovial fluid from patients with AS (Atagunduz et al., 2005). Further work is in progress and will, therefore, have to focus on T-cell responses against cartilage-derived antigens.

PSORIATIC ARTHRITIS

Clinical, Pathologic, and Epidemiologic Features

Psoriatic arthritis is a fascinating disease in combining features of an autoimmune skin disease (see Chapter 58) with those of a seronegative arthritis. The term "psoriatic arthritis" defines a heterogeneous group of arthritides characterized by peripheral monoarticular, oligoarticular, or polyarticular disease, potentially including axial skeletal involvement. Despite the quite different clinical expressions, common features include skin lesions of psoriasis, absence of rheumatoid factor (RF), similar HLA associations and characteristic radiologic findings.

Approximately 2% of the white population in Europe and North America suffer from psoriasis. Of these, some 5–10% have an inflammatory arthritis. Men and women are affected with equal frequency, and the peak incidence is in the fourth through sixth decades. Psoriatic skin disease precedes the onset of arthritis in some 80% of cases, occurs coincidentally with arthritis in some 15% of cases, and after the onset in about 5% of cases. There are even some (rare) cases in which overt psoriasis never develops; yet, the disease may have the typical clinical (usually radiologic) features of psoriatic arthritis ("psoriatic arthritis sine psoriase"). Especially in these cases, a thorough family history is of prime importance.

Clinical Manifestations

Although new attempts are being made to subclassify psoriatic arthritis, the following five different patterns of psoriatic arthritis are currently recognized, and these may shift from one to another.

1. **Asymmetric mono- and oligoarticular arthritis** in 30–50% of cases is the most common initial presentation of psoriatic arthritis.

2. **Symmetric polyarticular arthritis** in 30–50% of patients is the final form of psoriatic arthritis.
3. **Distal interphalangeal (DIP) joint involvement** in 25% of cases is nearly always associated with nail manifestations.
4. **Arthritis mutilans** in 5% of cases is characterized by resorption of the phalangeal bones leading to rapid invalidism.
5. **Axial arthritis** in 30–35% of cases can differ from AS, especially in its radiologic features, can present as sacroiliitis, which may be asymmetric and asymptomatic, or as spondylitis which may occur without sacroiliitis, can affect any level of the spine, and displays typical "parasyndesmophyte" lesions.

Even though, like all inflammatory rheumatic disorders, psoriatic arthritis is a systemic rheumatic disease, involvement of extra-articular sites excluding the skin is rare, but involvement of the eyes (uveitis), heart, lungs, and kidneys with amyloidosis (very infrequently) may occur. Patients with psoriatic arthritis can also develop inflammation of the tendons, especially Achilles tendonitis, and around cartilaginous tissue. Inflammation of the chest wall and of the parasternal cartilage can lead to painful costochondritis. In addition to the cutaneous psoriatic plaques, other characteristic features include nail involvement with pitting, ridging, and onycholysis, dactylitis with so-called "sausage fingers" or "sausage toes" in which there is diffuse swelling of the entire digit due to pronounced tenosynovitis (Figures 33.2 and 33.3).

Radiographically, psoriatic arthritis is a typical unique mixture of bone destruction and proliferation: "destructive and productive" lesions (Figure 33.4). Manifestations may include erosive arthritis giving rise to the classic "pencil-in-cup" deformity in the phalanges, osteolysis, articular ankylosis, sacroiliitis, spondylitis, enthesitis, and periostitis. There is no laboratory test to diagnose psoriatic arthritis, and, interestingly, unlike in rheumatoid arthritis, assays such as erythrocyte sedimentation rate (ESR) or CRP values can give values in the normal range despite severe joint inflammation.

FIGURE 33.2 Typical nail changes in psoriatic arthritis.

Genetic Features and Environmental Influences

As for psoriasis itself, the etiology of psoriatic arthritis is currently unknown and, as for all inflammatory rheumatic diseases, may involve a combination of genetic and (auto)immune, as well as environmental factors. An important link to the spondyloarthritides is the association among psoriatic arthritis patients with spine involvement with HLA-B27 in 70–80% of cases. Several other genes also have been described at higher frequency among patients with psoriatic arthritis. Thus, alleles associated with an adverse outcome, apart from HLA-B27, include HLA DR3 or DR4. There is a very high concordance for psoriasis in monozygotic twins (70%) and a 50-fold increased risk of developing psoriatic arthritis in first-degree relatives of patients with this disease. Interestingly, there is a two-fold increased risk of disease "transmission" by an affected father compared with an affected mother.

Alterations in the immune system also appear important in the development of psoriatic arthritis. A possible clue is provided by the finding that the decline in the number of $CD4^+$ helper T cells in patients with acquired immune deficiency syndrome (AIDS) often results in the development and progression of psoriasis. The importance of infectious agents and other environmental factors as a cause of psoriatic arthritis is a major focus of current research. Streptococcal infection can precipitate the development of guttate psoriasis. In addition, psychological stress and physical trauma has been reported to induce the development of arthritis, suggesting that psoriatic arthritis is the manifestation of a "deep Koebner" type of response.

Treatment and Outcome

Treatment generally starts with NSAIDs, which may suffice in mild cases. In patients with active and potentially destructive disease, DMARDs need to be added early. In contrast to rheumatoid arthritis, only a few studies have addressed effects of conventional DMARDs in psoriatic arthritis, and these have shown limited efficacy. The following drugs should be considered:

- **Methotrexate** is effective for both the cutaneous and peripheral articular manifestations of psoriasis, and is generally the first choice of DMARD due to its efficacy

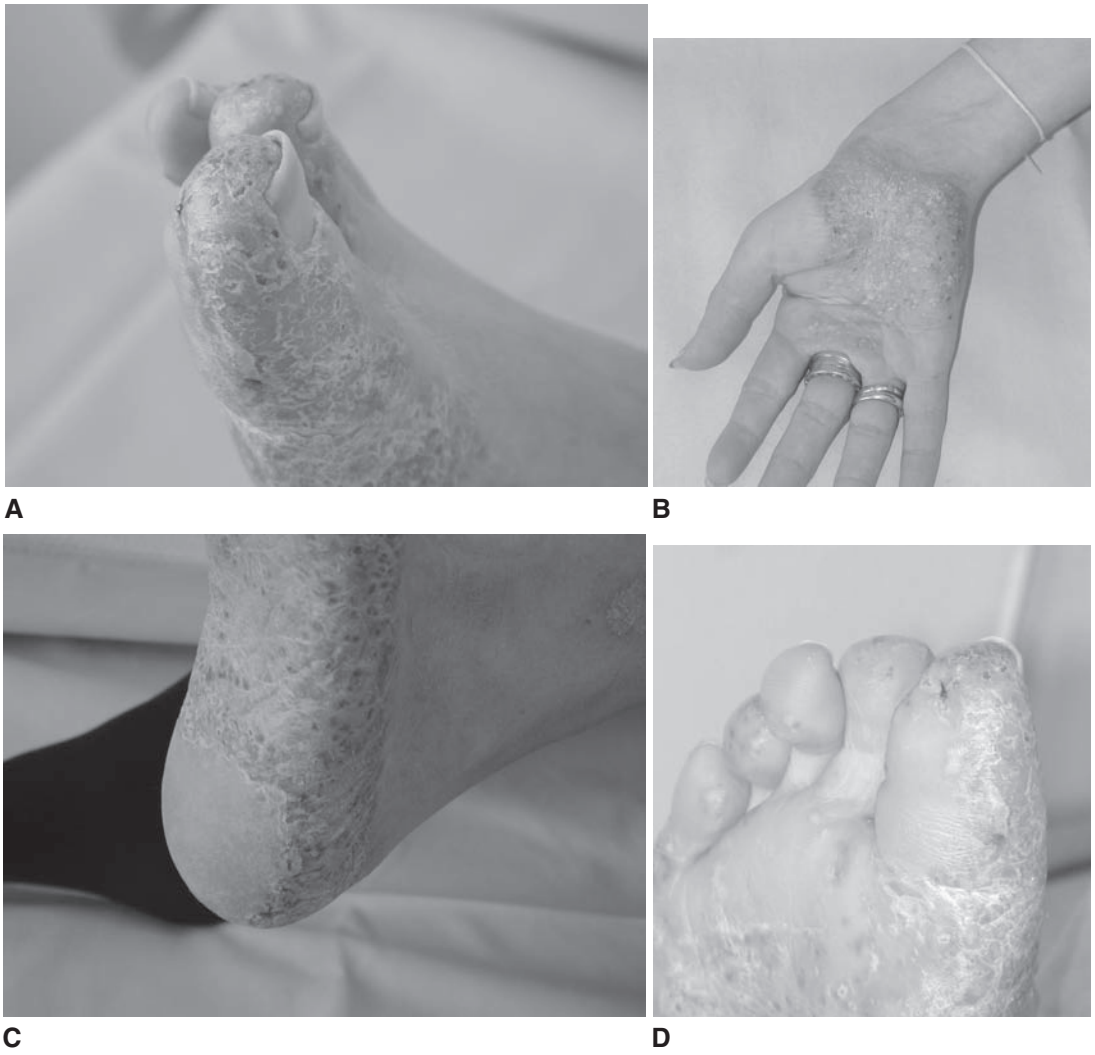

FIGURE 33.3 Characteristic skin changes in psoriatic arthritis.

and tolerability, but liver function should be assessed frequently (Willkens et al., 1984; Espinoza et al., 1992).

- **Sulfasalazine** is only moderately active and does not influence the cutaneous lesions.
- **Cyclosporine** may be effective for both cutaneous and articular disease (Gupta et al., 1989; Salvarani et al., 2001; Sarzi-Puttini et al., 2002), but with risk of hypertension and nephrotoxicity.
- The TNF inhibitors **etanercept**, **infliximab** and, recently, **adalimumab**, in contrast to conventional DMARDs, have proven very effective and well tolerated in the treatment of both psoriasis and psoriatic arthritis (Mease et al., 2000; Mease, 2001; Antoni et al., 2002; Cauza et al., 2002; Iyer et al., 2002) and are currently recommended when any of the above-mentioned DMARDs (usually methotrexate) is ineffective.
- Intra-articular and low-dose systemic glucocorticoids have been used as "bridging" therapy when treatment with a DMARD is instituted, but, as a note of caution, tapering of high-dose corticosteroids has been associated with the development of generalized and sometimes life-threatening pustular psoriasis; hence, systemic glucocorticoid treatment is best avoided when possible.

SAPHO SYNDROME

"SAPHO" is an acronym for a syndrome in which there is a combination of pathologic changes of the skeleton and skin. It is characterized by osteoarticular and dermatologic symptoms compiled by French rheumatologists after a national survey in 1987 (Chamot et al., 1987). Even more

FIGURE 33.4 Radiological changes in psoriatic arthritis. Both destructive and proliferative changes are characteristic.

FIGURE 33.5 Palmo-plantar pustulosis in SAPHO syndrome.

than psoriatic arthritis, this unique disease entity provides a striking link between disease expressions of bones, joints, entheses, and the skin.

Clinical, Pathologic, and Epidemiologic Features

All entities forming the SAPHO syndrome are linked by a frequent albeit non-obligate aseptic pustulous "dermatoskeletal" association that includes **s**ynovitis (inflammation of the joints), **a**cne (acne conglobata or fulminans), **p**ustulosis of the skin (purulent blisters), often psoriatic, mainly on the palms of hands and on the soles of feet (palmo-plantar pustulosis) (Figure 33.5), **h**yperostosis (increase in bone substance), **o**steitis (inflammation of the bones).

SAPHO has a clinical course that is marked by relapses and remissions. The major sites of involvement are the anterior chest wall, especially the sternoclavicular joint, the spine, long bones, flat bones, and large and small joints. The distribution and severity of involvement varies from the adult to the pediatric form referred to as chronic recurrent multifocal osteomyelitis (CRMO), which is closely associated with or a component of SAPHO, and is a systemic aseptic inflammation of the bone marrow (osteitis) (Björkstén et al., 1978; Chamot and Kahn, 1994; Handrick et al., 1998). It can occur in many sites, and there may be an association with pustulous acne-like dermatitis. The histopathology of the bone marrow lesions is pathognomonic with a lymphocytic/plasma cell infiltration without evidence of suppurative bacterial infection. Possibly because of its multifactorial nature, the incidence and prevalence of the SAPHO syndrome are still unknown (Chow et al., 1999). The diagnostic features lead to the diagnosis of CRMO being made more frequently, suggesting a frequency approaching that of some systemic autoimmune diseases, for example, scleroderma estimated to be 0.04%. Cases of "enteropathic CRMO" have been described showing resemblances to the enteropathic spondyloarthritides (Huber et al., 2002). Both diseases show osteoarticular manifestations, often preceding the gastrointestinal disease. Crohn's disease-like lesions may occur throughout the gastrointestinal tract (Greenstein et al., 1976; Schilling and Märker-Herrmann, 2003).

The number of affected areas in bones and joints in SAPHO decreases with increasing age of onset. In general, in half of the cases, patients are affected by an inflammatory thoracic wall syndrome with an inflammation of the sternum and neighboring joints (Dihlmann et al., 1997). A primary chronic osteomyelitis of the clavicle is very characteristic and can occur as a single lesion. The axial type of CRMO affects one or several vertebrae as in sterile spondylitis, possibly including the disks as a spondylodiscitis. The mandible may also be affected leading to facial swelling.

An aseptic inflammation of the bone marrow is revealed by typical MRI appearances showing inflammatory bone marrow edema at characteristic bony areas: sternum, clavicle, metaphyses of lamellar bones, pelvis bones, vertebrae, calcaneus, lower jaw, and others (Kohler et al., 1975; Kawei et al., 1988; Kahn and Khan, 1994; Kirchhoff et al., 1998), but the process is not always multifocal. Though rare, unifocal bone lesions may be observed most often at the clavicle or mandible. The results of laboratory tests are not characteristic, with variable indications of inflammation at low levels of activity.

Visceral complications occasionally occur in soft tissues surrounding the affected bones, clavicle, vertebrae and pelvis, the area being inflamed, edematous and fibrotic, possibly resulting in vascular stenosis, for example, subclavicular in osteitis of the clavicle, pelvic veins due to retroperitoneal fibrosis caused by osteitis of the iliac bone, vasculitis due to aortitis between spondylitis and sternal osteitis, neural inflammation due to brachial plexus neuritis in spondylitis of the lower cervical vertebrae or intercostal neuralgia or pleurisy and pericarditis in upper chest osteitis (Greenstein et al., 1976; Kerem et al., 1989; Kaiser, 1996; Schilling and Kessler, 2000).

Genetic and Environmental Features

The etiology of the SAPHO syndrome or CRMO is not known, and it is unclear if any single agent or factor is involved. Cutaneous lesions common to most patients may be an etiologic component. Defined genetic factors are still unclear, especially since neither HLA-B27 nor any other HLA allele is more prevalent (Kahn and Khan, 1994; Schilling and Kessler, 1998). Pathogenesis may involve enthesopathic alterations and has been attributed to immunologic effects (see below). No infectious agent has been found in the osteomyelitis of CRMO. However, *Propionibacterium acnes* (Kotilainen et al., 1996) is claimed to be important as a potential antigenic trigger, since in several cases anaerobic hypovirulent bacteria normally located on the skin have been observed. Thus, under certain circumstances, these organisms may trigger a bone marrow inflammation so leading to lymphoplasmacellular infiltrates with a sclerosing and hyperostosis reaction that may lead to sclerosing osteomyelitis. This process may determine CRMO, and so characterize this primarily chronic osteomyelitis as a reactive osteomyelitis. A "*cmo-mouse*" (chronic multifocal osteomyelitis) has been established as an experimental animal model for CRMO and will provide further insights into the immunopathogenesis.

Treatment

No specific drug exists for SAPHO syndrome. Treatment is mainly with NSAIDs or sulfasalazine (Otte et al., 1982). Glucocorticoids are indicated only in severe cases. Some trials have been carried out with various immunomodulating treatments including anti-TNF-α agents (Wagner et al., 2002). Methotrexate is frequently tried as an immunosuppressive treatment. Antibiotics, especially macrolides, have also been tried for the treatment of CRMO based on the assumption that this type of osteomyelitis is caused by an infection, for example, by *P. acnes* (Kotilainen et al., 1996). A frequently observed positive effect of azithromycin in the treatment of CRMO has suggested that this macrolide also may have anti-inflammatory and even immunomodulating effects (Schilling and Wagner, 2000). Therefore, long-term therapy with azithromycin as the first-line treatment of CRMO has been proposed. Biphosphonates have also been used either orally or as an infusion of pamidronat (Guignard et al., 2002; Marshall et al., 2002).

JUVENILE IDIOPATHIC ARTHRITIS

Juvenile idiopathic arthritis (JIA) is a chronic inflammatory disorder primarily affecting the joints. Diagnosis can be difficult because of diversity of symptoms at onset and course of diseases, and laboratory tests may not be helpful. Different diagnostic criteria used in the past have hindered consensus approaches to this disease. However, recently, JIA has been classified into seven categories, shown below (Petty et al., 2004). In North America, the term "juvenile rheumatoid arthritis" was common, whilst European rheumatologists used "juvenile chronic arthritis." Hence, the term "juvenile idiopathic arthritis" (JIA) was introduced as a diagnostic term generally accepted.

Epidemiology

An incidence for JIA of 13.9 cases per 100,000 per year was reported, with a female-to-male ratio of 2 : 1. African-American children are more likely to have a polyarticular onset than white children, who most often have a pauciarticular onset, indicating that genetic factors are likely to contribute to these differences. Overall, JIA appears to be less common in African-American and Asian populations than in whites.

Classification

A recent classification of JIA (Petty et al., 2004) in childhood defined separate categories of childhood arthritides. Notably, the common characteristics of JIA have an onset before age 16 years, and duration of symptoms of at least 6 weeks. In particular, exclusion criteria have been nominated and are applied as indicated in each of the seven categories below. These exclusions are:

a) Psoriasis including psoriasis in a first degree relative;
b) Arthritis in an HLA-B27$^+$ male before the age of 6 years;
c) Ankylosing spondylitis, enthesitis-associated arthritis, sacroiliitis in IBD, reactive arthritis, or acute anterior uveitis in a first degree relative;
d) Repeated positive tests of RF at least 3 months apart;
e) Systemic arthritis.

The subtype categories of JIA are as follows:

1. **RF$^+$ polyarthritis** with five joints affected in the first 6 months, and exclusion of a, b, c, e;
2. **RF$^-$ polyarthritis** with more than five joints affected in the first 6 months, and with exclusion of a–e;
3. **Systemic arthritis** with arthritis and fever (at least 3 days reaching 39°C) and one of the following criteria: exanthema, generalized lymphadenopathy, hepato/splenomegaly, serositis, and with exclusion criteria a, b, c, d;
4. **Oligoarthritis** is present, with between one and four joints affected within the first 6 months of illness, and with exclusion criteria a–e;
5. **Enthesitis-related arthritis** with two or more of the following involved: sacroiliac joint tenderness; inflammatory spinal pain; HLA-B27$^+$ family history of anterior uveitis with pain, spondyloarthritis, or inflammatory bowel disease; anterior uveitis associated with pain, redness, or photophobia; and with exclusion criteria a, d, e;
6. **Psoriatic arthritis** with arthritis and/or psoriasis and at least two of the following: positive family history of psoriasis in a first degree relative, and dactylitis or characteristic fingernail abnormalities, e.g., pitting or onycholysis, and with exclusion criteria: b–e;
7. **Other arthritides** which comprises patients who do not fulfill criteria for categories 1–6.

It is obvious that this nomenclature is far from complete, or informative on pathogenesis. Thus, there are children who do not fit into any particular category, or whose features overlap those of more than one category, and, therefore, category 7 has been introduced. Careful explanations should avoid any confusion, and the children with overlapping manifestations should be informed of the diagnosis of JIA.

Pathogenesis

The etiology and pathogenesis of JIA remains uncertain, although genetic factors, immune mechanisms and environmental influences are considered to be of importance.

Genetics

Familial predisposition

It is of interest, and in contrast to accepted autoimmune disorders, that there is no family clustering with multiple affected members.

Major histocompatibility genes

- Early-onset oligoarticular JIA is associated with various HLA class II DR and DP alleles, such as HLA-DR8, DR11, DR13, DPw2, whereas HLA-DR4 and HLA-DR7 were found very infrequently. Patients who are heterozygous for HLA-DR5/HLA-DR8 have an enhanced risk for uveitis;
- Polyarticular onset, RF$^-$ JIA has risk conferred by HLA-DPw3;
- RF$^+$, polyarticular JIA has an HLA-DR4 association: HLA-DRB1*0401 and HLA-DRB1*0101;
- Systemic onset JIA is associated with HLA-DR4;
- HLA-B27 associated forms of JIA can be triggered by bacteria.

Environment

Environmental agents are suspected to trigger JIA subtypes but none has been identified so far. Infectious agents have been suggested in particular, but there is also no solid evidence for any particular bacterial or viral trigger.

Immunologic Features

Immunoglobulins

The serum level of immunoglobulins is elevated in many patients with JIA, and those with polyarticular and systemic disease usually have higher levels than those with oligoarticular JIA.

Rheumatoid factor

Rheumatoid factor is infrequently detected in patients with early JIA, but its frequency increases in cases with later onset of the disease, and in longstanding JIA.

Antinuclear antibodies

The reported range of frequency of antinuclear antibodies (ANAs) in JIA patients is very wide: 5–90%, depending on the clinical subtype. Antinuclear antibodies are uncommon in systemic-onset disease but occur in over 50% of cases in oligoarticular JIA. Positivity for ANAs indicates a higher risk of chronic anterior uveitis. Whether the fine specificity of ANAs in uveitis is closely correlated with uveitis, remains uncertain. Overall antibodies to identified nuclear proteins, including Ro, La, centromeric proteins, topoisomerase (Scl-70), or double-stranded DNA are not characteristic of JIA and do not show an increased incidence.

Immune Complexes

Abnormal antibody production and defects in clearance by the reticuloendothelial system may result in an increased concentration of circulating immune complexes in serum and synovial fluid, possibly resulting in the induction of autoantibodies.

Complement Activation

No association has been identified between clinical activity of JIA and complement activation. However, it is considered to be involved in tissue damage. Here the complement activation cascade (C1–C5) participates in a number of inflammatory processes by releasing anaphylatoxins, while the terminal cascade results in the formation of the cytolytic macromolecular complex.

Cytokines

Tumor necrosis factor-α, IL-1β, IL-6, and IL-15 have been identified as important proinflammatory cytokines in JIA synovium indicating their pivotal role in the disease, and the likely role of T-cell activation, but the provocation for this is unknown.

LYME DISEASE (LYME BORRELIOSIS)

The disease was named after the town of Old Lyme, Connecticut, where in 1975 an accumulation of arthritis cases occurred in children of a rural community. These originally were suspected to be juvenile chronic polyarthritis, but a surveillance study revealed that 25% of patients had had an *erythema migrans* and recalled a tick bite prior to the development of arthritis. Erythema migrans had been known to be caused by an infective organism transmitted by ticks since 1910 (Afzelius, 1910). Moreover, an association of erythema migrans with neurologic features including a sensory radiculitis (Garin-Bujadoux, 1922) was also long known—features described by Bannwarth (1944) with pain, paresthesias, Bell's palsy, and lymphocytic pleocytosis of cerebrospinal fluid. In addition to arthritis, skin, and neurologic symptoms, the novel symptoms of the disease included cardiac conduction abnormalities. In 1981, Burgdorfer isolated a spirochete from ticks in an endemic area. This spirochete could also be cultured from skin, blood, and cerebrospinal fluid from patients with Lyme disease and was named *Borrelia burgdorferi* (Burgdorfer et al., 1982).

Clinical, Pathologic, and Epidemiologic Features

Epidemiology

Lyme borreliosis is the most common vector-borne disease in the USA, Europe, and parts of Asia, with annual reported incidences exceeding 100 cases per 100,000 inhabitants in certain areas (Huppertz et al., 1999). Approximately 15,000 cases of Lyme disease are reported in the USA annually (CDC 2000; Steere, 2001).

Etiology

Lyme disease is caused by *B. burgdorferi* sensu lato, a gram-negative spirochete. *B. burgdorferi* undergoes enzootic cycles between ixoid ticks, *Ixodes ricinus* in Europe and *Ixodes scapularis* and *Ixodes pacificus* in the USA, and small mammalian reservoirs. *B. burgdorferi* sensu lato is quite heterogeneous, and currently 11 different *Borrelia* species have been isolated from ticks. At least three species are pathogenic in humans: *B. burgdorferi* sensu stricto, *Borrelia garinii*, and *Borrelia afzelii*. In the USA, only *B. burgdorferi sensu stricto* occurs (Fraser et al., 1997; Steere, 2001), whereas all three species can be found in Europe (Berglund et al., 1995; Huppertz et al., 1995; 1999; Steere, 2001; Lünemann et al., 2001). These different species preferentially invade different organs (organotropism), which may partly explain the different clinical features of Lyme disease in the USA compared with Europe.

Clinical Manifestations

Although Lyme disease is usually grouped into three stages (early, stage 1; weeks after the tick bite, stage 2; or months-to-years after the tick bite, stage 3), earlier stages may be skipped, missed by the patients, or may overlap. Nevertheless, pragmatically, it is valid to allocate patients to these stages and to discriminate between early localized disease (erythema migrans), acute disseminated disease (neurologic or non-neurologic with carditis) and chronic disease (arthritis, acrodermatitis).

Early Lyme disease has two features: first, the characteristic erythema migrans (Figure 33.6), and second, systemic constitutional signs with low-grade fever, 'flu'-like symptoms, arthralgias, malaise, headaches, and paresthesias, which may accompany erythema migrans or occur without a recognized skin lesion. Erythema migrans starts as a red macula or papule at the site of the tick bite. After an incubation period of a few days up to 8 weeks, the lesions gradually expand, sometimes reaching a large size. Even without antibiotic treatment, erythema migrans will resolve within 4–12 weeks; however, in many cases bacteria will persist at other sites and will cause subsequent Lyme manifestations. An additional *dermatologic manifestation* in the early phase is the lymphocytoma cutis, especially in Europe, usually presenting as a purplish nodule at the ear lobe, the nose, the forehead, or the nipple.

In a minority of patients (about 15%), typical *neurologic symptoms* develop within weeks or months after the tick bite (Eskow et al., 2001); these are cranial neuropathy most

FIGURE 33.6 Erythema migrans.

FIGURE 33.7 Acrodermatitis chronica atrophicans of the right hand.

commonly involving the facial nerve, meningitis especially in children, and radiculoneuropathy alone or in combination. The rare manifestations of chronic neurologic Lyme disease occurring months to years after infection include demyelinating encephalopathy or myelopathy, chronic encephalopathy, peripheral polyneuropathy and transverse myelitis (Pachner et al., 1989; Eskow et al., 2001; Steere, 2001).

Lyme *carditis* is a rather rare entity occurring in 5–8% of patients (Steere et al., 1980). It belongs to stage 2 of the disease, frequently occurring after a preceding erythema migrans. Many patients also have neurologic symptoms and arthralgias. Typical manifestations are conduction abnormalities with varying degrees of atrioventricular block, right or left bundle block, atrial fibrillations, or tachycardias. Rare incidences of a chronic Lyme carditis have been described resulting in cardiomyopathy even with a fatal outcome (Steere, 2001).

In the USA, about 60%, and in Europe a much lesser proportion of untreated patients, develop arthritis usually weeks to years after the initial infection. Nevertheless, the onset of arthritis is acute, making discrimination from other acutely occurring arthritides difficult. The clinical course is usually intermittent with acute attacks, with transient apparent "remissions" and left untreated may go on for months and years (Shadick et al., 1999; Kalish et al., 2001; Karkkonen et al., 2001). In most cases, there is a mono- or oligoarticular course predominantly affecting the knees, ankles, and sometimes elbows, usually with massive effusions. There may be no overt arthritis with the disease characterized by nonspecific arthralgias, myalgias, and periarticular pain, with distinction difficult from functional syndromes and fibromyalgia, especially in seropositive individuals living in endemic areas (Shapiro and Gerber, 2000; Burmester et al., 2002).

Chronic borreliosis of the skin is rare in the USA, but frequent in untreated European patients. Acrodermatitis chronica atrophicans (ACA) occurs more than 12 months after the initial infection and is characterized by a unilateral extended distal atrophic skin lesion frequently preceded by an edematous violaceous stage (Figure 33.7).

Pathogenic Mechanisms

Upon transmission, the spirochetes *B. burgdorferi* invade several host tissues. They first encounter cells of the innate immune system predominantly polymorphonuclear cells and macrophages, but also innate T cells, natural killer (NK) and γδ-T cells as a first line of defense (Kamradt and Mitchison, 2001; Burmester et al., 2002). Binding of *B. burgdorferi* lipoproteins to Toll-like receptors induces a variety of pro-inflammatory mediators that account for the inflammatory reaction in the infected host tissue. There is also a strong but delayed adaptive immune response by B and T cells. Despite these innate and adaptive immune responses, about 80% of infected persons develop a systemic disease, with several properties of the spirochetes as well as host factors involved.

The pathogenesis of chronic persistent Lyme disease is still a matter of debate. Most patients with Lyme arthritis recover completely after antibiotic therapy; however, in some 10% of patients, inflammation persists even after

repeated courses of antibiotic therapy. Both persistent infection and induction of immunopathology by the spirochetes are currently discussed. A persistent infection is favored by isolation of spirochetes even at late stages of disease from involved tissues, for example, from acrodermatitis chronica atrophicans tissue after 10 years. Also by polymerase chain reaction (PCR), the *B. burgdorferi* genome could be detected in synovial tissue (Priem et al., 1998; Lünemann et al., 2001). Further, ultrastructural studies of synovial membranes from patients with chronic arthritis, and use of a three-dimensional *in vitro* model of Lyme arthritis, showed spirochetes not only in tissues with a low turnover rate, such as within bundles of collagen fibers, but also within macrophages and resident synovial fibroblasts (Franz et al., 2001).

On the other hand, in chronic therapy-resistant Lyme arthritis, the histologic lesions of affected synovial tissues resemble those of rheumatoid arthritis. Thus, together with the rare isolation of viable spirochetes from patients with chronic disease, the unresponsiveness to antibiotic treatment and the association with HLA DR4 and DR2 point towards an immunopathogenesis induced by the spirochetes. Hence, cross-reactivity between the outer surface protein A (OspA) of the spirochete and a self-antigen is discussed as cause of treatment-resistant Lyme arthritis. An alternative explanation for the development of treatment-resistant Lyme arthritis would be a hypersensitivity reaction that develops to traces of persistent antigen. Cytokines produced by cells of the innate immune system, including IL-1, IL-6, IL-10, IL-11, IL-12, IL-17, and TNF-α have all been implicated in the generation of arthritis severity in patients or animal models. Altogether, it is likely that non-antigen-specific mechanisms mediate, perhaps in synergy with antigen-specific mechanisms, the immunopathology that finally leads to treatment-resistant Lyme arthritis in susceptible patients.

Treatment and Outcome

All clinical manifestations of Lyme borreliosis should be treated with antibiotics as early as possible to shorten the clinical course and prevent the progression of the disease (for guidelines see URL http://www.dis.strath.ac.uk/vie/LymeEU). Amoxicillin, doxycycline and third-generation cephalosporins are the drugs of choice (Nadelmann and Wormser, 1998; Sigal, 1998; Shapiro and Gerber, 2000; Steere, 2001). In patients with persistent symptoms, a second parenteral antibiotic should be given, again following recommended guidelines. Using such approaches, the prognosis of Lyme disease is excellent, with almost all early infections cured rapidly without sequelae. In later disease stages, especially in Lyme arthritis, symptoms often disappear slowly, and clinical improvement is observed only several weeks after therapy. However, approximately 10% of patients with Lyme arthritis in the USA and probably a smaller percentage of patients in Europe do not respond sufficiently even to repeated courses of antibiotics. The pathogenesis of this so-called treatment-resistant Lyme arthritis is not fully elucidated but infection-induced immunopathology seems most likely. It is not easily claimed that persistent Lyme disease is truly autoimmune in its origin.

CONCLUDING REMARKS—FUTURE PROSPECTS

The spondyloarthritides and related diseases including psoriatic arthritis and the SAPHO syndrome are among the most fascinating rheumatic diseases, since they clearly demonstrate the close interplay of manifestations of the skin, the gut, the musculoskeletal system, and the immune system, especially with regard to the HLA complex. Long neglected, particularly because rheumatologists had little to offer, increasing awareness has been raised because of new treatment options, utilizing biologic therapy. We now recognize that these diseases are no longer rare, that they represent an enormous burden to the patients affected, and that they offer excellent opportunities to learn more about disease mechanisms in general. Despite, however, several decades of research, the riddles of the role of the HLA-B27 molecule and the triggering events of infections still remain. Even in Lyme borreliosis with its clearly defined causative microbial organism, important questions still remain, such as why only a minority of patients develop the disease after infection and why the courses differ so tremendously in individual patients. The next years will witness important new developments addressing these problems certainly leading to better lives for our patients.

Polymyositis and Dermatomyositis

REINHARD HOHLFELD*

**Institute for Clinical Neuroimmunology, Klinikum Grosshadern, University of Munich, Marchioninistr. 15, Munich, Germany*

ANDREW G. ENGEL†

†Department of Neurology, Mayo Clinic and Mayo Foundation, Rochester, MN, USA

Polymyositis (PM) and dermatomyositis (DM) are often categorized as "dysimmune myopathies" or "idiopathic inflammatory myopathies." The third member of this heterogeneous group of diseases is inclusion-body myositis (IBM). It is presently thought that PM is a T-cell mediated, presumably autoimmune disorder, whereas DM is an antibody-mediated vascular disorder. In contrast, it appears that the inflammatory changes observed in IBM are secondary to an unknown primary (degenerative, metabolic, infectious, or other) process. Therefore, while IBM was included in the Third Edition of this book, we elected not to include it in this chapter. The authors have drawn on material published in review form by Engel and Hohlfeld (2004) in assembling this chapter.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

In both PM and DM, proximal muscles are usually symmetrically affected. Respiratory, pharyngeal and neck muscles may be involved during later stages (Dalakas and Hohlfeld, 2003; Engel and Hohlfeld, 2004). Up to 50% of patients suffer from muscle pain or arthralgia. The history, clinical symptoms and signs, elevated serum levels of muscle enzymes, electrophysiological changes, and histologic findings together provide the basis for the diagnosis. The main diagnostic criteria and features of the different inflammatory myopathies are compared and summarized in Table 34.1. Some characteristic histologic features of DM and PM are shown in Figures 34.1 and 34.2, respectively.

Pure polymyositis is probably an overdiagnosed entity. At one extreme, represented by a recently published series of Dutch cases, only very few cases (less than 5%) were diagnosed as PM (van der Meulen et al., 2003). At the other extreme, application of the now obsolete Bohan and Peter criteria (Bohan and Peter, 1975a; 1975b) will lead to an overdiagnosis of PM, because these criteria ignore the immunohistologic characteristics of PM, DM, and IBM (Dalakas and Hohlfeld, 2003).

Characteristic skin changes may accompany the muscle weakness in DM. These include heliotropic erythema of the eyelids, cheeks, and trunk; chronic skin lesions with depigmentation and hyperpigmentation; painfully dilated capillaries at the base of the fingernails; erosions of the knuckles (Gottron's sign); dry and cracked skin of palms and fingers ("mechanic's hands"); subcutaneous calcifications in later stages (mainly juvenile DM); and cutaneous or intestinal ulcerations as a sign of generalized vascular injury (mainly juvenile DM).

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

TABLE 34.1 Clinical and diagnostic criteria of polymyositis, dermatomyositis and inclusion-body myositis

	Polymyositis	Dermatomyositis	Inclusion Body Myositis
Age at manifestation	>18 years	Any age, two peaks: 5–15 and 45–65 years	>50 years
Female : male ratio	2 : 1	2 : 1	1 : 3
Muscle involvement	Proximal symmetrical	Proximal symmetrical	Distal to proximal, asymmetrical
Atrophy	+	(+)	++
Muscle pain	(+)	+	(+)
Serum creatine kinase	Elevated up to 50-fold	Normal to 50-fold elevated	Normal to 10-fold elevated
Electromyography	Myopathic	Myopathic	Myopathic and mixed large units
Muscle biopsy	Peri- and endomysial infiltrate, invasion of MHC I^+ fibers	Perifascicular atrophy +/– infiltrate (perivascular and perifascicular)	Prominent endomysial infiltrate, atrophic fibers, "rimmed vacuoles", congophilic inclusions
Immunohistochemistry	Autoinvasive $CD8^+$ T cells, macrophages	B cells, macrophages $CD4^+$ T cells	Autoinvasive $CD8^+$ T cells, β-amyloid, prion-protein, and others in vacuolated fibers; enhanced αB-crystallin expression in numerous nonvacuolated fibers
Electronmicroscopy		Tubulovesicular inclusions in capillary endothelium; necrotic endothelial cells; platelet-fibrin thrombi in capillaries	Helical filaments, fibrils

+, present; –, absent; (+), weak or inconsistent.

Laboratory Markers of Muscle Fiber Injury

Of the enzymes released as a consequence of muscle fiber injury, the serum concentration of creatine kinase (CK) provides the best estimate of the extent of muscle damage and clinical activity. Both BB and MM isozymes may be elevated in myositis. Creatine kinase levels can be elevated up to 50 times normal in active disease phases of PM and adult DM. In contrast, the erythrocyte sedimentation rate is not a reliable parameter for disease activity and is normal in half of the patients.

Systemic Involvement

In both PM and DM, cardiac involvement with electrocardiography (ECG) changes, pericarditis, cardiomyopathy, or heart failure can occur during all stages of the disease. Pulmonary complications can be secondary to aspiration or a restrictive ventilatory defect (if the pharyngeal or respiratory muscles are affected). Further, approximately 10% of patients with PM or DM develop interstitial lung disease. Approximately 50% of these patients produce autoantibodies directed against histidyl transfer RNA (tRNA) synthetase, so-called Jo-1 antibodies. Interstitial lung disease predicts a severe course and poor prognosis (see section on "Immunologic markers").

Association with Malignancy

The exact nature of the relationship between malignancy and myositis has created continued controversy. Most of the evidence points toward an association between DM and malignancy. The relation with PM seems to be weaker (Yazici and Kagen, 2000). The weight of the available information suggests that a temporal association exists between DM/PM and malignancy over a period of about 2 years, and that the risk of malignancy in that period is increased several-fold. Although the types of malignancy seen in DM and polymyositis are similar to those in the general population, ovarian cancer seems to be more common in DM. Most experts recommend that otherwise asymptomatic patients with DM/PM have an age-specific examination for occult malignancy. All suggestive symptoms or clinical clues should be evaluated thoroughly (Yazici and Kagen, 2000).

In the absence of malignancy, 5-year survival rates of 70–90% have been reported (reviewed by Engel and Hohlfeld, 2004). Indicators for a poor prognosis include increased age, extramuscular organ involvement (heart, lung, pharyngeal muscles), acute onset of the disease, malignancy, and late or insufficient treatment. Functional recovery is best if treatment is started within the first 6 months of the disease.

B

FIGURE 34.1 *A,* Perifascicular atrophy in dermatomyositis muscle. Atrophic muscle fibers are located at the periphery of a muscle fascicle. This is a typical, even diagnostic feature of dermatomyositis. It reflects chronic ischemia of peripheral muscle fibers, due to an underlying vasculopathy (H&E stain). *B,* C5b9 membrane attack complex (MAC) deposits (green) on capillaries (red) in dermatomyositis. The capillaries are visualized with the lectin *Ulex Europaeus* agglutinin 1 and MAC with a monoclonal antibody. The MAC deposits appear on and surround the capillaries. The capillary density is markedly decreased and the remaining capillaries are dilated. See color plate section.

Principles of Treatment

The aims of therapy are to improve the ability to carry out activities of daily living. There have been relatively few controlled clinical trials. Overall, DM responds better to immunosuppressive treatment than PM. Corticosteroids remain the first-line immunomodulatory treatment both in DM and PM. Often it becomes necessary to add an immunosuppressive drug like azathioprine or methotrexate. Intravenous immunoglobulin was shown to be effective in DM and may be effective in a proportion of patients with PM.

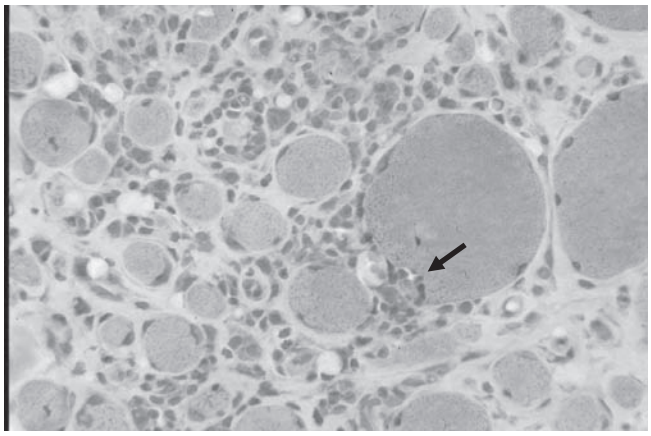

FIGURE 34.2 Dense endomysial inflammatory infiltrate in polymyositis muscle. Invasion of non-necrotic muscle fibers by $CD8^+$ T cells and macrophages is one of the hallmarks of polymyositis. The large fiber just right from the middle is invaded by a cluster of inflammatory cells (*arrow*; Gomori trichrome stain). See color plate section.

In severe, otherwise treatment-resistant cases, additional immunosuppressive agents, including cyclosporine, chlorambucil, and cyclophosphamide need to be considered. A more detailed discussion of the treatment of PM and DM may be found in Dalakas and Hohlfeld (2003) and Engel and Hohlfeld (2004).

AUTOIMMUNE FEATURES

The pathophysiological concepts of PM and DM rest mainly on morphologic, especially immunohistochemical studies. The latter are described in more detail in the next section. In essence, in PM there is a conspicuous endomysial inflammatory exudate containing mainly $CD8^+$ T cells and macrophages that surround and focally invade non-necrotic muscle fibers (Figure 34.3). Immunoelectron microscopy demonstrated that $CD8^+$ T cells and macrophages traverse the basal lamina; focally compress the fiber; and ultimately replace entire segments of muscle fiber (Arahata and Engel, 1986). All of the invaded fibers and some noninvaded fibers, express increased amounts of HLA-class I, but not class II molecules (reviewed in Hohlfeld and Engel, 1994; Engel and Hohlfeld, 2004). By contrast, normal muscle fibers do not express detectable amounts of HLA class I or class II antigens. Taken together, these observations are consistent with an HLA class I-restricted CTL-mediated response against antigen(s) expressed on muscle fibers in PM. Consistent with this hypothesis, $CD8^+$ T cells expanded from muscle of patients with different inflammatory myopathies may show low but significant cytotoxicity against autologous cultured myotubes (Hohlfeld and Engel, 1994).

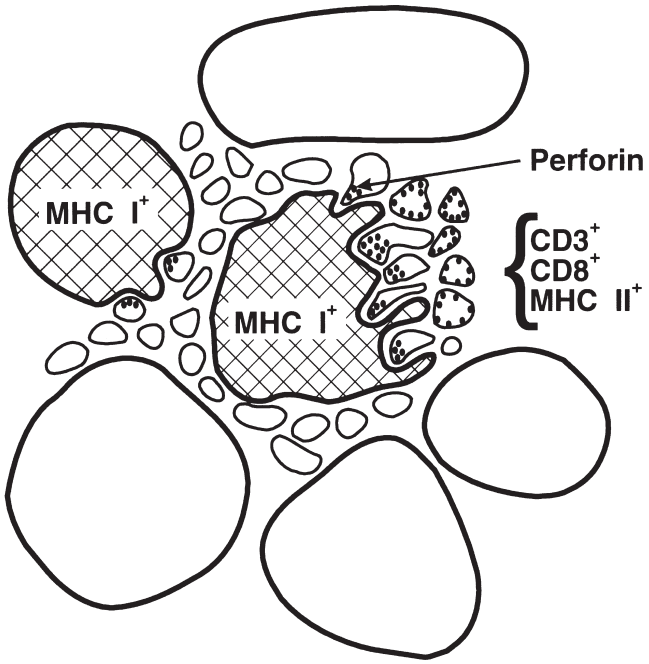

FIGURE 34.3 Schematic representation of a focal endomysial inflammatory infiltrate in polymyositis muscle. T cells focally surround and invade a non-necrotic muscle fiber. The majority of the autoinvasive T cells are $CD3^+CD8^+$. Many of the autoinvasive T cells are activated, as indicated by their expression of MHC class II (HLA-DR) antigen (MHC II^+). All invaded muscle fibers, and some that are noninvaded, show surface reactivity for MHC class I. The autoinvasive T cells express the cytotoxic effector molecule perforin, which is oriented towards the zone of contact with the invaded muscle fiber.

In DM, perifascicular atrophy is a highly characteristic microscopic feature, which is due to degeneration of muscle fibers at the periphery of muscle fascicles secondary to microvascular damage (see Figure 34.1). Quantitative morphologic analyses suggest that the depletion of capillaries is one of the earliest changes in DM. Immunofluorescence studies revealed the deposition of complement in or around microvascular endothelium in a significant proportion of capillaries (reviewed by Mendell et al., 1996). These observations support the concept that an antibody- or immune-complex-mediated response against a vascular-endothelial component is a primary pathogenetic mechanism in DM.

In juvenile inflammatory myopathies, especially juvenile DM, maternal chimerism has been implicated in the pathogenesis (Artlett et al., 2000; Reed et al., 2000). In one study, the families of 15 boys with DM were investigated for chimerism by polymerase chain reaction (PCR). Chimerism was noted in 13 of the 15 affected children with DM, compared with 5 of 35 siblings (Reed et al., 2000). Maternal cells among peripheral blood mononuclear cells were detected in 11 of the 15 boys, compared with 5 of 17 unaffected controls, and in muscle tissue of 12 of 15 compared with 2 of 10 unaffected siblings (Reed et al., 2000). Very similar results were obtained in another study (Artlett et al., 2000). Microchimerism could induce graft-versus-host reactions, which could manifest as autoimmune disease. For example, chimeric cells of fetal origin were identified in skin lesions and peripheral blood of women with systemic sclerosis (Artlett et al., 1998).

Immunohistologic Features of Polymyositis and Dermatomyositis

A number of studies have investigated the expression of inflammatory molecules such as cytokines, matrix metalloproteases, adhesion molecules, and costimulatory molecules in the different inflammatory myopathies (reviewed in Hohlfeld et al., 1997). Despite some discrepancies between the different studies, which are probably explained by methodologic aspects, it is safe to conclude that inflammatory cells, muscle fibers and endothelial cells express a complex array of different inflammatory mediators, adhesion and costimulatory molecules (Figarella-Branger et al., 2003). The local production of soluble mediators likely induces the expression of cell interaction and adhesion molecules in various cellular components of muscle tissue.

A crucial prerequisite for immunologic interaction between muscle fibers and inflammatory T cells is the expression of major histocompatibility complex (MHC, also called HLA) molecules. Muscle fibers normally do not express detectable amounts of MHC class I or II molecules. However, classical studies by the groups of George Karpati (Karpati et al., 1988; Karpati and Carpenter, 1993) and Andrew Engel demonstrated that MHC class I is strongly upregulated in pathologic conditions, especially inflammatory myopathies. In principle, muscle fibers also seem to be capable of expressing MHC class II (HLA-DR) antigen, although to a lesser extent (Bartoccioni et al., 1994; Inukai et al., 2000). Recently, the expression of a "nonclassical" HLA class I molecule (HLA-G) has been demonstrated in muscle of patients with PM, DM, and IBM (Wiendl et al., 2000).

In PM, the endomysial inflammatory infiltrate is typically dominated by $CD8^+$ T lymphocytes, which surround, invade and eventually destroy muscle fibers (see Figure 34.3). In a rare subtype of PM, the infiltrate consists of $\gamma\delta$ T lymphocytes (Hohlfeld et al., 1991). In contrast to non-inflamed muscle, the invaded muscle fibers express HLA class I molecules. This is a prerequisite for the immunologic interaction with $CD8^+$ T cells. The different stages of CTL-mediated myocytotoxicity were analyzed by immunoelectron microscopy (Arahata and Engel, 1986). Initially, $CD8^+$ cells and macrophages abut on and send spike-like processes into non-necrotic muscle fibers. Subsequently, an increasing number of $CD8^+$ cells and macrophages traverse the basal lamina and focally replace the fiber.

Approximately one-third of all autoinvasive cells and about one-half of the $CD8^+$ autoinvasive T cells is HLA-DR^+, suggesting that they have been activated (Engel and Arahata, 1984). The vast majority of the inflammatory $CD4^+$ and $CD8^+$ T cells display the phenotype of memory T cells, that is, they express the RO isoform of the leukocyte common antigen CD45 (De Bleecker and Engel, 1995). The intensity of the CD45RO signal was similar in all $CD8^+$ T cells regardless of their position relative to the invaded muscle fiber surface. A similar expression pattern was noted for the leukocyte function-associated antigen 1 (LFA-1) (De Bleecker and Engel, 1994; Iannone et al., 1996). The LFA-1 (CD11a/CD18) is a β2 integrin that has a key role in mediating leukocyte adhesion to endothelium and T-cell adhesion to target cells. Intercellular adhesion molecule 1 (ICAM-1), a ligand of LFA-1, was upregulated especially on T cells in the vicinity of invaded muscle fibers, suggesting that the expression of CD45RO and ICAM-1 is differentially regulated (De Bleecker and Engel, 1994). Indeed, LFA-1 is mainly constitutively expressed, whereas ICAM-1 is widely inducible on B and T cells. Taken together, these results establish that the autoaggressive (autoinvasive) T cells in the inflammatory lesions of PM and IBM muscle represent activated $CD8^+$ memory T cells.

In contrast to PM, perivascular and perifascicular infiltrates consisting predominantly of B lymphocytes, macrophages, and $CD4^+$ T lymphocytes prevail in DM. Immunohistochemistry shows immune complexes and C5b9-complement (membrane attack complex) on small blood vessels, suggesting a humoral immune effector mechanism (Mendell et al., 1996; Emslie-Smith and Engel, 1990). The immune processes affecting the muscle microvasculature lead to a reactive proliferation of endothelial cells and a reduction of muscle capillaries. Focal capillary depletion, with marked reduction of the capillary density, can be observed in DM specimens with minimal structural alterations, suggesting that the capillaries are an early and specific target of the disease process (Emslie-Smith and Engel, 1990). Electron microscopy demonstrates tubulovesicular inclusions in endothelial cells. Capillary changes are thought to be the cause of the characteristic perifascicular muscle fiber atrophy in DM. Perifascicular atrophy is diagnostic for DM, even in the absence of an inflammatory infiltrate. As in PM, the molecular target of the presumed humoral autoimmune reaction in DM has not yet been defined.

T-Cell Repertoire Studies

The characteristic lesion of PM has several features that make it an ideal paradigm to study $CD8^+$ T-cell-mediated immunopathology (see Figure 34.3). First of all, the muscle fiber target cells can be readily distinguished from the effector T cells. Secondly, different populations of inflammatory T cells can be discerned: one population, which deeply invades muscle fibers (the autoaggressive or autoinvasive T cells), and another, which remains in interstitial areas and, therefore, seems to represent regulatory or bystander cells (the interstitial T cells).

To address the question whether the two morphologically defined T-cell populations represent distinct clones, Bender et al. (1995) combined two independent PCR techniques with immunohistochemistry to characterize the T-cell receptor repertoire. The results show that the T-cell repertoire of the autoinvasive T cells is distinct from the repertoire of the interstitial T cells (see Figure 34.3). These findings are consistent with the results of previous studies, which however did not combine sequence with histologic analysis of T-cell receptor (TCR) Vβ expression (Mantegazza et al., 1993; Lindberg et al., 1994; O'Hanlon et al., 1994). Differences in TCR usage in the different studies presumably reflect differences between individual patients, for example, different HLA types.

More recently, clonal expansions of $CD8^+$ T cells were identified in muscle and blood of polymyositis patients by PCR techniques including TCR complementarity determining region 3 (CDR3) length analysis (spectratyping). To examine a possible pathogenic role of these clonally expanded T cells, CDR3 spectratyping was combined with laser-microdissection and single-cell PCR of individual myocytotoxic T cells that contact, invade, and destroy a skeletal muscle fiber (Hofbauer et al., 2003). First, cDNA from muscle biopsy specimens was screened by CDR3-spectratyping for expanded TCR BV sequences. To pinpoint the corresponding T cells in tissue, cryostat sections were stained with appropriate anti-TCR BV monoclonal antibodies (mAbs), isolated single BV^+ T cells that directly contacted or invaded a muscle fiber by laser-assisted microdissection and amplified their TCR BV chain sequences from rearranged genomic DNA. In this way the oligoclonal peaks identified by CDR3 spectratype screening could be related to morphologically characterized microdissected T cells. In one patient, a large fraction of the microdissected T cells carried a common TCR-BV amino-acid CDR3 motif and conservative nucleotide exchanges in the CDR3 region, suggesting an antigen-driven response. In several cases, these T-cell clones could be tracked for several years in $CD8^+$ (but not $CD4^+$) blood lymphocytes, and, in two patients, also in consecutive muscle biopsy specimens. During immunosuppressive therapy, oligoclonal CDR3 spectratype patterns tended to revert to more polyclonal, Gaussian distribution-like patterns (Hofbauer et al., 2003). The findings demonstrate that CDR3 spectratyping and single-cell analysis can be combined to identify and track autoaggressive T-cell clones in blood and target tissue.

A possible clue to the nature of the suspected autoantigen(s) was provided by the discovery of a rare variant of PM. In this variant, $CD3^+CD4^-CD8^-TCR\gamma\delta^+$ T cells surrounded and invaded non-necrotic muscle fibers in the same

way as $CD3^+CD8^+TCR\alpha\beta^+$ T cells in the more common forms of PM (Hohlfeld et al., 1991). The autoaggressive myocytotoxic γδ T cells were essentially monoclonal, and expressed an unusual Vγ3Jγ1Cγ1-Vδ2Jδ3Cδ disulfide-linked TCR (Pluschke et al., 1992). In γδ T-cell-mediated PM, all muscle fibers expressed MHC class I antigen and showed intense reactivity with a monoclonal antibody specific for the 65 kDa heat shock protein (hsp) (Hohlfeld et al., 1991). One possible implication of the striking co-localization of γδ T cells with the 65 kDa hsp is that the autoinvasive γδ T cells recognize hsp determinants on muscle fibers. Presently, however, the target autoantigens of this autoreactive human γδ T-cell receptor remain unknown, although it has been formally demonstrated that the TCR recognizes a muscle-associated autoantigen in a CDR3-dependent, MHC non-restricted way (Wiendl et al. 2002).

GENETIC FEATURES

There are numerous reports on the association of certain HLA haplotypes with subgroups of myositis (reviewed in Engel and Hohlfeld, 2004). In white people, there is an association with HLA-B8 with childhood DM and adult PM. This is attributed to the association of HLA-B8 with HLA-DR3 (which is linkage disequilibrium with HLA-B8). Childhood DM is also associated with HLA-DQA1*0501 on non-DR3 haplotypes. Different HLA associations have been documented in different ethnic groups. Interestingly, when patients are analyzed according to patterns of autoantibody production, additional associations emerge (Engel and Hohlfeld, 2004). Despite these observations, however, the evidence is still too fragmentary to identify primary susceptibility HLA alleles for specific types of inflammatory myopathy, and likely the HLA associations only partially account for the genetic risk.

IN VIVO AND *IN VITRO* MODELS

Animal Models of Myositis

Inflammatory and necrotizing lesions of muscle were experimentally induced in various animal species by the injection of Freund's complete adjuvant and homogenates of muscle or muscle protein preparations (Dawkins 1965; 1975; Uemura 1969; Webb, 1970a; 1970b; Currie, 1971; Morgan et al., 1971; Esiri and MacLennan, 1974; 1975). The majority of these models show only limited resemblance to human polymyositis. The pathologic changes in muscle usually consist of necrotic and regenerating fibers and mononuclear infiltrates in the perimysium and endomysium, particularly at perivascular sites. In some studies, the changes of experimental myositis were transferred with lymphocytes or serum. These early experiments were conducted when little or nothing was known about the mechanisms of antigen recognition and cytotoxicity. Their relevance to the pathogenesis of any human inflammatory muscle disease is uncertain.

Several reports described the induction of myositis in the SJL mouse (Rosenberg et al., 1987; Rosenberg and Kotzin, 1989; Matsubara et al., 1993; Matsubara and Okumura, 1996). However, SJL/J mice spontaneously develop a necrotizing myopathy (Hohlfeld et al., 1988). This myopathy is now known to be caused by a deletion in the dysferlin gene, defining a natural model for limb girdle muscular dystrophy (Bittner et al., 1999; Vafiadaki et al., 2001). Inflammatory changes are not uncommon in some human hereditary myopathies and muscular dystrophies, including facioscapulohumoral muscular dystrophy and dysferlinopathies. One important lesson from these observations is that, in any myopathy, the presence of inflammatory changes does not necessarily imply an (auto)immune pathogenesis but may be secondary to a metabolic or genetic defect.

A novel transgenic mouse model of myositis was recently described (Nagaraju et al., 2000b). The authors used a controllable muscle-specific promoter system to upregulate MHC class I expression in skeletal muscles of mice. The transgenic mice developed an inflammatory myopathy accompanied by autoantibodies against histidyl-tRNA synthetase, the most commonly observed antibody specificity in human myositis (Nagaraju et al., 2000b). This model indicates that the sustained upregulation of MHC class I antigen in a tissue that normally lacks MHC class I may be sufficient to induce T-cell and antibody responses to antigens expressed in the target tissue.

In another transgenic model, $CD8^+$ T-cell-dependent myositis develops in non-obese diabetic (NOD) mice made Th1 cytokine-deficient by expression of an interferon-γ receptor β chain transgene. This suggests that a disturbance of the normal cytokine balance might be sufficient to trigger myositis in susceptible animals (Serreze et al., 2003).

An infectious model of myositis has been described in CBA/J mice infected with *Trypanosoma cruzi* (Andersson et al., 2003). In this model, inflammatory infiltrates were predominantly found in the endomysium and, to a lesser extent, in perivascular areas. Furthermore, $CD8^+$ T cells invaded non-necrotic muscle fibers. In this regard, this infectious mouse model closely resembles human PM.

In Vitro Models using Cultured Myoblasts

Numerous studies have shown that cultured myoblasts (myogenic stem cells) can express a variety of immunologically important molecules (Table 34.2). Furthermore, myoblasts express a surprising number of cytokines and chemokines (reviewed in Hohlfeld et al., 1997; Figarella-Branger et al., 2003). For these and other reasons, it seems

TABLE 34.2 Immunologic properties of human myoblasts

Surface antigen	Constitutive expression	Interferon-γ-stimulated expression

CD40	+	+

+, present; –, absent; (+), weak or inconsistent.

Based on data from Goebels et al., 1992; Michaelis et al., 1993; Behrens et al., 1998b; Hohlfeld and Engel, 1990; Wiendl et al., 2000; 2003a; 2003b; 2003c.

likely that in myositis muscle cells play an active immunologic role in the affected tissue (Hohlfeld and Engel, 1994). Myoblasts are, therefore, extremely useful for functional studies of various aspects of the pathogenesis of myositis. For example, cultured human myoblasts can serve as targets for cytotoxic $CD8^+$ T cells and other cytotoxic effector cells. Perhaps even more interesting, myoblasts can present antigens to $CD4^+$ T cells (see below).

Myoblasts can be isolated and purified from muscle biopsy specimens and expanded in culture (Goebels et al., 1992). In contrast to fibroblasts, myoblasts express the cytoskeletal protein desmin and the neural cell adhesion molecule NCAM (CD56/Leu 19/NKH-1) (Hohlfeld and Engel, 1994). Myoblasts constitutively express HLA class I antigens and a low level of lymphocyte function-associated molecule 3 (LFA-3, CD58). Tumor necrosis factor α (TNF-α), a cytokine secreted by macrophages, T cells, and natural killer (NK) cells induces myoblasts to express the ICAM-1 (CD54) (Goebels et al., 1992). Interferon-γ, a cytokine secreted by T cells and NK cells, induces myoblasts to express HLA-DR and ICAM-1 (Hohlfeld and Engel, 1990; Goebels et al., 1992). HLA-DP and HLA-DQ are also inducible by interferon-γ but the kinetics of induction and the levels of expression vary with the different HLA class II molecules (Goebels et al., 1992).

Cultured myotubes and myoblasts express HLA class I molecules. This qualifies them as potential targets of $CD8^+$ CTL. Lysis of myotubes by CTL was shown in different experimental situations. On the one hand myotubes were lysed by allogeneic $CD8^+$ CTL lines raised against the allogeneic HLA antigens expressed by the myotubes (Hohlfeld and Engel, 1994). Autologous control myotubes were not lysed. Lysis involved the recognition of allogeneic class I HLA antigens, since it was completely blocked by a monoclonal antibody against a monomorphic determinant of HLA class I (Hohlfeld and Engel, 1994). Furthermore, myotubes were lysed by autologous polyclonal $CD8^+$ T-cell lines directly expanded from muscle of patients with different inflammatory myopathies (Hohlfeld and Engel, 1994). The results obtained in this model system clearly establish that cultured myotubes are fully susceptible to HLA-class I restricted lysis by $CD8^+$ CTL. The autoreactive myocytotoxicity is consistent with the hypothesis that some of the CTL isolated from muscle recognize the same antigen on myotubes *in vitro* that they recognize on muscle fibers *in vivo*.

Antigen presentation to $CD4^+$ T cells depends on the constitutive or induced expression of HLA class II on the presenting cell. Myoblasts can be induced to express HLA class II by interferon-γ (Hohlfeld and Engel, 1990). Highly purified human myoblasts were tested for their ability to present various protein antigens to autologous $CD4^+$ T-cell lines specific for tuberculin, tetanus toxoid or myelin basic protein (Goebels et al., 1992). Non-induced myoblasts or myoblasts treated with TNF-α alone could not present any of these antigens to T cells. However, interferon-γ-treated myoblasts induced antigen-specific T-cell proliferation and were killed by the T cells only in the presence of the relevant antigen (Goebels et al., 1992). Antigen-specific lysis was reduced to a background level by adding the anti-HLA-DR monoclonal antibody L-243. These results suggest that HLA class II-positive human myoblasts can act as facultative local antigen-presenting cells in muscle by providing the signals necessary to trigger both antigen-specific lysis and T-cell proliferation. In addition to presentation of exogenous antigens processed in the classical MHC class II-restricted pathway, human myoblasts seem to be capable of presenting endogenous antigen to MHC class II restricted $CD4^+$ T cells (Curnow et al., 2001).

It is clear from these studies that myoblasts have more than sufficient immunologic "potential" to qualify them for local (re)stimulation of memory and effector T cells. It is not clear, however, to what extent myoblasts can stimulate naïve (unprimed T cells). Myoblasts do not express the classical costimulatory molecules CD80 (B7.1) and CD86 (B7.2) (Behrens et al., 1998), but they do express CD40, another important costimulatory molecule (Behrens et al., 1998; Sugiura et al., 2000). Furthermore, a subpopulation of myoblasts express BB-1, a CD80 (B7)-related molecule that has not been molecularly defined (Behrens et al., 1998). In addition, myoblasts can express the CD80/CD86 (B7.1/2) related inducible costimulatory molecule ICOS-L (Wiendl et al. 2003c) and the B7-related molecule B7-H1 (Wiendl

et al., 2003b). The presence of these costimulatory molecules further emphasizes the important immunologic role of myoblasts.

In addition to the classical MHC class I molecules (HLA-A, -B, and -C), myoblasts can be induced to express the nonclassical HLA-G (Wiendl et al., 2000). HLA-G expression was first observed in cytotrophoblasts of the human placenta. The full functional potential of HLA-G is not yet known. Like the classical HLA class I molecules, HLA-G binds antigenic peptides and CD8. It should, therefore, be capable of presenting antigenic peptides to T cells in a way similar to the classical HLA class I molecules. This raises the possibility that in polymyositis, some of the autoaggressive T cells recognize their antigen in the molecular context of HLA-G. In addition, HLA-G interacts with different receptors expressed on various types of lymphocytes, monocytes, and dendritic cells. It is thought that the recognition of HLA-G induces immunoregulatory functions in these cells, raising the possibility that HLA-G protects muscle fibers from attack by certain types of immune cells, including T cells and NK cells (Wiendl et al., 2003a). Whether HLA-G has a protective (anti-inflammatory) or proinflammatory role in myositis is unknown.

PATHOGENIC EFFECTOR MECHANISMS

The precise mechanisms by which muscle fibers are injured in the different inflammatory myopathies remain to be defined. In PM (and IBM), there is strong evidence that muscle fibers are directly attacked by cytotoxic T cells. An additional possibility is that locally produced soluble inflammatory mediators and cytokines exert toxic effects on muscle fibers.

Cytotoxic T cells can kill by a variety of different mechanisms (Barry and Bleackley, 2002). A main pathway of cytotoxicity is mediated by the secretion of the pore-forming protein perforin by the cytotoxic T cell. An alternative, nonsecretory pathway relies on the interaction of the Fas ligand that is upregulated during T-cell activation with the apoptosis-inducing Fas receptor on the target cell. In PM, there is evidence that a perforin- and secretion-dependent mechanism contributes to the muscle fiber injury. Perforin has been localized in inflammatory T cells by immunohistochemistry (Orimo et al., 1994; Goebels et al., 1996) and by *in situ* hybridization (Cherin et al., 1996). In PM but not DM, the auto-invasive T cells orient their perforin-containing cytotoxic granules towards the target muscle fiber (Goebels et al., 1996), suggesting that secretion of this cytotoxic effector molecule contributes to muscle fiber injury.

Perforin is not the only potentially cytotoxic molecule expressed in inflammatory myopathies. For example, muscle fibers in myositis display distinct upregulation both of inducible and neuronal nitric oxide synthase (NOS) (Tews and Goebel, 1998). One may speculate that the enhanced expression of NOS with production of nitric oxide contributes to oxidative stress, mediating muscle fiber damage. Furthermore, different matrix metalloproteinases (MMPs) are expressed in PM and DM muscle (Choi and Dalakas, 2000; Kieseier et al., 2001). Matrix metalloproteinases are zinc-dependent endopeptidases capable of degrading extracellular matrix. MMP-1 (interstitial collagenase) is localized around the sarcolemma of injured muscle fibers and to fibroblast-like cells, whereas MMP-9 (gelatinase B) is localized mainly in inflammatory T lymphocytes (Kieseier et al., 2001). The matrix-degrading action of the MMPs could directly contribute to muscle fiber injury, or it could facilitate the access of cytotoxic factors and cells to muscle fibers.

If perforin is indeed involved in muscle fiber injury, why does the surface membrane of muscle fibers appear intact at the light microscopic (Engel and Arahata, 1984) and electron microscopic (Arahata and Engel, 1986) levels in the early stages of muscle fiber invasion? Pore-like structures could not be detected in the sarcolemma of muscle fibers attacked by T cells in PM (Arahata and Engel, 1986). One possible explanation is that perforin pores/channels on nucleated cells *in vivo* are smaller in size than the pores generated *in vitro* on erythrocytes and other target cells by the addition of purified perforin. Perforin pores containing less than 10–20 monomers would escape detection by electron microscopy (Liu et al., 1995). Another explanation for the lack of morphologically visible muscle cell damage is that the surface membrane of the muscle fiber is rapidly repaired at least during the early stages of muscle fiber invasion. Repair could occur, for example, by shedding or endocytosis of pore-damaged membrane (reviewed in Henkart, 1994).

It is interesting to note that the volume of a 25-mm-long and 50-μm-wide muscle fiber is nearly 28,000-fold larger than, for example, that of a spherical 15-μm tumor cell (Arahata and Engel, 1986). Perforin pores would allow the influx of calcium. Consistent with this assumption is the observation that invaded muscle fibers show signs of focal myofibrillar degeneration near invading cells (Arahata and Engel, 1986). These changes could be a consequence of membrane insertion of perforin and focal protease activation (Arahata and Engel, 1986). Another indirect sign of muscle fiber damage is the intense focal regenerative activity noted in areas immediately adjacent to autoinvasive T cells (Arahata and Engel, 1986).

In addition to the perforin-mediated killing mechanism, cytotoxic T cells can kill by a non-secretory, ligand-mediated mechanism (Barry and Bleackley, 2002). This second killing mechanism requires the interaction between Fas (expressed on the target cell) and Fas-ligand (expressed on the T cell). Fas-mediated cytotoxicity is thought to induce programmed cell death—apoptosis.

Ligation of Fas (CD95) recruits adaptor molecules (such as procaspase-8 and -10) to the receptor. By being brought into proximity with one another, these procaspases cleave their nearest neighbors and active, mature caspases form (Green, 2000). The active caspases efficiently cleave procaspase-3 and other executioner caspases, and apoptosis proceeds.

Different groups of investigators found no evidence that apoptosis is a mechanism of muscle fiber injury in human inflammatory myopathies (Schneider et al., 1996; Behrens et al., 1997; Fyhr and Oldfors, 1998). On the other hand, in PM, DM, and IBM many muscle fibers express Fas (Behrens et al., 1997; Fyhr and Oldfors, 1998). What could explain the discrepancy between the expression of the Fas "death receptor" on muscle fibers and the absence of signs of apoptosis? One possibility is that muscle fibers are intrinsically resistant to Fas-mediated classical apoptosis, at least *in vivo*. Resistance could be related to the peculiar properties of syncytial muscle fibers discussed above, or the expression of specific inhibitory factors such as Bcl-2, or both. Indeed, the majority of Fas^+ fibers coexpress Bcl-2 (Behrens et al., 1997; Vattemi et al., 2000). Further, muscle fibers constitutively express the human IAP (inhibitor of apoptosis)-like protein hILP (human IAP-like protein) (also called XIAP) (Li and Dalakas, 2000), which was found to be expressed in the sarcolemmal region, co-localizing with dystrophin (Li and Dalakas, 2000). The staining pattern for hILP was essentially identical in normal, PM, and IBM muscle. Furthermore, muscle fibers in PM muscle express the anti-apoptotic molecule FLIP (FLICE-inhibitory protein) (Nagaraju et al., 2000a). These authors provided evidence that FLIP indeed protects muscle cells from apoptosis in functional experiments with cultured human myoblasts (Nagaraju et al., 2000a).

In conclusion, the observation that the autoinvasive T cells express and orient perforin towards target muscle fibers is consistent with a secretion- and perforin-dependent cytotoxic mechanism of muscle fiber injury in PM. On the other hand, although many muscle fibers and inflammatory cells express Fas, the nuclear changes typical for apoptosis are essentially absent in the inflammatory myopathies (Schneider et al., 1996; Behrens et al., 1997). Resistance to Fas-mediated injury is probably related to the expression of protective (anti-apoptotic) factors in muscle fibers and inflammatory cells.

AUTOANTIBODIES AS POTENTIAL IMMUNOLOGIC MARKERS

Autoantibodies against nuclear or cytoplasmic antigens, directed against ribonucleoproteins involved in protein synthesis ("anti-synthetase") or translational transport (anti-signal-recognition particle), are detectable in about 20% of patients (Miller, 1993; Rider and Miller, 2000). Although the pathogenetic relevance of these autoantibodies has yet to be defined, they are associated with certain disease characteristics and HLA haplotypes (Miller, 1993; Engel and Hohlfeld, 2004). Antibodies against histidyl-tRNA synthetase, anti-Jo-1, accounts for 80% of all the anti-aminoacyl tRNA-synthetases, and seem to confer specificity for identifying a disease subset that combines myositis, non-erosive arthritis, and Raynaud phenomenon. A more detailed discussion of these antibodies may be found in Dalakas and Hohlfeld (2003) and Engel and Hohlfeld (2004).

Interestingly, histidyl-tRNA synthetase and asparaginyl-tRNA synthetase can activate chemokine receptors on T cells and dendritic cells (Howard et al., 2002). Thus, autoantigenic aminoacyl-tRNA synthetases, liberated from damaged muscle cells, might perpetuate the development of myositis by recruiting mononuclear cells. One could, therefore, speculate that the anti-aminoacyl-tRNA synthetase antibodies might not necessarily be harmful, but might inhibit the chemotactic properties of the aminoacyl-tRNA synthetases. Presently, however, there is no evidence that would support this possibility.

CONCLUDING REMARKS—FUTURE PROSPECTS

Much has been learned in the past two decades about the pathogenesis of the inflammatory myopathies. Different effector mechanisms have been attributed to PM (mainly T-cell-mediated) and DM (mainly antibody-mediated), and a unique $\gamma\delta$ T-cell-mediated subtype of PM has been described. Challenges for future research include the identification of the elusive (auto?)antigens and the triggering mechanisms of the immune reactions against muscle fibers. Eventually, progress in these areas should lead to advances in therapy.

AUTOIMMUNE THYROIDITIS

Historical Background

The clinical features of myxedema, the end stage of autoimmune thyroiditis (AT), were defined in 1874 by Gull, and Murray, in Newcastle-upon-Tyne, was the first to give thyroid extract as treatment in 1891. The characteristic lymphocytic infiltration (struma lymphomatosa) was first noted by Hashimoto's in 1912. Proof that AT was due to loss of self-tolerance came from Rose and Witebsky (1956) who showed that rabbits immunized with homologous thyroid extract and adjuvant developed a thyroid lymphocytic infiltrate and thyroglobulin (TG) antibodies. The latter were detected in Hashimoto's thyroiditis during the same year by Roitt and Doniach (Roitt et al., 1956).

Clinical, Pathologic, and Epidemiologic Features

Several types of AT exist (Table 35.1). Two in particular, goitrous (Hashimoto's) thyroiditis and atrophic thyroiditis (primary myxedema), result in hypothyroidism (Pearce et al., 2003), and it is likely these represent two ends of a spectrum of thyroid destruction. The goiter in Hashimoto's thyroiditis is usually firm and painless, with an irregular surface. Patients are often euthyroid at presentation but serum thyroid-stimulating hormone (TSH) levels can be elevated even if thyroxine (T4) levels are within the reference range, representing subclinical thyroid failure. Primary myxedema is identified only when hypothyroidism is apparent clinically and biochemically.

Autoimmunity accounts for over 90% of noniatrogenic hypothyroidism in iodine-sufficient countries. Women are 5–10 times more likely to be affected, with a peak incidence at 50–60 years of age (Vanderpump et al., 1995). The prevalence of autoimmune hypothyroidism in the general white population is 1–2% in women, whereas thyroid autoantibodies can be found in up to 20%, reflecting the presence of focal thyroiditis.

Pathologic changes in AT range from mild focal thyroiditis to extensive lymphocytic infiltration and scarring (Figure 35.1). In Hashimoto's thyroiditis there is a dense infiltration by lymphocytes, plasma cells, and macrophages,

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

TABLE 35.1 Types of autoimmune thyroiditis

Type	Course	Features
Goitrous (Hashimoto's) thyroiditis	Chronic: leads to hypothyroidism	Goiter: moderate to extensive lymphocytic infiltration and variable fibrosis
Atrophic thyroiditis (primary myxedema)	Chronic hypothyroidism	Atrophy: fibrosis and variable lymphocytic infiltrate
Juvenile thyroiditis	Chronic but may remit	Small goiter with moderate lymphocytic infiltrate
Postpartum thyroiditis	Transient thyrotoxicosis and/or hypothyroidism 3–6 months after delivery	Small goiter with some lymphocytic infiltrate
Silent thyroiditis	Transient thyrotoxicosis and/or hypothyroidism	Small goiter with some lymphocytic infiltrate
Focal thyroiditis	Progressive in some patients	Occurs in 20–40% thyroid specimens at autopsy; associated with thyroid carcinoma

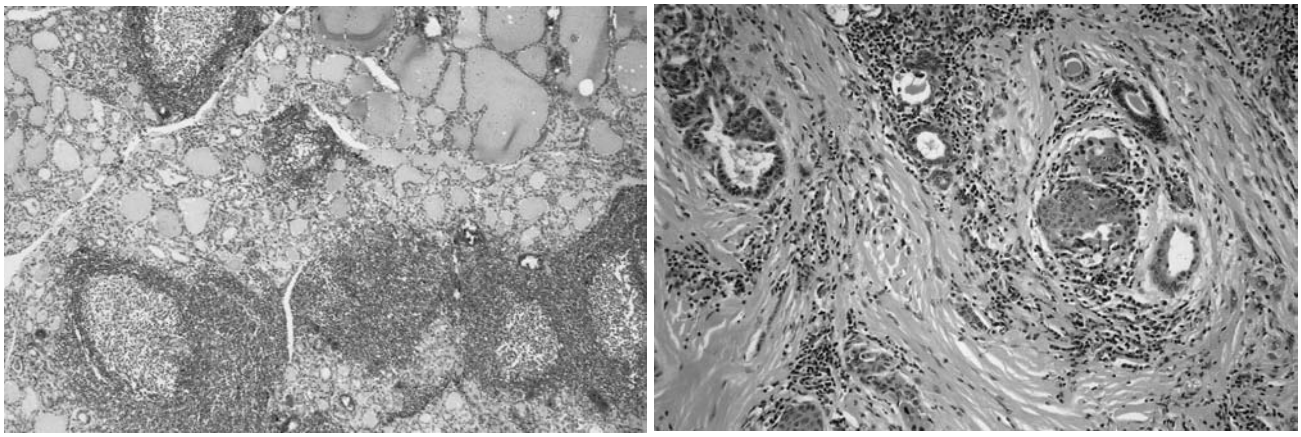

FIGURE 35.1 Pathology of autoimmune hypothyroidism. *A,* Hashimoto's thyroiditis showing germinal center formation. *B,* Primary myxedema with extensive fibrosis. (Original magnification: ×100.) See color plate section. Courtesy of Dr Judith Channer, Northern General Hospital, Sheffield.

and germinal center formation. Thyroid follicles are progressively destroyed and, in the process, the cells undergo hyperplasia and oxyphil metaplasia. In rare cases there are concurrent changes of Graves' disease, so-called hashitoxicosis. There is a variable degree of fibrosis and when this is extensive, the picture may resemble primary myxedema, in which the gland is atrophic and there is extensive fibrosis with loss of normal lobular architecture and minimal or modest lymphocytic infiltration. The histology in postpartum and silent thyroiditis resembles Hashimoto's thyroiditis.

Autoimmune Features

Autoantibodies

Circulating autoantibodies against TG and thyroid peroxidase (TPO) are found, often at very high levels, in most patients with AT. These antibodies are common, albeit at low levels, in association with focal thyroiditis.

Thyroglobulin Antibodies

Thyroglobulin is a 660 kDa homodimeric glycoprotein secreted by thyroid follicular cells (TFC) and stored in the luminal colloid. At 4–8 hormonogenic sites, iodinated tyrosine residues couple to form T4 or tri-iodothyronine (T3). The iodination state of TG alters its immunogenicity in animals and in man (Saboori et al., 1999). Oxidative stress during TG synthesis may be particularly critical in the generation of immunoreactive C-terminal fragments of the molecule (Duthoit et al., 2000). There are two major and one minor antibody epitopes on each 330 kDa subunit, and the wide spacing of these prevents IgG cross-linking and therefore complement fixation. The restriction of the response to three epitopes is only relative, as TG antibodies recognize an increasing number of determinants as their titer rises and

somatic hypermutation occurs (McIntosh et al., 1998). Antibody reactivity is predominantly in the IgG_1 and IgG_4 subclasses but not light chain restricted.

Thyroid Peroxidase Antibodies

TPO is a 100–105 kDa apical membrane protein responsible for tyrosine iodination and coupling in the formation of thyroid hormones. Molecular characterization of this autoantigen has been reviewed extensively (McLachlan and Rapoport, 1992). Antibodies to TPO have a similar IgG subclass distribution to TG, but are κ-light chain restricted (McIntosh et al., 1998). Eighty percent of TPO antibodies recognize an immunodominant region involving overlapping, conformational epitopes in two extracellular domains and specific patterns of TPO autoantibody recognition are genetically transmitted in AT families (Jaume et al., 1999). The epitopic domains have been defined (Gora et al., 2004) but full characterization will require crystallization of TPO. *In vitro*, TPO can bind C4 complement component, which may contribute to the susceptibility of TFC to destruction (Blanchin et al., 2003).

Other Autoantibodies

Thyroid stimulating hormone (TSH) receptor (TSH-R)-blocking antibodies are found in around 20% of patients with AT (Weetman and McGregor, 1994). Growth-stimulating and growth-blocking autoantibodies, operating independently of the TSH-R, have been suggested to determine thyroid size (Drexhage, 1996) but there is considerable controversy regarding the methodology used to detect these antibodies. Two thyroid-specific autoantibodies recognize a poorly characterized second (i.e., non-TG) colloid antigen and the Na^+/I^- transporter, but any importance of these in pathogenesis is unknown (Ajjan et al., 2000). Autoantibodies against T4 and T3 occur in 15–35% of patients with autoimmune thyroiditis.

T-Cell Responses

A major site of autoreactivity is within the thyroid itself, although autoimmune responses can also be detected within the draining lymph nodes and bone marrow (Weetman et al., 1984). Recruitment of lymphocytes to the thyroid requires upregulation, on endothelial cells, of various adhesion molecules and selectins, and the infiltrating lymphocytes express the reciprocal adhesion molecules, including CD11a, CD18, CD29, CD49a, and CD49e (Marazuela, 1999). The local infiltrate produces an array of chemokines which aid homing, including CXCL12, CXCL13 and CCL22, particularly when lymphoid follicles are present, and the TFC contribute to the chemokine pool, exacerbating the autoimmune process (Armengol et al., 2003; Kim et al., 2003). Most phenotyping and functional studies on T cells have used the readily sampled peripheral blood: this may reflect poorly (if at all) the responses within the autoimmune target.

Studies of T-Cell Phenotypes

The number of circulating $HLA\text{-}DR^+$ (activated) T cells is elevated and $CD8^+$ T cells are reduced, but only in active thyroiditis (Iwatani et al., 1992). $CD4^+$ T cells predominate in the thyroid infiltrate and many of these are activated (Aichinger et al., 1985). The majority of T cells express the αβ receptor and no obvious bias in T-cell receptor usage is apparent, despite initial claims (McIntosh et al., 1997). Although a pauciclonal T-cell response seems likely in early AT, by the time of clinical presentation there is spreading of the immune response to produce a polyclonal T-cell response, directed against an array of autoantigens and epitopes.

Functional Studies

Weak T-cell proliferative responses against TG and TPO are found in many patients and can be enhanced by IL-2 supplementation (Butscher et al., 2001). To identify T-cell epitopes for TPO, circulating T cells from patients with autoimmune thyroiditis have been stimulated with overlapping synthetic peptides (Tandon et al., 1991). No dominant epitope has been identified; instead there is considerable heterogeneity both within and between individual patients. Migration-inhibition factor-based assays have been used in attempts to identify a defect in thyroid antigen-specific suppressor T cells in AT (Volpe, 1988; Martin and Davies, 1992) but no consistent results have been produced and there is no evidence in man yet to implicate a defect in $CD4^+CD25^+$ T regulatory cells.

Cloned intrathyroidal T cells from patients release IFN-γ, IL-2, IL-6, and tumor necrosis factor (TNF) with no distinct Th1 or Th2 pattern (Grubeck-Loebenstein et al., 1990). Reverse transcription of cytokine mRNA and cDNA amplification has revealed a mixed Th1 and Th2 response in Hashimoto's thyroiditis (Ajjan et al., 1996). The demonstration of major histocompatibility complex (MHC) class II expression on TFC in Hashimoto's thyroiditis and Graves' disease gave rise to the concept that such "aberrant" expression could initiate or perpetuate the autoimmune response by converting the TFC into antigen-presenting cells (Bottazzo et al., 1983). However class II expression is restricted to TFC adjacent to T cells producing IFN-γ (Hamilton et al., 1991) and only this cytokine is capable of initiating class II expression *in vitro*. MHC class II expression is found on TFC in experimental autoimmune thyroiditis (EAT) induced by neonatal thymectomy (see below) but always follows the appearance of a lymphocytic infiltrate (Cohen et al., 1988). TFC do not express costimulatory molecules even after cytokine exposure (Marelli-Berg et al., 1997). Together these results indicate that TFC are unlikely to initiate the autoimmune response.

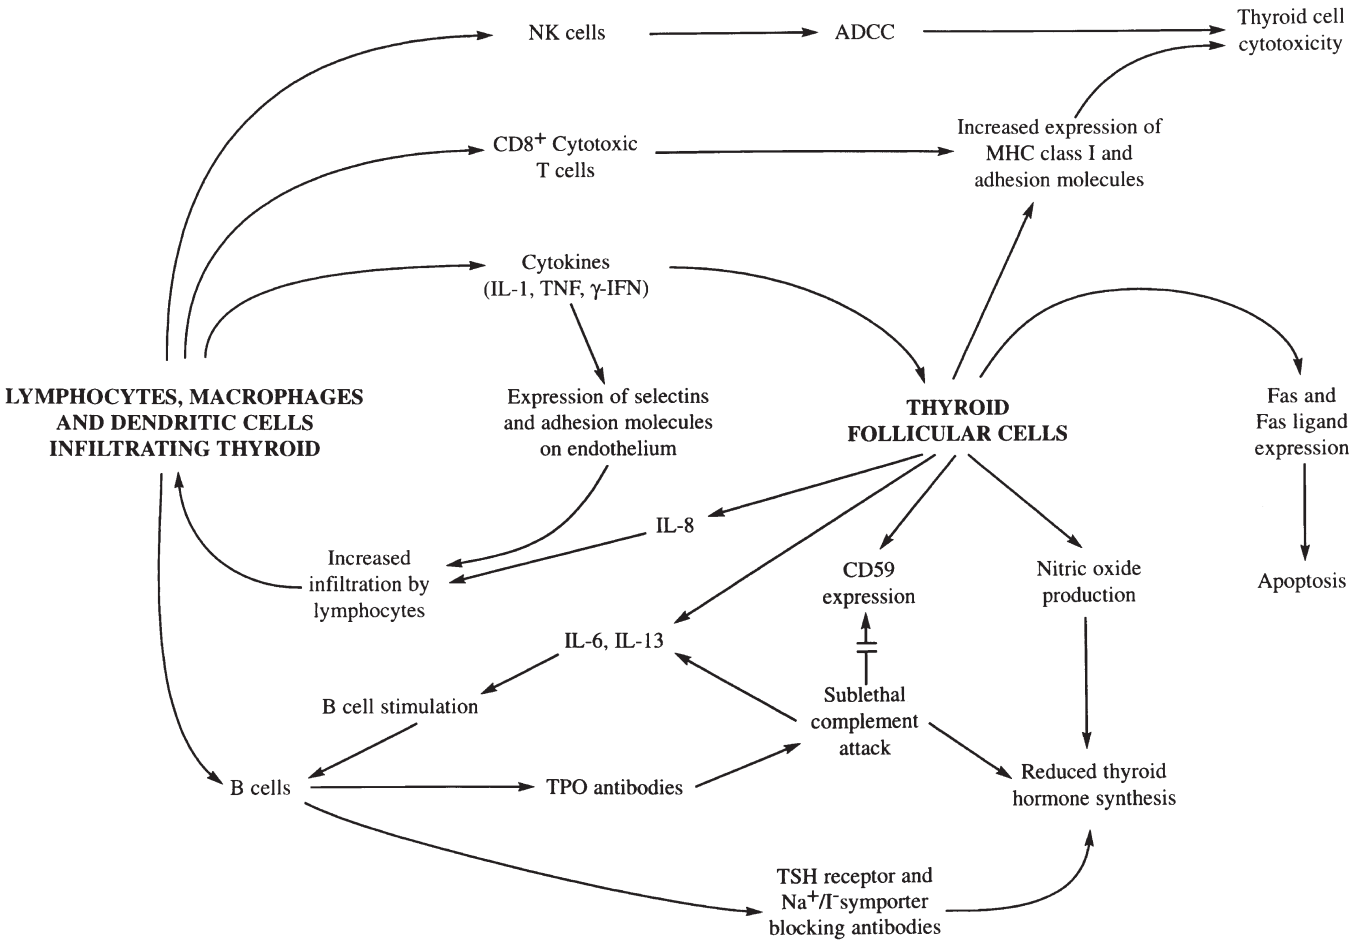

FIGURE 35.2 Role of thyroid follicular cells in autoimmune thyroiditis. From Weetman, A.P., Ajjan, R. and Watson, P.F. (1997) Cytokines and Graves' disease. *Baillière's Clin. Endocrinol. Metab. 11,* 481–497, with permission.

T-cell lines and clones derived from the thyroids of patients can be activated by class II-expressing TFC (Londei et al., 1985). Such T cells are likely to have been previously activated by classic antigen-presenting cells and are no longer dependent on B7 costimulation (Marelli-Berg et al., 1997). Anergy can be induced in CD80 (B7)-dependent, naïve T cells by class II-positive TFC and this type of peripheral tolerance may be important in regulating autoreactive T cells within the normal thyroid. In established AT, however, T cells are resistant to tolerance indication (Dayan et al., 1993) and class II-expressing TFC may then help to perpetuate the autoimmune response. TFC may participate in the autoimmune process in other ways besides MHC class II expression (Figure 35.2).

Genetic Features

The role of genetic factors in AT is suggested by the frequent presence of thyroid autoantibodies in other family members and the association of thyroiditis with other endocrinopathies as part of the type 2 autoimmune polyglandular syndrome. Twin studies show a 0.55 concordance rate in monozygotic but not dizygotic twins, and similar findings have been reported for the aggregation of thyroid autoantibodies in euthyroid twins of individuals with AT (Brix et al., 2000; 2004).

As with most autoimmune disorders, associations with HLA alleles have been extensively investigated, producing conflicting results (Tomer and Davies, 2003). Initially it appeared that primary myxedema and Hashimoto's thyroiditis in white people had distinct associations with HLA-DR3 and -DR5 respectively, but subsequent studies have shown that Hashimoto's thyroiditis is associated with HLA-DR3 and to a lesser extent -DR4. Postpartum thyroiditis has a weak association with HLA-DR5.

Another established susceptibility locus besides HLA is CTLA-4, with polymorphisms in this gene conferring a relative risk of around 2, possibly due to the increased

production of an alternative splice form of CTLA-4 with immunoregulatory consequences (Kotsa et al., 1997; Ueda et al., 2003). Genome-scanning methods, applied to relatively small series of families, have suggested a number of susceptibility loci on chromosomes 6p, 8q, 10q, and 12q (Tomer and Davies, 2003) but these have not yet been independently confirmed. Around 40% of Turner syndrome patients have TPO antibodies and 15% become hypothyroid, with a particularly high risk in women with an X-isochromosome (Elsheikh et al., 2001). Linkage and association studies have suggested that the gene-encoding TG may be a susceptibility locus, but the largest study to date in UK patients found no evidence to support this, emphasizing the replication difficulties that are posed by association studies looking at candidate loci (Collins et al., 2004).

Environmental Influences

The female preponderance of AT is in part due to the influence of sex steroids. Certainly in EAT, estrogens or progesterone exacerbate thyroiditis and this is reversed by testosterone (Okayasu et al., 1981; Ansar-Ahmed et al., 1983), while use of exogenous estrogens lowers the risk of developing TPO antibodies in genetically predisposed individuals (Strieder et al., 2003). Early nutritional factors may also have an impact, as low birth weight appears to be associated with an increased prevalence of thyroid autoantibodies (Phillips et al., 2002). Pregnancy ameliorates AT but there is an exacerbation in the year after delivery, reflected by a rise in TPO antibody levels. In some women with a previously mild thyroiditis, the enhanced autoimmune response is sufficient to cause biochemical or clinical thyroid dysfunction, and this is termed postpartum thyroiditis (Muller et al., 2001). Although usually a transient phenomenon, up to a quarter of such women develop permanent hypothyroidism within 10 years, so that pregnancy is a risk factor which precipitates clinical disease in predisposed subjects (Othman et al., 1990). The exacerbation of underlying thyroiditis is assumed to be due primarily to hormonal changes. Fetal microchimerism may play a role via intrathyroidal chimeric cells breaking immunologic tolerance (Ando and Davies, 2003).

There is no convincing evidence for a direct role of infection in etiology (Tomer and Davies, 1993). The prevalence of lymphocytic thyroiditis appears to be rising in developed countries, possibly as a result of increasing iodine intake. Certainly iodine is essential for the development of EAT in obese strain (OS) chickens, and increasing iodine administration worsens EAT in both OS chickens and BioBreeding (BB) rats (Ruwhof and Drexhage, 2001). As well as enhancing the immunogenicity of TG, iodine may be involved at an early stage in causing thyroid injury through the generation of reactive oxygen metabolites (Bagchi et al., 1995). Indirect evidence for iodine-induced injury is provided by studies of iodization programs in iodine-deficient regions showing an increase in thyroid autoantibodies and lymphocytic thyroiditis shortly after supplementation.

Anthracene derivatives and other chemicals induce EAT in the Buffalo strain rat. Administration of lithium may exacerbate autoimmune thyroiditis both immunologically and biochemically, but the adverse effect of the cytokine IFN-α on thyroid autoantibody development is more striking (Carella et al., 2001). Radioactive fallout from the Chernobyl nuclear disaster led to an almost 10-fold increase in the prevalence of thyroid autoantibodies in girls aged 9–10 at the time of the accident, presumably through release of thyroid autoantigens from the damaged thyroid (Pacini et al., 1998). Thyroid autoantibodies can appear transiently after subacute thyroiditis, supporting this mechanism (Iitaka et al., 1998).

Animal Models

AT can be induced experimentally in animals and also occurs spontaneously, with features most closely resembling Hashimoto's thyroiditis.

Immunization-Induced Thyroiditis

In mice and rats the strength of the autoimmune response to immunization with TG in adjuvant is strain dependent. Murine EAT susceptibility (as shown by the severity of lymphocytic thyroiditis) is governed by the class II I-A subregion of the H-2 major histocompatibility complex (Vladutiu and Rose, 1971). H-$2^{k,s}$ strains may even develop EAT with syngeneic TG immunization alone, demonstrating that untolerized autoreactive T cells exist in normal animals, in which they are usually under active regulation (ElRehewy et al., 1981). The influence of I-E is strain dependent but less clear. MHC class I K and D alleles also influence susceptibility, presumably by determining the strength of effector cytotoxic T-cell interaction with the thyroid cell target. Transgenic mice expressing HLA-DR3 but not HLA-DR2 develop EAT after TG immunization, confirming a role for this HLA specificity in thyroiditis (Kong et al., 1996). Genes outside the MHC have a minor role: TG antibody responses depend on both H-2 and immunoglobulin heavy chain genes. In the rat, immunization-induced thyroiditis is under partial MHC control but non-MHC genes possibly play a greater role than in mice (De Assis-Paiva et al., 1989).

Female animals have worse EAT than males and this is dependent on sex hormones, estrogen excess worsening thyroiditis and testosterone ameliorating it (Okayasu et al., 1981). Another important influence in mice is the level of circulating TG, which can induce $CD4^+$ and $CD8^+$ suppressor T cells (Kong et al., 1989). Other controlling factors are shown in Figure 35.3. The thyroiditis after immunization consists of $CD4^+$ and $CD8^+$ T cells and macrophages, with

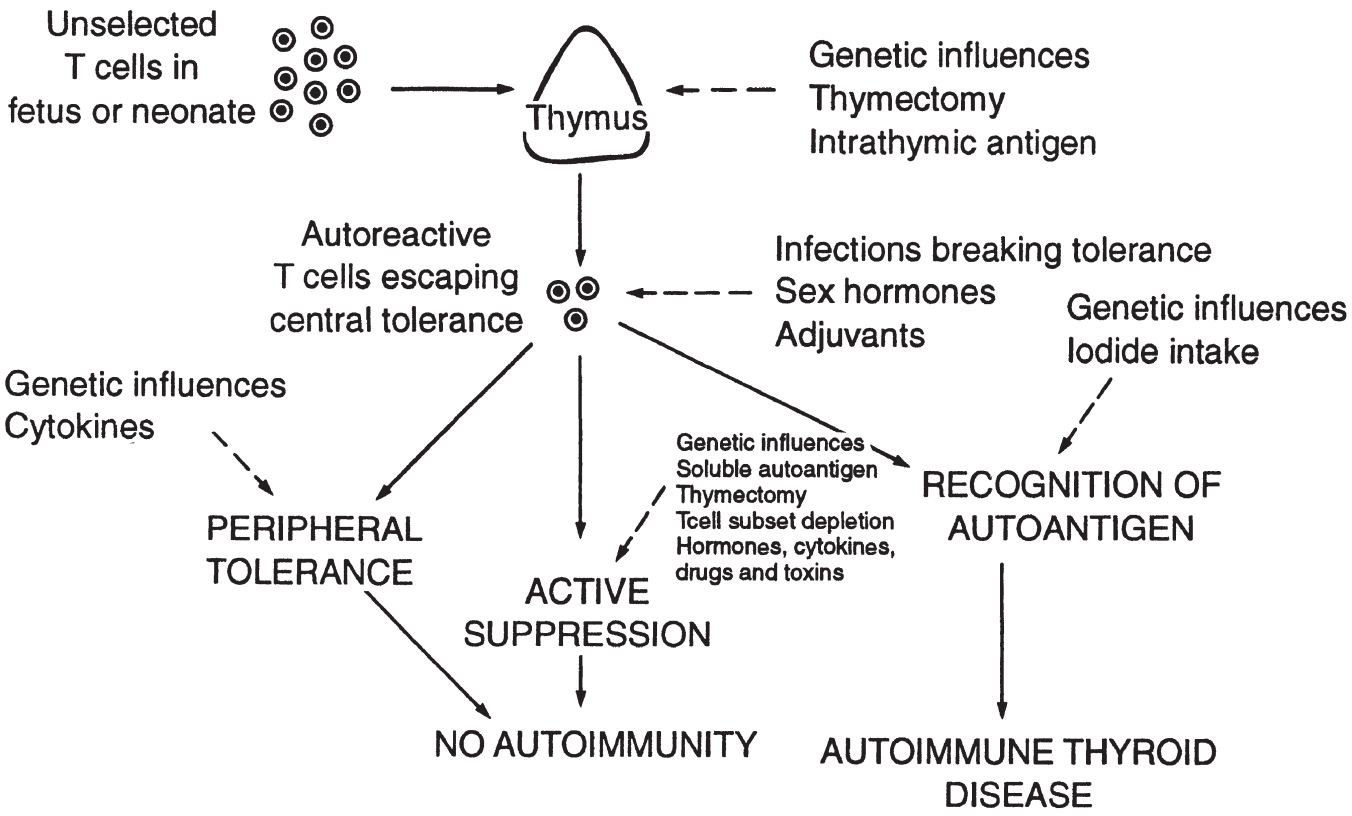

FIGURE 35.3 Sites of various controlling factors in the development of experimental autoimmune thyroiditis. From Weetman and McGregor (1994), with permission.

only a small percentage of B cells. Disease can be transferred by T cells but not by TG antibodies and the critical effector cells are $CD8^+$ cytotoxic T cells which require specific $CD4^+$ T cells for their induction (Creemers et al., 1983). TPO-based models have been difficult to establish, yet would more resemble the human counterpart. The major difficulty has been antigen availability; recombinant murine TPO will induce EAT after immunization of $H\text{-}2^b$ mice especially (Ng et al., 2004).

Experimental Autoimmune Thyroiditis Resulting from T-Cell Modulation

Neonatal thymectomy in certain strains of mice or rats, or thymectomy plus sublethal irradiation in certain strains of rats, results in severe EAT (Penhale et al., 1973; Kojima et al., 1976), as well as other autoimmune endocrinopathies. From these initial observations came the understanding of the crucial role of $CD4^+$, $CD25^+$ immunoregulatory T cells in preventing autoimmunity (Sakaguchi et al., 2001). Other maneuvers affecting T cells, such as treatment of neonatal mice with cyclosporine A or T-cell depletion and reconstitution, can induce EAT (Sakaguchi and Sakaguchi, 1989). Recent work has shown that depletion of CD7/CD28 in knock-out mice also prevents generation of $CD4^+$, $CD25^+$ regulatory cells and results in EAT (Sempowski et al., 2004). The induction of EAT by T-cell modulation elegantly demonstrates the presence of thyroid-reactive T cells in the normal newborn repertoire. These $CD4^+$ T cells may be destined for deletion after birth but there is now strong evidence for incomplete tolerance and active suppression even later.

In addition to MHC and non-MHC genes, environmental factors play an important role in susceptibility. Rats raised under specific pathogen-free conditions until weaning are resistant to EAT following thymectomy and irradiation, but transfer of normal gut microflora results in EAT in the germfree animals (Penhale and Young, 1988). It is unclear whether radiation-induced damage to the intestine is involved in this effect of gut microflora.

An extreme example of T-cell modulation has been the generation of mice transgenic for the T-cell receptor of a T cell clone specific for a cryptic epitope of TPO, derived from a patient with AT (Quaratino et al., 2004). These mice developed thyroiditis and hypothyroidism despite this being in the context of murine TPO and antigen presentation of the rel-

evant epitope by H-2 rather than HLA: the development of disease in these animals indicates that a cryptic epitope can have a significant pathogenic role in autoimmunity.

Spontaneous Autoimmune Thyroiditis

Several species develop spontaneous EAT but most is known about the BB and Buffalo strains of rat and the OS chicken. Lymphocytic thyroiditis and TG antibodies occur in around 60% of diabetic and 10% of nondiabetic BB rats but diabetes-prone sublines have a range of prevalence, from 100% in the NB line to 5% in the BE line, suggesting that diabetes is not tightly linked genetically to EAT (Crisa et al., 1992). The Buffalo strain rat has a low spontaneous incidence of thyroiditis, reaching a maximum of 25% in old, multiparous females (Noble et al., 1976).

Spontaneous autoimmune thyroiditis in the OS chicken is the closest animal model of Hashimoto's thyroiditis. The birds were originally bred from a White Leghorn flock of Cornell strain chickens for phenotypic features of hypothyroidism. Over time, the factors influencing disease development have changed: the importance of MHC genes and sex has diminished and the main genetic determinants in current OS chickens govern target organ susceptibility, T-cell hyperreactivity, and corticosteroid responses (Wick et al., 1989). Unlike other models, OS chickens develop severe hypothyroidism as well as a lymphocytic thyroiditis and TG antibodies, and require T4 supplementation to thrive. The disease is T-cell dependent as thymectomy at birth prevents disease, although later thymectomy exacerbates thyroiditis, presumably by altering the balance of T-cell-mediated suppressor activity (Pontes de Carvalho et al., 1981).

Pathogenic Mechanisms

Several antibody- and cell-mediated mechanisms contribute to thyroid injury in autoimmune hypothyroidism, and differences in the relative importance of each may determine some of the clinical and pathologic variants described above (Figure 35.4).

Antibody-Mediated Injury

Immune complexes are deposited in the basement membrane around the thyroid follicles in Hashimoto's thyroiditis (Pfaltz and Hediger, 1986) and terminal complement complexes are also present at this location, indicating the formation of membrane attack complexes (Weetman et al., 1989). TFC are relatively resistant to lysis, through enhanced expression of multiple regulators of complement activation, especially CD59, in response to cytokines derived from the infiltrating lymphocytes and macrophages (Tandon et al., 1994). After sublethal complement attack, TFC are less able to respond to TSH stimulation and also

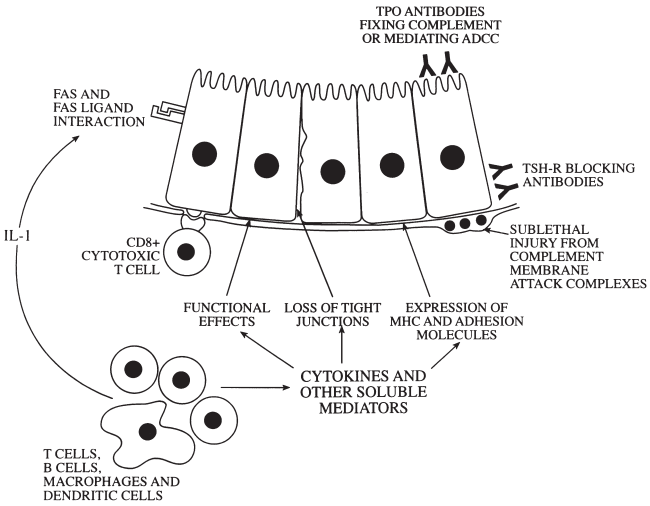

FIGURE 35.4 Mechanisms of thyroid destruction in autoimmune hypothyroidism. From Weetman, A.P. (2002) Autoimmune thyroid disease. In J.A.H. Wass and S.M. Shalet (eds), *Oxford Textbook of Endocrinology and Diabetes* (pp. 392–408). Oxford: Oxford University Press, with permission.

release cytokines (IL-1, IL-6), prostaglandin E2 and reactive oxygen metabolites, which may have proinflammatory effects (Weetman et al., 1992). TPO antibodies are generally assumed to be the major mediators of complement fixation and activation within the thyroid but unidentified autoantibodies are also involved (Chiovato et al., 1993) and additional activation via the alternative pathway probably occurs. Cytokines like IL-1 may be critical in dissociating the junctional complex and thus allowing access of autoantibodies to apically expressed TPO and other such antigens (Nilsson et al., 1998), in turn implying a secondary role for these antibodies in pathogenesis.

Autoantibodies may also provoke damage by antibody-dependent cell-mediated cytotoxicity (ADCC). A difference in the level of serum autoantibodies capable of mediating ADCC has been proposed to explain the clinical pictures of atrophic and goitrous thyroiditis, with more ADCC activity in the former (Bogner et al., 1995), but this has not proved reproducible, as others have found equally potent ADCC activity in patients with Hashimoto's thyroiditis, primary myxedema, and Graves' disease (Metcalfe et al., 1997).

Finally, autoantibodies can alter target cell function. TSH-R blocking antibodies have a clearly defined importance, as their placental transfer causes transient neonatal hypothyroidism (Matsuura et al., 1980). Although they appear to be particularly associated with atrophic thyroiditis in Asian patients (Arikawa et al., 1985), TSH-R blocking antibodies occur in both goitrous and atrophic thyroiditis in white people (Steel et al., 1984; Kraiem et al., 1987).

T-Cell Mediated Injury

Despite the strong lead provided by studies in EAT, there is only modest direct evidence that T-cell mediated injury is important in autoimmune hypothyroidism. Two groups have derived $CD8^+$ T-cell clones and lines from patients with Hashimoto's thyroiditis which lyse autologous TFC in a MHC class I-restricted fashion (MacKenzie et al., 1987; Sugihara et al., 1995). The autoantigen specificity of these T cells has not been elucidated. Indirect evidence for the importance of cytotoxic T cells in pathogenesis is provided by the demonstration of frequent perforin-containing T cells in the intrathyroidal $CD8^+$ T-cell population in Hashimoto's thyroiditis (Wu et al., 1994). In addition, TFC in Hashimoto's thyroiditis express adhesion molecules such as CD54 in response to cytokines and these increase the potential for T-cell binding, thereby enhancing cytotoxicity (Weetman et al., 1990). T cells may also provoke thyroid dysfunction by release of cytokines. Although there are only weak and inconsistent effects of IFN-γ, IL-1 and TNF on TFC survival in primary cultures (McLachlan et al., 1990), IFN-γ inhibits the response to TSH stimulation and TNF plus IFN-γ in combination have a marked inhibitory effect on TPO and TG expression in the FRTL-5 thyroid cell line (Mandrup-Poulsen et al., 1996).

Attention recently has focused on the occurrence of death receptor-mediated apoptosis as a major pathway for TFC destruction, based on the finding of both Fas (CD95) and Fas ligand (CD95L) on TFC in Hashimoto's thyroiditis (Giordano et al., 1997). Fas expression by TFC was upregulated by IL-1β, leading to the suggestion that cytokines could induce cytotoxicity through this pathway by suicide or fratricide as Fas interacted with FasL. Moreover, it has been proposed that FasL on TFC induces apoptosis in the infiltrating lymphocytes, suggesting that a T-cell mediated cytotoxic mechanism for thyroid destruction is less important than autocrine/paracrine Fas–FasL interaction (Stassi et al., 1999). Other interpretations have been put on the role of such apoptosis, not least because of the technical difficulty of quantitating FasL expression and the possible role of decoy death receptors and regulators of apoptosis signalling. An alternative proposal is that the infiltrating lymphocytes cause TFC apoptosis through their expression of TNF-related apoptosis-inducing ligand (TRAIL) engaging with various death receptors, induced by cytokines (Bretz and Baker, 2001).

Immunologic Markers in Diagnosis

The diagnosis of autoimmune hypothyroidism is usually straightforward, patients having biochemical evidence of hypothyroidism plus TG and/or TPO antibodies which can easily be measured by passive hemagglutination or ELISA (enzyme-linked immunosorbent assay). An abnormal thyroid ultrasound pattern is also highly predictive of AT (Raber et al., 2002). Fine needle aspiration biopsy is used in difficult cases, especially to exclude an associated lymphoma.

Treatment and Outcome

It is difficult to imagine a more straightforward treatment than T4 replacement and future attempts at immunomodulation seem unlikely (Roberts and Ladenson, 2004). In around 10% of patients there may be a spontaneous remission 4–8 years after starting T4, and this is associated with the disappearance of TSH-R blocking antibodies (Takasu et al., 1992). However, the permanence of such remissions has not been established and remission in other patients has not been associated with changes in TSH-R blocking antibody levels (Cho et al., 1995).

Concluding Remarks—Future Prospects

Considerable progress in understanding the pathogenesis of AT has been made in the half century since the first demonstration of EAT and the realization that a similar process accounts for Hashimoto's thyroiditis. A major future goal will therefore be to identify the earliest T-cell responses, as these may be restricted to single T-cell clones, recognizing restricted epitopes on a single inciting autoantigen, and have a particular Th1 or Th2 bias. Additional work is also needed to determine the exact genetic basis for AT and to clarify the relationships between primary myxedema, Hashimoto's thyroiditis, and postpartum thyroiditis. Finally, despite two decades of research, the role of T-cell mediated, thyroid-specific immunoregulation in man is still unclear. There is no doubt that T regulatory cells are important in EAT, but so far the mechanisms which control thyroid-specific T cells that have escaped central tolerance in human AT are elusive.

GRAVES' DISEASE

Historical Background

This disorder was first described by Caleb Parry in 1825 but it was Robert Graves' whose name became attached to the disease through his report of four cases published in 1835. Basedow was the first to highlight the association with exophthalmos in 1840. Originally believed to have a cardiac and then neurologic origin, the role of the thyroid in Graves' disease became established in the 1890s as thyroidectomy for apparently coincidental goiter improved the other disease manifestations. The cause remained obscure until Adams and Purves (1956) showed that the serum from Graves' patients contained a long-acting thyroid stimulator

which was distinct from TSH; working separately, Kriss and McKenzie went on to show that this stimulator was an IgG.

Clinical, Pathologic, and Epidemiologic Features

Although sharing many immunologic features with AT, it is the production of TSH-R stimulating antibodies which characterizes Graves' disease (Weetman, 2000). It is the most common cause of hyperthyroidism, accounting for 60–80% of cases. The prevalence is around 1% in women aged 35–60 years, with a 5–10-fold lower frequency in men (Vanderpump et al., 1995). Over 90% of patients with Graves' disease have thyroid-associated ophthalmopathy (TAO), which can be revealed by scanning techniques showing enlarged extraocular muscles (Bartalena et al., 2000). Clinically obvious eye disease is apparent in around 50% of patients (Figure 35.5). TAO is not exclusive to Graves' disease, as around 5% of patients have AT and another 5% have little evidence of thyroid dysfunction. Thyroid dermopathy (or pretibial myxedema, reflecting the usual site for this complication) occurs in only 1–5% of patients, who usually also have marked TAO (Schwartz et al., 2002).

In the untreated state there is both hypertrophy and hyperplasia of the thyroid follicles; the epithelium becomes columnar and folded into the follicular lumen, new small follicles form, and there is little colloid (Figure 35.6). A variable degree of lymphocytic infiltration occurs and germinal centers may form. Antithyroid drugs diminish the lymphocytic infiltrate and the epithelium reverts to a normal appearance. Lymphoid hyperplasia may occur in the lymph nodes, thymus, and spleen but reverses with antithyroid drugs.

Autoimmune Features

Autoantibodies

Thyroglobulin and TPO autoantibodies occur in 80% of patients. TSH-R stimulating antibodies (TSAb) can be detected in over 95% of patients with current assays. The TSH-R consists of a 398 amino acid extracellular domain, a 266 amino acid transmembrane spanning domain with seven hydrophobic regions, and an 83 amino acid intracellular domain (Rapoport et al., 1998). The receptor undergoes complex post-translational processing to form two subunits. TFC shed the A subunit, which binds TSAb more strongly than the holoreceptor, and this may be critical in initiating or amplifying the autoimmune response (Chen et al., 2003). TSH-induced activation of the TSH-R causes a rise in cAMP and, at high concentrations of the hormone, activation of the phosphatidyl-inositol intracellular signaling pathway.

The original bioassay method measured release of radioiodine from preloaded thyroid glands after injection of serum or IgG into intact animals and this activity was termed long-acting thyroid stimulator or LATS (Adams and Purves, 1956). Current assays measure cAMP release from primary TFC cultures, thyroid cell lines (such as FRTL-5), and most recently from TSH-R transfected eukaryotic cells (Ludgate and Vassart, 1995). A separate type of assay measures displacement of radiolabeled TSH from solubilized TSH-R derived from thyroid membranes by TSH-R antibodies; these antibodies are called TSH-binding inhibiting immunoglobulins or TBII. Although the TBII assay is robust and commercially available, both TSAb and TSH-R blocking antibodies (which inhibit TSH-induced cAMP release) are measured by it and therefore the level of TBII gives no direct information on functional activity. However, second-

FIGURE 35.5 Eye signs in a patient with thyroid-associated ophthalmopathy showing exophthalmos, scleral injection, and periorbital edema. See color plate section.

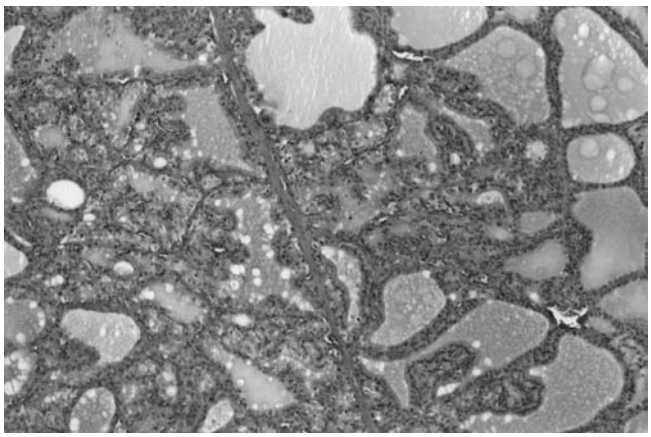

FIGURE 35.6 Pathology of Graves' disease showing columnar and folded thyroid epithelium, small new follicles, and active colloid resorption, with "scalloping" of the colloid. A lymphocytic infiltrate is not prominent in this specimen. (Original magnification: ×100.) See color plate section. Courtesy of Dr Judith Channer, Northern General Hospital, Sheffield.

generation TBII assays have a remarkable sensitivity and specificity when the clinical setting is taken into account (Costagliola et al., 1999). Monoclonal antibodies derived from animals have demonstrated the existence of a third group of neutral TSH-R antibodies, that recognize linear epitopes within the cleaved region of the receptor and neither stimulate nor block the receptor (Ando et al., 2004).

The majority of TSH-R B-cell epitopes appear to be conformational (Ludgate and Vassart, 1995). Heterogeneity between patients in their antibody-binding sites is apparent using chimeric TSH/LH hormone receptors, and mutated receptors have revealed that TSH-R blocking antibodies bind to the C terminus preferentially and recognize the holoreceptor more efficiently than TSAb, thereby having their inhibitory affect on TSH binding (Schwarz-Lauer et al., 2002). Further epitope mapping should be possible when panels of human monoclonal TSH-R antibodies are further developed (Sanders et al., 2003). A recent example of this approach has been the comparative modeling of the TSH-R interaction with a monoclonal TSAb, which indicates the possible importance of the leucine-rich repeat region of the receptor in activation by antibody (Miguel et al., 2004).

Unlike TG and TPO autoantibodies, TSAb are IgG_1 subclass restricted (Weetman et al., 1990) and are often λ-light chain restricted (Zakarija, 1983; Williams et al., 1988), suggesting a pauciclonal origin for TSAb in some patients. There is, however, heterogeneity in the activity of TSAb. Cluster analysis has grouped TSAb into four subsets based on the relative activity of their TSH-R antibodies in stimulating cAMP production and the phospholipase A_2–arachidonic acid cascade (Di Cerbo et al., 1995). Antibodies activating both pathways were found in patients with the most severe disease and largest goiters. In contrast, patients who produce both TSH-R blocking antibodies and TSAb can remain euthyroid.

T-Cell Responses

Many studies have found a reduction in circulating $CD8^+$ T cells and an increase in HLA-DR^+ T cells in active Graves' disease (Weetman and McGregor, 1994). Intrathyroidal T cells are $CD4^+$ and $CD8^+$ in varying proportions (Jansson et al., 1984). Similar homing mechanisms to AT account for this localization (Marazuela, 1999). Using overlapping TSH-R peptides covering the extracellular domain, a heterogeneous response was obtained using circulating or intrathyroidal T cells in proliferation assays, with multiple peptides stimulating different patients' cells (Tandon et al., 1992). IL-4 is not always detectable in Graves' thyroids and there is no distinct Th1 or Th2 pattern of response (Watson et al., 1994; Okumura et al.,1999). IL-1, IL-6, IL-8, and IL-10 are strongly expressed, the first two being in part derived from the TFC themselves.

Genetic Features

Monozygotic twins are around 20–30% concordant for Graves' disease, at least 10-fold higher than for dizygotic twins (Brix et al., 1998). A consistent but weak association exists between the serologically defined specificity HLA-DR3 and Graves' disease in white people, with a relative risk of around 2–3 (Tomer and Davies, 2003). The relative weakness of the contribution of HLA genes is underlined by the low concordance (7%) for Graves' disease in HLA-identical siblings (Stenszky et al., 1985). Polymorphisms in two genes expressed in T cells confer a relative risk of around 2: CTLA-4 (Yanagawa et al., 1995; Ueda et al., 2003) and PTPN22 (Velaga et al., 2004), in common with several other autoimmune disorders (see Chapter 21). As with AT, a number of polymorphisms in non-MHC candidate genes (encoding T-cell receptors, immunoglobulins, cytokines, and TSH-R) have been tested for associations with Graves' disease, with inconsistent results. The most recent candidate genes to be associated with Graves' disease are those encoding ICAM-1 and CD40 but it remains to be seen whether these will hold up after replication (Kim et al., 2003; Kretowski et al., 2003). Genome scanning methods have revealed other possible loci linked to Graves' disease (Tomer and Davies, 2003) but these have not yet been confirmed.

Environmental Influences

Women are predisposed to Graves' disease with an additional risk of developing the disease in the postpartum period: two-thirds of women with Graves' disease who had been pregnant noted the onset of their disease post partum (Jansson et al., 1987). Retrospective studies have shown a significantly higher number of adverse, major life events during the year preceding the recognition of Graves' disease when patients are compared to matched controls (Winsa et al., 1991; Matos-Santos et al., 2001). Presumably this effect of stress operates through the interactions between the nervous, endocrine, and immune systems. A high iodine intake increases the risk of developing an autoimmune response against the thyroid, the type being determined by genetic factors. For instance, within Europe the prevalence of Graves' disease increases with national iodine intake (Reinwein et al., 1986).

Evidence for a role of infections is circumstantial (Tomer and Davies, 1993). It remains possible that a variety of infections could precipitate Graves' disease, either specifically, by molecular mimicry or modulation of TFC behavior, or nonspecifically, by enhancing any ongoing immune responses. Such nonspecific enhancement, presumably mediated by cytokines, would explain the association between attacks of allergic rhinitis and recurrence of Graves' disease (Hidaka et al., 1993).

Smoking is strongly associated with the development of ophthalmopathy and weakly with the development of Graves' disease (Bartalena et al., 1995). Perhaps the most striking example of Graves' disease caused by an obvious external agent is its appearance several months after administration of a lymphocyte-depleting monoclonal antibody in a third of patients with multiple sclerosis (Coles et al., 1999). This type of response may be the result of Th2 deviation or alteration of T regulatory cells as the lymphocyte population is recovering, and such a phenomenon may underlie the similar appearance of Graves' disease occasionally after immune restoration of AIDS patients with highly active antiretroviral therapy (Gilquin et al., 1998).

Animal Models

There is still no entirely satisfactory animal model of Graves' disease. Immunization of BALB/c mice with the extracellular domain of TSH-R and adjuvant containing *Bordetella pertussis* induced TSH-R blocking but not stimulating antibodies and a severe thyroiditis (Costagliola et al., 1994), while genetic immunization with TSH-R cDNA produced thyroiditis but without TSAb production (Costagliola et al., 1998). Immunizing AKR/N mice with fibroblasts double transfected with human TSH-R and haploidentical MHC class II genes led to hyperthyroidism caused by TSAb, although without thyroiditis (Yamaguchi et al., 1997). The model appears to be successful because the murine fibroblasts used express the costimulatory molecule CD80 (B7), allowing them to stimulate naïve TSH-R specific T cells. A recent variant of this model has used the hamster and CHO cells expressing TSH-R, resulting in TSAb production and a focal thyroiditis (Ando et al., 2003).

Reproducing ophthalmopathy has proved even more challenging. Priming of T cells, derived from donor mice immunized with TSH-R, with TSH-R *in vitro* followed by transfer to naïve recipients elicited orbital changes that resemble ophthalmopathy pathologically, but there has been no replication as yet (Many et al., 1999).

Pathogenic Mechanisms

Clearly the main effector mechanism in Graves' disease is the production of TSAb but the circulating levels of these do not correlate closely with the level of thyroid hormones or the clinical severity of disease, because of a variable, concurrent response against other autoantigens and, in some patients, production of TSH-R blocking antibodies, which reduce the effects of TSAb. Women with the highest levels of TSAb who become pregnant give birth to babies with transient neonatal thyrotoxicosis.

Immunologic Markers in Diagnosis

TG and TPO antibodies provide readily available evidence for Graves' disease; although not specific, their presence in a patient with hyperthyroidism strongly suggests the diagnosis. TSAb are not generally measured because present bioassays are laborious. TBII estimation is a commercially available surrogate but these antibodies are absent in some newly diagnosed patients and present in AT patients who have TSH-R blocking antibodies. TSAb or TBII levels have been investigated as predictive markers for the success of antithyroid drug treatment in Graves' disease. Although patients with the highest levels tend to relapse the most, the results are insufficiently accurate for clinical use (Davies et al., 1998). The most important indication for TSAb assay in Graves' disease is during pregnancy to predict the risk of neonatal thyrotoxicosis (Laurberg et al., 1998).

Treatment and Outcome

Treatment consists of antithyroid drugs (carbimazole, methimazole or propylthiouracil), radio-iodine or thyroidectomy. Around 40% of patients treated with antithyroid drugs achieve a permanent remission. These drugs ameliorate EAT (Rennie et al., 1983) and TSAb levels fall during treatment due to a decrease in the expression of proinflammatory molecules by TFC (Weetman et al., 1992). Relapse after antithyroid drugs is particularly likely in those patients with evidence of a strong Th2 response (Komiya et al., 2001). Radio-iodine treatment is followed by a striking rise in TSH-R and other thyroid autoantibodies at 3–6 months. TSH-R antibody levels gradually fall in most but not all patients over the year following subtotal thyroidectomy (De Bruin et al., 1988). Complete ablation of thyroid tissue results in disappearance of all thyroid autoantibodies, confirming the need for these autoantigens to maintain antibody production (Chiovato et al., 2003).

Thyroid-Associated Ophthalmopathy and Dermopathy

These complications of Graves' disease are most likely due to an autoimmune response which stimulates fibroblasts localized within the extraocular muscle or dermis, causing glycosaminoglycan release and edema (Ludgate and Baker, 2002; Smith, 2005). Supporting this, the extraocular muscles and dermis are infiltrated by activated T cells and local cytokine production (IFN-γ, IL-1, and TNF) can be demonstrated; these cytokines stimulate glycosaminoglycan synthesis by fibroblasts *in vitro* (Figures 35.7 and 35.8). Orbital antibodies have been repeatedly sought in TAO with no consensus and the nature of the T-cell autoantigen is unknown although the TSH-R is a strong candidate. Treatment of TAO usually consists of supportive measures or corticosteroids

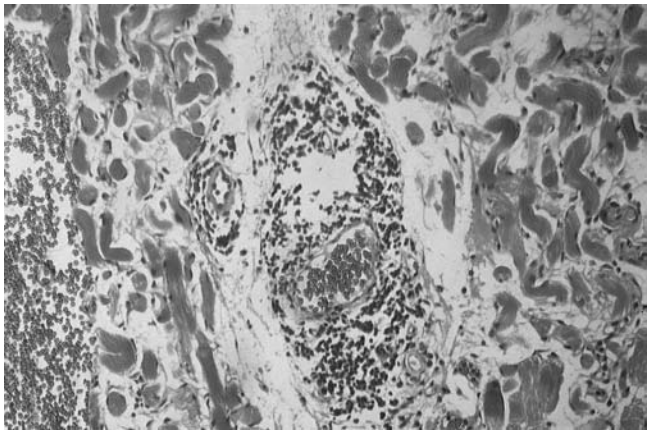

FIGURE 35.7 Photomicrograph of an extraocular muscle from a patient with thyroid-associated ophthalmopathy. There is an extensive lymphocytic infiltrate and edema; the muscle fibers are intact. (Original magnification: ×200.) See color plate section.

and in many the condition spontaneously becomes stable or regresses (Bartalena et al., 2000).

CONCLUDING REMARKS—FUTURE PROSPECTS

Graves' disease shares many features with AT and what determines the type of disorder is a critical issue. So far genetic susceptibility factors have proven nonspecific but more detailed analysis may reveal specific genotypes for Graves' disease. Future studies will clarify the relative importance of stress, iodine intake, infection, and hormonal alterations. It will be particularly important to study mechanisms at the earliest possible stage of disease so that an initiating rather than an enhancing role for these factors can be assessed. Experiments of nature, such as the appearance of Graves' disease after immunologic treatments, may provide fresh insights into regulatory mechanisms and the early phase of disease.

The development of a robust animal model with which the initiation and progression of disease can be analyzed would be a major step forward. Such a model would be especially welcome if TAO also occurred simultaneously and would help clarify the role of TSH-R as an autoantigen in TAO. Our current therapies for Graves' disease are not ideal, with many patients having recurrences or exchanging hyperthyroidism for permanent hypothyroidism. Immunologically directed treatment offers considerable potential advantages, but will need to be specific and innocuous. Such a strategy is even more appealing in TAO for which current treatment is unsatisfactory.

Type 1 Diabetes

JEAN-FRANÇOIS BACH

Immunologie Clinique Hôpital Necker, France

It was only in the 1950s that a clear distinction was made between insulin-dependent diabetes mellitus (IDDM), now called type 1 diabetes (T1D), and non-insulin dependent diabetes mellitus (NIDDM), now called type 2 diabetes (T2D).

The major discovery of the autoimmune origin of T1D was derived in large part from the availability of two spontaneous animal models of the disease, the nonobese diabetic (NOD) mouse and the Bio-Breeding (BB) rat.

In the years which have followed these major milestones, a considerable number of immunologic, genetic, and clinical studies have been performed which allow us to provide a comprehensive description of disease pathogenesis and to a lesser extent its etiology. This knowledge is central for the understanding of the natural history of the disease. It is also crucial to devise immune-based strategies which could substitute immunotherapy for the presently used palliative insulin therapy with its limitations.

The aim of this chapter is to review the main questions mentioned above, without going into the details of each aspect which can be found in more extensive or more specialized texts (Bach, 1994; Yang and Santamaria, 2003).

CLINICAL SPECTRUM AND EPIDEMIOLOGY

Disease Presentation

In most cases, T1D appears suddenly in previously apparently healthy individuals. The first clinical manifestations include polyuria, polydipsia and, if the disease is not recognized early on, weight loss. In some patients, in the absence of insulin therapy, ketosis appears with nausea, vomiting, and dehydration, rapidly leading to coma. When insulin

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

treatment is initiated, all these symptoms rapidly disappear. They may reappear, though, in the case of insufficient insulin dosage. Excessive dosage leads to hypoglycemia with sweating, malaise, and eventually coma. Once insulin dependency appears, it is usually definitive, even if in a few cases it may regress or disappear for a few months ("honeymoon"). This clinical remission is explained by the β cell rest afforded by intensive insulin therapy (Shah et al., 1989).

After a few years of disease, degenerative complications may appear with a risk directly related to the quality of metabolic control which in turn depends on the rigor of insulin therapy. Aggressive insulin therapy to the limit of hypoglycemia has been clearly shown to reduce the incidence and the severity of degenerative complications (DCCT, 1993). These complications include nephropathy leading to renal failure, retinopathy with possible blindness, neuropathy, and trophic complications (gangrene) which may be sufficiently severe to require amputation. Diabetic patients are also exposed to an increased risk of atherosclerosis-linked complications, heart involvement, and vascular cerebral accidents.

T1D may develop more progressively, preceded by a long phase of diabetes initially classified as T2D. This presentation, named latent autoimmune diabetes of the adult (LADA), is most likely a slowly progressing form of T1D (Pozzilli and Di Mario, 2001). It usually affects adults who present with T2D without excess body weight and who have a family history of T2D. The disease can be recognized by the presence of β cell-specific autoantibodies (Falorni and Calcinaro, 2002). LADA often, although not always, converts to T1D, justifying early insulin treatment when needed (Turner et al., 1997), and perhaps immunotherapy when the strategy becomes available. T1D includes a strong hereditary component. As we shall see, genetic inheritance is usually polygenic. There are exceptions to this rule which include a set of familial (highly hereditary) forms of the disease linked to a single mutation (APECED and IPEX) or to a limited number of predisposing genes.

APECED (Autoimmune Polyendocrinopathy, Candidiasis, Ectodermal Dysplasia) is a rare sex-linked hereditary syndrome including T1D, thyroiditis, parathyroiditis, and mucocutaneous candidiasis. The disease is due to a mutation in a gene coding for a transcription factor called AIRE (Halonen et al., 2004; Peterson et al., 2004) (see Chapter 38). IPEX is a severe autoimmune syndrome associating severe enterocolitis, T1D, and thyroiditis. It affects infants and is lethal without immunosuppressive treatment or bone marrow transplantation, essentially due to the severity of enterocolitis. The disease has recently been associated with a mutation in a gene coding for a transcription factor called FoxP3 involved in the differentiation of $CD4^+$ $CD25^+$ regulatory T cells (Bennett et al., 2001). There is an animal model of this syndrome, the scurfy mouse, with the mutation on the same gene (Wildin et al., 2001) (see Chapter 26). A familial form of T1D has been observed in Bedouins (Verge et al., 1998). Finally, there are the rare forms of T1D that are resistant to insulin therapy and are linked to autoantibodies specific to the insulin receptor (Flier et al., 1975).

Prediabetes

The onset of T1D is preceded by several years of a prediabetic phase where islet-specific autoimmunity has already developed but with insufficient intensity to destroy islet β-cells to a degree which would generate clinically detectable insulin dependency (Gottlieb and Eisenbarth, 1998). There is still debate about the percentage of persistent β cells at the time of clinical onset, a crucial issue when discussing immunotherapy in recently diagnosed diabetes. The autoimmunity-associated prediabetic phase can be defined in animal models by histopathology. In man, this definition relies on the detection of β cell-specific autoantibodies, a definition which is not really satisfactory since such autoantibodies are probably not directly pathogenic, at variance with T cells. Importantly, there is a short period of time during the few months preceding clinical onset when metabolic dysfunction can be detected by decreased C-peptide levels following glucose infusion.

Epidemiology

T1D most commonly starts during childhood but may appear in adulthood in a significant proportion (30–40%) of cases (Karvonen et al., 2001) and even more if one includes LADA. There is an equal sex frequency, except in cases associated with extrapancreatic autoimmunity (Umpierrez et al., 2003) in which females predominate.

The incidence and prevalence of T1D vary according to country. It is increasing in every country with more of a tendency toward earlier onset than in the past, and now the disease affects significant numbers of very young children (Gale, 2002). In the US, T1D patients are probably more than 10^6 and even more again if one includes LADA, the frequency of which is ill defined.

THE AUTOIMMUNE ORIGIN OF TYPE 1 DIABETES

The first suggestions of an autoimmune origin for T1D arose in the 1960s from the clustering of diabetes with other diseases of known autoimmune origin, notably thyroiditis, but the definitive evidence was the discovery of islet β-cell autoantibodies (ICA) by Bottazzo and Doniach (Bottazzo et al., 1974). Sera from T1D patients were shown by indirect immunofluorescence to bind to islets on sections of human

pancreas. Ultimately, several β-cell autoantigens were chemically characterized, notably insulin (Srikanta et al., 1986), glutamic acid decarboxylase (GAD) (Baekkeskov et al., 1990), and IA-2, a tyrosine phosphatase-like molecule (Lan et al., 1996). The presence of islet-specific antibodies in T1D is not constant, even at the onset of overt diabetes, but more than 90% of patients are positive by the ICA assay or one of the assays using chemically defined antigens. Normal sera are usually negative, though a very small percentage (<1%) may show low levels of antibodies.

Intensive research for islet-specific T cells has not provided clear-cut results. There have been multiple reports of islet antigen-induced proliferation of lymphocytes from T1D patients (Scheinin, 1988; Atkinson et al., 1992; Durinovic-Bello et al., 1996). Initially these reports proved difficult to reproduce and the results of international workshops attempting to demonstrate islet-specific T-cell reactivity were disappointing (Roep et al., 1999; Schloot et al., 2003), although the latest workshops have been more encouraging. Insulin- or GAD-specific T-cell lines and T-cell clones have been derived from peripheral blood lymphocytes (PBL) of T1D patients, but not more efficiently than from PBL of normal subjects (Endl et al., 1997; Bach et al., 1997). Interest in this central topic has been recently renewed by studies using HLA DR4 eluted peptides (Peakman et al., 1999) and from the usage of GAD-specific class II tetramers (Liu et al., 2000; Reijonen et al., 2002). In these two systems, a low number of GAD-reactive T cells could be shown after T-cell *in vitro* activation in conditions in which healthy controls remained negative.

More convincing are the limited data demonstrating the major T-cell infiltration of pancreata from recently diagnosed T1D patients (Bottazzo et al., 1985; Imagawa et al., 2001).

Collectively, these data provide good evidence for islet-specific autoimmunity in T1D patients. They do not demonstrate, however, the causal relationship between this autoimmunity and disease pathogenesis. This is inferential and is based on the following evidence:

- the inhibition of disease progression after T-cell blockade as achieved with cyclosporin-A (Feutren et al., 1986; CERCTG, 1988), or an anti-CD3 antibody (Herold et al., 2002);
- T1D association with well-defined HLA alleles, best explained by the presentation of selected autoantigenic peptides to T cells by T1D-predisposing HLA molecules (Nerup et al., 1974);
- the autoimmune origin of T1D in NOD mice and BB rats (see next section), assuming that the T1D observed in these two animal models does have a pathogenesis identical or close to that of human T1D.

The capacity to transfer the disease by administration of T cells from diabetic animals to healthy syngeneic recipients is highly convincing (Bendelac et al., 1987) as well as disease prevention by a number of T-cell-specific interventions (Like et al., 1979; Chatenoud et al., 1994). Disease transfer has been obtained with CD4 (Haskins and McDuffie, 1990) and CD8 (Wong et al., 1996) T-cell clones after infusion in immunoincompetent NOD recipients.

However, it has not proven possible to meet all the criteria for an autoimmune disease proposed by Rose and Bona (1993). Surprisingly, there has been no success with diabetes induction by immunization with islet extracts or chemically defined β cell antigens, except for the induction of severe insulitis without diabetes after immunization with an insulin peptide concomitant with administration of PolyIC (Moriyama et al., 2002). Tolerance induction to some beta cell antigens induces disease protection (Kaufman et al., 1993; Tisch et al., 1993; Muir et al., 1995) but to a large extent through a nonspecific bystander suppressive effect (Zhang et al., 1991).

A DIVERSITY OF ANIMAL MODELS

Spontaneous Models

The nonobese diabetic (NOD) mouse was first proposed as an animal model of T1D by Japanese investigators (Makino et al., 1980). The NOD mouse develops insulitis starting at 3 weeks of age. Overt diabetes appears at 4–6 months of age. The disease is consistently more common in females than in males. Its incidence varies dramatically in both genders according to the sanitary conditions of the animal facility. NOD mice show other clinical and biologic manifestations of autoimmunity, including thyroiditis (at a late age), sialadenitis, and mild colitis (Bach, 1994; Bach and Mathis, 1997). NOD mice may also produce antinuclear antibodies (Baxter et al., 1994) and anti-erythrocyte antibodies (Baxter and Mandel, 1991).

Bio-Breeding (BB) rats were initially discovered as a model of T1D in Canada (Nakhooda et al., 1977). These rats develop diabetes in a high percentage of cases at variance with genetically close but distinct (BB-R rat) strains that are diabetes resistant (Crisa et al., 1992). The main immunologic feature of BB rats is lymphopenia (Poussier et al., 1982) that depends on a single gene (Hornum et al., 1995). Like NOD mice, BB rats also develop thyroiditis at a high incidence.

Thymectomy-Induced Diabetes

In the rat, thymectomy followed by sublethal irradiation induces diabetes onset in some strains but not in others in which, however, thyroiditis is observed (Fowell and Mason, 1993). In BALB/c mice, thymectomy at 3 days of age, which induces selective depletion of $CD4^+CD25^+$ T cells, induces

insulitis in the context of a polyautoimmune syndrome, but diabetes is rarely observed (Asano et al., 1996). These effects of thymectomy are reminiscent of the acceleration of diabetes onset noted in NOD mice when thymectomy is performed at weaning (3 weeks of age) (Dardenne et al., 1989) and of diabetes induction in the BB-R rat after adult thymectomy and irradiation (Ramanathan et al., 2002).

The Low-Dose Streptozotocin Model

High doses of the alkylating agent streptozotocin (STZ), which is a selective toxin for β cells, produces irreversible T1D secondary to β-cell apoptosis, whereas multiple low doses of STZ insufficient to destroy enough β cells to directly cause T1D induce an autoimmune-related insulitis and T1D (Paik et al., 1980). Low-dose STZ T1D is inhibited by anti-T-cell antibodies (Herold et al., 1987) and can be transferred into normal animals by T cells from STZ-treated mice (Buschard and Rygaard, 1978). The mechanisms of disease induction by low-dose STZ are not clear, but probably involve enhancement of β-cell antigen presentation secondary to limited β-cell destruction and perhaps aberrant expression of MHC or costimulatory molecules under the local STZ effect (Campbell et al., 1988). The model is complicated by the overlap between STZ doses leading to toxic or autoimmune diabetes. Doses that induce autoimmune type T1D in some strains may induce diabetes in NOD SCID mice which are deprived of T cells (Gerling et al., 1994), an observation possibly related to the unique and intriguing sensitivity of NOD mouse β-cells to STZ-induced apoptosis (Orlow et al., 1987; Gonzalez et al., 2002).

TCR Transgenic Models

$CD4^+$ and $CD8^+$ diabetogenic T-cell clones can be derived from the islets of NOD mice. The TCR genes of such clones were used to generate TCR transgenic mice. The first reported model, the BDC2.5 mouse, used a TCR derived from a $CD4^+$ T-cell clone shown to be diabetogenic by transfer into young or SCID NOD mice. In the initial report, transgenic mice (backcross 6) showed accelerated onset of diabetes when compared to nontransgenic littermates (Katz et al., 1993). Ultimately, after backcross 12, transgenic mice never became diabetic (You et al., 2004). Fulminant diabetes could be induced, however, in such mice by backcrossing to $RAG^{-/-}$, SCID or TCR $Ca^{-/-}$ mice which cannot generate their own TCR gene rearrangements (Kurrer et al., 1997; You et al., 2004) (see page 489). Similar data were obtained in transgenic mice expressing a TCR derived from $CD8^+$ T-cell clones (Amrani et al., 2000). In both systems, it is important to realize that the antigenic specificity of the T-cell clones was not known. Synthetic peptide mimetopes were obtained. More recently, GAD-specific TCR transgenic mice were produced which, intriguingly, did not develop diabetes even when they were backcrossed to NOD mice (Tarbell et al., 2002).

RIP Transgenic Models

When transgenes are coupled to the rat insulin promoter (RIP), the product of the transgene is selectively expressed in the β cells where insulin is produced. Several models of experimental diabetes have been developed in transgenic mice expressing various antigens in β cells. The first model was described by Hanahan wherein the SV40T antigen was expressed in β cells under conditions in which mice were not tolerant and mounted an SV40T-specific T-cell response leading to severe insulitis (Adams et al., 1987).

Numerous studies have been performed with lymphochoriomeningitis virus (LCMV) in which LCMV proteins (glycoprotein, GP, or nuclear protein, NP) were selectively expressed in β cells (see Chapter 26). Expression of these viral antigens alone was insufficient to induce diabetes since the mice were tolerant to LCMV antigens, treating these as bona fide autoantigens. Double transgenic mice were obtained when RIP-LCMV mice were crossed to mice expressing a TCR specific to the LCMV β cell antigen. In both the single and the double RIP-LCMV transgenic mice, diabetes consistently appeared only when the animals were infected with LCMV which induces a major activation of LCMV-specific T cells (Ohashi et al., 1991; Von Herrath et al., 1997; Von Herrath, 2002). Similarly double transgenic mice have been produced that selectively express influenza virus hemagglutinin in β cells (RIP-HA) but, at variance with the LCMV model, RIP-HA × HA-TCR transgenic mice did develop diabetes in some cases, but not in others (Scott et al., 1994).

Other RIP transgenic models of diabetes have been described using RIP-driven β cell-specific expression of the T-cell costimulatory molecule CD80 (B7) (Wong et al., 1995), singly or in association with transgenic expression of the T1D-associated HLA allele HLA DR4 (Wen et al., 2001).

Conclusions

The wide diversity of animal models of T1D represents a major aid in the dissection of T1D mechanisms. The spontaneous models, the BB rat and especially the NOD mouse represent by far the closest models to human T1D, although others may be very interesting insofar as they simplify the analysis of ongoing autoimmune responses. There is debate on the significance of comparing NOD mice to human T1D. One major concern is the large number of treatments that prevent disease in NOD mice (see pages 494 and 495), as compared to the very few treatments that are effective at the

time of disease onset (Bach, 2002a). Other more minor concerns include the female predominance in NOD mice, which is not observed in humans, and the production of islet cell-specific antibodies which is much lower in animal models than in humans. In any event, NOD mice and BB rats, as well as the other models described above, represent multiple copies of just a single individual, whereas human T1D is a heterogeneous disease among affected individuals. One may assume that most patients share common disease mechanisms which are operative in NOD mice. A major difference contributing to the interest of these models is that NOD mice and BB rats can be monitored during their whole lifespan, whereas patients are usually only seen at the time of overt T1D.

IMMUNOPATHOGENESIS

The Nature of the Effector Mechanisms

Data supporting a role for β cell-specific autoantibodies in the pathogenesis of T1D are weak, if not lacking. Disease cannot be transferred to healthy recipients by antibody-positive immunoglobulins. Suggestive, albeit indirect data indicate that offspring of antibody-positive diabetic NOD females present diabetes more rapidly than do offspring of nondiabetic antibody-negative mothers (Greeley et al., 2002). However, data from humans are not in accord with this. Additionally, T cells from NOD mice can transfer diabetes to NOD mice that have been rendered unable to produce antibodies by postnatal anti-μ treatment (Bendelac et al., 1988). However, there is a possible role for B cells in disease pathogenesis as indicated by the absence of diabetes in B cell-less NOD mice. B cells could act in this setting ($Ig^{-/-}$) (Serreze et al., 1998) as antigen-presenting cells for β-cell antigens.

Referring to T cells in T1D, the T-cell infiltration of the pancreas in human and murine autoimmune diabetes, as well as the arrest of disease progression by selective T-cell blockade, is persuasive. Finally, for mice at least, the disease can be transferred into healthy nondiabetic syngeneic NOD recipients by pure populations of T cells or T-cell clones (Bendelac et al., 1987; Haskins and McDuffie, 1990; Wong et al., 1996).

The respective roles of $CD4^+$ and $CD8^+$ T cells in diabetes pathogenesis have long been debated. The observation that $CD4^+$ T-cell clones could transfer the disease alone in the absence of $CD8^+$ T cells, these having been depleted by anti-CD8 antibody treatment (Bradley et al., 1992), suggested that the disease was mediated entirely by CD4 T cells. However, $CD8^+$ T-cell clones alone can also transfer T1D (Wong et al., 1996) and, when polyclonal T cells are used, both $CD4^+$ and $CD8^+$ T cells are necessary to obtain transfer of diabetes (Bendelac et al., 1987), even though insulitis can be obtained with $CD4^+$ T cells alone (Thivolet et al., 1991).

Among $CD4^+$ T cells, the major contribution is from Th1 cells. The progression of diabetes is associated with increased intra-islet expression of IFN-γ (Rabinovitch et al., 1995), and anti-IFN-γ neutralizing antibodies prevent disease progression (Debray-Sachs et al., 1991). IFN-$\gamma^{-/-}$ and IFN-γ $R^{-/-}$ NOD mice still develop diabetes (Serreze et al., 2000), but gene redundancy cannot be excluded. Additionally, converging evidence shows a central role for IL-12, the major Th1-cell differentiation factor, in driving T1D in NOD mice. The disease is accelerated by IL-12 administration (Trembleau et al., 1995). Th2 cytokine expression is not enhanced at the time of diabetes onset and such cytokines inhibit disease onset when administered in young NOD mice (Rapoport et al., 1993; Pennline et al., 1994). Note lastly that anti-insulin and anti-GAD antibodies show a Th1-dependent IgG2a isotype.

Enumeration of diabetogenic $CD8^+$ T cells in NOD mice has been made possible by use of MHC class I tetramers. Numbers of $CD8^+$ T cells with high avidity for the target antigens increase with time during progression of insulitis, peaking at the time of diabetes onset (Amrani et al., 2000). The availability of tetramers has also shown the prevalence of $CD8^+$ T cells specific for limited number of islet-cell antigens, particularly insulin and IGRP (see page 488).

β-Cell Antigens Drive the Diabetogenic T-Cell Response

Indirect evidence suggests that β cells are important for stimulating islet-specific autoantibody production in T1D. Thus patients with long-standing T1D who are likely to have lost all their islet cells show a clear decrease in levels of islet-specific antibody production (Maugendre et al., 1999). Importantly, these autoantibodies reappear after pancreas transplantation (Bosi et al., 2001). Also, as mentioned, the HLA–T1D association further supports the "driving role" for β-cell autoantigens, as does the restriction of TCR heterogeneity in young NOD mice (Shizuru et al., 1991; Baker et al., 2002), a finding which, however, could not be confirmed in adult NOD mice (Sarukhan et al., 1995). In a more direct approach using NOD mice, we have shown that diabetogenic T-cell clones, which normally expand in irradiated recipients, are exhausted and progressively disappear after being "parked" in β-cell-depleted irradiated mice; that is, mice whose β cells had been destroyed by alloxan, a selective β-cell toxin (Larger et al., 1995).

Particular attention has been directed to the initial cellular events developing locally in the pancreas, or its vicinity, in the first weeks of life in NOD mice and, notably, the wave of β-cell apoptosis observed at 2–3 weeks of age just before onset of insulitis (Trudeau et al., 2000). It has been proposed

that $CD8^+$ T cells have a disease-triggering effect in inducing the initial β-cell lesion with B cells as antigen-presenting cells. The initial inductive cellular events do not take place in the islet itself, at least for the most part, but in peripancreatic lymph nodes which show intensive T-cell proliferation. (Hoglund et al., 1999).

If β-cell antigens do trigger the diabetogenic response, the nature of the responsible β-cell autoantigen is a central question. Several antigens expressed in β cells elicit B- and T-cell reactivity either in NOD mice and/or in man: insulin, GAD (Baekkeskov et al., 1990), and IA-2 (Lan et al., 1996), a tyrosine phosphatase-like molecule identified on the basis of its selective expression by β cells. Insulin and GAD can induce disease protection provided they are administered to young (prediabetic) NOD mice (Zhang et al., 1991; Kaufman et al., 1993; Tisch et al., 1993; Daniel and Wegmann, 1996). A specific role has been proposed for proinsulin in man (Narendran et al., 2003) and preproinsulin 1 in NOD mice. Mice genetically deficient in this protein are protected from diabetes, whereas mice genetically deficient in preproinsulin 2 show accelerated disease onset (Moriyama et al., 2003). A novel and likely important β-cell candidate (T-cell) autoantigen is islet-specific glucose-6-phosphatase catalytic subunit related protein (IGRP), recently described as the target molecule of the majority of $CD8^+$ diabetogenic T cells in NOD mice (Martin et al., 2001; Lieberman et al., 2003). Yet the problem remains that no decisive priority can be given to any of these autoantigens in contributing to disease induction, and the respective autoantibodies do not appear in the same sequential order in all patients with T1D.

Two explanations can be proposed for these intriguing findings. First, autoimmunization extends from one to another specificity by antigen (epitope) spreading. Thus, a primary antigen induces the differentiation of diabetogenic T-cell clones which induce a β-cell lesion and which, ultimately, lead to the recruitment of autoreactive T cells with other β-cell-associated specificities.

Second, the initial triggering event is not related to any particular autoantigen but could be essentially nonspecific, meaning that a pancreatic viral infection could increase the expression and "availability" of the various molecules necessary for antigen recognition by T cells, i.e., class I and class II MHC molecules, costimulatory molecules, adhesion molecules, and others.

In any event, there are no data as yet to incriminate a primary β-cell autoantigen in T1D even though the HLA–T1D association in humans would suggest that such an autoantigen must exist. Box 36.1 presents a partial list of the many candidate autoantigens which have been proposed in human or murine T1D, and Table 36.1 gives the main features of the four best-characterized of these.

Thus, T1D is marked by a selective breakdown of self-tolerance to β-cell antigens. As already discussed, however, there is no clear predominance of autoreactivity against a well-defined autoantigen. If any one were to be selected at present, it would be insulin. However, all in all, T1D appears as the result of the widespread rupture of the state of tolerance that normally exists to β-cell autoantigens, without excluding that the initial breakdown of tolerance takes place against a primary autoantigen which then extends through

Box 36.1 A nonexhaustive list of T1D candidate autoantigens

1. Insulin (proinsulin)
2. Glutamic acid decarboxylase (GAD) (GAD65/GAD67)
3. IA-2/ICA512/phogrin
4. Hsp 65/p277
5. Islet-specific glucose 6 phosphatase catalytic subunit related protein (IGRP) (T cells)
6. GLIMA (38 kDa)

TABLE 36.1 Requirements for candidate β-cell autoantigens

	Insulin	GAD	IA-2	IGRP

antigen spreading (Vanderlugt and Miller, 2002) to other β-cell autoantigens.

Rupture of Self-Tolerance to β Cells

The concomitant presence in NOD mice of a β-cell autoantigen and of T cells expressing the relevant specific TCR is not sufficient to trigger diabetes onset. This important statement is supported (as mentioned above) by the presence of β-cell-specific autoreactive T cells in healthy human subjects (Endl et al., 1997; Bach et al., 1997; Peakman et al., 1999) and by the absence of diabetes in double transgenic RIP-LCMV mice, until they are infected by LCMV (Ohashi et al., 1991). Two factors appear to be determinant for the triggering event. First, activation of β-cell-specific T cells, so bypassing the state of ignorance described above, and second, permissiveness of regulatory mechanisms which normally prevent the development of pathogenic autoimmunity.

In healthy subjects, humans and mice, tolerance to self-antigens normally involves initially the intrathymic destruction (negative selection) of T cells with high-affinity receptors for self-peptides present in the thymus, followed by mechanisms of peripheral tolerance that regulate the autoreactive T cells which have escaped intrathymic negative selection. The question posed is the mechanisms by which tolerance to β-cell autoantigens is lost in T1D: defect in deletion, regulation, or both.

T-Cell Activation

The multiplicity of concomitant β-cell-specific immune responses discussed above indicates that the most likely mechanism leading to T-cell activation involves islet inflammation, for example by a pancreatotropic virus, yet no direct evidence has been obtained to formally incriminate any particular virus in human T1D (see pages 492 and 493) or in NOD mouse T1D. The increased expression of IFN-α observed in islets of recently diagnosed diabetic patients (Foulis et al., 1987) is suggestive of a viral mechanism. Other mechanisms of non-antigen-specific T-cell activation could be considered, such as superantigens, but no evidence supports this hypothesis except the unsubstantiated report of a selective expression of Vβ7, which could be interpreted as a result of the expansion of T cells interacting with a specific endogenous retrovirus.

Arguments for Defective Intrathymic Negative Selection

The derivation of insulin- and GAD-reactive T-cell lines from normal peripheral blood lymphocytes in diabetic patients but also in healthy subjects (Endl et al., 1997; Peakman et al., 1999) clearly indicates that thymic negative selection does not fully operate for β-cell-specific autoantigens, as also pertains to other autoantigens. It might be, however, that negative selection is less effective for such antigens in T1D than in normal subjects. This notion is supported by some observations made in the NOD mouse, showing that NOD mouse thymocytes have a lower rate of apoptosis than normal strains (Kishimoto and Sprent, 2001; Bergman et al., 2003). The defect affects both Fas-dependent and Fas-independent pathways of apoptosis. For Fas-dependent apoptosis, the defective apoptosis of NOD thymocytes correlated with the strong T-cell receptor-mediated upregulation of caspase8-homologous FLICE (Fas-associated death-domain-like interleukin I beta-converting enzyme) inhibitory protein (Kishimoto and Sprent, 2001). Additionally, use of an RIP double transgenic model as described above shows that non-MHC genes from the NOD strain promote a failure to delete high-avidity autoreactive T cells during their development in the thymus, with subsequent spontaneous breakdown of $CD4^+$ T-cell tolerance to the islet antigen and formation of intra-islet germinal centers (Lesage et al., 2002). A failure of thymic negative selection is indirectly supported by the finding that human subjects with autoimmune polyendocrine syndrome I (APECED) may present diabetes due to a mutation on the AIRE gene (Peterson et al., 2004); AIRE is demonstrated in the mouse to control the intensity of negative selection against certain antigens, and mRNA expression for some autoantigens is decreased in $AIRE^{-/-}$ mice (Anderson et al., 2002) (see Chapter 38).

Lastly, some of the β-cell candidate autoantigens (insulin or proinsulin, GAD, and IA2) are expressed in the thymus in a subset of medullary antigen-presenting cells, either as the total protein or as fragments due to alternative splicing, and the level of such expression is correlated with predisposition genes for T1D, notably the insulin promoter gene (Diez et al., 2001; Pugliese et al., 2001). Presumably, the higher the level of the thymic expression of these autoantigens, the more efficient would be the negative selection for the corresponding autoreactive T cells. Thus defective expression of β-cell autoantigens in the thymus might well contribute to the pathogenesis of T1D.

Failure of Regulatory T Cells

Diabetes onset is accelerated by various manipulations that deplete certain T-cell subsets, including thymectomy at 3 weeks (Dardenne et al., 1989), blockade of costimulatory pathways (Lenschow et al., 1996) or cyclophosphamide treatment (Yasunami and Bach, 1988). Similarly, the backcrossing to immunoincompetent mice ($RAG^{-/-}$, SCID, TCR $Ca^{-/-}$) of transgenic mice expressing a diabetogenic TCR dramatically increases rapidity and incidence of diabetes (Kurrer et al., 1997; You et al., 2004). This observation illustrates the role of T cells having undergone endogenous TCR

rearrangements in disease control probably through immunoregulation, since diabetes associated with their absence is prevented by infusion of $CD4^+CD62L^+$ regulatory T cells (You et al., 2004).

Direct evidence for control of T1D by regulatory T cells has been obtained by showing the ability of $CD4^+$ T cells from prediabetic NOD mice to protect from diabetes in a cotransfer model in which such T cells are administered to NOD/SCID or irradiated NOD recipients concurrently with diabetogenic T cells derived from the spleen of NOD diabetic mice (Boitard et al., 1989). These regulatory T cells include not only $CD25^+$ T cells but also $CD25^-CD62L^+$ T cells (Alyanakian et al., 2003) and that regulation depends on TGF-β but not on Th2 cytokines (Chatenoud, in preparation; Green et al., 2003). However, Th2 cytokines do appear important for tolerance induction and disease prevention after giving soluble β-cell autoantigens, since such tolerance is not obtained in IL-$4^{-/-}$ NOD mice (Tisch et al., 1999). The role of Th2 cytokines in the physiologic control of the spontaneous disease is unlikely, as indicated by the normal disease incidence observed in IL-$4^{-/-}$ (Wang et al., 1998) and IL-$10^{-/-}$ (Serreze et al., 2001) NOD mice. Even so, this is an argument to consider with caution, because of the occurrence of autoimmune diabetes in IFN-$\gamma^{-/-}$ and IFN-$\gamma R^{-/-}$ NOD mice (Serreze et al., 2000). Also, a role for NKT cells has been suggested in the control of T1D. The number and function of these cells are deficient in NOD mice (Gombert et al., 1996). Diabetes onset is accelerated in NKT-cell-deficient $CD1^{-/-}$ NOD mice (Wang et al., 2001) and is slowed down in wild-type NOD mice by α-galactosyl-ceramide, a selective NKT-cell ligand (Hong et al., 2001; Sharif et al., 2001). A defect in NKT-cell function has been described in human T1D (Wilson et al., 1998; Kukreja et al., 2002). At present, however, some uncertainties persist on whether the involvement of NKT cells in the pathogenesis of T1D is really significant.

β-Cell Lesion

As extensively discussed above, T1D is the consequence of damage to β cells by β-cell-specific T cells. A central question is to determine the fine mechanisms at the origin of the reduction of insulin production.

First, what are the respective roles of β cell destruction ("atrophy") versus functional (reversible) inhibition of insulin production by residual living β-cells, i.e., inflammation? The existence of inflammation can be assessed in the NOD mouse and to a lesser extent in human T1D by the rapid recovery of insulin production observed after T-cell targeted intervention. Recent-onset diabetic NOD mice recover normal glycemia within 24–48 h of administration of anti-TCR (Sempe et al., 1991) or anti-CD3 monoclonal antibodies (Chatenoud et al., 1994) in the absence of insulin therapy. The recovery of insulin production by β cells derived from recently diabetic NOD mice, after *in vitro* culture in the absence of aggressive T cells, also suggests the persistence of functional β cells at the time of diabetes onset (Strandell et al., 1990).

The questions remain, however, of the percentage of intact residual β cells at diabetes onset and what the kinetics of β-cell destruction in the months and years preceding T1D onset are. Is there a regularly progressing destruction with a superimposed inflammation or does disease progression suddenly accelerate just before diabetes onset? If so, what is the triggering mechanism at the origin of this burst of β-cell aggression? Morphometric data available in the NOD mouse (Sreenan et al., 1999), and to a lesser degree in human T1D (Hanafusa et al., 1990; Imagawa et al., 2001), are not very informative on this point, especially since the authors use insulin as a β-cell marker. Indeed, this may create a bias since living β cells subjected to inflammation may drastically reduce their level of insulin production. Particular attention should be given to noninvasive approaches to determine β-cell mass, such as those using β-cell-specific radiolabeled monoclonal antibodies (Moore et al., 2001). At the molecular level, considerable effort has been devoted to understanding the mechanisms of β-cell destruction. Several studies shed light on the events leading to β-cell apoptosis; some show the important role of nitric oxide and free radicals (Brenner et al., 1993) in addition to the *putative* mechanisms usually associated with $CD8^+$ T-cell mediated β-cell lysis, perforin or Fas mediated. The role of cytokines, notably IL-1, has been documented by *in vitro* studies using normal β cells (Mandrup-Poulsen, 2003) but it is difficult to determine what their role is *in vivo.*

Lastly, there is a growing interest in the role of chemokines and their receptors in the attraction of effector cells into the islet (Atkinson and Wilson, 2002), exemplified by the suggested role of CXCR3 and CCR4 in the initiation of insulitis in NOD mice (Kim et al., 2002; Frigerio et al., 2002).

ETIOLOGY

T1D is a multifactorial polygenic disease. It is the result of the interaction of predisposing genes with unfavorable environmental factors, probably both triggering and permissive. We shall successively discuss genetic and environmental factors in light of the knowledge gained from experimental models and human T1D.

Genetics of T1D

The Weight of Heredity

When one member of a pair of monozygotic twins develops T1D, the other twin will develop the disease in

approximately 35–50% of cases, and more often (up to 60%) if the twins are DR3/DR4 heterozygotes (Bach, 1994; Ide and Eisenbarth, 2003). This high concordance rate provides a quantification of the hereditary nature of the disease and the disease penetrance. The fact that in these conditions as many as 7% of non-twin siblings are concordant for the disease indicates in a first analysis the existence of a limited number of disease predisposition genes, the more so since half of the genetic predisposition is due to genes of the major histocompatibility complex (MHC). HLA identical siblings have a concordance rate of approximately 16%, nearly half the monozygotic twin concordance rate (Bach, 1994; Ide and Eisenbarth, 2003).

We note that about 5% of children from diabetic patients become diabetic with, interestingly (and so far unexplained), a higher risk when the diabetic parent is the father (Warram et al., 1984). Perhaps the immune system of the embryo is influenced by its interaction with the mother's islet-specific antibodies, whatever the mechanisms of the apparent protection conferred might be. This interpretation is in opposition to the hypothesis, proposed on the basis of indirect data, that there is a diabetes-promoting effect of maternal anti-islet antibodies in NOD mice (Greeley et al., 2002).

Role of MHC Genes

The association between HLA antigens and T1D was discovered in 1974 (Nerup et al., 1974) but it proved difficult to identify the actual loci of the predisposing genes due to major linkage disequilibrium within the MHC. Convergent data indicate that predisposing genes are located at the DQ locus, though there is no absolute certainty about the absence of effects conferred by other loci, especially since some data argue for a haplotype effect wherein two genes on the same haplotype may be operational in a synergistic fashion. The two major predisposing haplotypes are DQA1*0501 DQB1*0201 and DQA1*0301 DQB1*0302 but other predisposing haplotypes exist in non-white populations (See Chapter 74). Particular attention is presently being paid to a locus located between HLA-B and TNF (Lie et al., 1999; Johansson et al., 2003). This haplotype effect would provide a good explanation for the discrepancy observed between the relatively low risk contribution of each HLA predisposition gene and the major risk among sibpairs associated with the sharing of the two HLA haplotypes (independently of DR3/DR4 heterozygosity). The HLA–T1D association also includes a major protective effect of HLA DR2 or the associated DQB1*0602 gene. Table 36.2 presents the list of HLA T1D predisposition genes as well as that of disease protection genes.

Postulated mechanisms of T1D–HLA association include presentation of β-cell antigen peptides by the corresponding HLA molecules (see Chapter 5). The sequence analysis of T1D-associated DQ and DR molecules has revealed the importance of particular amino acid residues. Thus T1D is strongly associated with the absence of aspartic acid in position 57 of the DQβ chain, a critical position for peptide binding to the DQ molecule (Todd et al., 1987). The protective effect is less easily explained but may involve peptide capture by the protective HLA molecule or the induction of regulatory T cells. But caution is necessary since, as stated above, there may be a strong haplotype effect with the possible role of non-HLA MHC genes influencing immune responsiveness in a non-antigen-specific fashion, as

TABLE 36.2 Association of HLA genes and human type 1 diabetes (IDDM1) in white people (after Pociot and McDermott, 2002)

HLA-DQ alleles	HLA-DR alleles	Relative risk
Positive associations (susceptibility haplotypes)		
A1*0301-B1*0302	DRB1*04	2.5–9.5
A1*0501-B1*0201	DRB1*301	2.5–5.0
A1*0501-B1*0302	DRB1*301/DRB1*04	12.0–32.0
A1*0301-B1*0201	DRB1*301/DRB1*04	
A1*0301-B1*0402	DRB1*04/DRB1*801	4.0–15.0
A1*0301-B1*0201	DRB1*701	8.0–13.0
A1*0301-B1*0201	DRB1*901	5.5
A1*0301-B1*0401	DRB1*04	3.5–4.5
A1*0301-B1*0303	DRB1*901	2.0–4.5
Negative associations (protective haplotypes)		
A1*0102-B1*0602	DRB1*1501	0.03–0.2
A1*0103-B1*0603	DRB1*1301	0.05–0.25
A1*0301-B1*0301	DRB1*04	0.2–0.5
A1*0501-B1*0301	DRB1*1101	0.05–0.5

indicated by studies in the NOD mouse (Boulard et al., 2002).

Role of Non-MHC Genes

The difference observed between concordance rates in monozygotic twins (35–40%) and HLA identical siblings (16%) demonstrates the role of non-MHC genes in disease predisposition, as described in Chapter 21. Recent updates on the state of the art can be found in reviews by Pociot and by Eisenbarth. The study of candidate non-MHC genes has not been very fruitful since only two have been clearly identified, insulin and CTLA-4, and for both there is a low relative risk and no absolute exclusion of neighboring genes. Also incriminated are the IL-12 p40 gene (Davoodi-Semiromi et al., 2002) and the IL-4 receptor gene (Mirel et al., 2002). Genome scanning approaches have been more successful, since both in NOD mice and human T1D more than 20 chromosomal regions have been characterized (Table 36.3) (Wicker et al., 1995; Todd, 1999; Pociot and McDermott, 2002; Ide and Eisenbarth, 2003). However, not all of these regions have been confirmed in various large-scale studies performed in the US and Europe (Pociot and McDermott, 2002), and the relative risk associated with each of these regions is relatively small.

The problem is complicated by the clustering of several predisposition genes in single regions, as in the case of Idd5 in the NOD mouse. Returning to the relatively high disease concordance rate in HLA identical siblings, it seems likely that only a few of these predisposition genes are important for disease predisposition or that many of them are present in a very high proportion of the general population. Converging evidence suggests that most, if not all, T1D-predisposing genes code for polymorphic variance of normal proteins. The hope is that recent progress in genome typing, together with the knowledge of the human genome and the haplotype map, will clarify genetic predisposition to T1D. It will also be important to relate the genes in question to their putative involvement in disease pathogenesis, which has so far essentially been possible only in the NOD mouse.

Environmental Factors

Since more than 50% of monozygotic twins are discordant for T1D, the importance of environment in the etiology of T1D seems substantial. However, it is difficult to distinguish whether this effect arises from abnormal triggering of the immune response by extrinsic factors or from a permissiveness due to insufficient stimulation of immunoregulation.

Triggering Factors

Viruses

Viruses have been considered major potential candidates for the etiology of T1D for several decades. The viral hypothesis was initially based on the temporal relationship between defined virus infections and onset of overt diabetes (Jun and Yoon, 2003). This sequence was notably invoked for Coxsackie B4 virus (Asplin et al., 1982) but the argument is not very robust when one considers, as mentioned above, that T-cell-mediated islet aggression probably begins many years before clinical onset in most patients and thus before the incriminated infection. The infection may at most exacerbate an already established anti-islet response and thereby accelerate disease onset. One should add that

TABLE 36.3 Non-MHC gene loci in type 1 human diabetes (after Pociot and McDermott, 2002)

Locus	Chromosome	Markers	Significance level
IDDM2	11	INS	LOD ≥ 2.0
IDDM3	15	D15S107	LOD ≥ 2.0
IDDM4	11	D11S1296-FGF3	LOD ≥ 3.6
IDDM5	6	D6S476-D6S473	LOD ≥ 3.6
IDDM7–IDDM12	2	HOXD8-D2S72-CTLA4	LOD ≥ 3.6

IDDM11	14	D14S67	LOD ≥ 3.6
IDDM13	2	D2D137-D2S301	LOD ≥ 2.0
IDDM15	6	D6S283	LOD ≥ 3.6
IDDM16	14	D14S292-D14S293	
IDDM17	10	D10S1750-D10S1773	
IDDM18	5	IL12B	LOD ≥ 3.6

serological evidence, i.e., the detection of antiviral antibodies in T1D patients, has always been indecisive, as are the episodic claims of virus isolation from pancreatic tissue (Burch and Harb, 1975). The interest in enteroviruses has recently been renewed by observations that the frequency of enterovirus infections studied using both serology and testing for the presence of enterovirus RNA could be correlated with islet-specific autoantibodies in subjects at risk for developing T1D (Honeyman et al., 2000; Lonnrot et al., 2000). Also, an increased T-cell response to Coxsackie B4 antigens was observed in recent-onset diabetic patients (Juhela et al., 2000). These data are interesting but their contribution to the etiologic role of enteroviruses remains indirect, since positive results are also observed in a large percentage of the normal population.

At the experimental level, the data are also rather limited. The encephalomyocarditis virus is said to induce T1D in mice (Craighead and McLane, 1968) but T1D here is of the cytopathic type without immunologic involvement. The Coxsackie B4 virus can induce diabetes in mice with some features of autoimmune T1D (Coleman et al., 1974) but it is not clear whether disease pathogenesis involves a direct cytopathic effect or an immune β-cell attack secondary to virus-induced inflammation. This interpretation is compatible with the report by Horwitz that Coxsackie B4 infection of BDC2.5 mice which have a limited nontransgenic TCR repertoire shows accelerated diabetes (Horwitz et al., 1998).

Other interesting data have been derived from the RIP-LCMV transgenic mice that develop T1D after LCMV infection according to a hit-and-run mechanism (Von Herrath et al., 1997; Von Herrath, 2002) (see Chapter 26). The virus infection stimulates the induction of LCMVgp-specific $CD8^+$ cytotoxic T lymphocytes (CTLs) which cause the disease, even though the virus is rapidly cleared through the action of such CTLs.

Collectively, these data are compatible with, but certainly not proof of, a viral etiology for T1D, noting also that the diabetogenic virus (or viruses) is still unidentified. It might well be that the etiologic infection takes place many years before clinical onset, calling into question the data on preclinical infections and seasonal prevalences. This lag time would explain the difficulty in identifying the diabetogenic viruses, which in addition might not be unique. Several pancreatotropic viruses could operate through nonspecific inflammatory mechanisms, as discussed earlier. There is also a possibility for antigen (epitope) mimicry but there is no good evidence for this hypothesis in man, except a homology between a Coxsackie B4 virus protein and GAD (Atkinson et al., 1994), and virtually no evidence in the mouse. We note that T1D is accelerated in BB rats infected with Kilham's virus (Guberski et al., 1991) but in this case the impact of the virus is on the immune system, rather than on islet β cells.

Diet

Cow's milk accelerates the onset of T1D in BB rats (Elliott and Martin, 1984). A gluten-free diet prevents T1D in NOD mice (Funda et al., 1999). These observations have led to a number of experimental studies and therapeutic trials in humans that are still in progress. Concerning cow's milk, a peptide from lactalbumin (called ABBOS) was shown to cross-react with a β-cell autoantigen named p69, suggesting again a possible form for antigen mimicry (Karjalainen et al., 1992).

Toxic Agents

Multiple low doses of STZ regularly induce T1D in susceptible strains of mice and rats, which suggests that toxic agents can induce T1D (see page 489). There is no evidence, however, documenting this hypothesis in human T1D.

Permissive Factors

As mentioned above, there has been a steady increase in the incidence of T1D over the last three decades in Western countries in line with the increase in incidence of other autoimmune and allergic diseases (EURODIAB, 2000; Bach, 2002b). T1D is more common in developed than in developing countries and within Europe there is a clear north–south gradient, as seen with other autoimmune diseases. These data suggest the role of a permissive environmental factor in the etiology of T1D.

The Nature of Protective Environmental Factors

Many differences exist between countries of the northern and southern hemispheres, including genetic traits, socio-economic level, climate, diet, and more generally, lifestyle. The role of genetic factors is probably not critical if we consider that migrating populations from low-incidence to high-incidence countries acquire a disease incidence similar to that of the inhabitants of the adopted country (Staines et al., 1997). Socio-economic factors are probably central, as demonstrated among countries by a correlation between the incidence of T1D and prosperity, but also among more limited neighboring regions within countries (Bach, 2002b). The most plausible explanation for this socio-economic influence is the high rate of infections, especially during childhood, in low socio-economic areas. This interpretation has been directly demonstrated in Northern Ireland for T1D (Patterson et al., 1996). A role for infectious agents was suggested for predisposition to atopic dermatitis and Crohn's disease by studies showing a correlation between sanitary conditions and disease incidence. In addition to this, the occurrence of T1D is greatest for the firstborn of large families, probably because of lower exposure to infections.

Animal Models

It has repeatedly been shown that NOD mice and BB rats have a diabetes incidence highly related to the sanitary conditions of breeding and maintenance: the cleaner these are, the higher the disease incidence (Bach, 2002b). Additionally, infection of NOD mice with bacteria, viruses or parasites totally prevents disease onset (Oldstone, 1990; Qin et al., 1993; Zaccone et al., 2003). The best-studied model is that of the prevention of T1D in NOD mice by administration of complete Freund's adjuvant (Qin et al., 1993).

Mechanisms

Infections may prevent insulitis progression in several ways. First, there is the possible role of homeostatic competition, wherein the anti-infectious immune response competes with autoreactive T cells for homeostatic maintenance signals such as IL-7 or peptide MHC recognition (King et al., 2004). Various other cellular or molecular protagonists involved in the immune response, notably in antigen processing, the binding of autoantigen peptides to HLA molecules, as well as the consumption of IL-2 or other helper cytokines could also play a role. Second, anti-infectious responses could elicit suppressor mechanisms which could extend their inhibitory effect to diabetogenic autoimmune responses through bystander suppression, whatever the underlying mechanisms might be: IL-10, TGF-β, NKT cells or other(s). Third, infectious agents could stimulate Toll-like receptors with convergent induction of suppressor mechanisms, as shown in our laboratory (unpublished) with agonists of TLR2, TLR3, and TLR4.

Conclusions

The two sets of considerations in regard to infections are not necessarily contradictory, even for those infectious agents that have been discussed among both triggering and protecting factors. The triggering of the T1D process could relate to some specific pancreatotropic viruses, whereas conversely, islet-specific immune responses could be inhibited non-antigen specifically by a spectrum of bacteria, viruses, and parasites.

IMMUNOTHERAPY OF TYPE 1 DIABETES

This aspect is treated in depth in two other chapters (Chapters 75 and 76). However, in brief, immunotherapy of T1D can be divided into five main approaches, as follows.

Non-Antigen-Specific Suppression of Islet-Specific Immune Responses

This is best achieved with conventional chemical immunosuppressive agents such as cyclosporin A and azathioprine which have both successfully been used in human T1D (Feutren et al., 1986; Silverstein et al., 1988; CERCTG, 1988). The problem is that the effect does not extend beyond the treatment period, imposing chronic treatment with its potential toxicity and risk of over-immunosuppression.

Antigen-Induced Tolerance

The second (much more attractive) approach consists of inducing antigen-specific tolerance to β-cell antigen peptides. This approach has proven very successful in the NOD mouse (Kaufman et al., 1993; Tisch et al., 1993; Muir et al., 1995; Daniel and Wegmann, 1996; Alleva et al., 2002) but its application to man is still limited, with the single exception of a trial using a heat shock protein peptide in recently diagnosed patients with T1D (Raz et al., 2001), but this is still to be confirmed. Several trials have been performed using GAD or insulin. In prediabetic or recently diagnosed diabetic patients, none so far has shown well-proven efficacy (see Chapter 75). As mentioned above, the mechanisms of such intervention probably involve stimulation of Th2 cells.

Combination of Immediate Freezing of the Islet Response and Ultimate Induction of Regulatory T Cells

This dual effect was obtained with anti-CD3 antibodies, first in NOD mice (Chatenoud et al., 1994; Belghith et al., 2003) then in man (Herold et al., 2002; Keymeulen et al., 2005). The effect is remarkable because it is immediate and does not expose patients to long-term immunosuppression, since the non-antigen-specific effect of the treatment is immediately reversible when the anti-CD3 antibody disappears from serum. Ultimately, regulatory mechanisms take over. The latter mechanism is probably islet specific, the antibody acting preferentially on preactivated T cells which mainly comprise islet-specific T cells. This is discussed in further detail in Chapter 76.

Replacement of the Protective Effect of Infections

The approach was explored with the bacillus Calmette–Guerin (BCG) (Allen et al., 1999) and Q fever vaccines (Bonn, 1999) but the duration of immunostimulation was probably too short to be effective. Hopefully, bacterial extracts or TLR agonists will be used in the future, as successfully done in the NOD mouse.

Inhibition of β-Cell Apoptosis

This has proven a difficult approach. Nicotinamide was used on this premise in major studies, but these have failed (Lampeter et al., 1998; Gale et al., 2004).

Other Measures

A multitude of other measures have been proposed and implemented in the NOD mouse. Caution is needed in the interpretation of the results obtained in the NOD model which is unusually sensitive to immunointervention except for mice at an advanced stage of the disease (Bach, 2002b).

GENERAL CONCLUSIONS

Whatever its etiology, it can be clearly stated that T1D is a T-cell-mediated autoimmune disease. Its evolution involves a slow progression of insulitis with both inflammation and destruction of β cells. The two timely questions concern triggering mechanisms, i.e., the event(s) that stimulate(s) the differentiation of β-cell-specific T cells, and the nature of the maneuvers that could arrest or reverse the otherwise inevitable progression that ultimately leads to the complete and selective destruction of β cells. Several strategies are being investigated, with those aimed at stimulating regulatory T cells using either β-cell antigen peptides or anti-CD3 monoclonal antibodies seeming particularly attractive. It is hoped that when these methods have proven their efficacy and safety, they will be applicable to prediabetic subjects, contingent on the predictive markers being sufficiently robust, as discussed in Chapter 74.

CHAPTER

37

Adrenalitis

CORRADO BETTERLE

Chair of Clinical Immunology
Department of Medical and Surgical Sciences, University of Padova, Padova, Italy

RENATO ZANCHETTA

Endocrinologist, Endocrine Unit, Department of Medical and Surgical Sciences, University of Padova, Padova, Italy

In 1564, Bartolomeo Eustachius wrote of the discovery of the "*glandulae quae renibus incumbent*" and subsequently Casserius (1561–1616) validated the discovery, depicting and naming them as "*corpuscola reni incumbentia sive renes succenturiati*" (Hiatt and Hiatt, 1997).

In 1855, Thomas Addison first proved that adrenals were vital organs when he described the symptoms and signs of patients with "anaemia . . . feebleness of the heart action . . . a peculiar change of colour in the skin occurring in connection with a diseased condition of the suprarenal capsules." He called this disorder "melasma suprarenale," postulating that it may be due to abnormal lesions in the adrenal glands. In this first description from the autopsies of 11 patients, he found six cases with tuberculosis, three with malignancies, one with adrenal hemorrhage, and one with adrenal fibrosis of an unknown origin. Probably, this last case was the first description of an autoimmune adrenalitis. In this case Addison reported: "The two adrenals together weighed 49 grains, they appeared exceedingly small and atrophied, so that the diseased condition did not result as usual from a deposit either of a strumous or malignant character, but appears to have been occasioned by an actual inflammation, that inflammation having destroyed the integrity of the organs, which finally led to their contraction and atrophy" (Addison, 1868). In 1856, the adrenal insufficiency was named "Addison's disease" by Trousseau.

ANATOMY AND PHYSIOLOGY OF THE ADRENALS

The adrenal glands develop from the mesenchyme: the outer part (cortex) from the mesoderm and the central part (medulla) from the neuroectoderm, which comprises part of the chromaffin system (Kannan, 1988).

The cortex is divided into three layers. The zona glomerulosa (5–10% of the cortex) comprises discontinuous subcapsular aggregates of small cells, containing less cytoplasm than the other cortical cells; the middle zone or fasciculata (70% of the cortex), is formed by radial cords of large cells arranged in columns with abundant lipid-filled cytoplasm; the inner cortical zone or zona reticularis is composed of cells arranged in cords with compact, finely granular, eosinophilic cytoplasm (Figure 37.1A).

The adrenal cortex synthesizes three main groups of hormones (the glucocorticoids, the mineralocorticoids, and the adrenal androgens) (Auchus and Miller, 2001). The homeostasis of glucocorticoids is regulated by a feedback mechanism through the hypothalamus by means of corticotropin-releasing hormone (CRH), the pituitary gland by ACTH, and the adrenal cortex by cortisol (Koch, 2004). The main steps in the synthesis of the adrenal cortex hormones and the enzymes involved are described in Figure 37.2.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

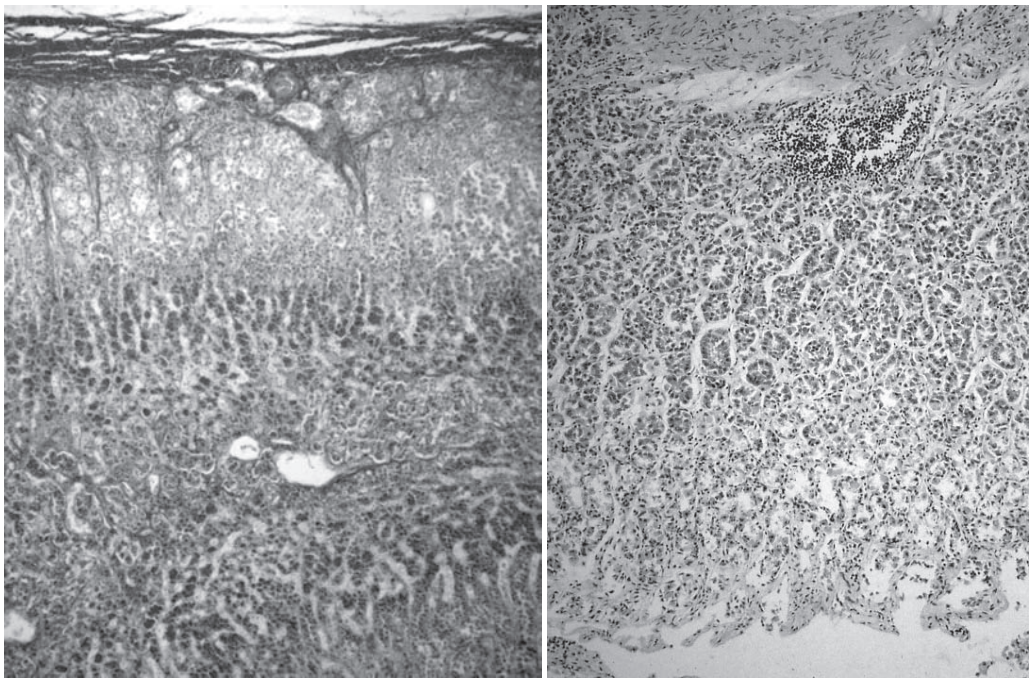

FIGURE 37.1 *A,* Histopathology of the normal adrenal cortex showing the typical three layers. *B,* Adrenal cortex from a patient with AAD showing atrophy of the cortex and a diffuse lymphocytic infiltration and, at top, a lymphoid follicle.

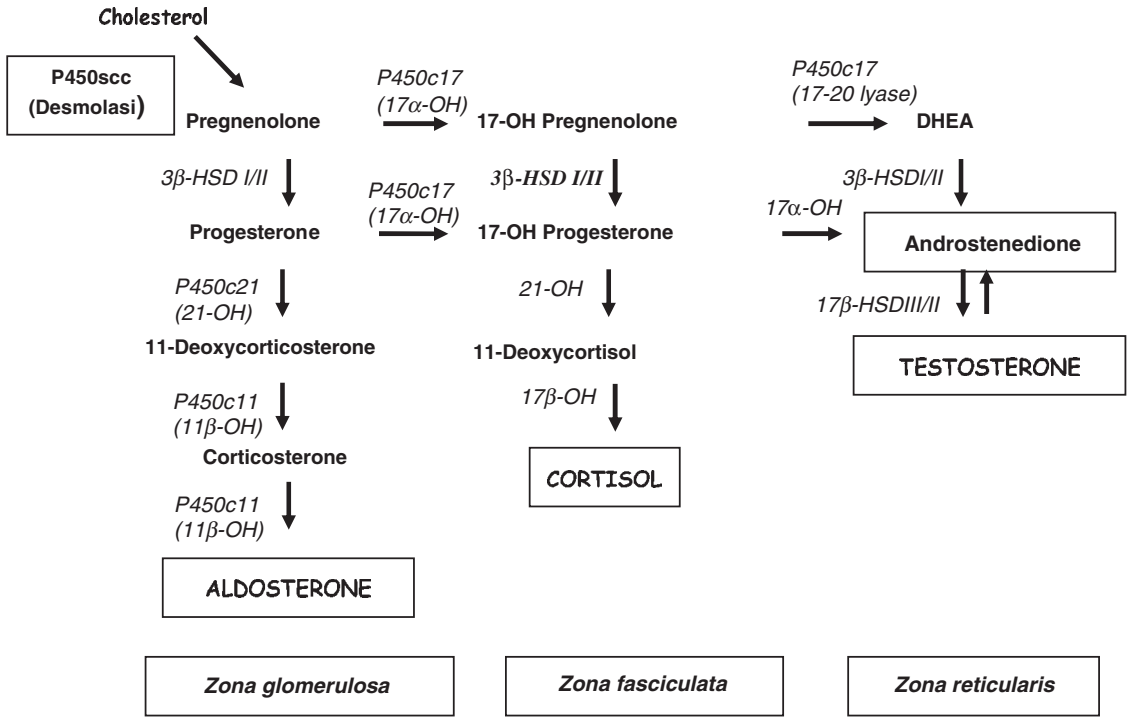

FIGURE 37.2 Main steps of the pathway of adrenal cortex hormone synthesis and the respective enzymes.

By immunocytochemical techniques, the normal adrenal cortex shows the presence of many proteins (Thiebaut et al., 1987; Henzen-Logmans et al.,1988; Sasano et al.,1989; 1994; Muscatelli et al.,1994; Fogt et al.,1998; Pelkey et al.,1998). Immunopositivity has been demonstrated for the class II major histocompatibility (MHC) complexes (found in 10–20% of the cortical cells) including the human antigen D-related leukocyte (HLA DR) (McNicol, 1986; Jackson et al., 1988) and interleukin-6 (Gonzalez-Hernandez et al.,1994) which is involved in the communication process between the immune and endocrine system. Using specific antibodies against the steroidogenic enzymes and cytochrome P450 (Sasano et al., 1992), it was demonstrated that cytochrome P450 is involved in the adrenal steroid biosynthesis process, while the AdBP/SF-1 transcription factor regulates the expression of the CYP genes (Orth and Kavacs, 1998).

EPIDEMIOLOGY OF ADDISON'S DISEASE AND AUTOIMMUNE ADRENALITIS

Addison's disease (AD) is a very rare disorder and formerly tuberculosis was the most frequent cause. Of the 11 cases of AD in 1855, six (55%) had tuberculosis and only one (9%) had autoimmune AD (AAD). Guttman (1930) examined 566 autopsied patients with AD and found 70% had tuberculous adrenalitis. Dunlop (1963) reviewed 86 cases of AD and reported 79% with tuberculous adrenalitis. In London, Mason et al. (1968) reported that 31% of cases had the tuberculous form of AD. In Denmark, Nerup (1974) found that tuberculosis was present in 17% of patients with AD. In more recent years, AAD has become the most frequent cause of AD. In Europe, from 1974 to 2002, 1557 patients with AD were evaluated and the frequency of AAD ranged from 44.5% to 94%; in contrast, AD due to tuberculosis was found with a frequency ranging from 0% to 33%, and the remaining forms of AD ranged from 1% to 22% (Betterle et al., 2002).

Despite a constant decrease of tuberculous forms of AD in recent years, the prevalence of AD has increased and this may be due to the absolute increase of AAD. Indeed, in London in 1968, Mason et al. found a prevalence of AD of 39 cases per million. In 1974 in Denmark, Nerup calculated a prevalence of 60 cases per million, while in Coventry in 1997, Willis and Vince found a prevalence of 93 cases per million. In Nottingham in 1994, Kong and Jeffocoate reported a prevalence of AD of 110 cases per million, while in Italy Laureti et al. (1999) calculated 117 cases per million. Recently the prevalence of AD was reported to be 140 cases per million in a population of western Norway with a calculated incidence, in the past decade, of 6.2 new cases per million per year (Løvås and Husebye, 2002).

The frequency of AD varies also in relation to different geographic areas: in New Zealand, Eason et al. (1982) calculated it to be 4.5 cases per million; in Japan it is five cases per million (Takayanagi et al., 2000); in the USA 50 cases per million (Jacobson et al., 1997); and in North Europe, more than 100 cases per million, as mentioned above (Kong and Jeffocoate, 1994; Laureti et al., 1999; Løvås and Husebye, 2002).

AUTOIMMUNE ADDISON'S DISEASE (AAD)

AAD depends on a combination of genetic, environmental, and endogenous factors able to both induce a break of immune tolerance and initiate an autoimmune attack on the adrenal cortex, as for other autoimmune diseases (Kamradt and Mitchinson, 2001).

Histopathology

Focal Lymphocytic Adrenalitis

In 1933 (Duff and Bernstein, 1933) and in 1969 (Kiaer and Rytter Norgaard, 1969) workers described a focal adrenalitis in patients without signs or symptoms of AD. Petri and Nerup (1971), studying two groups of patients (413 and 161 miscellaneous cases), reported the presence of very small numbers of lymphocytes in 15% and 18.6% of the adrenal glands, respectively. Subsequently, in up to half of the autopsied patients without AD, a focal accumulation of lymphocytes and plasma cells was demonstrated in the adrenal cortex, associated with chronic inflammatory diseases in the retroperitoneum (Fidler, 1977; Orth and Kavacs, 1998). The percentage of these infiltrates was similar to that reported in focal thyroiditis. In 1989, Hayashi et al. evaluated 174 cases at autopsy and demonstrated that mononuclear cell infiltration in the adrenal cortex increased with age, being present in about in 7.4% of those aged over 49 years and 63% aged over 60 years. Immunohistochemical studies revealed that the infiltrating mononuclear cells were mainly composed of $CD3^+$ T cells. The major proportion of $CD3^+$ T cells express the CD4 phenotype, whereas $CD8^+$ T cells were fewer. A proportion of the $CD4^+$ T cells were activated (Hayashi et al., 1989). These findings indicate that the focal lymphocytic infiltration of the adrenal glands is not rare and may represent a latent adrenalitis, which, however, rarely reaches clinical expression since symptomatic autoimmune adrenalitis (AA) is extremely rare in the population.

Diffuse Lymphocytic Adrenalitis

The pathologic findings initially described by Addison (1855) as "idiopathic" are constantly present in the adrenal

glands of patients affected by AA. On macroscopic examination, both the adrenals are small (weight 1–2 g) and sometimes it is difficult to identify them in the retroperitoneal tissue. The capsule is fibrous, so that the adrenal glands are not detectable macroscopically and adrenal tissue is not detectable in multiple sections (Drury et al., 1979).

On microscopic examination, there is complete destruction of the three-layer architecture. The adrenal cortical cells are single, enlarged or pleomorphic, with increased eosinophilia, depleted in lipids or present as part of a cluster. Residual cortical nodules are seen as the disease progresses. The tissue is diffusely infiltrated by small lymphocytes, plasma cells, and macrophages (Figure 37.1B) (McNicol and Laidler, 1996). The histopathologic finding of infiltrating lymphocytes sometimes is associated with follicle formation and fibrosis. The medulla remains normal. This pattern is present in patients with AA, either isolated or associated in the context of autoimmune polyendocrine syndromes (McIntyre Gass, 1962; Irvine and Barnes 1975; Betterle et al., 2002).

Animal Models

Induced Immunity

Colover and Glynn (1958) reported isoimmunization in guinea pigs by injection of adrenal antigens and complete Freund's adjuvant, with distinctive and "specific" lesions of the adrenals. Subsequently, many authors (for example, Steiner et al., 1960; Barnett et al., 1963) reported examples of experimental autoimmune adrenalitis (EAA) in different species (rabbits, guinea pigs, rats, monkeys), including an antibody reaction in the guinea pigs and a lymphocytic infiltration in the rabbit adrenal tissue (Witebsky and Milgrom, 1962; Barnett et al., 1963). The adrenal lesions in rabbits were characterized by foci of lymphocytes and histiocytes, with a small number of plasma cells and eosinophils, and degenerative changes in adrenal cells. In 1968 (Andrada et al., 1968) and in 1970 (Werdelin and Witebsky, 1970), EAA in a Lewis rat model was induced: adrenalitis occurred at day 7 after immunization. The histology was studied by autoradiographic tracing of H_3 thymidine and H_3 adenosine-labeled cells and demonstrated that adrenalitis was initiated with the appearance of a few specifically reactive lymphocytes, followed by an infiltration of mononuclear cells, mainly lymphocytes and plasma cells, throughout the adrenal cortex. Eosinophilia, cytoplasmic vacuolization, and a loss of nuclear definition were evident in cortical cells.

Using electron microscopy, Hoenig et al. (1970) studied the inflammatory lesions in paraffin-embedded tissues; 5 days after immunization, lymphocytes were present in sinusoids and adrenal parenchyma where damage was in the vicinity of lymphocytes, with enlargement of intercellular spaces and ischemic areas with inflammatory cells and fibrin.

It was demonstrated by Fujii et al. (1992) that in mice repeated immunizations caused a delayed type of hypersensitivity to adrenal antigens, and that transfer of adrenalitis from an affected to a healthy animal was not possible by serum but was possible using spleen cells, confirming previous reports (Levine and Wenk, 1968; Werdelin et al., 1971) in which the disease was passively transferred by immunocytes derived from lymph nodes.

Spontaneous Immunity

Spontaneous AA occurs in dogs (Harlton, 1976; Kaufman, 1984; Little et al., 1989; Kintzer and Peterson, 1994; Sadek and Schaer, 1996; Dunn and Herrtage, 1998) and cats (Kaufman, 1984; Peterson et al., 1989; Tasker et al., 1999; Stonehewer and Tasker, 2001) with hypoadrenocorticism due to immune-mediated destruction of the adrenal glands. While biochemical laboratory data were reported, none of the authors described positivity for adrenal cortex autoantibodies, but only the presence of lymphocytic infiltration in the adrenal glands, at autopsy.

Beales et al. (2002) found the adrenal glands of a nonobese diabetic (NOD) mouse to contain a mononuclear cell infiltration in the adrenal cortex, but without signs of hypoadrenalism. Thus the NOD mouse was proposed as a spontaneous model suitable for investigating mechanisms involved in diffuse lymphocytic infiltration of the adrenal glands.

Different Clinical Presentations of AAD

AAD can develop as a sole disease or associated with other autoimmune diseases. A review of the literature on 1557 patients with AA revealed that Hashimoto' thyroiditis was present in 3.7–32%, Graves' disease in 2–22.7%, atrophic gastritis in 25%, chronic candidiasis in 0.8–21%, diabetes mellitus in 1.2–20.4%, hypoparathyroidism in 1.2–20%, hypergonadotropic hypogonadism in 4.5–17.6%, vitiligo in 0.8–16%, alopecia in 0.8–12%, celiac disease in 1.2–8%, pernicious anemia in 0.8–6%, multiple sclerosis in 3.7%, inflammatory bowel diseases in 2.4%, Sjögren syndrome in 2.4%, chronic hepatitis in 1.6–3%, and lymphocytic hypophysitis in 0.8% (Betterle et al. 2002).

Neufeld and Blizzard (1980) proposed the classification of autoimmune syndromes into four main groups, involving different endocrine glands, and named them "autoimmune polyglandular syndromes" (APS) (see Box 37.1). According to this classification, AAD can be associated with type 1 and 2 APS.

Betterle et al. (2002), in a review of APS, proposed the existence of three different types of APS involving AAD (type 1, type 2, and type 4). So, AAD can present in four

TABLE 37.1 Four different clinical presentations of autoimmune adrenalitis

Characteristics	Type 1 APS	Type 2 APS	Type 4 APS	Isolated AD
Mean age at onset	13 years	36 years	36 years	30 years
F : M ratio	F ≥ M	F > M	F > M	M > F
Association with:				
1. Hypoparathyroidism and/or candidiasis	+	Absent	Absent	Absent
2. TAD and/or type 1 diabetes	Rare	+	Absent	Absent
3. Other disease (hypergonadotropic hypogonadism, vitiligo, alopecia, atrophic gastritis, pernicious anemia, celiac disease, myasthenia gravis)	Frequent (up to 70%)	Rare (up to 12%)	+	Absent
4. Ectodermal dystrophy	+	Absent	Absent	Absent
Genetic				
1. Mutations in the AIRE gene	+	Absent	Absent	Absent
2. HLA	No correlations	DR3 and/or DR4	?	DR3

Box 37.1 Clinical classification of APS according to Neufeld and Blizzard, 1980 (modified)

APS-1 Chronic candidiasis, chronic hypoparathyroidism, Addison's disease *(at least two diseases must be present)*

APS-2 Addison's disease *(always present)* + thyroid autoimmune diseases and/or type 1 diabetes mellitus

APS-3 Thyroid autoimmune diseases + other autoimmune diseases *(excluding Addison's disease and/or hypoparathyroidism)*

APS-4 Combinations of other autoimmune diseases not included in previous classifications

main clinical forms: isolated or associated with type 1, 2 or 4 APS.

The clinical and immunologic features of type 1, 2, 4 APS and of isolated AAD are summarized in Table 37.1. Below we describe isolated AAD; for APS see Chapter 38.

Isolated AAD

Isolated AAD is characterized by the presence of AAD without other clinically evident autoimmune disease. However, before considering such cases as true isolated AA, it is important to test for autoantibodies because in about one-third, a positive result will point to a potential APS (Betterle et al., 2002). Isolated AAD is more prevalent in males with a F : M ratio of 0.8 and a median age at onset of 30 years (Betterle et al., 2002). In isolated AD, HLA DR3-DQ2 and DR4-DQ8 were reported to be increased and DR1-DQ5 significantly reduced (Myhre et al., 2002). We studied 22 patients with isolated AD and found a significant correlation only with HLA DRB1*03-DQB1*02 (Albergoni et al., 2003).

In our experience, during the period 1968–2004, 434 cases of AD were seen and 353 (81%) were affected by AAD, 51 (12%) by tuberculosis, 12 by adrenoleukodystrophy (ALD) (2.8), 12 by other diseases (2.8%) (cancer 1.6%, infectious 0.5%, vascular 0.2%, genetic 0.2%) and six (1.4%) were unclassifiable, confirming that autoimmunity is by far the most frequent cause of AD in Italy.

Immunologic Studies

Cellular Immunity

The early studies on AD, using the assay for migration inhibition factor, reported cell-mediated immunity in affected patients, with claims for organ-specific hypersensitivity (Nerup and Bendixen, 1969). Subsequent studies, by means of an intracutaneous test with adrenal extracts, showed a cutaneous delayed-type hypersensitivity reaction but no collateral evidence based on blast transformation experiments (Nerup et al., 1970). Other studies reported a decrease in suppressor T-cell function (Verghese et al., 1980) and an increase in circulating Ia-positive T lymphocytes (Rabinowe et al., 1984), which indicated the involvement of cellular immunity. However, more thorough studies of cellular immunity in AA were not carried out until more recently (Freeman and Weetman, 1992) when a proliferative

T-cell response to an adrenal-specific protein fraction of 18–24 kDa molecular weight was described. However, T-cell reactivity to specific adrenal autoantigens has not yet been reported. As hypothesized by Volpé (1994), cell-mediated immunity seems to be the main pathogenic cause of organ-specific autoimmune diseases, involving both T-cell subsets (Liblau et al., 1995).

Humoral Immunity

Anderson et al. (1957), using a complement fixation test on a homogenate of adrenal cortex tissue, demonstrated that 2/8 (25%) of patients with idiopathic AD had antibodies (adrenal cortical antibodies – ACA). From 1957 to 1970, using this technique, ACA were cumulatively reported in 57/159 (36%) patients with idiopathic AD and in 2/23 (9%) of those with tuberculous form, reviewed by Betterle (2004). Subsequently, Blizzard and Kyle (1963), using indirect immunofluorescence (IIF) on animal adrenal gland sections, demonstrated that ACA are organ-specific antibodies which react with all three layers of the adrenal cortex, producing a homogenous cytoplasmic staining pattern (Figure 37.3). Sometimes, there is reactivity against one or two of the three layers of the cortex (Irvine and Barnes, 1975; Sotsiu et al., 1980). The autoantibodies also react with the surface of living cortical cells in culture (Khoury et al., 1981), indicating the existence of microsomal antigens on the surface of adrenal cells. Between 1963 and 2002, IIF was used on human or animal adrenal tissues in 1637 patients with autoimmune and 267 with tuberculous AD, and ACA were detected in 61% and 6.7% respectively, as reviewed by Betterle (2004).

The prevalence of ACA has varied considerably between different laboratories because of differences in the substrates used (animal or human), time of incubation, geographic or racial origins of individuals, gender, age of onset, duration of the disease or whether other associated diseases were present (Rees Smith and Furmaniak, 1995; Betterle et al., 2002; Nigam et al., 2003). Other studies (Kendall-Taylor et al., 1988; Wulfraat et al., 1989) have reported the presence of autoantibodies blocking the ACTH receptor in 90% of patients affected by AAD, but these data could not be confirmed (Wardle et al., 1993). Finally, autoantibodies to hydrocortisone were detected in patients with an Addison-like syndrome and AIDS (Salim et al., 1988).

In 1968, steroid-producing cell antibodies (StCA) were first described (Anderson et al., 1968) in males affected by AAD without gonadal failure (Figure 37.4). Subsequently, StCA were detected in 60–80% of the patients affected by type 1 APS, in 25–40% of those with type 2 APS and 18%

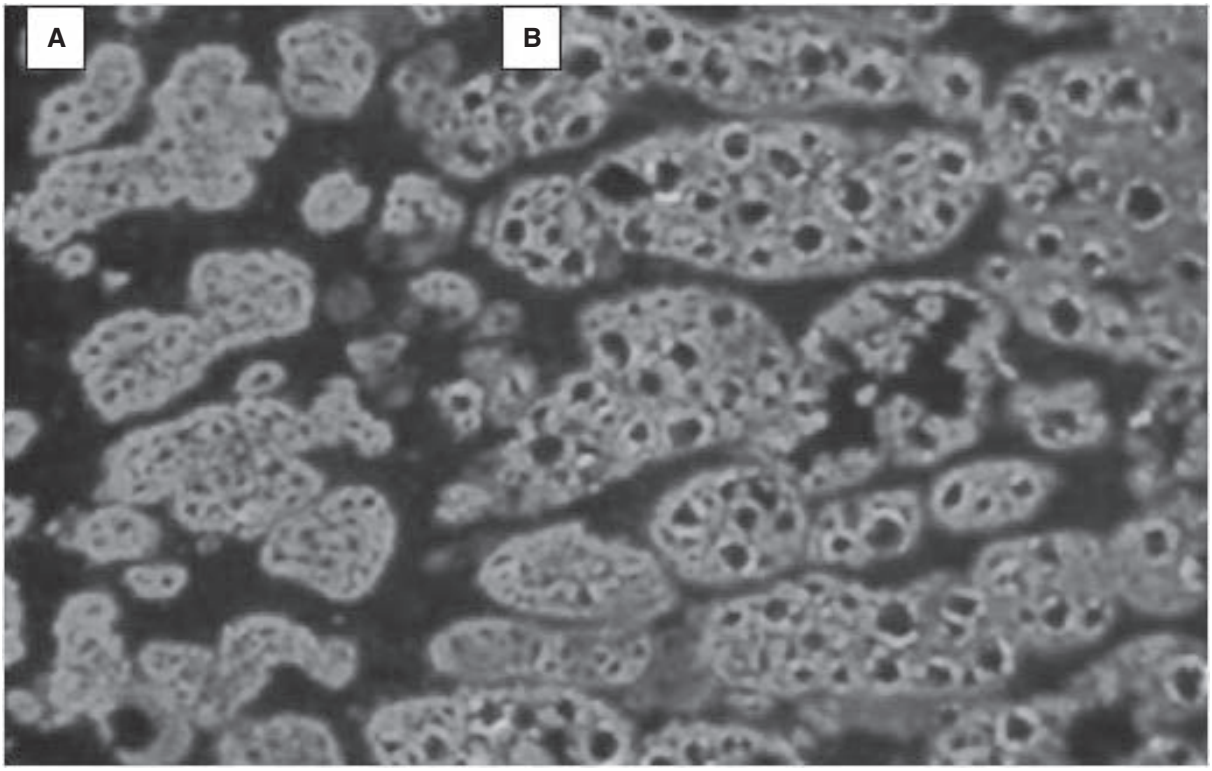

FIGURE 37.3 Immunofluorescence pattern on normal human adrenal cortex given by serum of a patient with AAD. This serum reacted with the cytoplasm of cells in all three layers of the cortex, but shown here are only glomerulosa (*A*) and fasciculata (*B*). See color plate section.

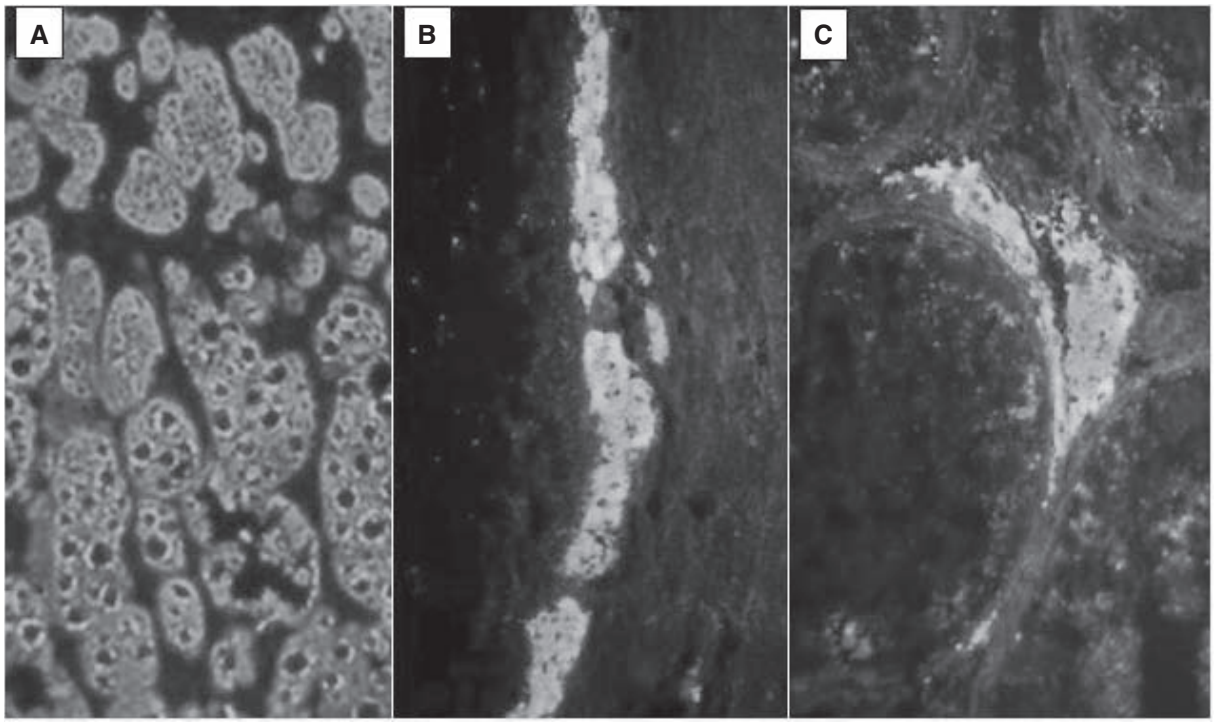

FIGURE 37.4 Immunofluorescence pattern given by serum of a patient with AAD and premature ovarian failure. This serum reacted against adrenal cortex (*A*), follicular theca of the ovary (*B*) and Leydig cells of the testis (*C*), and reflects autoantibodies to steroid-producing cells (StCA). See color plate section.

of those with isolated AA (Betterle et al., 2002; Betterle, 2004; Betterle et al., 2005). The presence of these antibodies correlates with premature ovarian failure characterized by lymphocytic oophoritis (Betterle et al., 1993; Hoek et al., 1997; Betterle and Volpato, 1998). These antibodies are not described in patients without AA or negative for ACA.

With regard to the identification of adrenal autoantigens, in 1988 Furmaniak et al. described a specific 55 kDa protein in human adrenal microsomes which was reactive with the ACA. In 1992, two independent laboratories (Baumann-Antczak et al., 1992; Bednarek et al., 1992; Winqvist et al., 1992) demonstrated by means of purification of native 21-hydroxylase (21-OH) that this adrenal enzyme is a major antigen of adrenal cortical cells. Subsequently, this was confirmed in experiments with specific absorption with purified human 21-OH, using sera from six patients with different forms of AAD (Morgan et al., 2000).

21-OH is an adrenal-specific enzyme of the cytochrome P450 family and plays a key role in the synthesis of the cortical hormones (Furmaniak et al., 1999; Furmaniak and Rees Smith, 2002). There are two 21-OH genes (CYP21): 21-OH is encoded by the CYP21B gene, whereas the CYP21A gene is inactive (Wilson et al., 1995). 21-OH catalyzes the conversion of progesterone and 17-hydroxyprogesterone into 11-deoxycorticosterone and 11-deoxycortisol (see Figure 37.2). It is a 55 kDa microsomal protein containing a heme group, located in the active site of the C-terminal end of the molecule that is important for autoantibody binding (Wedlock et al., 1993; Asawa et al., 1994) and in oxidation-reduction reactions (Picado-Leonard and Miller, 1987; Lin et al., 1994).

Analysis of autoantibody-binding sites on 21-OH indicated that the epitopes on 21-OH were conformational (Wedlock et al., 1993) and confirmed the participation of both the central and C-terminal parts of the molecule. These studies identified the presence of three different, short 5-, 6-, and 15-amino acid sequences in the C-terminal part of the 21-OH involved in the binding of antibodies to 21-OH (Chen et al., 1998). These observations are important in relation to effects of 21-OH antibodies on 21-OH enzyme activity. In fact, in studies *in vitro*, using sera positive for 21-OHAbs from patients with AA, a dose-dependent blocking activity was identified (Furmaniak et al., 1994), although this is not usually evident *in vivo* (Boscaro et al., 1996).

Following the discovery that 21-OH is the major adrenal cortex autoantigen, a specific and sensitive technique was described, by labeling the protein with ^{35}S-methionine in an *in vitro* transcription translation (TnT) system, and using an radioimmunoprecipitation assay (RIA) for the detection of antibodies (Colls et al., 1995; Falorni et al., 1995, Chen et al., 1996). Thereafter, because of certain limitations of this technique, a more convenient assay to measure 21-OHAbs

was developed based on the use of ^{125}I-labeled recombinant human 21-OH and the precipitation of the immuncomplexes using solid-phase protein A (RIA) (Tanaka et al., 1997). Using these techniques, from 1995 to 2002, a group of 572 patients with AAD and 76 with tuberculosis were studied; 78% and 1.9% respectively were 21-OHAbs positive, reviewed by Betterle (2004).

In order to compare techniques for ACA and 21-OHAbs determinations, we studied 165 patients with AD, with different durations of disease, and found that 81% of those with AAD were positive by both techniques, whereas none with non-AAD was positive (Betterle et al., 1999). The prevalence varied in relation to both the clinical presentation (type 1 or 2 APS or isolated AAD) and the duration of the disease, being higher (100%) in patients with recent onset than in those with long-standing disease (79%) and in those with type 2 APS than in those with isolated AD (Betterle et al., 2002). In these studies, results using IIF for ACA and IPA and RIA for 21-OHAbs were in good agreement.

Some discrepancies were reported by Falorni et al. (1997) on relationships between ACA measured using IIF and 21-OHAbs measured by RIA, probably related to laboratory-dependent technical aspects of the ACA measured by IIF. It would be very useful to set up an international proficiency program for adrenal autoantibody measurement, so that data across the world could be compared.

With regard to adrenal autoantigens, in addition to 21-OH, Krohn et al. (1992) reported that screening of a human fetal adrenal cDNA expression library with sera from patients with APS type 1 identified a protein with high homology to 17α-hydroxylase (17α-OH) reacting also with a fragment of recombinant 17α-OH expressed in bacteria. 17α-OH, coded by a single gene on the human chromosome 10, showed 30% homology with 21-OH antigen.

Winqvist et al. (1992), using immunoblotting and immunoprecipitation studies, also observed a reactivity of sera from APS type 1 patients with a cytocrome P450 side chain cleavage enzyme (P450scc), a heme-binding protein coded by a single gene on human chromosome 15, that showed 20% homology with 21-OH sequence (Chung et al., 1986).

The binding sites of these two antigens and their enzyme activity have not been studied, even though Peterson and Krohn (1994) reported the presence of four distinct, reactive regions in the 17α-OH molecule and an inhibiting effect *in vivo* of the P450sccAbs in the type 1 APS serum (Winqvist et al., 1993). The 17α-OHAbs and P450sccAbs are detectable by RIA, using recombinant human antigens, and are correlated with StCA detected by IIF (Chen et al., 1996).

In addition to the main antigens mentioned above, other autoantigens have also been discovered. Winqvist et al. (1996) identified an autoantibody of 51 kDa, recognizing the aromatic L-amino acid decarboxylase (Anti-AADC) involved in the generation of serotonin and dopamine. AADC was reported in the sera of patients with type 1 APS in association with chronic hepatitis, vitiligo, and type 1 diabetes mellitus (Husebye et al., 1997).

Other authors (Ekwall et al., 1998; 1999; Dal Pra et al., 2004) reported the presence of autoantibodies against a 230 kDa enzyme, tryptophan hydroxylase (TPH) involved in the synthesis of serotonin, or against histidine decarboxylase (Skoldberg et al., 2003) in patients with type 1 APS, who have a gastrointestinal dysfunction.

Again, patients with type 1 APS and autoimmune hepatitis recognize the cytochromes P450 CYPIA2 and CYP2A6 as autoantigens (Clemente et al., 1997; 1998).

Recently, an autoantibody to SOX9 and SOX10 was reported in patients with type 1 APS and vitiligo (Hedstrand et al., 2001), and an antibody to tyrosine hydroxylase in those with alopecia areata (Hedstrand et al., 2000).

Some authors reported reactivities against other antigens: to 3β-hydroxysteroid dehydrogenase (Arif et al., 1996), to candidal antigens, heat shock protein 90, pyruvate kinase and alcohol dehydrogenase, in patients with AAD and chronic mucocutaneous candidiasis (Peterson et al., 1996). Two different studies (Song et al., 1994; Peterson et al., 1997) were unable to confirm the reactivity to other enzymes (11α-hydroxylase, aromatase, adrenodoxin) in patients with AAD.

Natural History of AAD

Apart from the patients with AA, ACA can be detected in 0.2% of normal controls, in 4% of first-degree relatives of AA patients, 4% of hospitalized patients, and 1.3% of patients with organ-specific autoimmune disease, with a much higher prevalence (2.5–20%) in premature ovarian failure or idiopathic hypoparathyroidism (Nerup, 1974; De Bellis et al., 1993; Betterle et al., 1997a; 1997b).

AAD is a chronic disease with a long silent period marked by the presence of ACA. The natural history of the disease could entail five main phases: one potential, three subclinical, and one clinical (Betterle et al., 1988).

To recognize these different phases, it is necessary to basally measure levels of cortisol, ACTH, plasma renin activity (PRA) and aldosterone and cortisol 30–60 min after an intravenous injection of 250 μg of cosyntropin (α1-24-corticotropin) (ACTH test) (Stewart et al., 1988; Grinspoon and Biller, 1994). For the study of patients with ACA/21-OHAbs, it was proposed to use an ACTH test with a low dose (1 μg) of ACTH (Laureti et al., 2000), since the test with high doses might have inadequate sensitivity. However, the test with low doses of ACTH did not reveal differences in the cortisol response either in normal controls or in patients with ACA/21-OHAbs compared with results obtained using the test with high doses.

Stage 0 is characterized by the presence of adrenal-specific autoantibodies and a normal adrenal cortical mass, in the absence of detectable dysfunction of the adrenal glands by ACTH test, representing the "potential" phase of chronic adrenalitis. Stage 1 is characterized by an increase in PRA, together with normal/decreased levels of aldosterone; stage 2 by normal ACTH values with normal basal cortisol but a low cortisol peak; and stage 3 by an increase in ACTH and normal level of basal cortisol, representing subclinical adrenal function. Stage 4, the clinical adrenalitis stage, is when the ACTH is significantly increased and the basal cortisol is very low. Stage 1 (increase of PRA and normal/low levels of aldosterone) reveals that what is first affected by the autoimmune attack is the zona glomerulosa of the adrenal glands, perhaps because of its greater sensitivity to diffuse lymphocyte infiltration, but another explanation is that the other zones are protected by either locally produced high concentrations of corticosteroid hormones or the ability to self-regenerate (Betterle et al., 2002).

From 1983 to 2000, 236 ACA-positive patients were followed in 12 studies and 28% developed AAD, but the evolution varied greatly from 0% to 90% (Betterle, 2004; Betterle et al., 2005). The highest risk was found in children with high antibody titers and DR1*0404 (Betterle et al., 1997a; 1997b; Laureti et al., 1998; Yu et al., 1999).

Recently, in order to estimate risk of AD, 100 ACA-positive patients (21 children and 79 adults) with autoimmune diseases but without clinical AAD were studied over a period of 19 years; 31 of the seropositive patients developed clinical AAD. The overall cumulative risk of AAD in ACA/21-OHAb-positive patients was 47.5%, with an annual incidence of 4.9%. We assessed various indices, including clinical (gender and age), immunologic (type of preexisting autoimmune disease, titers of autoantibodies), genetic (HLA status) and functional (level of adrenal cortical function) by multivariate analysis. This demonstrated that the occurrence of AAD was independently associated with:

- the presence of chronic hypoparathyroidism and/or mucocutaneous candidiasis;
- thyroid autoimmune disease and/or type 1 diabetes mellitus;
- high antibody titers;
- abnormal adrenal function at entry.

The probability of developing AAD can now be estimated by a mathematical model. This risk evaluation yielded two practical outcomes:

1. individulization of the patients with different risk grades in order to monitor them at different rates;
2. selection of patients to begin an immuno-intervention trial treatment in order to prevent the development of the disease (Betterle et al., unpublished observations).

Diagnosis of AAD

Clinical Manifestations

AAD has a long preclinical period and clinical features do not appear until 90% or more of the adrenal cortex is destroyed. The main clinical signs at onset are general malaise, fatigue, weakness (99%), anorexia, nausea and vomiting (90%), weight loss (97%), cutaneous and mucosal hyperpigmentation (Figure 37.5) caused by the enhanced stimulation of the skin MC1-receptor by ACTH and other pro-opiomelanocortin-related peptides (98%), and severe hypotension (87%). Other signs (abdominal pain, salt craving, diarrhea, constipation, syncope) have a variable frequency (34–39%) (Williams and Dluhy, 1998). In women a loss of axillary and pubic hair, dry skin, reduced libido, and an impairment of well-being also occur.

General Biochemical Indices

In AAD at diagnosis, the serum levels of sodium, chloride and bicarbonate are reduced, while those of potassium are elevated. The hyponatremia (in 100% of patients) is due to loss of sodium in urine and increase in both plasma vasopressin and angiotensin II which impair free water clearance; hyperkalemia (in 50–70%) is due to aldosterone deficiency, impaired glomerular filtration, and acidosis. From 10% to 20% of patients have a mild or moderate hypercalcemia, for unknown reasons (Williams and Dluhy, 1998). Anemia is present in 40–50%, and eosinophilia and lymphocytosis in 10–15% of the cases.

Hormonal Tests

The association between a morning (8 am) immunometric determination of both plasma ACTH and basal cortisol levels differentiates cases of primary adrenal failure from both a healthy status and other types of adrenal disease (Oelkers et al., 1992).

An increase in levels of ACTH (higher than 22.0 pmol/L) and decrease (below 165 nmol/L) in basal cortisol indicate primary adrenal failure. In the initial phases of AD, plasma renin activity increases above the normal range, and serum aldosterone is either subnormal or low-to-normal. In relation to differential diagnosis, in the case of secondary adrenal failure, levels of both ACTH and cortisol are low and, in general, aldosterone and plasma renin activity are normal. Dehydroepiandrosterone, which is the major precursor of sex steroid synthesis, is involved in the adrenal failure, causing a pronounced androgen deficiency in women, with the loss of both axillary and pubic hair, dry skin, reduced libido and, frequently, an impairment in well-being (Arlt and Allolio, 2003).

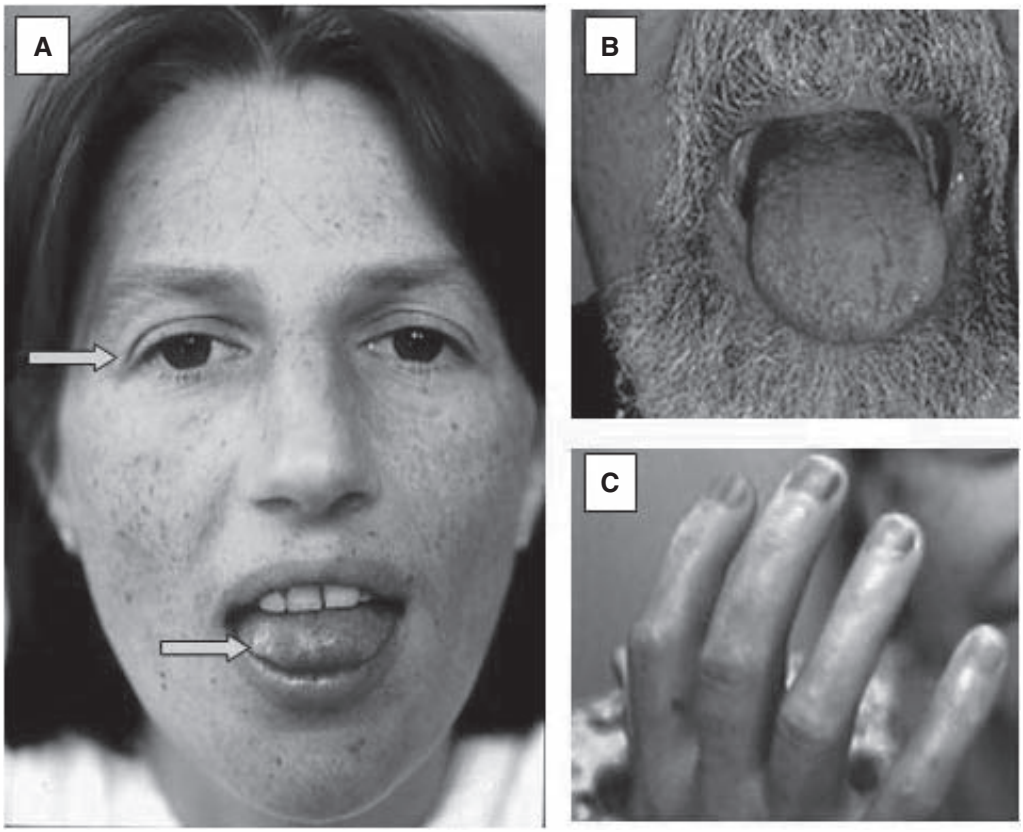

FIGURE 37.5 Clinical manifestations of AAD at onset. *A,* Hyperpigmentation of the skin, melanosis of the tongue, and enophthalmos as a sign of dehydration. *B,* Male showing a melanosis of the tongue. *C,* Hyperpigmentation of the nails. See color plate section.

In cases in which there are no clear clinical manifestations of AD, and/or in the presence of adrenal cortex antibodies, it may be necessary to perform an ACTH test (see above, Natural History). TSH levels are increased in 30% of patients, because of the lack of inhibiting effect of cortisol on TSH production or the presence of coexisting autoimmune hypothyroidism (Orth and Kavacs, 1998).

Imaging

Computed tomography (CT) and nuclear magnetic resonance (NMR) show the adrenals with optimal resolution and clarity, and greatly facilitate the diagnosis and characterization of adrenal insufficiency. In patients with AAD, either isolated or as a component of APS syndromes, the adrenal glands appear bilaterally miniscule without calcifications (Doppman, 2001) (Figure 37.6).

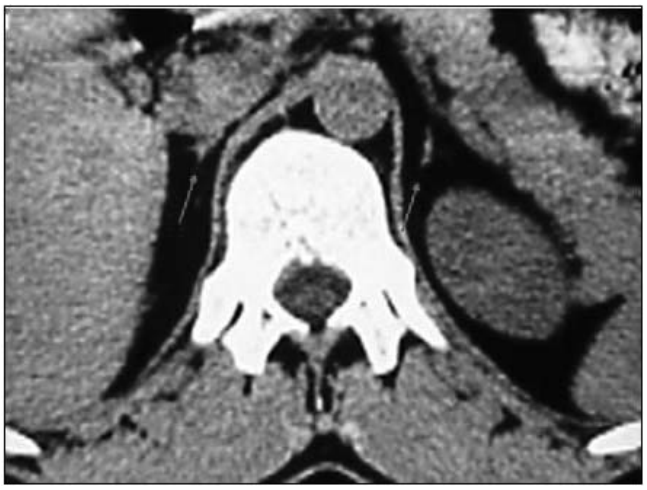

FIGURE 37.6 Adrenal imaging. CT of the adrenal glands of a patient with autoimmune Addison's disease at diagnosis. The adrenals are small (see arrows).

Therapy

The life-saving therapy for patients with chronic adrenal insufficiency is two or three daily doses of a specific hormone replacement (Groves et al., 1988; Williams and

Dluhy, 1998; Arlt and Allolio, 2003). 20–30 mg of hydrocortisone or 25–50 mg of cortisone acetate are required. The first dose is administered in the morning and the second in the afternoon, about 6–8 hours after the first, and the third at 6 pm or at least 4 hours before sleep. Substitutive glucocorticoid therapy is not taken with food. The dosage must be increased for obese individuals and those taking other drugs. Patients should be given relatively small doses to avert weight gain and osteoporosis. ACTH cannot be used for the purposes of treatment surveillance, whereas a 24-hour urinary free-cortisol test is a good marker for correct therapy (Burch, 1982; Howlett, 1997). Mineralocorticoid replacement is usually necessary and can be administered as a single daily dose of 0.05–0.1 mg of fludrocortisone or another aldosterone substitute. Patients should also receive an ample amount of sodium (3–4 g/daily), assessed by measurement of blood pressure, serum electrolytes, and plasma renin activity levels (Williams and Dluhy, 1998).

Complications are rare with this type of therapy. However, possible hypokalemia, hypertension, sodium retention or heart disease should be monitored. Patients with AAD should carry a medical identification card, stating the current therapy and recommendations for emergency situations such as febrile illnesses, injury, vomiting, surgical interventions, dental extractions or pregnancies, when the intake of glucocorticoids must be doubled or tripled (Oelkers, 1996).

Acknowledgments

We would like to thank all those who have cooperated with us over the years regarding the study of the clinical, genetic, immunologic, morphologic, and endocrine aspects of AD. The authors are also grateful to Mrs Helen Maguire for her assistance in reviewing this manuscript.

This work was partially funded by a Grant "Sugli aspetti immunologici della menopausa precoce" from MURST (Ministero dell'Università e della Ricerca Scientifica e Tecnologica.

In 1855, Thomas Addison published observations describing adrenocortical failure (Addison, 1855). This disorder has since been known as Addison's disease (Wilks, 1862). Schmidt (1926) later demonstrated that the detection of lymphocytic infiltration in both the adrenal and thyroid glands is more frequent than expected. The simultaneous occurrence of Addison's disease and thyroiditis became known as Schmidt syndrome (OMIM 269200). Several subsequent publications indicated that idiopathic Addison's disease and thyroid disease are often found together in one patient. In 1959 Beaven and coworkers reported that Addison's disease frequently occurred with diabetes mellitus in the same patient. Some years later, Carpenter et al. (1964) published an observation that insulin-dependent diabetes mellitus is more common in Schmidt syndrome than in the normal population, further establishing the association of the three endocrine diseases. Addison's disease was less frequently associated with diabetes than with thyroid disease, for which the majority of the cases were Hashimoto's thyroiditis.

The first clinical reports on patients with Addison's disease presenting with chronic candidal infection and hypoparathyroidism appeared in the 1950s (Etzel and Robson, 1958) and in the 1960s several reports pointed to the clinical and genetic heterogeneity among patients with Addison's disease (Spinner et al., 1968; Blizzard and Gibbs, 1968), suggesting that, depending on the associated disorders, Addison's disease can be part of two separate clinical syndromes. In 1981, on the basis of previous clinical and laboratory data, the occurrence of Addison's disease, when associated with other diseases, was divided by Neufeld and coworkers (1981) into two autoimmune polyglandular (polyendocrine) syndromes (APS), type 1 and type 2.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

APS-1 (OMIM 240300) has a broad spectrum of clinical manifestations. The disease is also referred to as autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) or polyglandular autoimmune syndrome (PAS) type 1 (Table 38.1). The most frequent clinical entities include chronic mucocutaneous candidiasis, hypoparathyroidism, and Addison's disease. At least two of the three major components need to be present in order to make a diagnosis. Usually, APS-1 starts in childhood with chronic candidiasis as a first manifestation followed by hypoparathyroidism and Addison's disease. Any one of the three major diseases may be absent, and APS-1 may clinically appear in adulthood. In addition, many other components of the disorder have been described in APS-1 patients.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

TABLE 38.1 Prevalences in APS-1 and APS-2 of particular clinical features and accompanying diseases (adapted from Perheentupa, 2002; Betterle et al., 2002; Schatz and Winter, 2002)

Disease components	APS-1	APS-2
Addison's disease	60–100	70–100
Hypoparathyroidism	77–100	Absent
Chronic candidiasis	73–100	Absent
Ectodermal dysplasia	10–77	Absent
Autoimmune thyroid disease	8–18	69–83
Type 1 diabetes	4–23	28–52
Hypogonadism	31–60	9
Alopecia	27–72	2–5
Vitiligo	4–26	4–11
Keratopathy	12–35	Absent
Autoimmune hepatitis	10–19	4
Pernicious anemia	12–15	2–25
Chronic gastritis	6	11

FIGURE 38.2 Vitiligo and nail candidiasis in a patient with APS-1.

FIGURE 38.1 Mucocutaneous candidiasis in a patient with APS-1.

Candida infection appears in more chronic cases as white thrush on the tongue (Figure 38.1). Candidal esophagitis is often present and the infection may spread to nails (Figure 38.2) and in some cases even to skin of the hands and face. Several cases of oral carcinoma have been reported, suggesting that oral candidiasis might be carcinogenic (reviewed in Perheentupa, 2002). Hypoparathyroidism is the most frequent, and sometimes the only, endocrine disease seen in APS-1 patients. For example, in the majority of Iranian Jews and in approximately 20% of Finnish patients, hypoparathyroidism remained the only endocrinopathy. In some cases hypoparathyroidism is followed by adrenocortical insufficiency, with an age at onset of about 4–12 years, but in other cases it may appear at 20 years of age (Perheentupa, 2002). Premature ovarian failure in females is far more common (female-to-male ratio, 3 : 1) than primary testicular failure in males. The blood–testis barrier could be a probable explanation for this gender difference. Type 1 diabetes, hypophyseal failure, autoimmune thyroid disease, keratoconjunctivitis, pernicious anemia, autoimmune hepatitis, and gastrointestinal dysfunctions consisting of malabsorption or diarrhea are less common components of the syndrome. While the chronic candidiasis is most likely due to the defect in cell-mediated immunity, the association of ectodermal dystrophy with autoimmunity is still an open question. Ectodermal skin diseases such as alopecia with patchy loss of hair, alopecia totalis with total hair loss and vitiligo with pigment-free skin areas, enamel hypoplasia and nail dystrophy can be present. In addition, urticaria-like erythema (Perheentupa, 2002) and hyposplenism or splenic atrophy have also been reported in APS-1 patients (Friedman et al., 1991).

APS-2 is a genetically complex disease with a multifactorial etiology. The clinical onset usually occurs in adulthood, although it can start at any time during the lifespan. The classic definition of APS-2 (Neufeld et al., 1981) comprises a combination of Addison's disease with autoimmune thyroid disease or type 1 diabetes, or both (see Table 38.1), although it is obvious that any combinations of autoimmune disorders within the complex represent the same disorder with a probably inherited propensity to develop organ-specific autoimmunity (Schatz and Winter, 2002). Type 1 diabetes develops often before the Addison's disease. Other diseases such as vitiligo, alopecia, hypergonadotropic hypogonadism, and chronic gastritis with or without pernicious anemia may occur but less frequently than in APS-1 and usually not in childhood. The prevalence of APS-2 is estimated to be 1.4–2.0 in 100 000 inhabitants. APS-2 affects

in particular middle-aged Caucasian women with a male-to-female ratio of 1 : 2–3.

APS-3 was included in the original classification of autoimmune polyendocrine syndromes (Neufeld et al., 1981) to define the clinical entity of autoimmune thyroid disease and one or more other autoimmune diseases, excluding Addison's disease. The genetic and etiological background of APS-3 is similar to that of APS-2. Sometimes, APS-4 is also mentioned but we suggest that for clarity, this entire complex of disorders (APS-2, APS-3, and APS-4) should be named APS-2 as distinct from APS-1 (APECED).

AUTOIMMUNE FEATURES

Seminal evidence on the autoimmune pathogenesis of Addison's disease was provided by Anderson et al. (1957) who reported the presence of adrenocortical antibodies (ACA) in patients with Addison's disease using complement fixation. The finding of autoantibodies to adrenal cortex was later confirmed by the immunofluorescence method (Blizzard et al., 1962). With indirect immunofluorescence, ACA were found in 50–90% of patients with Addison's disease (Blizzard and Kyle, 1963; Riley et al., 1980; Sotsiou et al., 1980) but were not detected in the tuberculous form of Addison's disease (Irvine and Barnes, 1975). The autoantibodies are usually IgG (Goudie et al., 1968), predominantly of the IgG1 subclass (Boe et al., 2004), and often react with all layers of adrenal cortex (Irvine and Barnes, 1975). Immunofluorescence studies revealed that in addition to ACA, autoantibodies to the steroid-producing cells (StCA) were consistently present, reacting with the theca interna and corpus luteum of ovary, interstitial cells of testis, and placental trophoblasts (Irvine and Barnes 1975, Maclaren and Blizzard 1985).

The characteristic feature of APS-1 is the presence of high-titer autoantibodies to several tissue-specific autoantigens. The nature of the proteins recognized by the autoantibodies began to emerge in the beginning of 1990s when the adrenal cortex-specific autoantigens were identified. Steroidogenic P450 cytochrome enzymes, steroid 17α-hydroxylase (P450c17 or CYP17), steroid 21 hydroxylase (P450c21 or CYP21) and side chain cleavage enzyme (P450scc or CYP11A1) were identified as the molecular targets of the adrenal specific autoantibodies (Krohn et al., 1992; Winqvist et al., 1992; 1993; 1995; Bednarek et al., 1992; Baumann-Antczak et al., 1992; Uibo et al., 1994). All three enzymes belong to the P450 cytochrome superfamily and are central in the steroidogenic pathway occurring in the adrenal cortex. P450c21 is highly expressed in the adrenal cortex whereas P450c17 and P450scc are also expressed in the gonads.

Autoantibodies to several other self-antigens have been reported in APS-1, which often belong to related protein families. For example, autoantibodies against glutamic acid decarboxylases (GAD65 and GAD67), major autoantigens in type 1 diabetes, are common in APS-1 (Björk et al., 1994; Velloso et al., 1994). Group II pyridoxal phosphate-dependent amino acid decarboxylases are structurally related to GAD enzymes, including aromatic L-amino acid decarboxylase (AADC), histidine decarboxylase (HDC), and cysteine sulfinic acid decarboxylase (CSAD), which all react as autoantigens in APS-1 (Husebye, et al., 1997; Sköldberg et al., 2003; 2004). Another set of autoantigens comprises tryptophan and tyrosine hydroxylases (TPH and TH, respectively), which belong to a group of pteridine-dependent hydroxylases (Ekwall et al., 1998; 2000; Hedstrand et al., 2000). APS-1 patients also develop antibodies to hepatic P450 cytochromes, P4501A2 and 2A6; however, only P4501A2 is associated with autoimmune hepatitis in APS-1 (Clemente et al., 1998; Gebre-Medin et al., 1997). In addition, immunoreactivity to the tyrosine phosphatase-like protein IA-2 (IA-2), intrinsic factor, thyroid peroxidase and thyroglobulin (Perniola et al., 2000) and to a transcription factor SOX10 have been reported (Hedstrand et al., 2001). The patients with hypoparathyroidism were found to have antibodies to calcium sensing receptor protein (Li et al., 1996; Goswami et al., 2004) but the result was not confirmed by other studies (Gylling et al., 2003; Söderbergh et al., 2004). The prevalence of autoantibodies among 90 Finnish, Swedish, and Norwegian APS-1 patients is shown in Table 38.2.

In APS-2, most of the patients have autoantibodies to P450c21, the major autoantigen of Addison's disease (Winqvist et al., 1992; Bednarek et al., 1992; Baumann-Antzcak et al., 1992). The P450c21 autoantibodies have been demonstrated by several methods including immunoblotting with recombinant protein expressed in

TABLE 38.2 Prevalence of autoantibodies in APS-1 patients (adapted from Perniola et al., 2000; Ekwall et al., 2000; Söderbergh et al., 2004; Sköldberg et al., 2003, 2004)

Autoantigen	Prevalence %
Steroid 21 hydroxylase (P450c21)	66
Side chain cleavage enzyme (P450scc)	52
Steroid 17α-hydroxylase (P450c17)	44
Aromatic L-amino acid decarboxylase (AADC)	51
Glutamic acid decarboxylase (GAD65)	37
Histidine decarboxylase (HDC)	37
Cysteine sulfinic acid decarboxylase (CSAD)	3.6
Tryptophan hydroxylase (TPH)	45
Tyrosine hydroxylase (TH)	44
Thyroglobulin (TG)	36
Thyroid peroxidase (TPO)	36
Transcription factor SOX10	22
Cytochrome P4501A2 (P4501A2)	8
Tyrosine phosphatase-like protein IA-2 (IA-2)	7

bacteria, yeast or mammalian cells or by immunoprecipitation with *in vitro* translated protein (for review, see Betterle et al., 2002 and Chapter 37). The P450c21 protein is also the molecular target of the ACA that have been widely used as a diagnostic marker for Addison's disease. In approximately 15–20% of female APS-2 patients, autoantibodies to P450c17 and P450scc are detectable, which are the targets of the StCA (Hoek et al., 1997; Betterle et al., 2002). APS-2 patients with type 1 diabetes frequently have autoantibodies to GAD65 and/or IA-2 protein. Autoantibodies to thyroid peroxidase proteins are common in patients with autoimmune thyroiditis.

GENETIC FEATURES

APS-1 is inherited in an autosomal recessive manner and occurs as a defect in the autoimmune regulator (AIRE) gene (Figure 38.3). The prevalence worldwide is very low and is population dependent. The frequency is higher among certain populations such as Finns (1/25,000), Sardinians (1/14,400) and Iranian Jews (1/9000), and lower among Norwegians, (1/80,000). A high prevalence (1/4400) occurs in the small town of Bassano del Grappa in Northern Italy (Betterle et al., 2002).

AIRE, the gene mutated in APS-1, was identified by positional cloning on chromosome 21q22.3 (Nagamine et al., 1997; Finnish-German Consortium 1997). To date, around 50 mutations have been found in the AIRE gene (reviewed in Heino et al., 2001; Kumar et al., 2002). The mutations are spread throughout the coding region but two mutational hotspots have emerged. The most common mutation is amino acid arginine change to stop codon (R257X) in exon 6, which is found in 83% of the Finnish APS-1 chromosomes (Björses et al., 2000). The R257X mutation is also common in Northern Italian and Eastern European APS-1 patients (Scott et al., 1998; Björses et al., 2000; Cihakova et al., 2001). The other frequently occurring mutation, 1094-1106del13bp, is the most common mutation in Anglo-American APS-1 patients, accounting for 70% of British and 53% of North American APS-1 alleles, as well as being reported in several APS-1 cases from other populations (Wang et al., 1998; Pearce et al., 1998; Heino et al., 1999). A large proportion of the AIRE mutations are nonsense mutations or deletions/insertions, usually resulting in a truncated protein lacking the PHD fingers, one of the characteristic domains of the protein. Most of the missense mutations occur in the N-terminal of AIRE, a region responsible for the homodimerization of the protein (reviewed in Pitkänen and Peterson, 2003).

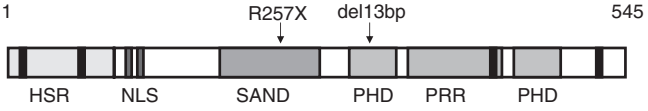

FIGURE 38.3 Schematic outline of the different domains of the AIRE protein. HSR: homogeously staining region, also present in Sp100 and Sp 140, a region that mediates homodimerization; NLS: nuclear localization signal; SAND: a putative DNA-binding region; PHD: plant homeodomain zinc fingers; PRR: proline-rich region. The four black boxes correspond to nuclear receptor binding LXXL motifs. The most common mutation in the Finnish population (R257X) and another common mutation, a 13 bp deletion, are denoted with arrows. The numbers correspond to the first and last amino acids of the protein. See color plate section.

Despite considerable variation in the APS-1 phenotype, no clear correlation with genotype has been found. The growing number of AIRE mutations will enable us to draw better conclusions in the future. However, it is evident now that other factors influence the outcome of the disease components. As an example, there is significant clinical variation among Finnish APS-1 patients carrying a homozygous R257X mutation and several reports describe intrafamilial differences among siblings having an identical AIRE genotype (Halonen et al., 2002).

APS-1 has no clear association with the HLA region, although some components of the disease seem to correlate with certain HLA alleles or haplotypes. For example, in one study, Addison's disease was found to be associated with HLA DRB1*03, alopecia with DRB1*04-DQB1*0302 and type 1 diabetes correlated negatively with DRB1*15-DQB1*0602 (Halonen et al., 2002). However, another study did not find an association with HLA alleles (Gylling et al., 2003).

APS-2, in contrast to APS-1, is a genetically complex disease. As for most autoimmune diseases, APS-2 is strongly associated with the HLA gene locus in chromosome 6p21. Genetic studies have demonstrated a consistent association of APS-2 with HLA DRB1*0301 (DR3), DQA1*0501 and DQB1*02 (DQ2) alleles, which are in strong linkage equilibrium with each other (Maclaren and Riley, 1986; Partanen et al., 1994). The haplotype is associated with isolated disease components of APS-2, type 1 diabetes, Graves' disease, autoimmune hypothyroidism, and Addison's disease. Most of the studies have not elucidated which of these three alleles is the primary etiological genetic factor. Another haplotype, consisting of DRB1*04 (DR4) DQA1*0301 DQB1*0302 (DQ8), is also associated with type 1 diabetes and Addison's disease (Partanen et al., 1994; Myhre et al., 2002) and the existence of both risk haplotypes in one individual confers high susceptibility for type 1 diabetes or Addison's disease alone or in combination. In addition, Myhre et al. (2002) reported that the haplotype DRB1*01 (DR1) DQA1*0101 DQB1*0501 (DQ5) is protective against Addison's disease. Alleles of other genes located in HLA region, such as TNF, P450c21 and MIC-A gene, have been associated with APS-2 (Partanen et al., 1994; Peterson et al., 1995; Gambelunghe et al., 1999) but

these associations are most likely to be secondary to the strong linkage disequilibrium in the HLA region and thus are not primary associations.

The cytotoxic T lymphocyte-associated protein-4 (CTLA-4) gene on chromosome 2q33 is associated with autoimmune endocrinopathies from different populations (reviewed in Vaidya and Pearce, 2004). In particular, the allelic variants of an A to G single nucleotide polymorphism at position 49 and microsatellite marker in the 3′ untranslated region of the CTLA-4 gene are associated with type 1 diabetes and thyroiditis in Italian, German, and British patients (Levin and Tomer, 2003). The CTLA-4 association with Addison's disease and APS-2 with 3′ untranslated region microsatellite was significantly increased among English but not among Norwegian, Finnish, and Estonian patients (Kemp et al., 1998). In another study on English patients with autoimmune Addison's disease and APS-2, a strong association of the G allele at position 49 was found with Addison's disease as a component of APS-2 (Vaidya et al., 2000). Recently, autoimmune disease susceptibility was mapped to a noncoding 6.1 kb 3′ region of CTLA-4, the common allelic variation of which was correlated with lower messenger RNA levels of the soluble alternative splice form of CTLA-4 (Ueda et al., 2003). Additionally, a number of other susceptibility genes have been characterized in APS-2; however, their role is not so universal and they will not be discussed here. These studies are reviewed by Redondo and Eisenbarth (2002), Bottini et al. (2004), MacMurray et al. (2004) and others.

An influence of AIRE gene polymorphisms in APS-2 or other major autoimmune diseases is possible but analyses of the AIRE mutations R257X and 967-979del13bp indicated no contribution to the susceptibility to type 1 diabetes, Graves' disease or autoimmune hepatitis (Vaidya et al., 2000; Nithiyananthan et al., 2000; Meyer et al., 2001; Djilali-Saiah et al., 2004).

ENVIRONMENTAL FEATURES

The environmental factors involved in autoimmune polyendocrine syndromes are less evident than genetic factors. A recent increase in the incidence of type 1 diabetes mellitus and probably other autoimmune endocrine diseases and polyendocrine syndromes in most of the developed countries points to the novel environmental influences as the genetic background has largely remained unchanged. The role of environment has been best studied in patients with type 1 diabetes (see Chapter 36), in which analysis of twins shows that the genetic background cannot be the only reason for the disease (Hyttinen et al., 2003). National prosperity and good hygiene levels seem to correlate in uncertain ways with type 1 diabetes (Patterson et al., 2001). The role of viral infections in polyendocrinopathies remains unclear.

ANIMAL MODELS

Spontaneous Animal Models

The most studied spontaneous animal models for polyendocrine autoimmunity are the Bio-Breeding (BB) rat, Komeda diabetes-prone (KDP) rat, nonobese diabetic (NOD) mouse, and obese-strain (OS) White Leghorn chicken.

The BB rat develops type 1 diabetes which is clinically similar to the diabetes seen in humans. In addition to destruction of the insulin-producing pancreatic β cells, BB rats frequently have lymphocytic infiltration in the thyroid gland, usually without hypothyroidism, but the thyroiditis can be potentiated by feeding rats with a high iodine diet (Allen et al., 1986). No evidence of lymphocytic infiltration to the adrenal gland has been observed but autoantibodies to gastric parietal cells and smooth muscle have been reported (Crisa et al., 1992). BB rats have severe T-cell lymphopenia which is a recessive trait and important in the development of diabetes. The mononuclear infiltration into islets starts within the first 3 weeks of life and the diabetes develops at 8–12 weeks. Genetic backcross experiments showed that both insulitis and thyroiditis develop through common immune defects involving T-cell lymphopenia, but the susceptibility of MHC class II alleles for disease development is distinct for insulitis and thyroiditis (Awata et al., 1995).

At least three susceptibility genes are important in development of diabetes in the BB rat: IDDM2 in the MHC gene region on chromosome 20, Ian5 (immune-associated nucleotide 5 on chromosome 4 (also called Ian4, IDDM1 or lyp), which is responsible for the lymphopenia (MacMurray et al., 2002; Hornum et al., 2002; Moralejo et al., 2003), and a third, so far unmapped gene on chromosome 2 (Jacob et al., 1992). Ian5 is a GTO-binding protein highly expressed in lymph node and spleen, and regulates apoptosis in the T-cell lineage (MacMurray et al., 2002).

Similarly to the BB rat, the KDP rat develops autoimmune diabetes but without significant T-cell lymphopenia. The disease onset is rapid with development of 100% diabetes by the age of 30 weeks (Yokoi et al., 1997). Both sexes are equally affected. In addition to pancreatic islets, KDP rats have severe lymphocyte infiltration into the thyroid glands and mild to moderate infiltration into the submandibular glands, kidney, adrenals, and pituitary (Yokoi et al., 1997). Most of the genetic predisposition to autoimmunity in the KDP rat is due to a specific nonsense mutation (R455X) in the Cblb (Casitas B-lineage lymphoma b) gene identified by positional cloning (Yokoi et al., 2002). Cblb is a ubiquitine ligase that negatively controls the CD28 costimulatory molecule in T-cell activation. T cells from homozygous Cblb-deficient mice do not require the CD28 costimulatory signal for activation and develop spontaneous

autoimmunity with T- and B-cell infiltrations in multiple organs (Bachmaier et al., 2000). It should be noted that neither Ian5 nor Cblb genes have been found so far as susceptibility genes for human type 1 diabetes (Payne et al., 2004; Kosoy et al., 2004) and hence it is unlikely that these genes will contribute to either type of APS.

The NOD mouse is mostly studied as a model for type 1 diabetes. In addition to pancreatic β-cell destruction, NOD mice have autoimmunity to submandibular and lacrimal glands, although to a lesser extent. The incidence of thyroiditis is low but high iodine in the diet has a triggering effect on development of thyroiditis (Many et al., 1996). Lymphocytic infiltration in the adrenal and parathyroid glands has been described in NOD mice (Krug et al., 1991; Beales et al., 2002). Insulitis starts at an early age (4–5 weeks old), reaching 70–90% by 9 weeks. Diabetes is mild and more prevalent in females (80–90%) than males (10–50%). The incidence of submandibular and lacrimal gland infiltration seems not to be secondary to insulitis and is more prevalent in females.

The genetic background of the NOD mouse has been extensively studied and approximately 20 different genetic loci have been reported (reviewed in Johansson et al., 2003, and see Chapter 36). IDDM1 located in the MHC gene region ($H2^{g7}$ on chromosome 17) is the major locus for diabetes. Additionally, the IDDM3 region and Il2 gene on chromosome 3, CTLA-4 and CD28 on chromosome 1, and CD30 and Tnfr2 on chromosome 4 have been suggested to be important. Genetic segregation experiments indicate a genetic heterogeneity in terms of different autoimmune disorders in the NOD mouse; it seems that each disorder is mainly controlled by unique sets of disease-promoting alleles but that some disorders are more similar than others (Johansson et al., 2003). In addition, many transgenic, gene-targeted and congenic variations of NOD mice have been developed with variable effects on development of diabetes (reviewed in Yang and Santamaria, 2003, and see Chapters 26 and 36). Despite the similarities between human type 1 diabetes and diabetes in the NOD mouse, it should be noted that NOD mice do not develop autoantibodies against the major human autoantigen GAD65 (Velloso et al., 1994; Mackay et al., 1996).

The OS chicken spontaneously develops lymphocytic thyroiditis and autoantibodies to adrenal gland. Mononuclear infiltration starts in the second week of life and results in complete destruction of the thyroid gland by 1–2 months of age. OS chickens, however, do not have adrenal insufficiency or type 1 diabetes.

Experimentally Induced Animal Models

One of the well-studied mouse models is thymectomy at day 3 in the BALB/C strain, which leads to multiorgan autoimmunity characterized by gastritis, thyroiditis, oophoritis, and other infiltrations. The infiltrations are T-cell dependent and the mice develop autoantibodies to affected tissues. Thymectomy-induced autoimmunity is strictly dependent on time of thymectomy, i.e., between the second and fifth days after birth. The autoimmunity occurs due to a lack of $CD4^+CD25^+$ regulatory T cells (see Chapter 26), which migrate out of the thymus in the early neonatal period, and injection of purified regulatory T cells back into the thymectomized mice prevents autoimmunity (reviewed in Sakaguchi et al., 2001).

Several transgenic and knockout animal models develop endocrine autoimmunity (reviewed in Lam-Tse et al., 2002). The transgenic models often use expression of autoantigen, MHC or costimulatory molecules in a tissue-specific manner, or overrepresentation of a certain T-cell receptor repertoire. The models are useful but often represent exaggerations of native autoimmune process. From gene knockout models, two recently generated mouse models have emerged: AIRE- and FoxP3-deficient mice, representing respectively APS-1 and IPEX (immune dysregulation, polyendocrinopathy, enteropathy, and X-linked inheritance) diseases in humans. AIRE-deficient mice do not express self-antigens in the thymus; hence there is impaired elimination of self-reactive T cells and as a result, the mice develop lymphocytic infiltrations and autoantibodies to multiple organs (see below). FoxP3 is a forkhead transcription factor family member that is essential for development in thymus of the $CD4^+CD25^+$ regulatory T cells which participate in the maintenance of immunologic tolerance (Fontenot et al., 2003; Khattri et al., 2003; Ochs et al., 2005; see Chapter 9). $CD4^+CD25^+$ regulatory T cells have been shown to suppress several experimental models of organ-specific autoimmune diseases. Lack of FoxP3 expression in mice leads to the overproliferation of $CD4^+$ lymphocytes with multiorgan infiltration and to elevation of numerous cytokines (Gavin and Rudensky, 2003).

PATHOGENIC MECHANISMS

The endocrine glands in APS-1 and APS-2 are affected by a similar histologic autoimmune destruction. The tissue is gradually destroyed, resulting in atrophy, or parenchymal cells are replaced by fat cells (Perheentupa, 2002). Adrenalitis in APS patients appears to be diffuse, affecting all three layers of the cortex. As an indication of T-cell-mediated autoimmunity, it mainly consists of lymphocytes but macrophages and plasma cells have also been detected (Carpenter et al., 1964; Muir et al., 1993). Indeed, there is significant support for a direct pathogenic role of T cells in autoimmune endocrine diseases, exemplified by type 1 diabetes as the most studied disorder among endocrinopathies (reviewed in Roep, 2002). Treatment with immunosuppressive drugs, cyclosporine A, directed against T cells, will

produce temporary remission of the disease in APS-2 patients (Csaszar and Patakfalvi, 1992). However, it has been difficult to characterize autoreactive T cells in APS patients, partly due to the lack of specific and sensitive methods, and to T cells that, in contrast to autoantibodies, are sequestered in the specific tissue lesions (Roep, 2002). Interestingly, a recent report by Kriegel and coworkers (2004) suggested that $CD4^+CD25^+$ regulatory T cells from peripheral blood of APS-2 patients are functionally defective in their suppressive capacity despite no evident differences in their quantity or in their T-cell surface markers between the patients and controls. The results concur with depletion of regulatory T cells in mice causing a syndrome resembling APS-2 (Sakaguchi et al., 2001). Although further confirmatory experiments are needed, these data highlight the possibility that an impaired function of regulatory T cells may have a pathogenic role in APS-2.

Autoimmunity in APS-1 is due to defective central tolerance to the autoantigens. Using a microarray approach and a gene knockout mouse as a model, Mathis and coworkers showed that AIRE gene deficiency in mice results in defective expression of the tissue-specific autoantigens in thymus, where negative selection of autoreactive T cells occurs (Anderson et al., 2002). The AIRE gene is predominantly expressed in thymic medullary epithelial cells (Figure 38.4) and acts as a transcriptional activator (reviewed in Pitkänen and Peterson, 2003). The lack of the AIRE expression in thymus thus leads to a defect in clonal deletion of autoreactive T cells and ultimately to autoimmunity (Liston et al., 2003; Mathis and Benoist, 2004). AIRE may regulate the processing and/or presentation of self-proteins so that the maturing T cells can recognize these self-antigens (Kuroda et al., 2005). AIRE also seems to have a role in peripheral tolerance as the peripheral T cells of AIRE-deficient mice have increased proliferative responses to foreign antigen (Ramsey et al., 2002). However, direct data are lacking on clonal deletion in human APS-1 patients. A report by Sediva et al. (2002) detected low IFN-γ levels in patients with APS-1 and marked elevation of IgM and an increase of numbers of $CD3^+CD4^+$ lymphocytes. Interestingly, fathers of APS-1 patients had elevated levels of IgA and activated T lymphocytes, which may indicate that heterozygous AIRE mutations may contribute at least to subclinical autoimmunity.

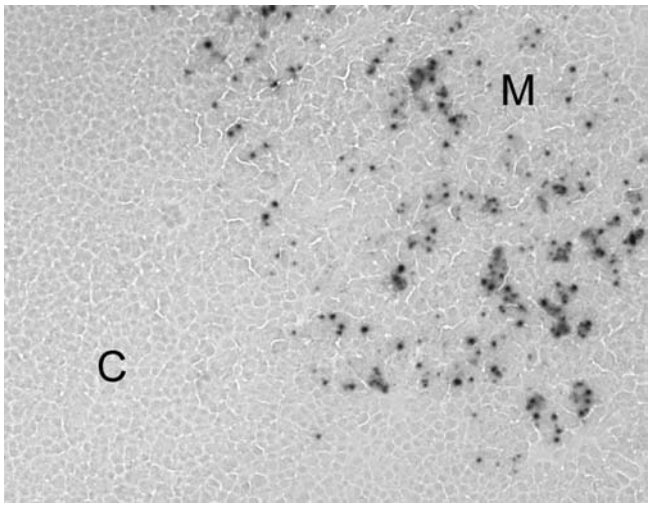

FIGURE 38.4 AIRE expression in thymic medullary epithelial cells visualized by beta-galactosidase staining of the heterozygous AIRE-deficient mouse thymus. The beta-galactosidase reporter gene has been inserted into the AIRE gene locus in these mice. C: cortex; M: medulla. ×200. Courtesy of Kaidi Möll and Dr Hamish Scott.

IMMUNOLOGIC MARKERS IN DIAGNOSIS

Autoantibodies are often diagnostic or even predictive markers for the clinical disease. In APS-1, for example, autoantibodies to the steroidogenic enzymes (P450c21, P450c17, and P450scc) are significant markers for Addison's disease. Antibodies against at least one of the three antigens are found in 84% of patients with Addison's disease (Söderbergh et al., 2004). As another example, hypogonadism is strongly associated with the presence of autoantibodies to P450scc protein. Autoantibodies to GAD65 that have high clinical association with isolated type 1 diabetes or diabetes in APS-2 are also associated with type 1 diabetes in APS-1. Autoantibodies to the IA-2 antigen, however, seem to have the strongest association with type 1 diabetes in APS-1 (Söderbergh et al., 2004). Autoantibody analyses in patients with APS-1 indicate serologic markers for hepatitis (aromatic L-amino acid decarboxylase, cytochrome P450 1A2 or tryptophan hydroxylase), gastrointestinal dysfunction (tryptophan hydroxylase), and vitiligo (SOX10; Hedstrand et al., 2001). Table 38.3 summarizes the associations between disease components and the presence of the more common autoantibodies in APS-1.

The vast majority (up to 90%) of patients with APS-2 have ACA or autoantibodies to P450c21. The titers of autoantibodies decrease to some extent as the disease progresses and therefore, the diagnostic value of the autoantibodies is highest at the onset of Addison's disease. P450c21 autoantibodies are generally a better marker for autoimmune Addison's disease than ACA, but it has been reported that 100% of APS-2 patients at the clinical onset of Addison's disease are positive for ACA (Betterle et al., 2002). The presence of ACA or anti-P450c21 antibodies in patients with autoimmune thyroid disease or type 1 diabetes but without Addison's disease (Barker et al., 2005) would indicate subclinical hypoadrenalism and be a predictive marker for later development of overt Addison's disease, although the

TABLE 38.3 Associations between APS-1 disorders and antibody reactivity (adapted from Söderbergh et al., 2004)

Disease	Autoantigen	Sensitivity %	Specificity %	Risk ratio
Addison's disease	Steroid 21 hydroxylase (P450c21)	75	63	7.9
	Sidechain cleavage enzyme (P450scc)	68	74	7.0
	Steroid 17α-hydroxylase (P450c17)	65	68	9
Hypogonadism	Sidechain cleavage enzyme (P450scc)	75	76	12.5
Type 1 diabetes	Tyrosine phosphatase-like protein IA-2 (IA-2)	33	87	14.9
Vitiligo	Aromatic L-amino acid decarboxylase (AADC)	63	69	3.8
	Glutamic acid decarboxylase (GAD65)	56	63	3.3
Hepatitis	Tryptophan hydroxylase (TPH)	86	79	27.0
	Cytochrome P4501A2 (P4501A2)	71	76	17.5
	Aromatic L-amino acid decarboxylase (AADC)	79	75	16.4
Intestinal dysfunction	Glutamic acid decarboxylase (GAD65)	75	74	10.8
	Tryptophan hydroxylase (TPH)	80	64	7.5

progression to overt disease may take years. StCA or autoantibodies to P450c17 and/or P450scc, when occurring in APS-2 patients, are good markers for gonadal insufficiency. For example, 85–100% of APS-2 patients with premature ovarian failure had detectable StCA (Betterle et al., 2002). StCA are also found in 18–40% of APS-2 patients without gonadal insufficiency (Hoek et al., 1997) and follow-up of StCA positive patients with Addison's disease has shown a high risk of developing gonadal failure in females but not in males (Betterle et al., 2002).

TREATMENT AND OUTCOME

In patients with APS-1, anticandidal drugs such as amphotericin B, ketoconazole or fluconazole are used in treatment of the candidiasis. Itraconazole has been reported to be effective for nail candidiasis but 4–6 months' treatment is needed to eliminate the infection (Perheentupa, 2002). Clinical follow-up of oral candidal infection is needed at least once or twice a year and because of the risk of cancer, attention should be paid to suppression of the oral infection. Replacement therapy with hormones has been efficiently used for Addison's disease and hypoparathyroidism. Patients with Addison's disease are treated with hydrocortisone at the smallest dose that relieves symptoms, usually 10 + 5 + 5 mg a day. The patients should also receive fludrocortisone as a substitute for aldosterone.

The therapy of hypoparathyroidism is aimed at maintaining a normal calcium plasma level and serum calcium and phosphate levels should be monitored regularly. Therapies are calciferol sterols (vitamin D hydroxylated forms, usually calcitriol) and calcium salt preparations, preferably calcium carbonate, but these do not efficiently substitute for parathyroid hormone and are difficult to regulate. As the calcium levels may vary significantly over a short time, there are significant risks of both hypo- and hypercalcemia. The patients should receive advice and written information about the symptoms, complications, and risk elements of the disease (Perheentupa, 2002). Recently available recombinant PTH may significantly improve the treatment of hypoparathyroidism in APS-1 patients.

CONCLUDING REMARKS—FUTURE PROSPECTS

Recent years have seen remarkable progress in our knowledge of the mechanisms of autoimmune polyendocrinopathies, including a clear pathogenetic distinction between APS-1 and APS-2. The endocrine organs, which often express tissue-specific proteins, are destroyed with high precision by the autoimmune reaction. The identification of the autoantibody targets in APS-1 has revealed that the autoantigens often belong to related protein families, raising the question of exactly how the immune system selects specific targets for autoimmune reactivity. The findings in AIRE-deficient mice suggest that AIRE has an important role in T-cell negative selection in being responsible for the expression of multiple tissue-specific autoantigens in thymus. From these data, many new questions also arise, including the molecular mechanism by which AIRE activates these genes and regulation of the expression of AIRE itself. According to expression microarray experiments in the mouse, AIRE activates approximately 1000 different tissue-specific genes in the thymus, and whether all of these proteins represent potential APS-1 autoantigens remains to be clarified.

Regulatory T cells have now been convincingly demonstrated to control self-reactive T cells and prevent autoimmunity. However, their role in complex autoimmune diseases has been unclear so far. Recent data showing that

regulatory T cells from APS-2 patients are defective in their suppressive capacity provide the first progress in this direction. It remains to be studied whether AIRE-regulated tissue-specific antigens could, in addition to deletion of reactive T cells, also promote development of regulatory T cells in the thymus. Further studies are needed to confirm these possibilities.

Systematic analyses of autoantigens and autoantibodies have provided a basis for clinical diagnostic approaches and will be useful in the prediction of autoimmune disease entities in subjects at high risk of developing the diseases. Much current research effort is going into the identification of genes involved in APS-2. Clearly, MHC genes have the dominant role and the CTLA-4 gene is a good example of another gene involved. It can be expected that, with the advent of whole genome scans, more genetic associations will be identified in future. Environmental factors in APS-2 certainly remain to be clarified and deserve more attention. Although a monogenic disease, APS-1 also seems to be influenced by environmental and/or other genetic factors to account for the variety of clinical symptoms and disease expressions. The possibility that heterozygous deficiency of AIRE, in combination with other genetic defects, might contribute to the occurrence of autoimmunity is worthy of further investigation.

Acknowledgments

The authors are grateful to Professor Ian Mackay and Professor Kai Krohn for their valuable comments on the manuscript.

Gastritis and Pernicious Anemia

BAN-HOCK TOH, SENGA WHITTINGHAM, AND FRANK ALDERUCCIO

Department of Immunology, Monash University Medical School, Prahran, Victoria 3181, Australia

Autoimmune gastritis is an asymptomatic and innocuous autoimmune disease. It claims significance among the autoimmune diseases because it is a forerunner of pernicious anemia.

At a South London Medical Society meeting in 1849, Thomas Addison reported the clinical features of a new disease that he described as a "very remarkable form of general anemia." In a lecture in 1860, Austin Flint linked the anemia to a "degenerative disease of the glandular tubuli of the stomach." Histologic evidence of the gastric atrophy was provided by Samuel Fenwick in 1870. A year later in 1871, a fatal anemia was termed *perniciosa* by Anton Biermer. Subacute combined degeneration was later applied to the posterolateral spinal cord lesions that can be associated with the anemia (Russell et al., 1900).

At first the causal connection between pernicious anemia and chronic gastritis was incomprehensible. In 1926 Minot and Murphy observed that feeding patients with large meals of cooked liver led to a reticulocyte response and cured the anemia (Minot and Murphy, 2001). Later Castle (1953) showed that the anemia was a result of a combined deficiency of an "extrinsic factor" subsequently identified as vitamin B12 and present in the liver (Lester-Smith, 1948; Rickes, 1948), and an "intrinsic factor" (IF) in gastric juice (Highley et al., 1967). Oral treatment with extracts of hog stomach (Sharp, 1929; Sturgis and Isaacs, 1929) resulted in remission for several years (Wilkinson, 1949). However, relapses tended to occur and some cases became refractory to increasing amounts of the extract (Berlin et al., 1958). This refractory state was due to a serum factor that inhibited the effectiveness of intrinsic factor (Schwartz, 1958). Subsequently, sera from patients with pernicious anemia were shown to contain autoantibodies to intrinsic factor (Jeffries et al., 1962; Jacob and Schilling, 1966; Bardhan et al., 1968) and to gastric parietal cells (Irvine et al., 1962; Markson and Moore, 1962; Taylor et al., 1962). However, little progress was made in understanding the pathology of the gastric lesion until a flexible biopsy tube was designed that permitted the taking of samples of the gastric mucosa for histologic examination (Wood et al., 1949).

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Pernicious anemia was observed to cluster in families (McIntyre et al., 1959; Whittingham et al., 1969) and to coexist with autoimmune thyroid diseases (Tudhope and Wilson, 1960), to which the term "thyrogastric autoimmunity" was applied (Whittingham et al., 1975). These observations suggested a genetic component to the disorder, a suggestion further strengthened by an association with another endocrine autoimmune disease, type 1 diabetes mellitus (Ungar et al., 1968). The suggestion by Taylor (1959; 1961) that the inhibitory substance to gastric intrinsic factor in the serum of patients with pernicious anemia was antibody and possibly autoantibody and the recognition that pernicious anemia fulfilled the markers of autoimmune disease put forward by Mackay and Burnet (1963) led to its acceptance as an autoimmune disease of the stomach and to the central questions of concern to immunologists today: What is the mechanism of immunologic tolerance to self, how is it abrogated to induce autoimmune lesions in tissues and how can tolerance be reestablished to prevent and reverse disease?

DIAGNOSIS

Autoimmune gastritis is in the early stages of the disease clinically "silent" and demonstrable only by serologic detection of antibodies to gastric parietal cells. It is only when stores of vitamin B12 are depleted that pernicious anemia manifests itself clinically. Only a small proportion (10–15%) of patients with autoimmune gastritis develop pernicious anemia (Irvine et al., 1974; Strickland and Mackay, 1973) after a latent period of 20–30 years (Toh et al., 1997). Nonetheless, at an estimated prevalence of about 2% in Western adult populations at or over the age of 60 years, pernicious anemia represents the commonest cause of vitamin B12 deficiency (Carmel, 1996). Although "silent" until the end stage, the gastric lesion can be predicted years before clinical presentation by immunologic markers specific for gastric autoimmunity. Terminally, the gastritis results in deficiency of intrinsic factor, a protein that binds avidly to dietary vitamin B12 (Glass, 1963) and promotes its transport to the terminal ileum for absorption (Donaldson et al., 1967; Kapadia et al., 1983) by ileal cubulin receptors, a multifunctional endocytic receptor (Lindblom et al., 1999). Consequently, the gastritis is expressed clinically as vitamin B12 deficiency associated with megaloblastic anemia arising as a consequence of the requirement of the vitamin for DNA synthesis. The megaloblastic anemia is demonstrated by examination of blood and bone marrow (Chanarin, 1979). The anemia was indeed "pernicious" when first discovered but is now readily controlled by vitamin B12 treatment.

Clinical Features

Pernicious anemia is uncommon before the age of 30. Racial groups other than those from northern Europe are not exempt as the disease has been reported in blacks and in Latin-Americans, with an earlier age of onset in black women (Carmel and Johnson, 1978). Advanced stages of pernicious anemia are rarely seen these days but the prototype would be a person, usually a woman in late middle age, who appears pale, tired, and depressed and may complain of a sore tongue and abdominal discomfort. There may be accompanying neuropsychiatric syndromes in about 40% of patients arising from progressive demyelination in the spinal cord (subacute combined degeneration), peripheral nerves, and cerebrum (Savage and Lindenbaum, 1995). The first neurologic abnormality is usually sensory impairment, most often presenting as distal and symmetrical paresthesiae of the lower limbs and frequently associated with ataxia. Corticospinal tract involvement is common in more advanced cases, with abnormal reflexes, motor impairment and, ultimately, spastic paraparesis. A minority of patients exhibit mental or psychiatric disturbances or autonomic signs but these rarely if ever occur in the absence of other neurologic changes. Neuropsychiatric abnormalities occur in about 30% of patients with vitamin B12 deficiency in the absence of anemia or psychosis (Lindenbaum et al., 1995).

Pernicious anemia associates predominantly with the autoimmune endocrinopathies and the antireceptor autoimmune diseases. The associated diseases include Hashimoto's thyroiditis, insulin-dependent type 1 diabetes mellitus, primary Addison's disease, primary ovarian failure, primary hypoparathyroidism, premature graying of the hair, vitiligo, thyrotoxicosis, myasthenia gravis, and the Lambert-Eaton syndrome (Table 39.1). These organ-specific "thyrogastric"

TABLE 39.1 Diseases associated with pernicious anemia that cluster in "PA families"

Diseases	References
Thyrotoxicosis, Hashimoto's thyroiditis	Ardeman et al. (1966b)
Primary hypothyroidism	Irvine et al. (1965), Irvine (1975), Schiller et al. (1968), Tudhope and Wilson (1960)
Insulin-dependent diabetes mellitus	Irvine et al. (1970), Whittingham et al. (1971)
Primary Addison's disease	Blizzard et al. (1967), Irvine (1978)
Primary ovarian failure	Irvine and Barnes (1974)
Primary hypoparathyroidism	Blizzard et al. (1966)

Vitiligo	Bor et al. (1969)
Myasthenia gravis	Mackay (1971)
Lambert–Eaton syndrome	Guttmann et al. (1972)

autoimmune diseases not only may occur in the same patient with pernicious anemia but aggregate in "pernicious anemia families" (Ardeman et al., 1966a; Wangel et al., 1968; Whittingham et al., 1969).

Immunologic Diagnostic Markers

Two circulating autoantibodies, parietal cell antibodies directed to gastric H^+/K^+ ATPase and autoantibodies to intrinsic factor, are typically found in patients with autoimmune gastritis or with autoimmune gastritis and pernicious anemia.

Parietal cell antibodies to gastric H^+/K^+ ATPase are diagnostic of the underlying pathologic lesion of autoimmune gastritis as gastric biopsies carried out in asymptomatic patients have revealed the presence of type A gastritis (Uibo et al., 1984). However, it is not known whether the titer of these antibodies reflects the severity of the underlying gastric pathology. These antibodies are routinely detected by indirect immunofluorescence or, to gastric H^+/K^+ ATPase, by ELISA (Chuang et al., 1992). Antibodies to gastric parietal cells are demonstrated by serum reactivity with the cytoplasm of gastric parietal cells in unfixed, air-dried, and frozen sections of mouse stomach (see Figure 39.4). Mouse stomach is preferable to rat stomach because of a lower frequency of heterophile reactions (Muller et al., 1971) that could be misinterpreted as antibody to parietal cells. The antibodies are detected by immunofluorescence in ~90% of patients with pernicious anemia, with a prevalence of 2–5% in the general population, and in about 30% of patients with other thyrogastric autoimmune diseases, including type 1 diabetes mellitus (De Block et al., 2001; 2003). These antibodies also increase in prevalence with age and are associated with rising serum gastrin levels (Jassel et al., 1999; De Block et al., 2001). With progression of autoimmune gastritis and the total loss of parietal cell mass, the prevalence of these antibodies decreases, possibly due to loss of antigenic drive (Davidson et al., 1989), and this may also explain the lower antibody prevalence (55%) in one study of pernicious anemia (Carmel, 1992).

For the diagnosis of pernicious anemia, intrinsic factor antibodies have a much higher disease specificity, albeit lower sensitivity than antibodies to gastric parietal cells. Titers of intrinsic factor antibodies appear to be of no value in predicting the development of pernicious anemia (Irvine et al., 1974). Since the Schilling test is no longer used as a diagnostic procedure, there has been increased dependence on intrinsic factor antibodies for diagnosis. Antibodies to the vitamin B12 binding site of intrinsic factor are demonstrable in serum of ~70% of patients and to a second site in ~50%. These frequencies are greater if gastric juice is assayed. There may be coexisting autoantibodies specific for the various other autoimmune diseases in the thyrogastric cluster (Table 39.2). The epitope for anti-intrinsic factor autoantibodies to the vitamin B12 binding site is located between amino acids 251 and 265 of the protein (Gueant et al., 1997) and is homologous with peptides from herpes virus Saimiri and from pathogenic *E. coli*. The incidence of these antibodies rises with increasing duration of disease, almost doubling after 10 years (Ungar et al., 1967). To explain these specificities, it is tempting to speculate that the production of autoantibodies to intrinsic factor and to the gastric H^+/K^+ ATPase is a consequence of intermolecular determinant spreading (Sercarz, 2000) from a membrane-associated self-antigen (gastric H^+/K^+ ATPase) to a secretory protein (intrinsic factor) in the gastric parietal cell.

Other Laboratory Indices

At the stage of pernicious anemia, all patients have a serum vitamin B12 level of <200 pg/ml (Ungar et al., 1968); >95% will have a level of serum pepsinogen I <20 ng/ml (Samloff et al., 1982); and 75–80% will have a serum gastrin level >100 pm liter (Varis et al., 1979). In keeping with the sparing of the antrum from the inflammatory process, the level of pepsinogen II is normal and the low ratio (<1.0; normal 6.2) of pepsinogen I to pepsinogen II is predictive of the histologic status of the gastric mucosa (Samloff et al., 1982). At earlier stages of autoimmune gastritis when the destructive lesion is "silent," there may be a reduction in levels of these various laboratory indices suggestive of the disease process that can eventually lead to pernicious anemia (Irvine et al., 1974). A biopsy of the stomach shows marked reduction of the secretory glands of the stomach or frank gastric atrophy (Figures 39.1 and 39.3), varying degrees of intestinalization (metaplasia) of the gastric glands (Strickland and Mackay, 1973) (Figure 39.3), and in the earlier lesions (Figure 39.3), prominence of lymphocytes and plasma cells in the inflammatory infiltrate in the submucosa and extending along the lamina propria into the mucosa. The acidity of gastric juice is lost due to functional impairment of gastric parietal cells. Absence of hydrochloric acid from the gastric juice is considered an essential prerequisite for the diagnosis of pernicious anemia (Chanarin, 1979). Confirmation of the presence of megaloblastic anemia is by the examination of the blood film and bone marrow and until recently, vitamin B12 absorption was measured by the Schilling test.

PATHOLOGY

The Type A-Type B Classification of Strickland and Mackay

Strickland and Mackay (1973) proposed a classification of gastritis based on histologic findings of the gastric

Inset is the microscopic appearance of the mucosa.

mucosa, the presence of gastric parietal cell antibody, and serum levels of gastrin. Type A gastritis, the "pernicious anemia type," is restricted to the fundus and body of the stomach. Early lesions are characterized by chronic inflammation in the submucosa that extends into the lamina propria of the mucosa between gastric glands (Figure 39.1) with accompanying loss of gastric and zymogenic cells. In advanced disease, gastric atrophy is readily recognized macroscopically and microscopically (Figure 39.2). The wall of the fundus and body of the stomach becomes paper

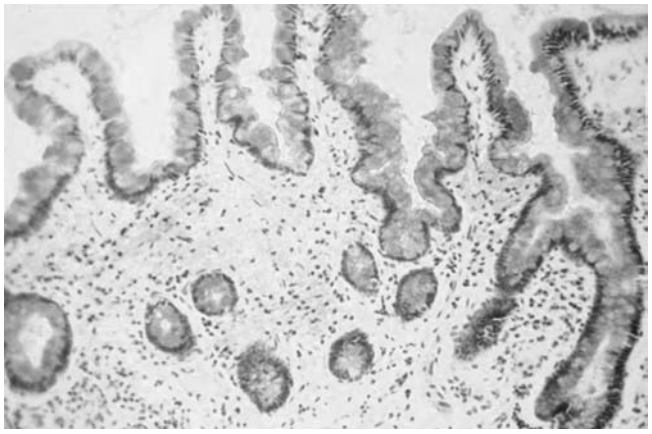

FIGURE 39.3 Microscopic appearance of the gastric mucosa of advanced autoimmune gastritis showing a chronic inflammatory infiltrate in the gastric mucosa and the loss of parietal and zymogenic cells and replacement with mucus-containing cells (brown stain).

thin because the gastric glands are markedly reduced or absent. In particular, parietal cells and zymogenic (chief) cells are absent from the gastric mucosa and replaced by mucus-containing cells resembling those of the intestine (intestinal metaplasia, Figure 39.3). It is unclear why zymogenic cells are lost because there is no convincing evidence of an immune response directed against them. Studies of mouse models of autoimmune gastritis (see below) suggest that the Fas-mediated loss of gastric parietal cells results in a maturation arrest and the failure of precursor stem cells to differentiate to zymogenic cells.

Type A gastritis is characterized by circulating antibodies to gastric parietal cells (Figure 39.4) that have subsequently been shown to be directed to the gastric H^+/K^+ ATPase (Toh et al., 1997), achlorhydria, and high levels of serum gastrin secreted by the intact antral glands. Strickland and Mackay observed that five out of 30 patients with type A gastritis (16%) developed overt or latent pernicious anemia during a follow-up period of 3–24 years. Type A gastritis is also the gastritis characteristic of families in whom pernicious anemia predominates (Varis, 1981; Kekki et al., 1983). The gastric parietal cell must be the target of the autoimmune process because the histologic findings in pernicious anemia are restricted to the parietal cell-containing fundus and body of the stomach and autoantibodies are directed against the gastric parietal cell, and to intrinsic factor, its secretory product.

Type B gastritis, the nonpernicious anemia type, involves the antrum initially but can extend to the fundus and body of the stomach and shows incomplete failure of acid secretion and low levels of serum gastrin because of the antral gastritis. Type B gastritis is usually associated with *Helicobacter pylori* infection; type A is not (Fong et al., 1991). Cloning of the *H. pylori* vacuolar cytotoxin gene and demonstration that the cytotoxin VacA can induce gastric lesions suggested a role for the cytotoxin in the induction of type B gastritis (Telford et al., 1994). The bacterium uses adhesins such as BabA to bind to fucosylated Lewis blood group B antigen on gastric epithelial cell surfaces but is noninvasive. The gastritis is the consequence of the host response to the organism (Suerbaum and Michetti, 2002). Most strains harbor the *cag* pathogenicity island that encodes proteins that translocate the Cag A protein into the cell, leading to cytokine production by the infected cell. *H. pylori*-infected patients with gastric autoimmunity harbor *in vivo*-activated gastric $CD4^+$ T cells that recognize both H^+/K^+ ATPase and *H. pylori* antigens. Characterization of the submolecular specificity of such gastric T-cells identified cross-reactive epitopes from nine *H. pylori* proteins. Cross-reactive *H. pylori* peptides induced T cell prolifera-

tion and expression of T helper type 1 functions. The data suggest that *H. pylori* infection can activate cross-reactive gastric T cells leading to gastric autoimmunity via molecular mimicry (Amedei et al., 2003), providing a plausible explanation for the extension of type B antral gastritis to the corpus of the stomach. Also, although the antral gastritis is not associated with circulating antibodies to gastric parietal cells, extension of pathology to the corpus has been reported to be associated with an anticanalicular antibody directed towards gastric H^+/K^+ ATPase (Appelmelk et al., 1998).

Pernicious anemia in patients with the common variable type of immunodeficiency associated with low levels of serum immunoglobulins can be distinguished from classic pernicious anemia on this classification. This former type of pernicious anemia usually occurs in a younger age group, is histologically type B, is associated with a negative test for antibodies to gastric parietal cells and intrinsic factor, and shows a low level of serum gastrin (Twomey et al., 1969; 1970; Hughes et al., 1972; Cowling et al., 1974). Pernicious anemia in childhood is not associated with gastritis or achlorhydria and is the result of inadequate intrinsic factor production. A 4-base deletion spanning positions 104 to 107 in exon 2, resulting in premature termination of translation, has been reported. This mutation also eliminates a site for Bst XI endonuclease and introduces a site for BsaBI for identifying this deletion in hereditary IF deficiency.

Evolution of Gastric Atrophy

The evolution of gastric atrophy in most cases of pernicious anemia probably spans 20–30 years but this is difficult to assess in individual cases. Nearly all patients with gastric parietal cell antibody whose gastric mucosae have been examined histologically have shown some evidence of gastritis (Serafini et al., 1970). Thus, the presence of gastric parietal cell antibody in the serum is predictive of autoimmune gastritis (Irvine et al., 1965). Conversely, gastric parietal cell antibody is not observed when gastritis is due to diseases affecting the body of the stomach that are not autoimmune (see Table 39.2). Why some patients with autoimmune gastritis progress to pernicious anemia while others maintain sufficient vitamin B12 absorption for long periods is not known. However, this point is interesting, because pernicious anemia is merely the terminal stage of the process. The youngest person studied with gastric parietal cell antibody was aged 13 years, and her gastric mucosa biopsied at age 17 showed mild gastritis (Whittingham et al., unpublished observation).

Reversibility of the Lesion

There are many reports of regeneration of gastric parietal cells, improvement in gastric function, and hematologic remission after treatment with corticosteroids (Figure 39.5; Doig et al., 1957; Gordin, 1959; Ardeman and Chanarin, 1965; Jeffries et al., 1966; Rodbro et al., 1967; Wall et al., 1968; Strickland et al., 1969; Baggett and Welsh, 1970) or azathioprine (Jorge and Sanchez, 1973). This suggests that the gastric mucosa is the direct target of an autoimmune process that can be checked by immunosuppressive drugs. The observations also suggest that precursor stem cells capable of differentiating into parietal cells and zymogenic cells are present in stomachs of patients with autoimmune gastritis and that these are responsible for the regeneration of the differentiated cells when the destructive autoimmune process is controlled. The suggestion is supported by observations in experimental models of autoimmune gastritis where there is evidence of the persistence, and even expansion, of these precursor stem cells in gastritic stomachs (see below). It is also of interest and relevance that reversal of recovery with degeneration of the gastric mucosa recurred once immunosuppressive treatment was halted (Wall et al., 1968). This highlights the ever-present destructive nature of the immune system in these patients.

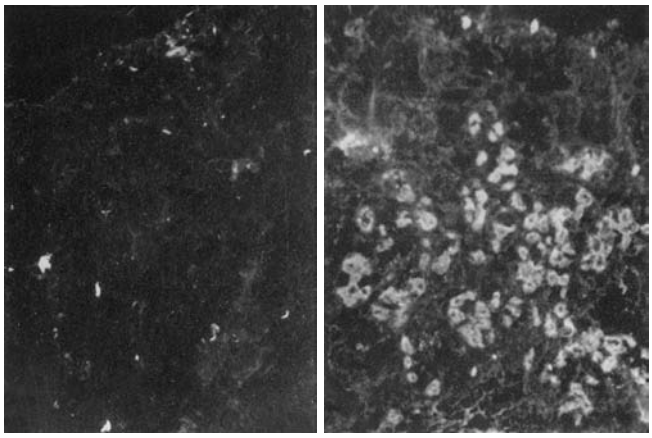

FIGURE 39.5 Indirect immunofluorescence staining showing (*A*) absence of gastric parietal cells in the stomach of a patient with pernicious anemia and (*B*) re-emergence of gastric parietal cells after treatment with 20 mg prednisolone daily for 6 weeks. Parietal cells were demonstrated with serum from a patient with pernicious anemia. ×400.

Gastric Neoplasia

There is historical evidence for a link between type A atrophic gastritis and its sequel, gastric atrophy, and adenocarcinoma of the stomach, but the association may not be strong. Only 2% of all gastric cancers were associated with pernicious anemia in a large autopsy survey in Malmö, Sweden (Eriksson et al., 1981), even when pernicious

anemia had been present for >15 years. In a study by Walker et al. (1971) of cases of type A and type B gastritis, gastric cancer supervened only in patients with type B gastritis. None was observed among patients with type A gastritis. These findings were corroborated by Irvine et al. (1974). The studies of earlier years, which reported an increased risk (Kaplan and Riglar, 1945; Mosbech and Videbaek, 1950; Elsborg and Mosbech, 1979), would not have taken account of the heterogeneity of atrophic gastritis. More recent studies, however, suggest that the risk of gastric cancer is increased 3–5 times in patients with pernicious anemia (Sjoblom et al., 1993; Hsing et al., 1993; Fuchs and Mayer, 1995; Kokkola et al., 1998). Intestinal metaplasia is a risk factor for gastric adenocarcinoma. Also, achlorhydria and bacterial overgrowth may contribute to the formation of carcinogenic nitrosoamines.

Patients with pernicious anemia have a much higher risk (13 times) of developing gastric carcinoids (Kokkola et al., 1998). The carcinoids are likely a consequence of the trophic action of the elevated serum gastrin levels consequent to the achlorhydria that stimulates the proliferation of endocrine cells in the stomach (Rode et al., 1986; Kulke and Mayer, 1999).

AUTOIMMUNE FEATURES

Autoantibodies to Gastric Parietal Cells and to Intrinsic Factor

Autoimmune gastritis is associated with autoantibodies to gastric parietal cells and to its secreted product, intrinsic factor. Like most autoantibodies, these autoantibodies are polyvalent but are predominantly of the IgG isotype (Serafini et al., 1970). IgA antibodies to gastric intrinsic factor have been demonstrated in gastric juice (Goldberg and Bluestone, 1970). Autoantibodies to gastric parietal cells are routinely detected by immunofluorescence (see Figure 39.4). These autoantibodies are directed toward both the catalytic 100 kDa α-subunit and the 60–90 kDa glycoprotein β-subunit of the gastric H^+/K^+ ATPase (Figure 39.6; Karlsson et al., 1988; Toh et al., 1990; Callaghan et al., 1993; Ma et al., 1994). The gastric H^+/K^+ ATPase is the enzyme responsible for acidification of gastric juice (Rabon and Reuben, 1990). It belongs to a family of ion-motive P-type ATPases including other H^+ ATPases as well as the Na^+/K^+ ATPase and the Ca^{2+} ATPase. P-type ATPases have highly conserved catalytic α-subunits that are phosphorylated during their reaction cycles (Pedersen and Carofoli, 1987; van Driel and Callaghan, 1995). Only the H^+/K^+ ATPase and the Na^+/K^+ ATPase have an associated β-subunit comprising a heavily glycosylated 35 kDa core protein. The gastric enzyme is located on specialized secretory membranes of

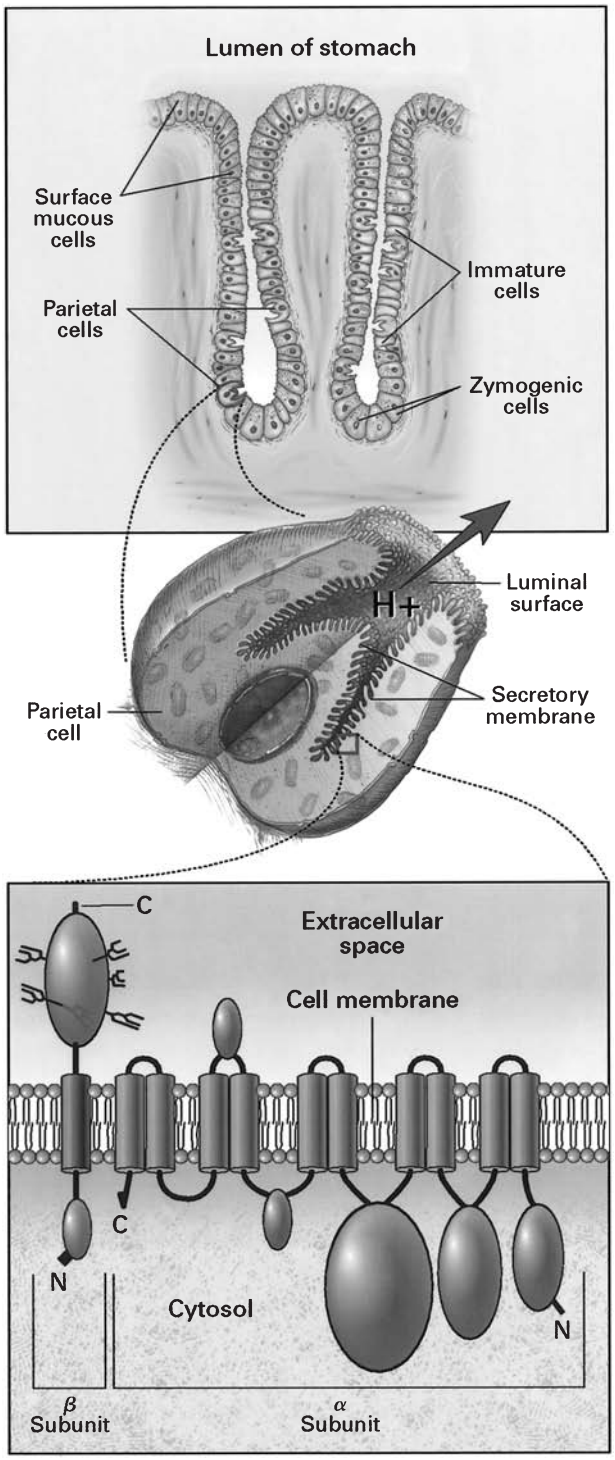

FIGURE 39.6 Gastric parietal cell H^+/K^+ ATPase as the molecular target in autoimmune gastritis associated with pernicious anemia. Top panel represents a gastric gland showing location of parietal cells in relation to zymogenic cells, immature cells, and surface mucus cells. Middle panel represents a stimulated gastric parietal cell showing the lining membrane of the secretory canaliculus on which gastric H^+/K^+ ATPase is located. Bottom panel represents the catalytic α- and the glycoprotein β-subunits of gastric H^+/K^+ ATPase showing their orientation in the lining membrane of the secretory canaliculus of the parietal cells. gastric parietal cells (Hoedemaeker and Ito, 1970; Pettitt et al., 1995; 1996). Parietal cell antibodies have been shown to deplete H^+/K^+ ATPase activity from parietal cell membranes *in vitro* (Burman et al., 1989). Antibody reactivity with the α-subunit of the H^+/K^+ ATPase includes an epitope on the cytosolic side of the secretory membrane (Song et al., 1994). Antibody reactivity with the β-subunit requires the antigen to be disulfide bonded and glycosylated, suggesting that the β-subunit autoepitopes are located in the luminal domain of the glycoprotein (Goldkorn et al., 1989). The N-glycans of the β-subunit bear polylactosamine sequences permitting the purification of gastric H^+/K^+ ATPase by tomato lectin affinity chromatography (Callaghan et al., 1992).

Parietal cell autoantibodies also react with the surface membrane of dissociated parietal cells by immunofluorescence (Masala et al., 1980; de Aizpurua et al., 1983a) and are cytolytic to parietal cells *in vitro* (de Aizpurua et al., 1983b). The suggestion that the surface membrane antigen may be the gastrin receptor (de Aizpurua et al., 1985) has not been confirmed (Burman et al., 1989). Further, immunoblots and immunoprecipitates of gastric membrane extracts with parietal cell autoantibody have demonstrated reactivity only with the two subunits of the gastric H^+/K^+ ATPase. Autoantibody binding with the surface membrane of parietal cells is most likely due to reactivity with the gastric H^+/K^+ ATPase exposed on the plasma membrane of parietal cells that have lost their polarity following dissociation by collagenase.

In rats, hypochlorhydria and atrophy of gastric parietal cells were induced by infusion of an IgG fraction of human serum containing gastric parietal cell antibodies (Tanaka and Glass, 1970). However, it is unlikely that the gastric lesion is mediated by antibody because these parietal cell autoantibodies are directed solely against the gastric H^+/K^+ ATPase, an autoantigen sequestered in the internal and apical secretory membranes of the parietal cell and absent from the basolateral membranes and the autoantigen is inaccessible to circulating autoantibodies.

Human intrinsic factor is a glycoprotein with a molecular weight of ~44,000. Each molecule of intrinsic factor has the capacity to bind to one molecule of vitamin B12 (Chanarin, 1979). Two distinct antibodies are detected by radioimmunoassay; one reacts with the binding site for vitamin B12 and blocks subsequent binding of intrinsic factor with free vitamin, and the other reacts with an antigenic determinant remote from this site (Samloff et al., 1968; Rothenberg et al., 1971).

Cell-Mediated Immunity to Gastric Antigens

Studies of animal models suggest that $CD4^+$ T cells mediate the gastritic lesion (see below). In humans, a significant increase in $CD4^+$ and $CD8^+$ T cells and a six-fold increase in non–T cells (probably B cells) have been observed in the cellular infiltrate of stomachs of patients with pernicious anemia (Kaye et al., 1983). Irvine et al. (1965) have shown by electron microscopy that lymphocytes line up against the membranes of gastric parietal cells and zymogenic cells in the gastric mucosa. A similar observation has been reported in a mouse model of autoimmune gastritis induced by neonatal thymectomy (Toh et al., 1993). Phenotypic analysis of the peripheral blood T cells from patients with pernicious anemia have not shown any significant differences compared to age-matched controls (Vargas et al., 1995). To our knowledge, no studies have been made on the sentinel gastric lymph nodes which are the sites appropriate for such studies.

Interpretation of the early experiments on the contribution of cell-mediated immunity to the gastric lesion was difficult because of the paucity of knowledge about the cellular immune system. Cell-mediated immunity *in vitro* was demonstrated by the proliferation of peripheral blood lymphocytes in the presence of human intrinsic factor, gastric juice or an homogenate of gastric mucosa (Tai and McGuigan, 1969) or by inhibition of migration of peripheral blood leukocytes in the presence of human gastric juice or intrinsic factor (Fisher et al., 1966; Rose et al., 1970; Fixa et al., 1972; Goldstone et al., 1973). Glass (1977) reported positive cutaneous delayed-type hypersensitivity (DTH) reactions in autoimmune gastritis to gastric intrinsic factor and extracts of gastric mucosa; the number of positive responses was low and in one study inhibition of leukocyte migration was as effective with liver mitochondria as it was with gastric antigens (Goldstone et al., 1973). Later, assays by one of us using gastric parietal cell microsomes as antigen gave us clearer results in a leukocyte migration inhibition assay (Whittingham et al., 1975).

With identification of the gastric H^+/K^+ ATPase as the major gastric antigen, $CD4^+$ T-cell clones have been isolated from the infiltrates of the gastric mucosa of patients with autoimmune gastritis and shown to proliferate in response to porcine H^+/K^+ ATPase and display a Th1 profile. Virtually all of the H^+/K^+ ATPase-specific clones produced TNF-α and provided help for B-cell immunoglobulin production, and most expressed perforin-mediated cytotoxicity against antigen-presenting cells and induced Fas-Fas ligand-mediated apoptosis in target cells (D'Elios et al., 2001). The human $CD4^+$ T-cell clones recognized six epitopes in the α-chain and five in the β-chain (Bergman et al., 2003), of which four overlapped with epitopes relevant to experimental autoimmune gastritis, including a previously described gastric epitope (Alderuccio et al., 2000). Gastric T-cell recognition of the peptide epitopes resulted in secretion of Th1 cytokines. The data suggest a striking similarity between human and mouse autoimmune gastritis, at the epitope level, with regard to cytokine secretion and likely also with regard to pathogenic mechanisms.

TABLE 39.3 Frequency of coexisting autoantibodies in 90 patients with pernicious anemia

Autoantibodies to	Number positive (%)
Thyroid microsomes	41 (46)
Thyroglobulin	9 (10)
Pancreatic islet cells	5 (6)
Adrenal cortical cells	4 (4)
Ovarian cells	2 (2)

Clustering of Autoantibodies and Thyrogastric Autoimmunity

The detection in patients with pernicious anemia of a high frequency of thyroid autoantibodies and a lower but clearly increased frequency of autoantibodies to pancreatic islet β cells, adrenal cortical cells, and ovary (Table 39.3) is in keeping with the clinical association of pernicious anemia with the autoimmune diseases that these autoantibodies specify. Also in accord with this clustering of disease is the increased frequency of gastric parietal cell and intrinsic factor antibodies observed in these diseases (see Table 39.2). Approximately 15–20% of type 1 diabetic patients exhibit parietal cell antibodies targeting gastric H^+/K^+ ATPase. It has been suggested that these patients, and in particular those who are hypergastrinemic, should be screened for autoimmune gastritis, iron deficiency, and pernicious anemia. The clustering of these autoimmune diseases points to a shared genetic predisposition, although the nature of the responsible gene(s) remains unknown.

Immunologic Mechanisms of Vitamin B12 Malabsorption

Two immunologically mediated processes lead to malabsorption of vitamin B12. The first is depletion of gastric parietal cells, which secrete gastric intrinsic factor. Normally, intrinsic factor is secreted far in excess of that required for absorption of vitamin B12, but as immunologic destruction of gastric parietal cells proceeds to gastric atrophy, the level of secretion falls below that required for complexing with dietary vitamin B12. Over and above this effect, there are autoantibodies reactive with the receptor site for vitamin B12 on intrinsic factor. These are demonstrable in serum and gastric juice (Fisher et al., 1966; Schade et al., 1966), and interfere with formation of the stable complex required for transport of vitamin B12 from the stomach to the absorption site on epithelial cells in the distal ileum (Donaldson et al., 1967; Kapadia et al., 1983). This complex may be present exclusively with no free intrinsic factor detectable (Goldberg and Bluestone, 1970; Rose et al., 1970). Serum from rabbits injected with intrinsic factor contained similar inhibitory properties (Taylor and Morton, 1959). In pernicious anemia, megaloblastic anemia and neuropathy are the direct effects of the ensuing deficiency of vitamin B12 (Chanarin et al., 1981).

GENETIC FEATURES

Predisposition to pernicious anemia appears to be genetically determined, at least in part, although the mode of inheritance is unknown. Evidence for genetic factors influencing the expression of pernicious anemia includes clustering of this disease in families and with other autoimmune diseases (see Table 39.1), as well as a racial predilection for northern Europeans. Pernicious anemia is rare among southern Europeans and earlier reports suggest that it is almost nonexistent among black and Asian people (Jayaratnam et al., 1967; Irvine et al., 1969). In keeping with racial differences, pernicious anemia is associated with phenotypic markers that are absent or occur with low frequency in these racial groups. These markers include blue eyes, fair skin, and blood group A (Callender and Denborough, 1957). However, a more recent study by Carmel (1996) reported a higher prevalence in black people, particularly among black women.

There have been reports of a number of white families with a high frequency of pernicious anemia over several generations (Callender and Denborough, 1957; McIntyre et al., 1959; Doniach et al., 1965; Ardeman et al., 1966b; Wangel et al., 1968; Whittingham et al., 1969). A raised but not absolute concordance of pernicious anemia has been observed in monozygotic twins (Delva et al., 1965; Irvine et al., 1965; Balcerzak et al., 1968). HLA markers B7, B12, DR2, and DR4 have been reported with increased frequency in patients with pernicious anemia, and B8, B18, and Bw15 in patients with pernicious anemia and autoimmune endocrinopathies (Ungar et al., 1977). The data of Ungar et al. (1981) suggest that DR2 may protect against the development of autoimmune endocrinopathies in patients with pernicious anemia. However, an association of HLA markers with pernicious anemia has not been substantiated in other studies (reviewed by Whittingham, 1991).

ENVIRONMENTAL INFLUENCES

An environmental trigger for the initiation of autoimmune gastritis remains uncertain. A case has been made for *H. pylori* as the principal environmental trigger for this disease (Appelmelk et al., 1998; Bergman et al., 2005). This rests primarily on reports that while *H. pylori* initially colonizes the antrum, resulting in antral gastritis, extension of the chronic inflammatory process to the body of the stomach is associated with an autoimmune reaction to gastric H^+/K^+

ATPase. In support of this hypothesis, $CD4^+$ T-cell clones isolated from stomachs of patients with autoimmune gastritis have been reported to cross-react with nine epitopes shared between *H. pylori* and gastric H^+/K^+ ATPase (Amedei et al., 2003). The *H. pylori* peptides induced T-cell proliferation and expression of Th1 function. However, whether *H. pylori* is the environmental trigger for autoimmune gastritis with sparing of the gastric antrum arising from the conversion of type B pangastritis to type A gastritis remains unproven. The epidemiologic data are suggestive but not conclusive (Uibo, 2005). In the mouse, autoimmune gastritis initiated by neonatal thymectomy regressed after infection with *H. pylori* (Okazaki et al., 2003).

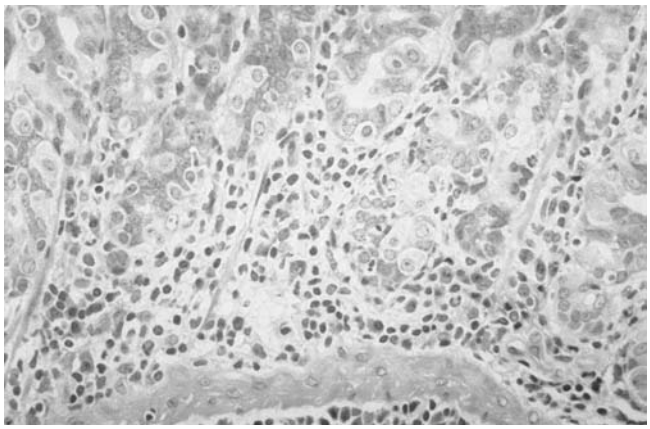

FIGURE 39.7 Microscopic appearance of the gastric mucosa of a mouse with autoimmune gastritis showing a chronic inflammatory infiltrate in the gastric submucosa with extension into the lamina propria between gastric glands. ×300.

ANIMAL MODELS

While studies of autoimmune gastritis and pernicious anemia have suggested that the parietal cell is targeted in the gastric lesion and that the associated parietal cell antibodies are directed against the gastric H^+/K^+ ATPase, they do not directly address the critical question of the role of the gastric H^+/K^+ ATPase in disease induction. Most investigations of organ-specific autoimmunity in humans have identified autoantigens associated with advanced disease. Much less is known of the early events that initiate an autoimmune response to self-antigens and, in particular, the way in which self-antigens are presented by antigen-presenting cells for recognition by T cells to activate the self-destructive autoimmune process. These molecular and cellular events associated with the onset of disease can most readily be studied in animal models of autoimmunity. Using animal models, considerable effort is now directed at identifying the relevant autoantigens responsible for the initiation of the disease, as these represent the key targets for intervention therapies. These issues are especially relevant to autoimmune gastritis and pernicious anemia where the clinical signs of disease can occur decades after the event which initiated the primary autoimmune response.

Experimental autoimmune gastritis is an excellent animal model of the human disease in that its pathology and its autoimmune response to the gastric H^+/K^+ ATPase are very similar to those of the human disease (Jones et al., 1991). As in humans, the gastric lesion is characterized by a chronic inflammatory infiltrate in the gastric mucosa that extends into the lamina propria between gastric glands (Figure 39.7) and is accompanied by loss of gastric parietal and zymogenic cells that is best revealed by the modified Maxwell's histochemical stain (Figure 39.8). Murine gastritis differs from the human disease in the presence of hypertrophy arising from expansion of a mucosal precursor population. While there is some evidence of progression to macrocytic anemia, the question of whether the mice develop autoantibodies to intrinsic factor remains unresolved. Gastritis is readily induced by neonatal thymectomy and by a range of other procedures (Figure 39.9); its strain dependence allows for analysis of genetic factors and as a nonlethal disease it allows for the investigation of treatment strategies. Indeed, the mouse model has proven to be a powerful tool for the identification of the initiating autoantigens, the role of dendritic cells and macrophages in the initiation of the autoimmune response, the role of regulatory T cells, the mechanisms for the loss of tolerance to a peripheral tissue-specific autoantigen, and for devising novel strategies to

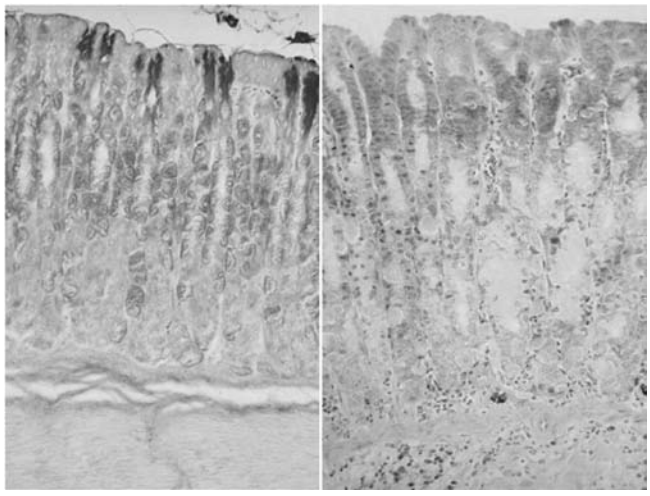

FIGURE 39.8 Microscopic appearance of the normal gastric mucosa of a mouse (left panel) and of the mucosa of a mouse with autoimmune gastritis (right panel). With modified Maxwell's stain, gastric parietal cells in the normal gastric mucosa located towards the base of the glands stain blue while zymogenic cells in the mid-portions of the gland stain purple. In the mouse with autoimmune gastritis, the mucosa is hypertrophied and the gastric parietal and zymogenic cells have been lost and replaced by mucus-containing cells that stain yellow.

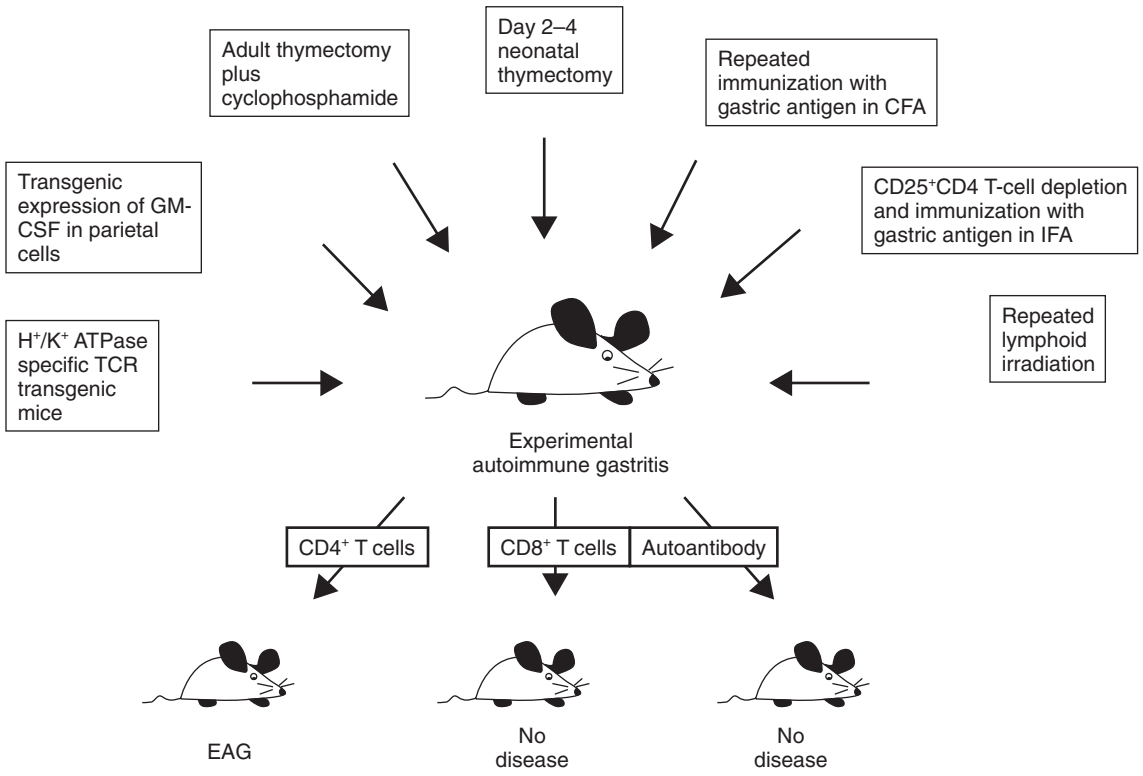

FIGURE 39.9 The range of procedures that can induce experimental autoimmune gastritis (EAG) in BALB/c mice. The readout of EAG includes the generation of autoantibodies to the H^+/K^+ ATPase of gastric parietal cells and a chronic inflammatory infiltrate with tissue destruction within the gastric mucosa. Transfer experiments have shown that $CD4^+$ T cells are the critical pathogenic cells in this model, with no demonstrable role for $CD8^+$ T cells or autoantibody.

reestablish tolerance and reverse pathology (Alderuccio and Toh, 2000; Alderuccio et al, 2002).

Spontaneous Autoimmune Gastritis

Spontaneous autoimmune gastritis has been reported in animals. For instance, autoantibodies to rat gastric parietal cells were demonstrated in 68% of Bio-Breeding (BB)/W rats with spontaneous insulin-dependent diabetes mellitus (Elder et al., 1982). These antibodies were associated with mild to moderate gastritis and loss of specialized cells, fibrosis, and squamous metaplasia, although no significant reduction in acid secretion or fall in serum level of vitamin B12 was detected in the 90–300-day-old rats studied. Antibodies to gastric parietal cells have also been shown to coexist serologically with thyroid antibodies in obese strain chickens with thyroiditis (Khoury et al., 1982) but gastritis in the chicken is difficult to interpret and considered to be an unsatisfactory model of human autoimmune gastritis. Spontaneous gastritis has more recently been reported in C3H/He mice with an incidence of about 20% (Alderuccio and Toh, 1998) and may prove to be an informative model of human autoimmune gastritis.

Post-thymectomy Autoimmune Gastritis

The first report of autoimmunity following neonatal thymectomy was the induction of autoimmune thyroiditis (Nishizuka et al., 1973). Since then organ-specific autoimmunity closely mirroring the spectrum of human thyrogastric autoimmunity has been observed following neonatal thymectomy in a variety of mouse strains (Kojima and Prehn, 1981). Removal of the neonatal thymus 2–4 days after birth has been shown to prevent the emigration of $CD4^+CD25^+$ regulatory T cells from the thymus to the periphery (Fehervari and Sakaguchi, 2004). The removal of this regulatory population is held to be primarily responsible for the subsequent unchecked expansion of pathogenic self-reactive T cells that leads to autoimmune disease. However, manipulation of mice during the neonatal period is not an essential prerequisite for the development of autoimmunity. Adult thymectomy combined with repeated low-dose radiation (Penhale et al., 1975) or with a single dose of cyclophosphamide can also initiate autoimmunity (see Figure 39.9; Barrett et al., 1995a). In adults, neither adult thymectomy alone nor cyclophosphamide-induced transient lymphopenia alone can initiate gastritis, yet the

degree of the transient lymphopenia induced by combined adult thymectomy and cyclophosphamide treatment, compared to that induced by cyclophosphamide treatment alone, is indistinguishable. These observations underpin the essential role of the thymus as the source of $CD4^+CD25^+$ regulatory T cells that maintain tolerance to self-antigens in neonatal and adult life (Sakaguchi et al., 1995; Sakaguchi, 2004; Field et al., 2005). The importance of this population for tolerance is further supported by the need to remove these T cells using depleting anti-CD25 antibody to establish sustained autoimmune gastritis following immunization with gastric antigen (McHugh and Shevach, 2002). These regulatory T cells constitute 2–5% of CD4 single positive thymocytes and 5–10% of peripheral $CD4^+$ T cells, are of high avidity, are positively selected in the thymus, require expression of the transcriptional factor Fox3p for suppressor activity and are thought to prevent expansion of pathogenic T cells by a cytokine-independent, cell-to-cell contact mechanism. However, the precise mechanism of suppression remains unknown (Sakaguchi, 2004). It seems likely that, in addition to the removal of this T regulatory population, the homeostatic expansion of the pathogenic T cells also plays a role in the initiation of autoimmunity (King et al., 2004).

Following neonatal thymectomy, the particular organ affected by autoimmune disease is dependent on the mouse strain, indicating genetic factors determining tissue tropism. For autoimmune gastritis, BALB/c mice are most susceptible to disease, in both the neonate (see Figure 39.9; Kojima and Prehn, 1981; Tung et al., 1987) and the adult. Autoimmune gastritis is not dependent on the presence of a particular H2 haplotype as mice with several different major histocompatibility complex (MHC) haplotypes develop gastritis (Kojima and Prehn, 1981). Four linkage regions, two on distal chromosome 4 (*Gasa1* and *Gasa2*), one on chromosome 6 (*Gasa3*) and one in the H2 (*Gasa4*), have been identified (Silveira et al., 1999; 2001; Baxter et al., 2005). Three of these four genes colocalize with NOD mouse diabetes susceptibility genes, the strongest concordance identified to date between any two autoimmune diseases. The incidence of gastritis in BALB/c mice is 60–90%, although other strains develop gastritis with lower incidences. These glands show destructive changes in parietal cells and zymogenic cells (Martinelli et al., 1996).

Autoimmune Gastritis Induced by Immunization

Early attempts to induce autoimmune gastritis used crude gastric extracts as the immunogen. For example, immunization of rhesus monkeys with extracts of gastric mucosa in complete Freund's adjuvant (Andrada et al., 1969) resulted in gastritis, gastric parietal cell antibodies, and cutaneous delayed-type hypersensitivity reactions to gastric antigens. Immunization of dogs with gastric juice and extracts of gastric mucosa also resulted in gastritis and equivalent humoral and cellular reactions to gastric antigens but in this model, unlike the human disease, there was severe atrophy and only a minimal inflammatory response in the gastric mucosa (Hennes et al., 1962; Fixa et al., 1964; 1972; Krohn and Finlayson, 1973). The cellular response was thought to be more important in the production of gastritis in dogs (Krohn and Finlayson, 1973), although a combined humoral and cellular response to immunization has been demonstrated. Autoimmune gastritis has also been induced in mice by immunization with gastric parietal cells (Kontani et al., 1992).

The discovery of the gastric H^+/K^+ ATPase as the molecular target of parietal cell antibodies in both human autoimmune gastritis with pernicious anemia and in thymectomy-induced models of gastric autoimmunity prompted the use of purified gastric H^+/K^+ ATPase containing both the α- and β-subunits for the induction of autoimmune gastritis by immunization. Gastritis and circulating parietal cell autoantibodies to gastric H^+/K^+ ATPase developed maximally in BALB/c mice after four immunizations of the mouse gastric enzyme emulsified in Freund's complete adjuvant. The gastritis was accompanied by destruction of both gastric parietal cells and zymogenic cells. This suggests that the loss of zymogenic cells is secondary to an immune response to the gastric parietal cells H^+/K^+ ATPase. The mucosal lesion was accompanied by expansion in the population of precursor stem cells similar to that seen in the gastritis induced by neonatal thymectomy. The gastritis was transferred to BALB/c mice by splenic T cells from gastritic mice to immunocompromised hosts. It was reversible following cessation of immunization which resulted in regeneration of parietal cells and zymogenic cells, derived presumably by differentiation of the expanded stem cell production (Scarff et al., 1997). Reversibility of the lesion appeared to be the consequence of the presence of regulatory $CD4^+CD25^+$ T cells in these mice because the antibody-mediated removal of this population together with a single immunization with gastric antigen was sufficient to initiate an irreversible gastritis (McHugh and Shevach, 2002).

Transgenic Mouse Models of Autoimmune Gastritis

Autoimmune gastritis has been reported in transgenic mice that express the proinflammatory cytokine GM-CSF in the stomach (Biondo et al., 2001) and in mice that express rearranged TCR genes with specificity for the α- or β-subunits of the gastric H^+/K^+ ATPase (Alderuccio et al., 2000; McHugh et al., 2001).

In mice that express GM-CSF in the stomach, infiltration of macrophages and dendritic cells into the stomach precedes $CD4^+$ T cells. It seems likely that the local presence

of GM-CSF leads to recruitment of macrophages and dendritic cells followed by their activation and migration to the draining lymph node, where they break tolerance by activating potentially pathogenic $CD4^+$ T cells that migrate to the stomach to initiate gastritis. The development of autoimmune gastritis in BALB/c mice following transgenic expression of GM-CSF in parietal cells in the stomach indicates that the actions of these $CD4^+CD25^+$ regulatory T cells can be overridden by the presence of a local proinflammatory cytokine in the stomach (Biondo et al., 2001). Pathogenic $CD4^+$ T cells isolated from PC-GMCSF transgenic mice transferred disease to naïve syngeneic recipients.

T-cell receptor (TCR) transgenic mice bred to the gastritis-susceptible BALB/c genetic background and expressing a TCR specific for the gastric H^+/K^+ ATPase α-subunit develop gastritis (100%) at a much greater frequency than do TCR β-subunit transgenic mice (20%). This difference in disease incidence in these two TCR transgenic models remains unexplained. It is possible that the lower incidence of gastritis in the TCR β-subunit transgenic mice depends on the influence of a $CD4^+CD25^+$ regulatory T-cell population that is absent in the TCR α-subunit transgenic mice.

PATHOGENESIS

For most autoimmune diseases, it is not known whether the molecules recognized by autoantibodies are also T-cell targets or whether the immune response to these antigens is involved in initiation of disease. The gastric H^+/K^+ ATPase targeted by parietal cell autoantibodies in human and in murine autoimmune gastritis is a peripheral autoantigen. Although peripheral antigens are not expected to be present in the thymus, there are increasing reports of promiscuous expression of these antigens, particularly in thymic medullary epithelial cells (Gotter et al., 2004) where ectopic presence of these antigens has been suggested to shape the T-cell repertoire (Anderson and Kuchroo, 2003). This suggestion has gained added relevance with reports of the AIRE transcriptional factor in a small subset of thymic medullary epithelial cells and its postulated role in tolerance to organ-specific autoantigens, presumably through clonal deletion (Vernanzi et al., 2004). However the role of AIRE in tolerance to gastric autoantigens remains uncertain. The α- but not the β-subunit of the gastric H^+/K^+ ATPase has been identified in thymic dendritic cells, suggesting that self-antigen expression by dendritic cells may have a role in maintenance of tolerance. Nonetheless, the capacity to initiate experimental autoimmune gastritis indicates that potentially pathogenic T cells are still present in the periphery.

To ascertain whether the presentation of self-antigen by MHC class II positive cells in the thymus has a role in tolerance induction, transgenic mice were generated that express the α- or β-subunit of the gastric H^+/K^+ ATPase in the thymus driven by an MHC class II promoter (see Figure 39.8). Transgenic mice that expressed the β-subunit in the thymus failed to develop gastritis initiated by a variety of methods as judged by histologic evidence of gastritis and production of circulating antibodies to gastric H^+/K^+ ATPase (Alderuccio et al., 1995; Barrett et al., 1995b; Alderuccio and Toh, 1998). In contrast, transgenic mice that expressed the α-subunit in the thymus driven by the same MHC class II promoter remained susceptible to gastritis initiated by neonatal thymectomy (Figure 39.10). These observations suggest that the β-subunit of the gastric H^+/K^+ ATPase contains the causative autoepitope (Toh et al., 2000).

Studies in mice have clearly indicated that autoimmune gastritis is initiated by $CD4^+$ T cells. First, gastritis can be transferred to immunocompromised hosts by $CD4^+$ T lymphocytes but not by sera from animals with autoimmune gastritis (see Figure 39.9; reviewed by Gleeson and Toh, 1991; Toh et al., 1992; 1997). In addition, histopathologic features of gastritis occur in mice before the appearance of autoantibodies. The early gastric lesion is composed predominantly of $CD4^+$ T cells and macrophages with production of a mix of Th1 and Th2 type cytokines but not interleukin-4 (IL-4), suggesting a key role for these cells and their cytokines in initiation of the disease (Martinelli et al., 1996; Katakai et al., 1998). Interferon-γ, probably produced by the Th1 cells, appears to be crucial for the induction of gastritic lesion as a single injection of antibodies to interferon-γ immediately following neonatal thymectomy prevents autoimmune gastritis (Barrett et al., 1996). $CD8^+$ T cells do not seem to have a role in this disease since depletion of this T-cell population by treatment with anti-CD8 antibody did not reduce the capacity of the remaining T cells to transfer disease (De Silva et al., 1998). B lymphocytes are late migrants to the inflamed gastric mucosa and aggregate in follicular-like structures (Martinelli et al., 1996), likely mediated by the expression of a B-cell homing chemokine, CXC chemokine ligand 13, by dendritic cells within the follicles (Katakai et al., 2003).

The identification of the β-subunit of the gastric H^+/K^+ ATPase as the causative antigen and of $CD4^+$ T cells as the effectors of gastric injury suggests the following model for the genesis of autoimmune gastritis. Gastric antigen released following cell death is taken up locally in the stomach by dendritic cells that migrate to the draining lymph node, resulting in the activation of naïve pathogenic $CD4^+$ T cells. The activated T cells initiate tissue damage, possibly by binding to MHC class II molecules that are upregulated in the inflamed gastric mucosa. Support for this model is provided by the observation by immunofluorescence microscopy of a physical association of $CD11c^+$ dendritic cells with parietal cells in the gastric mucosa. H^+/K^+ ATPase protein was found within vesicular compartments of a few $CD11c^+$ dendritic cells only in the draining gastric lymph node and these antigen-containing dendritic cells increased

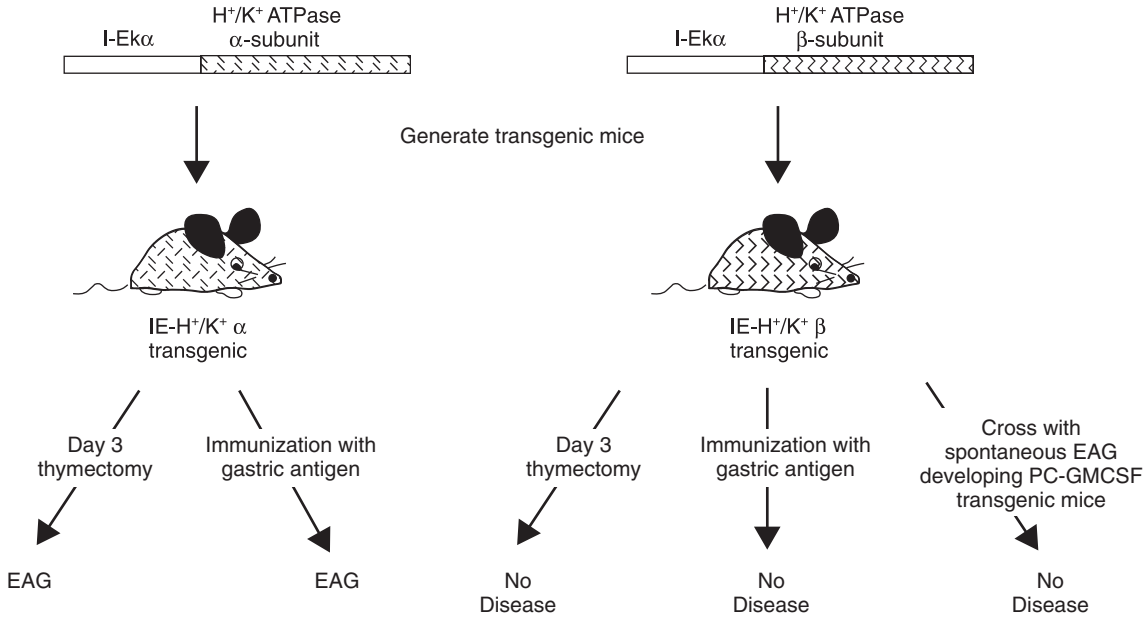

FIGURE 39.10 Experimental evidence suggesting the autoimmune response to gastric H^+/K^+ ATPase β-subunit is critical for EAG induction. Transgenic mice were generated expressing gastric H^+/K^+ ATPase α- or β-subunit under the control of the E-I MHC class II promoter. IE- H^+/K^+ α transgenic mice remained susceptible to EAG induction following day 3 neonatal thymectomy or immunization with gastric autoantigen. In contrast, IE- H^+/K^+ β mice were EAG resistant following neonatal thymectomy or immunization or when crossed to PC-GMCSF transgenic mice that spontaneously develop EAG.

markedly in number with the onset of tissue destruction in autoimmune animals. Both CD8α(hi) and CD8α(lo) gastric dendritic cells showed evidence of constitutive *in vivo* processing and presentation of H^+/K^+ ATPase. These data also demonstrate that dendritic cells in the draining lymph node can present a tissue-specific self-antigen under noninflammatory conditions without fully deleting autoreactive T cells or inducing active autoimmunity (Scheinecker et al., 2002). The homing of the activated $CD4^+$ T cells to the gastric mucosa appears to be mediated by the interaction of α4 β7 on the lymphocytes with mucosal MAdCAM-1, given that a significant increase in the area of mucosal endothelium expressing MAdCAM-1 in gastritic mice was observed and that treatment of mice with either a MAdCAM-1-specific or α4 β7-specific monoclonal antibody reduced the incidence of gastritis (Barrett et al., 2000; Katakai et al., 2002). While neither the chemokine receptor CCR5 nor TNF-α appears to have a role in the inflammatory process (Field et al., 2003; Marshall et al., 2004), the expression pattern of the cytokines and chemokines expressed in the stomach includes lymphotoxin-β and is consistent with a Th1-biased, memory T-cell-dependent immunomicroenvironment (Katakai et al., 2003). Fas/FasL interaction appears to be required for the initiation of parietal cell death in the gastric mucosa (Nishio et al., 1996; Marshall et al., 2002).

TREATMENT AND OUTCOME

The standard treatment is to correct the deficiency of vitamin B12 by the administration of vitamin B12. While the time-honored route of vitamin delivery is by parenteral injection, there is increasing evidence that the oral route is equally effective, particularly with the vitamin given at a high dosage (1000 μg) (Kaltenbach et al., 2002; Lane and Rojas-Fernandez, 2002; Nyholm et al., 2003). This corrects the anemia but there are no adequate data at present to indicate whether oral vitamin B12 can correct the neuropathy, particularly when it is severe. Erroneous treatment of patients with folic acid may not only mask the anemia caused by vitamin B12 deficiency but lead to irreversible neurologic damage (Dhar et al., 2003).

The identification in mouse models of autoimmune gastritis of proinflammatory Th1 $CD4^+$ T cells directed against the β-subunit of the gastric H^+/K^+ ATPase has suggested a novel therapeutic approach to reestablish tolerance to self-antigen and the prevention and/or reversal of autoimmune disease. The approach uses transplantation with bone marrow stem cells that have been genetically engineered to direct expression of culprit antigen in bone marrow-derived antigen-presenting cells in the thymus (Alderuccio et al., 2003). Initial reports have shown that transplantation with

bone marrow from transgenic mice that have been engineered to express the gastric H^+/K^+ ATPase β-subunit antigen (Murphy et al., 2003) or proinsulin II in the thymus (Steptoe et al., 2003) has succeeded in establishing tolerance to the antigen in the case of autoimmune gastritis and of preventing disease in the case of diabetes in NOD mice. These highly promising results suggest that this strategy may have application for autoimmune diseases that respond poorly to replacement therapy or immunosuppressive drugs.

CONCLUDING REMARKS—FUTURE PROSPECTS

Pernicious anemia and gastric atrophy are terminal events in a protracted chronic autoimmune gastritis that affects the fundus and body of the stomach. They are usually expressed clinically in late middle age. The vitamin B12 deficiency and ensuing megaloblastic anemia are the result of gastric parietal cell loss with failure of production of intrinsic factor, an obligatory factor for absorption of the vitamin from the terminal ileum.

Autoimmune gastritis fulfills the criteria for an organ-specific autoimmune disease: autoantibodies to gastric antigens, infiltration of mononuclear cells into the target organ with evidence of destruction, a regenerative response of the affected tissue to corticosteroid drugs, familial predisposition, and association with other autoimmune diseases, mostly the autoimmune endocrinopathies. The molecular target of parietal cell autoantibodies is the gastric H^+/K^+ ATPase located on secretory membranes of gastric parietal cells and autoantibodies to gastric intrinsic factor.

Animal models have provided insights into the pathogenesis of autoimmune gastritis. The BB/W rat, obese chicken, and C3H/He mouse represent spontaneous animal models of autoimmune gastritis. It can be induced in susceptible mouse strains by removal of $CD4^+CD25^+$ regulatory T cells (e.g., neonatal thymectomy), by immunization with gastric H^+/K^+ ATPase emulsified in Freund's complete adjuvant, and by the generation of transgenic mice that express either the proinflammatory cytokine GM-CSF in the stomach or rearranged TCRs directed against gastritogenic epitopes of the α- or β-subunits of the gastric H^+/K^+ ATPase. The murine disease is initiated by proinflammatory Th1 $CD4^+$ T cells that are activated in the draining gastric lymph node by dendritic cells, loaded with the gastric antigen, that have migrated to this location from the stomach. These T cells are directed initially against the β-subunit of the gastric H^+/K^+ ATPase since active T-cell tolerance to this subunit alone prevents the development of autoimmune gastritis induced by a variety of methods such as thymectomy or immunization with the ATPase. Mucosal damage is initiated through engagement of Fas expressed by parietal cells in the inflamed gastric mucosa. Genetic engineering of bone marrow stem cells to target the gastric autoantigen to the thymus points the direction towards testing strategies directed towards reestablishment of tolerance and the prevention and reversal of pathology in intractable autoimmune diseases in which causative antigens are known.

CHAPTER

40

Hypophysitis

PATRIZIO CATUREGLI AND SHEY-CHERNG TZOU
The Johns Hopkins University, Department of Pathology, Baltimore, MD

DEFINITION AND CLASSIFICATION

Hypophysitis is an inflammation of the pituitary gland that originates directly within the pituitary (primary forms) or from neighboring or systemic diseases (secondary forms). Primary hypophysitis comprises three main histologic types: granulomatous, xanthomatous, and lymphocytic.

Granulomatous hypophysitis was first described in 1917 by Simmonds (Simmonds, 1917). He reviewed 2000 pituitary glands at autopsy and found four cases not related to tuberculosis or syphilis, characterized by diffuse collections of multinucleated giant cells and histiocytes, with surrounding lymphocytes and plasma cells. The first antemortem patient was reported in 1980 (Taylon and Duff, 1980). The disease is rare, affects males and females equally, and can occur together with lymphocytic hypophysitis (McKeel, 1983; Miyamoto et al., 1988; Madsen and Karluk, 2000). For this reason, McKeel suggested that the two diseases are part of the same autoimmune spectrum, with a purely lymphocytic form constituting the predominant early lesion and a granulomatous component appearing later (McKeel, 1984). Different histologic appearance from other classic organ-specific autoimmune diseases and different epidemiologic data (lack of female bias and association with other autoimmune diseases) suggest, however, that lymphocytic and granulomatous hypophysitis are two distinct diseases.

Xanthomatous hypophysitis was originally described in three women in 1998 (Folkerth et al., 1998) and in six other patients thereafter (Burt et al., 2003). The pituitary is infiltrated by foamy histiocytes, small lymphocytes, and cyst-like areas of liquification. The rarity of this disease has hampered the understanding of its pathogenesis, natural history, and prognosis. Similar concepts apply to necrotizing hypophysitis, which has been demonstrated histologically only once in two patients (Ahmed et al., 1993) and suspected radiologically in another (Ogawa, 1995). Histologically, the pituitary appears destroyed by diffuse necrosis with surrounding lymphocytes, plasma cells, and a few eosinophils. It is unclear whether this represents a fourth histologic type or a variant of the other three.

Lymphocytic (autoimmune) hypophysitis is the most frequent among the primary hypophysitides (Caturegli et al., 2005). It is known in the literature by several names. Originally it was called "lymphocytic adenohypophysitis" (or just lymphocytic hypophysitis) because the infiltration, which was mainly lymphocytic, and the symptoms were thought to be limited to the anterior hypophysis. It was then realized that the autoimmune attack could also and exclusively involve the infundibular stem and the posterior lobe, and so the term "lymphocytic infundibulo-neurohypophysitis" was created. Finally, it was realized that both the adenohypophysis and the infundibulo-neurohypophysis could be affected; hence the term "lymphocytic panhy-

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

pophysitis" arose. We will refer to the disease as autoimmune hypophysitis, followed by the specific anatomic location when known.

HISTORICAL BACKGROUND

Autoimmune hypophysitis of the anterior lobe (lymphocytic adenohypophysitis, LAH) was first described in 1962 by Goudie and Pinkerton in Glasgow, UK (Goudie and Pinkerton, 1962). The authors reported a 22-year-old woman who died 14 months after her second delivery, probably because of adrenal insufficiency. Two months before admission, the patient felt increasingly tired and noticed a neck enlargement; she then developed severe lower abdominal pain, radiating to the right iliac fossa, associated with vomiting and diarrhea. She was brought to the operating room for suspected appendicitis. Surgery revealed an acutely inflamed, gangrenous appendix that, however, had not ruptured. The appendix was removed but 8 hours later the patient went into peripheral circulatory shock and died. The autopsy revealed a firm, enlarged thyroid gland infiltrated by lymphocytes, atrophic adrenal glands, and a small pituitary. Surprisingly for that time, the adenohypophysis was extensively infiltrated by lymphocytes and few plasma cells, aggregating in some areas to form lymphoid follicles. The neurohypophysis was normal. Noting the presence of Hashimoto's thyroiditis, a more extensively characterized autoimmune disease, the authors concluded their discussion by writing: "It seems reasonable to assume that the coexistence of Hashimoto's disease and the mononuclear cell infiltration of the anterior pituitary is not fortuitous. Both may be explained by the onset of autoimmune reaction to thyroid and pituitary antigens released during the puerperal involution of these glands." There is no doubt that Goudie and Pinkerton were the first to postulate the autoimmune nature of this condition, at a time (1962) when the field of autoimmunity had just begun. Earlier cases, however, are probably hidden in hospital archives or published without recognition of the disease (Duff and Bernstein, 1933; Rupp and Paschkis, 1953).

Autoimmune hypophysitis of the posterior lobe and infundibular stem (lymphocytic infundibulo-neurohypophysitis, LINH) was first described in 1970 by Saito et al. in Tokyo. They reported a 66-year-old asthmatic woman with a 1-month history of severe dehydration that responded strikingly to the administration of pitressin. Two months after discharge, however, she developed a severe attack of bronchial asthma and died. Autopsy revealed a marked infiltration of the neurohypophysis and the infundibular stem with lymphocytes and plasma cells, aggregating in some areas in lymphoid follicles. The adenohypophysis was normal, except for vacuolar degeneration of the basophilic cells, likely due to the prolonged use of steroids for asthma.

Autoimmune hypophysitis involving both the anterior and posterior lobe (lymphocytic panhypophysitis, LPH) was first described histologically in 1991 by Nussbaum et al. in New York. Their first case was a 40-year-old male with a 3-month history of headache, impotence, polyuria, and polydipsia. Transsphenoidal surgery showed that the sella turcica was filled with whitish, fibrous tissue that was almost completely removed. Histology revealed extensive infiltration of the adenohypophysis and the neurohypophysis by lymphocytes, plasma cells, and histiocytes.

CLINICAL AND EPIDEMIOLOGIC FEATURES

Very limited data exist on which to estimate the incidence of autoimmune hypophysitis. Sautner and Fehn analyzed 2500 surgical pituitary specimens collected at Hamburg, Germany, from 1970 to 1996 and found six cases (0.24%) (Sautner et al., 1995; Fehn et al., 1998). Honegger et al. analyzed 2362 specimens collected from 1982 to 1995 in Erlagen, Germany, and found seven cases (0.3%) (Honegger et al., 1997). Leung et al reported in Charlottesville, Virginia, 13 cases of autoimmune hypophysitis among 2000 patients who underwent transsphenoidal surgery for pituitary mass lesions from 1992 to 2003 (0.65%) (Leung et al., 2004). Buxton and Robertson analyzed 619 consecutive pituitary surgeries performed over 15 years at Nottingham, UK, and found five cases (0.8%) (Buxton and Robertson, 2001). Considering that their hospital served a population of approximately 3 million and that all surgery for pituitary masses was dealt with there, the yearly incidence in Nottingham can be estimated to be one case in every 10 million people. Thus, using the United States as an example, 28 new cases of autoimmune hypophysitis can be expected every year. This incidence may well be an underestimate of today's incidence, also considering that some autoimmune hypophysitis cases may go undiagnosed because of their indolent, subclinical course.

A total of 379 cases of autoimmune hypophysitis were reported in the literature from 1962 to 2004 (Caturegli et al., 2005). The incidence appears to have increased over time. In the first 20 years (1962–1981), in fact, only 16 cases were reported (11 at autopsy and five from surgical pathology specimens). In the next 20 years (1982–2001), 290 appeared in the literature, and 73 cases have been reported just in 2002–04. This exponential increase likely reflects an ascertainment bias, due to the widespread introduction of non-invasive imaging techniques of the sella turcica (mainly MRI), transsphenoidal surgery and also increased awareness in the medical community.

LAH is more common in women (F : M ratio of 6), who present at a younger age (35 ± 13) than men (43 ± 12). In a significant percentage of women (57%), LAH manifests

during pregnancy or post partum. Figure 40.1 shows the distribution of symptom appearance centered at delivery: most women present in the third trimester or early post partum. A history of previous pregnancies does not increase the risk of developing LAH in subsequent pregnancies. This striking temporal association is one of the most interesting features of autoimmune hypophysitis and, at the moment, remains unexplainable.

LINH affects males and females equally and is not associated with pregnancy. LPH is slightly more common in women (F : M ratio of 1.9), but does not show association with pregnancy.

The clinical presentation of autoimmune hypophysitis includes four categories of symptoms. Symptoms of local compression are the most common and usually the first complaint. They include headache and visual disturbances (either defects in the visual field or decreased acuity; more rarely, diplopia). Compression symptoms originate because a pituitary infiltrated by immune cells initially enlarges, expanding usually upward to stretch the dura mater and the optic chiasm. Next are symptoms due to a partial or complete deficit of the anterior pituitary function, more commonly ACTH deficiencies. These defects are considered the direct result of the autoimmune attack on the pituitary acinar cells. Next are symptoms due to deficit of the posterior pituitary (diabetes insipidus), which can be attributed either to direct immune destruction or to compression of the posterior lobe and infundibular stem. We favor the first mechanism considering that diabetes insipidus is very rare in pituitary adenomas. Last are the signs due to hyperprolactinemia (mainly amenorrhea/oligomenorrhea and galactorrhea), which occur in about a quarter of the patients. These clinical features of autoimmune hypophysitis are indistinguishable from those of any other expanding mass located in the sella turcica.

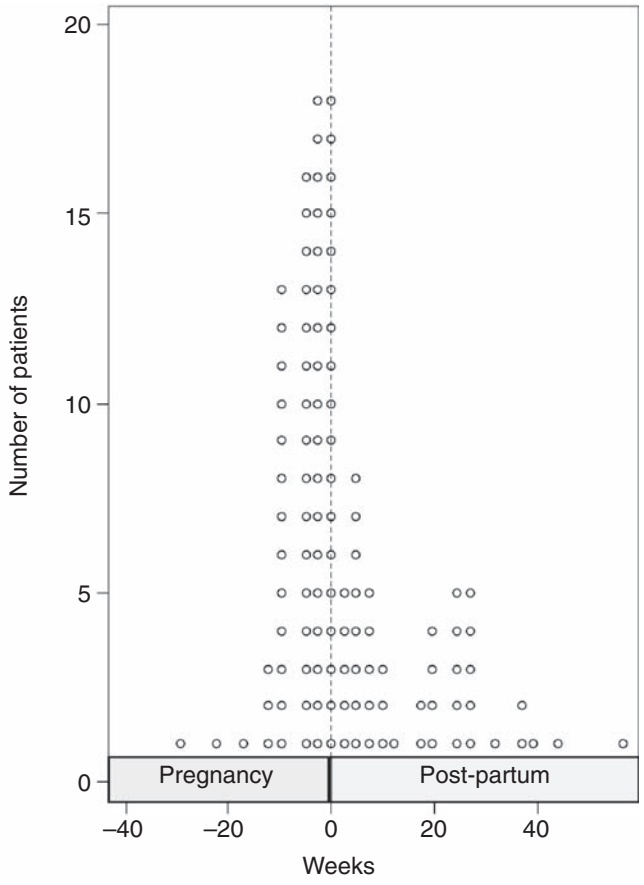

FIGURE 40.1 Distribution of symptom appearance in autoimmune hypophysitis in relation to delivery (indicated as week 0).

PATHOLOGIC FEATURES

The defining histologic feature of autoimmune hypophysitis is the diffuse infiltration of the pituitary gland with lymphocytes that sometimes aggregate to form true lymphoid follicles, often with germinal centers. Immunohistochemistry reveals a mixture of T and B lymphocytes (Gutenberg et al., 2005), without a dominant subset, as frequently seen in other autoimmune diseases. Other cell types are also present in the infiltrate and may play a dominant role in immunopathology. Plasma cells are frequently seen (53% of the cases) but also eosinophils (12%), macrophages, histiocytes and neutrophils (6%) and, more recently, mast cells (Vidal et al., 2002). Fibrosis is common (46%) and often severe, explaining the toughness and adherence the surgeon finds upon entering the sella turcica. Necrosis is rare (3%) and usually of modest and focal nature. Little is known of the mechanisms by which the infiltrate causes loss of function/destruction of the endocrine cells or impairment of vasopressin release. Little is also known about the natural history of autoimmune hypophysitis. It is believed that the initial phases are characterized by swelling and edema of the pituitary, which then later becomes small and fibrotic.

AUTOIMMUNE FEATURES

That autoimmune hypophysitis is truly an autoimmune disease is indicated by animal models (indirect evidence) and by circumstantial evidence (Rose and Bona, 1993). No case of autoimmune hypophysitis transmission from mother to newborn (direct evidence) has been reported, suggesting that pituitary antibodies described thus far in this disease are not pathogenic. Circumstantial evidence of autoimmunity derives from the association between autoimmune hypophysitis and other diseases of known autoimmune nature, such as Hashimoto's thyroiditis, Addison disease and systemic lupus erythematosus, and by the improvement of

symptoms upon usage of immunosuppressive drugs such as glucocorticoids, methotrexate, and azathioprine.

The autoantigen recognized by the autoimmune attack awaits identification. Kobayashi's laboratory first described sera from patients with pituitary disorders that, when reacted with pituitary cytosolic extracts, recognized a 22 kDa protein (Yabe et al., 1995; Kikuchi et al., 2000), later identified by Takao et al. (2001) as growth hormone. Crock's laboratory later reported that seven of 10 patients with biopsy-proven lymphocytic hypophysitis and 12 of 22 patients with suspected hypophysitis had a low titer antibody that recognized a 49 kDa cytosolic pituitary protein (Crock, 1998), subsequently identified as α-enolase (O'Dwyer et al., 2002b). The authors concluded that α-enolase is the autoantigen targeted by the immune system in autoimmune hypophysitis which, considering its coexpression in the placenta, explains the strong association between autoimmune hypophysitis and pregnancy (O'Dwyer et al., 2002a). Antibodies recognizing α-enolase, however, have been reported in many other diseases, ranging from endometriosis to discoid lupus and Wegener's granulomatosis (Crock, 1998). In addition, Tanaka et al. (2003) showed that the antibody was present in seven of 17 patients (41%) with autoimmune hypophysitis, but similarly in six of 13 (46%) patients with non-functioning pituitary adenoma, and in four of 17 (24%) patients with other pituitary diseases, making the α-enolase antibody inadequate as a diagnostic marker of autoimmune hypophysitis. Finally, Nishiki et al. (2001) reported that five of 13 patients with LAH and one of 12 patients with LINH had antibodies that recognized 68, 49, and 43 kDa proteins in pituitary membrane extracts.

GENETIC AND ENVIRONMENTAL INFLUENCES

Insufficient data are available to establish associations between the genes that are classically thought to influence autoimmunity, such as the MHC locus and CTLA-4, and autoimmune hypophysitis. Also no environmental agent has been involved, with the exception of four cases presenting after a viral infection of the meningi (Vanneste and Kamphorst, 1987; Honegger et al., 1997; Sandler et al., 1998; Matta et al., 2002).

ANIMAL MODELS

Only a few papers have been dedicated to the establishment of animal models of autoimmune hypophysitis. In 1964 Beutner and Witebsky immunized 16 rabbits up to five times with rabbit anterior pituitary extracts, emulsified in complete Freund's adjuvant. They were able to induce specific antibody responses but no pituitary pathology (Beutner et al., 1964). In 1967 Levine reported the first successful model of experimental autoimmune hypophysitis by immunizing rats with a single intracutaneous injection of rat pituitary tissue, emulsified in complete Freund's adjuvant. Two to three weeks after the injection, in six of the 14 rats (43%) the adenohypophysis showed focal and diffuse infiltration with mononuclear cells, mainly lymphocytes, monocytes, and occasional epithelioid cells. A few posterior and intermediate lobes had minimal inflammation. Disease incidence could be increased to 75% (15/20 rats) by addition of a second immunologic adjuvant, pertussis toxin. Levine subsequently showed that pituitary extracts from guinea pig were the most potent inducer of experimental autoimmune hypophysitis (6/6 rat recipients), whereas human and cow extracts were poorly effective, and dog and rabbit extracts not effective at all (Levine, 1969). In 1970 Beck and Melvin induced experimental autoimmune hypophysitis in one rhesus monkey by injecting her multiple times, over the course of 3 years, with human placental extracts and human chorionic gonadotropin, both emulsified with Freund's adjuvant. Histology showed infiltration of the adenohypophysis with lymphocytes and scattered plasma cells; the neurohypophysis was normal.

In 1982 Klein induced lymphoplasmacytic infiltration of the anterior pituitary by injecting 12 rabbits (seven cases and five controls) three times, at 2-week intervals, with rabbit pituitary tissue, emulsified in complete Freund's adjuvant. Eight weeks (10 rabbits) or 16 weeks (two rabbits) after the first injection, five of the seven experimental rabbits showed focal infiltration of the adenohypophysis with lymphocytes, some plasma cells, and a few eosinophils and fibrosis. None of the five controls showed histologic abnormalities. In 1992, Yoon et al. immunized over 100 hamsters by injecting intradermally three times, at 1-week intervals, recombinant rubella virus E1 and E2 glycoproteins. Three weeks after the first injection, specific antibodies against the adenohypophysis were found in 95% of the hamsters. Eleven weeks after the first injection, a diffuse lymphocytic infiltration occurred throughout the adenohypophysis. None of the hamsters that had received the control protein (nonglycosylated rubella nucleoprotein C) developed such lesions. The disease could be prevented by neonatal thymectomy and could not be produced by passive transfer of the autoantibodies, thus indicating that T cells are critical for disease induction and that antibodies are more important as markers of disease, rather than as a pathogenic player (Yoon et al., 1992). Finally, Watanabe et al. in 2001 immunized 12 Lewis rats twice, at 1-week intervals, with rat pituitary extract emulsified in complete Freund's adjuvant. Three (N = 6) or 6 weeks (N = 6) after the first immunization, rats showed minimal lymphocytic infiltration in the adenohypophysis and developed antibodies directed against growth hormone, thyroid-stimulating hormone and luteinizing hormone (Watanabe et al., 2001). It is unclear, however, whether these hormones represent the initiating autoantigens or are rather

the natural response of the immune system to the injection of hormone-rich pituitary extracts.

A somewhat different experimental approach has been recently published by Stockinger's laboratory (De Jersey et al., 2002; 2004). The authors have designed a transgenic mouse that expresses specifically in the anterior pituitary (because under transcriptional control of the growth hormone promoter) a nucleoprotein from the influenza virus, thus a foreign antigen. This influenza nucleoprotein contains a peptide that binds to the D^b allele of the mouse MHC locus and is recognized by specific $CD8^+$ T cells. When the authors crossed the nucleoprotein transgenic mice to TCR transgenic mice that have $CD8^+$ T cells specific for that nucleoprotein, they observed growth hormone defect due to destruction of the growth hormone cells expressing the viral antigen. Although informative about accessibility and homing of $CD8^+$ T lymphocytes to the pituitary, this transgenic model is likely remote from the human disease where $CD8^+$ T lymphocytes are rarely seen in the infiltrate and somatotrophs are usually spared by the autoimmune attack.

IMMUNOLOGIC MARKERS IN DIAGNOSIS

The main diagnostic issue is the differentiation between the rare autoimmune hypophysitis and the overwhelmingly more common pituitary tumors (mainly adenomas). Of all pituitary expanding lesions, 92% are tumors; the remaining 8% are nontumorous and include cysts, hyperplasia, vascular lesions, bony lesions, primary and secondary hypophysitides (Saeger, 2003). All expanding lesions located in the sella turcica have similar clinical findings, so the distinction among them can be achieved with certainty only by examining under the microscope the pituitary tissue obtained from surgical procedures. Surgery, however, is invasive and costly and can injure the patient. For this reason, authors have struggled to define criteria more suggestive of autoimmune hypophysitis. These include clinical hints, endocrinologic testing, imaging studies, and immunologic markers.

Clinical suspicion of autoimmune hypophysitis should be raised if symptoms appear in striking temporal relationship with pregnancy and post partum, if the degree of hypopituitarism (partial or complete) appears disproportionate to the size of the radiologically evidenced pituitary mass (Guay et al., 1987), and if the hypopituitarism involves mainly the adrenal and thyroidal axis, rather than growth hormone and gonadotropins. Clinical criteria, however, have extremely low predictive values.

Endocrine evaluation of anterior pituitary hormones shows that corticotrophs are the most frequently impaired cells (59% of patients), followed by gonadotrophs, somatotrophs, and thyrotrophs. Based on these data and on the notion that the deficiency of ACTH can be observed in isolation (Jensen et al., 1986; Escobar-Morreale et al., 1994), some authors consider it the earliest functional alteration in autoimmune hypophysitis. It is important to note, however, that isolated ACTH deficiency can be observed in the absence of autoimmune hypophysitis (Sauter et al., 1990; Nagai et al., 1997) and that isolated deficiencies of other pituitary hormones have been described in autoimmune hypophysitis. The greater frequency of ACTH defects may simply represent a selection bias, considering that these patients may come to medical attention more promptly than patients with other tropin deficiencies.

Imaging studies are currently the most powerful tool to differentiate autoimmune hypophysitis from pituitary tumors, although this distinction is not always possible (Caturegli et al., 2005). Computed tomography was used in the first patient diagnosed ante mortem (Mayfield et al., 1980), and exclusively until 1988. Since then, MRI has become the most commonly used imaging study. In patients with LAH, MRI shows a symmetrical enlargement of the pituitary, with symmetrical suprasellar extension; the stalk may be thickened but not deviated. In pituitary adenomas, in contrast, the mass and the suprasellar extension are asymmetric and the stalk is deviated contralaterally. After injection of the contrast medium (gadolinium), the enhancement in LAH is intense and homogeneous and creates strips of abnormal enhancing tissue adjacent to the enlarged pituitary (the so-called "dura tail"), whereas in adenomas the enhancement is slight, delayed, inhomogeneous, and without a dura tail. In patients with LINH, MRI shows a thickened stalk and a swollen posterior lobe that has lost its normal hyperintense signal, observed after contrast enhancement.

Antibodies against pituitary antigens were measured in 83 of 379 patients, mainly by indirect immunofluorescence (Bottazzo et al., 1975) or Western blotting (Crock et al., 1993). They were found positive in a minority of patients, yielding an extremely poor sensitivity (37%) (Caturegli et al., 2005). They are also not specific for autoimmune hypophysitis, considering that they have been described in type 1 diabetes (Mirakian et al., 1982), Hashimoto's thyroiditis (Kobayashi et al., 1988), Graves' disease (Hansen et al., 1989), and normal women post partum (Engelberth and Jezkova, 1965). This lack of sensitivity and specificity may have several explanations. Patients with autoimmune diseases come to medical attention long after the onset of disease and it is known that antibodies against endocrine glands disappear over the years. In addition, the autoantigen/s targeted by autoimmune attack in autoimmune hypophysitis is/are still unknown.

TREATMENT AND OUTCOME

The treatment of autoimmune hypophysitis is, at the moment, only symptomatic. It includes reduction of the pituitary mass and replacement of the defective hormones. Mass

reduction treatment comprises surgery, lympholytic drugs, and radiotherapy. Surgery has been the most commonly used form of treatment thus far and in some cases is the only means to control rapidly increasing serious defects of the visual pathway. Surgery is usually performed using the transsphenoidal approach, more rarely by craniotomy. If a diagnosis of autoimmune hypophysitis is suspected and there are no urgent compressive symptoms, the best management is to reduce the pituitary mass with glucocorticoids, monitoring the patient clinically and radiologically (Caturegli et al., 2005).

The majority of patients (72%) require long-term replacement with one or more pituitary hormones. More rarely, autoimmune hypophysitis resolves after mass reduction treatment without need of hormone replacement (16%) or spontaneously (4%). In the remaining 8% of patients, autoimmune hypophysitis has resulted in death, considered secondary to irreversible adrenal insufficiency. Deaths have occurred almost constantly through the years (11 deaths from 1962 to 1982 and 14 deaths from 1983 to 2003), to remind us that autoimmune hypophysitis can be fatal if unrecognized.

CONCLUDING REMARKS— FUTURE PERSPECTIVES

Autoimmune hypophysitis is rare but increasingly recognized. It offers a fascinating model to study the effect of pregnancy on autoimmune diseases and the interactions between nervous, endocrine, and immune systems. Patient management will be improved when a reliable serologic test that identifies the autoimmune nature of the pituitary disease becomes available. Much remains to be learned about the natural history of autoimmune hypophysitis. Establishment of experimental models in mice and of a disease registry in humans will greatly advance the field.

Hemolytic Anemia

BRUCE C. GILLILAND

Department of Medicine, Division of Rheumatology, and Department of Laboratory Medicine, University of Washington School of Medicine, Washington, DC, USA

HISTORIC BACKGOUND

Autoimmune hemolytic anemia (AIHA) is characterized by the presence of autoantibodies directed to antigens on the individuals' own red cell membrane, and by evidence of decreased red cell survival mediated by the red cell autoantibody. AIHA was the first autoimmune disorder in which an autoantibody was clearly shown to be involved in its pathogenesis. Historically, paroxysmal cold hemoglobinuria, described by Donath and Landsteiner (1904), was the first example of an autoimmune disease. Chauffard and Colleagues (1908, 1909) reported a case of acute hemolytic anemia in which an active hemolysin was demonstrated. Over the next three decades, the failure to identify a hemolytic serologic factor led many investigators to the concept that acquired hemolytic anemia was caused by a latent cell defect similar to that observed in familial hemolytic anemia. During these years, the main focus of interest was familial forms of hemolytic anemia. Interest in an extrinsic hemolytic factor was renewed when Dameshek and Schwartz (1938) demonstrated a hemolysin in the sera of three patients that caused destruction of transfused normal red cells. Dacie and Mollison (1943) distinguished familial hemolytic anemia from acquired hemolytic anemia. They demonstrated that normal red cells transfused into patients with familial hemolytic anemia had a normal lifespan, in contrast to a drastically shortened lifespan when transfused into patients with acquired hemolytic anemia. These observations indicated that patients with acquired hemolytic anemia had an extrinsic factor, presumably antibody, which led to accelerated destruction of normal transfused red dells. Young et al. (1951) applied the term "autoimmune" to those cases of acquired hemolytic anemia in which patients had developed antibodies reacting with their own red cells.

Coombs et al. (1945) developed an antiglobulin test for the detection of weak and incomplete Rhesus (Rh) agglutinins, thus providing a method for detection of antibody on the red cell surface. Boorman et al. (1946) and Loutit and Mollison (1946) applied the antiglobulin (Coombs) technique to detect autoantibodies on the red cells of patients with acquired hemolytic anemia, thus establishing a role for these antibodies in the pathogenesis of AIHA. Dacie (1951) reported that the red cells in acquired hemolytic anemia were either sensitized with gamma-globulin or non-gamma-globulin. Subsequently, Harboe et al. (1963) demonstrated that complement components were responsible for the non-gamma-globulin reactions. Today, specific antisera allow for the detection of immunoglobulins and their subclasses, as well as complement components on the red cell membrane.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

CLASSIFICATION

Autoimmune hemolytic anemias are usually classified into warm reactive type and cold reactive type based on the optimal temperature at which autoantibodies react with red cells *in vitro* (Box 41.1). Drug-induced autoantibodies comprise a third group and are usually of the warm reactive type. Warm reactive type autoantibodies react optimally at 37°C but also react at lower temperatures. Cold reactive type autoantibodies react optimally at 0–5°C and show decreasing red cell affinity as the temperature is raised to 37°C. They do not usually bind to the red cell at 37°C. A small number of patients have both cold and warm reactive autoantibodies, each having its own red cell antigen specificity.

Both warm and cold reactive types of AIHA are referred to as idiopathic or primary when no underlying or associated disorder can be recognized. When AIHA occurs in associations with another disorder, it is referred to as secondary. Secondary AIHA is most often associated with lymphoproliferative disorders, including lymphomas. A smaller number of cases occur in patients with systemic lupus erythematosus (SLE) and other multisystem autoimmune disorders, and also in inflammatory bowel disease (see Section II-A and Chapter 52).

Box 41.1
Classification of Autoimmune Hemolytic Anemia (Gilliland, 1996)

Warm autoantibody type
1. Idiopathic
2. Secondary: lymphoma, chronic lymphocytic leukemia, systemic lupus erythematosus, other autoimmune disorders, ovarian tumors, chronic inflammatory disorders

Cold autoantibody type
- Cold hemagglutinin disease
  1. Idiopathic
  2. Secondary: transient (acute)—*M. pneumoniae* infection, infectious mononucleosis, other infections; chronic—lymphoreticular malignancies
- Paroxysmal cold hemoglobinuria
  1. Idiopathic
  2. Secondary: viral and other infections, syphilis

Drug-induced immune hemolytic anemia
- Drug adsorption (hapten) type (e.g., penicillin)
- Drug-dependent antibody type, also referred to as immune complex (e.g., second- or third-generation cephalosporins)
- Autoimmune induction type (e.g., α-methyldopa)
- Nonimmunologic adsorption of protein (e.g., cephalothin)

WARM AUTOANTIBODY TYPE

Warm autoantibodies are most frequently encountered in AIHA. The onset of hemolytic disease is usually after the age of 40, and the incidence increases with age, reflecting the association of AIHA with lymphoproliferative disorders. Idiopathic warm type AIHA is more common in women, as is secondary AIHA associated with SLE. Idiopathic AIHA occurs sporadically and usually without a precipitating event such as an infection. Warm autoantibodies occasionally are accompanied by autoantibodies to platelets, which is referred to as Evans syndrome (Evans and Duane, 1949). Patients with warm type AIHA usually present with symptoms attributable to their anemia, such as fatigue, weakness, and pallor. In older patients, the anemia may lead to angina, myocardial infarction or heart failure. In patients with brisk hemolysis, urine is dark secondary to hemoglobulinuria. Jaundice may also be present. Patients usually have only a moderate degree of splenomegaly; however, with severe hemolytic anemia there may be significant hepatosplenomegaly. In patients with mild hemolytic anemia, a large spleen is usually indicative of an underlying lymphoproliferative disorder.

Pathophysiology

The coating of the red cell with autoantibody leads to the destruction of red cells by intravascular, extravascular, and/or cell-mediated mechanisms. The spleen plays a key role in the removal of IgG autoantibody-coated red cells (Jandl et al., 1957; Mollison et al., 1965; Schreiber and Frank, 1972; Chang et al., 1993). When blood enters the spleen, red cells become highly concentrated and pass through fine fenestrations between macrophages, enhancing their interaction with these cells. Macrophages have receptors for the Fc portion of IgG (subclasses IgG1 and IgG3), which bind IgG-coated red cells (LoBuglio and Jandl, 1967; Huber et al., 1968; Abramson et al., 1970). This interaction of red cell-bound autoantibody with macrophages results in either phagocytosis of the entire red cell or partial internalization of a portion of the red cell membrane. In the latter situation, the remaining red cell reseals and re-enters the circulation as a microspherocyte. Microspherocytes, because of their rigidity and increased osmotic fragility, have a greatly shortened lifespan (Fleer et al., 1978). They are fragmented or destroyed in the circulation and in subsequent passages through the spleen. Microspherocytes in the peripheral circulation signify ongoing hemolysis, usually through the process of IgG-mediated erythrophagocytosis.

The degree of microspherocytosis correlates with the severity of the hemolytic process. Some warm type autoantibodies fix complement on the red cell; however, complement-mediated hemolysis is unusual in warm type AIHA. Human red cells are relatively resistant to complement lysis because of several membrane regulating proteins that block complement activation at specific steps. Decay-accelerating factor (DAF, CD55) acts by binding to C3 convertases of both the classical and alternative complement pathways, leading to increased spontaneous decay of C3 convertase, and thereby limiting the amount of C3 membrane deposition (Fujita et al., 1986; Kinoshita et al., 1986). CD59 is a regulatory protein which is able to bind to C8 in the C5b-8 complex and interfere with the incorporation of C9 (Rollins et al., 1991). CD59 also can bind to C9 in the membrane attack complex, preventing polymerization of C9 and the full development of the transmembrane pore (Rollins and Sims, 1990). Another membrane protein proposed to regulate the formation of C5b-9 complex is homologous restriction factory/C8-binding protein (HRF/C8bp) (Zalman, 1992). This protein has been reported to block C8 and C9 deposition into membranes, thereby preventing red cell lysis.

The rate of hemolysis is dependent on several factors, including the quantity of cell-bound IgG subclass, other cell-bound immunoglobulin classes, the affinity of the autoantibody, the presence of cell-bound complement, and activated receptors on macrophages for IgG and/or complement (Chaplin, 1990). In addition, the chemical and physical characteristics of the antigen on the red cell also are determinants for the effectiveness of autoantibodies to cause hemolytic anemia. Although there are exceptions, the rate of hemolysis correlates with the amount of IgG autoantibody on the red cell membrane, particularly in the individual patient (Garratty and Nance, 1990; Garratty, 1991; Dubarry et al., 1993). The quantity, however, of autoantibody required to produce hemolytic anemia varies among patients. The presence of IgA and/or IgM in association with IgG was reported by Sokol et al. (1990) to be more likely associated with hemolytic anemia than those cells coated with IgG alone. IgG1 and IgG3 are most often found in patients with active hemolysis. IgG3 was reported by Engelfriet et al. (1981) to be commonly associated with active hemolytic anemia. The quantity of IgG1 and/or IgG3 is an important determinant for red cell destruction (Abramson et al., 1970; Huber et al., 1971). When red cells were coated with IgG1 alone or in combination with IgG2 or IgG4, 2000 or more molecules of IgG1 per red cell were necessary to stimulate phagocytosis and rosette formation *in vitro*, while an average of only 230 molecules of IgG3 per red cell were required to produce monocyte binding (Zupa'nska et al., 1986). When complement accompanies IgG on the red cell, binding to monocytes *in vitro* was enhanced and fewer molecules of IgG were required.

Autoantibody Characteristics

Warm type autoantibodies are usually IgG and polyclonal. Their restriction to the Gm allotype and/or light chain type has been reported (Leddy and Bakemeier, 1965; Litwin et al., 1973). In patients with AIHA, the subclass of IgG is most often IgG1 and frequently is the only subclass identified on the red cell. IgG3 alone on the red cell was reported by Engelfriet et al. (1982) in 2% of patients and in combination with other subclasses in approximately 5%. IgA or monomeric IgM was found in only 1% of patients and was frequently associated with complement on the red cell.

The specificity of many of these autoantibodies has been thought to be directed to the Rh antigen complex. This was based on the observation that these antibodies reacted weakly or not at all with Rh_{null} red cells that lacked determinants of the Rh complex. Furthermore, some autoantibodies reacted with Rh antigens such as E, e, or C (Weiner and Vos, 1963; Leddy et al., 1970; Dacie, 1975; Garratty, 1991). Rh_{null} cells have now been recognized to be deficient in the membrane antigens LW and Fy, and to have decreased amounts of U and Ss, and of glycophorin B (Dahr et al., 1987; Avent et al., 1988). It is now appreciated that many of these autoantibodies that did not react in the past with Rh_{null} cells had specificities outside the Rh system (Celano and Levine, 1967; Marsh et al., 1972). Red cell autoantibodies reacting equally well with Rh_{null} and normal red cells have specificities outside of the Rh system, including Wr^b, En^a, Ge, A, B, and antigens within the Kidd and Kell blood group systems (Issitt et al., 1976; Bell and Zwicker, 1978; Marsh et al., 1979; Mollison et al., 1993a; Garratty, 1994).

Red cell autoantibodies have been shown to be reactive with specific membrane proteins by immunochemical techniques. Some autoantibodies have been shown to recognize red cell protein Band 4.1 or red cell membrane Band 3 glycoprotein (Wakui et al., 1988; Victoria et al., 1990). Red cell protein Band 4.1 binds the spectrin–actin matrix to transmembrane proteins of phospholipids (Sato and Ohnishi, 1983; Anderson and Lovrien, 1984). Protein Band 3 traverses the lipid membrane and functions as an anion transport channel (Steck, 1978; Jennings, 1984). Victoria et al. (1990) demonstrated the reactivity of 12 warm IgG autoantibodies with Band 3. Barker et al. (1992), however, were unable to show reactivity with Band 3 with 11 eluates obtained from patients with AIHA. Eluates did react with a polypeptide band of 32 kDa and a band of 38–51 or 40–51 kDa, which corresponded with a pattern produced by two Rh-specific monoclonal antibodies. Leddy et al. (1993) studied the autoantibodies of 20 patients and found that these antibodies reacted with four distinct membrane proteins alone or in combinations. Nine of the eluates recognized Rh-containing polypeptides, five reacted strongly with only Band 3, and six reacted with both Band 3 and

glycophorins A (GPA). In a subsequent study, Leddy et al. (1994) examined these six eluates for their reactivity with $Wr(b^+)$ red cells because the Wr^b antigen is formed by the interaction of Band 3 and GPA (Telen and Chasis, 1990). One eluate was found to have a specificity to Wr^b, while two had evidence of Wr^b reactivity as well as other specificities, and three did not show any reactivity to Wr^b antigens. The latter three eluates apparently reacted with an antigen(s) dependent on the Band 3-GPA interaction, which was not $Wr(b^+)$ related.

A naturally occurring red cell autoantibody has been identified that recognizes an antigen on aging red cells (Kay, 1986 and 1994; Branch et al., 1984; Galili et al., 1986). The antigen (referred to as senescent red cell antigen) has been identified as a degradation product of Band 3 (Kay, 1975; 1986; 1994). It is speculated that these autoantibodies serve to remove old red cells from the circulation.

Autoimmune hemolytic anemia has been associated with antiphospholipid autoantibodies (Cabral et al., 1990; Arvieux et al., 1991; Sthoeger et al., 1993). Red cell eluates were shown to have IgG anticardiolipin reactivity. These autoantibodies may account for the antiglobulin (Coombs)-positive hemolytic anemia found in some patients with primary antiphospholipid syndrome or with antiphospholipid syndrome secondary to SLE. It also may explain the finding of IgG and complement on the red cells of some patients with SLE who do not have immune hemolytic anemia.

Antiglobulin Test

Antiglobulin tests are usually performed with a broad-spectrum antiglobulin antiserum directed primarily against IgG and C3. Antiserum should recognize C3d/C3dg, which remain on the red cell membrane after degradation of C3. Under special circumstances, IgA and IgM antisera are used. Three basic patterns are observed: IgG only, IgG plus C3, and C3 alone (Table 41.1). In various reports of warm-reacting type AIHA (Dacie and Worlledge, 1969; Petz and Garratty, 1980a; Engelfriet et al., 1982), IgG alone ranged from 18 to 64%, IgG plus C3 from 34 to 65%, and complement alone from 10 to 33%. A positive indirect antiglobulin test signifying free serum autoantibodies is not common in the absence of a positive direct antiglobulin test (DAT). Sensitivity of the indirect antiglobulin test can be increased by using enzyme-treated donor red cells, but care must be taken to exclude alloantibodies when interpreting the test.

Hemolytic anemia occurs in a small number of patients with warm autoantibodies who have a negative antiglobulin test as performed by conventional methods. The DAT requires the presence of 300–500 molecules of IgG per red cell using quantitative methods (Gilliland et al., 1971). AIHA, therefore, can occur in some instances with levels of IgG autoantibody below this threshold. The frequency of antiglobulin-negative disease has been reported as 2–4% of patients, but with more sensitive techniques, small amounts of red cell-bound autoantibody can be identified in many of these patients (Chaplin, 1973; Worlledge, 1978).

Treatment

Glucocorticoids remain the mainstay of treatment. The initial dose is usually 40–60 mg/day given in divided doses for the first 14 days. Patients will respond with an increase in hematocrit and decreased hemolysis. Prednisone is gradually reduced to the lowest level to maintain an adequate hematocrit. Prednisone is thought to decrease red cell destruction by interfering with the monocyte–red cell interac-

TABLE 41.1 Autoimmune hemolytic anemia (Gilliland, 1996)

DAT, direct antiglobulin test.

*IgG can be detected on red cells apparently coated with C3d alone by more sensitive techniques, warm-reacting IgM antibodies also may fix complement to red cells.

tion that occurs predominantly in the spleen and liver (Schreiber et al., 1975; 1977; Kay and Douglas, 1977). It also leads to a reduction of autoantibody production and decreased binding affinity of autoantibody to red cell antigens (Rosse, 1971).

In patients who have not had a satisfactory response to prednisone, splenectomy should be considered. Approximately two-thirds of patients will have a complete or partial response to splenectomy, allowing the dose of prednisone to be reduced or even discontinued (Christensen, 1973; Bowdler, 1976; Petz and Garratty, 1980b; Zupa'nska et al., 1981). Splenectomy increases the risk of pneumococcal sepsis, especially in children; therefore, pneumococcal vaccine should be given prior to the surgery and in subsequent years (Allgood and Chaplin, 1967).

Immunosuppressive therapy is reserved for those patients who have not responded well to glucocorticoids and/or splenectomy (Mueller-Eckhardt and Kretschmer, 1972; Skinner and Schwartz, 1972; Habibi et al., 1974; Worlledge, 1974; Murphy and LoBulgio, 1976; Panceri et al., 1992). In patients who cannot tolerate a splenectomy, immunosuppressive therapy is a reasonable next step. When an immunosuppressive agent does not lead to a reduction in the prednisone dose after 4–6 months, other immunosuppressive agents may be tried, including azathioprine (1–2 mg/kg/day), cyclophosphamide (1–2 mg/kg/day), and chlorambucil (0.1–0.2 mg/kg/day). Cyclophosphamide can also be given intravenously once a month as in the treatment of lupus nephritis (Austin et al., 1986). The intervals and duration of pulsed cyclophosphamide therapy depend on the clinical response. The dose is 0.5–1.0 g/m^2 of body surface area. Cyclosporine A (4 mg/kg/day) has been reported to be effective in some patients (Hershko et al. (1990). Intravenous gamma-globulin (IVIG) may also be effective (Macintyre et al., 1985; Bussel et al., 1986; Leickly and Buckley, 1987; Blanchette et al., 1992; Flores et al., 1993). In resistant disease, treatment with rituximab, a monoclonal anti-CD20 antibody, has been successful (Ahrens et al., 2001; Zecca et al., 2001; Gupta et al., 2002). Another monoclonal antibody, anti-CD52 Campath-1H (alemtuzumab), has also been beneficial in some patients (Willis et al., 2001). Other forms of treatment include danazol (Ahn, 1990; Chan and Sack, 1991; Pignon et al., 1993), antilymphocyte or antithymocyte globulin, vincristine-loaded platelets (Ahn et al., 1983), and plasmapheresis. Patients with chronic hemolytic anemia should receive folic acid (1 mg/day).

COLD AUTOANTIBODY TYPE

Cold-reacting red cell autoantibodies comprise 15–25% of patients with AIHA (Dausset and Colombani, 1959; Van Loghem et al., 1963; Dacie and Worlledge, 1969; Petz and Garratty, 1980c; Engelfriet et al., 1982). Cold autoantibodies react optimally with red cells at 0–5°C, but their thermal amplitude must extend to 25–31°C to be reactive *in vivo* to cause hemolytic anemia. These temperatures are normally encountered in the microvasculature of the skin in the distal extremities, ears, and tip of the nose. The two types of cold autoantibody disorders are cold hemagglutinin disease and paroxysmal cold hemoglobinuria. Both types depend on autoantibodies fixing and activating complement on the red cell membrane, which leads to varying degrees of intra- and extra-vascular hemolysis.

Cold Hemagglutinin Disease

Landsteiner (1903) described that the serum of an animal could agglutinate its own red cells at temperatures near 0°C. Subsequently, Landsteiner and Levine (1926) reported that sera from most normal persons agglutinated their own red cells at 0°C. The term "cold agglutinin disease" was credited to Schubothe (1952) who used this designation to distinguish it from paroxysmal cold hemoglobinuria. Cold hemagglutinin disease can manifest as an acute/transient disease, which is most often associated with infectious mononucleosis or mycoplasma pneumonia. Young persons are most commonly affected. The cold agglutinin in acute/transient disease is usually a polyclonal IgM. Cold hemagglutinin disease also occurs as a chronic disease, found most often in persons over the age of 50. The associated cold agglutinin is usually a monoclonal IgM. Chronic cold hemagglutinin disease occurs as a primary or idiopathic disorder in which no underlying disease can be identified. Cold agglutinin disease can also be associated with chronic lymphocytic leukemia or Waldenström macroglobulinemia, but a malignant lymphocytic disorder occurs in only a few patients.

Patients with the chronic monoclonal cold agglutinin disease usually present with manifestations of chronic anemia, the most common being shortness of breath, fatigue, and in older patients congestive heart failure. Patients may have episodes of hemoglobinemia and hemoglobinuria manifested by passage of dark urine after cold exposure. Patients who live in cooler climates may experience acrocyanosis of the fingers and blueness of the nose and ears when outdoors. Raynaud phenomenon may also be a manifestation. Prolonged cold exposure of an extremity may lead to vascular occlusion and gangrene. In patients with monoclonal IgA cold agglutinins, these cutaneous manifestations occur in the absence of hemolytic anemia because IgA cold agglutinins do not activate the classical complement pathway. Mild splenomegaly is usually present. The spleen may become enlarged during an episode of acute hemolysis. A persistently enlarged spleen suggests an underlying malignant lymphoma. Patients with secondary chronic cold agglutinin disease may present with features of lymphoma (e.g., lymphadenopathy, hepatosplenomegaly,

anemia), and the finding of a cold agglutinin may be incidental.

The hemolytic anemia that develops in patients with infectious mononucleosis or *Mycoplasma pneumoniae* infection usually has an abrupt onset in the second or third week of the illness. It is transient, usually disappearing in 1–2 weeks. Patients may have marked hemoglobinemia and hemoglobinuria, which can lead to transient renal failure. Cold agglutinins are found in approximately 45% of patients with *M. pneumoniae* infections, but hemolytic anemia is unusual. Hemolytic anemia in infectious mononucleosis is also uncommon. Cold agglutinins uncommonly develop following chicken pox or other viral infectious diseases (Friedman and Dracker, 1992).

Pathophysiology

Cold hemagglutinins produce red cell destruction through activation of the complement system, resulting in red cell destruction. The hemolytic potential of cold agglutinins depends on their titer and thermal amplitude, which is the temperature *in vivo* at which cold agglutinins bind to red cells and fix complement (Dacie, 1962; Evans et al., 1968; Brown et al., 1970; Atkinson and Frank, 1974; Jaffe et al., 1976; Rosse and Adams, 1980). The temperature in the microvasculature of the skin in distal extremities usually ranges from 28 to 31°C; therefore, cold agglutinins must be able to react with red cells at these temperatures in order to cause hemolytic anemia. Cold agglutinins with a lower thermal amplitude produce significant hemolytic anemia only when the patient is exposed to cold temperatures. In patients with high titers of cold agglutinins, the thermal amplitude is usually in the temperature range to produce hemolytic anemia at ordinary room temperatures. Acute episodes of hemolysis are exacerbated by cold exposure. Hemolytic anemia has been reported in patients with low titers of IgM cold agglutinins with a higher thermal range (Schreiber et al., 1977; Rousey and Smith, 1990).

When IgM cold agglutinins react with red cells at sites of cooler temperatures in the extremities, the classical complement pathway is activated (Sokol et al., 1982; Frank, 1988). The binding and activation of C1 requires only one IgM molecule to react with the red cell membrane. C1 then activates C4 and C2 to form a C3 convertase, which in turn activates several hundred molecules of C3 that bind to the red cell membrane on return of the red cells to warmer body temperatures. The subsequent binding of C5-9 leads to the lysis of red cells. Red cell destruction to a lesser extent occurs by the mechanism of erythrophagocytosis. Circulating red cells coated with C3b or iC3b bind, respectively, to CR1 and CR3 receptors on macrophages, predominantly in the liver (Berger et al., 1981–1982; Fearon and Wong, 1983). This interaction, as described previously for IgG-coated red cells, results in sphering and eventual destruction of red cells (Huber et al., 1968).

The interaction of C3b- and iC3b-coated red cells with CR1 and CR3 receptors, respectively, on hepatic macrophages can produce degradation of C3 without damaging red cells. C3b is degraded in iC3b by factor 1, with factor H and CR1 acting as cofactors. Further degradation results in the formation of C3dg and C3d. A substantial number of C3d- and C3dg-coated red cells are then released from the liver back into the circulation and are no longer recognized by complement receptors (Jandl et al., 1957; Schreiber and Frank, 1972; Lachmann et al, 1982). Red cells with a sufficient coating of C3d and C3dg become resistant to further interactions with cold agglutinins and to further activation of complement, and have a normal survival (Evans et al., 1967).

Autoantibody Characteristics

The specificity of the majority of cold agglutinins is directed to the i/I blood group system. These antigens are oligosaccharides and are closely related to the ABH and Lewis blood groups (Feizi, 1977). They are also expressed on human neutrophils, lymphocytes, and monocytes (Pruzanski and Shumak, 1977). The adult red cells of normal individuals express predominantly I antigen. At birth, however, cord (neonatal) red cells express i antigen, which is gradually replaced by I antigen in the first 18 months of life (Jenkins et al., 1960; Marsh and Jenkins, 1960; Marsh, 1961). The transformation of i to I is through the action of a branching enzyme on this glycoprotein (Watanabe and Hakomori, 1976). This process occurs as red cells leave the marrow and mature. Reticulocytes express more i antigen than adult red cells. Stimulation of the bone marrow by repeated phlebotomy results in the emergence of red cells into the peripheral circulation that have more i reactivity (Hillman and Giblett, 1965). The amount of i is inversely proportional to the length of the transit time of red cells from the bone marrow. A rare normal individual expresses only i on adult red cells, indicating a lack of branching enzyme (Race and Sanger, 1975). When the glycoprotein antigen is extracted from the red cell membrane, cold agglutinins react with their respective I or i antigen at 37°C, indicating that cold-induced conformational changes of the antigen are required for *in vivo* reactivity (Rosse and Lauf, 1970; Lau and Rosse, 1975).

Cold agglutinins may infrequently be specific for Pr antigen, which is so designated because of its sensitivity to protease treatment. Cold agglutinins directed against Pr antigens and other antigens outside the I/i system are recognized by the finding that the patient's serum reacts equally well with adult and cord (neonatal) red cells (Roelcke, 1974; Roelcke and Kreft, 1984). Cold agglutinins with anti-Pr specificity will not bind to papain-treated red cells. Other

specificities of cold agglutinins are rarely observed (Mollison et al., 1993b).

Molecular studies have shown that the highly restrictive V_H4–21 germline gene segment is essential for the generation of cold agglutinins with either anti-I or anti-i specificity (Silverman and Carson, 1990; Silberstein et al., 1991; Pascual et al., 1992). Cold agglutinins share a common idiotype as first shown by Williams et al. (1968). Later, in studies using a rat monoclonal anti-idiotype antibody (9G4), a conformation-dependent idiotype encoded by the V_H4–21 gene segment was found in cold agglutinins from different individuals (Pascual et al., 1992; Thompson et al., 1991). The anti-idiotype antibody also has been shown to inhibit cold agglutinin activity, suggesting that it recognizes an epitope close to the antigen-binding site (Thompson et al., 1991). The idiotype generated by the V_H4–21 gene segment has also been identified in a high proportion of circulating B-cells and marrow lymphoplasmacytoid cells in patients with chronic cold agglutinin disease, and in a small proportion of B-cells in the circulation and lymphoid tissue of normal individuals (Stevenson et al., 1989). Cold agglutinins also have restricted light chain variable gene segment expression. Anti-I cold agglutinins preferentially use κ light chains (Harboe et al., 1965; Capra et al, 1972) restricted to the V_κ III family (Silverman and Carson, 1990), whereas cold agglutinins with anti-i specificity use several V_L gene segment families also involving λ light chains (Feizi, 1967; Pruzanski et al., 1974; Roelcke et al., 1974; Silberstein et al., 1991). The restriction of V_L gene segment usage may be a factor in determining anti-I or anti-i specificity.

Thompson et al. (1991) reported the usage of the V_H4–21 gene segment by human alloantibodies against a diverse group of red cell antigens. This would indicate that the V_H4–21 gene segment can encode IgM anti-red cell antibodies having specificities to structurally diverse red cell antigens. In addition, antibodies to exogenous carbohydrate antigens have been shown to be encoded by a restricted set of V_H and V_L genes (Adderson et al., 1992, 1993).

The characteristics and specificity of the cold agglutinins have clinical associations. Monoclonal IgM cold agglutinins with i specificity have been reported to be associated with malignant lymphoma (Crisp and Pruzanski, 1982). In patients with infectious mononucleosis, the IgM cold agglutinins are polyclonal and frequently have i specificity, whereas in *M. pneumoniae* infection the cold agglutinins are directed to the I antigen (Jenkins et al., 1965; Rosenfield et al., 1965; Costea et al., 1966; Feizi and Schumacher, 1968; Dacie and Worlledge, 1969). In some patients with infectious mononucleosis or angioimmunoblastic lymphadenopathy, a polyclonal nonagglutinating IgG reactive with i antigen was shown to bind to red cells at reduced temperatures. Hemagglutination observed *in vitro* was produced by IgM anti-IgG autoantibodies that react with red cells coated with IgG anti-i in the cold (Goldberg and Barnett, 1967; Capra et al., 1969).

Antiglobulin Test

The DAT shows only C3d or C3dg on the red cell membrane (see Table 41.1). The titer of cold agglutinins in patients with chronic cold hemagglutinin disease is usually 1:1000 or greater at 4°C (Petz and Garratty, 1980d). When titers are below 1:1000, the thermal range of cold agglutinins reactivity should be determined. Cold agglutinins that are not able to agglutinate cells in saline at 20°C are usually not pathologic. When agglutination is seen at 20°C, the cold agglutinin titer is determined at 30°C with the red cells suspended in albumin; positive results indicate that these cold agglutinins are capable of producing hemolytic anemia *in vivo* and are of clinical significance (Petz and Garratty, 1980d).

Treatment

Treatment of acute/transient cold agglutinin disease is mainly supportive. Patients should be protected from the cold and kept well hydrated to minimize the effects of hemoglobin on the kidney. Corticosteroids and/or cytotoxic drugs are usually not indicated. Transfusion should be avoided except in life-threatening situations.

In chronic cold hemagglutinin disease treatment depends on the degree of hemolysis and anemia. In patients with well-compensated hemolytic anemia, no specific treatment is required. These patients should, however, be given approximately 1 mg of folic acid/day and advised to avoid cold exposure, including exposure through drinking large quantities of cold beverages. Cytotoxic drugs are reserved for patients with more severe hemolytic anemia. The two most commonly used drugs are cyclophosphamide and chlorambucil (Dacie and Worlledge, 1969; Schubothe, 1966; Hippe et al., 1970; Evans et al, 1973). These drugs lead to a decrease in the amount of cold agglutinins and therefore decreased hemolysis. Corticosteroids and splenectomy usually are not beneficial except in those patients who have low titers of IgM cold agglutinins with high thermal range and in patients with IgG cold agglutinins (Silberstein et al., 1987). They also may be beneficial in patients who have evidence of red cell destruction occurring by erythrophagocytosis, a process that involves the spleen and is responsive to glucocorticoids. Plasmapheresis may provide transient improvement (Andrzejewski et al., 1988). There are conflicting reports of the effectiveness of interferon-α, being beneficial in some patients (O'Connor et al., 1989) and ineffective in others (Hillen and Bakker, 1994). An overall response rate of 54% was reported in patients treated with rituximab, a monoclonal anti-CD20 antibody (Berentsen et al., 2004). Transfusion should be reserved for those patients

with life-threatening degrees of anemia. The patient should be kept warm during the transfusion and the donor red cells warmed to body temperature before administration (Rosenfeld and Jagathambal, 1976).

Paroxysmal Cold Hemoglobinuria

Paroxysmal cold hemoglobinuria (PCH) is a rare form of AIHA which is most commonly observed in children following a viral infection. Historically, Donath and Landsteiner (1904) were the first to describe the biphasic hemolysis test necessary to demonstrate the presence of the responsible autoantibody. A positive test was attributable to a cold-reacting autohemolysin and a warm-reacting lytic factor. Acute episodes of hemolysis following cold exposure led to this disorder being termed "paroxysmal cold hemoglobinuria" (Donath and Lansteiner, 1925). PCH was initially observed to be often associated with syphilis, but today is most commonly associated with a variety of viral infections (Wolach et al., 1981; Sokol et al., 1982; Lau et al., 1983; Göttsche et al., 1990).

Hemolytic anemia usually develops at the time when patients are recovering from a recent upper respiratory infection. Episodes are characterized by the sudden onset of shaking chills, back and leg pain, and abdominal cramps followed by fever which may be as high as 40°C. Hemoglobin is present in urine. Attacks are not always associated with cold exposure. The constitutional symptoms usually abate after several hours. In most cases of acute/transient PCH the patient recovers in a few days to several weeks without further occurrences. Severe attacks may be life-threatening. Cold urticaria has also been associated with episodes. Renal failure, secondary to hemolysis, may occur and anemia can be quite severe.

Pathophysiology and Autoantibody Characteristics

The autohemolysin in PCH is termed the Donath–Landsteiner (D–L) antibody. The autoantibody is IgG and reacts with red cells at reduced temperatures found in the microvasculature of extremities, resulting in fixation of the early components of complement. Complement activation continues as the blood returns to the warmer core temperature with eventual lysis of the red cells. In patients with the acute transient form of disease, the D–L antibody does not bind to the red cells *in vitro* at temperatures higher than 20°C, yet hemolysis occurs even in the absence of significant cold exposure, indicating that this antibody may react with red cells at higher temperatures *in vivo*. The reason for this is unknown. On the other hand, patients with chronic PCH usually experience hemolysis with cold exposure, similar to patients with cold agglutinin disease. The D–L antibody is usually IgG and has anti-P specificity (Levine et al., 1965; Worlledge and Rousso, 1965). The P antigen is a globoside. Reactivity of the D–L autoantibody with P antigen can be inhibited by globoside and Forssman glycolipids, which are found in a variety of microorganisms (Schwarting et al., 1979). This suggests that the autoantibody response may be to a cross-reacting antigen present in some microorganisms. Infections associated with PCH include measles (also measles vaccination), mumps, infectious mononucleosis, chicken pox, mycoplasmal pneumonia, cytomegalovirus virus, *Haemophilus influenzae, Klebsiella pneumoniae*, and *Escherichia coli*. Even though an infectious etiology is suspected, the microorganism is usually not identified (Vogel et al., 1972; Bird et al., 1976).

Antiglobulin Test

The DAT shows C3d (see Table 41.1). The D–L antibody is detected by mixing serum from the patient with donor red cells in the presence of normal serum as a source of complement (Petz and Branch, 1983). The mixture is incubated at 4°C and then warmed to 37°C, resulting in hemolysis when D–L antibody is present. The D–L antibody may persist for several weeks to months following an acute episode.

Treatment

PCH is usually a self-limited disease and treatment is largely symptomatic. When transfused blood is necessary, it should be warmed. Corticosteroids are sometimes given but are usually of little value in this disorder.

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

Drug-induced immune hemolytic anemia (IHA) has been reported in as many as 18% of patients with AIHA (Petz and Garratty, 1980e). The frequency of drug-induced disease may be even higher because the association between anemia and the drug may not be immediately evident. In addition, patients are often on several drugs and there may be other explanations for anemia. Another problem is that most clinical laboratories are not prepared to perform tests for drug-related antibodies. The concept of the pathogenesis of drug-induced IHA has evolved over the past several decades. Three mechanisms have been defined (Petz and Garratty, 1980e): 1) drug adsorption (hapten); 2) production of drug-dependent antibody (formerly called immune complex/innocent bystander); and 3) induction of autoantibodies (Table 41.2). In the case of some drugs, more than one of these mechanisms may be operative. In addition, certain drugs can produce a coating of red cells with immunoglobulins and other serum proteins (nonimmuno-

TABLE 41.2 Drug-induced immune hemolytic anemia (IHA) (Gilliland, 1996)

Mechanism	DAT	Detection of antibody	Clinical features
Drug absorption, e.g., penicillin	IgG C3d*	Antibody reacts with drug-coated red cells; eluate reacts only with drug-coated red cells	Moderate degree of hemolysis, usually extravascular mechanism
Drug-dependent antibody type, e.g., cefotetan	C3d	Antibody + drug + red cell → sensitization, agglutination, or hemolysis of red cells. Antibody is IgG or IgM; eluate is negative	Abrupt onset of severe intravascular hemolysis; renal failure
Autoimmune induction, e.g., α-methyldopa	IgG	Autoantibodies against red cell; eluate reacts with red cells	Mild-to-moderate degree of extravascular type hemolysis

DAT, direct antiglobulin test.
*Present in approximately 40% of patients with penicillin-induced IHA.

logic adsorption), resulting in a positive DAT but not hemolytic anemia.

Drug Adsorption Mechanism

In the drug adsorption mechanism, drug-induced antibodies react with a drug or one of its metabolic products that is firmly bound to the red cell membrane. Penicillin is the prototype for this mechanism of drug-induced IHA (Van Arsdel and Gilliland, 1965; Swanson et al., 1966; Levine and Redmond, 1967; White et al., 1968). Penicillin is one of a few drugs that have been shown to strongly bind to the red cell membrane and to not be removed with washing of the red cells. Approximately 90% of patients who have been given penicillin in the past will have IgM antipenicillin antibodies, but these antibodies are not involved in the positive antiglobulin test or hemolytic anemia (Garratty and Petz, 1975). Those patients who do develop hemolytic anemia have an IgG antibody directed against the benzylpenicilloyl determinant or other metabolites of penicillin (White et al., 1968). The onset of hemolytic anemia usually occurs after 7 days of treatment but can appear shortly after the beginning of treatment in patients previously sensitized to penicillin. Hemolysis is usually moderate and usually subsides once the drug is discontinued. Prednisone is usually not required. The DAT is positive for IgG accompanied in some instances by complement. The indirect antiglobulin test is negative unless donor red cells coated *in vitro* with penicillin are used.

Drug-Dependent Antibody Mechanism

The drug-dependent antibody mechanism (formerly termed the immune complex/innocent bystander mechanism) was first described by Ackroyd (1949) who observed drug-induced thrombocytopenia following Sedormid administration. He demonstrated that serum antibody against Sedormid was only able to produce agglutination of platelets in the presence of this drug. The drug could be easily removed from the cells by conventional washing or by dialysis against saline. He proposed that the drug transiently bound with the cell membrane protein to form an immunogen which stimulated antibodies that recognize the drug as part of a drug–cell membrane protein antigen. More recent studies have indicated that in many cases, antibody and drug do not bind to the red cells in a nonspecific (innocent bystander) manner. Instead, it appears that a red cell glycoprotein in combination with drug is the immunogen for antibody stimulation and the target for antibody reactivity (Mueller-Eckhardt and Salama, 1990; Salama and Mueller-Eckhardt, 1992). Demonstration of antidrug antibody reactivity with red cells requires the presence of free drug or its metabolite. Furthermore, the antidrug antibodies plus drug may react only with red cells of a specific blood group.

The onset of hemolysis is usually abrupt. Hemolytic anemia can be quite severe, manifested by hemoglobinemia and hemoglobinuria, and complicated by real failure, shock, and/or disseminated intravascular coagulation. Renal failure is a common complication. Hemolysis usually subsides once the putative drug is discontinued; however, drug-dependent antibodies may persist for years, placing the patient at risk for subsequent hemolysis when re-exposed to the drug. The responsible antibodies are either IgG or IgM, which are capable of activating complement, which binds to the red cell. The DAT is positive only for C3d as the drug and antidrug antibody dissociate from the red cell by conventional washing.

Autoimmune Induction Mechanism

Drugs may stimulate the production of autoantibodies, leading to hemolytic anemia. Drug-induced autoantibodies react with antigens intrinsic to the red cell membrane and do not require the presence of drug for their detection. The prototype drug is α-methyldopa. Autoantibody usually appears after 3–6 months of α-methyldopa therapy. The reason for the infrequency of hemolysis, even though approximately 20% of patients develop a positive DAT, was addressed by Kelton (1985), who demonstrated that α-methyldopa impaired Fc-dependent reticuloendothelial

function. A patient who had a positive DAT and hemolysis was shown to have normal reticuloendothelial function, whereas patients who were DAT positive without hemolysis or were DAT negative were found to have impaired reticuloendothelial function, indicating that the drug was responsible.

The DAT may remain positive several months to years after the drug is stopped (Worlledge, 1969b). When the patient is re-exposed to α-methyldopa after autoantibodies have disappeared, it again takes 3–6 months for the autoantibody to appear. The mechanism by which α-methyldopa induces autoantibody is not known. Initially, Worlledge et al. (1966) and Green et al. (1980) suggested that the red cell membrane was altered by α-methyldopa, which resulted in autoantibodies to this neoantigen. Subsequent studies made this unlikely. α-Methyldopa has been shown to increase lymphocyte cyclic adenosine monophosphate, leading to the inhibition of suppressor T-cells (Kirtland et al., 1980) and therefore overproduction of autoantibody-producing B-cells. Garratty et al. (1993), however, were unable to demonstrate depression of suppressor T-cell function.

The DAT shows IgG, occasionally accompanied by complement. Serum autoantibody and eluates react with normal red cells in the absence of free drug. The specificity of autoantibodies has been shown to be directed to the Rh complex (Worlledge, 1969a; LoBuglio and Jandl, 1967; Bakemeier and Leddy, 1968). Studies by Leddy et al. (1993) showed that autoantibodies induced by α-methyldopa recognized a 34-kDa polypeptide and a 37–55-kDa glycoprotein, which are both related to the Rh complex.

The degree of hemolytic anemia is usually mild to moderate. Once the drug is discontinued, hemolysis usually subsides within a few days, but in some cases may continue for several weeks to months (Ewing et al., 1968). Corticosteroids may be required in patients with more severe hemolytic anemia, shortening the period of recovery. The DAT may remain positive for several weeks or even years after discontinuation of the drug (Worlledge, 1969b). Induction of red cell autoantibodies has also been associated with levodopa (Henry et al., 1971; Lindstrom et al., 1977), mefenamic acid (Scott et al., 1968), and procainamide (Kleinman et al., 1984). α-Methyldopa occasionally induces other immunopathic reactions affecting the liver, e.g., hepatitis, as described in Chapter 53.

AUTOIMMUNITY

Most cases of primary warm type AIHA arise spontaneously and appear to be unrelated to a specific HLA haplotype or other genetic factor. In primary or idiopathic disease, the red cell autoantibody is usually not accompanied by polyclonal gammopathy. A small number of cases of AIHA occur in patients with disorders that have other features of autoimmunity, e.g., SLE, lymphoproliferative disorders, and inflammatory bowel disease.

Evidence indicates that warm autoantibodies arise from a selective process that is most likely antigen driven. Warm type autoantibodies also have a well-defined specificity to red cell antigen and a high binding affinity. Clonal selection is also supported by the restriction of IgG subclasses and light chain types of these autoantibodies (Leddy and Bakemeier, 1965; Litwin et al., 1973) and electrophoretic dispersion (Andrzejewski et al., 1991). The specificity and high binding affinity of these autoantibodies indicate somatic mutations of immunoglobulin variable region genes. Many of the findings in warm type AIHA are similar to observations in New Zealand Black mice AIHA (see below).

The emergence of anti-red cell autoantibodies is related to the breakdown of immunologic tolerance (see Chapters 8 and 13). Autoreactive T and B cells are clonally removed in the thymus and bone marrow (central tolerance); however, there remain in normal individuals self-reactive T- and B-cells. These self-reactive cells are controlled by mechanisms of peripheral tolerance, including T-cell anergy and ignorance, and by a unique population of $CD4^+CD25^+$ lymphocytes (see Chapter 9). The anti-self reactivity of these cells is well controlled in view of the low incidence of positive DATs in the normal population and the infrequency of AIHA (Pirofsky, 1969).

T and B cells specific for self-antigens can be activated when exposed to antigens that are normally not presented *in vivo* by antigen-presenting cells (APCs). Helper T (Th) cells from normal individuals respond *in vitro* to synthetic peptides from the red blood cell (RBC) Rh complex (Barker and Elson, 1995; Barker et al., 1997). The proliferation of these T cells was blocked by anti HLA-DR antibodies. The presence of self-reactive T cells in normal individuals indicates that these T cells escaped removal by the thymus. These T cells respond *in vitro* to Rh synthetic peptides, which are cryptic antigens not normally processed *in vivo* by APCs (see Chapter 14). The T cells from normal individuals that recognize these cryptic antigens remain inactive unless stimulated by cross-reactive environmental agents and/or change in antigen processing with presentation of these cryptic antigens (Elson et al., 1995).

Natural self-reactive autoantibodies found in normal individuals include those directed against nuclear antigens, plasma proteins, and cell membrane components (Guilbert, et al., 1982; Coutinho et al., 1995). In normal individuals, IgG and IgM anti-idiotype autoantibodies directed against natural self-reactive autoantibodies act to control the expression of these potentially pathologic autoantibodies (Hurez et al., 1993). Self-reactive antibodies in normal individuals have been identified that react with ABO blood groups (Spalter et al., 1999), with the red cell anion transporter, Band 3 (Lutz et al., 1984), and with the red cell cytoskele-

tal protein, spectrin (Lutz and Wipf, 1982). In addition, T-cell reactivity with the Rh polypeptide has been observed in normal individuals (Barker and Elson, 1994). Spalter et al. (1999) showed that purified IgG and IgM from normal individuals reacted with autologous ABO blood group antigens, but when nonfractionated serum was used, the expression of these autoantibodies was restricted, suggesting an idiotype complementary interaction between the IgG and IgM. Similar findings were reported in a study of patients with warm type AIHA (Stahl et al., 2000). These investigators demonstrated that autologous IgM in patients with AIHA was defective in restricting the reactivity of anti-red cell autoantibodies. This study suggests that within the IgM population of normal individuals there are anti-idiotype antibodies controlling the expression of anti-red cell autoantibodies and their absence in patients with AIHA may be important in the development of clinical AIHA.

The type of T-cell response and resultant cytokine profile play a role in the pathogenesis of AIHA. Barcellini et al. (2000), using whole blood cultures from patients with warm type hemolytic anemia, examined the cytokine profile after mitogen stimulation, and in parallel experiments, measured anti-red cell antibody production after mitogen and cytokine stimulation. In the AIHA patients, mitogen stimulation of the whole blood culture increased the Th2 cytokines, interleukin (IL)-4, IL-6, and IL-13, and reduced production of interferon (IFN)-γ, a Th1 cytokine. IFN-γ along with IL-2 were further reduced in those patients with active hemolytic anemia. In addition, the secretion of transforming growth factor (TGF)-β was increased in these patients. The addition of Th2 cytokines (IL4, IL-6, IL10 and IL-13) to whole red cell cultures from patients stimulated increased anti-red cell antibody production and increased binding to red cells. The production of anti-red cell antibodies also increased after stimulation with TGF-β. These results suggest that AIHA is mediated by a Th2 response. TGF-β may facilitate B-cell hyperactivity and anti-red cell antibody production by downregulating the Th1 response. Subsequent studies by Fagiolo and Torrani-Terenzi (2002) examined the *in vitro* secretion of cytokines from peripheral blood mononuclear cells of AIHA patients, basally and after mitogen stimulation. Basal secretion of IL-4 was increased, while IFN-γ synthesis was decreased compared to healthy controls. Also, basal levels of IL-10 were elevated in AIHA patients and further increased with mitogen stimulation. IL-12 levels did not increase with mitogen stimulation. This cytokine has been shown to promote development of Th1 cells, leading to inhibition of antibody production. The increased levels of Th2 cytokines and decreased levels of Th1 cytokines suggest an imbalance of IL-10/IL-12 that leads to heightened Th2 cell differentiation and antibody production in AIHA patients.

The role of $CD4^+CD25^+$ regulatory T cells (Tregs) in AIHA has been described in a mouse model (see below). These regulatory cells, derived from the thymus, require activation via their T-cell receptor (TCR) to become suppressive and to inhibit proliferation of $CD4^+$ or $CD8^+$ T cells (see Chapter 9).

Molecular mimicry may be involved in the development of transient postinfectious warm type AIHA in children following a brief viral illness or of cold type AIHA in adults with acute cold hemagglutinin disease associated with mycoplasmal pneumonia or infectious mononucleosis. Approximately 45% of patients with mycoplasmal pneumonia develop cold agglutinins with anti-I specificity (Chanock et al., 1961). This close association between an infectious microorganism and the development of a red cell autoantibody suggests the possibility of cross-antigenicity between red cell antigens and membrane antigens on microorganisms. Rabbits injected with *M. pneumoniae* were demonstrated to develop cold agglutinins with anti-I specificity that cross-reacted with antigenic determinants on the membrane of the microorganism (Janney et al., 1978). Another concept proposed is that *M. pneumoniae* binds to the I antigen, rendering this self-antigen immunogenic. Studies have shown that the I antigen, which is a branched oligosaccharide, has sialic acid-containing receptors for *M. pneumoniae* (Loomis et al., 1983). Injection of human I-positive red cells treated initially with live *M. pneumoniae* into rabbits resulted in enhanced elevated titers of anti-I antibodies in about 30% of rabbits (Feizi et al, 1969). Another study, however, demonstrated that modification of the I red cell antigen was not required for induction of cold agglutinins with anti-I specificity (Costea et al., 1971). Injection of *M. pneumoniae* into mice, which do not possess I antigen on red cells, still resulted in the production of cold agglutinins with anti-I specificity. Furthermore, prior incubation of I-positive human red cells with *M. pneumoniae* did not enhance the cold agglutinin response in rabbits following immunization with these red cells. In infectious mononucleosis, cold agglutinins may develop as a result of polyclonal stimulation by Epstein–Barr virus. Why the specificity of these cold agglutinins is frequently anti-i is not understood. Perhaps here also molecular mimicry is involved.

ANIMAL MODELS

Several murine models have furthered our understanding of AIHA. New Zealand Black (NZB) mice spontaneously develop AIHA (Bielschowsky et al., 1959). Red cell autoantibodies and AIHA are not seen before the age of 3–6 months and by 15 months all mice have AIHA. These mice also develop anti-DNA autoantibodies and renal lesions resembling human SLE. Polyclonal B-cell activation occurs spontaneously early in the life of the NZB mice and is characterized by increased secretion of IgM and production of IgM anti-DNA, but no anti-mouse RBC (MRBC)

autoantibodies (Moutsopoulos et al., 1977; Jyonouchi and Kincade, 1984). The development of AIHA in these mice therefore is not a result of polyclonal B-cell activation but requires T cells. Young Coombs-negative NZB mice (12–14 weeks old) given nondepleting monoclonal anti-CD4 over several weeks did not develop MRBC autoantibodies (Oliveira et al., 1994). Older female Coombs-positive NZB mice were also given anti-CD4 for several weeks and eventually became Coombs negative. On withdrawal of the anti-CD4 antibodies, anti-MRBC autoantibodies appeared in the young mice and reappeared in the older mice.

Antigen specificity of the CD4 cells in Coombs-positive NZB mice was shown by Perry et al. (1996) to be directed to the membrane glycoprotein Band 3, a specificity also found in human AIHA. In subsequent studies, Elson and Barker (2000) and Shen et al. (1999) demonstrated that the dominant epitope eliciting a CD4 T-cell response was the 861–874 peptide sequence of Band 3.

The transgenic mice (anti-RBC Tg) model developed by Okamoto et al. (1992) has furthered our understanding of B-cell autoreactivity, tolerance and the role of cytokines in AIHA. This mouse model carries the immunoglobulin genes that encode an anti-MRBC autoantibody isolated from the anti-red cell autoantibody-producing hybridoma derived from NZB mice (Ozaki et al., 1984). Approximately half of these mice develop AIHA, with individual mice showing variable phenotypes ranging from severe disease to no disease. The source of anti-RBC autoantibody is B-1 cells found primarily in the peritoneum and lamina propria of these mice. These mice do not have conventional B-cells (B-2 cells), which reside primarily in the bone marrow, spleen, and lymph nodes, as these cells are clonally deleted on exposure to red cells. The B1 cells in the peritoneum, however, do not come into contact with red cells and thus persist. On injection of red cells into the peritoneum of these mice, the B-1 cells are removed through clonal deletion by apoptosis. Administration of lipopolysaccharide (LPS) into asymptomatic anti-RBC Tg mice led to activation of B-1 cells and autoantibody production, followed by AIHA (Murakami et al., 1994). When these mice are raised under germ-free and specific pathogen-free conditions, few peritoneal B-1 cells are found. When these mice are placed in a conventional environment or given LPS, there is activation and differentiation of these B-1 cells into autoantibody-producing cells and subsequent AIHA (Murakami et al., 1997). These studies suggest that the intestinal bacteria play a role in the stimulation of anti-red cell antibody production in these mice, possibly by acting as an adjuvant.

Activation and differentiation of B-1 cells into autoantibody-producing cells was also induced by administration of Th2-cell-derived cytokines (Nisitani et al., 1995). To further define the role of IL-10, Nisitani et al. (1998) crossed $RAG2^{-/-}$ mice with anti-RBC Tg mice, the former lacking mature T and B cells. These recombinant mice have few B-1 antibody-producing cells. The transfer of fetal thymus from C57BL/6 mice into these recombinant mice resulted in proliferation and differentiation of B-1 cells into antibody-producing cells, indicating a requirement for T cells. The requirement for T cells, however, could be bypassed by the administration of LPS, IL-5 or IL-10. LPS was shown to increase serum levels of IL-10. Activation of B-1 cells by LPS, IL-5 or IL10 was blocked by administration of an anti-IL-10 antibody, indicating a pivotal role for this cytokine.

Further studies by Sakiyama et al. (1999) defined the role of IL-5 in the induction of AIHA in anti-RBC Tg mice. IL-5 receptor α chain-deficient mice were crossed with anti-RBC Tg mice. The number of B-1 antibody-producing cells in the recombinant mice was negligible, although the total number of peritoneal B-1 cells was approximately 30% that found in anti-RBC Tg mice. When the recombinant mice were given LPS or IL-10, the differentiation of B-1 cells into antibody-producing cells was greatly reduced; however, these cells still showed spontaneous proliferation. IL-5 therefore was essential for the terminal differentiation of B-1 cell into antibody-producing cells.

Recent studies by Mqadmi et al. (2005) demonstrated a critical role of $CD4^+CD25^+$ regulatory cells in a murine model of AIHA. The investigators utilized the Marshall/Clarke and Playfair murine model in which AIHA is induced by repeatedly immunizing C57/B16 mice with rat RBCs (Playfair and Marshall-Clarke, 1973). These mice develop autoantibodies to MRBCs, as well as alloantibodies to rat RBCs. Approximately 30% of these mice develop AIHA. When these mice are depleted of $CD4^+CD25^+$ T cells by injecting anti-CD25 prior to immunization with rat RBCs, 90% develop AIHA. Transfusion of $CD4^+CD25^+$ T cells but not $CD4^+CD25^-$ T cells, which were purified from the spleens of mice immunized with rat RBCs, completely suppressed autoantibody production. When these mice were subsequently immunized with rat RBCs, they did not make anti-MRBC autoantibodies. They continued to produce anti-rat alloantibodies, indicating that suppression by these cells was autoantigen specific.

CONCLUDING REMARKS

AIHA was the first autoimmune disorder in which autoantibodies were shown to be involved in the pathogenesis of the disease state. Early studies were directed to the characterization of the putative autoantibodies and the mechanisms of how these antibodies produced red cell damage. Later, the specificities of anti-red cell autoantibodies were defined by determining their reactivity with antigens isolated from the red cell membrane. T cells from AIHA patients have been shown to recognize specific blood group antigens. The type of T-cell response and accompa-

nying cytokine profile in AIHA appears to be predominantly Th2, a pattern seen in other autoimmune diseases. Studies have shown abnormal anti-idiotype responses in patients with AIHA, which might lead to a loss of peripheral tolerance. The NZB mouse, transgenic mouse, and other animal models have furthered our understanding of the role of immunoregulatory T cells and the effects of cytokines in AIHA. Selected peptides from red cell membranes have been shown to alter the immune response to one that ameliorates the disease. It is possible that the administration of such peptides might be beneficial in the treatment of AIHA. Recent studies in a mouse model demonstrated the importance of $CD4^+CD25^+$ T reg cells for the control and induction of AIHA. These Tregs offer the possibility of novel treatment intervention. In the treatment of warm type AIHA, the chimeric, human, IgGκ monoclonal antibody (rituximab) specific for the CD20 antigen expressed on the surface of mature B cells has been found to be effective in those patients refractory to conventional treatment. It has also been beneficial to a lesser extent in cold agglutinin disease. As in other autoimmune disorders, the future research in AIHA should be directed to the further understanding of the intricacies of immunoregulation and the influence of genetics and environment on the immune system.

Thrombocytopenic Purpura

DAVID GREEN AND SIMON KARPATKIN
New York University Medical School, New York, New York, USA

HISTORIC BACKGROUND

The humoral nature of autoimmune thrombocytopenic purpura (ATP) has been recognized since the seminal and dramatic studies conducted by Harrington in the early 1950s. Prompted by the observation that pregnant women with ATP often give birth to infants with thrombocytopenia, he infused himself and other volunteer subjects with ATP plasma. This resulted in the rapid onset of thrombocytopenic purpura, followed by recovery within 6–8 days (Harrington et al., 1951). Interestingly, only 63% of ATP plasmas studied by Harrington were capable of inducing thrombocytopenia in transfused recipients, indicating that platelet destruction by autoantibody is probably not the sole effector of autoimmune pathogenesis. The antiplatelet factor was present in the IgG-containing serum fraction (Shulman et al., 1965). IgG autoantibody was first detected in the serum of ATP patients by a platelet immunoinjury assay (Karpatkin et al., 1972a; 1972b). A quantitative immunoassay of antiplatelet antibody was developed in 1975 (Dixon et al., 1975). In 1982, van Leeuwen et al. (1982) demonstrated that antibody eluates from ATP platelets bound to normal platelets, but not to thrombasthenic platelets lacking platelet glycoprotein (GP) IIb and GPIIIa; similar conclusions were drawn by Beardsley et al. (1984). Varon and Karpatkin (1983) demonstrated the absence of binding of a monoclonal antiplatelet GPIIb antibody to platelets of ATP patients with thrombocytopenia, but the presence of binding to platelets of patients in remission, suggesting that GPIIb is a major antigen on the platelet surface but which is not detectable in thrombocytopenic patients because it is blocked by patient antibody. This has recently been confirmed (McMillan et al., 2002). Direct binding of antiplatelet antibody to platelet membrane GPIIb, GPIIIa, and GPIb has been reported using antigen-specific assays (McMillan, 2000); however, the pathophysiology of these *in vitro* studies has not been studied *in vivo*, i.e., some of the antibodies were directed against intracellular components of GPIIIa. The spleen is the predominant site of destruction initially, as well as a major source of autoantibody production (McMillan et al., 1972; Karpatkin et al., 1972b).

GENERAL FEATURES

ATP, also referred to as idiopathic thrombocytopenic purpura (ITP) (Karpatkin, 1997), is an autoimmune condition causing platelet destruction, as documented by kinetic studies showing shortened platelet survival and/or platelet

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

production (Ballem et al., 1987). In ATP, autoantibody binds to platelets, resulting in clearance of the opsonized platelets by the phagocytic cells of the reticuloendothelial system (RES) (Figure 42.1). It also crosses the placenta and can result in neonatal ATP (Burrows and Kelton, 1993).

Specific criteria to establish the diagnosis are lacking since the etiology is unknown and other causes of thrombocytopenia must be ruled out. The diagnostic criteria for ATP include: 1) thrombocytopenia and/or shortened platelet survival, as shown by kinetic studies or increased large "stress" platelets or megathrombocytes (which represent increased platelet turnover) (Garg et al., 1971); 2) increased (or occasionally normal) numbers of megakaryocytes in the bone marrow; 3) bound antiplatelet antibody; 4) absence of palpable splenomegaly; 5) increase in platelet count in response to corticosteroids or intravenous gamma-globulin (IVIG); 6) history of a thrombocytopenic mother giving birth to a thrombocytopenic infant; and 7) exclusion of other causes of thrombocytopenia. All are usually present.

ATP is classified as either chronic (duration longer than 6 months) or acute, with the former more common in adults and the latter in children. Chronic ATP is more common in women than in men (3:1), particularly in younger adult patients. The overall incidence based on limited epidemiologic data is 16–66 cases in a million (George et al., 1996; Frederikson and Schmidt, 1999; Neylon et al., 2003). Acute ATP in children often follows an acute viral illness in the winter or spring. It is self-limiting, remitting within 6 months of onset, affects both sexes equally, and has an incidence of 1–4 cases in 100,000 (Cohn, 1976; Walker and Walker, 1984). Adult patients typically have a chronic and variable course lasting more than 6 months. Spontaneous complete remission occurs infrequently and usually in the setting of mild ATP with or without compensated thrombocytolysis (shortened platelet survival with normal platelet count). In contrast, remissions of purpura are commonly seen as the majority of patients will achieve a platelet count sufficient for normal hemostasis (>30,000/mm^3) spontaneously or with treatment.

Coexisting autoimmune cytopenias may be seen, including hemolytic anemia (Evans syndrome) or autoimmune neutropenia. ATP may also be seen in association with other autoimmune diseases such as SLE (Rabinowitz and Dameshek, 1960), rheumatoid arthritis, and autoimmune thyroid disease (Hymes et al., 1981). Presence of antiphospholipid antibody or lupus anticoagulant is a frequent finding in ATP but does not correlate with disease severity or progression (Stasi et al., 1994). ATP has been reported in connection with lymphoproliferative diseases (Lim and Ifthikharuddin, 1994) and has been reported after autologous (Jillella et al., 2000) and allogeneic bone marrow transplantation. A variety of infectious diseases are associated with ATP, particularly human immunodeficiency virus (HIV) infection (Morris et al., 1982), but also hepatitis B and C (Samuel et al., 1999). In 1998, Gasbarrini et al. reported that eradication of *Helicobacter pylori* was associated with a significant rise in platelet count in patients with ATP. This has been confirmed in studies in Italian and Japanese patient populations (Franchini and Veneri, 2004). However, lack of correlation and response to treatment has also been reported (Jarque et al., 2001; Michael et al., 2004). A recent review of the published experience noted a complete or partial response to successful eradication therapy in 101 of 191 (52.9%) ATP patients (Franchini and Veneri, 2004). The pathophysiologic mechanism wherein *H. pylori* infection contributes to the development or progression of ATP is unknown; however, molecular mimicry of the CagA protein may play a role (Takahashi et al., 2004).

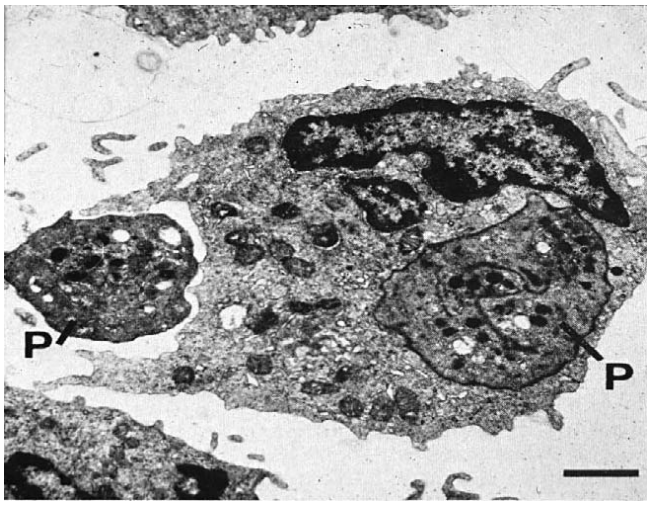

FIGURE 42.1 Monocyte (from the buffy coat of a patient with autoimmune thrombocytopenic purpura), containing one intact platelet and, apparently, in the process of phagocytosing another. The phagocytosed platelet is not degranulated. P, platelet.

CLINICAL FEATURES

The clinical presentation of ATP is highly variable and unpredictable. Patients may initially present with severe mucocutaneous bleeding, including petechiae, ecchymoses, and hemorrhagic bullae, signs that may herald more serious bleeding complications. Intracranial hemorrhage is a feared complication, although fortunately quite rare. The overall disease-specific mortality in chronic ATP in a reviewed case series was 0.0162–0.0389 cases per patient-year at risk (platelet count <30,000) (Cohen et al., 2000). Significant treatment-related mortality resulting from infections is an important consideration (Portielje et al., 2001). Some patients tolerate exceedingly low platelet counts and remain

asymptomatic for years without treatment. Putative factors that may influence predilection to bleeding in addition to the severity of the thrombocytopenia may include platelet age and size (Karpatkin, 1978), capillary vascular integrity (Spaet, 1952), and functional inhibition of platelet membrane glycoproteins by bound platelet autoantibody (McMillan et al., 1996).

GENETICS

Major histocompatibility complex (MHC) susceptibility genes have been associated with chronic ATP, as well as with treatment response to steroids or splenectomy and autoantibody specificity. A study in Japanese patients showed increased prevalence of DRB1*0410 in ATP patients (Nomura et al., 1998) and associated poor response to steroids. Taken together, the results of numerous studies in white and ethnic populations are inconsistent, limited by small sample size, and at best support weak associations between ATP and HLA class I and class II alleles.

THROMBOKINETICS

Studies evaluating platelet turnover are conflicting. Platelet survival is often reduced to 10% of normal and has been reported to be inversely related to antiplatelet antibody in older studies (Najean et al., 1967; Harker, 1970; Branehog et al., 1975). Turnover is increased 2 to 5 times above normal in some studies (Harker, 1970; Branehog et al., 1975), whereas studies using autologous platelets demonstrated impaired production in the majority of untreated ATP patients (Ballem et al., 1987). In this respect, binding of antiplatelet antibody to shared antigens on megakaryocytes may inhibit platelet production (McMillan et al., 1978). *In vitro* megakaryocytopoiesis is inhibited by ATP plasma and by monoclonal antiplatelet antibody (Chang et al., 2003; McMillan et al., 2004). Impaired thrombopoiesis may be clinically significant in some patients with ATP and could explain favorable responses to thrombopoietin therapy (Nomura et al., 2002). However, increased platelet destruction is likely to be the predominant mechanism. This is supported by the classical experiments of Harrington et al. (1951), who, as described above, reported a precipitous drop in platelet count shortly after infusion of ITP plasma into 63% of volunteers with a nadir of 4 h (Figure 42.2); see also Figure 42.3. It is unclear whether the two mechanisms described for the induction of thrombocytopenia represent two different autoimmune diseases or heterogeneity within the same disease.

Megakaryocytes are usually increased in number and size (Garg et al., 1971). Platelets are decreased in number and increased in volume (Garg et al., 1971).

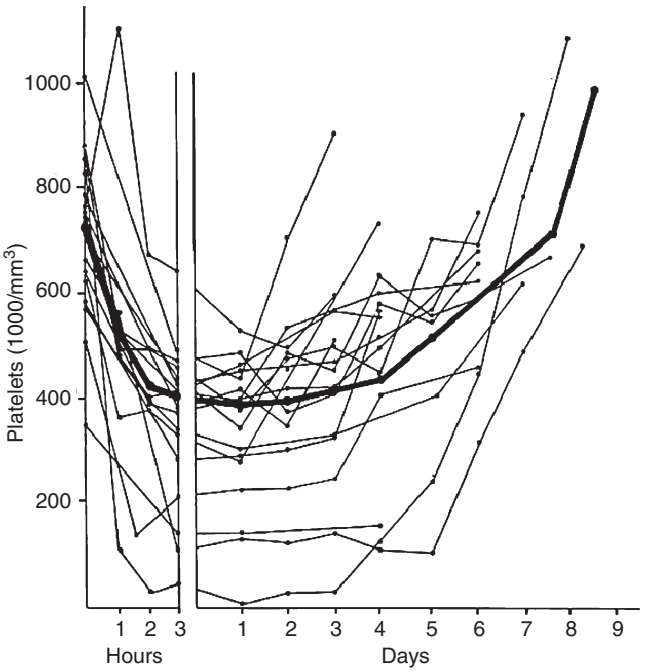

FIGURE 42.2 Thrombocytopenic effect produced by transfusing 500 ml of citrated blood or its plasma equivalent from 17 patients with idiopathic thrombocytopenic purpura. Recipients were healthy laboratory workers or patients with inoperable carcinoma; line shows mean. Platelet counts are older, indirect measurements, which are about twice current direct measurements.

Adapted from Harrington et al. (1951), with permission.

Platelets

Megathrombocytes are commonly seen in ATP. They are representative of a change in the platelet volume distribution curve and are indicative of stress platelets released upon increased turnover of megakaryocytes (Garg et al., 1971). Approximately 50% of ATP patients in remission have increased megathrombocytes and increased platelet IgG, which may reflect a compensated thrombocytolytic state (Garg et al., 1971). An inverse relationship exists between platelet diameter and lifespan (Branehog et al., 1975).

AUTOANTIGENS

Specific antiplatelet antibodies targeting platelet membrane glycoproteins have been described in ATP (Karpatkin and Siskind, 1969; McMillan et al., 1972; Dixon et al., 1975; van Leeuwen et al., 1982; Varon and Karpatkin, 1983; Beardsley et al., 1984; Fujisawa et al., 1991; 1993; Kekomaki et al., 1991; McMillan, 1990; 2000; McMillan et al., 2002). Antigen-specific antibody is detected in up to 70% of ATP patients and in most cases localizes to platelet glycoprotein IIb–IIIa or Ib–IX complexes (McMillan, 1990). Epitope mapping to both linear and conformational

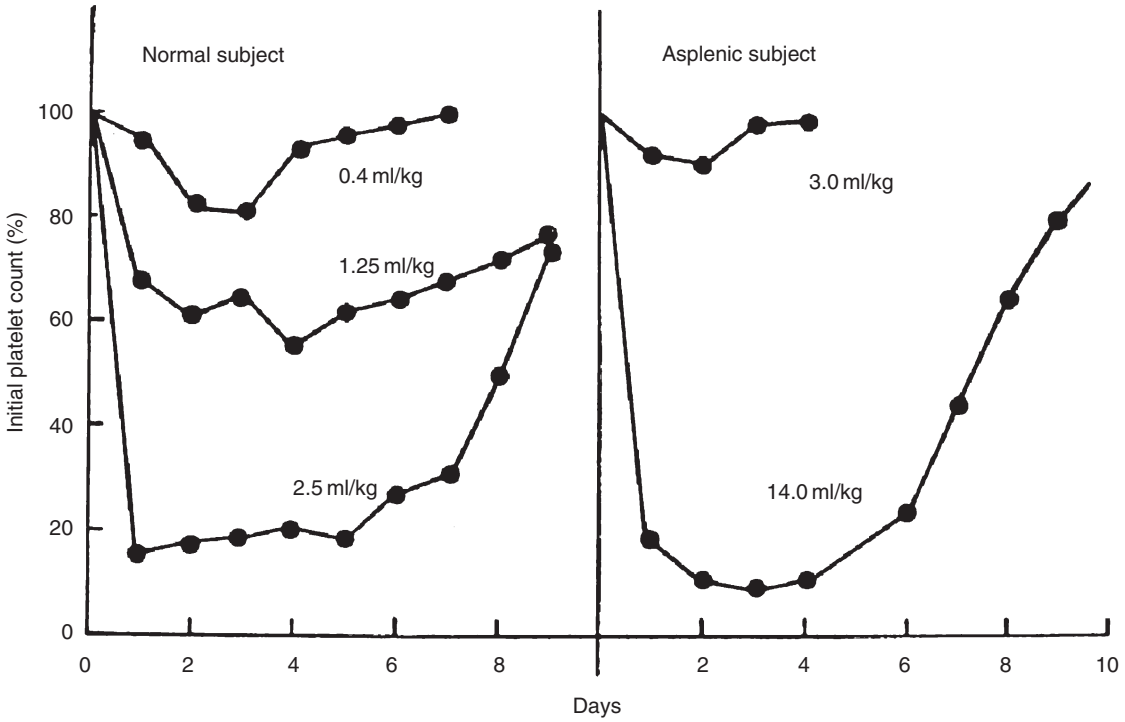

FIGURE 42.3 Effect of plasma from a patient with autoimmune idiopathic thrombocytopenic purpura (ATP) on platelet counts in a normal and asplenic volunteer subject.
Reproduced from Shulman et al. (1965), with permission.

sites on the IIb–IIIa and Ib–IX receptors has been achieved using synthetic or recombinant peptides and phage display libraries of random peptides (McMillan, 2000). Autoepitopes are frequently conformational and calcium-dependent (Fujisawa et al., 1993). Cross-reactivity of ATP autoantibody (sharing of epitope) has been reported, suggesting that epitopes are often shared or clustered, but these observations need to be confirmed by more extensive epitope scanning (McMillan, 2000). The cysteine-rich and intracytoplasmic regions of GPIIIa are targets of autoantibody (Fujisawa et al., 1991; Kekomaki et al., 1991). Many of the IIb–IIIa autoepitopes localize to the N-terminus of IIb (McMillan et al., 2002). The pathophysiologic significance of these antigen-specific antibodies is not clear. In most cases, the receptor function appears to be spared by bound autoantibody; although platelet dysfunction similar to Glanzmann thrombasthenia (Balduini et al., 1992) and Bernard–Soulier (Varon et al., 1992) has been reported, as has platelet activation and thrombosis (Pfueller et al., 1990).

ANTIPLATELET ANTIBODY

Numerous immunologic assays for the detection of antiplatelet antibody have been evaluated as potential diagnostic and predictive markers in ATP. Serum antiplatelet antibody is detected in 50% of patients (Karpatkin and Siskind, 1969; Dixon et al., 1975; Karpatkin et al., 1992), but results do not correlate with disease severity or response to treatment. Platelet-associated antibody is usually IgG but can be IgM or IgA. It is detected in a majority but not all patients with ATP and may persist in spite of apparent clinical remission. However, 99% of the total platelet IgG reflects internal stores (George and Saucerman, 1988) and is believed to result from fluid-phase pinocytosis of serum IgG by megakaryocytes. Platelet-associated IgG is increased in hypergammaglobulinemic states. Platelet-associated IgG can also result from immune-complex deposition, which results in relatively high levels of platelet surface IgG compared to classical ATP (Walsh et al., 1984; Kurata et al., 1985; Samuel et al., 1999), and can therefore be used to distinguish the two entities (Walsh et al., 1984; Kurata et al., 1985; Samuel et al., 1999). IgG can also be increased in apparent nonimmune conditions, such as sepsis and cirrhosis (Samuel et al., 1999). Platelet-associated IgG is increased in ATP and correlates with disease severity (Hymes et al., 1979; Kernoff et al., 1980). Platelet IgG is increased in many patients with Graves' disease and Hashimoto's thyroiditis (Hymes et al., 1981), and 10% of patients with ATP have associated thyroid disease (Bechgaard, 1946; Branehog et al., 1979). Platelet IgG is also increased in patients with systemic lupus erythematosus (SLE) and thrombocytopenia

(Karpatkin and Siskind, 1969; Samuel et al., 1999). Elevated antinuclear antibody (ANA) antibody is sometimes found in ATP, but does not correlate with the development of SLE (Kurata et al., 1994).

Initially, it was held that antiplatelet autoantibody was polyclonal, although this assumption has been challenged since much of the platelet-associated IgG is not autoantibody. Evidence in support of clonality of autoantibody in chronic ATP includes the findings of clonal B-cells in blood and spleen as well as clonal serum and platelet-associated autoantibody (Van der Harst et al., 1990; McMillan, 2000).

Assays of antigen-specific platelet-bound antibody have a sensitivity of 39–49%, specificity of 78–91%, and a positive predictive value of 80% (Brighton et al., 1996; Warner et al., 1999).

In summary, serum antiplatelet antibody, platelet-associated and platelet-surface IgG, as well as antigen-specific assays have been developed but their clinical utility in diagnosis and management of ATP patients remains controversial.

IMMUNOPATHOGENESIS

Mechanisms of escape from normal self-tolerance that result in autoimmunity in general and that may be applicable to ATP in particular include molecular mimicry, antigenic determinant spreading, type 1 helper T-cell (Th1)–Th2 balance, and a skewing of the cytokine microenvironment (Semple, 2002). In the context of pro-inflammatory cytokines and costimulation of Th cells, autoreactive B-cells are activated to produce platelet autoantibody, which is the primary effector of ATP.

Effector Mechanisms

The role of complement in the pathophysiology of platelet destruction is unclear. Platelet-associated C3, C4, and C9 have been detected in some ATP patients (Walsh et al., 1984; Kurata et al., 1985) and complement-dependent platelet lysis induced by autoantibody has been demonstrated *in vitro* (Cines and Schreiber, 1979; Tsubakio et al., 1986). Complement activation may function to enhance phagocytosis and induce platelet lysis *in vivo*.

Fc receptors for IgG (FcγR) on phagocytic cells of the RES, particularly in the spleen, play a pivotal role in the clearance of opsonized platelets. Clinical data and mouse models of ATP implicate the low-affinity activating receptors FcγRIIA and FcγRIIIA, which bind immune-complexed IgG, as the primary mediators of platelet clearance. FcR polymorphisms may influence disease susceptibility or severity (van der Pol and van der Winkel, 1998).

T-cell Abnormalities

While ATP is primarily antibody mediated, antiplatelet autoantibody production is regulated by T cells. Indeed, abnormal T-cell proliferation and activation is a hallmark of chronic ATP (Borkowsky and Karpatkin, 1984; Semple, 2002; 2003). T cells from ATP patients secrete IL-2 when challenged with autologous platelets *in vitro* (Semple and Friedman, 1991). Oligoclonal Th cells are detected in the peripheral blood of ATP patients. Autoreactive T cells to chemically modified GPIIb–IIIa are present in peripheral blood mononuclear cell cultures derived from ATP patients, and stimulate the *in vitro* production of IgG anti-GPIIb–IIIa antibody, which is capable of binding to normal platelets (Kuwana et al., 1998). Immunodominant epitopes have been localized to the N-terminal regions of GPIIb and GPIIIa in studies using recombinant fusion proteins (Kuwana et al., 2001). Platelet autoantibody derived from splenic B cells showed somatic hypermutation, a process that is dependent upon T-cell help (Roark et al., 2002).

Several studies have examined the Th-cytokine profiles in active ATP with inconsistent results, but most studies reveal a polarized type 1 response. Th1 cells elicit delayed-type hypersensitivity, cell-mediated immunity, and production of complement-fixing IgG responses with characteristic cytokine production of IL-2, IFN-γ, granulocyte-macrophage colony-stimulating factor (GM-CSF) and tumor necrosis factor (TNF)-α (Mosmann and Coffman, 1989). Expression of type 1 pro-inflammatory cytokines, such as IL-2 and IFN-γ, is observed in the peripheral blood mononuclear cells of ATP patients with active disease. ATP remission in children was associated with a polarized type 2 cytokine response (Mouzaki et al., 2002). Alternatively, a Th3 response with upregulation of the immunosuppressive cytokine TGF-β has been reported in ATP patients in remission. TGF-β could exert a bystander immune suppression effect (Andersson et al., 2000), resulting in remission, while reduction in TGF-β production by mononuclear cells is found in patients with active ATP (Andersson et al., 2002).

An additional, recently established pathogenic mechanism is direct T-cell-mediated cytotoxicity toward platelets in active chronic ATP (Olsson et al., 2003). Specific platelet lysis was observed in 6 of 8 chronic ATP patients (Olsson et al., 2003). DNA microarray analysis showed increased expression of Apo-1/fas, granzyme A, granzyme B, and perforin in ATP patients (Olsson et al., 2003), a finding consistent with activation of cytotoxic T cells. Increased expression of natural killer (NK) cell immunoglobulin-like receptors (KIRs) was observed in T cells from ATP patients in remission (Olsson et al., 2003). KIRs are known to inhibit cytotoxic and NK cell responses by binding to MHC class I (Boyington et al., 2001), and may provide an additional molecular mechanism for immunologic remission in ATP (Olsson et al., 2003).

TREATMENT

With the exception of those patients responding to splenectomy, treatment for ATP is palliative. A normal platelet count does not necessarily indicate eradication of autoimmune disease, since splenectomized women with normal platelet counts can give birth to thrombocytopenic neonates.

Numerous uncontrolled case series have evaluated various treatment modalities, as summarized in the practice guidelines from the Executive Committee of the American Society of Hematology (George et al., 1996). The goal of therapy is to achieve a "safe" platelet count (>30,000/mm) (George et al., 1996; 2002). Options for the management of symptomatic acute ATP include corticosteroids (prednisone, methylprednisolone, or high-dose decadron), IVIG (1 g/kg) or intravenous anti-D immunoglobulin (50 μg/kg) (Stasi and Provan, 2004).

Splenectomy is reserved for younger patients (generally younger than 40 years) who have had the disease for 6 months (some adult patients will remit during this interval) and respond to prednisone or IVIG, or require >10 mg of prednisone/day to maintain a safe platelet count. The response to splenectomy is due to the removal of an organ producing significant amounts of antiplatelet IgG (Karpatkin et al., 1972b; McMillan et al., 1972). Long-term durable responses (normal platelet counts) are achieved in 60–70% of patients who undergo splenectomy (Kojouri et al., 2004).

IVIG or anti-Rh (D) antibody, like corticosteroids, transiently increase the platelet count within 1 day of treatment in most patients with severe ATP and are useful as emergency therapy in addition to platelet transfusions and intravenous corticosteroids in the acutely bleeding patient. The mechanism of IVIG was initially attributed to blockade of the RES with inhibition of phagocytosis; or by anti-idiotype antibody with resultant neutralization of pathologic antiplatelet antibody. More recently, it has been established in mouse models of ATP that IVIG results in both IgG receptor FcγRIII blockade and upregulation of the inhibitory IgG receptor FcγRIIb (Clynes and Ravetch, 1995), which downregulates phagocytic activity. Both of these mechanisms are presumed to contribute to the therapeutic effect of IVIG. The salutary effect of anti-D immunoglobulin for treatment of ATP, restricted to Rh(D)-positive presplenectomy patients, is assumed to be similar to the mechanism of IVIG, although differences have been proposed on the basis of their distinct patterns of cytokine responses. A proportion of newly diagnosed ATP patients treated with anti-D as initial therapy may be spared splenectomy (Cooper et al., 2002; George et al., 2003).

There has been reported success with the anti-B-cell, anti-CD20 antibody (rituximab) in the treatment of refractory ATP (Stasi et al., 2001; Cooper et al., 2004). There are no randomized clinical trials to guide treatment of the refractory patient and no consensus of opinion. Other treatment options for the refractory ATP patient include azathioprine, vinca alkaloids, danazol, cyclosporine A, cytoxan, and combination chemotherapy.

Benefits of treatment must be carefully weighed against side effects. Ongoing and encouraging investigational approaches include the use of thrombopoietin, anti-CD154 (CD40 ligand), anti-FcγRI, the TNF inhibitor, etanercept (McMinn et al., 2003), anti-CD25, and the CD80(B7)-blocking agent, soluble cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) (Stasi and Provan, 2004).

AUTOIMMUNE THROMBOCYTOPENIC PURPURA IN PREGNANCY

ATP may complicate pregnancy and it may be difficult at times to distinguish it from benign gestational thrombocytopenia (Hart et al., 1986; Burrows and Kelton, 1993). Fifty percent of mothers with ATP infants have mild transient thrombocytopenia (Epstein et al., 1950). Five percent have platelet counts <20,000/mm (Burrows and Kelton, 1993). The duration of thrombocytopenia averages 3–4 weeks but can last up to 3 months. Bleeding complications are rare (Burrows and Kelton, 1990). ATP in pregnancy is treated with corticosteroids or IVIG. Splenectomy is usually deferred until after the pregnancy. Little correlation is observed between the mother's platelet count and that of the fetus (Scott et al., 1983).

HUMAN IMMUNODEFICIENCY VIRUS-ASSOCIATED THROMBOCYTOPENIC PURPURA

HIV-seropositive individuals may develop ATP early in the course of the infection or late in the course of the disease (Najean and Rain, 1994), and is seen in sexually-active homosexuals, hemophiliacs, and intravenous drug abusers and their heterosexual partners (Morris et al., 1982; Ratnoff et al., 1983; Walsh et al., 1984; 1985; Kurata et al., 1985; Savona et al., 1985; Karpatkin et al., 1988; 1995). The disease is clinically indistinguishable from classical ATP but differs with respect to male predominance and markedly increased platelet-associated IgG, IgM, and C3C4, and circulating immune complexes (Walsh et al., 1984; Kurata et al., 1985). Impaired platelet production is also seen with acquired immunodeficiency syndrome (AIDS). Increases in platelet count may be seen with antiretroviral therapy (Hymes et al., 1988). Patients with HIV-TP have an immunodominant epitope GPIIIa49–66 (Nardi et al., 1997). Serum anti-GPIIIa49–66 correlates inversely with platelet

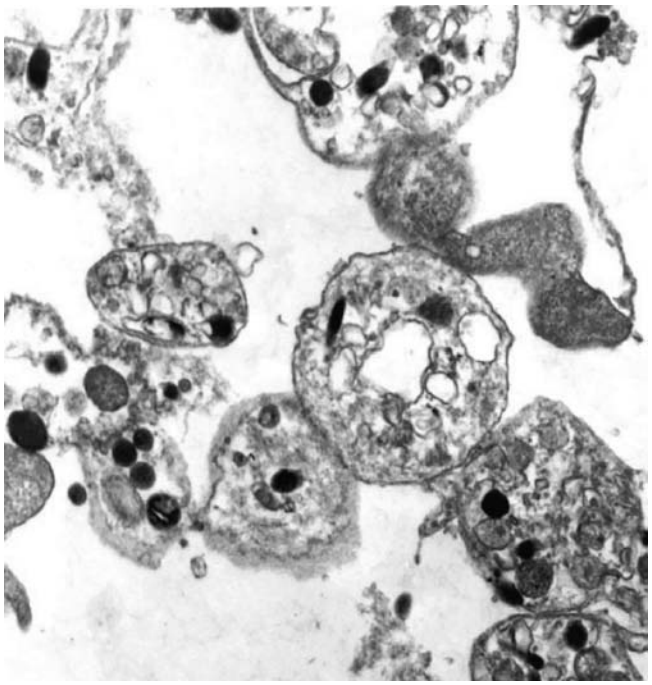

FIGURE 42.4 Electron microscopy of damaged platelets treated with anti-GPIIIa49–66 antibody. Patient sample at 4 h showing degenerating platelets and disintegration of the cell membrane. None of these changes was present in IgG controls at 4 h. Original magnification: ×40,000.

count and is enriched in circulating immune complexes (Karpatkin et al., 1995; Nardi et al., 1997). Antibody directed against the epitope induces thrombocytopenia and platelet fragmentation in mice, as well as human platelet fragmentation (Figure 42.4). Platelet fragmentation occurs by a unique complement-independent mechanism triggered by antibody-induced production of reactive oxygen species via both platelet NADPH oxidase and 12-lipoxygenase pathways (Nardi et al., 2001; 2004). Platelet destruction is likely to be due to a combination of platelet fragmentation and clearance by phagocytic cells. There is recent evidence that the antibody against the immunodominant epitope is secondary to molecular mimicry, i.e. cross-reactivity with HIV peptides gag and nef (Li et al., 2003).

CONCLUSION

ATP is an immunologic platelet disorder of exclusion, the etiology of which is unknown. It is unclear whether this represents a single disorder or multiple disorders. This is supported by observations that some patients have predominant increased peripheral platelet destruction whereas others have decreased platelet production, and still others have both. Antibody against platelets and megakaryocytes could explain this apparent heterogeneity—yet why one predominates in some patients and another in other patients is unclear.

In this respect, the work of Olsson et al. (2003) on the role of NK cells and cytotoxic T-cells against platelets is intriguing. They also noted a counterbalanced expression of the inhibitors of cytotoxic T- and NK cell receptors, called KIRs, in patients in remission. The role of T-cell-mediated in platelet destruction is also unclear and deserves to be studied.

Treatment responses cytotoxicity appear to be heterogeneous. Whereas most patients respond to antiphagocytic agents [steroids, danazol, IVIG, and anti-Rh(D)], others require immunosuppression with imuran, cytoxan, or cyclosporine, and still others do not appear to respond at all—yet have responded in the past. In addition, some patients will respond to steroids and not to IVIG, whereas others will respond to IVIG but not to steroids. The response to splenectomy is also variable. Some patients, particularly younger ones (under 40 years) who respond to steroids will respond to splenectomy, while older patients tend to be less responsive. Perhaps this relates to the fact that the spleen is an organ of platelet antibody production as well as platelet phagocytosis in younger patients but not in older ones. Older nonresponsive patients could have hepatic destruction of platelets, or antibody production from other organs.

The significance of platelet-associated antibody or platelet surface antibody is also unclear. These measurements are useful in distinguishing diseases with immune-complex-associated thrombocytopenia, such as SLE, HIV-1-TP or hepatitis, from classical ATP. The platelet antibody levels do not appear to be related to disease severity. However, in some situations they improve and/or disappear with successful treatment.

Finally, the etiology is also unclear. One possible clue is the frequent onset of childhood acute ATP following a viral infection, as well as the occasional stable chronic ATP adult patient who becomes severely thrombocytopenic following a viral infection. Molecular mimicry may also play a role. Recent reports of the association of Epstein–Barr virus with SLE secondary to the sharing of an EBNA-1/SLE-Ro antigen (McClain et al., 2005), cross-reactivity of *H. pylori* CagA protein with platelets (Takahashi et al., 2004), and the cross-reactivity of HIV-1-TP antibody against HIV-1-nef protein with platelet GPIIIa49–66 (Li et al., 2005) are intriguing. In the later report, induction of murine thrombocytopenia could be induced with antibody against these HIV-1 peptides.

Recent developments in our understanding of a new mechanism for platelet destruction in HIV-1-TP is intriguing. Patients with antibody against platelet integrin GPIIIa49–66 undergo oxidative damage and platelet fragmentation through the activation of platelet 12-lipoxygenase and NADPH oxidase. It will be of interest to determine whether other platelet immunologic disorders associated

with circulating immune complexes might have a similar mechanism.

Neutropenia

PARVIZ LALEZARI

The Biomedical Research Institute, and Departments of Medicine and Pathology, Montefiore Medical Center and Albert Einstein College of Medicine, New York, New York, USA

HISTORIC BACKGROUND

In 1926, Doan observed that sera from some patients agglutinated leukocytes from other individuals. Subsequent work by Dausset and Nenna (1952), Moeschlin and Wagner (1952), and Goudsmit and van Loghem (1953) laid the foundation for leukocyte immunology. Further progress in the field came with the discovery that leukocyte antibodies develop during pregnancy (Payne and Rolfs, 1958; van Rood et al., 1959), and that fetal–maternal neutrophil incompatibility causes neonatal neutropenia (Lalezari et al., 1960). Cooperative research on leukocyte immunology, initiated in 1964, then led to the discovery of the HLA system. The finding that certain leukocyte antigens were exclusively expressed on neutrophils (Lalezari and Bernard, 1966) separated immunology of neutrophils from histocompatibility, where the cells of interest are the lymphocytes.

In early reports on autoimmune neutropenia, Moeschlin and Wagner (1952) and Butler (1958) showed that infusion of plasma from neutropenic patients into normal recipients caused leukopenia. Boxer and Stossel (1974) designed novel techniques for detection of neutrophil antibodies, and autoantibodies in autoimmune neutropenia of infancy were shown to be directed against neutrophil-specific antigens (Lalezari et al., 1975).

Since the first edition of *The Autoimmune Diseases* two decades ago, new information has become available on the structure, function, and genetic control of neutrophil-specific antigens, the main targets of neutrophil autoimmunity. New serologic methods for antibody detection have been developed, and the use of colony-stimulating factors has had major impact on the management of the disease.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

The levels of blood cells in the circulation are determined by the rate of their production and destruction. Neutrophil levels are also influenced by their large marginal pool. Neutropenia is defined by the fall of absolute neutrophil and band forms below 1.5×10^9/L. Immunologically-induced neutropenias are probably as common as the more familiar autoimmune disorders of red cells and platelets, with clinical manifestations varying from being asymptomatic to severe forms complicated by overwhelming sepsis. Most patients develop intermittent mucocutaneous infections. Splenomegaly is an exception rather than the rule, and the hematologic profile is that of selective absence or reduction in the number of neutrophils, while monocytes, eosinophils, and basophils are either normal or increased. Lymphocyte counts are normal or occasionally reduced. Platelets are normal, and a mild anemia together with hypergammaglobulinemia may exist due to persistent infections in chronic

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

forms. Bone marrow shows myeloid hyperplasia with a distinctly diminished number of mature cells, resembling "maturation arrest." Autoimmune neutropenia is divided into primary and secondary forms, depending on whether or not neutropenia is part of a complex autoimmune disease. In the primary forms, "autoimmune neutropenia of infancy (AINI)" is distinct from the adult forms.

Autoimmune Neutropenia of Infancy

Since the first reports (Boxer et al., 1975; Lalezari et al., 1975), many cases with identical features have been reported (Bux et al., 1998; McCullough et al., 1988). AINI is characterized by a severe neutropenia diagnosed when infants are about 5–7 months old. Neutropenia is commonly associated with bacterial or fungal infections, and spontaneous recovery within 1–4 years is the rule. Diagnosis is made by demonstrating neutrophil-bound and circulating antineutrophil antibodies. In many cases, the antibodies are directed against neutrophil-specific antigens (Lalezari et al., 1986). The cause of AINI remains unclear. The disease may represent a "physiologic state" where the autologous antigens, or the antigens shared with the mother, provoke an immune response in an infant in whom the immune regulatory system is underdeveloped. The process reverses when the child's regulatory mechanism reaches maturity. A long-term follow-up of AINI has confirmed that affected children remain immunologically normal after recovery. On rare occasions, patients remain chronically and severely neutropenic. These patients represent a subgroup of true autoimmune disease, similar to the chronic forms seen in adults and adolescents.

Primary Autoimmune Neutropenias of Adults and Adolescents

Neutropenia in adults and adolescents is often a chronic and debilitating disease with a preponderance in females. In pregnant women, the infants may develop transient neutropenia (Stefanini et al., 1958). The acute forms are relatively rare and are self-limited. Little information is available on the specificities of the antibodies in the adult forms of autoimmune neutropenia. In a report by McCullough et al. (1988), the antibody had partial specificity for NA1, the first neutrophil-specific antigen. We documented NA1 specificity in a 73-year-old man who had acute neutropenia. The patient had a past history of sarcoidosis and had not received transfusion of blood or blood products. He suddenly developed fever, pharyngitis, and a severe gingivitis. His leukocyte count was below 800/μl with absent neutrophils. Platelets were normal but he had a mild anemia. All other laboratory data were normal except for a positive test for antinuclear antibodies. Bone marrow was hyperplastic but mature neutrophils were absent. After 15 days of persistent severe neutropenia, treatment with prednisone was initiated and continued for 3.5 months. Within 10 days after the start of treatment, the neutrophil count rose to 12,000/μl and remained normal. The blood sample obtained before prednisone treatment contained a strong agglutinating antibody that reacted with neutrophils from all 28 NA1-positive donors and none of the 12 NA1-negative donors. The blood samples obtained 3 and 6 months after recovery did not react with neutrophils from any of 30 donors tested. The patient's neutrophils, obtained after recovery, were typed as NA1/NA2 and reacted strongly with the autologous serum obtained during the neutropenic phase, but not with the recovery samples. It is of interest that the target of the autoantibody was NA1 and not NA2, the allele also expressed.

Secondary Autoimmune Neutropenias

Association of neutropenia with autoimmune hemolytic anemia or thrombocytopenia is not uncommon, as in Evans syndrome (Evans et al., 1951). A special combination, which we have designated "alternating autoimmune hemocytopenia," is characterized by being multiphasic. Initially, cytopenia is limited to either thrombocytopenia, neutropenia or hemolytic anemia, and responds to treatment. After an interval, which may last from months to years, the autoimmune process recurs, this time involving another cell type. Alternation between neutropenia, hemolytic anemia, and thrombocytopenia continues for several years, and eventually a combination prevails that is severe and resistant to treatment.

Nonhematologic autoimmune disorders associated with neutropenia include systemic lupus erythematosus (SLE), Sjögren syndrome, Graves' disease, rheumatoid arthritis, lymphoproliferative disorders (e.g., T-cell and hairy cell leukemia), Felty syndrome, common variable immunodeficiency, and immune complex diseases. Coppo et al. (2004) have reported 9 patients with secondary neutropenia who had antineutrophil cytoplasmic antibodies (ANCAs). Many infectious diseases are associated with neutropenia, which may be due to myelosuppression, especially in infants who have a small bone marrow reserve. In viral diseases such as mycoplasma pneumonia and infectious mononucleosis, cold-reacting antibodies are likely to be a contributory factor.

IMMUNOLOGIC MARKERS IN DIAGNOSIS

NA and NB neutrophil-specific antigens are often the target of autoantibodies in autoimmune neutropenias. These antigens are anchored to the outer leaflet of the lipid bilayer

of neutrophils via a glycosyl phosphatidyl inositol structure. The NA gene has been mapped to chromosome 1q22 and is the low-affinity receptor for IgG (FcγRIII) (Ory et al., 1989). The alleles of the NA gene are NA1, NA2, and SH (Bux et al., 1997). Some rare individuals lack both NA1 and NA2 and are called NA^{null}. It is not clear whether NA^{null} represents the lack of the NA gene or a mutant that fails to react with the currently available typing reagents. The NB antigen is expressed on CD177 glycoprotein (Stroncek et al., 2001) and its gene is located on chromosome 19 at 19q13.2 (Kissel et al., 2001). Recently, a glycoprotein called PRV-1 has been identified and has been shown to be overexpressed in polycythemia vera, in some essential thrombocythemic patients, and during pregnancy (Temerinac et al., 2000). Caruccio et al. (2004) have provided evidence that PRV-1, which belongs to the LY6/snake toxin gene and differs from NB1 in four nucleotides, is an allele of NB1, although the possibility of a gene duplication has not been excluded. The i and I antigens, which are known to react with cold agglutinins, are also expressed on neutrophils and platelets, and in high titers their antibodies can cause neutropenia and thrombocytopenia (Lalezari and Murphy, 1967; Markenson et al., 1975). The antigens that react with ANCA (Hagen et al., 1993) and may be involved in secondary autoimmune neutropenias are intracellular neutrophil proteins, such as proteinase 3, elastase, myeloperoxidase, lysozyme lactoferrin, catepsin G, azurocidin, and bactericidal/permeability-increasing protein.

MECHANISMS OF CELL DESTRUCTION

Most information on the mechanisms of neutrophil destruction in immunologic diseases is based on laboratory observations, and the relevance to *in vivo* events has not been established. Neutrophils usually respond to their antibodies by agglutination, which, unlike with red cells, is an active process requiring living cells. Neutrophils also aggregate in the presence of the activated complement and adhere to endothelial cells (Jacob et al., 1980). Some neutrophil antibodies are known to activate the complement system, and thereby initiate complement-induced neutrophil aggregation. Thus, the *in vivo* neutrophil aggregation may be a mechanism for neutrophil removal in some autoimmune neutropenias.

Boxer and Stossel (1974) have shown that neutrophils coated with auto- or allo-antibodies can stimulate phagocytic cells. Leukophagocytosis is seen in the spleen of some patients with autoimmune neutropenia and indicates that this organ is a location for the clearance of opsonized neutrophils. Using ^{111}In-radiolabeling techniques, McCullough et al. (1988) have shown that neutrophils are not cleared at any selective site, but are removed by phagocytic cells distributed in many tissues. Cytotoxicity, either complement-mediated or antibody-dependent cell-mediated, has been shown *in vitro* by dye exclusion or the release of ^{51}Cr. Inhibition of colony-forming unit (CFU)-C colonies by lymphocytes from neutropenic patients has been demonstrated in Felty syndrome, rheumatoid disorders, and SLE. The mechanism of this suppression is not clear. Neutrophils bind circulating immunoglobulins. This binding, especially when high levels of immune complexes exist, may not be innocuous and may lead to neutropenia, either by complement activation or by phagocytosis. Many patients with known immune complex diseases, however, are not neutropenic. Neutropenia in acquired immune deficiency syndrome (AIDS) may be due to myelosuppression or to immune complexes. A positive test for a high level of neutrophil-bound immunoglobulins is a common finding in AIDS patients.

Many drugs cause dose-dependent neutropenia due to myelotoxicity and interference with protein synthesis and cell replication. Some drug-induced neutropenias are not dose related and are considered to be immunologic in origin. In rare cases, the antibodies or the suppressor cells are directed against progenitor cells, causing pure white cell aplasia (Levitt, 1983).

Finally, alteration of neutrophil functions may result from reaction with autoantibodies. Thus far, the functional consequences of the binding of autoantibodies to Fc receptors or to NB1 have remained unknown. The report by Kramer et al. (1980) exemplifies the inhibition of neutrophil motility by an IgG autoantibody, causing a non-neutropenic clinical condition indistinguishable from chronic neutropenic states. Thus, neutrophil dysfunction may explain the severity of clinical manifestations in cases where symptoms are disproportionate to the number of neutrophils.

LABORATORY DIAGNOSIS

Techniques available for detection of neutrophil antibodies have been summarized elsewhere (McCullogh et al., 1988). In autoimmune neutropenia, as in other autoimmune diseases, direct examination of the target cells should be most relevant. Because of limitations in obtaining adequate number of neutrophils, however, it is often necessary to use indirect techniques. One exception may be the immunofluorescence (IF) test (Verheugt et al., 1977), which requires fewer cells. In addition, by using labeled antiglobulin reagents and flow cytometry, IF allows determination of the class and subclass of antibodies. Despite these technical advances, the tests for autoimmune neutropenia have many shortcomings. In the IF, as it is used with microscopic aid, neutrophils should be differentiated from the frequently present monocytes that give strong reactions with dye-labeled antihuman immunoglobulin reagents. In addition,

neutrophils of patients who receive granulocyte–colony-stimulating factor (G-CSF) treatment overexpress Fc receptors, leading to a nonspecific positive direct IF.

Among the indirect tests, reliable neutrophil agglutination can be obtained only in the presence of EDTA, which prevents spontaneous neutrophil aggregation. Unfortunately, the EDTA-dependent agglutination test is more sensitive for detection of alloantibodies, and autoantibodies may be missed if the required incubation period is shortened. Cytotoxic antibodies are less useful, because sera from many non-neutropenic, normal individuals produce a positive reaction, and the results can be considered positive only if high titers are obtained. Enthusiasm for the tests based on opsonization and inhibition of phagocytosis is tempered by their complexity. Moreover, examples of strong agglutinating antibodies have been found in severe cases of alloimmune neonatal neutropenias that have failed to cause neutrophil opsonization. The quantitative immunoglobulin assays also have limitations because of the presence of large amounts of immunoglobulins on normal neutrophils, and potential difficulties in distinguishing specific antibodies. MAIGA (monoclonal antibody immobilization of granulocyte antigens) has been a successful method for defining neutrophil antigens (Metcalfe and Waters, 1992). Unfortunately, unlike hemoglobin in hemolytic anemia, simple and reliable markers for *in vivo* neutrophil lysis are not available. For this purpose, measurement of the released neutrophil lysozyme (Boxer et al., 1975) has had limited clinical value.

Considering the difficulties in detecting neutrophil antibodies, multiple techniques must often be used. The observations on a possible role for ANCA in neutropenia suggest that in secondary cases, and when antibodies to surface antigens are not found, tests for ANCA should be included in the diagnostic work-up.

TREATMENT

The introduction of CSFs has changed the outcome of all neutropenias, including autoimmune forms. Many patients with primary autoimmune neutropenia, especially children, tolerate the condition well and need antibiotics and other treatments only for the management of intercurrent infections.

Splenectomy and steroid therapy are not as effective as they are in autoimmune hemolytic anemia and thrombocytopenia. These differences may reflect pathophysiologic features unique to neutrophils, especially the multiplicity of mechanisms involved in their destruction. It may be reasoned that neutrophil destruction by cytotoxicity, aggregation, and embolization is unlikely to be affected by splenectomy. Steroids are not fully effective when phagocytosis by macrophages plays an essential role. Neutropenic patients often have chronic infection, which activates macrophages. Activated macrophages are known to be more destructive and less susceptible to inhibition by steroids. Despite these shortcomings, and before the introduction of CSFs, when there were no alternative treatments, most severe cases of chronic neutropenia were treated with steroids and some with splenectomy. Some patients were subjected to plasmaphereses with doubtful results, and in some cases, granulocytes obtained from compatible normal donors were transfused. In one example, repeated transfusions of NA2-negative neutrophils controlled the lung and brain abscesses in a 12-year-old boy who had a severe neutropenia due to anti-NA2 autoantibody. Unfortunately, after multiple transfusions, the patient developed resistance and succumbed to infection. Another modality is intravenous gamma-globulin, which temporarily reverses neutropenia (Bussel et al., 1988). These treatments should be considered in rare cases where G-CSF is not effective.

The effectiveness of G-CSF may be due to increased neutrophil production and mobilization of the marginal pool, which may result in consumption of the antibodies by mass action. Plausible though this hypothesis may be, alternative mechanisms such as an increase in the expression of neutrophil antigens or suppression of the lymphoid system cannot be excluded. The dose of G-CSF must be individualized. Most patients do not require more than 2 to 3 subcutaneous injections at $2.5 \pm 1\,\mu g/kg$. The treatment should be given only for control of complications and in preparation for surgical procedures.

PERSPECTIVES AND FUTURE DIRECTIONS

CSFs have become the treatment of choice for neutropenias regardless of their etiology. Because of this, and for economic considerations, an increasing number of physicians avoid laboratory work-up. Consequently, availability of clinical material for research has noticeably diminished, and in the past two decades few new antigens have been discovered and it has not been possible to confirm several antigens described by single examples. By contrast, the shift of research to molecular biology has led to much progress in our understanding of the molecular genetics of neutrophil antigens. Further research on the function of neutrophil antigens, especially on the possible role of NB1/PRV-1 glycoprotein in hematopoiesis, is likely to reveal that autoantibodies against these antigens have consequences beyond the obvious numerical reduction of neutrophils. At the clinical level, more research on secondary autoimmune neutropenias and the potential role of ANCAs and their targets may produce valuable new information.

CHAPTER

44

Aplastic Anemia

ROBERT A. BRODSKY*
**John Hopkins Medicine, Division of Hematology*

RICHARD JONES†
†The Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Division of Hematologic Malignancies, Baltimore, Maryland, USA

Aplastic anemia may be congenital or acquired. The acquired form represents over 90% of cases and usually results from an autoimmune attack against hematopoietic stem cells. Congenital forms of aplastic anemia are not due to autoimmunity, but it is important to recognize these disorders since they do not respond to immunosuppressive therapy. Congenital aplastic anemia tends to present in the first decade of life and is often, but not always, associated with other physical anomalies. Fanconi anemia, the most common form of congenital bone marrow failure, predisposes to cancer and is frequently associated with other congenital abnormalities, including short stature, upper limb anomalies, hypogonadism, and café-au-lait spots (Bagby, 2003). Dyskeratosis congenital (DKC) is another congenital bone marrow failure disorder that can be either X-linked recessive, autosomal dominant, or autosomal recessive (Dokal and Vulliamy, 2003). The X-linked recessive form results from mutations in the gene DKC1 whose gene product, dyskerin, is important for stabilizing telomerase. The resulting telomerase deficiency leads to bone marrow failure and premature aging. The autosomal-dominant form of DKC results from hTERC gene mutations, the RNA component of telomerase. This chapter will focus on the acquired form of aplastic anemia.

HISTORIC BACKGROUND

The earliest case description of acquired aplastic anemia was by Dr Paul Ehrlich in 1888. He described a young woman who died following an abrupt illness characterized by severe anemia, bleeding, high fever, and a markedly hypocellular bone marrow. The term aplastic anemia was first introduced in 1904 by Chauffard. Until the early 1970s, most patients with severe aplastic anemia died within a year of diagnosis. The advent of potent immunosuppressive treatments, particularly antithymocyte globulin (ATG) and allogeneic bone marrow transplantation (BMT), markedly improved the outcome of these patients and prompted vigorous clinical and laboratory investigation. These studies have generated important insight into hematopoietic stem cell biology, immunology, and autoimmunity. A patient with aplastic anemia became the first long-term survivor after receiving an allogeneic BMT in 1972. Today, the majority of patients survive this potentially devastating autoimmune disorder.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Aplastic anemia manifests as pancytopenia in conjunction with a hypocellular bone marrow. The disease may present abruptly (over days) or insidiously (over weeks to

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

months). The most common clinical manifestations reflect the low blood counts and include dyspnea on exertion, fatigue, easy bruising, petechia, epistaxis, gingival bleeding, heavy menses, headaches, and fever. The primary diagnostic procedure, in addition to a complete blood count, leukocyte differential, and reticulocyte count is the bone marrow aspirate and biopsy (>1 cm core). Flow cytometry on peripheral blood and cytogenetics should be performed on the bone marrow aspirate to rule out paroxysmal nocturnal hemoglobinuria (PNH) (Hall and Rosse, 1996; Brodsky et al., 2000) and hypoplastic myelodysplastic syndromes (hMDS). Patients under the age of 40 years should be screened for Fanconi anemia using the clastogenic agents diepoxybutane or mitomycin C (Bagby, 2003).

A hypocellular bone marrow is required for the diagnosis of aplastic anemia. However, most patients will have residual pockets of ongoing hematopoiesis; thus, an adequate biopsy is essential for establishing the diagnosis, as spicules from the aspirate may be surprisingly cellular given the degree of hypocellularity on the biopsy. Dyserythropoiesis is not uncommon in aplastic anemia, especially in cases with coincidental small-to-moderate PNH populations; however, a small percentage of myeloid blasts, or dysplastic features in the myeloid or megakaryocyte lineages, is more typical of hMDS. CD34 is expressed on early hematopoietic progenitors and the number of $CD34^+$ cells has also been used to help discriminate between aplastic anemia and hMDS. In aplastic anemia the percentage of cells expressing CD34 is usually <0.1%; in hMDS the CD34 count is either normal (0.5–1.0%) or elevated (Orazi et al., 1997).

As with other autoimmune diseases, there is a wide spectrum of disease severity in aplastic anemia. The prognosis in aplastic anemia is proportional to the quantitative depression of peripheral blood counts, most notably the absolute neutrophil count. Accordingly, aplastic anemia is classified as nonsevere, severe, and very severe based largely upon the degree of neutropenia (Table 44.1). The 2-year mortality rate with supportive care alone for patients with severe or very severe aplastic anemia approaches 80% (Camitta et al., 1979), with invasive fungal infections and overwhelming bacterial sepsis being the most frequent causes of death. Nonsevere aplastic anemia is seldom life-threatening and in many instances requires no therapy. Although some cases of nonsevere aplastic anemia will progress, many will remain stable for years, and some may spontaneously improve.

Epidemiologic data are sparse. Precise estimates of incidence and prevalence of aplastic anemia are confounded by its rarity, imprecision in establishing the diagnosis, and difficulty in identifying the onset of the disorder. The best estimates of incidence are from case–control studies, which report an incidence of 2 cases in a million inhabitants in Europe (Kaufman et al., 1991) and Israel (Modan et al., 1975), but the incidence may be two- to three-fold higher in South-East Asia (Szklo et al., 1985; Issaragrisil et al., 1997b). The disease most commonly affects children and young adults but may occur at any age. Acquired aplastic anemia has been associated with drugs, benzene exposure, insecticides, viruses, and other agents. However, over 80% of cases are classified as idiopathic since no etiologic agent is identified (Issaragrisil et al., 1997b; Bacigalupo et al., 2000b). A population-based case–control study of aplastic anemia in Thailand found that drugs, the most commonly implicated etiology, explain only 5% of newly diagnosed cases (Issaragrisil et al., 1997b).

AUTOIMMUNE FEATURES AND PATHOGENIC MECHANISMS

Aplastic anemia was originally thought to result from a quantitative deficiency of hematopoietic stem cells precipitated by a direct toxic effect on stem cells. However, attempts to treat aplastic anemia by simple transfusion of bone marrow from an identical twin failed to reconstitute hematopoieisis in most patients. Retransplant of many of these patients following a high-dose cyclophosphamide preparative regimen was successful, suggesting that the pathophysiology of aplastic anemia was more intricate (Champlin et al., 1984; Hintererger et al., 1997).

In the late 1960s, Mathé et al. (1970) were among the first to postulate an immune basis for aplastic anemia. They performed BMT in patients with aplastic anemia using partially mismatched donors after administering antilymphocyte globulin as an immunosuppressive conditioning

TABLE 44.1 Aplastic anemia: diagnosis and definitions. Bone marrow cellularity must be <25% to diagnose aplastic anemia

Peripheral blood counts	Nonsevere aplastic anemia (not meeting criteria for severe disease)	Severe aplastic anemia (any 2 of 3 criteria below)	Very severe aplastic anemia (meets criteria for severe disease and absolute neutrophils <200)
Absolute neutrophils		<500/μl	<200/μl
Platelets		<20,000/μl	
Reticulocyte count		<1.0% corrected or <60,000/μl	

regimen. Although the patients failed to engraft, the investigators witnessed autologous recovery of hematopoiesis in some patients. This suggested that functional hematopoietic stem cells existed in aplastic anemia patients and that the immune system was somehow suppressing their growth and the differentiation of hematopoietic stem cells. The response to immunosuppressive therapy was the first clear evidence that aplastic anemia was truly an autoimmune disease. Additionally, there appears to be an underlying genetic predisposition to acquired aplastic anemia, as evidenced by the over-representation of the HLA-DR2 subtypes (Nimer et al., 1994).

The first laboratory experiments suggesting an autoimmune pathophysiology were co-culture experiments showing that T lymphocytes from aplastic patients inhibited hematopoietic colony formation *in vitro* (Nissen et al., 1980; Hoffman et al., 1997). Since then, it has been shown that the immune destruction of hematopoietic stem cells in aplastic anemia is mediated by cytotoxic T cells, and involves inhibitory type 1 helper T-cell (Th1) cytokines and the Fas-dependent cell death pathway. The cytotoxic T cells are usually more conspicuous in the bone marrow than in the peripheral blood (Zoumbos et al., 1985; Maciejewski et al., 1994; Melenhorst et al., 1997b) and overproduce interferon (IFN)-γ and tumor necrosis factor (TNF) (Nakao et al., 1992; Nistico and Young, 1994). TNF and IFN-γ are direct inhibitors of hematopoiesis and appear to upregulate Fas expression on $CD34^+$ cells (Maciejewski et al., 1995). Immortalized $CD4^+$ and $CD8^+$ T-cell clones from some aplastic anemia patients have been shown to secret Th1 cytokines and are capable of killing autologous CD34 cells (Nakao et al., 1997; Zeng et al., 2001). Recently, evidence for a humoral autoimmune response in aplastic anemia has also been reported; 7 of 18 aplastic anemia patients were found to have autoantibodies against kinectin, a 1300 amino acid molecule expressed on human hematopoietic cells, as well as liver, ovary, testis, and brain cells (Hirano et al., 2003).

Studies examining T-cell diversity using complementarity-determining region (CDR3) spectratyping have further implicated the immune system in aplastic anemia. Several groups have found limited heterogeneity of the T cell receptor β chain (Vβ) in aplastic anemia, suggesting that there is oligoclonal or even monoclonal expansion of T-cells in response to a specific antigen (Manz et al., 1997; Melenhorst et al., 1997a; Zeng et al., 1999; 2001). Thus, it is likely that, regardless of the inciting event in aplastic anemia, damage to hematopoietic progenitors initiates an immune process that inhibits hematopoiesis.

An intriguing association exists with hepatitis and is seen in about 1% of newly diagnosed cases. Virtually all cases of the hepatitis–aplastic anemia syndrome are seronegative for known hepatitis viruses (non-A through -G hepatitis). The disease predominantly affects young males, with a precipitous onset of severe pancytopenia occurring within 2–3 months after the onset of hepatitis (Brown et al., 1997; Hagler et al., 1975). Moreover, aplastic anemia has been reported to occur in up to 30% of patients following orthotopic liver transplantation for seronegative hepatitis (Tzakis et al., 1988; Cattral et al., 1994). The aplastic anemia in the hepatitis/aplastic anemia syndrome is autoimmune since most cases respond to immunosuppressive therapy; however, it remains unclear whether the hepatitis results from an undiscovered virus or whether this too is autoimmune.

ENVIRONMENTAL INFLUENCES

The medical literature is replete with case reports of environmental exposures, most notably benzene, causing aplastic anemia. However, rigorous epidemiologic studies supporting an association between environmental toxins and aplastic anemia are lacking. A major confounder is that benzene and other toxins also predispose to MDS and leukemia. The older literature was unlikely to have been able to distinguish the different types of marrow failure, such as aplastic anemia, MDS, and hypoplastic leukemia, leading to an overestimation of the association between benzene and aplastic anemia. While the magnitude of the risk remains uncertain, benzene is probably not a major risk factor for aplastic anemia in countries with modern standards of industrial hygiene. A large case–controlled study in Thailand employing modern diagnostic and epidemiologic methods found that individuals of lower economic status and younger age are at greater risk than their counterparts in other countries following exposure to solvents, glues, and hepatitis A (likely a surrogate marker). Grain farmers were also found to have higher risk of developing aplastic anemia (relative risk, 2.7) regardless of whether or not they used insecticides (Issaragrisil et al., 1997a). These same investigators noted marked differences in incidence between northern and southern rural regions of Thailand and among Bangkok suburbs, implicating potential environmental factors causing the disease (Issaragrisil et al., 1999).

ANIMAL MODELS

Animal models of bone marrow failure exist, but none fully approximate the human disease of acquired aplastic anemia. Busulfan, benzene, and irradiation have all been used to establish models of marrow failure (Knospe et al., 1971; Morley and Blake, 1974; Hak, 1980). All three agents lead to pancytopenia and a hypocellular marrow but the marrow failure is due to stem cell injury and damage to the microenvironment rather than autoimmune-mediated suppression of hematopoiesis.

TREATMENT AND OUTCOME

There are three principle therapies for severe aplastic anemia: 1) allogeneic bone marrow (stem cell) transplantation (BMT); 2) immunosuppressive therapy with antithymocyte globulin and cyclosporine (ATG/CSA); and 3) high-dose cyclophosphamide without BMT. Allogeneic BMT is the treatment of choice for young patients with aplastic anemia who have an HLA-matched sibling donor. Unfortunately, this approach is available to a minority of patients since less than 30% of patients have a matched sibling donor. The most important factors that influence outcome following allogeneic BMT for aplastic anemia are the age of the patient and the type of allograft (HLA-matched sibling versus unrelated or mismatched donors) (Figure 44.1). In patients younger than 30 years, the cure rate after an HLA-matched sibling BMT ranges from 70 to 90% (Horowitz, 2000; Storb et al., 2001; Ades et al., 2004). However, with increasing age over 30 years, the risk for graft-versus-host disease (GVHD) steadily increases, leading to reduced survival.

Transplant-related mortality approaches 50% in patients over the age of 40 years (Doney et al., 1997; Horowitz, 2000). Late BMT-related complications, including chronic GVHD, occur in up to one-third of patients, with over 40% requiring immunosuppressive therapy for their GVHD at 3 years (Storb et al., 2001). Thus, despite the high probability of curing severe aplastic anemia with BMT, many patients develop long-term complications from the procedure.

BMT from unrelated donors or mismatched donors for patients with severe aplastic anemia is usually reserved for patients who do not respond to immunosuppressive therapy; the transplant-related mortality and the risk of GVHD are roughly double with this approach. The best results are seen in patients younger than 21 years with a disease duration of under 1 year (Deeg et al., 2001).

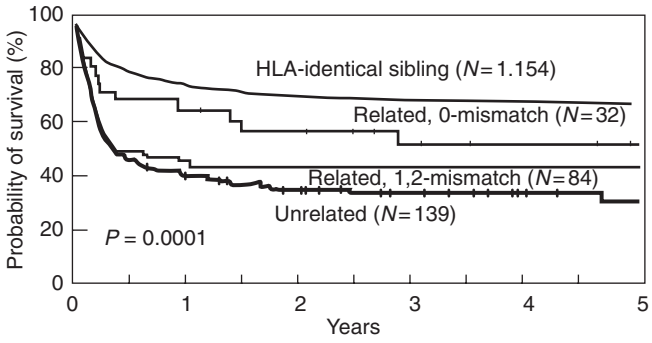

FIGURE 44.1 Survival after allogeneic bone marrow transplantation for severe aplastic anemia. Data for HLA-identical siblings and related match/mismatched transplants are from the International Bone Marrow Transplant Registry (IBMTR). Data for unrelated donor transplants are from the European Bone Marrow Transplant registry (EBMT), Fred Hutchinson Cancer Research Center, IBMTR, and the International Marrow Unrelated Search and Transplant (IMUST) study group. Survival curves are not adjusted for varying patient, disease, and transplant regimen characteristics.

Courtesy of the National Bone Marrow Donor Program.

Immunosuppressive Therapy with Antithymocyte Globulin/Cyclosporine

The combination of ATG/CSA leads to 5-year survival rates comparable to BMT, but most of these patients are not cured of their disease (Bacigalupo et al., 1995; Marsh et al., 1999). Response rates to ATG/CSA range between 60 and 80%, but in contrast to BMT, most patients do not acquire normal blood counts (Frickhofen et al., 1991; Rosenfeld et al., 1995). Another limitation of this approach is that many patients relapse, become dependent on CSA, or develop a secondary clonal disease such as PNH or MDS (Bacigalupo et al., 2000a; Rosenfeld et al., 2003). These late events often lead to substantial morbidity and mortality. Therapists at The National Institute of Health treated 122 patients (median age, 35 years) with the combination of ATG/CSA and methylprednisolone (Rosenfeld et al., 2003). The response rate was 58% and actuarial survival at 7 years was 55%; 13% of patients died within 3 months of treatment, most from fungal infections (Figure 44.2). The relapse rate for responders was 40% and at 8 years the actuarial rate for developing MDS was 15%.

High-Dose Cyclophosphamide Without Bone Marrow Transplantation

The first successful human allogeneic BMT, reported in 1972 by Thomas et al. in a patient with aplastic anemia, employed high-dose cyclophosphamide, and this remains (often in conjunction with ATG) the most commonly employed conditioning regimen for aplastic anemia (May et al., 1993; Storb et al., 2001). Interestingly, complete autologous recovery occurs in up to 20% of patients undergoing allogeneic BMT for aplastic anemia when cyclophosphamide alone is the conditioning regimen (Thomas et al., 1976; Sensenbrenner et al., 1977; Gmur et al., 1979; Weitzel et al., 1988). The unique pharmacology of cyclophosphamide is responsible for these occurrences. As a prodrug, cyclophosphamide is converted to 4-hydroxycyclophosphamide and its tautomer aldophosphamide in the liver. These compounds diffuse into the cell and are converted to the active compound phosphoramide mustard, or they are inactivated by aldehyde dehydrogenase to form the inert carboxyphosphamide. Lymphocytes have low levels of aldehyde dehydrogenase and are rapidly killed by high doses of cyclophosphamide; hematopoietic stem cells possess high levels of aldehyde dehydrogenase and are resistant to cyclophosphamide (Hilton, 1984; Kastan et al., 1990; Jones

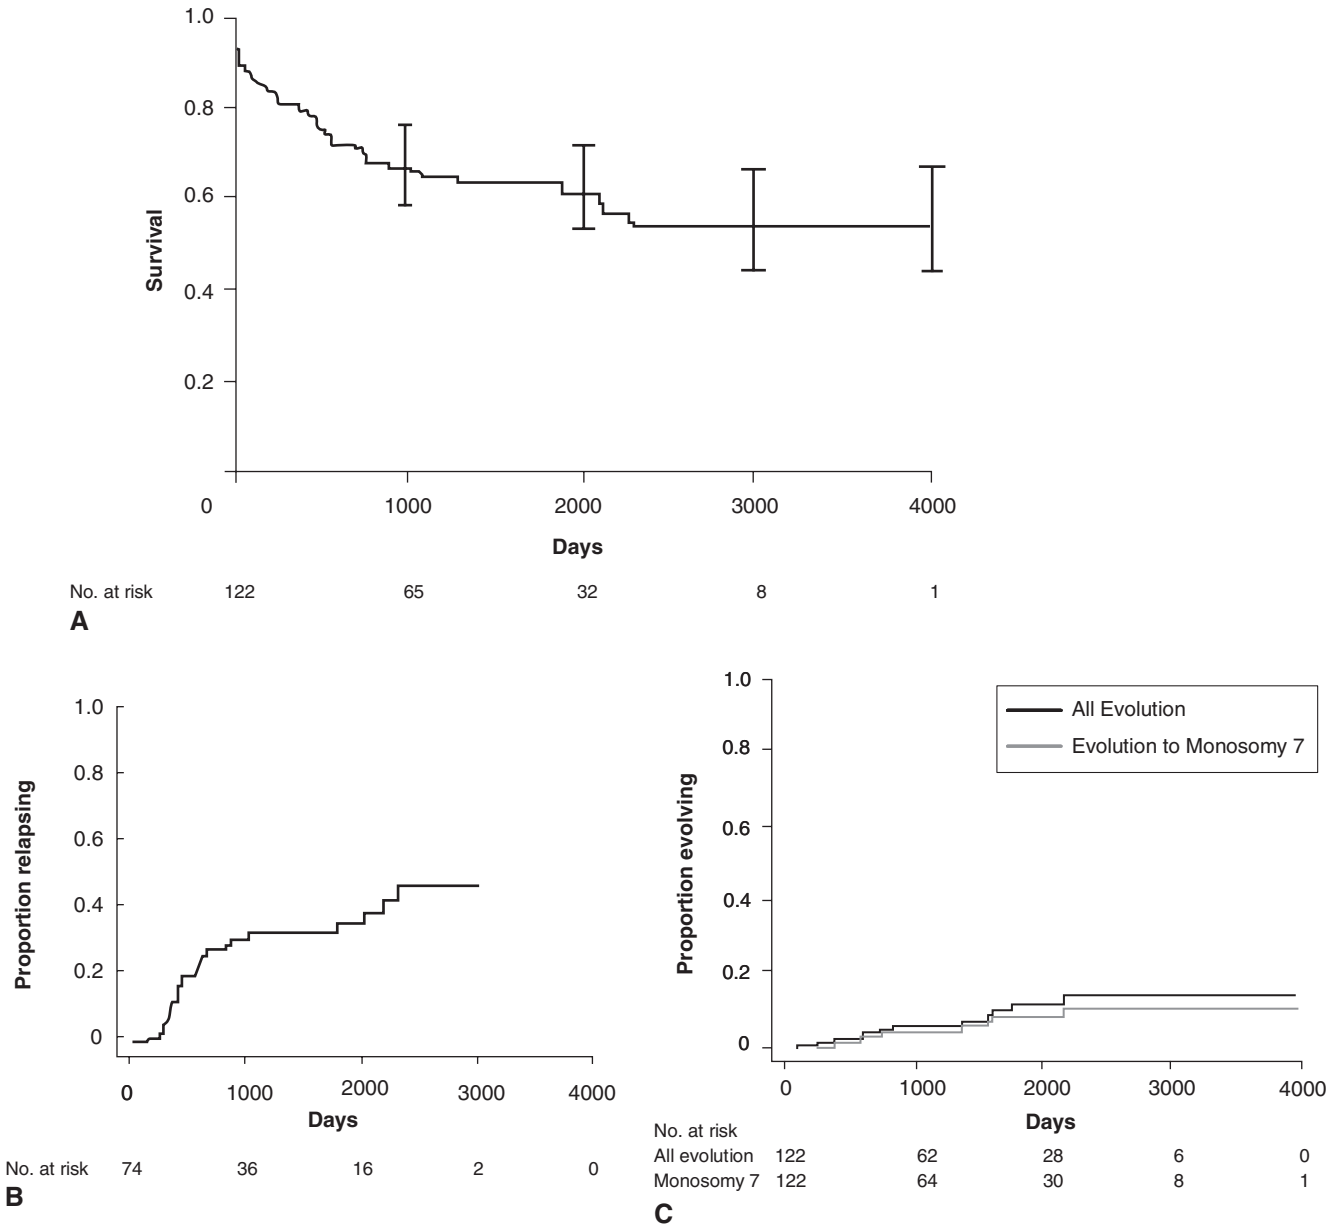

FIGURE 44.2 *A*, Survival probability for 122 patients with severe aplastic anemia following treatment with antithymocyte globulin and cyclosporine. *B*, Probability of relapse in 74 patients with aplastic anemia classified as responders at 3 months after treatment with antithymocyte globulin and cyclosporine. *C*, Proportion of patients experiencing clonal evolution.

Reproduced from Rosenfeld et al. (2003), with permission.

et al., 1995). Thus, high-dose cyclophosphamide is highly immunosuppressive, but not myeloablative, allowing endogenous hematopoietic stem cells to reconstitute hematopoiesis. With this background, high-dose cyclophosphamide without BMT was used successfully in aplastic anemia patients who lacked appropriate donors (Baran et al., 1976; Brodsky et al., 1996; 2001; Tisdale, 2000; Jaime-Perez et al., 2001). Based on these early promising studies, high-dose cyclophosphamide without BMT is now considered first-line therapy for severe aplastic anemia by some centers, but others have raised concerns about the toxicity of this approach (Figure 44.3).

High-dose cyclophosphamide has also been shown to salvage many patients who relapse or fail to respond to ATG/CSA (Brodsky et al., 2004). Similar to BMT, the early toxicity of high-dose cyclophosphamide may exceed that of ATG/CSA; however, the quality and duration of response appear to be superior.

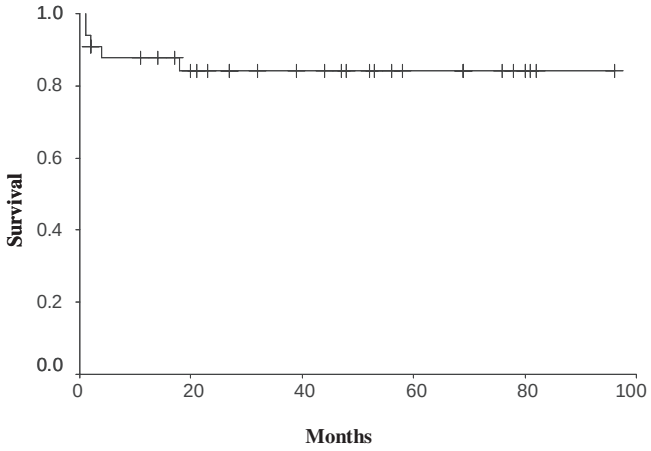

FIGURE 44.3 Survival probability following high-dose cyclophosphamide without bone marrow transplantation in 33 patients with severe aplastic anemia (SAA) (median age 42 years) followed at Johns Hopkins and Drexel University.

Clonality

Survivors of aplastic anemia are at high risk of clonal progression following immunosuppressive therapy, but not after allogeneic BMT (Socie et al., 1993). PNH and MDS are the most common clonal disorders to evolve from aplastic anemia (Tichelli et al., 1988; de Planque et al., 1989; Nagarajan et al., 1995). Even before the widespread use of immunosuppressive therapy, 5% of patients progressed to clonal hematopoiesis. This suggests that the increase in MDS and PNH following immunosuppressive therapy is not caused by the immunosuppression; rather, the increased survival following immunosuppressive therapy may allow time for these underlying clones to expand (Moore and Castro-Malaspina, 1991; Mukhina et al., 2001).

PNH results from the expansion of an abnormal hematopoietic stem cell that harbors a somatic mutation of the X-linked gene, termed PIGA (Rosse, 1997; Moyo, 2004). The product of the PIGA gene is required for the first step in the biosynthesis of glycosylphosphatidylinositol (GPI) anchor biosynthesis; consequently, PNH cells are deficient in GPI-anchored proteins. Several GPI-anchored proteins (CD59 and CD55) protect cells from complement-mediated destruction, and their absence explains the hemolytic anemia associated with PNH. However, it is unclear why the defective PNH stem cell and its progeny displace normal hematopoiesis, despite the fact that PNH cells are more vulnerable to complement-mediated destruction. One hypothesis to explain the relationship between aplastic anemia and PNH is that PNH cells resist the immune attack in aplastic anemia, ostensibly due to the lack of GPI-anchored proteins, but direct data supporting this hypothesis are still lacking.

MDS also commonly arises in aplastic anemia patients treated with immunosuppressive therapy (Tichelli et al., 1988; Socie et al., 1993). In a retrospective review of children with severe aplastic anemia, 11 of 86 patients who received immunosuppressive therapy developed MDS (Ohara et al., 1997). Up to 15% of adult patients with aplastic anemia will also develop MDS following immunosuppressive therapy with monosomy 7 being the most common chromosomal abnormality (Rosenfeld et al., 2003).

Although it is unclear why patients with aplastic anemia are predisposed to develop PNH and MDS, it is possible that all three diseases have a common pathogenesis. Damage to a hematopoietic progenitor cell that leads to an autoimmune response directed against the bone marrow in aplastic anemia (Thomas and Storb, 1984) could also produce genetic mutations (PNH/MDS) that give these hematopoietic progenitors a relative growth advantage. Over time, an abnormal clone arising from a slowly proliferating, transformed progenitor cell could eventually become dominant. The finding that almost 70% of patients with aplastic anemia have detectable PNH cells at diagnosis supports this hypothesis (Mukhina et al., 2001). Alternatively, prolonged immune attack against hematopoietic stem cells may lead to DNA damage, ultimately leading to clonal disorders.

CONCLUDING REMARKS AND FUTURE PROSPECTS

Only recently has acquired aplastic anemia been recognized as an autoimmune disease. Studies into the biology of aplastic anemia have been inherently difficult. In patients with active disease, the targets of the immune attack, hematopoietic stem cells, are exceedingly rare; these cells probably represent <0.1% of bone marrow cells in normal individuals and are even less frequent in patients with aplastic anemia. BMT restores hematopoiesis from the donor, making it impossible to study the affected host stem cells and the immune system. The clinical response of aplastic anemia to immunosuppressive therapy provided the first data suggesting that aplastic anemia was immune mediated. More recently, it has been shown that the bone marrow in aplastic anemia is infiltrated with lymphocytes that secrete Th1 cytokines. Skewing of the Vβ repertoires demonstrated by CDR3 spectratyping further suggests that this is an antigen-driven autoimmune disorder. Moreover, newer methodologies are beginning to allow the study of the rare target cell populations in aplastic anemia. In fact, emerging data suggest that the most primitive hematopoietic stem cells may not be the target of the immune attack in aplastic anemia, and that these cells persist in many patients. Rather, the immune attack in aplastic anemia may be against more committed myeloid or "low-quality" (Van Zant et al., 1997) stem cells, while the most primitive hematopoietic stem

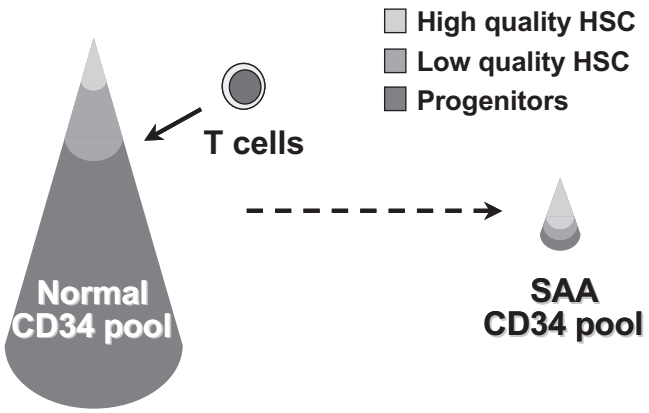

FIGURE 44.4 Model depicting the pathophysiology of bone marrow failure in acquired aplastic anemia. Autoagressive lymphocytes lyse $CD34^+$ bone marrow progenitor cells but seem to spare more immature $CD34^+$ cells, known as high-quality stem cells.

cells elude or are resistant to attack (Figure 44.4). There are a number of potential mechanisms by which primitive hematopoietic stem cells could evade immune attack. Data suggest that the antigens targeted in aplastic anemia are presented by HLA class II molecules (Nakao et al., 1997; Zeng et al., 2001). Primitive hematopoietic stem cells appear to express little or no HLA class II (Rusten et al., 1994; Van Zant et al., 1997), which may account for their relative invisibility to autoreactive effector lymphocytes. In addition, the Fas–Fas ligand plays an important role in the pathophysiology of aplastic anemia (Maciejewski et al., 1995), and Fas appears to be absent on primitive hematopoietic stem cells with its expression increasing as they differentiate (Nagafuji et al., 1995; Stahnke et al., 1998). Recent advances in the understanding of the immunobiology of aplastic anemia make it very likely that future editions of this textbook will fully define the basis of the autoimmune attack in this disease.

CHAPTER

45

Clotting Disorders

JEAN-MARIE R. SAINT-REMY
Center for Molecular and Vascular Biology, University of Leuven, Belgium

Disorders related to coagulation factor autoimmunity are rare but underestimated. Clinical manifestations are obviously dominated by bleeding, but these can be acute and life-threatening, or progressive with formation of hematomas in various organs. The circumstances under which an autoimmune coagulation disorder appears also vary from spontaneous occurrence in an otherwise healthy individual, as a complication in the context of a systemic autoimmune disease, to association with postpartum, surgery, drug intake or exposure to a cross-reactive antigen. The purpose of this chapter is to offer a comprehensive overview of autoimmune coagulation disorders to help clinicians and clinical investigators to establish an early diagnosis. A diagram showing the general organization of the coagulation system is provided in Figure 45.1.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

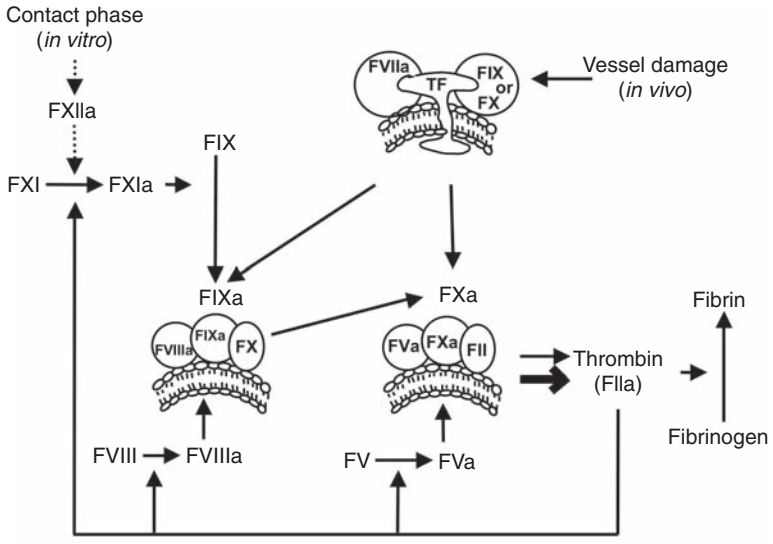

FIGURE 45.1 Overview of the coagulation pathways. 1) *In vivo*, the coagulation process is initiated when tissue factor (TF) expressed on injured vessel walls is exposed to activated Factor VII in the bloodstream. Small amounts of thrombin are generated through activation of Factor IX and Factor X. 2) Thrombin activates Factor VIII and Factor V, thereby triggering an amplification phase through the formation of the tenase complex (FVIIIa–FIXa–FX), which converts Factor X to its activated form, and the prothrombinase complex (FVa–Factor Xa–prothrombin/Factor II), which converts prothrombin into thrombin. Thrombin also activates Factor XI, which amplifies the generation of Factor IXa. 3) Thrombin converts fibrinogen into fibrin. It activates protein C, which triggers a negative feedback through inactivation of Factor VIIIa and Factor Va (not shown). Thrombin also activates the thrombin-activable fibrinolysis inhibitor (TAFI), which stabilizes the clot (not shown). 4) Direct activation of Factor XI also occurs through Factor XIIa via the contact phase system.

AUTOANTIBODIES TO FACTOR VIII

Clinical Presentation and Associated Conditions

This represents by far the most commonly encountered autoimmune reaction to a coagulation factor, although it affects only 0.2–1 individuals in a million population per year (Garvey, 1995). The precise incidence of anti-Factor VIII (FVIII) inhibitors is difficult to establish, as it can occur with only minimal symptoms (Green and Lechner, 1981). In addition, inhibitors to FVIII are also detectable in a majority of healthy donors, although in such cases inhibitors appear to be neutralized by anti-idiotypic antibodies.

The clinical picture varies from minimal signs such as easy bruising to very severe bleeding affecting the gastrointestinal tract, skin, and muscles. Epistaxis and hematuria are frequent but, in contrast to antibodies elicited by infusion of FVIII in congenital hemophilia A patients, joints are not affected. Large hematomas may form with nerve or tracheal compression. These signs can appear suddenly or very progressively. There is no gender or race preference. The vast majority of cases are observed in elderly people, yet children can be affected, too (Moraca and Ragni, 2002). The mortality rate lies between 10 and 20%.

Forty-five percent of cases are observed in individuals with no underlying disease. Associated conditions belong mainly to four groups: malignancies, systemic autoimmune diseases and/or chronic inflammation, postpartum (Hauser et al., 1995), and iatrogenic.

Malignancies include lympho- and myelo-proliferative disorders (Lin et al., 1991; Meek and Haak, 1986), and lung (Shwaiki et al., 2001) and prostate carcinomas, but this is not exclusive (Hultin, 1991). Systemic autoimmune diseases include systemic lupus erythematosus (SLE), rheumatoid arthritis, Sjögren syndrome (Vignes et al., 1996), multiple sclerosis, and pemphigus vulgaris. Graft-versus-host disease (Seidler et al., 1994) and chronic inflammation, such as that of Crohn's disease, thyroiditis (Sievert et al., 1996), chronic hepatitis C (Sugishita et al., 1999), and tuberculosis (Aurousseau et al., 1996), have been described. Autoantibodies to FVIII appearing in the postpartum phase are usually of short duration. Anti-FVIII antibodies have also been shown during therapy with penicillin sulfamides (sulfonamide) (Annichino-Bizzacchi and Machado, 1991), and interferon (IFN)-α (Stricker et al., 1994), and after Bacillus Calmette–Guerin (BCG) vaccination. A few cases of inhibitors occurring after surgery have also been described (Alumkal et al., 1999).

Diagnosis

Prolonged activated prothrombin time (APTT) with normal prothrombin time (PT) and thrombin time (TT), and normal platelet count should prompt a search for an inhibitor to FVIII. Direct evaluation of FVIII, Factor IX (FIX), Factor

FXI (FXI), and Factor FXII (FXII) ensures the specificity of the antibodies. Mixing experiments in which varying volumes of normal plasma are mixed with the plasma suspected to contain an inhibitor show partial or no correction of APTT. The Bethesda assay, or better its so-called Nijmegen modification, is carried out by mixing vol/vol varying dilutions of the plasma under investigation with normal plasma. The dilution of plasma containing the inhibitor that still inhibits 50% of FVIII activity from normal plasma is taken as the number of Bethesda units. As most autoantibodies to FVIII are type II inhibitors (see below), which are time and temperature dependent, it is current practice to incubate the mixture for 2 h at 37° C.

Pathophysiology

FVIII has a mature sequence of 2332 amino acids organized in domains with the structure A1-A2-B-A3-C1-C2 (Figure 45.2). A number of functional inhibitor epitopes have been identified (arrows in Figure 45.2), corresponding to sites at which FVIII interacts with phospholipids, von Willebrand factor (vWF), FIX, and FX. As for alloantibodies to FVIII, acquired inhibitors belong primarily to the IgG4 isotypes, with some IgG1 isotypes also in a significant proportion of cases (Gilles and Saint-Remy, 1996; Matsumoto et al., 2001). A limited attempt to map the FVIII epitopes recognized by autoantibodies has indicated that, as for alloantibodies, the C2 domain is most often the main target (Di Giambattista et al., 2001), followed by the A2 domain (Scandella et al., 1989). The C2 domain contains the binding sites for phospholipids and some of the binding sites for vWF. It is therefore inferred that acquired inhibitors neutralize FVIII function by inhibiting the binding of FVIII to phospholipids, a necessary step in the formation of the tenase complex, and/or to vWF, the function of which is to protect FVIII from proteolytic inactivation and rapid clearance from the circulation. One of the mechanisms suggested by the binding to the A2 domain is related to inhibition of FVIII binding to FIX or acceleration of the release of the noncovalently bound A2 domain from A1–A3-light chain. Such an interpretation is, however, difficult to reconcile with the kinetics of FVIII inactivation usually observed with auto–anti-FVIII antibodies. Recent evidence suggests that at least some of the autoantibodies to FVIII act by inducing a conformational change in the molecule, resulting from binding to a distant site (Jacquemin et al., 2000). Recent studies have addressed the question of T-cell epitopes (Reding et al., 2003).

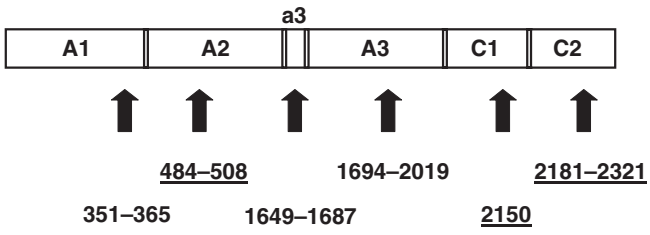

FIGURE 45.2 Major B-cell epitopes on the activated Factor VIII (FVIII) molecule. FVIII is represented in its activated form with the six identified major B-cell epitopes. For the sake of clarity, the molecule is shown as a single polypeptide chain instead of in its heterotrimeric configuration. Underlined sequences have been mapped directly with autoantibodies. Epitope mapping used to be carried out with recombinant FVIII domains, but recently a method was developed using combined transcription–translation of radiolabeled peptides made with rabbit reticulocytes. This method allows much more precision in epitope delineation. There is no current evidence to conclude that epitopes recognized by autoantibodies differ from those of alloantibodies.

According to the kinetics of FVIII inhibition, FVIII inhibitors are usually separated into two categories (Gawryl and Hoyer, 1982). Type I inhibitors inhibit FVIII function completely following second-order kinetics, while type II inhibitors inhibit FVIII function in two phases, a rapid inactivation followed by a much slower phase, and never inactivate FVIII completely. The vast majority of autoantibodies to FVIII described so far are type II inhibitors. Interestingly, there is some suggestion that idiopathic autoantibodies present type II characteristics, while antibodies appearing in the context of an autoimmune disease, or associated with a malignancy, could primarily be type I.

Treatment

Therapy includes two steps, namely the control of bleeding and the eradication of the inhibitor (Roberts, 1998). Control of bleeding is achieved by different methods. rFVIIa administration is probably the treatment of choice for acute situations that are life-threatening (Hay et al., 1997; von Depka, 2002). The success rate with rFVIIa is high, but such a treatment carries the risk, albeit limited, of thrombotic events. The therapy is nevertheless very expensive and thereby not accessible in many centers throughout the world. Low-titer inhibitors can be treated by infusion of FVIII or use of desmopressin (DDAVP) (Mudad and Kane, 1993); the latter mobilizes vWF and FVIII from storage in endothelial cells.

An alternative, though equally costly, therapy is porcine FVIII (Hoyle and Ludlam, 1986; Morrison et al., 1993). This is based on the observation that, although there exists an extensive homology between human and porcine FVIII, inhibitors elicited towards human FVIII do not cross-react with porcine FVIII. The latter is, however, immunogenic, which precludes its use over prolonged periods of time. Activated prothrombin complexes can also be used in emergency situations.

Eradication of the inhibitor is usually achieved by a therapy based on high-dose corticosteroids (Spero et al., 1981), often combined with cytostatic agents such as cyclophosphamide (Green et al., 1993; Shaffer and Phillips, 1997). Cyclosporine and calcineurin inhibitors have been used with success. Intravenous gamma-globulin (IVIG) infusion has been advocated (Crenier et al., 1996; Schwartz

et al., 1995) on the basis of the presence of anti-idiotypic antibodies that can neutralize the inhibitory activity of anti-FVIII antibodies (Sultan et al., 1984; Rossi et al., 1988). This is considered as a second-line treatment. In some instances, extracorporeal removal of immunoglobulins combined with IVIG, with or without cytostatic agents, has been recommended in refractory cases (Nilsson et al., 1984).

Recently, an antibody directed towards CD20, a B-cell surface protein, has shown efficacy in the treatment of acquired anti-FVIII inhibitors (Stasi et al., 2004). Controlled trials are underway to determine whether this constitutes a valuable alternative therapy to those listed above.

The apparent absence of consensus about treatment reflects the lack of controlled studies as well as the variety of conditions that are associated with this syndrome. Efforts are underway to validate some of these therapeutic approaches.

AUTOANTIBODIES TO FACTOR IX

The occurrence of antibodies to FIX in patients without hemophilia is very rare and only single case reports are found in the literature. Clinical presentation includes hematomas and gastrointestinal bleeding, but in some cases the discovery of an inhibitor is made by routine evaluation of a prolonged APTT. Association with pathologic conditions relies most often on single cases: postpartum, nephrotic syndrome, adenocarcinoma (Collins and Gonzalez, 1984), arteritis (Torres et al., 1980), SLE (Castro et al., 1972), and more convincingly, gastrointestinal diseases such as Crohn's and ulcerative rectocolitis (Kyriakou, 2002).

Diagnosis relies on the direct assessment of the inhibitor in a modified Bethesda assay (see above). APTT is prolonged with normal PT. FIX activity is generally <1% of normal level. Autoantibodies to FIX belong to the IgG isotype but have not been characterized in detail. It is, however, likely that they show specificity and isotype distribution similar to that of alloantibodies found in hemophilia B patients undergoing replacement therapy (Greenwood et al., 2003).

A safe and rapidly efficient treatment involves a combination of IVIG and corticosteroids (Mazzucconi et al., 1999).

AUTOANTIBODIES TO FACTOR V

Clinical Presentation and Associated Conditions

This is a rare disorder with fewer than 250 cases described, but is likely to be underdiagnosed because of the large variety of associated syndromes or triggering factors (see below) and the fact that 40% of cases are asymptomatic. The bleeding diathesis is variable with epistaxis, intestinal bleeding or occurrence of retroperitoneal or brain hematomas (Kapur et al., 1993; Schleinitz et al., 2001).

The majority of cases are discovered after cardiovascular or gastrointestinal surgery (Leclerc et al., 1995), with the suspicion that antibiotics (Thomas et al., 1989) and/or blood transfusion could play a role. The use of aminoglycosides has been associated with rare occurrences of factor V (FV) autoantibodies. As for other antibodies to coagulation factors, an association has been found with cancer, paraproteins, and benign gammopathies (van Spronsen et al., 1998), autoimmune diseases such as SLE, Hashimoto's thyroiditis (Takahashi et al., 2003), rheumatoid arthritis, and celiac diseases (Taillan et al., 1989). A special case should be made for autoantibodies occurring after the use of fibrin glues (Berruyer et al., 1993; Cruickshank et al., 1994; Muntean et al., 1994), which contain bovine thrombin contaminated with trace amounts of bovine FV (Spero, 1993), and trigger the production of cross-reactive antihuman FV antibodies. New biomaterials and use of recombinant thrombin should prevent further emergence of such cross-reacting antibodies.

Diagnosis

Laboratory investigations show prolonged APTT and PT in the presence of normal TT. Mixing experiments show lack of correction of the coagulation defect when normal plasma is added to the patient's sample.

Pathogenesis

A limited number of investigations have been carried out to characterize such autoantibodies (Nesheim et al., 1986; Kalafatis et al., 2002). Not all antibodies are inhibitors of FV function. Some appear to increase the clearance of FV. Antibodies recognize the FV light chain (Suehisa et al., 1995) and in particular the C2 domain (Ortel et al., 1998), thereby inhibiting the binding of FV to phospholipids and the formation of the prothrombinase complex. There is no obvious difference in specificity between inhibitory and noninhibitory antibodies. Interestingly, anti-FV antibodies have no effect on platelet FV, which represents ± 20% of total FV, which could explain why a significant proportion of patients with auto–anti-FV antibodies have no obvious bleeding tendency.

Treatment

There is no validated therapy for FV autoantibodies. Apart from the treatment of the underlying disease and the use of corticosteroids and/or immunosuppressants (Bayani et al., 2002), some authors advocate the use of platelets

based on the storage of FV in α granules. Infusion of IVIG is probably the treatment of choice, which, although its mechanism of action is not entirely elucidated (Fu et al., 1996), is often efficient. Prothrombin-rich complexes are used for emergency situations. Anti-CD20 antibodies (rituximab) should be considered in the context of systemic autoimmune disease.

ACQUIRED FACTOR X DEFICIENCY

Clinical Presentation and Associated Conditions

The bleeding diathesis affects the gastrointestinal tract and other mucosa (Edgin et al., 1980; Lankiewicz and Bell, 1992). Hematuria and bleeding in the oropharyngeal area are frequent, as well as cutaneous hematomas (Mulhare et al., 1991). It can present at any age as it is not necessarily associated with neoplasia or autoimmune diseases.

The presence of an autoantibody to Factor X (FX) is most often suspected from *in vitro* evaluation of FX (see below). It is likely that such antibodies are present in a majority of cases, with the exception of the classical demonstration of FX-irreversible adsorption on amyloid fibrils (Furie et al., 1981; Greipp, 1981). Infections of viral or mycoplasma origin are frequently reported. Large traumas, extensive burns (Matsunaga and Shafer, 1996), and carcinomas can be associated in some instances. Single case reports of FX autoantibodies after fungicide or paint solvent exposure and in leprosy (Ness et al., 1980) have been described, but idiopathic cases are known.

Diagnosis

A prolonged PT with a normal or moderately prolonged APTT is found. Levels of FX are very low. Mixing experiments do not show correction of PT. Activation of FX by either the FVIII/FIX or tissue factor (TF)/FVII pathways is impaired. Inhibition of direct FX activation in the Russell viper venom test can also be observed.

Pathogenesis

Antibodies that increase the clearance rate of FX and inhibitor antibodies have both been described. The mechanism by which antibodies inhibit FX function is not precisely identified, but includes inhibition of FX activation as seen in the Russell test.

Treatment

Recommended treatment combines plasma exchange and infusion of IVIG (Smith et al., 1998). The use of prothrombin-rich complexes is deemed to carry a high risk of thrombotic complications. The prognosis is dependent on the underlying cause, but in most cases the inhibitor is only transient.

AUTOANTIBODIES TO FACTOR VII

Clinical Presentation and Associated Diseases

Signs of bleeding vary between minimal and life-threatening, and appear to have no direct relationship with the residual level of Factor FVII (FVII) (Weisdorf, 1989; Okajima and Ishii, 1999; Aguiar, 2003). Bleeding affects the gastrointestinal and urinary tracts, often accompanied by ecchymoses, but the limited number of cases described also points to internal hematomas, notably retroperitoneal and intracranial (Delmer et al., 1989). Autoantibodies to FVII have been observed in the postpartum period, and in the context of SLE, carcinomas or penicillin treatment. It occurs without obvious association in 30% of cases.

Diagnosis

A prolonged or very prolonged PT with a normal APTT and platelet count point to a defect in the extrinsic pathway of coagulation. Levels of FVII are reduced to a variable extent, which is of no predictive value.

Pathogenesis

Antibodies inhibit FVIIa activity. Binding to the FVIIa light chain prevents its binding to tissue factor and/or phospholipids (Kamikubo et al., 2000).

Treatment

Prothrombin complexes and steroids are recommended (Annichino-Bizzachi et al., 1993).

AUTOANTIBODIES TO FACTOR XI OR FACTOR XII (CONTACT PHASE)

Clinical Presentation and Associated Diseases

Antibodies to FXI or FXII usually go unnoticed, as they are not associated with a bleeding diathesis. Antibodies to FXI can be associated with recurrent thrombosis or even disseminated intravascular coagulation (DIC). Associations have been described with SLE (Di Sabatino, 1979; Vercellotti and Mosher, 1982), psoriasis (Rustgi et al.,

1982), and adenovirus infection for FXI antibodies and with liver diseases such as chronic hepatitis, SLE, Waldenstrom's macroglobulinemia, and glomerulonephritis for FXII-specific antibodies (Chalkiadakis et al., 1999).

Diagnosis

The discovery of a prolonged or very prolonged APTT in patients with no apparent bleeding or a history of recurrent thrombosis is highly suggestive of either a deficiency in FXI or FXII, or for the presence of specific antibodies. This finding should be followed by evaluation of single components.

Pathogenesis

Information on anti-FXI antibodies is derived from alloantibodies generated in patients with FXI deficiency (Stern et al., 1982). Such antibodies are of the IgG isotype and bind to two distinct epitopes (De La Cadena et al., 1988) involved in the binding of FXI to high molecular weight kallikrein (Page et al., 1994; Sugi and McIntyre, 1995), or in the activation of FIX by FXI, respectively. No reports on the specificity or mechanisms of inhibition of anti-FXII antibodies have been published.

Treatment

No treatment is generally required, except for treatment of the underlying disease and for prevention of recurrent thrombotic episodes.

AUTOANTIBODIES TO FACTOR XIII

Clinical Presentation and Associated Diseases

This is a rare but often fatal bleeding diathesis, including intracranial hemorrhage, due to a lack of fibrin stabilization (Lorand et al., 2002). It has been observed in the context of systemic autoimmune diseases, such as SLE, but occurs without any apparent cause, most often in elderly patients (Lorand et al., 1999). A possible association with treatment with isoniazide has been described, with disappearance of the inhibitor upon drug withdrawal.

Diagnosis

A characteristics feature is that extensive bleeding is associated with normal APTT, PT, and bleeding time, and with normal platelet counts. This should prompt studies on fibrin stabilization and evaluation of Factor XIII (FXIII) levels.

Pathogenesis

FXIII is activated by thrombin, which induces a conformational change in the molecule so that it can cross-link fibrin I and II. Antibodies can prevent activation by thrombin or the conformational change required for full FXIIIa activity (Lorand et al., 1988). Some antibodies interfere with the activity of FXIIIa or with its binding to fibrin.

Treatment

Withdrawal of drugs such as isoniazide and cryoprecipitate to support fibrin stabilization are required. Eradication of the anti-FXIII antibody usually requires corticosteroids and cyclophosphamide (Nakamura et al., 1988).

AUTOANTIBODIES TO PROTHROMBIN

Clinical Presentation and Associated Diseases

The heterogeneity of antiprothrombin antibodies is well illustrated by association with either thrombotic events or bleeding, or sometimes as a chance discovery of routine laboratory assessment. Apart from its association with SLE (see Chapter 27) and the antiphospholipid syndrome (see Chapter 30), antibodies to prothrombin are found as a spontaneous primary event as a consequence of drug intake (phenytoin and chlorpromazine), in the context of human immunodeficiency virus (HIV) infection (37% of the cases), syphilis or even in infectious mononucleosis (3%) (Atsumi et al., 2000). Such antibodies can also be induced by exposure to bovine thrombin used in biologic glues. In such cases, IgE-mediated anaphylaxis can be observed (Wai et al., 2003).

Diagnosis

There is an increase in both PT and APTT. The level and activity of prothrombin are grossly altered. The search for antiprothrombin antibodies can be carried out with prothrombin directly insolubilized on an enzyme-linked immunosorbent assay (ELISA) plate or by interposition of a phospholipid layer. These two tests detect antibodies with different specificities and different pathologic meaning. Only antibodies binding to phospholipid–prothrombin complexes correlate with the presence of SLE (Simmelink et al., 2003).

Pathogenesis

Antibody-binding sites on prothrombin are located outside the functional domain. It is therefore thought that the

major effect of these antibodies on prothrombin results from an increase in clearance rate. At least some of the antiprothrombin antibodies cross-react with plasminogen, which could explain the thrombotic tendency by reduced fibrinolysis (Roubey, 1998).

Treatment

High-doses of prednisolone appear to reduce the clearance rate of complexes of antibodies with prothrombin. Steroids could also increase the rate of prothrombin production by the liver.

AUTOANTIBODIES TO FIBRINOGEN/FIBRIN

Clinical Presentation and Associated Diseases

When searched for, autoantibodies to fibrinogen and/or fibrin are often found in pregnancy and the peripartum period, apparently with no pathologic association (Kondera-Anasz, 1998). Such antibodies are also found in cord blood. In rare cases in which antibodies to fibrinogen and/or fibrin have been described, abnormal bleeding is found, but this is usually not severe. These antibodies can occur in the context of gammopathies or liver disease, but are most often a primary finding (Nawarawong et al., 1991). Patients developing antibodies when exposed to bovine fibrin glue represent a special case (Seifert et al., 1994; Chouhan et al., 1997; Fastenau and Mcintyre, 2000).

Diagnosis

An increased TT with normal or slightly prolonged PT and APTT is the usual finding. Levels of fibrinogen are usually within the normal range. Antibodies are thought to circulate in the form of immune complexes with fibrinogen.

Pathogenesis

Antifibrinogen antibodies either delay the release of fibrinopeptide obtained by thrombin activation of fibrinogen (Marciniak and Greenwood, 1979) or interfere with the process of fibrin polymerization (Hoots et al., 1981). Although mostly belonging to the IgG class, cases of IgM and IgA antibodies have been described.

Treatment

Corticosteroids, cyclophosphamide, and IVIG should be considered for therapy.

ACQUIRED VON WILLEBRAND SYNDROME

Clinical Presentation and Associated Diseases

Acquired von Willebrand syndrome (AvWS) is rare but most likely underdiagnosed (Veyradier et al., 2000; Budde et al., 2002; Kumar et al., 2002; 2003). It should be suspected in late-onset bleeding diathesis in patients with no personal or familial history of bleeding (Mohri, 2003). Symptoms are indistinguishable from those of congenital von Willebrand disease, except for those related to the accompanying disease. Bleeding occurs at the mucosal level: epistaxis, gingivorrhagia, menorrhagia, and often gastrointestinal, the latter being very severe. Ecchymoses are also common (Mohri et al., 1998). In a number of cases, AvWS is a fortuitous discovery. It should, however, be actively searched for in diseases commonly associated with it.

AvWS is associated with lympho- (Hunault-Berger et al., 2001) and myelo-proliferative diseases (Federici et al., 2001), multiple myeloma (Mohri et al., 1995), and benign gammopathy, or in the context of autoimmune diseases such as SLE (Hanley et al., 1994; Michiels et al., 2001; Niiya et al., 2002), and thyroiditis (Bruggers et al., 1994; Aylesworth et al., 1995). Association has also been described with uremia, Crohn's disease (Sokol et al., 2002), aortic stenosis (Vincentelli et al., 2003; Warkentin et al., 2003), Epstein–Barr virus infection (Kinoshita et al., 1991) and ciprofloxacin therapy (Castaman and Rodeghiero, 1994). AvWS can also present without any underlying association (Lazarchick et al., 1986).

Diagnosis

Apart from the evaluation of the associated condition, laboratory tests should first assess bleeding time (prolonged) and APTT (often prolonged due to the reduction in FVIII levels secondary to a decrease in vWF concentrations), in the presence of a normal platelet count and normal thrombin time. Specific tests for vWF should then include an assay for vWF antigen and an evaluation of its function in the presence of ristocetine (binding to platelets) or thrombin-activated platelets. vWF's capacity to bind to collagen is useful (van Genderen et al., 1994). Electrophoresis to evaluate for the presence of multimers is key to diagnosis, as such multimers tend to be cleared from the circulation more rapidly (see below). Finally, platelet vWF should be normal, which distinguishes AvWS from congenital forms of the diseases. If available, an evaluation of vWF propeptide level (normal in AvWS) will further establish the diagnosis.

A search for autoantibodies to vWF should be carried out (Fricke et al., 1985; Lazarchick and Green, 1986), although there is no standard method for it. Mixing experiments are recommended, by which it is possible to detect interference in normal vWF function. However, anti-vWF antibodies often exist in the form of complexes with vWF and are therefore not readily detectable with such an assay. Some recommend preparing an IgG-enriched fraction from plasma followed by dissociation of the complexes with vWF before assessing antibody activity. A negative result has little meaning as many anti-vWF antibodies recognize epitopes located outside the functional domains (see below).

Pathogenesis

Not all cases of AvWS are antibody mediated, although the proportion of cases in which antibodies play a role is not yet precisely established. It is useful to distinguish between antibody-mediated mechanisms and those that are not.

Most antibodies are thought to increase the clearance rate of vWF (Inbal et al., 1997), especially through the recognition of multimers. Clearance is mediated by the reticuloendothelial system. In a minority of cases, antibodies have been shown to bind to the sites of vWF that interact with glycoprotein (GP)Ib and/or GPIIb/IIIa receptors on platelets or collagen, thereby interfering with the normal function of vWF. Interference with the FVIII-binding site has not been described. A case of antibodies directed towards ADAMTS-13, the vWF cleaving protease, has been described and they resulted in a lack of generation of functional vWF (Scheiflinger et al., 2003).

Non-antibody-mediated mechanisms include adsorption of vWF at the surface of tumor cells with aberrant expression of GPIb and/or GPIIb/IIIa receptors or on activated platelets. Iatrogenic causes include the use of plasma expanders made from starch, which are also known to adsorb multimers of vWF (Casonato et al., 2002). vWF proteolysis by plasmin or elastase has been described in conditions with increased fibrinolysis or sepsis. Lastly, vWF can be disrupted by high shear stress, such as that occurring in aortic stenosis, together with platelet activation brought about by the same stress conditions.

Treatment

This includes the treatment of the underlying diseases (Federici et al., 1998; Federici, 2000). DDAVP is the treatment of choice as it has the capacity to mobilize vWF from storage sites (Frank et al., 2002). However, such treatment is of limited use in antibody-mediated AvWS, in which the rapid clearance compensates for increased production. Under such circumstances, infusion of IVIG is advocated (Arkel et al., 1994). Emergency situations require the use of FVIII concentrates with a high content of vWF. The prognosis is dictated by the capacity to overcome the initial bleeding episode and the underlying disease.

FUTURE PROSPECTS

Autoantibodies to coagulation factors represent unique situations that can be exploited to increase our understanding of the mechanisms leading to autoimmunity. Such autoantibodies have a narrow range of specificity, offering the possibility of evaluation at clonal level. Methods to carry out such an evaluation for both B and T cells are now accessible in many laboratories. Besides, the pathology created by autoantibodies to coagulation factors is easy to identify by routine functional assays. Further, in many circumstances, a corresponding allogeneic immune response can be found in coagulation factor-deficient patients treated with specific replacement therapy (FVIII and FIX to cite the most frequent). Likewise, an in-depth knowledge of the mechanisms leading to autoimmunity should help improve the quality of recombinant proteins for therapeutic use, from soluble coagulation factors to fibrin sealant glues.

Acknowledgment

The author wishes to express his gratitude to Dr Marc Jacquemin and Dr Claudine Mazurier for critical reading of the manuscript and constructive comments.

Multiple Sclerosis

STEVEN D. BRASS, HOWARD L. WEINER AND DAVID A. HAFLER

Harvard Medical School, Center for Neurologic Diseases, Brigham and Women's Hospital, Boston, Massachusetts, USA

HISTORIC BACKGROUND

A French neurologist at the Salpetriere in Paris, Jean Martin Charcot, first gave a comprehensive account of the features of multiple sclerosis (MS) in 1868 by correlating the clinical and pathologic features of the illness in patients he examined both while alive and at autopsy. He noted both the accumulation of inflammatory cells in a perivascular distribution and demyelination accompanied by axonal sparing within the lesions or "plaques" found in the brain and spinal cord white matter of patients with intermittent episodes of neurologic dysfunction (Charcot, 1868a; 1868b; 1877). This led to the term "*sclérose en plaques disseminées,"* or multiple sclerosis. Towards the end of the 19th century, physicians throughout the Western hemisphere began to accept that MS was a specific disease. In 1868, Morris was the first physician to report an autopsy case of MS in North American, while in 1875 Moxon reported eight cases of "insular sclerosis affecting the brain and spinal cord" in a patient from England.

Over the past 100 years there have been many important historical milestones relating to MS that have advanced the field. The demonstration of an autoimmune, at times demyelinating, disease in mammals immunized with central nervous system (CNS) myelin [experimental autoimmune encephalomyelitis (EAE)] was first made by Thomas Rivers at the Rockefeller Institute in 1933 with the repeated injection of rabbit brain and spinal cord into primates (Rivers et al., 1933). This led to the generally accepted hypothesis that MS is secondary to an autoimmune response to self-antigens in a genetically-susceptible host. It should be pointed out that although the inflammation found in the CNS of patients with MS is thought to represent an autoimmune response, this is based on the inability to consistently isolate a microbial agent from the tissue of diseased patients. Nevertheless, primary viral infections in the CNS may induce an autoimmune response (Hafler, 1999), and the recurring lesson from the EAE model is that the minimal requirement for inducing inflammatory, autoimmune CNS demyelinating disease is the activation of myelin-reactive T cells in the peripheral immune system (Ben-Nun et al., 1981; Goverman et al., 1993). In 1948, Elvin Kabat described the increases in oligoclonal immunoglobulin in the cerebrospinal fluid (CSF) of patients with MS, which provided further evidence of an inflammatory nature to the disease (Kabat et al., 1948; 1950). In the past half-century, several large population-based MS twin studies have demonstrated a strong genetic basis to this clinical–pathologic entity (Mackay and

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Myrianthopoulos, 1966; Williams et al., 1980; Heltberg and Holm, 1982; Ebers et al., 1986; Kinnunen et al., 1987; French Research Group on MS, 1992; Mumford et al., 1992; Utz et al., 1993). In 1965, Schumacher et al. (1965) defined clinical diagnostic criteria based on the notion that MS is a disease that is disseminated in time and throughout the CNS. In 1981, magnetic resonance imaging (MRI) was first used to examine patients with MS (Young et al., 1981). The use of MRI in MS has since revolutionized how patients are diagnosed and further enlightened researchers on the pathophysiology of the illness.

In 1993, interferon (IFN)-β-1b was the first FDA-approved immunomodulatory drug shown to alter the clinical course of MS by reducing both disability and MRI lesion burden (Arnason, 1993). In the past 15 years, MS has evolved from a disease with no therapy to one with five approved immunomodulating treatments in the USA. These major advances have established MS as a treatable neurologic illness. Nonetheless, the development of more effective and safe treatments that can be used at the time of diagnosis for this potentially disabling illness is paramount, and predicated on a more thorough understanding of the underlying immunopathology.

Advances in immunology have provided clinicians with powerful tools to better understand the underlying causes of MS, leading to new therapeutic advances. The future calls for extending the original observations of Charcot and Kabat by defining the molecular pathology of MS at the levels of DNA haplotype structure, CNS, and peripheral mRNA and protein expression, leading to the generation of a new series of disease-related hypotheses.

CLINICAL FEATURES

The symptoms and signs of MS are variable as the disease can affect the CNS anywhere. Demyelinating lesions may develop at any site along myelinated CNS white matter tracts, and symptoms of MS therefore depend on the functions subserved by the pathways involved. In addition to demyelination, edema, inflammation, gliosis, and axonal loss all contribute to the symptomatology of a lesion. The most common symptoms and signs involve alteration or loss of sensation due to involvement of spinothalamic or posterior column fibers; visual loss from optic neuritis; limb weakness and spasticity related to disruption of corticospinal tracts; tremors and incoordination of gait or limbs, largely related to cerebellar or spinocerebellar fiber involvement; and abnormalities of cranial nerve function (such as double vision due to disturbance in conjugate eye movement) secondary to brainstem lesions. Bowel, bladder, and sexual dysfunction occur in over two-thirds of patients at some time during the course of their illness (Betts et al., 1993; Mattson et al., 1995), largely due to disruption in spinal cord pathways. Fatigue, depression, and cognitive changes are common symptoms of elusive etiology that may significantly interfere with daily functioning and are now being recognized as significant contributors to disability. A correlation with progressive brain atrophy on MRI has implicated axonal loss as the pathologic substrate of the cognitive deterioration in MS (Whitlock and Siskind, 1980; Freal et al., 1984; Rao et al., 1989; 1991; Sadovnick et al., 1996; Hohol et al., 1997).

The hallmark of MS is the great variability in the clinical presentation and course of the illness. MS may be divided into four clinical categories: clinically isolated syndrome (CIS), relapsing–remitting multiple sclerosis (RRMS), secondary progressive multiple sclerosis (SPMS), and primary progressive multiple sclerosis (PPMS). Most patients change from a CIS to RRMS and then gradually become SPMS.

The CIS occurs when a patient presents with a first episode of demyelination in the form of optic neuritis, cerebellar or brainstem syndrome, or transverse myelitis accompanied by brain MRI lesions, making them at higher risk for further attacks and then being labeled as having "multiple sclerosis." Not all patients with CIS go on to develop MS. During an episode, neurologic symptoms develop over hours to several days, persist for days to several weeks and gradually dissipate. The resolution of symptoms appears to be due to the reduction of inflammation and edema at the site of the responsible lesion rather than to the reversal of demyelination, which may persist even in the absence of symptoms (Achiron and Barak, 2000). In a recent prospective study, patients experiencing their first episode suggestive of CNS demyelination and having MRI evidence of at least three typical lesions were followed for an average of 42 months. Within that period, a significant proportion of patients developed an additional relapse, thus qualifying for the diagnosis of clinically definite MS. If there were no MRI lesions, the probability of developing MS was substantially less. More than half of those developing MS experienced the additional relapse within 1 year of their first episode (Achiron and Barak, 2000). Thus, it seems reasonable to label the first attack of what appears to be MS as a "clinically isolated syndrome," explaining to patients that there is a high likelihood of developing MS. This indicates to the patient that there is a good understanding of the underlying problem, but the prognosis is not as yet clear, allowing patients who never have another attack to be saved from carrying a diagnosis of MS.

If a patient with a CIS develops further episodes of relapses followed by a recovery with a stable course between relapses, patients are referred to as having RRMS. At the beginning of MS, patients often make complete recovery from relapses. As the disease goes on, the recovery from a relapse diminishes, and the patient accrues disability. A relapsing–remitting onset is observed in 85–90%

of patients, with relapses often lasting 4 weeks in duration. The outcome in patients with RRMS is variable; untreated, approximately 50% of all MS patients require the use of a walking aid by 10 years after clinical onset (Svenson et al., 1994), although the consequences on prognosis of newer treatment regimens are not as yet clear. Increased attack frequency and poor recovery from attacks in the first years of clinical disease predict a more rapid deterioration. Multiple T2-weighted and/or gadolinium-enhancing lesions on the first MRI scan also predict a more severe subsequent course.

Ultimately, approximately 40–50% of relapsing–remitting patients stop having attacks and develop what may be a neurodegenerative progressive disease secondary to the chronic CNS inflammation, known as secondary progressive multiple sclerosis (SPMS) (Confavreux et al., 2000). The evolution to this secondary progressive form of the disease is associated with significantly fewer gadolinium-enhanced lesions and a decrease in brain parenchymal volume (Khoury et al., 1994; Filippi et al., 1995). Similarly, while earlier RRMS is sensitive to immunosuppression (Hohol et al., 1999), as times goes on, responsiveness to immunotherapy decreases and may disappear in later forms of SPMS. Thus, rather then conceiving of MS as first a relapsing–remitting and then a secondary progressive disease, it could be hypothesized that MS is a continuum where there are acute inflammatory events early on with secondary induction of a neurodegenerative process refractory to immunologic intervention. This hypothesis awaits experimental verification where early immunotherapy prevents the onset of secondary progressive disease. Such critical investigations require new models of investigation using natural history studies that can be performed over decades.

Primary progressive MS (PPMS) is characterized from the onset by the absence of acute attacks and instead involves a gradual clinical decline. Close to 15% of patients have a gradual clinical decline from the onset, usually in the form of a progressive myelopathy. Patients may also present with a progressive cerebellar syndrome in the form of ataxia. Clinically, this form of the disease is associated with a lack of response to any form of immunotherapy. This leads to the notion that PPMS may in fact be a very different disease from RRMS. A recent commentary points out the similarities between primary progressive MS and human T-lymphocyte virus (HTLV)-I-associated myelopathy (Hafler, 1999).

In the absence of a specific immune-based assay, the diagnosis of MS continues to be predicated on the clinical history and neurologic examination demonstrating multiple lesions disseminated in time and space in the CNS (McDonald et al., 2001). Although using McDonald's criteria, the diagnosis of MS can be made solely on the basis of a history of two relapses and objective findings on examination of two lesions disseminated in the CNS. MRI of the neuroaxis is often sought to confirm the diagnosis or to rule out other mimics of the illness. The use of MRI has had a major impact on early diagnosis by establishing newer criteria for the diagnosis of the disease, as well as providing a means to determine prognosis, and to monitor disease course and response to therapy. As part of McDonald's criteria, new T2-weighted lesions or T1-weighted gadolinium-enhancing lesions on follow-up MRI scans may serve as criteria for dissemination in space or time, thus allowing the diagnosis fulfilling the criteria of MS to be made with further confidence (McDonald, et al 2001).

MRI has allowed clinicians to further understand the pathophysiology of the lesions and ultimately the overall illness. The conventional MRI measures of disease burden include the quantification of brain hyperintense lesions on T2-weighted images, hypointense lesions on T1-weighted lesions, and the post-gadolinium-enhancing T1-weighted lesions and unconventional measures such as brain and spinal cord atrophy. Each of these markers has a neuropathologic correlate. T2-weighted cranial MRI lesions correlate well with the location on plaques in the CNS of postmortem MS patients (Newcombe et al., 1991). The lesions on MRI are often ovoid in shape and perpendicular to the ventricles, representing the perivenular location of demyelination (Bakshi et al., 2004). These lesions on T2-weighted images represent many possible histopathologic correlates, including demyelination, edema, axonal loss, and inflammation (Bakshi et al., 2004). Lesions on T2-weighted images are often clinically silent and correlate weakly with a patient's disability. This discrepancy between lesions on T2-weighted images and clinical status is labeled the clinical–imaging paradox (Bakshi et al., 2004). Hypointense lesions on T1-weighted images may be persistent or nonpersistent (Rovaris and Filippi, 1999). Persistent hypointense T1-weighted lesions represent areas of axonal loss and are labeled as "black holes," and their numbers have shown to correlate better than T2 lesion load with clinical severity of the disease (Rovaris and Filippi, 1999). Nonpersistent hypointense lesions on T1-weighted images that disappear represent reversible edema (Rovaris and Filippi, 1999). Postcontrast gadolinium enhancement of lesions on T1-weighted images represents acute disruption of the blood–brain barrier (BBB) from inflammation and lasts on average 3 weeks, but may range anywhere from 1 to 13 weeks (Bakshi et al., 2004). Brain and spinal cord atrophy may occur in MS and represents axonal loss. Brain and spinal cord atrophy has been shown to correlate with disability, and brain atrophy alone has also been correlated with cognition and depression (Bakshi et al., 2004). Other MRI techniques, such as magnetic resonance spectroscopy and magnetization transfer imaging have been used to study the brains of patients with MS; however, at present, given the lack of standardization, they are not being applied widely in the clinical setting.

IMMUNOLOGIC MARKERS IN DIAGNOSIS

CSF findings can be used as immunologic markers that serve as adjuncts to clinical findings when considering the diagnosis of MS. The CSF of patients with MS typically shows normal glucose, a few lymphocytes (mostly T cells), normal to mildly elevated total protein, and oligoclonal immunoglobulin bands (OCBs).

When CSF from healthy controls is electrophoresed, the cathode region demonstrates a homogeneous blur of immunoglobulin. When CSF from MS patients is electrophoresed, the cathode region reveals a number of discrete bands that represent excess antibody production by one or more clones of B-cells. Often absent early in the disease, OCBs can eventually be detected in over 90% of patients with MS (McLean et al., 1990). CSF OCBs have also been described in conditions such as subacute sclerosing panencephalomyelitis (SSPE) (Mattson et al., 1980), neurosyphilis (Pedersen et al., 1982), varicella zoster virus infection (VZV) (Vartdal et al., 1982), human immunodeficiency virus (HIV) infection (Skotzek et al., 1988), and in multisystem autoimmune diseases, cerebrovascular accidents, and up to 5% of normal individuals. In diseases such as the viral encephalitides, OCBs commonly seem to bind virus determinants, in contrast to MS, where the antigen against which the majority of bands are directed has not been identified (Olek et al., 2000).

When CSF is examined for albumin, 20–30% of MS patients have an elevated level (Olek et al., 2000). Albumin is not made in the CSF, and thus when elevated implies that there is BBB disruption. Due to intrathecal synthesis from plasma cells, CSF immunoglobulin levels are also elevated in patients with MS. The immunoglobulins are mainly composed of IgG, with lesser amounts being IgM and IgA. Nearly 90% of patients demonstrate elevated levels of CSF IgG production when calculating the IgG index formula [(spinal fluid IgG/spinal fluid albumin)/(serum IgG/serum albumin)]. A spinal fluid IgG index >0.58 implies that IgG is being synthesized in the CNS.

The role of serum antibodies against myelin oligodendrocyte glycoprotein (MOG) and myelin basic protein (MBP) is not clear in MS. While there are many reports of serum and CSF anti-MBP and anti-MOG autoantibodies (Berger et al., 2003), they appear to represent predominantly low-affinity, nonspecific binding. However, using sensitive solution-phase assays, high-affinity autoantibodies to MBP and MOG can be detected in the serum and CSF of patients with acute disseminated encephalomyelitis (O'Connor et al., 2003). Moreover, high-affinity anti-MOG autoantibodies can be eluted from the brain tissue of a subset of patients with MS (unpublished data).

More recently, a serum autoantibody, neuromyelitis optica immunoglobulin (NMO-IgG), was identified in patients with neuromyelitis optica, an inflammatory demyelinating disease similar to MS, affecting the optic nerves and spinal cord. The NMO-IgG was found to have a sensitivity of 73% and a specificity of 91% among patients with demyelinating conditions affecting the spinal cord and optic nerves, and was determined to be useful in differentiating this disease from MS (Lennon et al., 2004).

PATHOLOGY

Gross examination of MS brain tissue reveals multiple sharply demarcated gray plaques in the CNS white matter with a predilection to the optic nerves and white matter tracts of the periventricular regions, brain stem, and spinal cord (Figure 46.1). The gray matter contains less myelin, and thus lesions in the gray matter are less conspicuous on gross examination; however, it too is affected by MS lesions (Geurts et al., 2005). When examining the histologic features of a MS lesion there exist three major components: inflammation, demyelination, and gliosis. The inflammation in lesions is composed of lymphocytes, monocytes, and macrophages, whose proportions depend on the activity and age of the lesion. Demyelination is also an important feature of the MS lesion, as evident by reduced myelin. Although MS is described as a disease causing a loss of myelin, the notion of axonal loss is becoming more important. Trapp et al. (1998) reported that substantial axonal injuries with axonal transections are also abundant throughout active MS lesions, even in patients with early stages of the disease process. The axonal loss is evident by the presence of terminal axonal swellings on confocal microscopy, resulting from the "build up of axonally transported

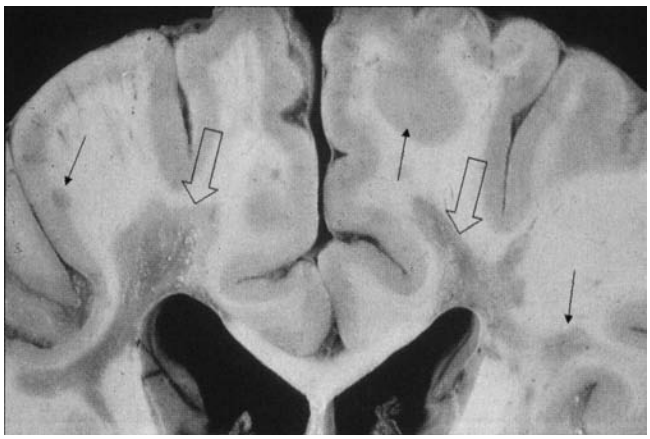

FIGURE 46.1 Coronal slice of cerebral hemispheres from a patient with multiple sclerosis. Note the extensive areas of demyelination in the periventricular regions of the lateral ventricles (open arrows) and in the subcortical white matter (small arrows). There is evidence of an increased size of the lateral ventricles as well.

material collecting at the proximal end of a transected axon" (Trapp et al., 1998). The third component of a lesion is seen when reactive astrocytes and fibrillary gliosis are present in the lesion.

MS lesions can also be classified from a pathogenesis point of view into three types based on the age of the lesion: active, chronic active, and chronic inactive (Lassman, 1998). Macrophages are most prominent in the center of the *active plaques* and are seen to contain myelin debris, while oligodendrocyte counts are reduced. Lymphocytes may be found in normal appearing white matter beyond the margin of active demyelination (Prineas and Wright, 1978). The inflammatory cell profile of active lesions is also characterized by perivascular infiltration of oligoclonal T cells (Oksenberg et al., 1990; 1993; Wucherpfennig et al., 1992a), consisting of $CD4^+$ cells invading the normal appearing white matter around the lesion and $CD8^+$ T cells in the plaque margins and perivascular cuffs (Figure 46.2) (Traugott et al., 1983; Hauser et al., 1986). The inflammatory infiltrate may also include monocytes, occasional B cells, and infrequent plasma cells (Wucherpfennig et al., 1992b). In *chronic active lesions*, inflammation composed of macrophages and activated microglia are found at the border of the lesion and disappear from the center core, suggesting the presence of ongoing inflammatory activity along the lesion edge. The *chronic inactive plaque* does not have the macrophages at the border or center of the plaque. There is no ongoing demyelination and the histology demonstrates demyelinated axons with fibrillary gliosis (Lassman, 1998).

Four pathologic categories of the lesions have been described related to potentially different immunopathophysiologic disease mechanisms, although this has yet to be demonstrated at a molecular level (Lucchinetti et al., 1996): 1) T-cell- and macrophage-mediated demyelination; 2) T-cell- and macrophage-mediated, plus antibody-induced or complement-mediated, demyelination; 3) oligodendrocyte dystrophy and apoptosis with myelin protein dysregulation; and 4) primary oligodendrocyte degeneration with features similar to viral, ischemic or toxic oligodendrocyte damage. Patterns 1 and 2 are seen in acute, early active multiple sclerosis, with an intense perivenous immune reaction causing a sharply-demarcated area of demyelination and destruction of oligodendroglia, astrocytes, and axons. There is preservation of oligodendrocytes and significant remyelination (shadow plaques), and less expression of multiple myelin proteins, without pattern 1 or with pattern 2 deposition of activated complement and IgG. Pattern 3 consists of a cellular infiltrate of macrophages, microglia, and T cells, no immunoglobulin, ill-defined, nonperivenous areas of demyelination (preservation of oligodendroglia near venules, oligodendroglial destruction, loss, and apoptosis), and a marked fall in myelin-associated glycoprotein (MAG) compared to other myelin proteins. Pattern 4 consists of an inflammatory perivenous plaque with a sharp border of destruction and apoptotic loss of oligodendroglia with little remyelination. This rare pattern is exclusively seen in some patients with PPMS. It was of interest that the pattern of pathology tended to be the same in multiple lesions from any single individual with MS. These different pathologies may explain why some patients with MS have a heterogenous response to the same therapies.

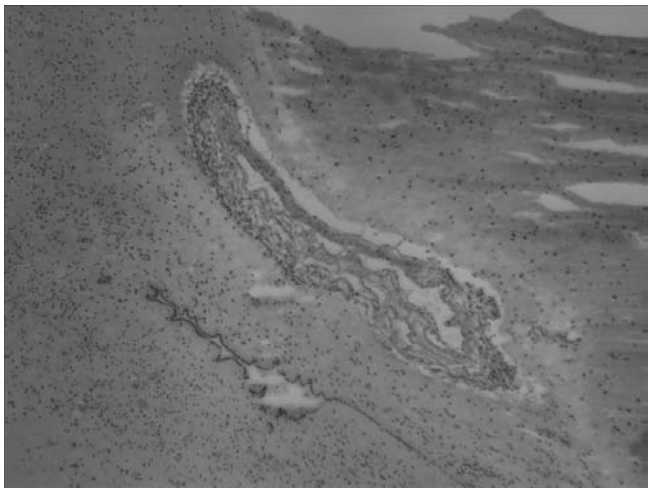

FIGURE 46.2 Inflammatory cells composed of lymphocytes and monocytes are present in the perivascular cuff of a white matter lesion (specific cell type staining not shown). Hematoxylin-eosin × 4. EPIDEMIOLOGY

The prevalence rates of MS in North America range between 30 and 150 in 100,000. Based on a weighted mean of several studies, the average annual incidence of MS in the US is 3.2 in 100,000 per year. The median age of onset of symptoms is 23–24 years of age, with a peak age of onset for women in the early 20s, and for men in the late 30s (Schumacher et al., 1965; Studney et al., 1993; Paty et al., 1994). As in most diseases classified as autoimmune, there is a clear female predominance in MS cases (3 : 2) (Olek et al., 2000).

Evidence exists that the genetic make-up of the individual and certain unspecified environmental exposures may each play a role in making someone susceptible to MS. Studies in twins (Mackay and Myrianthopoulos, 1966; Williams et al., 1980; Heltberg and Holm., 1982; Ebers et al., 1986; Kinnunen et al. 1987; French Research group on MS, 1992; Mumford et al., 1992), which are discussed below, demonstrate shared genetic risk factors for MS. At the same time, studies of MS incidence rates in migrants (Alter et al., 1966) and apparent epidemics of MS at

geographic locations (Haines et al., 1996), also discussed below, indicate a clear role for environmental factors.

Genetic Factors

Approximately 15–20% of patients have a family history of MS, but large extended pedigrees are uncommon, with most MS families having no more than two or three affected individuals. Detailed population-based studies of familial recurrence risk (Sawcer et al., 1996) have provided estimates for familial clustering with $\lambda_{s,}$ the ratio of the risk of disease in the siblings of an affected individual compared with the general population, of approximately 15 (Margolis and Graves, 1945; Holmes et al., 1967; Shakir et al., 1983; Bias et al., 1986; Trostle et al., 1986; Sadovnik et al., 1997; Sawcer et al., 1997). In studies of twins, the monozygotic concordance rate is 30% versus the dizygotic rate of 5% (Sadovnick et al., 1993). When both parents are affected with MS, 9% of the children develop the disease (Hogancamp et al., 1997). To date, the only confirmed genetic feature to emerge from these efforts is the association and linkage of the disease with alleles and haplotypes from the major histocompatibility complex (MHC) on chromosome 6p21. It has become clear that MS represents a complex genetic disease with no clear mode of inheritance.

An alternative hypothesis emerging from the linkage studies is that MS, as a common disease, is caused by common allelic variants, each with only subtle but important variations on function. Crude theoretical modeling of human population history suggests that variants that have a high population frequency as a whole, and are likely to be responsible for complex traits (the common disease–common variant hypothesis), will generally be very old and therefore accompanied by rather little linkage dysequilibrium (Daly et al., 2001). Quantitatively, this may translate to dozens of gene regions each with risk factors of less then ×1.1–×1.4, but which in concert lead to major risk for disease development. It may be postulated that as populations emerged out of Africa between 60,000 and 100,000 years ago, exposure to new microbes resulted in what are thought to be major population bottlenecks with survival of individuals with allelic variants allowing for resistance to the novel infectious event. These combinations of different genes providing resistance to the population, when randomly coming together, result in a hyper-responsive immune system with subsequent autoimmune diseases; the price an individual may pay for the protection of the general population. Organ specificity may have emerged because each infectious agent involved with a population bottleneck would select for a single MHC-restricting element and subsequent antigen specificity. As MS is a complex genetic disease, understanding which combinations of genes provide the multitude of perhaps relatively minor risk factors, which in the population as a whole provide protection from microbial disease but together, in unfortunate random combinations, result in human autoimmune disease, is a central goal of present genetic research efforts.

Environmental Factors

Global maps of MS prevalence rates, constructed based on multiple descriptive epidemiologic studies, reveal a nonrandom geographic distribution of the disease. A diminishing North to South gradient of MS prevalence was described in the Northern hemisphere (Beebe et al., 1967; Kurtzke, 1977; Kurtzke et al., 1979; Hammond et al., 1987), with an opposite trend identified in the Southern hemisphere (Hammond et al., 1988; Hogancamp et al., 1997). This distribution likely reflects a combination of genetic and environmental influences. For example, in both Europe and the US, the prevalence of MS may reflect the degree of Scandinavian and Northern European heritage in resident populations (Hammond et al., 1988). Nonetheless, the several-fold difference in the South–North prevalence in Australia, across a genetically homogeneous population, argues for a nongenetic effect (Armon et al., 1991). The identity of such a latitude-based risk factor remains elusive (Lauer, 1995; Weinshenker, 1996; Bar-Or and Smith, 2000). Environmental deficiencies have also been known to be associated with MS, as seen by the inverse correlation of the world prevalence of MS and the environmental supply of vitamin D via sunlight exposure or dietary intake of vitamin D3 (VanAmerongen et al., 2004). At higher latitudes, the lower exposure to the sun in the winter months is insufficient to produce vitamin D given the lower exposure to the sun in winter months (VanAmerongen et al., 2004). Vitamin D is known to have some anti-inflammatory effect based on the reduction of EAE incidence and severity in animal models given the active vitamin D metabolite. Subtle defects in vitamin D metabolism by "polymorphisms in the vitamin D receptor gene could be a link in determining susceptibility to MS" (VanAmerongen et al., 2004).

Migration studies in MS have suggested that migrants from high- to low-risk areas show a decreased rate of MS (Alter et al., 1966; Kurtzke et al., 1970; Dean and Kurtzke, 1971; Gale and Martyn, 1995; Lauer, 1995). Furthermore, the age at emigration appears to influence whether the migrants acquire the risk of the new environment or retain the risk of their home country. While such comparison studies are fraught with difficulties because of differences in study design (Stazio et al., 1964; Sweeney et al., 1986; Lauer, 1995), they do suggest that some environmental exposure during a particular window of time (likely in early adolescence) may contribute to the risk of developing MS. These observations, together with studies of proposed "MS epidemics" (Lauer, 1995), have contributed to the hypothesis that MS has an infectious etiology. Despite multiple

candidate organisms, to date no infectious agent has been established as the cause of MS.

The "hygiene hypothesis" as a factor in explaining the environmental risks associated with MS has been raised by a recent study examining the correlation of exposures to infant siblings in early life and the risk of acquiring MS (Ponsonby et al., 2005). The "hygiene hypothesis" states that children who are exposed to infections early in life are less susceptible to autoimmune disorders and allergies as infections may alter T-cell receptor (TCR) diversity, B-cell maturation, and increasing IgG synthesis with re-exposures. Children growing up without exposures to siblings show increases in type 2 and type 1 helper T-cell (Th2 and Th1) immune disorders. A "mature" immune system from an early age may prevent infectious triggers in later years from causing an immunologic response that can potentially lead to an autoimmune disease such as MS. The risk of MS was reduced when sibling exposure was present in the first 6 years of life, and it was hypothesized that this related to changes in immune response and childhood infection patterns, which may lead to a reduction in MS risk (Ponsonby et al., 2005).

ANIMAL MODELS

Experimental autoimmune encephalomyelitis (EAE) is an immune-mediated disease of the CNS that is characterized by multifocal demyelinating plaques and perivascular inflammatory infiltrates, primarily comprised of T cells and monocytes, and associated with a paralytic illness. These pathologic and clinical features provide the impetus for studying EAE as a model of MS. EAE is mediated by $CD4^+$ T cells that recognize a variety of CNS autoantigens and secrete pro-inflammatory Th1-associated cytokines, such as IFN-γ and tumor necrosis factor (TNF)-α. It can be induced in several species of animals by injection of adjuvant with homogenized whole myelin or myelin components, such as MBP, proteolipid protein (PLP) or MOG. The ability to induce EAE by passive transfer of $CD4^+$ MHC class II-restricted T cells that are reactive with these antigens (Ben-Nun et al., 1981; Mokhtarian et al., 1984; Fritz et al., 1985; Zamvil et al., 1985) but not by serum from affected littermates, establishes EAE as a T-cell-mediated disease. Susceptibility to EAE and disease severity is dictated by different infectious exposures and the MHC background of the animal. The latter influences the T-cell repertoire, as well as which portions of the myelin proteins are encephalitogenic in any given strain.

Susceptibility to EAE is dependent on the strain of the animal (Baker et al., 1995; Sundvall et al., 1995; Encinas and Kuchroo, 1999). For example, mice such as the B10.Pl, SJL/J, and PL/J are susceptible, while BALB/c and C57BL/6 are relatively resistant. Disease severity and course are also influenced by the genetic background and may range broadly from a mild, uniphasic illness, through to aggressive relapsing–remitting and progressive disease patterns. Thus, there exist a variety of EAE models, each of which represents a distinct aspect of human MS. It is now recognized that the development of EAE and the pattern of EAE pathology are dictated by the coordinated expression of a number of genes that are involved in the activation and effector functions of inflammatory cells. The expression of these genes, in turn, is modulated by the animal's environment, such that genetically identical animals with different infectious exposures may manifest distinct profiles of EAE induction and phenotype. As mentioned above, an important component of susceptibility to EAE relates to the MHC background of the animal, which influences the T-cell repertoire as well as which portions of the myelin proteins are encephalitogenic in any given strain (Fritz and McFarlin, 1989). Genes that encode for costimulatory molecules, cytokines, chemokines, and adhesion molecules have been the focus of intense study. Molecular genetic techniques have enabled the dissection of the effects on disease phenotype, of under- ("knock-out") and over-expression ("transgenic") of an ever growing array of immune-related molecules.

The limitation of the EAE model is that a single inbred strain of animals may reflect single patients, and the wide range of genetic diversity and broad environmental exposure of highly outbred humans is clearly not well modeled by EAE. For example, the anti–TNF-α receptor antibody ameliorates EAE but worsens disease in patients with MS (Andersson et al., 1997).

Another use of the EAE model relates to the therapeutic application of altered peptide ligands (APLs). In the animal model, a single amino acid substitution within the peptide sequence of an encephalitogenic myelin epitope resulted in an APL that induced TCR antagonism, partial agonism, and anergy when used to stimulate T-cell clones generated against the original encephalitogenic antigen. Treatment of EAE with the APL induced a myelin-reactive T-cell repertoire that was shifted with respect to its cytokine responses from an inflammatory (Th1) towards an anti-inflammatory (Th2) profile, and was associated with improved disease (Karin et al., 1994; Nicholson et al., 1995). Based on these results, an APL of the immunodominant MBP epitope was used in a trial of MS (Nicholson et al., 1995; Windhagen et al., 1995a; Brocke et al., 1996; Ausubel et al., 1997; 1999; Bielkova et al., 2000; Kappos et al., 2000). Unfortunately, clinical deterioration and a dramatic increase in new gadolinium-enhancing lesion formation was seen in 3 of the 10 patients receiving the APL in the non-placebo-controlled trial (Bielekova et al., 2000). In contrast, Kappos et al. (2000), reporting results using the same APL in a placebo-controlled double-blinded randomized trial, found no increase in the rate of exacerbation in patients given APL

compared to those given placebo. Despite the trial ending early because of hypersensitivity reactions, Kappos et al. reported that there was evidence of improvement in lesions on MRI at the lowest 5-mg dose. They noted a regulatory Th2 cell response to altered peptide ligand that cross-reacted with the native peptide. Antagonists of the very late antigen-4 (VLA-4) were very effective in treating many inflammatory animal models, including EAE (Yednock et al., 1992; Lin and Castro, 1998). In preliminary trials the humanized anti-α4 antibody was shown to be effective at reducing new gadolinium-enhancing lesions and relapses in MS patients, but was later pulled from the market by the manufacturer after patients were diagnosed with progressive multifocal encephalopathy.

Newer experimental techniques involving EAE and the use of *antigen-specific tolerance* have emerged, including the use of active induction of tolerance by DNA vaccination. There have been mixed results in these EAE models. Animal models of EAE that were injected with DNA coding for MBP or PLP suppressed EAE but vaccination with MOG DNA worsened the EAE (Hohlfeld and Wekerle, 2004). The DNA vaccine may also be used to co-deliver genes for cytokines and the DNA of the autoantigens, which can change the clinical outcome of EAE. Garren et al. (2001) used the vaccine combination of the DNA-encoding PLP and the IL-4 gene, which helped to prevent EAE by shifting the local cytokine profile from the Th1 to the Th2 pathway. This same vaccine combination was also shown to reverse established EAE.

PATHOGENIC MECHANISMS

Current understanding of MS immunopathology is that autoreactive proinflammatory T cells are critical to the propagation of CNS tissue injury. It appears likely that when a genetically susceptible host immune system encounters a common environmental antigen (such as an infectious organism), a process of "molecular mimicry" results in the peripheral activation of cross-reactive T cells that can migrate to the CNS and mount pro-inflammatory responses to myelin epitopes. However, the mere presence of autoreactive cells in the periphery is an insufficient explanation for the development of autoimmune disease, given that myelin-reactive T cells can be found in the peripheral blood of both normal individuals and patients with MS.

Studies demonstrate that MBP-reactive T cells in MS patients are in an enhanced state of activation in the periphery of those with MS and have less stringent stimulation requirements compared to those isolated from normal individuals, suggesting a breach in peripheral tolerance. Zhang et al. (1994) found that the IL-2 receptor, a hallmark of activated T cells, was expressed on MBP-reactive T cells from MS patients but not on those obtained from normal individuals. The T-cell costimulatory pathway is represented by the engagement of CD28 on T cells by the CD80 or CD86 molecules, typically expressed on the surface of activated antigen-presenting cells (APCs). Reports have demonstrated that MBP-reactive T cells from the peripheral blood of MS patients are also less dependent upon CD80 (B7) costimulation for their activation, compared to MBP-reactive T cells from normal individuals (Williams et al., 1994; Windhagen et al., 1995b). Enhanced expression of CD80 was detected on B cells in peripheral blood, in the CSF, and in CNS plaques of MS patients compared to controls, while levels of CD86 expression were the same. The increased expression of CD80 appeared to correlate with disease activity and, in one study, treatment response to IFN-β-1b was associated with normalization of the levels of CD80 expression on the B cells of patients (Figure 46.3) (Gene et al., 1997).

Upon interaction of the T cell with the APC, the antigen-specific T cells proliferate and divide into two subsets, classified according to the cytokine profiles that they produce upon activation (Abbas et al., 1996; O'Garra, 1998). MHC class II-restricted $CD4^+$ T cells, producing IFN-γ, IL-2, lymphotoxin, and TNF-α, have been termed Th1 (inflammatory) cells and have been clearly shown to be pathogenic in most EAE models (Leonard et al., 1995; Segal et al., 1998). The Th1 cytokines activate macrophages for cellular immunity. In contrast, $CD4^+$ T cells producing IL-4, IL-5, IL-10 or IL-13 have been termed Th2 (anti-inflammatory) cells and have a protective role in EAE (Khoury et al., 1992; Owens et al., 1994; Begolka et al., 1998; Antel and Owens, 1999). TGF-β-producing cells have been termed Th3 cells and are also protective in EAE. Th2 cytokines promote humoral immune responses. Although Th2 cells are defined as anti-inflammatory cells, this is in the context of EAE.

Several lines of evidence support the hypothesis that Th1 cells may be pathogenic in MS. Th1 and Th2 cells express distinct profiles of chemokine receptors. An increased proportion of T cells from MS patients were shown to express the characteristic Th1 chemokine receptor pattern and MS plaques were found to express increased levels of the corresponding chemokine (Siveke and Hamann, 1998; Balashov et al., 1999; Sorensen et al., 1999). Analysis of cytokine mRNA in the CSF from MS patients showed a bias towards Th1 cytokines (Blain et al., 1994). Immunohistochemical studies of MS plaques *in situ* have demonstrated the presence of the proinflammatory cytokines TNF-α and IL-12 (Hofman et al., 1989; Selamj et al., 1991; Windhagen et al., 1995b). Interventions that shift or deviate the cytokine responses away from a Th1 and towards a Th2 profile have been an exploitable drug targeting route for MS.

Selective expression of adhesion molecules, chemokines and chemokine receptors, and matrix metalloproteinases (MMPs) has also been demonstrated on inflammatory cells, endothelial cells, and glial cells in samples from patients with MS. These molecules are likely to be important in

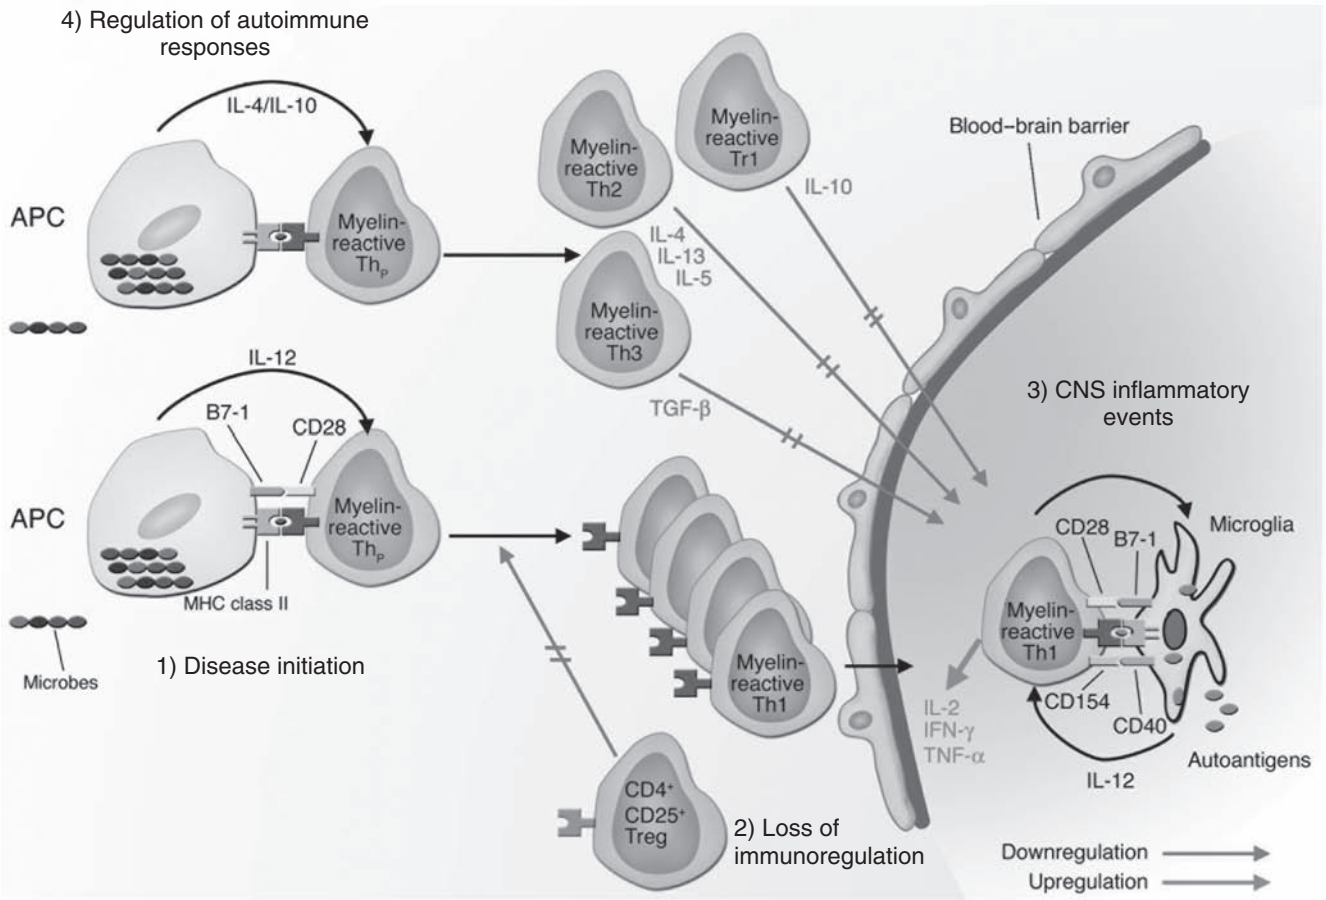

FIGURE 46.3 Presumed pathophysiology of multiple sclerosis (MS). Four main components contribute to the pathophysiology of MS. 1) *Initiation*, a presumed microbe may be taken up by an antigen-presenting cell (APC) and is presented to a myelin-reactive precursor T cell (Th_p). 2) *Loss of immunoregulation*, $CD4^+CD25^+$ regulatory T-cells (Tregs) are thought to be reduced in MS patients, which causes a decrease in the overall autoregulation of the autoimmune process. 3) *Central nervous system (CNS) inflammatory events*, in the CNS, local APCs, microglia, present antigen to myelin-reactive type 1 helper T (Th1) cells that secrete Th1 cytokines such as interleukin (IL)-2, interferon (IFN)-γ, and tumor necrosis factor (TNF)-α, which permit the inflammation to continue. 4) *Regulation of the autoimmune responses*, three cell types enter the CNS to counterbalance the pro-inflammatory Th1 cells, which are part of the naturally-occurring regulatory mechanisms that bring the inflammatory cascade into check by counterbalancing the Th1-mediated proinflammatory response. The three cell types are the Th3 cells which secrete transforming growth factor (TGF)-β; Th2 cells which secrete Th2-mediated cytokines, including IL-4, IL-13, and IL-5; and regulatory T cells (Tr1), which secrete IL-10. See color plate section.

mediating the transmigration of effector cells across the BBB and into the CNS perivascular tissue. Invading autoreactive T-cells can then become reactivated upon encounter with their antigen in the CNS. The effector profile of such cells is likely to depend on several factors in the microenvironment, including the cytokine milieu and the costimulatory profile of local and infiltrating APCs. Further release of local cytokines, chemokines, and MMPs may support the recruitment of subsequent waves of infiltrating effector cells, including T cells, monocytes, and B cells. Mechanisms of myelin destruction and axonal damage are likely to be multiple and include direct effects of pro-inflammatory cytokines, oxygen radicals, and complement-fixing antibodies; antigen-specific and -nonspecific cytotoxicity; and apoptosis. Local damage results in exposure of additional myelin components that may become primary targets of subsequent waves of infiltrating cells, leading to the phenomenon of "epitope spreading." Myelin-producing oligodendrocytes scarcely produce MHC class II molecules, and thus cannot present their own autoantigens to T cells. The autoantigens must be transferred to nearby microglia or macrophages and are then taken up, processed, and presented by these APCs. Activation of resident CNS glial cells, such as microglia, may provide the basis for the generation

or maintenance of pathologic responses, even in the absence of further infiltration of exogenous inflammatory cells. In contrast, evidence that glial elements may play a role in the repair and recovery from myelin injury may lead to the development of novel therapeutic approaches in MS, and underscores the importance of elucidating the complexities of glial–immune interactions.

TREATMENT

Therapeutic approaches in MS may be broadly divided into treatments that are symptomatic and/or supportive in nature, and treatments that are directed at the underlying pathophysiology of the disorder. Effective medical management of spasticity, bladder symptoms, dysesthesias, fatigue, and depression may significantly improve daily functioning and enhance quality of life. Ambulatory aids, patient education, appropriate use of physical and occupational therapy services, and psychological and social supports should all be elements of the comprehensive management plan.

Over the past 6 years, the US FDA has approved six agents (subcutaneous IFN-β-1b, Betaferon/Betaseron®; intramuscular IFN-β-1a, Avonex®; subcutaneous IFN-β-1a, Rebif®; glatiramer acetate, Copaxone®; mitoxantrone, Novantrone®; and natalizumab, Tysabri®) as disease-modifying therapies that have been shown to alter the course of MS (Table 46.1). They are all expensive and only partially effective on average, yet their current use has marked a milestone for both patient care and the overall understanding of the pathogenesis of MS given that this disease was until recently considered to be untreatable.

The differences in study design and outcome measure definitions make direct efficacy comparisons between the approved therapies problematic.

Interferons

Compared to placebo-treated RRMS controls, treatment with alternate-day subcutaneous injections of 8 MU of IFN-β-1b (Betaseron) was shown to decrease the primary efficacy outcome measure of frequency of relapses by 34% after

TABLE 46.1 FDA-approved therapies for multiple sclerosis

Therapy	Brand name	Indications	Results	Mechanism of action
IFN-β-1a (IM, weekly)	Avonex®	Treatment of RRMS	33% reduction in relapses Reduction of new MRI T2-weighted lesions and the volume of enlarging T2-weighted lesions Reduction in the number and volume of gadolinium-enhancing lesions Slowing of brain atrophy	Acts on blood–brain barrier by interfering with T-cell adhesion to the endothelium by binding VLA-4 on T cells or by inhibiting T-cell expression of MMP Reduction in T-cell activation by interfering with HLA class II and costimulatory molecules B7/CD28 and CD40/CD40L Immune deviation of Th2 over Th1 cytokine profile
IFN-β-1a (SC, three times/week)	Rebiff®	Treatment of RRMS	Same as IFN-β-1a above	Same as IFN-β-1a above
IFN-β-1b (SC, every other day)	Betaseron®	Treatment of RRMS	Same as IFN-β-1a above	Same as IFN-β-1a above
Glatiramer acetate (SC, daily)	Copaxone®	Treatment of RRMS	33% reduction in relapses Reduction in the number and volume of gadolinium-enhancing lesions	Induces Th2 cells that enter the CNS and mediates bystander suppression at sites of inflammation
Mitoxantrone (IV infusions every 3 months)	Novantrone®	Worsening forms of RRMS SPMS	67% reduction in relapses Slowed progression in EDSS, ambulation index, and MRI disease activity	Antineoplastic that intercalates DNA Suppresses cellular and humoral immune response
Natalizumab (IV, monthly injections)	Tysabri®	Relapsing MS	Reduced rate of relapse (in up to 66%) and reduced development of new MRI lesions	Monoclonal antibody that blocks α4-integrin on surface of T cells, preventing them from crossing the blood–brain barrier

EDSS, Expanded Disability Status Scale; MMP, metalloproteinase; RRMS, relapsing–remitting multiple sclerosis; SPMS, secondary progressive multiple sclerosis.

2 years (The IFNB Multiple Sclerosis Study Group, 1993). A significant decrease in the accumulation of MRI lesions was observed with treatment (The IFNB Multiple Sclerosis Study Group, 1993), although no beneficial effect on clinical disability was seen over the study period. More recent 5-year follow-up data reported that disease progression in the IFN-β-1b treated group was 35%, compared with 46% progression in the placebo group (The IFNB Multiple Sclerosis Study Group and The University of British Columbia MS/MRI Analysis Group, 1995). A 30% decrease in the annual exacerbation rate in the treated group was maintained and MRI data showed significantly less accumulation of lesion burden in the IFN-β-1b-treated group (3.6%) compared to the placebo-treated patients (30.2%) over 5 years.

IFN-β-1a (Avonex, weekly intramuscular injections), a glycosylated recombinant IFN-β, was evaluated in a 2-year study of weekly intramuscular injections of 6 MU (30 μg). The primary efficacy outcome measure was timed to the onset of a sustained deterioration in disability. The proportion of patients progressing by the end of the trial was 21.9% in the treated group compared to 34.9% in the placebo group. The annual exacerbation rate was decreased by 32% in the treated group versus the placebo group. Treatment was also associated with a 40% reduction in mean MRI lesion load (Jacobs et al., 1995; 1996). The mean number of new enhancing lesions on MRI over the 2 years was 0.80 in the IFN-β-1a-treated group versus 1.65 in the placebo. In the PRISMS trial, a double-blinded placebo-controlled, phase III trial of INF-β-1a (Rebif, subcutaneous, three times weekly) in RRMS, treatment was associated with significant improvement in MRI parameters, which extended the prior evidence of benefit on relapse rate and disease progression (Li and Paty, 1999).

Common side effects of the IFN-βs include flu-like symptoms and injection site reactions (rarely necrosis with IFN-β-1b). Headache and depression are less common and, rarely, hepatotoxicity or bone marrow suppression may occur. Neutralizing antibodies (NABs) have been reported for both IFN-βs and remain a contentious issue. Some reduction in the biologic effect and clinical benefit of IFN-β in NAB^+ patients has been suggested (Cohen et al., 1999). The relative antigenicity of IFN-β-1b (alternate-day subcutaneous administration) may be greater than that of IFN-β-1a (weekly intramuscular administration); however, a prospective comparison has not been made. The effect of dose on the generation of NABs is also not established.

As a class, the IFN-βs appear to exert their effects on the pathophysiology of MS at several sites. Converging studies have suggested that they inhibit the migration of activated inflammatory cells across the BBB and into the CNS parenchyma. The IFN-βs may exert this effect at the level of adhesion molecules and/or MMPs. As noted above, the adhesion molecule VCAM-1 has been identified on both microglia and endothelial cells in chronic–active MS lesions, and its ligand, VLA-4, has been identified on the perivascular inflammatory cells of MS lesions. Treatment with IFN-β-1b was associated with decreased levels of VLA-4 on inflammatory cells in MS patients, which correlated with a decrease in the MRI lesion burden (Calabresi et al., 1997; Trojano et al., 1997). Interferon-β-1b has also been shown to suppress T-cell expression of MMPs and inhibit T-cell migration across the BBB (Stone et al., 1995; Leppert et al., 1996). The rapid effect of IFN-βs on the gadolinium-enhancing lesions of MS (Stuve et al., 1996; Stone et al., 1997) represents a promising biologic marker of treatment response and establishes the BBB as an important site of action of IFN-β therapy. A possible role for IFN-β treatment in shifting cytokines in MS from a pro-inflammatory profile to an anti-inflammatory profile is suggested by reports that treatment may decrease levels of TNF-α while enhancing levels of IL-6 (Brod et al., 1996) and of immunosuppressive cytokines (Rudick et al., 1998). Finally, by decreasing the molecules needed for antigen presentation, IFN-β leads to a decreased generation of autoreactive T cells, which limits T-cell activation. The increased levels of the costimulatory molecule CD80, reported on mononuclear cells in MS blood and CSF, are reversed in response to treatment with IFN-β-1a (Genc et al., 1997).

Glatiramer Acetate

Treatment with glatiramer acetate/copolymer 1 (Copaxone, GA), a 20 mg/day subcutaneous injectable synthetic polymer, was associated with a 2-year relapse rate reduction (primary outcome measure) of 29% compared to placebo control (Johnson et al., 1995). A subsequent MRI study revealed a beneficial effect of GA on newly forming gadolinium-enhancing lesions (Mancardi et al., 1998). GA is relatively well tolerated with typically mild injection site reactions, infrequent urticarial responses, and an occasional stereotypical vasomotor reaction. Laboratory abnormalities have not been reported and neutralizing antibodies are not an issue.

The differences in the side effect profiles of the IFN-βs and GA suggest that these treatments have distinct mechanisms of action. GA is a random sequence polypeptide of the four amino acids alanine (A), lysine (K), glutamate (E), and tyrosine (Y). In contrast to the interferons, GA has little effect on the BBB. GA treatment appears to induce GA-reactive Th2-polarized T cells that are more degenerate in their antigen recognition (Duda et al., 2000). These activated Th2 T cells may enter the CNS, where they may mediate bystander suppression at sites of inflammation, leading to decreased disease activity and the observed efficacy of GA on both clinical and MRI parameters (Yong, 2002).

Overall, the approved immunomodulating agents provide a measurable, though only partial, benefit in the treatment of RRMS. The suggestion that the mode of action of

interferons differs from that of GA raises the possibility that together these therapies may provide additive benefit, and such a combination trial is underway.

Natalizumab

Natalizumab (Tysabri) is a monoclonal antibody to the VLA-4 expressed on activated T cells and monocytes. It prevents adhesion of activated T cells to endothelial cells. The FDA approved this drug for relapsing MS patients based on data from the first year of two ongoing trials studying RRMS patients. The AFFIRM study compared natalizumab alone to placebo and the SENTINEL study looked at adding natalizumab to ongoing IFN-β-1a therapy. The initial 1-year results demonstrated that monthly intravenous infusions reduced clinical relapses by 66% when compared to the placebo arm, and a significant decrease in gadolinium-enhancing lesions was seen. However, early in 2005, the manufacturers of the drug voluntarily removed it from the market following the death of patients, who had been on combination therapy for 2 years, from progressive multifocal leukoencephalopathy; these patients had no history of HIV (National Multiple Sclerosis Society, 2005).

Other Therapies

Corticosteroids

Corticosteroids are used widely in the treatment of MS, although data supporting their use is sparse. In general, treatment of acute relapses with intravenous methylprednisolone may lead to more rapid improvement in symptoms but does not appear to change the ultimate outcome of the flare or the subsequent disease course. The mode of action of corticosteroids is not established. Relatively nonspecific suppression of T-cell responses is suspected, although differential effects on T-cell subsets have been reported. Steroids have been shown to reduce the activity of MMPs and MRI evidence of a decrease in gadolinium-enhancing lesions following treatment with steroids supports a possible therapeutic role at the BBB (Miller et al., 1992).

Cyclophosphamide

Cyclophosphamide is an alkylating agent with potent cytotoxic and immunosuppressive effects. A randomized, triple arm study demonstrated a positive effect in SPMS patients treated with a 2-week course of cyclophosphamide/ACTH as compared to patients who received ACTH alone (Hauser et al., 1983). These findings led to a randomized single-blind trial by the Northeast Cooperative Treatment Group that tested the efficacy of outpatient intravenous cyclophosphamide pulses every 2 months in 236 patients who had initially received an intravenous cyclophosphamide/ACTH induction (Weiner et al., 1993). Patients with disease for shorter durations had a more beneficial effect from cyclophosphamide treatment as compared to those not receiving the pulsed cyclophosphamide treatment.

Emerging Therapies

Daclizumab

Daclizumab is a humanized monoclonal antibody against CD25 that is expressed on activated T cells. CD25 serves as the IL-2 receptor on T cells, and when T cells are activated by IL-2, causes further T-cell expansion. Bielekova et al. (2004) reported on an open label phase II baseline to treatment trial of daclizumab in 10 RRMS patients with breakthrough disease on IFN-β therapy. Overall, there was a 78% decrease in new gadolinium-enhancing lesions on T1-weighted images and positive outcome with respect to safety and improvement in clinical outcome measures.

Statins

Statins are oral lipid-lowering agents that have immunomodulatory actions. They work by inhibiting MHC class II expression and costimulatory molecule expression and affect T-cell regulation. In a recent study of 30 patients with RRMS who received simvastatin, 80 mg/day per os for 6 months, the mean number of lesions decreased by 44% ($P = <0.0001$), and the total lesion volume decreased by 41% ($P = 0.0018$) compared to pretreatment MRI (Vollmer et al., 2004).

Bone Marrow Transplantation

Bone marrow transplantation (BMT) is currently being studied to treat severe MS. The host immune system is first ablated with chemotherapy or radiation therapy. Autologous stem cells are then infused to reconstitute a new healthy immune system to minimize the greater morbidity and mortality associated with allogenic transplantation. The objective of BMT is to stabilize patients suffering from active forms of disease (Fassas et al., 2002; Blanco et al., 2005). Autologous hematopoitic stem cell transplantation has been performed on 250 MS patients as part of open label phase I and phase II trials in which both clinical and MRI measures are followed. From a radiologic point of view, BMT causes a long-standing suppression of gadolinium-enhancing lesions on T1-weighted MRI scans up to 3 years in duration after the procedure. Only 50% of the patients had a 3-year activity-free course of MS (Yolanda et al., 2005). A preliminary summary of the results shows that BMT is most appropriate for patients with RRMS with an expanded disability status scale (EDSS) of <6 on entry, those with active disease,

and those who have failed conventional treatments (Yolanda et al., 2005). While better designed double-blind randomized trials might be indicated to examine the true effect of BMT on the progressive course of the disease, it is not clear if ultimately the benefit of this approach will ever outweigh the potentially severe side-effects associated with it.

Summary

It appears likely that immunomodulating and immunosuppressive therapies provide their greatest benefit early in the disease, during a period in which inflammatory responses are major contributors to tissue injury. As progressive disease sets in and irreversible axonal injury becomes the major process underlying clinical deterioration, the relative contribution of inflammation to ongoing injury diminishes and with it the role of anti-inflammatory therapies. This may explain why treatment of patients in the progressive phase of MS with immunomodulating therapies has been less successful.

CONCLUDING REMARKS AND FUTURE PROSPECTS

Major strides have been made over the past years in our understanding of the immunopathogenic processes underlying the development and course of MS. Classical themes have been revisited with the application of modern techniques. The demonstration of distinct pathologic patterns in MS plaques suggests that several different mechanisms may contribute to tissue injury, and that the prevailing mechanism may not be the same across patients. In part, this may reflect the remarkable genetic diversity and broad range of environmental exposures that together define the human experience. Differences in pathogenic substrates may explain the observed heterogeneity of clinical disease course and severity, and the differential response to therapy. A more meaningful classification of MS that is based on defining the underlying process in individual patients may lead to more effective therapeutic approaches.

A variety of imaging modalities have combined with pathologic studies to highlight the substantial degree of axonal injury involved in both MS lesions and in normal appearing white matter. These abnormalities are detected early in the course of MS and may be better predictors of subsequent disability than clinical measures of disease activity. Indeed, neurologic disability in MS is likely to have at least two pathologic underpinnings: inflammatory demyelination and axonal transection. Episodic demyelination involving infiltration of inflammatory cells is the likely substrate of clinical flares. Recovery from these probably reflects resolution of local inflammation and edema in the short term. Axonal transection may remain largely silent for extended periods, due in part to the redundancy and functional compensation potential of CNS pathways. The process of axonal loss, however, is irreversible and beyond a certain threshold further degeneration translates into a slow progressive clinical decline (Bradley, 1998; Trapp et al., 1999a; 1999b). This underscores the importance of early diagnosis and intervention in MS.

While proven effective, current treatment approaches are only able to modestly impact disease progression. The development of more effective therapies will be predicated on advancing our understanding of the underlying disease process. A wealth of animal and human studies have contributed to a model of MS immunopathogenesis in which activated autoreactive T cells are likely to play an important role. By a process of molecular mimicry, exposure to an infectious agent may activate cross-reactive autoaggressive T cells that may then enter the CNS and mediate injury. Alternatively, direct insult to the CNS, such as by a neurotropic virus or trauma, may expose CNS epitopes in the setting of local inflammation, and trigger autoreactive T cells in a susceptible host. Migration of pro-inflammatory immune cells across the BBB in MS may reflect dysregulation of the complex molecular interactions involving adhesion molecules, chemokines, and MMPs. It remains to be determined whether the abnormalities in expression levels of these molecules associated with MS reflect a true pathogenic role or a mere epiphenomenon of the inflamed state. The microenvironment in which autoreactive T cells become activated, both in the periphery and in the CNS, is defined in part by the local profile of cytokines and costimulatory molecules, and influences the effector profile of the T cells, which may adopt an inflammatory or anti-inflammatory character. A pro-inflammatory environment is likely to promote "epitope spreading" and propagation of disease. In contrast, anti-inflammatory cells may mitigate the injurious responses by "bystander suppression." The roles of B cells and humoral responses, as well as the contributions of innate immunity, are receiving renewed attention. In some settings, antibodies have been implicated in augmenting or even inducing disease. In others, they may play a protective role. Studies into the neurobiology of MS, and in particular the roles of microglia and astrocytes, and the interactions of neural elements, endothelia, and inflammatory cells, have been revealing. Neural–immune interactions occur in the normal physiologic state and may represent important homeostatic mechanisms capable of promoting repair and regeneration. Indeed, these principles must be incorporated in any serious attempt to comprehensively understand MS.

Finally, ongoing studies into the mechanisms of action of the available immunomodulators are contributing to our understanding of the immunopathology and neurobiology of MS, and these insights will guide the development of the next generation of safe and effective therapies. In addition

to targeting inflammation, future approaches will undoubtedly explore neuroprotective strategies designed to prevent oligodendrocyte death and axonal transection, and complementary approaches that promote remyelination and recovery.

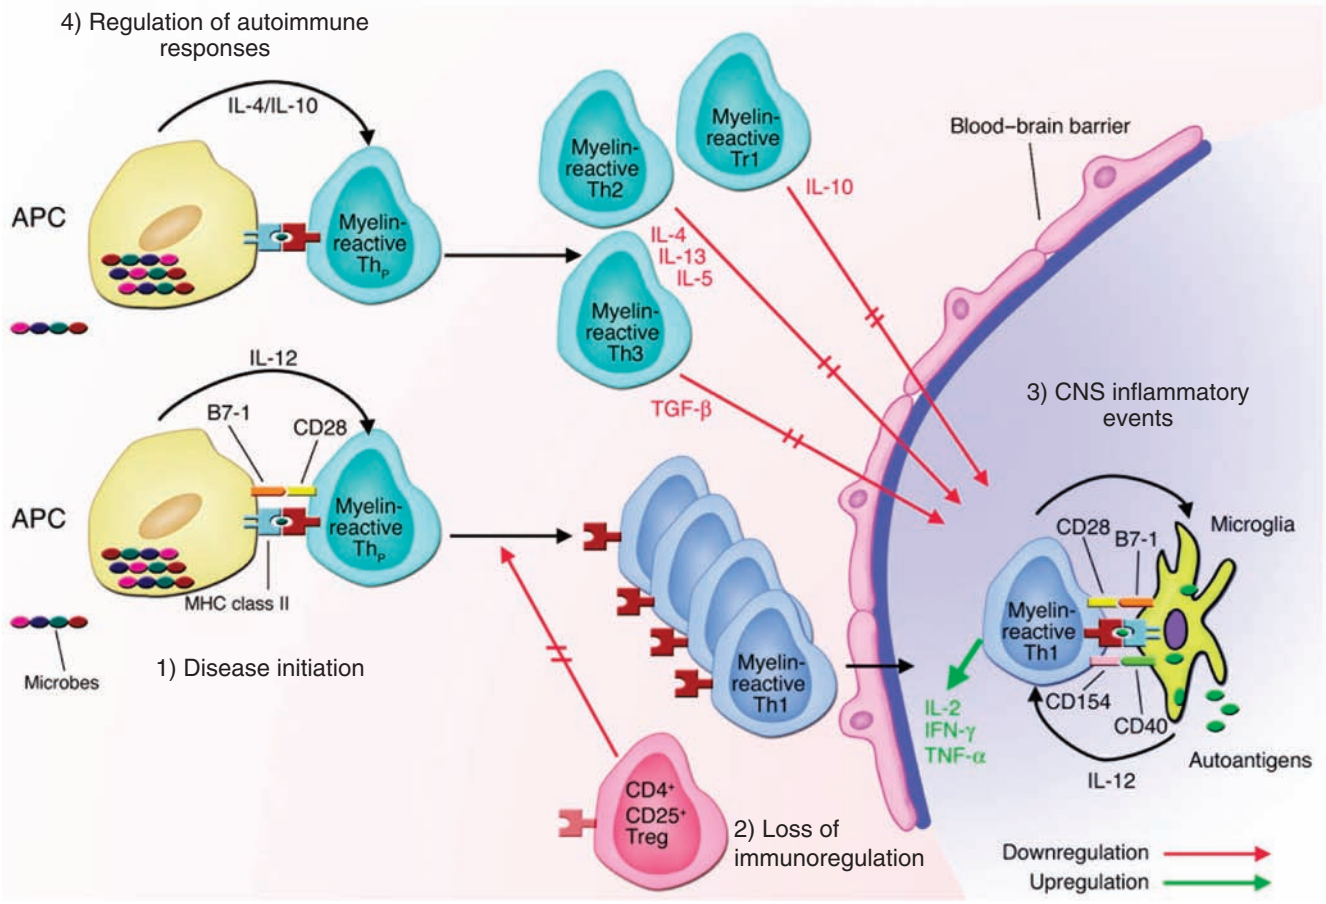

FIGURE 46.3 Presumed pathophysiology of multiple sclerosis (MS). Four main components contribute to the pathophysiology of MS. 1) *Initiation*, a presumed microbe may be taken up by an antigen- presenting cell (APC) and is presented to a myelin-reactive precursor T-cell (Th_p). 2) *Loss of immunoregulation*, $CD4^+CD25^+$ regulatory T-cells (Tregs) are thought to be reduced in MS patients, which causes a decrease in the overall autoregulation of the autoimmune process. 3) *Central nervous system (CNS) inflammatory events*, in the CNS, local APCs, microglia, present antigen to myelin-reactive type 1 helper T (Th1)-cells that secrete Th1 cytokines such as interleukin (IL)-2, interferon (IFN)-γ, and tumor necrosis factor (TNF)-α, which permit the inflammation to continue. 4) *Regulation of the autoimmune responses*, three cell types enter the CNS to counterbalance the proinflammatory Th1 cells, which are part of the naturally-occurring regulatory mechanisms that bring the inflammatory cascade into check by counterbalancing the Th1-mediated proinflammatory response. The three cell types are the Th3 cells which secrete tumor growth factor (TGF)-β; Th2 cells which secrete Th2-mediated cytokines, including IL-4, IL-13, and IL-5; and regulatory T-cells (Tr1), which secrete IL-10.

Peripheral Neuropathy

MICHAEL P. T. LUNN*
*National Hospital for Neurology and Neurosurgery, Queen Square, London, UK

KAZIM A. SHEIKH†
†Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Autoimmunity is implicated in a small but important group of peripheral nerve diseases. These include the acute inflammatory neuropathies eponymously referred to as the Guillain–Barré (GBS) and Fisher syndromes, and the chronic inflammatory demyelinating polyradiculoneuropathies, both idiopathic and associated with a serum paraprotein. Substantial evidence exists for an autoimmune pathogenesis in GBS and its subtypes. Evidence is still being gathered to support similar processes in the chronic inflammatory neuropathies, including the demyelinating neuropathy associated with antibodies to myelin-associated glycoprotein (MAG). Although most current evidence supports an antibody-driven pathogenesis triggered by infection, T cell and other cellular immune components are crucial effectors of disease. Experimental allergic neuritis (EAN), an inflammatory model of neuropathy, has been instructive in the detailed study of the pathogenesis of immune-mediated neuropathies and will be discussed.

ACUTE NEUROPATHIES: THE GUILLAIN–BARRÉ SYNDROME

Historic Background

Guillain, Barré, and Strohl described a rapidly evolving flaccid paralysis with areflexia and albuminocytologic dissociation in the cerebrospinal fluid (CSF) in 1916 (Guillain et al., 1916). Early autopsy demonstrated both T-cell inflammation and demyelination in peripheral nerves (Haymaker and Kernohan 1949; Ashbury et al., 1969), leading to the notion of GBS being a single pathophysiologic entity synonymous with acute inflammatory demyelinating polyradiculoneuropathy (AIDP). AIDP is by far the most common variant of GBS in the developed world. Variants such as the Fisher syndrome (Fisher, 1956) and the axonal variants (Feasby et al., 1986), acute motor axonal neuropathy (AMAN) and acute motor and sensory axonal neuropathy (AMSAN) (Yuki et al., 1990; McKhann et al., 1991; 1993), are now part of a spectrum of disease with variable worldwide occurrence (Box 47.1; see below).

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Box 47.1
Diversity of Guillain–Barré variants

- Acute inflammatory demyelinating polyradiculoneuropathy (AIDP); regional variants, e.g., pharyngo-cervical-brachial
- Acute motor axonal neuropathy (AMAN)
- Acute motor and sensory axonal neuropathy (AMSAN)
- (Miller) Fisher syndrome (ataxia, ophthalmoplegia, and areflexia)
- Acute panautonomic neuropathy
- Acute pure sensory neuropathy
- Acute motor conduction block neuropathy

Epidemiology

Since the near eradication of poliomyelitis, GBS has become the most common cause of acute flaccid neuromuscular paralysis in the world. The incidence of GBS is 1–1.5 in 100,000 (range 0.4–4) (Hughes and Rees, 1997; Rees et al., 1998; Emilia-Romagna Study Group, 1998). The incidence increases steadily with advancing age and males are affected more often than females by 1.25 : 1 (Hadden and Gregson, 2001). Case–control studies implicate infections as precipitating events (see below).

Severity varies from mild with full recovery in 10% of patients, to bedbound in 40%, to complete paralysis with ventilatory dependence in 20%. Death occurs in 5–8% of patients (Guillain–Barré Syndrome Study Group, 1985; Rees et al., 1998).

Clinical Features and Subtypes

The diagnosis of GBS remains clinical, but electrophysiologic studies help to subtype patients into diagnostic categories.

Acute Inflammatory Demyelinating Polyradiculoneuropathy

AIDP accounts for >95% of patients with GBS in Europe and North America. Patients present with a rapidly evolving neuropathic (sensory) motor paralysis, usually ascending, in two or more limbs over less than 4 weeks. The illness is monophasic. Most patients have numbness, tingling or pain and many complain of bladder disturbance, facial weakness or swallowing difficulty (Hughes, 1990). Autonomic disturbance is common with arrhythmia and fluctuating blood pressures. Tendon reflexes are absent or reduced. The CSF contains fewer than 50 leucocytes/μl (Asbury and Cornblath, 1990) and CSF protein is raised in 80% of cases. Antiganglioside antibodies may be detected in the serum (see below) by enzyme-linked immunosorbent assay (ELISA), often with thin layer chromatography confirmation. Assays should be performed in an experienced laboratory. Electrophysiologic studies typically show slowed motor conduction velocities, delayed F-waves and preserved compound muscle action potential (CMAP) amplitudes consistent with demyelination, but conduction failure and axonal degeneration may complicate the picture.

Multifocal perivascular T-cell infiltration with demyelination, typically patchy with involvement of proximal and terminal nerve segments, characterizes the pathology of AIDP (Asbury et al., 1969; Hall et al., 1992; Reisin et al., 1993; Massaro et al., 1998). Indications of blood–nerve barrier (BNB) breakdown and deposition of activated complement components can be seen in some but not all cases of AIDP (Hafer-Macko et al., 1996b). These observations raise the possibility that T-cell- or antibody-mediated immune injury can predominate in an individual case.

Acute Motor Axonal Neuropathy

AMAN is a pure motor variant of GBS seen most commonly in China, Japan, and Mexico (Ramos-Alvarez et al., 1969; McKhann et al., 1991; 1993; Ogawara et al., 2000), where it accounts for almost half of cases. In Europe and North America it accounts for only 5–20% of cases (Rees et al., 1995b; Visser et al., 1995), probably nearer 5%. The reasons for this are unknown. In China, AMAN occurs in seasonal epidemics, affects more children (McKhann et al., 1991), and is strongly associated with *Campylobacter jejuni* infection. Sensory impairment is minimal and autonomic involvement less common. Electrophysiologic studies are characterized by reduced CMAP amplitudes and absent F-waves, with normal distal motor latencies and conduction velocity (Kuwabara et al., 2000). Sensory involvement is absent.

The pathology of axonal GBS has largely been described from AMAN cases in northern China. The pathologic changes indicate an antibody-mediated immune attack directed preferentially against motor axons, causing primary axonal degeneration in the absence of prominent T-cell inflammation (Griffin et al., 1995; 1996a; Hafer-Macko et al., 1996a). Macrophages may be found in the periaxonal space, suggesting that the antigen of interest is on the axolemma (Figure 47.1). However, since in some patients little pathology is found (Griffin et al., 1996b) and in others recovery is too rapid for nerve fiber degeneration and regeneration (Ho et al., 1997; Kuwabara et al., 1998), axonal conduction failure and distal neuromuscular terminal failure must also make a prominent contribution to clinical weakness in AMAN.

Acute Motor and Sensory Neuropathy

AMSAN is a more severe form of AMAN, with a more severe course, sensory involvement, and delayed recovery

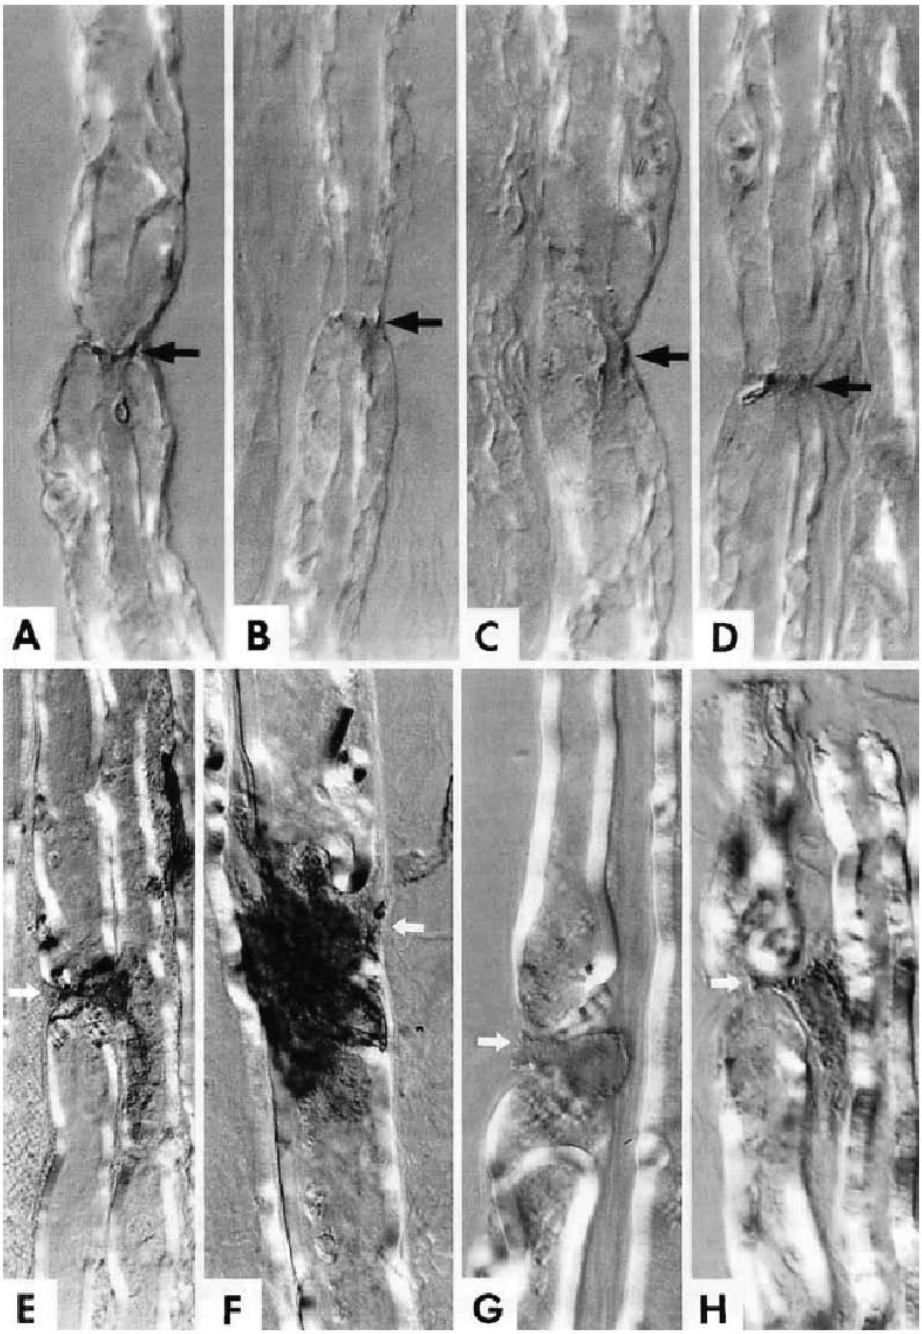

FIGURE 47.1 Immunostained teased ventral root fibers from a patient with acute motor axonal neuropathy (AMAN), 4 days after the onset of neurologic symptoms. *A–D*, The complement activation product C3d was localized discretely at the nodes of Ranvier (arrows) of the large myelinated motor fibers. The golden–brown immunoreaction product is at the nodes. *E–H*, Many motor fibers had macrophages overlying, and extending processes into, the nodes of Ranvier (arrows). [*E* and *F* were immunostained with the macrophage marker HAM-56; *G* and *H* for HLA-DR (major histocompatibility locus class II)]. See color plate section.

Reprinted from Hafer-Macko et al. (1996a).

(Feasby et al.,1986; Griffin et al., 1995). Sensory as well as motor nerve roots are involved. The pathology is similar to AMAN.

Fisher Syndrome

The Miller Fisher or Fisher syndrome (FS) (Fisher, 1956) accounts for approximately 5% of GBS cases and comprises ophthalmoplegia, ataxia, and areflexia without limb weakness. In common usage, facial and bulbar weakness have been included as part of the syndrome. Overlapping forms with AIDP are not uncommon. This syndrome is strongly associated with preceding *C. jejuni* infection and over 85% of patients have antibodies to the ganglioside GQ1b, which are almost certainly pathogenic (see below) (Willison et al., 1993; Mizoguchi, 1998; Willison and O'Hanlon, 1999; O'Hanlon et al., 2001). Anti-GQ1b antibodies are also found in GBS patients with ophthalmoplegia. The pathophysiologic and structural bases of the clinical manifestations in FS are still not completely resolved.

Acute Idiopathic Autonomic Neuropathies

These neuropathies are rare but are probably variants of GBS (Kissel et al., 2001; Freeman, 2005). They present with acute or subacute autonomic failure manifesting as presyncope and syncopal episodes with a viral prodrome in 50%. Abdominal symptoms with diarrhea, constipation, vomiting or pain, impotence, bladder dysfunction, sweating abnormalities, and pupillary symptoms and signs are variable and not uncommon. Pandysautonomia is most common but both pure sympathetic and parasympathetic failure are described. There are often few sensory or motor features other than subjective sensory disturbance and hyporeflexia. There is albuminocytologic dissociation in the CSF, and recently an association has been described with neuronal nicotinic acetylcholine receptor antibodies in the serum (Vernino et al., 2000). Recovery is often slow and incomplete.

Autoimmune Features

Molecular Mimicry

Molecular mimicry has been invoked as a mechanism in a variety of autoimmune diseases. AMAN and FS provide some of the best available evidence to support the hypothesis of molecular mimicry as a pathogenetic mechanism underlying postinfectious autoimmune disorders. AMAN and FS fulfill some of the Koch-Witebsky postulates supporting autoantibody as pathogenic (Witebsky et al., 1957; Rose and Bona, 1993). Antiganglioside antibodies can be demonstrated in patient serum. They have cognate antigens (gangliosides) enriched in peripheral nerve. It is possible to immunize animals (see below) with ganglioside antigens, either purified or as whole bacteria, to produce autoantibody and disease, albeit with difficulty. Transfer of antibody from patient/model animal to a normal subject can sometimes transfer disease. Furthermore, mechanisms of antibody action are now starting to be understood.

Antiganglioside Antibodies in Guillain–Barré Variants

Antibodies to ganglioside species are found in the serum of patients with GBS. They are polyclonal, predominantly IgG, and generally complement-fixing IgG1 and IgG3 (Willison and Veitch, 1994; Ogino et al., 1995; Yuki et al., 1995; Ho et al., 1999). This implies class-switching usually with T-cell help, both atypical of human anticarbohydrate responses (see below). Antibodies to gangliosides GM1, GM1(NeuGc), GM1b, GalNAc–GM1b, GD1a, GalNAc–GD1a, GD1b, 9-O-acetyl GD1b, GD3, GT1b, GQ1b, GQ1bα, LM1, galactocerebroside, and SGPG have been reported in more than 200 papers on inflammatory neuropathies (Willison and Yuki, 2002). Clinicoserologic correlations between GBS subtypes and serum antibodies to putative ganglioside antigens have been drawn (Rees et al., 1995a; Jacobs et al., 1996; Ho et al., 1999; Ogawara et al., 2000). Antibodies to gangliosides GM1 and GD1a, implicated as the major target antigens in AMAN (Yuki et al., 1993b; Rees et al., 1995a; Jacobs et al., 1996; Hadden et al., 1998; Ho et al., 1999; Ogawara et al., 2000), can be detected in 50–60% of AMAN patients in the Far East (Ho et al., 1999; Ogawara et al., 2000). Antibodies to GalNAc–GD1a and GM1b are found in motor predominant GBS in about 10–15% of cases (Ang et al., 1999; Yuki et al., 1999; 2000). Anti-GQ1b antibodies, frequently cross-reactive with structurally-related gangliosides, are present in 80–90% of patients with FS (Willison et al., 1993; Yuki et al., 1993a; Carpo et al., 1998). This correlation provides the strongest association between antibodies to a specific ganglioside and a clinical phenotype.

Gangliosides in Peripheral Nerve

Gangliosides are sialic acid-containing glycolipids (Figure 47.2), widely distributed in mammalian tissues, but enriched in the nervous system. GM1, GD1b, GD1a, and GT1b are the most abundant. A simple hypothesis to explain the differences between GBS variants is based on the premise that target gangliosides have differential distribution in the peripheral nervous system (PNS). In relation to FS, GQ1b is relatively enriched in the oculomotor cranial nerves (Chiba et al., 1993; 1997), although anti-GQ1b antibodies may bind elsewhere (Willison et al., 1996; Goodyear et al., 1999). Although ganglioside immunolocalization studies are technically difficult, the AMAN-associated gangliosides GM1 and GD1a, are localized at the nodes of

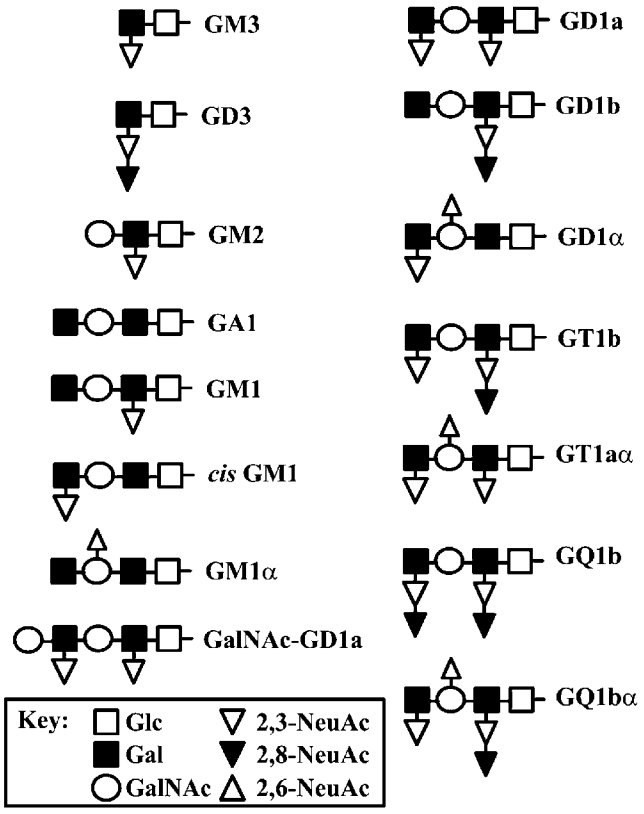

FIGURE 47.2 Ganglioside species in peripheral nerve that are potential targets for neuropathy-associated antibodies. Note the similarity in structures between species, which allows for some cross-reactivity. All have an intramembrane ceramide and display cell-surface oligosaccharides. IgG antibodies to GQ1b are associated with over 90% of cases of Fisher syndrome, but commonly demonstrate cross-reactivity with related species GT1b and GD1b. Antibodies to GM1 are associated with multifocal motor neuropathy with conduction block and a worse prognosis in Guillain–Barré syndrome. IgG antibodies to GD1a are strongly associated with acute motor axonal neuropathy. Antibodies to GM1 and GalNAc-GD1a are also less commonly found (see text). Gal, galactose, GalNAc, N-acetylgalactosamine; Glc, glucose; NeuAc, neuraminic (sialic) acid.

Ranvier and in motor nerve terminals (Sheikh et al., 1999; Gong et al., 2002). Furthermore, preferential staining of motor nerve fibers has been demonstrated with monoclonal anti-GD1a antibodies in rats (Gong et al., 2002) (Figure 47.3) and also with human anti-GD1a antibodies from a patient with AMAN (De Angelis et al., 2001). Other factors, such as variations in permeability of the BNB, density, and accessibility of target gangliosides, and relationship to functional components of the axolemma, such as ion channels, are likely to be relevant.

Functional Effects of Antibodies

Antibodies bind to nerves at nodes of Ranvier where gangliosides (especially GM1) and channels are enriched. Some studies indicate that anti-GM1 antibodies may block or alter

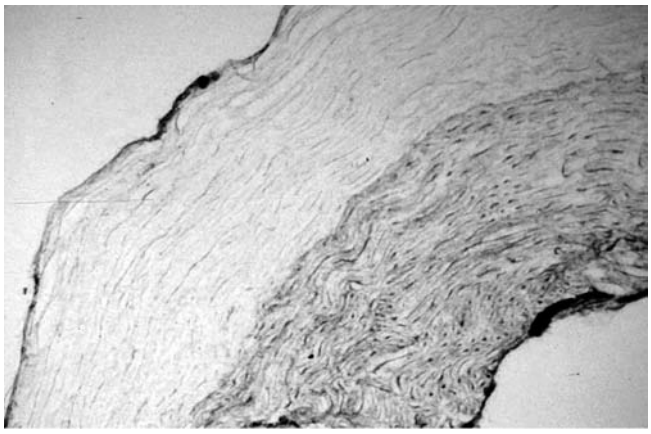

FIGURE 47.3 Unfixed fresh-frozen rat motor-sensory nerve root stained with a monospecific murine IgG anti-GD1a antibody. There is preferential strong staining of the motor axons of the ventral root (below) compared to the sensory axons of the adjacent dorsal root (above). Original magnification ×320.

channel function (Takigawa et al., 1995; 2000; Weber et al., 2000), although the exact mechanisms remain unclear (Sheikh et al., 1999). Intraneural injection of GBS patient serum, purified immunoglobulin or specific antiganglioside antibodies has produced mixed results (Saida et al., 1979; Winer et al., 1988; Sumner et al., 1992).

An alternative site of attack is at the roots and motor nerve terminals (MNTs) where the BNB is relatively deficient. MNTs degenerate in AMAN (Ho et al., 1997) and are disturbed electrophysiologically in FS (Uncini and Lugaresi, 1999). In an *ex vivo* phrenic nerve-diaphragm preparation, Willison et al. have clearly shown that anti-GQ1b antibodies bind to nerve terminals and cause complement-dependent quantal acetylcholine (ACh) release, resulting in neuromuscular blockade and a calcium-dependent disruption of the terminal bouton (Willison et al., 1996; Goodyear et al., 1999; Plomp et al., 1999; O'Hanlon et al., 2001). They have recently shown the same effect with anti-GD1a antibodies, and that this effect is dependent upon GD1a antigen density (Goodfellow et al., 2005).

In a parallel series of patch-clamp experiments, IgG GQ1b, GD1a, GD1b, and GM1 antibodies have been shown to cause reversible complement independent pre- and post-synaptic blockade, depending upon the antibody used (Buchwald et al., 1995; 1998; 2002; Buchwald and Sheikh, unpublished results).

Environmental Effects

C. jejuni is a gram-negative non-spore-forming enteropathogen that is one of the most common causes of bacterial gastroenteritis worldwide (Hughes and Rees, 1997; Friedman et al., 2000; Oberhelman and Taylor, 2000).

Infection with *C. jejuni* is found in 13–72% of patients with AMAN or GBS (Hughes and Rees, 1997; Hadden and Gregson, 2001), with an overall prevalence estimated to be around 30% (Moran et al., 2002). Only 1 in 1000 cases of *C. jejuni* infection is complicated by GBS. The exact characteristics of *C. jejuni* that determine whether GBS follows infection are still unclear. However, a relationship of GBS with a number of Penner serotypes is recognized (Prendergast and Moran, 2000). Penner serotyping distinguishes *C. jejuni* strains on the basis of strain-specific, heat-stable, extractable, capsular lipopoly- and lipooligosaccharides. Penner strains HS:19 (Fujimoto et al., 1992; Yuki et al., 1992; Kuroki et al., 1993; Rees et al., 1995b; Jacobs et al., 1997b; Sheikh et al., 1998) and HS:41 (Goddard et al., 1997) are especially over-represented in GBS and are uncommon in patients with uncomplicated gastroenteritis.

The lipopolysaccharide (LPS) and lipooligosaccharide (LOS) of *C. jejuni* carry ganglioside-like moieties. Several studies have characterized these in GBS- and diarrhea-associated *C. jejuni* strains. GM1-, GD1a-, GalNAc–GD1a-, GM1b-, GT1a-, GD2-, GD3-, and GM2-like structures have all been identified (Aspinall et al., 1993; 1994a; 1994b; Yuki et al., 1994; 1996; Sheikh et al., 1998; Nachamkin et al., 1999; 2002). Although no GQ1b-like structure exists, antibody-binding assays have shown the presence of GQ1b- and GT1a-cross-reactive moieties in *C. jejuni* LPS/LOSs (Yuki et al., 1994; Jacobs et al., 1995; 1997a). It is these structures that are likely to provide the initial stimulus to autoimmune activation.

Upper respiratory tract infection or other febrile episodes caused by cytomegalovirus (CMV) (5–22%), Epstein–Barr virus (EBV) (2–10%), *Mycoplasma pneumoniae* (5%), and *Haemophilus influenzae* have all been identified as potentially causative (Hadden and Gregson, 2001; Ju et al., 2004). *H. influenzae* carries ganglioside-like moieties (Mori et al., 2000). Swine flu and rabies vaccinations have also been causatively implicated (Kaplan et al., 1982; Hemachudha et al., 1988).

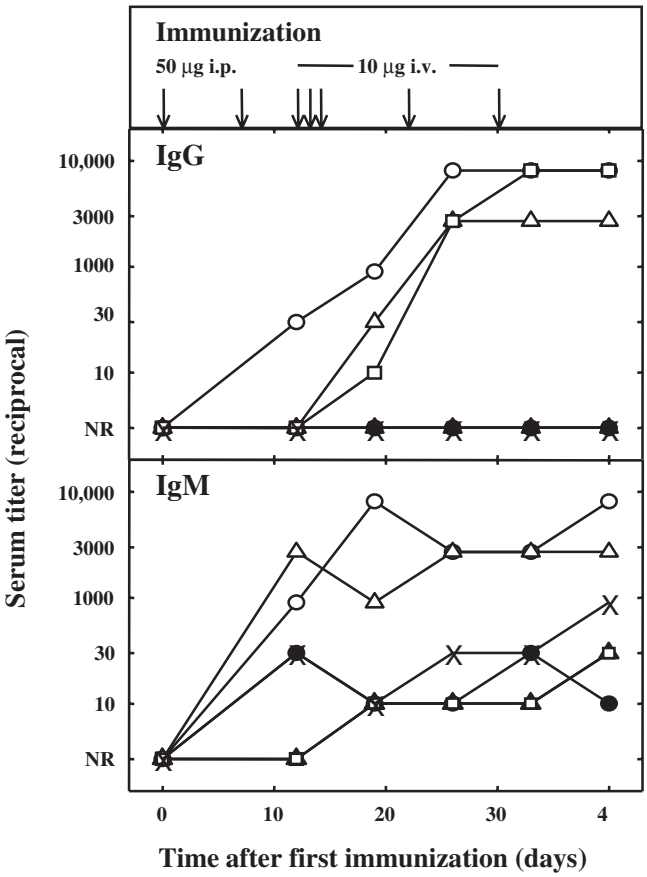

FIGURE 47.4 Mice lacking complex ganglioside species (GalNAcT$^{-/-}$) are able to switch class to complement-fixing IgG production when immunized with keyhole limpet hemocyanin (KLH)-conjugated ganglioside. Serologic responses of three individual GalNAcT$^{-/-}$ mice (open symbols) and three wild-type mice (closed symbols) immunized with GD1a-KLH, and a GalNAcT$^{-/-}$ mouse immunized with unconjugated KLH (X). Sera collected at the indicated times were tested for IgG and IgM anti-GD1a antibody titers by ELISA. Titer values are presented as the greatest dilution resulting in a signal which exceeded 3 SD above the control mean. Values were tested in triplicate. i.p., Intraperitoneal; i.v., intravenous.

Animal Models

Attempts to generate either IgG antiganglioside antibodies or neuropathy in animals by immunization with *C. jejuni* were for a long while either unforthcoming or not reproducible (Nagai et al., 1976; Kusunoki et al., 1996; Li et al., 1996; Prendergast and Moran, 2000). Immunization of mice with *C. jejuni* LPSs/LOSs generates mainly low-titer IgM antibodies (Wirguin et al., 1997; Goodyear et al., 1999), reflecting a high level of tolerance to self-gangliosides (Bowes et al., 2002). Tolerance to self-gangliosides can be overcome by immunization with gangliosides or *C. jejuni* LPSs conjugated to adjuvant in transgenic animals lacking complex gangliosides (Lunn et al., 2000; Bowes et al., 2002) (Figure 47.4). This model illustrates that where tolerance is circumvented, potentially pathogenic antibodies can be generated.

A sensory ataxic neuropathy with pathologic changes in the nerve and cord has been induced in rabbits by GD1b immunization and passive antibody transfer (Kusunoki et al., 1996; 1999a; 1999b). Immunization with mixed bovine brain gangliosides or GM1 alone produced an acute flaccid paralysis in rabbits reminiscent of human disease (Yuki et al., 2001; Susuki et al., 2003). The implantation of a murine IgG anti-GD1a-secreting hybridoma into mice, but not passive transfer of the same antibody, led to an axonal neuropathy (Sheikh et al., 2004). Additional cytokine factors may be required to initiate the neuropathy.

Cellular Mechanisms

Comprehensive evidence of T-cell involvement in GBS has not been so forthcoming despite the central role of T cells in the pathogenesis of EAN. Studies of animal models and predominantly human AIDP have generated a complex multistep pathogenesis for cellular involvement in the autoimmune neuropathies (Figure 47.5). Macrophages are essential effectors of damage and recovery, targeted by antibody and T cells (see below).

Multifocal lymphocytic infiltration was established as the hallmark of the pathology of GBS in early postmortem studies (Asbury et al., 1969), but it is not always seen (Cornblath et al., 1990; Honavar et al., 1991). Circulating activated T cells are found early in the course of GBS (Taylor and Hughes, 1989; Hartung and Toyka, 1990). αβ T cells with CD4 and CD8 ratios in similar proportions to peripheral blood (Cornblath et al., 1990) are the predominant cells found in nerve. Restricted usage of Vβ genes, especially Vβ15, suggests activation by a common antigen or superantigen (Khalili-Shirazi et al., 1997). Furthermore, γδ T cells have also been found in, and isolated from, GBS-affected nerves (Khalili-Shirazi et al., 1998; Winer et al., 2002). γδ T cells are capable of recognizing non-protein antigen and are thus candidates for responding to putative carbohydrate and ganglioside antigens (see above)

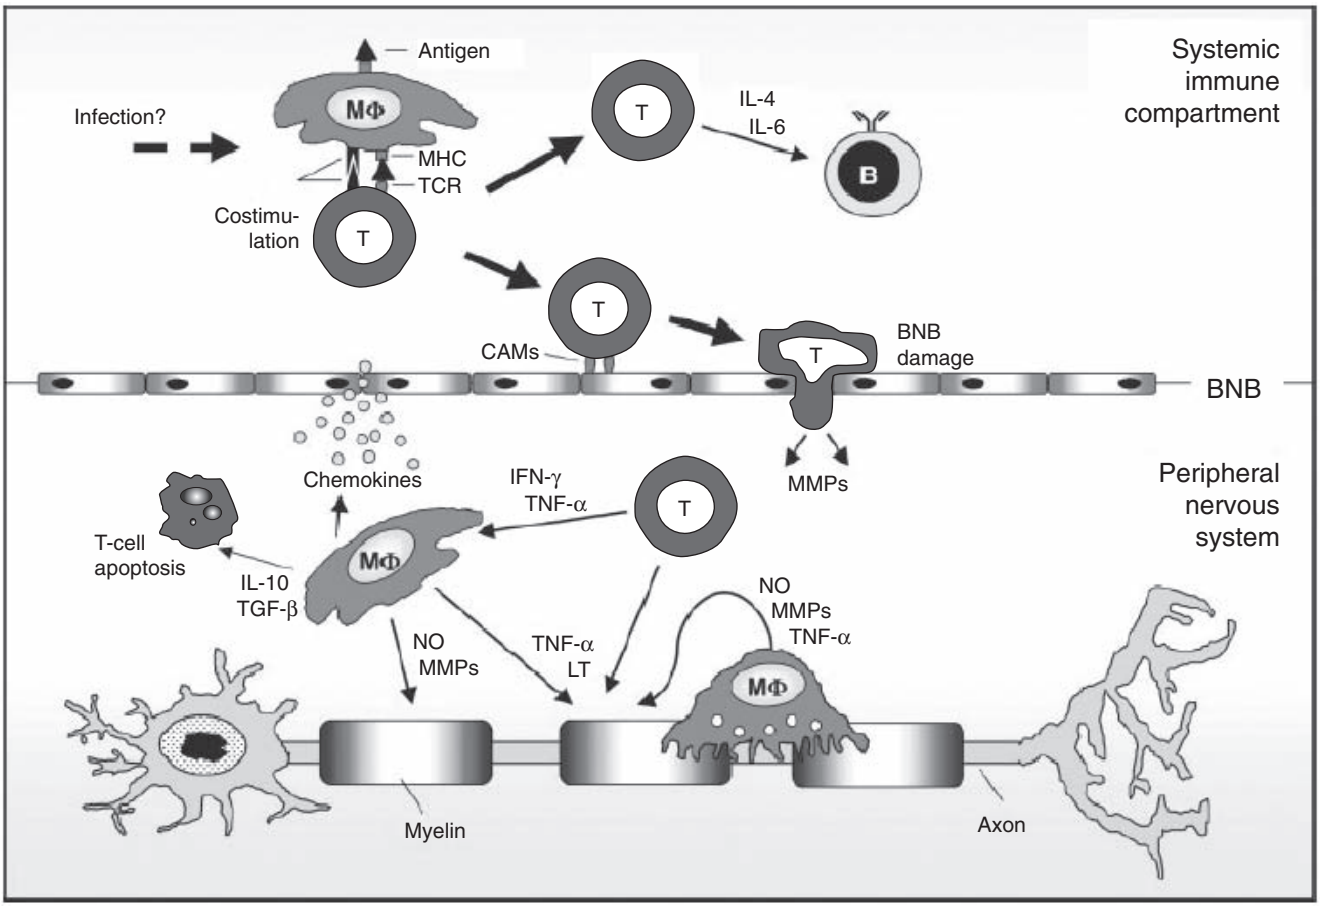

FIGURE 47.5 Schematic of the immune responses in the inflamed peripheral nervous system. Basic principles of the cellular immune responses: autoreactive T cells (T) recognize a specific autoantigen presented by major histocompatibility complex (MHC) class II molecules and the simultaneous delivery of costimulatory signals on the cell surface of antigen-presenting cells, such as macrophages (MΦ), in the systemic immune compartment. Activated T lymphocytes can cross the blood–nerve barrier (BNB) in order to enter the peripheral nervous system (PNS). Within the PNS, T cells activate macrophages that enhance phagocytic activity, production of cytokines, and the release of toxic mediators, such as nitric oxide (NO), matrix metalloproteinases (MMPs), and proinflammatory cytokines, propagating demyelination and axonal loss. The termination of the inflammatory response is mediated, in part, by macrophages by the induction of T-cell apoptosis and the release of anti-inflammatory Th2/Th3 cytokines, such as interleukin-10 (IL-10) and transforming growth factor-β (TGF-β). CAMs, cell adhesion molecules; LT, leukotrienes; TNF-α, tumor necrosis factor-α.

Reproduced from Kieseier et al. (2004), with permission.

(Bukowski et al., 1998). They proliferate *in vitro* in response to *C. jejuni* sonicates, but require either αβ T cells or interleukin (IL)-2/IL-15 to do so (Van Rhijn et al., 2003). Predominant use of Vγ8δ1 suggests activation of epithelially (possibly gut) resident γδ T cells (Cooper et al., 2000). αβ and γδ T cells also probably provide the necessary help to orchestrate class-switching of antiganglioside antibodies to IgG1 and IgG3.

Autoantigen in the systemic compartment is processed and presented by antigen-presenting cells (APCs). EAN can be initiated with neuritogenic epitopes of peripheral nerve proteins P0, P2, and PMP22 (Hughes et al., 1999) or by adoptive transfer (AT) of sensitized T cells. Disease severity depends upon the cell or antigen dosage (Hartung et al., 1996). Processed and unprocessed gangliosides presented in the context of CD1 molecules on APCs also stimulate T-cell activation in *in vitro* assay systems (Prigozy et al., 2001; Shamshiev et al., 2002). A limited literature is emerging demonstrating T-cell responses to glycolipids in multiple sclerosis (Shamshiev et al., 1999). The development of EAN or GBS is dependent on the presence of T cells (Holmdahl et al., 1985) and their normal function (Holmdahl et al., 1985; Hartung et al., 1987; Jung et al., 1992), and the normal function of the costimulatory partners CD80/B7.1 or CD86/B7.2 and CTLA-4/CD28 (Kiefer et al., 2000; Zhu et al. 2001a; 2001b; Zehntner et al., 2003).

Lymphocyte activation is revealed by greater numbers of circulating T cells bearing activation markers and increased concentrations of type 1 helper T-cell (Th1) cytokines, such as interferon (IFN)-γ, IL-2, IL-2 receptor, and tumor necrosis factor (TNF)-α (Taylor and Hughes, 1989; Hartung and Toyka, 1990; Hartung et al., 1991; Exley et al., 1994; Creange et al., 1996; Dahle et al., 1997). Levels of transforming growth factor (TGF)-β1 are depressed (Creange et al., 1998). In EAN, levels of IFN-γ, IL-1β, IL-6, TNF-α, TNF-β, and IL-12 are raised during development of disease (Zhu et al., 1994; 1997).

Homing and migration of activated T cells to the peripheral nerve is modulated by E-selectin and mucins binding L-selectin and sialyl Lewis antigens (Hartung et al., 2002), and then VCAM-1 and ICAM-1, which are both upregulated early in GBS and EAN progression (Enders et al., 1998; Creange et al., 2001). Blockade of VCAM-1 or its ligand VLA-4/α4β1 integrin ameliorates EAN (Enders et al., 1998). Selectin and integrin are released into the circulation and may downregulate inflammation (Hartung et al., 1988). Chemokines assist in leukocyte recruitment, localization, and trafficking (Baggiolini, 1998; Campbell et al., 1998). Recently, the chemokine receptors CCR1, CCR2, CCR4, CCR5, and CXCR3 were characterized in AIDP-affected nerves, differentially upregulated in infiltrating cell populations (Kieseier et al., 2002).

Diapedesis through the vascular endothelium and basal lamina is facilitated by matrix metalloproteinases (MMPs). MMP-2, MMP-3, MMP-7, and especially MMP-9 have been implicated in the pathogenesis of EAN and GBS (Kieseier et al., 1998b; Creange et al., 1999) and correlate with GBS severity.

Macrophages, both resident and recruited from the circulation (Hartung et al., 2002), remain the key component in perpetuating endoneural inflammatory damage through the release of specific immune mediators. Under inflammatory conditions they continue to present antigen and induce Schwann cells to do so also (Gold et al., 1995). Depletion of macrophages abrogates the development of EAN, indicating their central role in the final common pathway of nerve damage. Activated macrophages target normal-looking nerves and Schwann cells in EAN and AIDP (Prineas, 1972; 1981; Hartung et al., 1996; Hughes et al., 1999), probably by antibody-targeted cellular cytotoxicity and complement-dependent mechanisms (Hafer-Macko et al., 1996a; 1996b). Macrophage processes insinuate themselves between myelin lamellae and strip the myelin in AIDP (Hughes et al., 1999) or directly attack the axon in AMAN (see Figure 47.1) (Hafer-Macko et al., 1996a). In the endoneurium, macrophages secrete a host of inflammatory mediators, including MMPs, TNF-α, nitric oxide, eicosanoids, neutral proteases, lipases, and phospholipases, which all contribute to nerve damage (Gregson and Hall, 1973; Watson et al., 1994; Redford et al., 1997a; 1997b; Smith et al., 1999).

Macrophages may also direct the recovery. They direct T-cell apoptosis, reducing the ongoing response. During recovery, the T-cell response shifts towards Th2 with rises in IL-4 in patients (Dahle et al., 1997) and upregulation of TGF-β1, IL-10, and cytolysin in models of disease (Kiefer et al., 1996; Zhu et al., 1997). TGF-β1 favors recovery (Czarniecki et al., 1988; Miller et al., 1992; Vriesendorp et al., 1996; Zhu et al., 1997) and levels correlate with severity of GBS (Creange et al.,1998).

Synergistic Nature of Cellular and Humoral Immune Elements

Understanding of the pathomechanisms of the acute inflammatory neuropathies is incomplete. Neither antibodies nor T cells generate disease in isolation and immunization with any antigen induces responses in both cellular and humoral arms of the immune system. The absence of T cells in some biopsies is discussed above. Arguments against the early and significant involvement of antibodies include the absence of detectable antiganglioside antibodies, using current methodology, in a significant proportion of GBS (usually AIDP) cases, and the onset of AT-EAN 4 days after transfer, before antibodies could be synthesized. However, disease severity in AT-EAN is usually enhanced by cotransferring antibodies recognizing myelin or oligodendrocytes/Schwann cell epitopes (Hahn et al., 1993; Spies et al.,

1995), although this was not confirmed when pretreatment AIDP GBS sera were coadministered to rats with mild EAN (Hadden et al., 2001).

Genetic Aspects

Understanding of the role of host genetics in susceptibility to GBS is still in its infancy. No strong correlations have been established between disease susceptibility or GBS subtypes and host major histocompatiblility complex (MHC) class I or class II haplotypes in several studies (Magira et al., 2003; Geleijns et al., 2005a). The study of single nucleotide polymorphisms in genes for various components of the immune response has not identified any significant contributors (Myhr et al., 2003; Geleijns et al., 2005a; 2005b). One Dutch study identified that GBS patients homozygous for the Fcγ receptor IIa-H131 had a higher chance of developing severe disease than patients with FcγRIIa-R131, FcγRIIIa or FcγRIIIb genotypes or normal controls (van der Pol et al., 2000).

Treatment and Outcome

The effectiveness of immunotherapy for GBS is supported by good evidence (Hughes et al., 2003). Two to five sessions of plasma exchange (PEx) hastens recovery in non-ambulant patients, preferably started within 2 weeks of disease onset. Intravenous immunoglobulin (IVIG) is as effective as PEx and is still probably the intervention of choice. The concern about possible contamination of IVIG with prions means that written informed consent is essential before administration. The drive to search for new, more effective and safer therapies is stronger than ever.

A recent large randomized controlled trial (van Koningsveld et al., 2004), previous smaller trials, and a Cochrane meta-analysis, have shown steroids to be at best ineffective, and in some cases harmful. There is no indication for their use in GBS.

Complement inhibitors are already available and clinical trials in the treatment of GBS are planned. Specific, targeted immunoadsorption of pathogenic antiganglioside antibodies is being developed for possible clinical use (Willison et al., 2004).

CHRONIC NEUROPATHIES: CHRONIC INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is an acquired peripheral nervous system disease characterized by progressive or relapsing proximal and distal weakness with or without sensory loss. There is good evidence to indicate that CIDP is autoimmune.

Historic Background

Osler (1892) recognized a chronic relapsing or progressive form of "multiple neuritis." Austin (1958) described a slowly progressive or recurrent "steroid responsive polyneuropathy," with histology indistinguishable from that seen in GBS (Thomas et al., 1969). The term chronic inflammatory demyelinating polyradiculoneuropathy was coined in 1975 (Dyck et al., 1975).

Epidemiology

The prevalence of CIDP is 1.25–7 in 100,000 (Lunn et al., 1998; McLeod et al., 1999; Mygland and Monstad, 2001).

Clinical Features and Subtypes

The course may be progressive, relapsing–remitting, monophasic or have a GBS-like onset. Symmetrical sensory and motor deficits, both proximal and distal, reach their nadir over more than 8 weeks. The cranial nerves and diaphragm are infrequently involved. CSF examination demonstrates albuminocytologic dissociation with raised protein in over 90% of cases (Bouchard et al., 1999) and the cell count is <10 mm^3 unless complicated by human immunodeficiency virus (HIV). Electrophysiology typically demonstrates multifocal motor conduction slowing, and temporal dispersion and block, with delayed or absent F-waves. Half of patients require treatment at any one time and 13% require long-term aid to walk (Lunn et al., 1999). In a single study, 6 of 21 patients were shown to have serum antibodies to the peripheral myelin protein P0 (Yan et al., 2001), but this awaits confirmation. Morphologic examination demonstrates macrophage-associated demyelination in nerve roots, plexuses, and nerve trunks with T cells in the endoneurium. The edema, Schwann cell proliferation, and inflammatory infiltrates testify to the ongoing inflammation. Axonal degeneration occurs in severe or late cases, or in distal sensory nerve biopsies (Hadden and Hughes, 2003).

As with GBS, CIDP is heterogeneous and a number of subtypes or related conditions have emerged.

Multifocal Motor Neuropathy with Conduction Block

Multifocal motor neuropathy with conduction block (MMNCB) (Pestronk et al., 1988) is a rare but treatable condition sometimes misdiagnosed as motor neurone disease (Nobile-Orazio, 2001). Wasting and weakness begin asymmetrically in the distribution of a motor nerve, usually more distal than proximal, most commonly in the upper limb. Fasciculations and cramps occur. Males account for 70% of cases. Sensory symptoms are reported in 20% of patients.

Depending upon assay methods, between 30 and 80% of patients have anti-GM1 antibodies in the serum (Nobile-Orazio, 2001; Sander and Latov, 2003), some as a paraprotein. Rarely, anti-GD1a antibodies are described (Carpo et al., 1996). Electrophysiologic studies demonstrate multifocal conduction blocks in two or more nerves with normal sensory conduction. Many studies demonstrate evidence of more widespread slowing or axonal degeneration (Nobile-Orazio, 2001; Sander and Latov, 2003).

The etiology of MMNCB remains unresolved, as it is seldom fatal and neuropathologic material is seldom sought. Perivascular CIDP-like inflammation has been described in a motor nerve biopsy (Kaji et al., 1993), and there are minimal findings in sensory nerves (Corse et al., 1996). Inflammatory cellular infiltration and immunoglobulin deposition were described in the motor roots of an autopsy case (Oh et al., 1995). Therapeutic response to immunomodulation supports an autoimmune pathogenesis (Azulay et al., 1994; Levine and Pestronk, 1999; Federico et al., 2000; Van den Berg-Vos et al., 2000; Leger et al., 2001; Umapathi et al., 2002).

Multifocal Acquired Demyelinating Sensory and Motor Neuropathy

Lewis and Sumner described the entity now referred to as multifocal acquired demyelinating sensory and motor neuropathy (MADSAM) in 1982 (Lewis et al., 1982). Electrophysiologic examination demonstrates multifocal sensory and motor involvement with conduction block.

Multifocal Acquired Sensory and Motor Neuropathy

This group of patients is only recently described (Alaedini et al., 2003). Antiganglioside antibodies are found in the serum of 48% of multifocal acquired sensory and motor neuropathy (MASMN) cases and there is a beneficial response to immunomodulation with IVIG and steroids. The nerve conduction studies do not suggest demyelination and are more consistent with axonal degeneration. These findings require confirmation.

Paraproteinemic Demyelinating Peripheral Neuropathy

Ten percent of patients with a peripheral neuropathy will have a paraprotein in their serum. Although this should initiate a search for a malignant source, such as multiple or solitary myeloma, most are monoclonal gammopathies of undetermined significance (MGUS). A number of MGUS-neuropathy syndromes are described. The most common is a progressive sensory ataxic neuropathy with unsteadiness and tremor associated with an IgMκ paraprotein that reacts with the HNK-1 epitope of the peripheral nerve antigen myelin-associated glycoprotein (MAG). Up to 80% of patients with an IgM paraprotein and a demyelinating neuropathy have anti-MAG antibodies. Nerve conduction studies reveal motor conduction slowing, particularly distally (Kaku et al., 1994; Cocito et al., 2001). Electron microscopic examination of myelin in sural nerve biopsies reveals characteristic widening of the intraperiod line not seen in other conditions (Figure 47.6).

Neuropathies associated with IgG or IgA paraproteins present in a diverse group of patients with axonal and demyelinating forms of disease. No consistent pathogenesis has yet emerged. The demyelinating cases have a similar therapeutic response to CIDP (Suarez and Kelly, 1993; Notermans et al., 1994; Saperstein et al., 2001).

Chronic ataxic neuropathy with ophthalmoplegia, M-protein, and antidisialosyl antibodies (CANOMAD) is a rare paraproteinemic syndrome rather like a chronic FS. Its pathogenesis is not yet resolved.

The POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes) is a rare condition associated with both osteosclerotic myeloma and Castleman disease. The pathogenesis does not seem to relate to the paraprotein as that is not an essential feature of the diagnosis. Cytokines and vascular growth endothelial factor (VGEF) are implicated in causation (Lagueny et al., 2004).

Autoimmune Features

Many of the features of autoimmunity displayed in the acute neuropathies are also seen in CIDP. Both cellular and

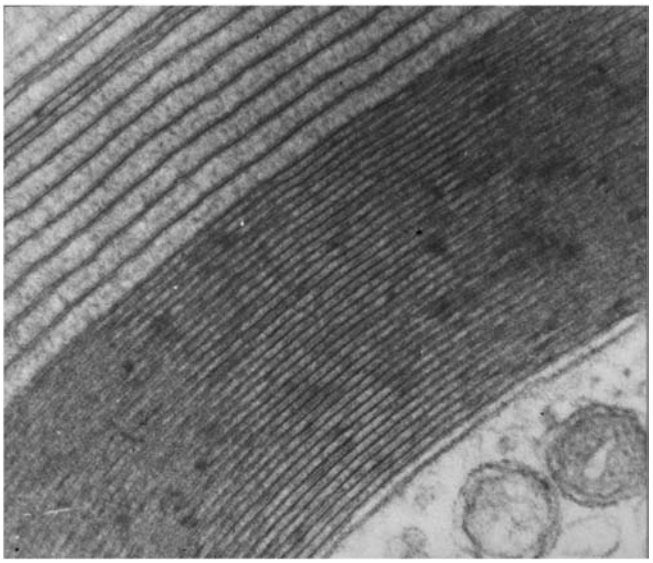

FIGURE 47.6 Widely spaced myelin. The normal myelin lamellae are tightly compacted and have a periodicity in electron microscope preparations of 12–15 nm. In the demyelinating neuropathy associated with IgM paraprotein that has activity against myelin-associated glycoprotein (MAG) (anti-MAG PDPN), the intraperiod line becomes split, giving an overall periodicity of 30–40 nm. Note the suggestion of material within the widened spaces, possibly IgM. Original magnification $\times 10^5$.

humoral responses are important to the pathogenesis. Raised circulating levels of IL-2 and TNF-α correlate with disease activity (Hartung et al., 1991; Misawa et al., 2001). T-lymphocyte migration into the endoneurium is facilitated by increased levels of chemokines, cell adhesion molecules, and MMPs (Previtali et al., 1998; 2001; Kieseier et al., 1998a; 2004). Expression of the BNB constituents claudin-5 and ZO-1 is altered in CIDP, perhaps contributing to the increased BNB permeability (Kanda et al., 2004). Within the endoneurium T cells secrete IFN-γ, IL-2, TNF-α (Mathey et al., 1999), and probably others, contributing to the inflammatory upregulation of effectors such as macrophages, continued recruitment, and direct nerve damage. Expression of downregulatory cytokines IL-4, IL-10, and TGF-β is also found, and in CIDP expression of NGF, GDNF, LIF, and their receptors may contribute to nerve regeneration (Yamamoto et al., 2002).

Unlike GBS or CIDP, in the anti-MAG paraproteinemic demyelinating peripheral neuropathy (anti-MAG PDPN) there is evidence only of antibody-mediated immunity. There is no evidence of macrophage-associated demyelination, T-cell infiltration into the endoneurium or upregulation of T-cell costimulatory molecules. There is quite strong evidence that anti-MAG antibodies may fulfill the Koch–Witebsky postulates. Anti-MAG antibodies can be found in the serum of patients with characteristic clinical presentation. MAG is expressed at the Schmidt–Lantermann incisures, the paranodes, and on the periaxonal myelin (Gabriel et al., 1998). It displays the HNK-1 carbohydrate epitope shared by several other peripheral nerve antigens. Histologic studies demonstrate IgM anti-MAG deposits on Schwann cells that colocalize with MAG (Takatsu et al., 1985; Gabriel et al., 1998). Electron-dense material seen between widened lamellae is consistent with anti-MAG IgM insinuated between the layers (Mendell et al., 1985; Ritz et al., 1999) (see Figure 47.6). Activated complement components have been described by some (Monaco et al., 1990; Ritz et al., 1999). The disruption of MAG functions and complement-mediated damage may result in alterations in the axonal neurofilament cytoskeleton (Ritz et al., 1999; Lunn et al., 2002) and these in turn may lead to slowing of nerve conduction and axonal degeneration.

Immunogenetic Features

Restricted usage of T-cell receptor (TCR) genes has been demonstrated in CIDP. The predominant TCR in CIDP is αβ but γδ T cells are found in the majority of nerve biopsy specimens (Winer et al., 2002), again implying a possible nonprotein immune response. No clonality has been demonstrated in isolated T cells (Bosboom et al., 2001). However, significant numbers of highly Th1 inflammatory natural killer T cells, identified by expression of Vα24JαQ invariant TCR chain, are found (Illes et al., 2000).

Environmental Influences

A preceding illness, infection or vaccination has been identified in 16% and 32% of patients with CIDP in the 6 weeks and 6 months preceding their illness, respectively (McCombe et al., 1987; Bouchard et al., 1999). Others have found no convincing evidence of vaccination being a trigger (Pritchard et al., 2002). No specific provoking environmental events have so far been recognized for CIDP or the paraproteinemic peripheral neuropathies.

Animal Models

The pathogenesis of CIDP is in many respects similar to that of the acute neuropathies. There is no specific animal model for CIDP. Yan et al. (2000) have demonstrated that purified IgG from patients with CIDP responsive to plasma exchange produced conduction block and demyelination by passive transfer when the BNB was breached, either by direct injection or by preceding passive T-cell transfer.

In anti-MAG PDPN, passive transfer of antibodies results in complement-mediated demyelination in cats and rabbits (Hays et al., 1987; Willison et al., 1988), although the pathologic features were not similar to those seen in human disease. Widened myelin lamellae, almost pathognomic of the condition, were demonstrated after passive transfer to chicks (Tatum, 1993). Induction of high-titer IgM antibodies cross-reactive with human MAG by immunization with the peripheral nerve glycolipid sulfated glucuronyl paraglboboside (SGPG) has been achieved in rats, rabbits, and cats (Yamawaki et al., 1996; Kohriyama et al., 1988; Kahn et al., 1989; Ilyas et al., 2002). However, no convincing neuropathy has been demonstrated as a result.

Pathogenic Mechanisms

The final common path of macrophage-mediated demyelination in CIDP is thought to be similar to that seen in GBS (see above).

Treatment and Outcome

Steroids, IVIG, plasma exchange, and immunosuppressive drugs have all been used in the treatment of CIDP. Plasma exchange and IVIG are both very potent (Hahn et al., 1996; van Doorn, 1996; Van Schaik et al., 2002; Mendell et al., 2001). There was no statistically significant difference between steroids and IVIG in a recent trial (Hughes et al., 2001), and even though steroids are cheaper in the short term, IVIG is currently the treatment of choice. Interferon-β-1a was shown to be ineffective in treatment-resistant patients (Hadden et al., 1999). There is inadequate evidence to properly assess anecdotally beneficial drugs,

such as azathioprine, cyclosporine, and mycophenolate mofetil.

In MMNCB a dramatic therapeutic response is sometimes seen to IVIG demonstrated in controlled trials, and cyclophosphamide, interferon-β-1a, and anti-CD20 antibody are also of benefit (Levine and Pestronk, 1999; Azulay et al., 1994; Federico et al., 2000; Umapathi et al., 2002; Leger et al., 2001; Van den Berg-Vos RM et al., 2000). Plasma exchange has no effect and interestingly steroids often worsen the condition by an unknown mechanism. Predictors of favorable outcome are anti-GM1 antibodies, younger age, presence of conduction block, a normal centine kinase (CK), and less severe disease at outset (Hadden and Hughes, 2003). Despite treatment, conduction blocks are dynamic and weakness probably progresses slowly over time (Taylor et al., 2000).

Anti-MAG PDPN patients only need treatment for their neuropathy if it becomes severe and disabling. Randomized controlled evidence of benefit is available for IVIG in the short term (Lunn and Nobile-Orazio, 2003). Fludarabine and anti-CD20 have been beneficial in small series of patients (Wilson et al., 1999; Renaud et al., 2003).

CONCLUDING REMARKS AND FUTURE PROSPECTS

The last decade has witnessed huge advances in the understanding of the pathogenesis of both acute and chronic inflammatory peripheral neuropathies. GBS and CIDP are heterogeneous clinical conditions in which humoral and cellular mechanisms conspire to cause disabling diseases. Although there are still innumerable advances to be made, our greater understanding of pathomechanisms is inspiring trials of novel agents for treatment. The next decade will see the emergence of further exciting discoveries that will significantly reduce death and disability from GBS and CIDP.

Myasthenia Gravis and other Antibody-Associated Neurological Diseases

ANGELA VINCENT AND CAMILLA BUCKLEY

Neurosciences Group, Department of Clinical Neurology, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK

THE NEUROMUSCULAR JUNCTION AS A MODEL SYNAPSE

The neuromuscular junction (NMJ) is a relatively simple synapse that consists of a motor nerve terminal and postsynaptic motor "endplate." The presynaptic nerve terminal contains mitochondria and many synaptic vesicles that store the neurotransmitter, acetylcholine (ACh). There are specialized active zones, which are the site of ACh release and where voltage-gated calcium channels (VGCC) are concentrated. Voltage-gated potassium channels (VGKC) are also found in the presynaptic motor nerve membrane. The postsynaptic membrane is highly specialized and thrown into a series of postsynaptic or junctional folds. The peaks of the postsynaptic folds are electron dense, corresponding to the distribution of the highly concentrated (10,000/μm^2) ACh receptors (AChRs). The AChRs are anchored by a cytoplasmic protein called RAPsyn. During development, a soluble protein, agrin, is released from the motor nerve terminal, interacts with muscle-specific kinase (MuSK) on the postsynaptic membrane and leads to clustering of RAPsyn and the AChRs.

Neuromuscular transmission depends on the arrival of a nerve impulse which depolarizes the motor nerve terminal (Figure 48.1A). This leads to opening of the VGCCs, influx of calcium, the calcium-dependent release of many packets, or quanta, of ACh from the motor nerve terminal, and the binding of ACh to the postsynaptic AChRs. The AChRs open and allow positively charged ions to enter the muscle fiber, leading to a depolarization of the motor endplate. This results in the generation of an action potential that initiates contraction of the muscle fiber. The release of ACh is stopped when the VGKCs open and the motor nerve repolarizes. Meanwhile, ACh is hydrolyzed by acetylcholine esterase (AChE), which is present in the basal lamina between the motor nerve and the postsynaptic membrane and in the secondary clefts (which are particularly long in humans).

Neuromuscular transmission defects can be caused in two main ways: a reduction in the amount of ACh released or a reduction in the number of AChRs. In both cases, increasing the duration of action of ACh by inhibition of AChE can be a helpful symptomatic treatment. In addition, a reduction in the number of VGKCs leads to an increase in ACh release and muscle hyperactivity. Each of these situations can arise as the result of the presence of autoantibodies directed towards the AChRs or voltage-gated ion channels.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

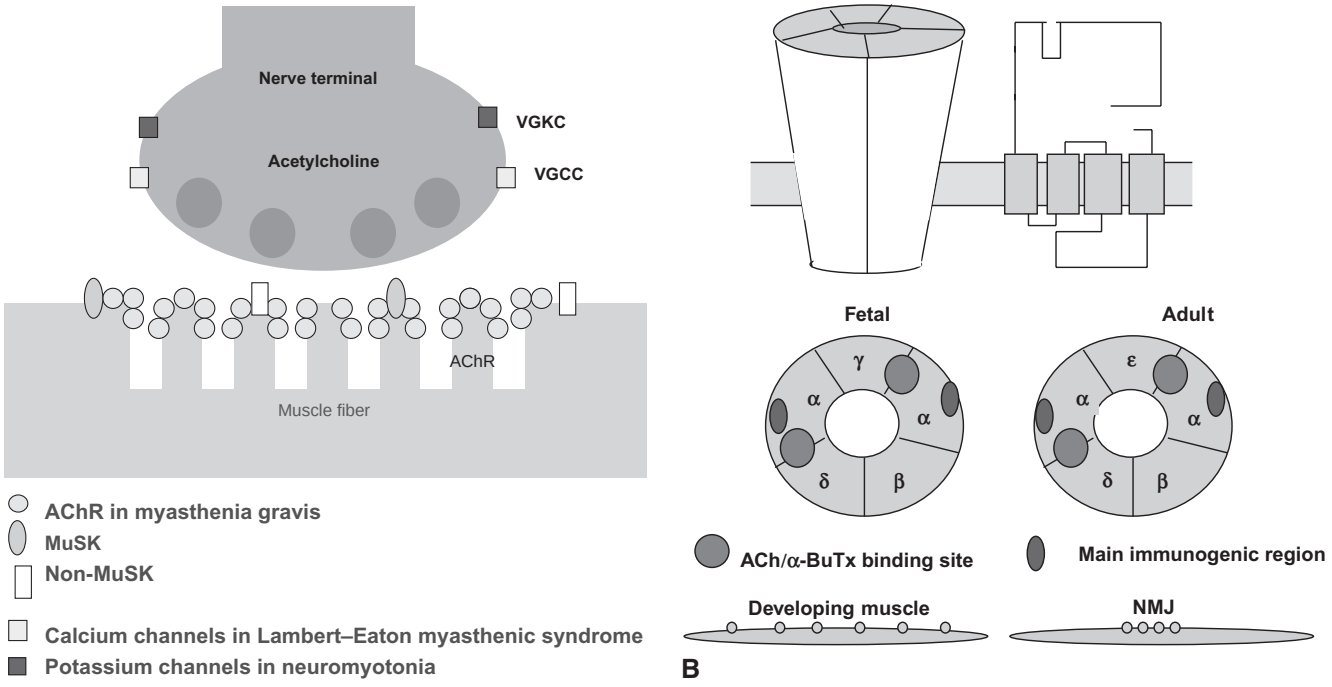

FIGURE 48.1 Ion channel targets for autoantibodies at the neuromuscular junction (NMJ). *A*, Neuromuscular transmission depends on the calcium-dependent release of vesicles of acetylcholine (ACh). ACh binds to the ACh receptors (AChRs) on the postsynaptic membrane, resulting in a depolarization. If depolarization reaches a critical threshold, an action potential is initiated in the muscle, leading to contraction. ACh is immediately destroyed by acetylcholinesterase. AChRs, voltage-gated calcium channels (VGCCs), and voltage-gated potassium channels (VGKCs) are all targets for antibody-mediated neurologic diseases. Recently, the receptor muscle-specific kinase (MuSK) has been found to be a target for antibodies in a proportion of patients with myasthenia gravis (MG) without AChR antibodies. *B*, The AChR is a transmembrane protein with $(\alpha)_2,\beta,\gamma,\delta$ subunits in the fetal form and $(\alpha)_2,\beta,\delta,\varepsilon$ subunits in the adult form. A high proportion of antibodies in MG bind to the main immunogenic regions that are on both the α subunits. In addition, many patients' antibodies bind to the fetal-specific γ subunit. In some cases, antibodies that inhibit the function of the fetal form, selectively cross the placenta, causing fetal muscle paralysis with severe and often fatal deformities. α-BuTx, α-bungarotoxin.

In this chapter, myasthenia gravis will be discussed as the model antibody-mediated disease, and the newer neurologic diseases will be reviewed only briefly.

PERIPHERAL DISORDERS ASSOCIATED WITH ANTIBODIES

Myasthenia Gravis

Historic Background

Table 48.1 lists some of the landmarks of myasthenia gravis (MG) research, which are also reviewed by Vincent and Drachman (2002) and Vincent (2002). Early studies on MG indicated that the muscle weakness was associated with a defect in neuromuscular transmission (Jolly, 1895) and that the symptoms of MG were partially reversed by AChE inhibitors (Walker, 1934). The special involvement of the thymus in MG was demonstrated by the improvement that followed removal of the gland during thyroid surgery by Ernst Sauerbruch in 1913 (Sauerbruch et al., 1913) and the surgical treatment of a patient with thymoma (Blalock et al., 1939).

In 1905, Buzzard reported collections of lymphocytes—"lymphorrhages"—in MG patients' muscles and suggested that MG might be due to "autotoxicity." However, the most dramatic advances in understanding the pathophysiology of MG were not made until the 1960s and 1970s. Nastuk et al. (1960) and Strauss et al. (1960) proposed an autoimmune basis for the disease and examined the role of complement. The occurrence of MG in young females, its association with other autoimmune diseases, the presence of thymic pathology, and the transfer of MG from mothers to their neonates, leading to a reversible "neonatal MG," led Simpson (1960) to propose that MG was an autoimmune disease with antibodies directed against an "endplate" protein. Subsequent studies by Elmqvist et al. (1964) showed that the miniature endplate potentials (MEPPs) were substantially reduced at the endplates from MG muscle biopsies, compared with control biopsies. (MEPPs are the small postsynaptic depo-

TABLE 48.1 History of myasthenia gravis (MG) research

Date	Key observation	Reference
1672	Thomas Willis publishes what is arguably the first clinical description of MG	Willis (1672)
1895	Jolly shows that defect is at the neuromuscular junction	Jolly (1895)
1913; 1939	Thymectomy appears to produce clinical improvement in patients with thymoma or nonthymomatous MG	Sauerbruch et al. (1913); Blalock et al. (1939)
1934	Mary Walker demonstrates the effectiveness of cholinesterase inhibitors as treatment	Walker et al. (1934)
1960	Simpson proposes that MG is caused by antibodies to an "endplate" protein	Simpson (1960)
1962	The snake toxin, α-bungarotoxin, can be used as a label for acetylcholine receptors at the neuromuscular junction	Chang and Lee (1962)
1964	Elmqvist et al. show that the miniature endplate potentials are reduced in MG	Elmqvist et al. (1964)
1971	Several groups begin to purify acetylcholine receptors (AChRs) from electric organs of electric rays using affinity chromatography on neurotoxin columns	
1973	Immunization against purified electric ray AChRs leads to an experimental autoimmune MG (EAMG) in rabbits	Patrick and Lindstrom (1973)
1973	AChRs are reduced in number at neuromuscular junctions, as determined by ^{125}I-α-bungarotoxin binding	Fambrough et al. (1973)
1975	MG can be passively transferred to mice by injection of patients' IgG	Toyka et al. (1975)
1976	MG patients have AChR antibodies as shown by radioimmunoprecipitation of ^{125}I-α-bungarotoxin-labeled AChRs	Lindstrom et al. (1976a)
1976–1978	Plasma exchange produces striking clinical improvement in MG, which correlates inversely with AChR antibody levels	Pinching et al. (1977), Newsom-Davis et al. (1978)
1977	IgG and complement are present at the neuromuscular junctions in MG patients and in mice with EAMG	Engel et al. (1977)
1980	MG can present with different HLA, thymic pathology, age at onset, and muscle antibodies	E.g.; Compston et al. (1980)
1981	The MG thymus contains plasma cells making AChR antibody	Scadding et al. (1981)
1977–present	Experimental autoimmune model used to determine pathogenic and immunologic mechanisms	
1984–present	Study of T cells from MG patients and their responses to AChR epitopes	

larizations that occur each time a packet of ACh is released spontaneously.) In theory, the cause of this reduced MEPP could be either presynaptic (less ACh released) or postsynaptic (fewer AChRs). However, at that time, there was no way of measuring directly the concentration of AChRs, and it was several years before a method was recognized. In 1973, Fambrough et al., using the snake toxin α-bungarotoxin (α-BuTx) that binds specifically to AChRs (Chang and Lee, 1962), showed that the number of AChRs was reduced in MG. The same year, Patrick and Lindstrom (1973) showed that immunization against affinity-purified AChRs induced weakness and paralysis in rabbits that, like MG, was responsive to AChE inhibitors. It was then relatively simple to show that AChR antibodies were present in MG patients (Lindstrom et al., 1976b), and that transfer of MG immunoglobulins to mice produced signs and electrophysiologic evidence of the disease (Toyka et al., 1975).

Electron microscopy of the NMJ shows an essentially normal nerve terminal but the postsynaptic membrane lacks junctional folds, there are reduced areas of contact between the presynaptic nerve terminal and the muscle membrane, and there is debris within the synaptic cleft (Engel et al., 1977). These changes are consistent with an immune-mediated attack on the postsynaptic membrane; there are only very infrequent reports of cellular infiltration and the mechanisms are now thought to be entirely antibody driven. The major pathology in MG is in the thymus gland (see below).

Clinical and Pathophysiologic Features

Myasthenia gravis (MG) is an acquired autoimmune disorder in which the postsynaptic AChRs are reduced in number or function, leading to muscle fatigue and weakness. The weakness often starts in the eye muscles, resulting in double vision and ptosis (drooping eyelids), but may involve any muscle group. MG is frequently associated with thymic abnormalities, so-called thymitis, in around 60% and thymoma in around 10% of patients. The clinical features are reviewed in more detail by Vincent and Drachman (2002) and Vincent et al. (2001).

Pathogenic Role and Mechanisms of Action of Acetylcholine Receptor Antibodies

The AChR antibodies were first measured by immunoprecipitation of ^{125}I α-BuTx-labeled AChR in detergent extracts of human muscle (Lindstrom et al, 1976a), but most current assays employ AChRs extracted from muscle-like cell lines that express a mixture of fetal and adult AChRs (Figure. 48.1B) (Beeson et al., 1996). Enzyme-linked immunosorbent assay (ELISA) and other alternative assays

have not proved successful. AChR antibody titers are highly variable among MG patients, ranging from 0 to >1000 nm/L, and between individuals titers do not correlate well with clinical severity, although the level of antibody within an individual correlates well with clinical scores after plasma exchange (Newsom Davis et al., 1978), thymectomy (Vincent et al., 1983; Kuks et al., 1991), or immunosuppressive treatment. The presence of anti-AChR antibody is diagnostic for MG and the levels reflect the severity of the disease within an individual; however, by itself this does not prove that the antibodies cause the disease. Nevertheless, MG fulfills the criteria of Witbesky: the presence of antibodies to a defined antigen, the induction of disease experimentally by immunization with the purified antigen (Patrick and Lindstrom, 1973), and transfer of such disease to naïve litter mates by injection of serum (Lindstrom et al, 1976a); transfer by patient's serum (Toyka et al., 1975), and the demonstration that these antibodies are involved in the pathology of the human disease (Rose and Bona, 1993). The beneficial effects of plasma exchange and immunosuppression provide further confirmation.

Information concerning the mechanisms of action of the antibodies came from Engel et al. (1977; Engel and Arahata, 1987) who showed that IgG and complement components are present at the NMJ, both on the postsynaptic membrane and in the synaptic debris; the distribution of IgG corresponds well with the distribution of AChRs, as shown by peroxidase α-BuTx binding; and the amount of membrane attack complex is inversely related to the number and density of AChRs.

In addition, the divalent antibodies can cross-link the AChRs, leading to their internalization and degradation. Drachman et al. (1978) and Stanley and Drachman (1978) showed that the rate of AChR degradation in cultured cell lines was increased several fold. It was particularly striking that *in vivo* the half life for AChRs at the NMJ was reduced from about 10 days to less than 5 days. However, there may be a compensatory increase in AChR synthesis, as shown in experimental studies of AChR turnover (Wilson et al., 1983) and in raised mRNA levels for AChR subunits in MG (Guyon et al., 1994) and in experimental autoimmune myasthenia gravis (EAMG) (Asher et al., 1990).

Only a few investigators have described direct functional effects of serum or an IgG preparation on the amplitudes of MEPPs *in vitro* (Burges et al., 1990), although MG sera can acutely reduce AChR function in cultured human cells (Lang et al., 1988). Antibodies specifically inhibiting fetal AChRs were found in two mothers with a history of recurrent fetal arthrogryposis (see below). Potential mechanisms of functional antibodies are discussed in Chapter 17.

The Acetylcholine Receptor and Antibodies

The AChR is an oligomeric membrane protein with five subunits: (α^2, β, γ, and δ in embryonic or denervated muscle, and α^2, β, δ, and ε at the adult endplate (Figure 48.1B)). The AChR has not been crystallized for structural studies (this is very difficult for multimeric membrane proteins), but studies by Unwin (2002) have demonstrated many of the features of the molecule.

AChR antibodies are heterogeneous in their characteristics both within and between individual MG patients. The antibodies have variable light chain and IgG subclass, although IgG1 predominates in most patients (Vincent et al., 1987). In many patients, a high proportion of the anti-AChR antibody competes with monoclonal antibodies directed toward the main immunogenic region (MIR) on the α subunits, which is the epitope to which a majority of experimentally-induced antibodies bind (Tzartos et al., 1980; 1982; 1998). However, some antibodies bind to other sites (Whiting et al., 1986), which appear to be on other AChR subunits (Jacobson et al., 1999a).

The antibodies are highly specific for the intact human autoantigen and bind badly or not at all to denatured AChR subunits or recombinant polypeptides. Their high affinity (around 10^{10} M) and specificity for the human AChR suggest that the antibodies are induced by some form of the native AChR molecule (Vincent et al., 1987; 1998a).

There have been few reports of monoclonal antibodies derived from immortalized AChR-specific MG cells, owing to the low precursor frequencies and to the difficulty in obtaining stable IgG-secreting, rather than IgM-secreting, hybrids or Epstein–Barr virus (EBV)-transformed lines. On the other hand, phage-display techniques have produced high-affinity Fabs that bind to human AChR and compete with monoclonal AChR antibodies (Graus et al., 1997; Farrar et al., 1997; Matthews et al., 2002).

Clinical Heterogeneity

Myasthenia is not a single disease. In the majority of MG patients, generalized weakness with AChR antibodies develops after puberty, without obvious precipitating factors. Patients are divided in terms of their age at onset into early and late onset, after separating out those patients who have a thymic tumor (thymoma). This division exposes the different thymic pathology and HLA associations in early- and late-onset patients (Table 48.2) (Compston et al., 1980), and it seems likely that these two subgroups reflect different precipitating factors, rather than an intrinsic difference in the patients' immune responses to a single precipitating factor. In addition, many non-HLA immunogenetic associations have been reported in MG, suggesting that polymorphisms in other immune mediators are important (Hjelmstrom et al., 1997; 1998), but few of these studies have divided the patients into the subgroups described in Table 48.2, and the associations are often weak and not always reproducible.

TABLE 48.2 Myasthenia gravis patients divided on the basis of age at onset, thymic pathology, HLA association, and associated autoantibodies

Subtype*	Age at onset	Sex M : F	Typical thymic pathology	HLA association	Associated autoantibodies
Early onset	<41 years	1 : 3	Thymitis	B8, DR3	May have other tissue antibodies, e.g., thyroid,
Thymoma associated	Mainly 40–60 years	1 : 1	Epithelial tumor containing many lymphocytes	No clear association	Titin and ryanodine receptor antibodies very common. Also cytokine antibodies
Late onset	>40 years	1.5 : 1	Normal or atrophied	B7, DR2 in males	Titin and ryanodine receptor antibodies common, particularly after age 60 years
AChR antibody negative MuSK antibody positive	2–70 years	1 : 3	Normal or atrophied in most	Not known	Not clear
AChR antibody negative MuSK antibody negative	1–80 years	2 : 3	Mild thymitis in some	Not known	Not clear

*These subtypes are not appropriate in patients with purely ocular MG and in other ethnic populations.

There are also patients without detectable AChR antibodies, some of whom have antibodies to MuSK. In addition, there are patients with purely ocular myasthenia; whether these have a distinct form of disease is not altogether clear. The patients with AChR antibodies and generalized MG will be considered first, divided into the three main subgroups shown in Table 48.2.

Early-Onset Acetylcholine Receptor-Positive Myasthenia Gravis

These patients present before 40 years of age and frequently have thymitis. In Northern Europeans, there is a strong association with the HLA A1 B8 DRB1*0301 DRB*0101 DQB1*0201 DQA1*0501 ancestral haplotype (Carlsson et al., 1990; Viera et al., 1993).

Involvement with a particular AChR α subunit microsatellite, i.e., a noncoding region of the gene, has also been reported (Garchon et al., 1994) and this may be associated with the DRB1*0301 (Djabiri et al., 1997). This raises the possibility that polymorphisms in gene regulatory sequences that increase AChR expression lead to presentation of AChR by DRB1*0301 to a susceptible immune system. Alternatively or in addition, AChR coding sequence polymorphisms or heteroallelic mutations might result in abnormal antigen processing. For instance, a single case report of MG arising in a woman who had a recessive inherited form of myasthenia, with heteroallelic AChR mutations, suggested that clinically-silent AChR mutations on a single allele might predispose to development of the autoimmune disease (Croxen et al., 2002). However, preliminary investigations in a large number of early-onset MG patients have not proved fruitful (Bonifati et al., 2004).

Although the pathogenic autoantibodies depend on class II-restricted helper T (Th) cells, the associations are stronger with B8 than with DR3 (Compston et al., 1980), and the hot spot appears to be between the class II and class I region. Various possibilities, such as genes for tumor necrosis factor (TNF), heat-shock proteins, and transporter proteins associated with antigen processing (TAP) have been considered (Janer et al., 1999), but it is still not clear which gene is responsible for conferring susceptibility.

In early-onset MG the thymus gland often contains T-cell areas in the medulla, some containing lymphoid follicles (Levine and Rosai, 1978; Hohlfeld and Wekerle, 1994). Lymphocytes cultured from the thymus gland synthesize anti-AChR antibody (Scadding et al., 1981), and serum anti-AChR levels frequently decline slowly after thymectomy (Vincent et al., 1983). Germinal centers of the MG thymus contain polyclonal activated B cells expressing a range of V_H and V_K genes, similar to those in the peripheral blood lymphocytes (Guigou et al., 1991) and somatic hypermutation of B-cells occurs in thymic germinal centers (Sims et al., 2001). These findings suggest that B cells somatically mutate and mature in these germinal centers, but that similar B cells are present in the periphery. It is not clear, therefore, whether or not the disease starts in the thymus. In favor of this possibility, the thymus contains the antigen, AChR, on muscle-like "myoid" cells in the thymic medulla (Kao and Drachman, 1977; Wekerle and Ketelsen, 1977; Schluep et al., 1987), and sometimes in the germinal centers themselves. Careful examination of the pathology suggests that the myoid cells are targets for autoantibody attack and that this provokes germinal center formation (Roxanis et al., 2002). Moreover, some of the germinal centers can be shown to bind AChR, suggesting that they contain many AChR-specific B cells. But whether or not germinal center formation is a primary event in the disease, or occurs secondary to the autoimmune response, is still not clear.

In fact, molecular studies show that all five AChR subunits, including a differentially spliced isoform, are expressed in MG thymuses (Andreetta et al., 1997), and AChR may be expressed not only in the myoid cells but also in thymic epithelia (Salmon et al., 1998). The presence of AChR in normal as well as MG thymus suggests that it may be involved in inducing T-cell tolerance in normal individuals or in breaking tolerance in MG, but why the latter occurs in MG is still unknown.

It is widely believed that the thymus in MG generates AChR-specific T-cells that direct antibody synthesis by B cells both in the germinal centers in the thymus and elsewhere. Since the antibody response in MG is thought to be directed towards the native AChRs, the T cells should be able to recognize AChR taken up and presented by AChR-specific B cells. Many studies have looked at T-cell responses, lines and clones, generated from peripheral blood lymphocytes or thymic suspensions and stimulated either with AChR peptides or with recombinant or purified AChR (Hawke et al., 1996; Conti-Fine et al., 1998). The rare T cells generated against recombinant polypeptides frequently respond to very small amounts of purified AChR antigen, processed and presented by appropriate antigen-presenting cell (APC), as well as to the relevant smaller peptides, suggesting that they could recognize the autoantigen *in vivo*. Conversely, the much more plentiful T cells that can be generated against synthetic AChR peptides do not appear to respond strongly to purified AChR. These results question the relevance to the disease of the T-cell responses generated against antigenic peptides rather than against native antigen or larger recombinant fragments.

Muscle does not normally express MHC class II, but there is evidence that MHC class II can be induced by viral infections *in vivo* (Bao et al., 1992) or by interferon (IFN)-γ *in vitro* (Hohlfeld and Engel, 1990). The possibility that the T-cell response is initiated or perpetuated by presentation of AChR peptides by class II on nonprofessional presenting cells has been addressed. T-cell clones specific for AChR α144–163 recognized AChR endogenously presented by the TE671 muscle cell line after it was transfected with DNA for the α and β chains of DR4.Dw4.2, or by human myotube cultures stimulated with IFN-γ (Baggi et al., 1993; Curnow et al., 2001). The responding T cells showed only modest proliferation, but bound to the presenting cells, secreted IFN-γ, and killed the presenting cells.

Late-Onset Acetylcholine Receptor Antibody Positive Myasthenia Gravis

Recent surveys of AChR antibodies in sera sent for routine diagnosis have shown a striking increase in incidence after the age of about 60 years, peaking in the late 70s (Vincent et al., 2003a). Even when the declining numbers of the population are taken into account, there is a fall off in diagnosis of MG after the age of 75 years, which suggests that MG is being underdiagnosed in the elderly. In patients who present with symptoms of MG after the age of 40 years, the thymus is mainly atrophic or involuted, and there are weak biases toward males and HLA B7, DR2 (Compston et al., 1980) or DR4, DQw8 (Carlsson et al., 1990). These patients do not have a thymoma (by definition), but nevertheless are often positive for antibodies to titin, ryanodine receptor, and cytokines (Aarli, 2001; Buckley et al., 2001b; Somnier and Engel, 2002). The cause of the disease is entirely unknown, and given its increasing incidence, more efforts should be directed towards defining immunogenetic and environmental factors that might predispose to the development of this condition.

Thymoma-Associated Myasthenia Gravis

Thymoma, which occurs in about 10% of patients in reported studies (a figure that may need to be revised with the increasing number of older patients) can arise at any age, but most patients with MG and thymoma present between the ages of 30 and 60 years. The thymus gland is usually removed, but the myasthenia rarely improves (Palmisani et al., 1994; Somnier, 1994), anti-AChR levels seldom fall (Kuks et al., 1991), and immunosuppressive therapy is often required. HLA associations have been reported in single studies but no consensus has emerged. Thymomas associated with MG are epithelial in origin, corresponding mainly to the World Health Organization type B1 and B2 (Muller-Hermelink and Marx, 2000).

The thymus adjacent to a thymoma often shows changes of thymitis, and a few B-cells are present in thymoma tissue. However, anti-AChR synthesis by thymoma cells is rare (see above), contrasting with that which occurs in early-onset thymuses and suggesting that the thymoma tissue does not initiate and/or sustain the antibody response to this antigen. However, >90% of patients with thymoma have antibodies to antigens of striated and cardiac muscle (Aarli, 2001). These include myosin, actin, α-actinin, ryanodine receptor, and a particular epitope on the giant structural protein titin (Gautel et al., 1993). Both titin and ryanodine receptor epitopes are expressed in cortical thymomas (Mygland et al., 1995; Marx et al., 1996; Romi et al., 2002), although there is some question as to their relevance (Kusner et al., 1998). In addition, and surprisingly, antibodies to the cytokines, IFN-α and interleukin (IL)-12, are also present in both thymoma-related MG patients and older MG patients (Meager et al., 1997), and in the former may predict the recurrence of a thymoma (Buckley et al., 2001b). Both cytokines are expressed by immune cells (probably macrophages; Y. Kadota and N. Willcox, personal communication) in thymoma. Moreover, B cells from MG thymoma tissue synthesize IFN-α antibodies in culture, and IFN-α-specific IgG Fabs can be cloned and expressed by combinatorial library techniques from B cells present in thymoma tissue (Shiono et al., 2003). These observations support the

idea that the thymoma can initiate and sustain the B-cell response to certain antigens, such as IFN-α and IL-12.

Cultured neoplastic epithelial cells from thymomas express epidermal growth factor receptor and Ki67, indicative of their growth potential (Gilhus et al., 1995a). Interestingly, CD80 expression is high in thymoma epithelial cells in comparison with those in normal cortex, indicating the potential for these cells to activate T-cell responses (Marx et al., 1994). Moreover, these cells can process and present antigens to class II restricted T cells (Gilhus et al., 1995b), indicating that they express both the appropriate class II molecule and the necessary processing apparatus and accessory molecules. However, functional AChR does not appear to be present in thymoma tissue; the AChR α subunit is present but only at very low levels in the thymoma tissue itself, as identified by polymerase chain reaction (Hara et al 1991; Geuder et al 1992).

The typical MG thymoma contains large numbers of polyclonal developing T-lymphocytes, many double positive for CD4 and CD8 and others with the single markers of maturing T cells (Fujii et al., 1990). The number of T cells is often drastically depleted owing to preceding steroid therapy (Willcox et al., 1989). The remaining lymphocytes might either escape deletion in the disorganized cortical epithelium, or be specifically sensitized to antigens presented and expressed by the thymoma epithelium. Although studies on specific T cells have been difficult, there is no doubt that the thymoma does generate potentially functional T cells. The proportion of both CD4 and CD8 T cells containing TRECs (T-cell receptor excision circles), which gives an indication of the number of T cells recently emigrated to the periphery, is greatly raised in thymoma MG cases and falls after thymomectomy (Figure 48.2) (Buckley et al., 2001a). By contrast, TRECs are only slightly increased in patients with early-onset MG, and are not increased in patients with late-onset MG, indicating that they are not just the result of thymic perturbation. Moreover, they rise again in thymoma cases if the tumor recurs (Figure 48.2). On the other hand, double-negative $CD4^-/CD8^-$ T cells were not abnormal in thymoma cases and did not change after surgery (Reinhardt and Melms, 2000).

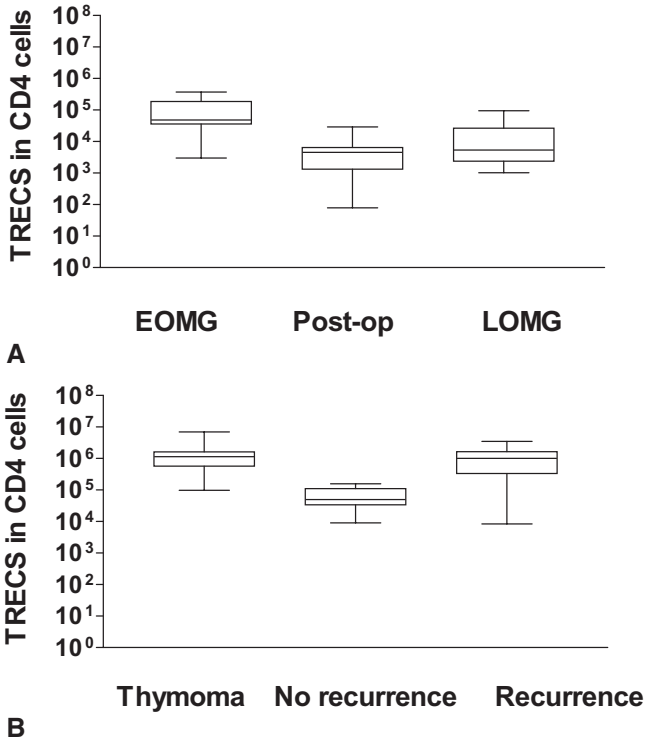

FIGURE 48.2 Thymomas export large numbers of T cells to the periphery. The number of T-cell receptor excision circles (TRECS) in peripheral $CD4^+$ T cells from patients with different forms of myasthenia gravis (MG). *A*, TREC levels in CD4 cells from patients with early-onset MG (EOMG), late-onset MG (LOMG), and appropriate post-operative controls who are age matched for each group. There are no significant differences between patients and controls. *B*, TREC levels in CD4 cells from patients with thymoma and MG on the day of their operation (thymoma), and a mean of 10 years after thymomectomy for patients who either had no evidence of recurrence (no recurrence) or had a recurrence of their tumor (recurrence). The mean ages were equivalent for each group. Results are presented as box and whisker plots.

Neonatal Myasthenia Gravis and Arthrogryposis Multiplex Congenita

A proportion of babies born to MG mothers have transient respiratory and feeding difficulties, owing to transplacental transfer of maternal anti-AChR. These problems may be more common in the offspring of mothers who have a high proportion of antibodies reactive with fetal-type AChR (Vernet der Garabedian et al., 1994), although the fetal form is thought to be replaced by the adult form from around 33 weeks' gestation. Occasionally, neonatal MG occurs without maternal disease or when the mother is anti-AChR negative.

A few cases of severe arthrogryposis multiplex congenital have been found in a number of consecutive pregnancies in mothers with MG. Arthrogryposis is a condition that develops during intrauterine life as a result of lack of fetal movement. The baby is born with fixed joint contractures, which can be associated with inadequate development of lungs and failure to survive after birth. Maternal anti-AChR antibodies, which even at high dilution completely inhibit the function of fetal AChR (see Figure 48.1B) in an *in vitro* assay, but have no affect on adult AChR function, were present in these mothers (Polizzi et al., 2000). Moreover, AChR-specific Fabs were relatively easy to select from the combinatorial libraries prepared from the mothers and were highly specific for fetal AChR (Matthews et al., 2002). These antibodies appeared to be responsible for the complete loss of fetal movement *in utero* and the subsequent deformities that are incompatible with survival after birth. An animal model of this condition has been induced

by injecting the maternal plasmas into pregnant mice (Jacobson et al., 1999b).

Etiology of Acetylcholine Receptor-Positive Myasthenia Gravis

It is clear from the above discussion that there are probably different etiologies for the different subgroups of MG, and that little is still known about the precipitating factors. During the 1980s there were several reports of idiotypic networks involving AChR antibodies, but these findings have not been pursued. Other evidence for molecular mimicry between the *Torpedo* AChR α subunit and microbial proteins, and between human AChR α157 170 and herpes simplex glycoprotein D, have also not been followed up [for a review see Vincent et al. (1998)]. In general, it seems unlikely that cross-reacting antibodies could demonstrate the heterogeneity, high affinity, and specificity that characterize MG anti-AChR. Nevertheless, such a cross-reaction could be an initiating event that leads subsequently to autosensitization against the muscle AChR by a process of determinant spreading. Such a process has been demonstrated in a rabbit model (see Vincent et al., 1998).

Animal Models

The experimental autoimmune myasthenia gravis (EAMG) model was important in stimulating the search for AChR antibodies in MG, but will not be discussed in any detail here [see Lindstrom (2000) and Christadoss et al. (2002) for reviews].

The AChR is very immunogenic. Rats and mice can mount strong immune responses even to syngeneic AChR in the absence of adjuvant (Jermy et al., 1993). It is important to realize that the proportion of antibodies that cross-react between the immunizing protein and the recipient's muscle AChR depends on the closeness of the species, whereas the clinical effects of immunization depend mainly on the susceptibility of the immunized animal's NMJs to changes in AChR numbers. Studies on inbred rodents demonstrated the importance of immunogenetic factors in the susceptibility to EAMG. C57B1/6 mice and AKR mice are the most susceptible mouse strains, correlating with H-2^b and Ig-1^b, respectively, whereas BALB/c strains are relatively resistant (Berman and Patrick, 1980; Christadoss et al., 1979). The basis for these differences in susceptibility, however, is still not clear. It does not relate to the serum antibody levels (Berman and Patrick, 1980), or to intrinsic muscle factors. The I-A^{bm12} mutation in C57B1/6 mice confers resistance to EAMG, probably by changing the T-cell repertoire and preventing recognition of α146–162, a dominant T-cell epitope (Biesecker and Koffler, 1988). Detailed analysis of the role of class II and T-cell receptor (TCR) genes in EAMG is provided elsewhere (Kaul et al., 1994). Recently, EAMG has been induced in mice deficient for cytokines or accessory molecules, or treated with soluble forms of these substances. In general, the results demonstrate the involvement of Th1-dependent mechanisms in the pathogenic immune response to AChR. For instance, not surprisingly, these studies have shown that CD28–CD80 and CD154 (CD40L)–CD40 interactions are important, and that IFN-γ is essential for the full immune response, whereas IL-4 does not play a major role. Mice deficient in IL-6, by contrast, are less likely to develop EAMG and show less germinal center formation (Christadoss et al., 2000).

The experimental model continues to be used for testing approaches to specific treatments for MG, despite the fact that the relevance of the animal model to the human disease must be limited. Many of these approaches are reviewed elsewhere (Christados et al., 2000; Vincent and Drachman, 2002).

Myasthenia Gravis Without Acetylcholine Receptor Antibodies

About 10–15% of all MG patients with generalized symptoms do not have detectable anti-AChRs. Traditionally they have been termed as having "seronegative MG (SNMG)." Their symptoms are similar to those of patients with AChR antibody "seropositive" generalized MG, but there are some subtle differences (Vincent et al., 2003b). An important feature is the relative lack of thymic changes in most of these patients (Willcox et al., 1991; Verma and Oger, 1992). Thymoma is never found, and no HLA association has been identified. Thus, on clinical and pathologic grounds, the disease appears to have several unusual features.

SNMG is clearly an antibody-mediated disease because patients get better with plasma exchange, and passive transfer to mice results in defects in neuromuscular transmission (Vincent et al., 2003b). However, the actual mechanism by which the antibodies cause these defects is not clear. A series of studies indicated that SNMG is likely to be heterogeneous. Some patients have an IgG antibody to MuSK (Figure 48.3) (Hoch et al., 2001; Scuderi et al., 2002). MuSK is the receptor tyrosine kinase that is essential for clustering AChRs during development. Interestingly, the antibodies are not found in patients with AChR antibody-positive MG, in patients with purely ocular MG, or in other control groups, and thus they define a distinct form of MG (McConville et al., 2004). They appear to be found often in patients with marked combined ocular and bulbar symptoms (Scuderi et al., 2002). How these antibodies affect neuromuscular transmission is not clear, but given the role of MuSK during development (Liyanage et al., 2002), it is likely that they interfere with some aspect of MuSK signaling and alter

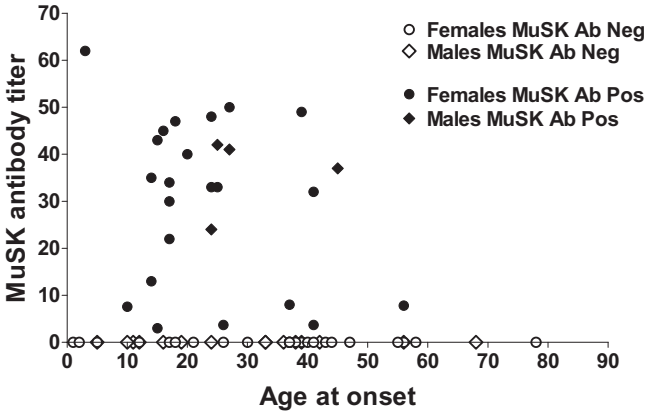

FIGURE 48.3 Muscle-specific kinase (MuSK) antibodies in patients without acetylcholine receptor (AChR) antibodies. MuSK antibody titers (in nmoles of ^{125}I-MuSK precipitated/L of serum, solid symbols) in patients with myasthenia gravis related to sex and age at presentation. MuSK antibodies are found mainly in young women. One patient presented at age 2 years with very high titers. MuSK-antibody negative patients (open symbols) present at any age and are both male and female. Many patients are negative for MuSK antibodies.

AChR localization or stability. Interestingly, the MuSK antibodies are predominantly IgG4 with smaller amounts of IgG1 and IgG2 (McConville et al., 2004). This contrasts with the AChR antibodies (see above), further emphasizing the differences between AChR antibody-positive and MuSK antibody-positive MG.

In some SNMG patients, including those with and without MuSK antibodies, an IgM-containing fraction inhibits AChR function in the muscle-like TE671 cell line. This inhibition is rapid and reversible, and may be linked to AChR desensitization (Plested et al., 2002; Spreadbury et al., 2005), but the target of these antibodies is not yet clear.

Lambert–Eaton Myasthenic Syndrome

In 1957 Eaton and Lambert described a myasthenic syndrome that was electrophysiologically distinct from MG (O'Neill et al., 1988). Subsequent studies showed that the defect was a reduction in the number of packets of ACh released per nerve impulse, contrasting with MG in which the defect is in the number of AChRs. Lambert–Eaton myasthenic syndrome (LEMS) is often associated with small cell lung cancer (SCLC), and is also sometimes found with paraneoplastic cerebellar degeneration and paraneoplastic encephalomyelitis. Thus, LEMS is a member of the expanding family of paraneoplastic neurologic conditions that can be associated with CNS disease (see Chapter 68). However, about 50% of patients never develop a tumor and have an acquired autoimmune disease of unknown etiology.

There are certain features of LEMS that contrast with those in MG. First, there is more prominent involvement of lower limb muscles and less significant involvement of ocular muscles in LEMS. Second, muscle strength improves after maximal voluntary contraction and third, autonomic features, such as dry mouth, constipation and impotence are common.

Pathophysiology

Freeze-fracture electron microscopic studies of motor nerve terminals in healthy human muscle biopsy samples reveal, as in other species, double parallel rows of intramembranous particles (each about 10^{-2} nm in diameter). These particle arrays are associated with the presynaptic active zones that are known to be close to the site of exocytosis of the transmitter (see Figure 48.1). The particles themselves (active zone particles) appear to represent voltage-gated calcium channels that are known to be important for ACh release (see above). Engel and colleagues found a highly significant reduction in the number of active-zone particles and the number of particles per active-zone in LEMS patients, and an increase in the number of clusters of particles (Engel et al., 1989; Engel, 1991).

Autoimmunity

Many LEMS patients, particularly those without a tumor, have other autoimmune disorders or organ-specific autoantibodies (Lennon et al., 1982), and an increased association with HLA-B8 and IgG heavy chain markers (Demaine et al., 1988). The evidence for an antibody-mediated pathogenesis followed the paradigms outlined above. Plasma exchange was clinically effective with the maximal response occurring about 10 days after the treatment. Patients also respond well to immunosuppressive drugs or intravenous immunoglobulin (IVIG) therapy (O'Neill et al., 1988).

Daily injection of LEMS plasmas or IgG fractions into mice reproduced the principal neurophysiologic changes of LEMS (Lang et al., 1983; Kim, 1985), although there was little clinical evidence of disease. However, there were changes in the number and clustering of active-zone particles, similar to those found in patients. Interestingly, complement did not seem to be involved as C3-deficient mice were as susceptible as normal mice (Prior et al., 1985), and purified IgG was as effective as plasma. In most cases, acute incubation in LEMS sera or IgG (1–3 h) did not affect neuromuscular transmission, indicating that the antibodies did not inhibit function directly.

The clustering of the active zone particles suggested that the divalent antibodies were acting by cross-linking adjacent particles (Fukuoka et al., 1987), and the importance of divalent antibodies was confirmed by studies on monovalent Fab′ (Peers et al., 1993).

Using a sensitive immunoelectron microscopy technique, Engel et al. (1989) localized IgG at the sites of presynaptic active zones in mice that had received multiple intraperitoneal doses of LEMS IgG. The amount of IgG detected was small, reflecting the low number of active zone particles and their restricted localization.

Voltage-Gated Calcium Channel Antibodies

The data above strongly suggested that the active zone particles, thought to be voltage-gated calcium channels (VGCC), were the target for the LEMS antibodies. Moreover, it was known that SCLC cells express VGCCs on their surface. Roberts et al. (1985) showed that the function of these VGCCs were reduced when the cells were grown for several days in the presence of LEMS IgG.

The cone snail derived toxin ω-conotoxin (ω-CmTx) MVIIC binds to the P or Q type VGCCs that are involved in ACh release at the NMJ. Solubilized VGCCs prelabeled with ^{125}1 ω-CmTx can be immunoprecipitated by 80–90% of LEMS sera (Lennon et al., 1995; Motomura et al., 1995). A direct relationship between the anti-VGCC antibody titer and clinical severity was demonstrated in a longitudinal study on individuals receiving immunosuppressive therapy, and after a double-blind cross-over trial of IVIG treatment in eight LEMS patients (Bain et al., 1996). Of note, the clinical improvement and fall in VGCC antibodies that followed IVIG treatment were delayed, and there was no evidence that the injected immunoglobulins were anti-idiotypic.

Autonomic dysfunction is common in LEMS, suggesting that LEMS IgG may interfere with neurotransmission at autonomic synapses. Mice injected with LEMS IgG show reduced smooth muscle activity (Waterman et al., 1997). However, there was no obvious clinical effect and it would be interesting to know more about the role of these channels in normal autonomic functions.

These studies in LEMS reflected many of the approaches that had already proved successful in the study of MG, emphasizing the use of experimental clinical and laboratory techniques to investigate neurologic autoimmune diseases.

Acquired Neuromyotonia

Neuromyotonia (NMT), or Isaacs syndrome (Isaacs, 1961), is a rare syndrome of spontaneous and continuous muscle fiber contraction resulting from hyperexcitability of motor nerves. Like MG and LEMS, it can be paraneoplastic when associated with thymoma or SCLC (Newsom-Davis and Mills, 1993).

Clinical Features

Clinical features include muscle stiffness, cramps, myokymia (visible undulation of the muscle), and weakness, most prominent in the limbs and trunk. Increased sweating is common. Pseudomyotonia, a slow relaxation of muscles after contraction, may also be present. For detailed reviews of the clinical and electrophysiologic findings, the reader is referred to Newsom-Davis and Mills (1993) and Hart et al. (2002). Sensory symptoms are present in some patients and CNS symptoms, such as insomnia, hallucinations, delusions, and personality change may also be present, when the condition is usually referred to as Morvan syndrome (see below).

The abnormal muscle activity is the result of neuronal hyperexcitability, which may be generated anywhere along the peripheral motor nerve (Vincent, 2000). The diagnosis can be confirmed by typical findings on electromyography (Newsom-Davis and Mills, 1993), which include high frequency spontaneous discharges, and by the detection of antibodies to VGKCs in some patients.

Autoimmunity and Antibodies to Voltage-Gated Potassium Channels

As in MG and LEMS, NMT may be associated with other autoimmune diseases or other autoantibodies, and is relatively frequently found in patients with thymoma (Hart et al., 2002). CSF analysis occasionally shows a raised total IgG level or oligoclonal bands, suggesting that there is intrathecal IgG synthesis (Newsom-Davis and Mills, 1993).

The evidence for a pathogenic antibody was demonstrated before its target was known. Patients respond to plasma exchange and immunosuppression (Sinha et al., 1991), and some signs of neuronal hyperexcitability can be transferred to mice by injection of plasma or IgG from patients with NMT (Shillito et al., 1995). Importantly, the effects seen were very similar to those with the drugs 3,4-diamino-pyridine or 4-amino pyridine, which block VGKCs.

Antibodies to VGKCs can be detected in about 40% of NMT patients by immunoprecipitation of ^{125}I-α-dendrotoxin-labeled VGKCs extracted from human frontal cortex (Hart et al., 2002), and the level of this antibody is reduced by immunosuppressive treatment. A proportion of the 60% of sera negative for these antibodies may contain antibodies to some other peripheral nerve or motor nerve terminal protein, such as the neuronal α-7 AChR (Vernino and Lennon, 2002).

As for the other diseases considered in this chapter, there is no clear information regarding the etiology of NMT. However, there are anecdotal reports of the condition occurring in association with infections and some patients seem to have a monophasic illness that recovers spontaneously within 1–2 years (A. Vincent, unpublished observations). These observations suggest that there may be specific con-

ditions, probably infections, which can lead to the development of these antibodies.

CNS DISORDERS ASSOCIATED WITH ANTIBODIES

A number of diseases are strongly associated with antibodies to neuronal antigens, and in some of these the antibodies are likely to be pathogenic. This opens a new area of antibody-mediated CNS disorders.

Glutamic Acid Decarboxylase Antibodies with Stiff-Person Syndrome, Cerebellar Ataxia, and Other Disorders

Glutamate acid decarboxylase (GAD) is the enzyme responsible for the synthesis of the inhibitory neurotransmitter, γ-aminobutyric acid (GABA), and antibodies to GAD are best known for their association with type 1 diabetes (T1D). Nevertheless, they were first detected in a patient with stiff-person syndrome (SPS) associated with diabetes (Solimena et al., 1988). SPS is a very rare condition characterized by severe muscle stiffness, particularly affecting the spine and lower limbs, with superimposed muscle spasms. The clinical picture appears to result from lack of muscle relaxation that should occur in one set of muscles when the antagonistic muscles are activated.

GAD antibodies can now be detected by immunoprecipitation of ^{35}S-labeled rabbit reticulocyte lysates expressing GAD, or of ^{125}I-recombinant GAD. The levels of GAD antibodies in patients with neurologic diseases are usually much higher than those of patients with T1D (Dalakas et al., 2001b). GAD antibodies are also found in other disorders, particularly encephalomyelitis with rigidity and myoclonus, and sporadic cerebellar ataxia (Meinck et al., 2001).

SPS is associated with other autoimmune diseases and with HLA-DR3 (DRβ1 0301) (Nicholas et al., 1997). In many cases, oligoclonal bands are present in the CSF, and the CSF antibody/CSF IgG index is higher than the serum antibody/serum IgG index, suggesting that some of the GAD antibody is actually made in the CNS (Dalakas et al., 2001b), but generally the serum levels are substantially higher than the CSF levels (Vincent et al., 1997).

The striking association of SPS with high titers of a very specific antibody, which is not present in the great majority of individuals with other neurologic disorders, suggests that the disease is immune-mediated. Moreover, one study showed clinical improvement following administration of IVIG (Dalakas et al., 2001a). However, since GAD is an intracellular antigen, it may not, itself, be the target for the pathogenic immune response. There could be other antibodies directed against cell-surface determinants that are pathogenic.

Rasmussen Encephalitis

Rasmussen encephalitis (RE) is a very rare, chronic inflammatory disease of the brain, usually occurring in young children, and characterized by intractable focal seizures. It typically involves one side of the brain only and often progresses to hemiparesis. It does not respond well to typical anticonvulsant therapy and hemispherectomy is often performed in order to stop the seizures.

A recent study detailed clinical and pathologic evidence from 13 cases with histologically proven RE (Bien et al., 2002b). After a prodromal phase, the acute phase with seizures and focal inflammatory lesions develops. This leads to permanent and stable hemiparesis with cerebral atrophy and decreased seizure frequency. The histopathology of the brains showed perivascular and parenchymal CD3 T-cells, CD68 and HLA-DR positive microglial cells and glial fibrillary acidic protein (GFAP)-positive astrocytes, the majority of which were characterized as "reactive," and neuronal cell density was reduced. In fact, the pathology of RE is not unlike that of multiple sclerosis and is consistent with a T-cell-mediated process (Bien et al., 2002a).

However, there are reports of antibodies to glutamate receptor in RE. Two of three GluR3 immunized rabbits developed seizures (Rogers et al., 1994) and postmortem examination showed inflammatory changes not unlike those in patients. GluR3 antibodies were found in sera from two of four children using Western blot and antibody-binding assays. Most significant was that one child showed a remarkable improvement after plasma exchange (Rogers et al., 1994). This latter finding has been confirmed in other patients, and a number of studies have looked at possible mechanisms by which GluR3 antibodies could cause increased neuronal excitability and seizures (Whitney and McNamarra, 1999).

Although several reports confirm the presence of GluR3 antibodies in patients with RE, some find them also in patients with other forms of intractable epilepsy (Wiendl et al., 2001), and there was little GluR3 antibody in the CSF (Mantegazza et al., 2002). Moreover, other groups have failed to find GluR3 antibodies by a range of techniques (Watson et al., 2004).

Potassium Channel Antibodies in Morvan Syndrome and a New Form of Immune-Responsive Limbic Encephalitis

Antibodies to potassium channels were first identified in patients with acquired NMT (see above), but about 20% of these patients have CNS symptoms, such as depression, anxiety, memory loss or sleep disorders (Heidenreich and Vincent, 1998; Hart et al., 2002). In a few cases, NMT is associated with autonomic dysfunction, including increased sweating, and marked CNS abnormalities, including

insomnia, hallucinations, altered behavior, and cognitive dysfunction, known as Morvan syndrome or Morvan fibrillary chorea.

Only a few cases of Morvan syndrome have been described but several recent cases have been shown to have raised levels of VGKC antibodies, and symptoms improve following plasma exchange (Liguori et al., 2001). Thymoma has been reported in around 20% of cases, sometimes with associated MG. In one case with CNS symptoms of memory loss, confusion and seizures, the seizures and cognitive dysfunction improved slowly over a period of 2 years, while VGKC antibodies spontaneously fell (Buckley et al., 2001c and Vincent et al., 2004). A recent study has reported 10 patients with similar "limbic" symptoms and highly raised VGKC antibodies, several of whom improved quite markedly following immunotherapies (Vincent et al., 2004). Interestingly, some patients have presented first to psychiatric or epilepsy clinics before developing other neurologic features (McKnight et al., 2005).

Importantly, the limbic symptoms are highly similar to those experienced by patients with paraneoplastic limbic encephalitis, which is normally considered to respond very poorly to treatments. In patients with VGKC antibodies, by contrast, tumors are not common, and the response to treatments is often good. How the antibodies gain access to the CNS, why only some patients have peripheral symptoms, and why the hippocampus is the main target will be the topics for further experimental studies.

SUMMARY

Autoimmune diseases of the nervous system are particularly interesting because they include disorders caused by highly specific antibodies directed against equally specific ion channels or receptors. The role of antibodies to the muscle nicotinic AChR in MG is well established and much is now known about the immunology of the disease. The division of MG into groups, depending on antibody status, thymic pathology, and age at onset, has been useful in defining the existence of different clinical subtypes that may result from different etiologies. Treatment includes anticholinesterases, nonspecific immunosuppression and, in appropriate younger patients, thymectomy. Despite much work in animal models of MG, no disease-specific immunosuppressive treatments are currently available. A new form of MG, associated with antibodies to MuSK, has been identified, and found to present some distinct clinical features.

The experimental approaches that led to the successful work on MG have been equally successful in demonstrating other rare diseases caused by, or strongly associated with, antibodies to different ion channels or other neuronal proteins. Antibodies to calcium and potassium ion channels are found in LEMS and acquired NMT, respectively, and to the ganglionic form of AChR in some cases of autonomic neuropathy (see Chapter 17). Antibodies to glutamic-acid decarboxylase (GAD) and to a particular form of glutamate receptor (GluR3) have been detected in SPS and RE, respectively, although their roles in causing these disorders are not yet clear. More recently, antibodies to VGKCs have been detected in a form of limbic encephalitis with memory loss, confusion, and seizures. These patients often improve with immunotherapies, suggesting an antibody-mediated CNS disorder.

The next 10 years should show an explosion of interest in antibody-associated CNS disorders, leading to improved diagnosis and the development of new experimental paradigms to demonstrate the pathogenic relevance of antibodies to CNS antigens.

CHAPTER

49

Ocular Disease

GRACE A. LEVY-CLARKE, ZHUQING LI, LEILA I. KUMP, AND ROBERT B. NUSSENBLATT

The Laboratory of Immunology, National Eye Institute, National Institutes of Health, Bethesda, Maryland, USA

HISTORIC BACKGROUND

The concept that the eye harbors autoimmune-inducing or uveitogenic materials has been suggested by many since the beginning of the last century. It was the demonstration by Uhlenhuth (1903) of autoantibody production to the lens that pioneered investigation in this area. Several investigators used homogenates from the eye, which when injected into an animal appeared capable of inducing an intraocular inflammatory response. Noteworthy of mention are Wacker and Lipton (1968) and Faure (1980).

The presence of uveitogenic antigens in the eye that are capable of inducing disease is a well-established concept, proposed as early as 1910 by Elschnig. Since then several antigens have been isolated that are capable of inducing ocular inflammatory disease similar to that seen in humans. Retinal S-antigen or arrestin was isolated and its immunologic properties partially characterized by Wacker et al. (1977). It is one of the most potent uveitogenic antigens defined to date. It causes an immune-mediated, bilateral inflammatory response in the eye, or experimental autoimmune uveitis (EAU), when injected in microgram quantities at a site far from the globe (Pfister et al., 1985). Several other uveitogenic antigens have since been identified, such as interphotoreceptor retinoid-binding protein (IRBP) (Hirose et al., 1986); recoverin (Gery et al, 1994); bovine melanin protein (Chan et al., 1994); rhodopsin (Schalken et al., 1989); phosducin (Lee et al., 1990); RPE 65 (Ham et al., 2002), and tyrosinase proteins (Yamaki et al., 2000).

These studies have broadened our understanding of the ocular immune response and allowed templates to be developed with which newer approaches to immunosuppression can be tested.

CLINICAL FEATURES

The uveal tract can be divided anatomically into the iris, ciliary body, and choroid (Figure 49.1). Uveitis is usually defined as any inflammation of the uveal tract. This inflammation may be an antigen-specific, immune-mediated response or a nonspecific response, which can be elicited by infection, trauma or surgery. In clinical practice, any inflammatory reaction involving the structures of the eye—sclera, cornea, lens, vitreous, retina, retinal pigment epithelium or choroid (see Figure 49.1)—is considered to be uveitis.

Episcleritis is an inflammatory disease involving the tissue that lies superficial to the sclera. Scleritis is a painful and potentially sight-threatening inflammatory disease involving the sclera. Episcleritis is typically more acute and less severe than scleritis and it is often idiopathic; however,

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

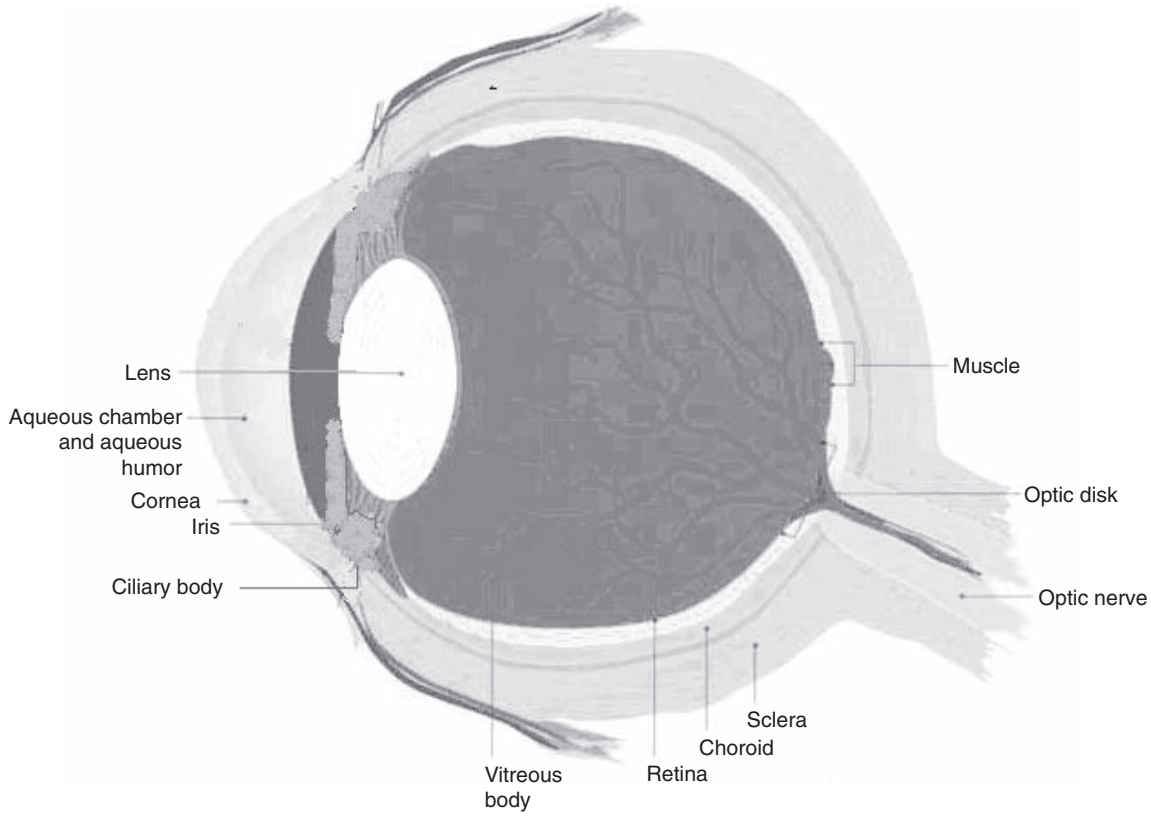

FIGURE 49.1 Key anatomic features of the eye.

many of the diseases associated with scleritis have also been associated with episcleritis. The clinical examination evaluates for the presence of erythema and edema of episclera or sclera (Figure 49.2). The inflamed sclera is usually characterized by a violaceous hue. Many inflammatory systemic disorders are associated with scleritis: rheumatoid arthritis, juvenile idiopathic arthritis, Reiter syndrome, Crohn's disease, ankylosing spondylitis, ulcerative colitis, polymyositis, polyarteritis nodosa, systemic lupus erythematosus (SLE), Wegener's granulomatosis, sarcoidosis, Lyme disease, and Cogan syndrome.

Uveitis can be classified based on anatomic location: anterior, intermediate, posterior, and diffuse or panuveitis. *Anterior uveitis* describes a disease predominantly limited to the anterior segment. In the literature it is also called iritis, iridocyclitis, and anterior cyclitis. There are many inflammatory systemic diseases associated with anterior uveitis, including juvenile idiopathic arthritis, HLA-B27-associated diseases, Behçet's disease, and sarcoidosis. The corneal examination may reveal keratic precipitates (Figure 49.3), small aggregates of inflammatory cells that accumulate on the endothelial surface of the cornea. Examination of the anterior chamber via biomicroscopy will reveal the presence of inflammatory cells and increased protein (flare), resulting from spillover of inflammation from the iris and the ciliary body, graded in a standardized fashion (Nussenblatt and Whitcup, 2004). An accumulation of leukocytes associated with fibrin, layered in the lower angle of the anterior chamber, is called a hypopyon (Figure 49.4), and is commonly associated with Behçet's disease and the HLA-B27-associated uveitidies. Inflammation of the iris may

cause synechiae (adhesions) between the iris and the lens capsule (Figure 49.5) or the cornea. It may also develop accumulations of inflammatory cells called nodules on the papillary margin, referred to as Koeppe nodules, or on the iris surface, known as Busacca nodules, commonly seen with sarcoidosis.

Intermediate uveitis designates that subset of uveitis where the vitreous is the major site of inflammation. Inflammation in the vitreous is characterized by increased cells and protein, vitreous haze (Nussenblatt et al., 1985) or pars plana exudates. Retinal inflammation may cause cystoid macular edema and retinal vasculitis. There are specific systemic autoimmune diseases associated with this type of uveitis: multiple sclerosis, sarcoidosis, and Lyme disease. A common form of intermediate uveitis is referred to as pars planitis, which is idiopathic. Syphilis and tuberculosis are common infectious etiologies of intermediate uveitis.

Posterior uveitis refers to inflammation affecting the posterior segment, particularly the retina and the choroid. There are numerous autoimmune diseases that are associated with posterior uveitis: Behçet's disease, SLE, polyarteritis nodosa, Wegener's granulomatosis, sarcoidosis, syphilis, and Vogt–Koyanagi–Harada (VKH) syndrome. There are also many infectious etiologies: ocular histoplasmosis, cytomegalovirus retinitis, acute retinal necrosis (varicella zoster virus, herpes simplex virus), toxoplasmosis, and immune-mediated local ocular disorders: sympathetic ophthalmia, birdshot retinochoroidopathy, and the "white-dot syndromes," which can cause posterior uveitis. In addition, primary intraocular lymphoma can masquerade as an intermediate or posterior uveitis.

Finally, *panuveitis* is a term reserved for inflammation involving all segments of the eye and in which there is no predominant site of inflammation (Nussenblatt and Whitcup, 2004). Typical systemic diseases associated with this form of uveitis are Behçet's disease, sarcoidosis, VKH syndrome, and syphilis.

PATHOLOGIC FEATURES

Uveitis can be classified as granulomatous or nongranulomatous. This is a clinical definition, based on the type of inflammatory cells infiltrating the ocular tissues, as seen by biomicroscopy. It is not based on histopathologic analysis. Biomicroscopy will reveal inflammatory precipitates throughout the eye. The most common type of corneal (keratic) precipitates are nongranulomatous. They are characterized by fine, white-colored lymphocytes, plasma

cells, and pigment. Many etiologic factors may be responsible for this type of inflammation. Granulomatous inflammation forms large, greasy-appearing collections of lymphocytes, plasma cells, and giant cells, also called "mutton-fat" keratic precipitates. It can also cause iris nodules, vitreous inflammatory cells, called "snowballs," and retinal vascular inflammation, called "candle wax drippings." This clinical classification is an important diagnostic clue, because the etiologic agents associated with granulomatous uveitis form a fairly short list, including sarcoidosis, VKH syndrome, syphilis, tuberculosis, and toxoplasmosis.

EPIDEMIOLOGIC FEATURES

Studies of the prevalence of uveitis tend to compare community-based practices with tertiary or university-based referral centers. An analysis of the publication by McCannel et al. (1996) estimates that approximately 20% of community and 18% of university or referral-based uveitis are autoimmune in nature. A similar study by Henderly et al. (1987) gives an estimate of approximately 23% in a university or referral-type practice.

There are many demographic features that offer important clues when evaluating a patient with uveitis. These include age, sex, race, ethnic heritage, and geographic residence. Specific examples include juvenile idiopathic arthritis associated with chronic anterior uveitis seen in children under age 16. One half of the patients in one study reportedly had chronic uveitis by the age of 6 (Key and Kimura, 1975). It is seen in young females with pauci-articular arthritis and a positive antinuclear antibody (ANA) test (Cassidy et al., 1986). The uveitis associated with ankylosing spondylitis is typically a recurrent anterior uveitis seen in young men between the ages of 20 and 30 years (Brewerton et al., 1973). Sarcoidosis affects young adults aged 20–50 years and has a slightly increased prevalence in women. It can affect all races, but African-Americans are 10 times more likely to be affected compared to white persons, and with chronic sarcoidosis they are more likely to develop ocular manifestations than white persons (Jabs and Johns, 1986). VKH syndrome is a multisystem disorder, with ocular, central nervous system, cutaneous, and vestibulo-auditory manifestations; the ocular manifestation is usually a severe, bilateral, granulomatous panuveitis. It is common in Japan and certain parts of Latin America (Sugiura, 1988). We have also noted a fairly high Native-American ancestry among our patients. Finally, Behçet's disease is a multisystem disorder with ocular involvement; it is especially common in the Far East and the Mediterranean basin (Ohno and Matsuda, 1986). The ocular disease may be an anterior and/or posterior uveitis, associated with retinal vasculitis (Figure 49.6).

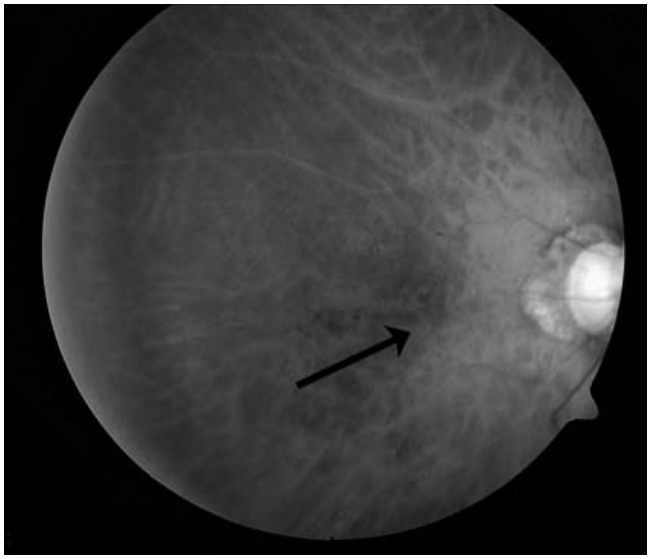

FIGURE 49.6 Fundus photograph of a patient with Behçet's disease and retinal vasculitis. The inferior arcade shows a branch vein occlusion. Arrow points to areas of bleeding in the retina.

AUTOIMMUNE FEATURES

Immunity in the eye is deviant and atypical. The eye's ability to regulate local immune responses has been attributed to several factors. First, there are several immunosuppressive substances in the aqueous humor of the eye, such as α-melanocyte-stimulating hormone (α-MSH), vasoactive intestinal peptide (VIP), transforming-growth factor-β (TGF-β), and macrophage-migration-inhibitory factor (MIF), which act to modulate ocular immune responses. Second, there are bone marrow-derived cells in the vascularized tissues of the eye that may capture and present antigens to immune cells. Third, surface markers, such as CD95 ligand (Griffith et al., 1996; Ferguson and Griffith, 1997), CD46 (Bora et al., 1993), and CD59 are expressed in ocular parenchymal tissues; they directly inhibit effector T-cell components of complement, thus saving the eye from tissue damage. Also, inside the eye, both retina and anterior chamber have a well-structured vascular network with blood–ocular barriers that protect the eye from intruding macromolecules.

The ability to discriminate between self and nonself is used for elimination of autoreactive cells. Because the eye is considered to be an immunologically privileged organ, it is believed that expression of ocular autoantigens occurs exclusively within the intraocular environment (Gery and Streilein, 1994). A classic example of organ-specific autoimmune disease caused by autoantigens is sympathetic ophthalmia, a rare form of intra-ocular inflammation in which the fellow eye develops inflammation after penetrat-

ing injury of the opposite eye. The inflammation may develop as early as several days after the penetrating insult to decades later. Typically, it occurs in the first several weeks (4–12 weeks). It is speculated that the injury causes primary immunization to self-antigens. Although the target antigen is still unknown, an experimental animal model has been developed. In this model cutaneous immunization of animals with retinal antigens (arrestin, rhodopsin, interphotoreceptor retinol-binding protein), retinal pigment epithelial-associated antigens, and melanocyte-associated tyrosinase results in an autoimmune uveitis, with features characteristic of sympathetic ophthalmia (Rao, 1997).

Substantial evidence exists that autoimmune diseases may also be initiated or aggravated by infection. This happens presumably when nonspecific polyclonal activation of the immune system, either by virus or immunostimulatory agents such as gram-negative bacterial cell wall components, overwhelms the normal regulatory mechanisms and permits "forbidden clones" of cells to proliferate and cause tissue damage. The molecular mimicry theory states that structural similarity between invading organism and organ tissue components may lead to persistence of the inflammatory response even after the inciting agent has been quickly cleared. It has been postulated as a mechanism for uveitis. The primary amino acid sequence of the hepatitis B virus DNA polymerase shows sequence homology to the retinal S-antigen. An experimental autoimmune uveitis was induced in Lewis rats using synthetic peptides (Singh et al., 1990). Lymph node cells from rats immunized with this synthetic peptide or peptide M in S-antigen showed a significant degree of cross-reaction. As a clinical corollary, some types of idiopathic posterior uveitis have been reported in association with immunization with hepatitis B virus vaccine (Brezin et al., 1995; Baglivo et al., 1996). However, no definitive etiologic link has been made via histopathology or immunohistochemistry.

HORMONAL INFLUENCES

Hormones play a significant role in immunomodulation, yet the exact mechanism is not understood. Certain hormones of pregnancy, such as progesterone, α-fetoprotein, α-2 pregnancy-associated globulin, and early pregnancy factor are thought to have immunomodulating properties (Anon, 1976; Chakraborty and Mandal, 1993; Harness et al., 2003). Other hormones, the levels of which increase during pregnancy, such as corticotrophin-releasing hormone, α-melanocyte stimulating hormone, estrogens, or altered estrogen/androgen ratios, are thought to be immunosuppressive (Ilias and Mastorakos, 2003; Lipton and Catania, 1997). We and other researches have reported that flares of uveitis decrease during pregnancy compared to the nonpregnant state (Rabiah and Vitale, 2003). Many women with chronic recurrent noninfectious uveitis report an association between flares and point in the menstrual cycle. Further studies are needed to more definitively delineate hormonal influences on uveitis.

GENETIC FACTORS

Genetic factors play a significant role in the development of endogenous uveitis. The ability to respond to a specific immune stimulant is genetically determined. Genes for human leukocyte antigens (HLA) are clustered in major histocompatibility complex (MHC) proteins, located on the short arm of chromosome 6. They have been linked to various uveitic syndromes (Table 49.1).

Brewerton et al. (1973) were among the first to observe that a high percentage of white patients with ankylosing spondylitis showed HLA-B27 positivity. Khan et al. (1977) demonstrated that HLA-B7 was associated with ankylosing spondylitis in African-Americans to a greater degree than HLA-B27. It is clear that HLA associations may be different for various ethnic groups. It is possible that different genes initiate responses that finally lead to a common pathway resulting in a particular disease. The reasons for the association between HLA and diseases are unclear. It has been hypothesized that exogenous environmental factors

TABLE 49.1 Association of selected ocular diseases with human leukocyte antigens

Human leukocyte antigen	Ocular disease
HLA-A11	Sympathetic ophthalmia
HLA-A24	Tubulointerstitial nephritis–uveitis syndrome
HLA-A29	Birdshot retinochoroidopathy
HLA-B5	Adamantiades-Behçet's disease
HLA-B7	Presumed ocular histoplasmosis, serpiginous retinochoroidopathy, acute posterior multifocal placoid epitheliopathy, ankylosing spondylitis
HLA-B8	Acute anterior uveitis
HLA-B12	Ocular cicatricial pemphigoid
HLA-B27	Acute anterior uveitis, Reiter syndrome
HLA-B51	Adamantiades–Behçet's disease
HLA-DQw3	Vogt–Koyanagi–Harada (VKH) syndrome
HLA-DR2	Presumed ocular histoplasmosis
HLA-DR4	Rheumatoid arthritis, VKH syndrome, relapsing polychondritis
HLA-DR6	Tubulointerstitial nephritis–uveitis syndrome
HLA-DR15	Intermediate uveitis
HLA-DRB1*0405	Sympathetic ophthalmia
HLA-DRw53	VKH syndrome

may play a role in expression of a disease. For example, it has been suggested that Ia antigens are required for antigen presentation and initiation of the immune response; if Ia expression is inappropriate and other defects of immunosurveillance occur, it may result in a disease (Botazzo et al., 1983).

Most researchers agree that mechanisms of the autoimmune disease of the eye are multifactorial, so several factors must be present to cause the disease, otherwise disease expression would be far more common. MHC plays an important role in determining disease susceptibility. Family studies in patients with uveitis show that susceptibility to particular types of idiopathic uveitis is possibly due to genetic background (Kimura and Hogan, 1963; Hogan et al., 1965; Giles and Tranton, 1980; Augsburger et al., 1981; Culbertson et al., 1983; Doft, 1983; Wetzig et al., 1988; Duinkerke-Eorela et al., 1990; Tejada et al., 1994; Lee, 1995). Genetic predisposition may determine the severity of the disease. A permissive MHC in a nonpermissive background will result in a mild disease or no disease at all (Caspi et al., 1992).

Single-nucleotide polymorphisms (SNPs) are genetic variations found normally in genes that mediate the immune response as opposed to those that control it. For example, one cytokine may have several SNP variations. Some SNPs may change the functioning of the protein. Population studies of disease groups versus controls are able to identify SNPs more commonly seen in disease groups and thus, are associated with these particular autoimmune or neoplastic diseases (Shastry, 2002). A report of 102 patients with ocular Behçet's disease, who were tested for a possible link between a specific tumor necrosis factor (TNF) SNP and the disease, found no TNF gene polymorphisms to be associated with the disease (Verity et al., 1999).

ANIMAL MODELS

Several species of mammals have been used to establish experimental autoimmune uveitis (EAU) models, including guinea pigs (Collins, 1949; Kalsow and Wacker, 1973), rabbits (Wacker and Lipton, 1968), rats (Faure, 1980; de Kozak et al., 1981; Gery and Nussenblatt, 1986), mice (Caspi et al., 1988), and primates (Nussenblatt et al., 1981). Currently, mice and rats are probably the two most commonly used animals for EAU studies due to the availability of inbred and other genetically-modified strains, such as gene knock-out or transgenic animals. Typically, uveitogenic antigens such as S-antigen, interphotoreceptor retinoid-binding protein (IRBP), retinal pigment epithelium-specific 65kDa protein (RPE65) or crude extract of retina/uvea are emulsified with complete Freund adjuvant (CFA) and injected subcutaneously into the animals ("active immunization"). Coinjection of pertussis toxin intravenously or intraperitoneally has been routinely administered to achieve maximum EAU score. EAU can also be induced by adoptively transferring primary T cells from diseased animals with active EAU or uveitogenic cell lines to syngeneic normal recipients. EAU induced by adoptive transfer typically has a shortened clinical course because of the lack of an induction phase compared to the active immunization protocol.

It is noteworthy that despite the fact that both rat and mouse EAU models have been extensively used for studying molecular mechanisms of uveitis, the clinical manifestations of the two models differ. Murine EAU seems to be less acute than rat EAU, with a later onset and longer duration. In addition, pathologic changes in murine EAU primarily involve the posterior segment with little anterior segment involvement, while rat EAU usually manifests inflammation in both anterior and posterior segments (Gery and Nussenblatt, 1986; Caspi et al., 1988). Although it was shown that passive transfer of immune serum from humans induced ocular retinitis in guinea pigs (de Kozak et al., 1976) and there is evidence of involvement of humoral immunity in EAU (Faure, 1980; Gery and Nussenblatt, 1986), humoral immune response-mediated uveitis animal models have not been widely reported or used.

PATHOGENIC MECHANISMS

The establishment of and extensive studies using EAU models have greatly facilitated the understanding of autoimmune uveitis. Despite some evidence of the involvement of humoral immunity (Faure, 1980; Gery and Nussenblatt, 1986), cellular immunity is primarily responsible for the disease (Nussenblatt et al., 1980; Gery and Nussenblatt, 1986; Caspi et al., 1986; Nussenblatt, 1987). The majority of data support the notion that helper T-cells (Th) are the key players in the molecular pathogenesis of EAU models (Caspi, 1999). While the Th1 subset has been shown to play the predominant role, accumulated data also point to a role for the Th2 subset (Caspi, 2002; Kim et al., 2002). In addition, the pertussis toxin, an adjuvant routinely administered to maximize induction of EAU, has been shown to block the induction of EAU by adoptive transfer (Su et al., 2001) underscoring a delicate balance of the immune system in this disease setting. Although limited, some data have also suggested an important role for immunosuppressive regulatory T cells (Tregs) and/or cytokines in EAU. Coadministration of interleukin (IL)-2 could potentiate induction of oral tolerance by IRBP, accompanied by increased levels of IL-10, IL-4, and TGF-β (Rizzo et al., 1994). Induced tolerance to S-antigen after intratesticular injection of S-antigen into the Lewis rat was shown to be associated with the induction of regulatory T cells capable of secreting immunosuppressive cytokines such as IL-4, IL-10, and TGF-β (Yotsukura et al., 1997). An immunosuppressive neuropeptide believed to be associated with immune privilege of the eye, α-melanocyte-

stimulating hormone, was shown to induce $CD4^+CD25^+$ Tregs.

Besides T-cells, other immune cells have also been investigated for their roles in the pathogenesis of EAU. For example, dendritic cells and macrophages have been shown to be important in EAU induction and tissue destruction (Jiang et al., 1999). In addition, natural killer (NK) cells and natural killer T (NKT) cells have also been implied in the pathogenesis of EAU. One report suggested that NK cells might play a detrimental role in EAU (Kitaichi et al., 2002) while another study showed increased NK and NKT cells in association with interferon (IFN)-β amelioration of EAU (Suzuki et al., 2002). Nonetheless, the data point to potential roles for other cellular components of the immune system that could be critical in the pathogenesis of EAU.

Ocular Immune Responses

The ocular immune system is thought to have an innate set of mechanisms for "effector blockade" that protects the ocular tissue from the destructive effects of the secondary effector phase of the immune response arc. This blockade in the anterior chamber is known as anterior chamber-associated immune deviation (ACAID), where immunization by an anterior chamber injection in experimental animals results in an altered form of systemic immunity to that antigen (Streilein, 1993; 1997; Streilein-Stein and Streilein, 2002). The eye also has soluble and membrane-bound inhibitors, such as CD178 (FasL), which can induce apoptosis (Green and Ferguson, 2001). Additionally, the eye appears to have an immunosuppressive microenvironment of chemokines and cytokines (Granstein et al., 1990; Foxman et al., 2002). Finally, it is believed that a state of tolerance can be induced in the eye (Ferguson and Griffiths, 1997; Ferguson et al., 2002).

Tissue Destruction

During ocular inflammatory processes, there is an influx of T cells, B cells, macrophages, and polymorphonuclear leukocytes (PMNs) into the choroids, choriocapillaris, and retina. There is also local synthesis of cytokines by ocular tissue. These changes in the ocular milieu most likely contribute to the ocular tissue damage seen clinically and experimentally. The underlying pathogenesis depends on the disease process involved and thus will vary. Immunohistopathology in ocular sarcoidosis shows a predominance of lymphocytes and macrophages (Chan et al., 1987), while ocular Behçet's disease revealed predominantly lymphocytic infiltration, with some B cells and plasma cells (George et al., 1997). These reports indicate that cell-mediated immunity may play a pivotal role, while others have reported humoral-mediated immunity and also the involvement of immune complex formation (Reinsh and Moyer, 1991).

Macrophages are reported to be important effector cells for retinal tissue destruction in the animal model (Forrester et al., 1998). However, the macrophage-mediated retinal tissue destruction is probably under the control of antigen-specific T cells and the cytokines that T cells release (Jiang et al., 1999). TNF-α is a well-known cytokine capable of tissue destruction either by direct tissue damage or by induction of apoptosis (Selmaj et al., 1991; Zheng et al., 1995), but other factors such as free radicals, e.g., nitric oxide, could also contribute to inflammation-induced retinal damage (Hoey et al., 1997).

IMMUNOLOGIC MARKERS

Recent advances have demonstrated that cytokines are equally important in the pathogenesis of noninfectious uveitis. The Th1 types of cytokines, such as IFN-γ, IL-2, TNF-α, and IL-12 are considered to be the primary factors in the pathogenesis of uveitis. In humans, IFN-γ and IL-2 were found to be elevated in ocular tissues with concomitant infiltrating T cells in uveitic patients (Hooks et al., 1988). IL-6 has been shown to be elevated in the aqueous humor of patients with noninfectious uveitis (Murray et al., 1990; Franks et al., 1992). Higher levels of TNF-α and IL-1 have also been demonstrated in both peripheral sera and aqueous humor samples (Palexas et al., 1992; Sakaguchi et al., 1998). Cytokine profile analysis of peripheral T-cells from uveitic patients suggested that the intracellular level of IFN-γ was increased (Frassanito et al., 2003), but similar analysis of T-cells derived from aqueous humor samples showed decreased IFN-γ compared to those from peripheral blood (Hill et al., 2005).

Data derived from animal EAU studies, however, have provided more consistent insights into the molecular mechanisms of autoimmune uveitis. TNF-α was shown to be detrimental to the development of EAU (Nakamura et al., 1994; Dick et al., 1996; Robertson et al., 2003), while IL-10 and IL-12 were suggested to be protective to the development of EAU (Rizzo et al., 1998; Tarrant et al., 1999). Consistent with findings in humans, IFN-γ was also found in the ocular tissues of EAU animals, and correlated with the disease course (Charitéris et al., 1992). However, treatment with anti-IFN-γ antibody exacerbated EAU, while treatment with rIFN-γ ameliorated the diseases in a murine EAU model (Caspi et al., 1994), leading investigators to conclude that endogenous IFN-γ was protective for EAU. The same investigators also showed that IFN-γ gene-deficient mice developed EAU similar to their wild-type littermates, suggesting that IFN-γ is not necessary for the development of EAU (Jones et al., 1997). To further complicate the issue, an independent study using IFN-γ transgenic rats showed that overexpression of IFN-γ resulted in more severe EAU (Egwuagu et al., 1999). These studies

underscore the complexity of cytokine networks in the pathogenesis of EAU.

TREATMENT AND OUTCOMES

Corticosteroids have been the mainstay of therapy for ocular inflammatory disease since the early 1950s. However, some diseases are steroid-resistant and for others long-term steroid therapy carries the risk of developing unacceptable side effects. For these patients other immunomodulatory agents need to be added as steroid-sparing agents, so that lower steroid doses or none at all can be used. The steroid-sparing agents include alkylating agents (cyclophosphamide, chlorambucil), antimetabolites (azathioprine, methotrexate, mycophenolate mofetil), cyclosporine, tacrolimus, rapamycin, antibodies, and monoclonal antibodies (daclizumab, etanercept, infliximab).

Antibodies and monoclonal antibodies directed against various parts of the immune cascade have not yet been used extensively in the treatment of uveitis, with the exception of daclizumab (Zenapax). This is a humanized anti-Tac monoclonal recombinant antibody. Tac is a subunit of the IL-2 receptor (IL-2R) high-affinity complex. Caspi et al. (1986) demonstrated the presence of high affinity IL-2Rs in animal models of uveitis. A trial of daclizumab at the National Eye Institute (NEI) (Nussenblatt et al., 1999), suggested that there is a benefit from daclizumab therapy for the treatment of noninfectious uveitis. Subsequent trials at the NEI indicated its usefulness for controlled disease, allowing tapering of other immunosuppressive therapy and maintenance of patients on daclizumab only (Nussenblatt and Whitcup, 2004); subsequent trials are underway for pediatric uveitis and to evaluate the efficacy of various doses for noninfectious uveitis.

TNF-α is found during the acute phase of experimental autoimmune uveoretinitis (Kim et al., 2001). Enbrel is a TNF fusion protein that binds to and inactivates TNF, while infliximab is a chimeric monoclonal antibody directed against TNF-α. Our experience with both for uveitis is still developing. We conducted a randomized, placebo-control trial of 12 patients, to investigate the efficacy and safety of etanercept in the treatment of juvenile idiopathic arthritis (JIA)-associated uveitis. In this small pilot study there was no apparent difference in anterior segment inflammation between patients treated with etanercept and placebo (Smith et al., 2005). Smith et al. (2001) evaluated 16 patients, 14 receiving etanercept and 2 infliximab, for ocular and systemic inflammatory disease. All 12 patients with articular disease saw benefits, while only 6 of the 16 with uveitis showed any benefit. We are currently investigating infliximab for the treatment of noninfectious scleritis in an open label feasibility study; initial results appear very promising.

In our treatment approach cytotoxic agents are often used last, after corticosteroids, cyclosporine, and monoclonal antibodies, for sight-threatening intraocular inflammation. Other less widely used therapeutic modalities include intravenous immunoglobulin therapy, oral tolerance, plasmapharesis, and IFN-α. In addition, nonsteroidal anti-inflammatory agents have been used for specific diseases; however, they have not been shown to be effective as a sole agent in the treatment of noninfectious uveitis.

In general, the following therapeutic guidelines can be used:

- Topical corticosteroids for anterior segment disease.
- Periocular corticosteroid for unilateral disease, the presence of intermediate or posterior complications, and in children to avoid systemic complications of corticosteroids.
- Systemic immunosuppressive agents for bilateral, sight-threatening intermediate or posterior uveitis, or panuveitis
- Reserve cytotoxic agents for therapeutic failures.
- For uveitis associated with infectious etiologies, specific agents are indicated, including antivirals and antitoxoplasmosis therapy.

CONCLUDING REMARKS AND FUTURE PROSPECTS

We have learned a great deal since the advent of steroids for uveitis in the early 1950s. Most therapies during the 20th century tended to be monotherapy and combination therapy only began to be used more frequently during the 1990s. Concerns about the side effects of steroids, i.e., osteoporosis, came to the attention of treating physicians relatively early, as did the goals for therapy, including long-term approaches that reduced secondary effects. Because of this the use of local therapy, including intraocular therapy, whether by injection or a time-released device, has become more popular. So where will we be going in the 21st century? Some of the possibilities include pharmacogenetics study of variability in drug responses attributed to hereditary factors in different populations; pharmacogenomics determination and analysis of the genome and its products (RNA and proteins) as they relate to drug response; evaluation of patient genomes to identify which patients are the best candidates for a specific therapy; and finally, using cytokines as a marker for inflammation, as potential therapeutic targets, and to determine the level of quiescence in chronic uveitis.

Inner Ear Disease

CLAUDIO LUNARDI*

**Department of Clinical and Experimental Medicine, University Hospital, Verona, Italy*

ANTONIO PUCCETTI†

†Institute Giannina Gaslini and Department of Experimental Medicine, University of Genova, Genova, Italy

The hypothesis that a syndrome of sudden sensorineural hearing loss (SNHL) often accompanied by vestibular symptoms might be of autoimmune origin was firstly proposed by McCabe (1979) who based his findings on clinical features, presence of abnormal immunologic tests, and a positive response to immunosuppressive therapy. Since then, a number of syndromes characterized by SNHL with overlapping clinical features have been described and termed in different ways: autoimmune SNHL, immune-mediated inner ear disease (IMIED), idiopathic progressive bilateral SNHL, sudden SNHL, idiopathic SNHL, bilateral immune-mediated Menière's disease, autoimmune vestibulo-cochlear disorders (Rahman et al., 2001a), generating a great confusion in the identification of patients and in the evaluation of different studies. It is still debated whether we can define as autoimmune all the cases of SNHL without any apparent cause. Although most of the authors in the field refer to these cases with the term "autoimmune inner ear disease" or "autoimmune sensorineural hearing loss" (Solares et al., 2003; Mathews and Kumar, 2003), others (Stone and Francis, 2000; Garcia-Berrocal et al., 2003) still prefer the definition of IMIED, since an autoimmune process can not always be identified. Immune-mediated inner ear disease may be a process confined to the inner ear, and antibodies against a vast array of different molecular weight inner ear antigens may be found in a percentage of these patients; in this case, the process can be identified as an organ-specific autoimmune disease. In other cases, IMIED is a feature of a systemic disorder, such as primary vasculitides, or of systemic autoimmune diseases. Indeed a systemic autoimmune disorder can be present in nearly one-third of patients with IMIED.

CLINICAL FEATURES

Immune-mediated inner ear disease is characterized by the presence of rapidly progressive, often bilateral SNHL, and frequently by vertigo, tinnitus, and a sense of aural fullness, sometimes indistinguishable from Menière's disease at the beginning. Immune-mediated inner ear disease usually leads to irreversible damage within hours or days of the onset and involves both ears, often asynchronously. Sometimes the disease shows an initial fluctuating course of remissions and relapses typical of an autoimmune disease. Since the devastating sequelae of IMIED may be avoided with the early institution of aggressive immunosuppression, a prompt diagnosis represents a major goal for the clinician. The clinical manifestations are shared with entities of different etiologies such as vascular, toxic, metabolic, genetic, traumatic, and infective; therefore, all the possible non-immune-mediated causes of SNHL need to be excluded. Menière syndrome, characterized by hearing loss and episodes of vertigo, tinnitus, and aural fullness, may accompany several causes of inner ear inflammation, including IMIED. In the absence of an identifiable cause, this syndrome is termed Menière's disease considered of autoimmune origin at least in 30–40% of the cases (Yoo et al., 2001; Riente et al., 2004). Time course is the most important criterion to differentiate IMIED from Menière's

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

disease—in the latter hearing loss occurs over a long period of time, sometimes of several years. Moreover Menière's disease is usually limited to one ear in the majority of the cases. Due to the many different etiologies which can lead to SNHL and to the absence of specific diagnostic markers, Garcìa-Berrocal et al. (2002a) have proposed the following criterion to correctly assess IMIED as a distinct entity:

1. Major criteria: bilateral involvement, presence of systemic autoimmune disease, positive antinuclear antibodies (ANA), reduced number of naïve T-cells (CD4RA), and recovery of more than 80% of hearing.
2. Minor criteria: unilateral involvement, young/middle aged patient, often female, presence of antibodies against HSP70, and good response to steroid therapy.

The suspicion of IMIED would be supported by the presence of three major criteria or two major and more than two minor criteria. The same authors (Garcìa-Berrocal et al., 2003) used these criteria to characterize and evaluate the response to therapy of 69 patients with recent-onset SNHL of different origin, such as viral, vascular, immune-mediated, and idiopathic. Patients with IMIED had the best and the earliest recovery rate of hearing after therapy, but also a higher rate of recurrence, typical of an autoimmune disorder. However, patients with profound hearing loss (>90 dB) have a low percentage of recoveries, regardless of the etiology. The criteria proposed by Garcìa-Berrocal et al. need to be validated by different groups in a greater number of patients. In particular, we think that the presence not only of ANA but also of other autoantibodies such as anticardiolipin antibodies, antithyroid antibodies, rheumatoid factor, or myeloperoxidase-antineutrophil cytoplasmic antibodies (Bachor et al., 2005; Toubi et al, 2004; Takagi et al., 2004) may suggest the presence of an autoimmune response also against the inner ear. Moreover, we believe that a positive therapeutic response to corticosteroid administration has to be considered a major criterion for the diagnosis of IMIED (Ruckenstein, 2004).

Due to the lack of a reliable diagnostic test, limited positron emission tomography of the inner ear, in association with anti-HSP70 antibody determination, has been proposed as a useful technique for assessing IMIED (Mazlumzadeh et al., 2003).

Association with Systemic Autoimmune Diseases

Hearing loss, both sensorineural and conductive, has been reported in patients with rheumatoid arthritis (Raut et al., 2001; Ozcan et al., 2002; Salvinelli et al., 2004) and with primary Sjögren syndrome (Boki et al., 2001). Anticardiolipin antibodies have been found associated with the presence of SNHL in patients with Sjögren syndrome (Tumiati et al., 1997) and with systemic lupus erythematosus (SLE) (Naarendorp and Spiera, 1998; Green and Miller, 2001; Kastanioudakis et al., 2002). Moreover SNHL can be present in patients with primary antiphospholipid syndrome (Vyse et al., 1994; Chapman et al., 2003). The histopathologic features of temporal bone described in eight subjects affected by SLE showed various degrees of hair-cell loss and atrophy of the organ of Corti, marked cochlear inflammatory infiltrate or formation of fibrous tissue and new bone throughout the cochlea, and degeneration of the spiral ligament, findings very similar to the known features of IMIED (Yoon et al., 1989; Sone et al., 1999). Sensorineural hearing loss has also been reported in progressive systemic sclerosis (Kastanioudakis et al., 2001) and in ulcerative colitis (Kumar et al., 2000).

Association with Primary Vasculitides

Sensorineural hearing loss is often an early symptom of primary vasculitides, which usually affect both the middle and the inner ear. The best example is Wegener granulomatosis (Kempf, 1989; Takagi et al., 2002) characterized by chronic otitis media leading to conductive hearing loss; SNHL is often associated and is related to vasculitis of the inner ear. Similar findings may be present in patients with relapsing polychondritis (Trentham and Le, 1998; Malard et al., 2002) characterized by vasculitis of the labyrinthine artery and inflammation of the cartilage within the inner ear. Sensorineural hearing loss has been described in polyarteritis nodosa (Tsunoda et al., 2001), microscopic polyangiitis (Koseki et al., 1997), Behçet disease (Narvaez et al., 1998; Adler et al., 2002), and Kawasaki disease (Silva et al., 2002).

Cogan Syndrome

Cogan syndrome is a chronic inflammatory disease characterized by three main clinical features: vestibulo-auditory dysfunction, interstitial keratitis, and vasculitis (St. Clair and McCallum, 1999). It occurs primarily in children and young adults and was first described by Cogan in 1945. Systemic manifestations occur in approximately half of the cases (Van Doornum et al., 2001); fever and weight loss are associated with active vasculitis, which can involve the aorta, aortic arch vessels, or medium vessels (Vollersten, 1990). Central and peripheral nervous system abnormalities may be present in up to 50% of the subjects (Bicknell and Holland,1978; Albayram et al., 2001).

Morbidity in Cogan syndrome results from permanent hearing loss and from cardiovascular disease.

Inner ear pathology reveals endolymphatic hydrops, infiltration of the spiral ligament with lymphocytes and plasma cells, degeneration of the sensory receptors and supporting structures of the cochlea and vestibular apparatus, and demyelinization and atrophy of the vestibular and cochlear

branches of the eighth cranial nerve. In some cases extensive new bone formation can be observed.

The cause of the disease is unknown; upper respiratory tract infections may precede the onset of the disease, suggesting an infectious origin (Vollertsen et al., 1986). Autoimmunity has been implicated because of the presence of serum antibodies to a mixture of corneal antigens and inner ear extracts (Helmchen et al., 1999; Disher et al., 1997). We have demonstrated that Cogan syndrome is an autoimmune disease and that DEP1/CD148 is the pathogenetically relevant autoantigen (Lunardi et al., 2002). Using the peptide library approach (Devlin et al.,1990), already applied to the study of systemic sclerosis (Lunardi et al., 2000), we identified a peptide recognized by the sera of all the patients. The peptide is homologous to autoantigens and the major core protein λ1 (Bartlett and Joklik, 1988) of reovirus type III, which causes mild rhinitis and pharyngitis. Peptide-specific IgG antibodies isolated from patients' sera recognized the viral protein, suggesting a viral involvement in the pathogenesis of the disease, possibly through a molecular mimicry mechanism (Zhao et al., 1998).

The peptide showed homology with the high cell density enhanced protein tyrosine phosphatase-1 (DEP1/CD148), which is highly expressed on both endothelial cells (Takahashi et al., 1999) and supporting cells of the inner ear (Kruger et al., 1999) and with connexin-26, a gap-junction protein expressed in the inner ear (Kikuchi et al., 2000). Affinity-purified antibodies against the peptide obtained from the patients recognized CD148 and connexin-26 in human cochlear extracts. DEP1/CD148 is a widespread cell-surface antigen, and its distribution explains the clinical spectrum of Cogan syndrome. Connexin-26 represents a major system of intercellular communication and its loss results in injury to the organ of Corti, leading to hearing loss; moreover, mutations in the connexin-26 gene are responsible for the majority of cases of congenital deafness. Connexin-26 shows homology with connexin-43 and connexin-50, gap-junction proteins present in corneal fibroblasts and epithelium, and this homology may explain the involvement of the eye in the disease. Peptide-specific antibodies were shown to bind human cochlea by immunohistochemistry (Figure 50.1).

To prove that these autoantibodies are pathogenic and that the identified autoantigen is relevant to Cogan syndrome, we induced the clinical features of the disease in animals (Balb/c mice and rabbits New Zealand White (NZW)) following either passive transfer of peptide-specific autoantibodies or active immunization with autoantigen peptides. The animals developed hearing loss as assessed by auditory brainstem responses (Figure 50.2).

We have tested patients with Cogan syndrome and isolated SNHL for the presence of antibodies directed against the DEP1/CD148, reovirus, and connexin-26 peptides. Table 50.1 shows the results obtained so far: sensitivity and specificity were respectively: 93.7% and 75% for anti-CD148 antibodies, 87.5% and 43.8% for antireovirus antibodies and 81.5 and 62.5% for anti-connexin-26 antibodies (Lunardi C. and Puccetti A. unpublished data).

EVIDENCE OF AUTOIMMUNITY

Different antibodies directed against autoantigens that are either specific to the inner ear or widely distributed have been described in patients with SNHL of unknown origin. The presence of antibodies against type II and type IX collagens as well as against other autoantigens in patients with Menière's disease and with IMIED has been reviewed by

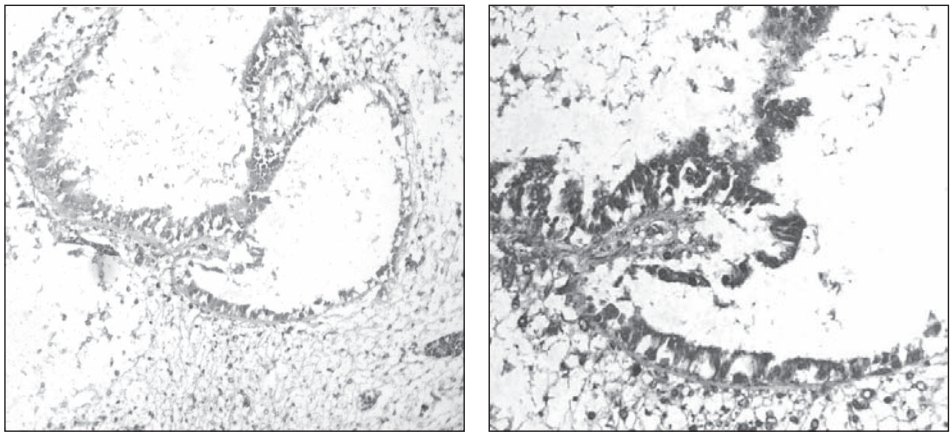

Figure 50.1 Antibodies against the Cogan peptide bind human cochlea. Human cochlea immunostained with antibodies purified against an irrelevant peptide (negative control, *A*) and with antibodies purified against the Cogan peptide (higher magnitude, *B*). (See color plate section).

Reprinted with permission from Elsevier, from Lunardi et al. (2002).

Yoo et al. (2002). The Kresge Hearing Research Institute-3 (KHRI-3) antibody binds to guinea pig inner ear supporting-cell antigen, which has been found to be homologous to the human choline transporter-like protein 2, expressed in the inner ear, making this protein a possible target for autoimmune aggression in IMIED (Nair et al., 2004). Anti-endothelial cell autoantibodies have been reported in some patients with SNHL and may represent a marker of vasculitis or vascular damage of the inner ear, which leads to leukocyte infiltration and local immunoglobulin production (Cadoni et al., 2002; Mathews and Kumar, 2003). The detection of antibodies against the myelin protein P0 (30 kDa) has given conflicting results (Boulassel et al., 2001a; Nuti et al., 2002; Passali et al., 2004). Besides antibodies against the 30 kDa protein, Boulassel et al. (2001a) reported also the presence of antibodies against a 42 kDa protein identified as β-actin and against a 68 kDa protein, identified as HSP70 by some authors (Billings et al., 1995; Bloch et al., 1999), but not by others (Yeom et al., 2003). The Western blot test for HSP70 has a very low sensitivity (Garcia-Berrocal et al., 2002b); however, its positivity seems to correlate with steroid responsiveness in subjects with IMIED (Hirose et al., 1999). The 58 kDa inner ear protein recognized by the sera of some patients with SNHL, has been identified as cochlin, a molecule highly expressed in the cochlea (Boulassel et al., 2001b). Cochlin and β-tectorin have been used to induce SNHL in animal models (see below). Table 50.2 summarizes the putative autoantigens believed or proved to be involved in the pathogenesis of IMIED.

We can conclude that sera of patients with SNHL recognize a large array of proteins of variable molecular weight,

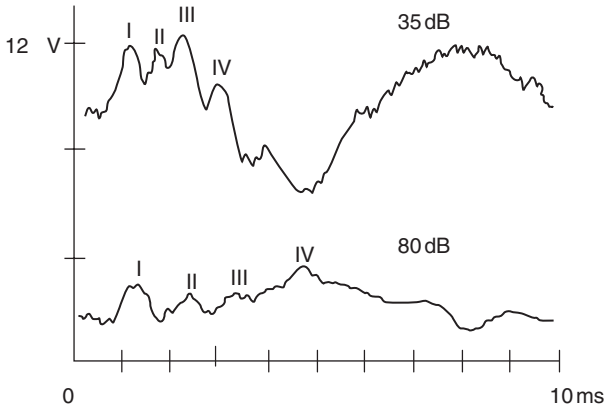

Figure 50.2 Grand average of auditory brainstem responses (ABRs) obtained from the same 6 mice before *(upper trace)* and 1 week after *(lower trace)* the third injection of purified antibodies directed against the Cogan peptide. A higher stimulus intensity (80 versus 35 dB) was needed to obtain much smaller and delayed responses (lower trace), consistent with hearing loss. The traces shown were obtained with above threshold stimuli in order to clearly identify the single components. The delay of waves II, III, and IV suggests an impaired transmission along the auditory pathway from the acoustic nerve to the midbrain. Data represent amplitude of the response in microvolt (μV) (y axis) versus time elapsed from stimulus in milliseconds (x axis). The time of stimulus delivery (click) is coincident with the 0 of the x axis; no pre-stimulus baseline is shown.

only a few of which have been identified so far. However, there is no direct proof that any of the antibodies directed against such autoantigens may be immunopathogenic and cochleopathic in IMIED. Indeed, the majority of them could not induce SNHL in immunized animals (see below).

The first evidence for an implication of autoreactive T-cells was reported by McCabe and McCormick (1984) who observed leukocyte migration inhibition by T cells exposed to inner ear extracts. More recently, Lorenz et al. (2002) reported an increased number of inner ear-specific IFN-γ producing T cells in the peripheral blood of patients with SNHL believed to be of autoimmune origin. These findings indicated that pro-inflammatory T cells specific for as yet unknown inner ear antigens may play a role in the development and progression of inner ear autoimmunity.

ANIMAL MODELS

A major barrier in understanding the pathophysiology of IMIED derives from the paucity of inner ear tissue available. This problem underlines the importance of animal models for this disorder, which may provide insights into pathogenesis, diagnosis, and treatment of IMIED. Immunization with the better characterized putative autoantigens, such as collagen type II, HSP70, and myelin P0, have failed to elicit hearing loss (Harris et al., 1986; Billings et al., 1998; Boulassel et al., 2001c). Attempts to develop animal models of IMIED have been made by immunizing guinea pigs with either isologous or bovine inner ear homogenates (Harris, 1987; Yamanobe and Harris, 1993; Gong et al., 2002); this model was hampered by the vast array of immunologically active components involved, making it impossible to identify the specific self-antigens involved in disease initiation and progression. The use of fractions of inner ear proteins has partially addressed this problem (Tomiyama, 2002), which will be solved by the availability of recombinant antigens (Billings, 2004). Gloddeck et al. (1999) induced SNHL in naïve Lewis rats following passive transfer of activated T cells specific for bovine inner ear extract, demonstrating the role of T cells in the initiation and pathogenesis of SNHL. A recent experimental confirmation of the importance of T cells was recently provided by Solares et al. (2004), who showed that SWXJ mice immunized with peptides derived from two proteins of the inner ear, cochlin and β-tectorin, had significant hearing loss. Two selected peptides elicited a $CD4^+$ T-cell response of the Th1-like phenotype. Moreover, the passive transfer of peptide-activated $CD4^+$ T cells into naïve SWXJ recipients induced leukocytic infiltration of the inner ear and hearing loss. However, it is not clear whether cochlin and β-tectorin are implicated in IMIED in humans, or how accurately this model reflects events occurring in the spontaneous disease (Billings, 2004).

The administration of monoclonal antibody (KHRI-3) directed either against the guinea pig inner ear supporting cell antigen (Nair et al., 1995) or against the type II collagen fragment CB11 induced SNHL with loss of hair cells, inflammatory cell migration, and endolymphatic hydrops (Matsuoka et al., 2002) suggesting that these antibodies also play a critical role in autoimmunity of the inner ear.

TREATMENT

Since IMIED may result in severe deafness and vestibular dysfunction, patients must be treated aggressively and immediately after the onset of the symptoms. The mainstay of therapy is high dose corticosteroids (1 mg/kg/day) (Chen et al., 2003) continued for at least 2 weeks and then for another 2 weeks in case of improvement. The steroid is then tapered over a period of between 2 and 3 months, and in some cases maintained at low dosage for a long period (e.g. methylprednisolone 4 mg/day). In case of deterioration of symptoms or of no significant improvement during the first 2 weeks of treatment, other immunosuppressive agents are added such as cyclophosphamide (CYP), 2 mg/kg/day, or methotrexate (MTX), 7.5–20 mg/wk. Because of the well-known side effects of CYP, clinicians prefer the use of MTX; however, despite the preliminary favorable responses (Kilpatrick et al., 2000; Matteson et al., 2001; Rahman et al., 2001a; Matteson et al., 2003), the only controlled trial published so far does not support the efficacy of long-term MTX in maintaining the improvement achieved with glucocorticoid therapy (Harris et al., 2003). Since MTX is slow acting, its effect may start too late in a disease that rapidly leads to hearing loss. McCabe (1989) reported the promising results obtained with the CYP-prednisolone combination therapy. We have used oral methylprednisolone and CYP pulse therapy in two particularly rapid and severe cases; this therapy blocked and reverted the hearing loss.

The results obtained with steroids and aggressive immunosuppression are variable (Broughton et al., 2004; Loveman et al., 2004; Ruckenstein, 2004) depending on the characteristics of the patients included, on the severity of the hearing loss at the beginning of the treatment, and on how early the therapy is started.

Etanercept, a tumor necrosis factor-α receptor blocker, has been used in a few cases with apparent efficacy; the addition of leflunomide or of other immunosuppressive agents was necessary to maintain the results obtained in some patients (Rahman et al., 2001b). However recent reports do not support the efficacy of etanercept (Choi et al., 2004; Cohen et al., 2004). There are reports on the utility of plasmapheresis (Luetje, 1989; Luetje and Berliner, 1997), therapeutic apheresis of low-density lipoproteins (LDL) (Bosch, 2003), and fibrinogen (Suzuki et al., 2003).

Suckfull et al. (2002) reported the beneficial effects of a single fibrinogen/LDL apheresis compared with conventional infusion treatment and prednisolone for 10 days. In controlled studies, the use of antiviral therapy with valacyclovir (Tucci et al., 2002) and acyclovir (Uri et al., 2003; Westerlaken et al., 2003) in addition to steroids was not more beneficial than steroids alone. Finally, there are recent reports on the utility of low-molecular-weight heparins (Yue et al., 2003; Mora et al., 2004) and antioxidants (Joachims et al., 2003) in addition to the usual therapy, and on the efficacy of intravenous infusion of tissue plasminogen activator (Mora et al., 2003) alone. In case of permanent severe bilateral hearing loss, the auditory function may be partially replaced with a cochlear implant—an electrical prosthesis with electrodes inserted into the cochlea through mastoidectomy (Cohen et al., 1993). Cochlear implants have been successfully used in patients with Cogan syndrome (Minet et al., 1997; Cinnamon et al., 1997). Of the 16 patients with Cogan syndrome we are following at the moment, eight (age range 7–25 years) have undergone multichannel cochlear implant, resulting in a great improvement of their quality of life, without any complication.

CONCLUDING REMARKS

It is now evident that the inner ear is not an "immunologically privileged" site and may mount an immune response against both foreign and self-antigens. The association of IMIED with systemic autoimmune diseases provides evidence that autoimmunity can damage the inner ear, but it does not address organ-specific disease. Antibodies directed against different inner ear antigens have been identified in some patients; however, they are neither diagnostic nor correlate with disease state. In the future the major goals for research in this field will be: 1) the identification of pathogenetically relevant autoantigen(s); 2) the development of a highly specific diagnostic test; and 3) a better knowledge of the immunopathologic mechanisms in an organ as inaccessible as the inner ear.

Acknowledgments

We are grateful to Dr. C. Bason, Dr. D. Peterlana and to Prof. R. Corrocher.

Celiac Disease

LUDVIG M. SOLLID,* ØYVIND MOLBERG,*† AND KNUT E. A. LUNDIN*‡

*Institute of Immunology, †Department of Rheumatology, and ‡Department of Medicine, University of Oslo University Hospital, Oslo, Norway

Celiac disease (also called gluten-sensitive enteropathy or celiac sprue) has autoimmune components of which the highly disease-specific antibodies to the enzyme tissue transglutaminase (TG2) are particularly striking. Notwithstanding, celiac disease is most often categorized as a food hypersensitivity or intolerance disorder. The disease is precipitated in genetically susceptible individuals by the ingestion of wheat gluten and similar proteins of other cereals. Some historic findings that have led to our current understanding of celiac disease as a chronic inflammatory disorder with autoimmune components are listed in Box 51.1. If the critical role of gluten were not known, celiac disease would likely have been considered as a classical autoimmune disease.

Among the chronic inflammatory disorders with autoimmune components, celiac disease stands out as a particularly good model since the precipitating antigen is known and the affected organ—the small intestine—is easily accessed. Insight into the pathogenesis of this disorder is relevant for a large group of diseases for which the genetic and environmental components are poorly characterized.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Clinical Features and Associated Disorders

Celiac disease may present in early childhood soon after the introduction of gluten-containing food. Previously, a dramatic and even fatal clinical picture with diarrhea, anorexia, failure to thrive, abdominal distention, and growth retardation was regarded as typical. Today, most children present with a milder, pauci- or mono-symptomatic disease that

Box 51.1
Important historical achievements in the study of celiac disease pathogenesis

First description of a condition resembling celiac disease by Aretheus from Cappodocia (second century AD)
First precise description of the disorder (Gee, 1888)
Suggestion that banana diet can cure the disease (Haas, 1932)
Wheat gluten identified as a causative agent (Dicke, 1950)
Villous atrophy and crypt hyperplasia found to be pathognomonic for the disease (Paulley, 1954)
Celiac disease of childhood and adult nontropical sprue share the same pathogenesis (Rubin et al., 1960)
Familial clustering of biopsy-proven celiac disease (MacDonald et al., 1965)
First diagnostic criteria of pediatric celiac disease from ESPGAN (Weijers et al., 1970)
Celiac disease found to be an HLA-associated disorder (Falchuk et al., 1972; Stokes et al., 1972)
Existence of autoantibodies to reticulin detected (Alp and Wright, 1971; Seah et al., 1971)
Cell-mediated immunity to gliadin in celiac disease intestinal biopsy specimens (Ferguson et al., 1975)
HLA-DQ2 heterodimer (DQA1*05/DQB1*02) identified as the primary HLA susceptibility factor (Sollid et al., 1989)
Criteria for histological classification of the mucosal lesion (Marsh, 1992)
Isolation of gliadin-specific, HLA-DQ2 restricted T cells from intestinal biopsies (Lundin et al., 1993)
Celiac disease autoantigen identified as tissue transglutaminase (Dieterich et al., 1997)
Role of tissue transglutaminase (TG2) for making gluten peptides more immunogenic by deamidation recognized (Molberg et al., 1998; van de Wal et al., 1998a)

resembles the picture in adults (Mäki et al., 1988). Many of the symptoms associated with the milder disease form, like chronic fatigue, joint pain, and neuropsychological problems do not directly point to a small intestinal disorder (Murray, 1999; Fasano and Catassi, 2001; Farrell and Kelly, 2002), and neither do complications like osteoporosis, reduced fertility, peripheral neuropathy, epilepsy with cerebral calcifications or the blistering skin disorder dermatitis herpetiformis (Ciacci et al., 1996; Hin et al., 1999; Collin and Reunala, 2003; Fasano et al., 2003; Hadjivassiliou et al., 2003; Sanders et al., 2003). The changes in the phenotype have been paralleled by an increase in incidence, which is mostly attributable to better diagnosis and identification of the pauci- or mono-symptomatic cases. The coexistence of (auto)immune diseases is striking, particularly type 1 diabetes (Green et al., 1962; Cronin et al., 1997; Koletzko et al., 1998), Sjögren syndrome (Collin et al., 1994), autoimmune thyroid disorders (Collin et al., 1994; Counsell et al., 1994) connective tissue disease (Collin et al., 1994), and IgA deficiency (Mawhinney and Tomkin, 1971; Cataldo et al., 1997; Heneghan et al., 1997). One study indicated that prolonged gluten exposure in patients with celiac disease increases the risk of contracting autoimmune diseases (Ventura et al., 1999), but this has not been confirmed (Sategna et al., 2001). Like many of the autoimmune disorders, pediatric and adult celiac disease show a gender bias with a female-to-male ratio of approximately 2 : 1 (Ciacci et al., 1995; Ivarsson et al., 2003b).

Pathologic Features

The diagnosis of celiac disease is defined by typical gluten-induced alterations of the small intestinal mucosa. These changes can, according to the criteria introduced by Marsh (1992), be classified into three stages: the infiltrative, the hyperplastic, and the destructive lesion. In the infiltrative lesion the mucosal architecture is normal, but there is an increased infiltration of intraepithelial lymphocytes (IELs) in the villous epithelium. The hyperplastic lesion is similar to the infiltrative lesion, but in addition has hypertrophic crypts. The last stage, the destructive lesion, is now often subgrouped into partial, subtotal or total villous atrophy (Marsh 3A–C); the latter corresponding to the classic flat lesion (Oberhuber et al., 1999). The classic flat lesion, in addition to the increased IELs, is characterized by swelling of the lamina propria and infiltration of $CD4^+$ $\alpha\beta$ T-cells, plasma cells, macrophages/dendritic cells, mast cells, and neutrophils in the same compartment. Typical examples of small intestinal biopsies of celiac disease patients are shown in Figure 51.1.

Several molecules with immune function have altered expression in the celiac lesions (Figure 51.2). Particularly striking is the epithelial expression of HLA class II molecules, with strong expression of DR and DP molecules but little or no expression of DQ molecules (Marley et al., 1987; Scott et al., 1987). Another interesting molecule with increased expression in untreated celiac disease (and other autoimmune diseases, including type 1 diabetes) is the tight junction modulator zonulin (Fasano et al., 2000; Wang et al., 2000). This upregulation of zonulin is potentially important as it leads to an increased intercellular transport across the epithelium.

Epidemiologic Features

Celiac disease is primarily a disease of white persons. More than half the cases are now diagnosed in adult life,

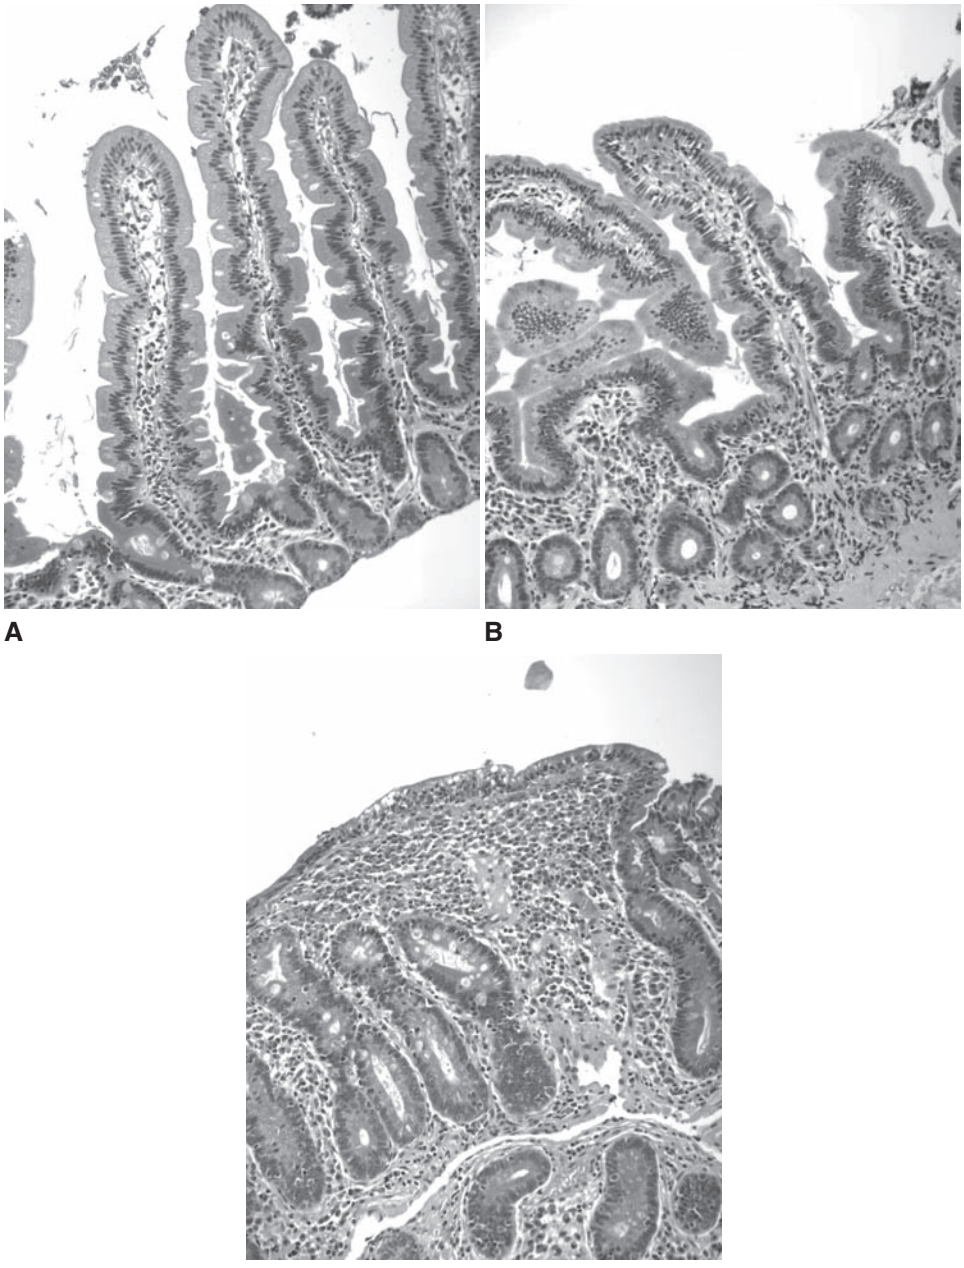

FIGURE 51.1 Histology of small intestinal biopsies. *A*, Normal intestine with long, slim villi and discrete crypts. *B*, Celiac disease Marsh 1 lesion (often referred to as an infiltrative lesion). The epithelium is seeded by intraepithelial lymphocytes (IELs) but the villi are not significantly shortened and there is little crypt hyperplasia. The patient had a positive endomysium test and clinical celiac disease. *C*, Celiac disease Marsh 3C lesion. No villi are seen and there is predominant crypt hyperplasia. Note the marked increase of intraepithelial lymphocytes. The different stages of villous structure that define the Marsh 2, 3A (partial villous atrophy), and 3B (subtotal villous atrophy) lesions are not shown. See color plate section.

Courtesy of I. N. Farstad, Rikshospitalet.

even after the age of 60 years. Many of these cases may have had undetected celiac disease in childhood, whereas in others the disease appears to have started later. The natural history and timing of conversion to seropositivity and/or mucosal inflammation are not fully understood.

Until recently, celiac disease was considered a fairly rare disorder, except in some European countries. Recent serologic screening studies have, however, shown a uniform prevalence throughout Europe of around 1 in 130 to 1 in 300 in the USA (Fasano et al., 2003). Even higher prevalences

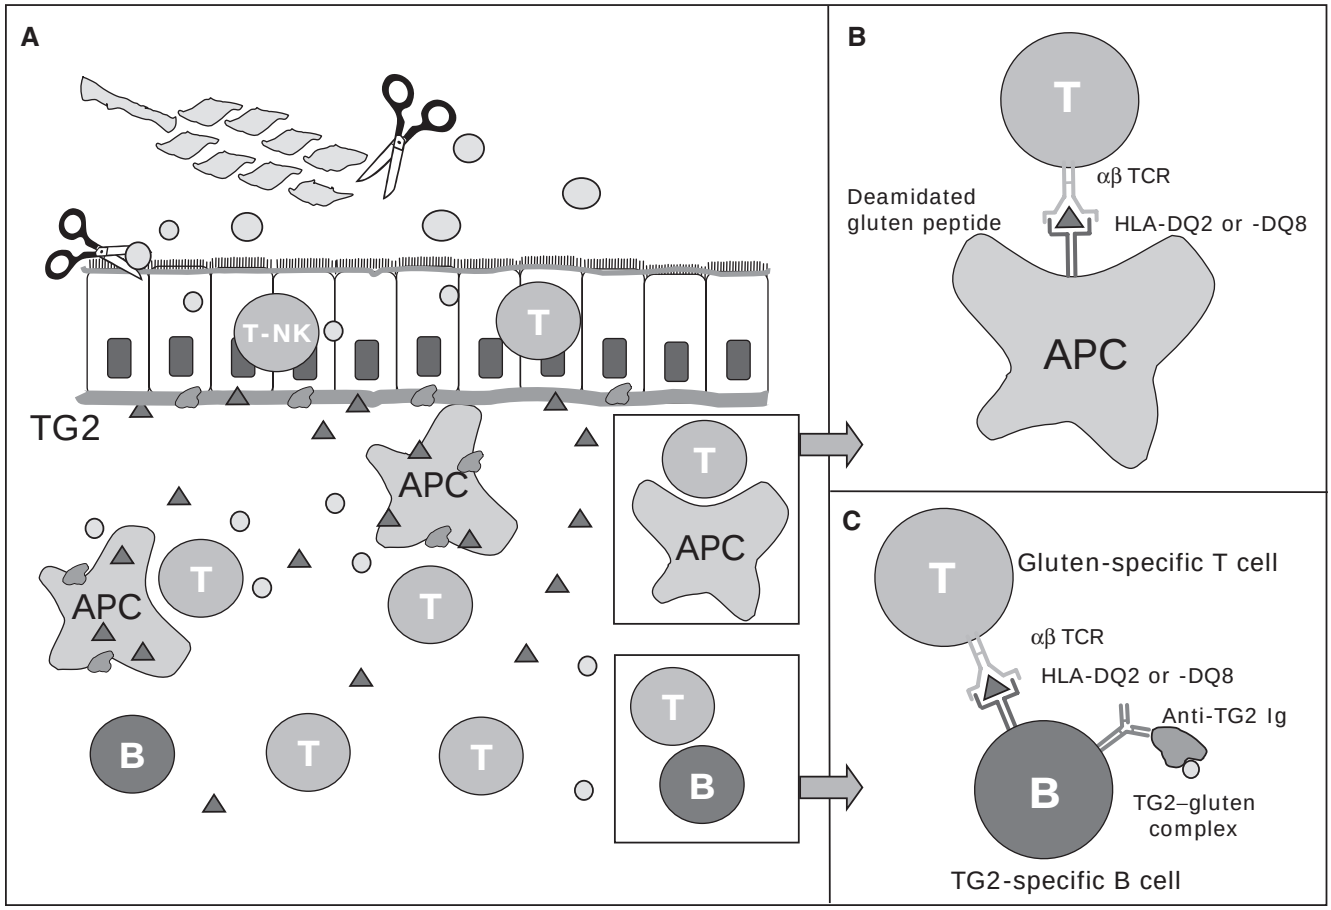

FIGURE 51.2 The celiac small intestinal lesion. *A*, Depiction of the intestinal mucosa with emphasis on the factors taking part in the development and control of celiac disease. The parts of the gluten proteins that are resistant to processing by luminal and brush border enzymes will survive digestion, and can be transported across the epithelial barrier as polypeptides. Gluten peptides are deamidated by tissue transglutaminase (TG2), which, in the intestinal mucosa, is mainly located extracellularly in the subepithelial region, but is also found in the brush border. TG2 may also be expressed by antigen-presenting cells (APCs) like macrophages and dendritic cells. $CD4^+$ T cells in the lamina propria recognize predominantly deamidated gluten peptides, presented by HLA-DQ2 or -DQ8 molecules on the cell surface of the APC. *B*, HLA-DQ2 and -DQ8 molecules have preference for binding peptides with negatively-charged amino acids (DQ2 in positions P4, P6, and P7; and DQ8 in positions P1 and P9) and thereby bind gluten peptides deamidated by TG2 (illustrated by conversion of small circles to triangles) with increased affinities. *C*, Model of how gluten-reactive T cells control the formation of antibodies to TG2 with intramolecular help. During the deamidation reaction, gluten peptides and TG2 form enzyme–substrate intermediates that are fairly stable (thiolester linkage). Such complexes of gluten and TG2 bound by surface immunoglobulin (Ig) of TG2-specific B cells will be endocytosed, and deamidated gluten peptides will be released for binding to DQ2 or DQ8 molecules. After transport to the cell surface of the HLA molecules with bound peptides, gluten-reactive T cells can recognize the deamidated gluten peptides and thereby provide T-cell help to the TG2-specific B cell. TCR, T-cell receptor.

(1 in 100) have been found in Finnish and UK schoolchildren (Mäki et al., 2003; Bingley et al., 2004) and among 45–76-year olds in the UK (West et al., 2003).

Between 1985 and 1995 there was an epidemic of celiac disease in Sweden among children younger than 2 years with a three-fold increase in incidence (Ivarsson et al., 2000). The sharp rise and subsequent abrupt decrease in incidence was likely related to changes in infant feeding habits, including the amount of gluten given, the age at introduction of gluten to the diet, and whether or not breastfeeding was ongoing when gluten was introduced. Notably, the risk for celiac disease was reduced in those children who were breastfed at the time of gluten introduction (Ivarsson et al., 2002).

AUTOIMMUNE FEATURES

Autoantibodies

Untreated celiac disease patients (on a wheat-containing diet) usually have increased levels of antibodies against wheat gluten, several other food antigens, and autoantigens present in the mucosa. The autoantibodies in celiac disease are primarily directed against the Ca^{2+}-activated (extracellular) form of the enzyme TG2 (Dieterich et al., 1997), although antibodies to calreticulin and actin are also found (Clemente et al., 2000; Sanchez et al., 2000, Granito et al., 2004). The antibodies to TG2 are both of the IgA and IgG isotypes, but the IgA antibodies, which are primarily produced in the intestinal mucosa (Marzari et al., 2001), demonstrate the highest disease specificity.

It is uncertain whether autoantibodies play a role in the pathogenesis of celiac disease. A weak inhibitory effect of the autoantibodies on certain TG2-catalyzed reactions has been reported (Esposito et al., 2002; Dieterich et al., 2003). This may be relevant to lesion formation. TG2 is involved in the formation of active transforming growth factor (TGF)-β by cross-linking of the TGF-β-binding protein (Nunes et al., 1997). Indirect inhibition of TGF-β activation may have broad effects, including dysregulation of the enterocytes and immune cells. Outside of its enzymatic activity, TG2 is involved in the attachment and motility of fibroblasts and monocytes via interactions with integrins and fibronectin (Akimov and Belkin, 2001; Balklava et al., 2002). Hence, the celiac villous atrophy could be caused by TG2 autoantibodies disturbing the migration of fibroblasts and epithelial cells from the crypts to the tips of the villi (Halttunen and Mäki, 1999). Autoantibodies to TG2 may also be involved in the extra-intestinal manifestations of celiac disease, although the mechanisms are not understood. One interesting observation comes from celiac patients with dermatitis herpetiformis. It appears that these patients, in addition to their anti-TG2 antibodies, have antibodies that target TG3, a transglutaminase that is uniquely found in the dermal papillae of dermatitis herpetiformis patients (Sardy et al., 2002).

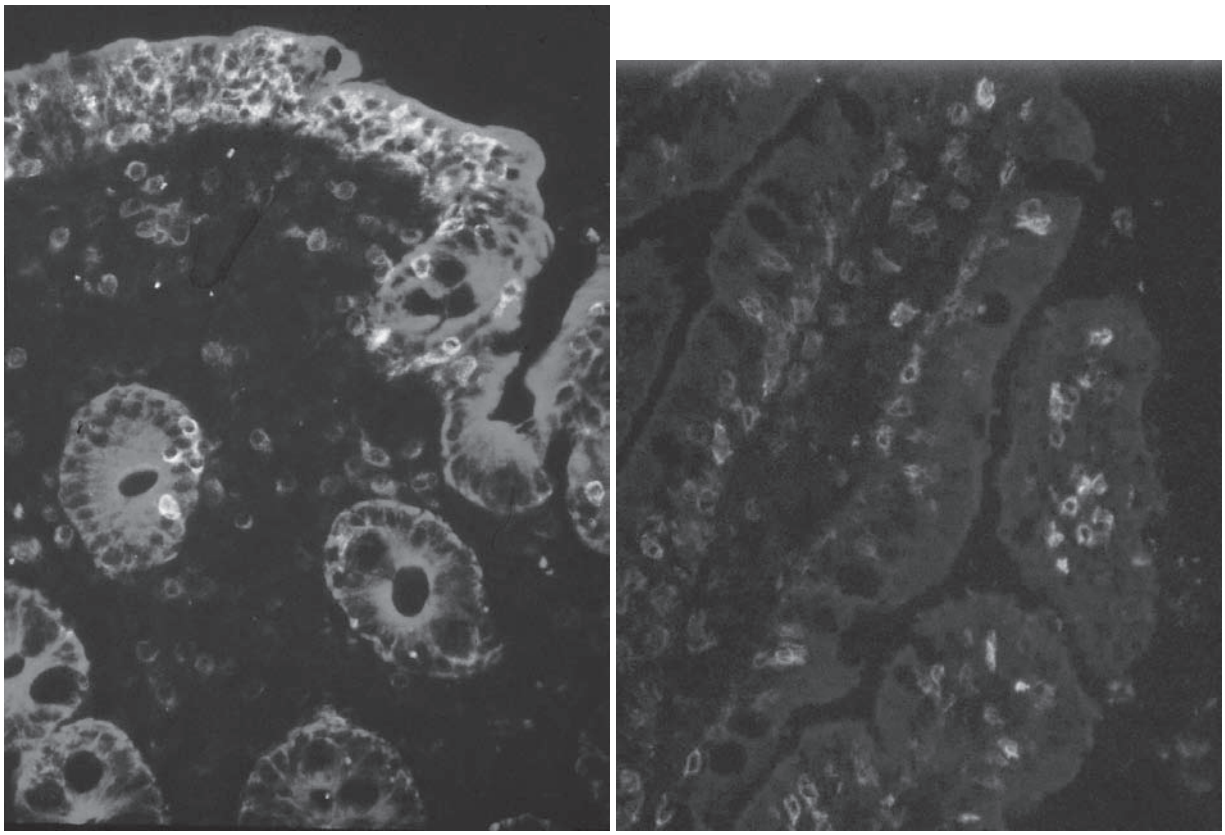
The mechanism underlying the formation of the autoantibodies in celiac disease is not understood. The production of anti-TG2 IgA antibodies is likely to be dependent on cognate T-cell help to facilitate isotype switching of autoreactive B cells (Sollid et al., 1997). Autoreactive T cells specific for TG2 could provide the necessary help for B-cell production of anti-TG2 IgA, but since TG2 is expressed in the thymus such cells are unlikely to survive thymic selection. An alternative explanation could be that the complexes of gluten and TG2, likely in the form of thiolester-linked enzyme substrate intermediates (Fleckenstein et al., 2004), permit the gluten-reactive T cells to provide help to the TG2-specific B cells by a mechanism of intramolecular help (see Figure 51.2C). This model can explain why the serum TG2 antibodies in celiac disease disappear when patients are put on a gluten-free diet. When the gluten goes, so does the T-cell help needed for the B cells to switch isotype and differentiate into plasma cells (Sollid et al., 1997).

Autoreactive Intra-epithelial Lymphocytes

Untreated celiac disease is characterized by an increased density of proliferating T-cell receptor (TCR) $\alpha\beta^+$ $CD8^+CD4^-$ and TCR $\gamma\delta^+$ $CD8^-CD4^-$ cells in the villous epithelium. All these IELs express the epithelial homing marker CD103 (integrin $\alpha_E\beta_7$) (Jabri et al., 2000). In contrast to the TCR $\alpha\beta^+$ $CD8^+$ IELs that return to normal when gluten is removed from the diet, the TCR $\gamma\delta^+$ IELs remain at an elevated level. A typical immunohistochemistry slide demonstrating some of these TCR subsets is shown in Figure 51.3. Many of the IELs coexpress innate [natural killer (NK) cell] receptors recognizing nonclassical HLA molecules. IELs expressing CD94/NKG2, a receptor for HLA-E, are increased in active celiac disease (Jabri et al., 2000), and many IELs express the NK receptor NKG2D (Roberts et al., 2001) and/or the Vγ1Vδ1 γδ TCR (Halstensen et al., 1989) (Figure 51.3B). Both these receptors recognize the non-classical MHC molecules expressed by stressed enterocytes (Groh et al., 1998; Bauer et al., 1999). The innate immune system has developed mechanisms to eliminate stressed cells (Gleimer and Parham, 2003). Killing of MIC-expressing stressed enterocytes by NKG2D-expressing IELs or by Vγ1Vδ1 γδ T cells may be an important autoimmune component of celiac disease. The expansion and activation of IELs in celiac disease seems to be driven by interleukin (IL)-15 (Jabri et al., 2000; Mention et al., 2003), but the mechanism leading to this increased expression is poorly understood.

GENETIC FEATURES

The high prevalence of celiac disease (10%) among first-degree relatives indicates that the susceptibility to this disease is strongly influenced by inherited factors (Ellis, 1981). Familial clustering is stronger in celiac disease than in most other chronic inflammatory diseases with a multifactorial etiology (Risch, 1987). The strong genetic influence in celiac disease is further supported by a very high concordance rate (around 75%) in monozygotic twins (Greco et al., 2002). Both HLA and non-HLA genes contribute to the genetic predisposition, and assuming a multiplicative model of disease genetics, it has been estimated that the overall importance of non-HLA genes is greater than that of HLA genes (Petronzelli et al., 1997; Risch, 1987). This estimation is, however, uncertain as increased sharing of environmental factors within families may lead



A B

FIGURE 51.3 Typical features of celiac disease lesions as illustrated by immunohistochemistry. *A*, Marsh 3C lesion. $CD3^+$ T cells are stained green and the epithelium is stained red. The striking and typical finding is the heavy infiltration of T cells within the epithelium. *B*, Marsh 1 lesion. $CD3^+$ T cells are stained green, T-cell receptor (TCR) $\gamma\delta^+$ cells are stained red and the epithelium is stained blue. There is a high proportion of intraepithelial lymphocytes (IELs) expressing both CD3 and TCR $\gamma\delta$ (seen as yellow cells), but the majority of $CD3^+$ IELs is TCR $\gamma\delta^-$ (i.e., TCR $\alpha\beta^+$). The significance of the infiltration of T cells in the lamina propria and the epithelium is discussed in the text. See color plate section.

to an overestimation of the role of the non-HLA linked genes.

HLA Genes

The current data suggest that the overall susceptibility to develop celiac disease is associated with two conventional DQ molecules: primarily to DQ(α1*05,β1*02) (=DQ2) and less pronounced to DQ(α1*03,β1*0302) (=DQ8). DQ molecules bind peptides and present these to $CD4^+$ helper T cells (Th) carrying the $\alpha\beta$ TCR. This genetic evidence points towards a central role for $CD4^+$ T-cells in controlling disease development.

Most celiac disease patients carry the DR3–DQ2 haplotype (the DRB1*0301–DQA1*0501–DQB1*0201 haplotype), or are DR5–DQ7/DR7–DQ2 heterozygotes (i.e., they carry the DRB1*11/12–DQA1*0505–DQB1*0301/DRB1*07–DQA1*0201–DQB1*0202 haplotypes) (Keuning et al., 1976; Ek et al., 1978; Mearin et al., 1983; Tosi et al., 1983; Trabace et al., 1984). Celiac disease patients with these DR–DQ haplotype combinations thus share the same functional DQ molecule on the cell surface, encoded by genes carried in the cis (e.g., DQA1*05 and DQB1*02 carried on the same haplotype) or trans position (e.g., DQA1*05 carried on a different haplotype from DQB1*02) (Figure 51.4) (Sollid et al., 1989). Celiac disease patients who are DQA1*05 and DQB1*02 negative frequently carry the DRB1*04–DQA1*03–DQB1*0302 haplotype (i.e., DR4–DQ8 haplotype). Taken together, the genetic and functional data favor DQ8 as the primary disease-susceptibility determinant in these patients. The very few remaining celiac disease patients who are neither DQ2 (DQA1*05/DQB1*02) nor DQ8 (DQA1*03/DQB1*0302) carry either the α or the β chain of the DQ2 heterodimer (i.e., DQA1*05 or DQB1*02) (Karell et al., 2003).

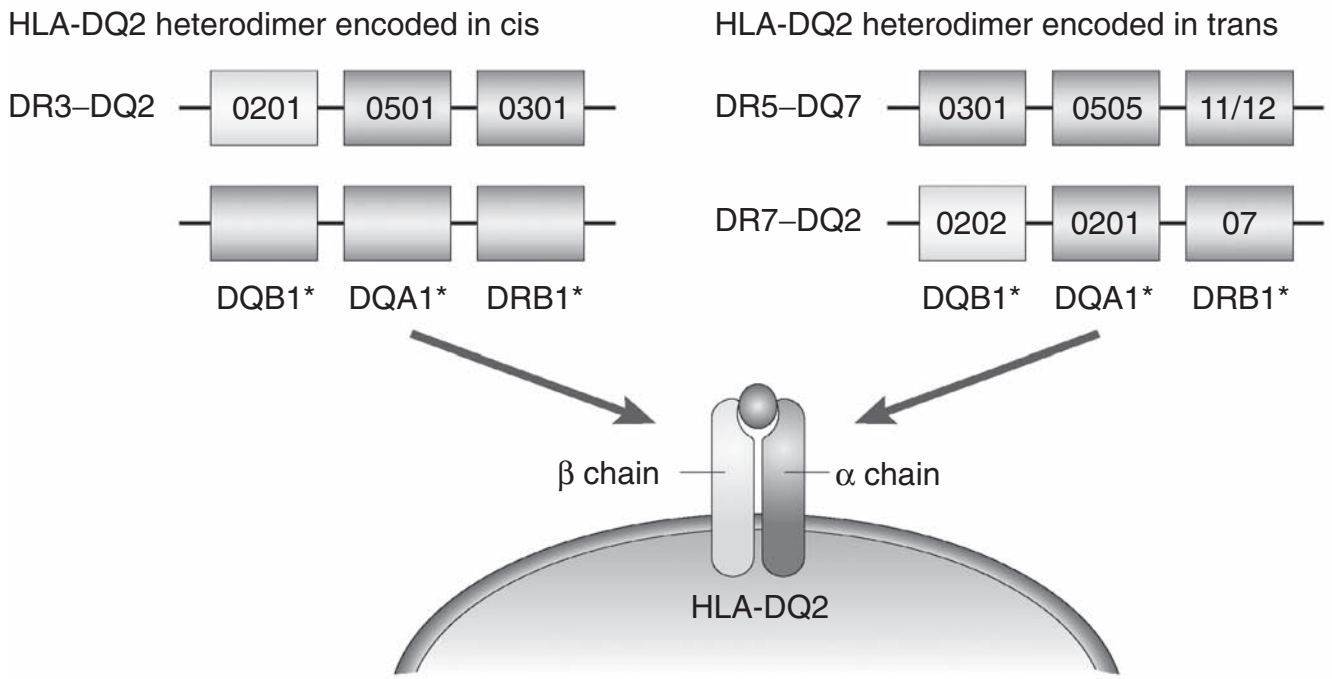

FIGURE 51.4 HLA association in celiac disease. The majority of celiac disease patients expresses a particular HLA-DQ2 (DQA1*05/DQB1*02) heterodimer. This HLA molecule is either encoded in the cis position in individuals who are DR3-DQ2, or in the trans position in individuals who are DR5–DQ7/DR7–DQ2 heterozygous. The polypeptides encoded by DQA1*0501 and DQA1*0505 differ by one residue in the leader peptide, whereas those encoded by DQB1*0201 and DQB1*0202 differ by one residue in the membrane proximal domain. It is unlikely that these substitutions have functional consequences.

Courtesy of Nature Publishing Group.

Non-HLA Genes

Much less is known about the non-HLA genes in this disorder. There are several reports that imply involvement of the gene for the negative costimulatory molecule CTLA4, or a neighboring gene (such as those encoding CD28 or ICOS). However, the overall effect of this gene is small (Holopainen et al., 1999; Naluai et al., 2000; King et al., 2002; Popat et al., 2002).

Several genome searches for risk factors have been performed in celiac disease (Houlston et al., 1997; Greco et al., 1998; 2001; King et al., 2000; Holopainen et al., 2001; Naluai et al., 2001; Liu et al., 2002; van Belzen et al., 2003) With the exception of the HLA genes, there is relatively little consensus between the results, which most likely indicates that each of the non-HLA genes has a relatively modest effect. Gene–gene interactions and disease heterogeneity in the outbred human population could also produce such a picture. The region that has most consistently been linked to celiac disease is on the long arm of chromosome 5 (5q31–33) (Greco et al., 2001; Naluai et al., 2001; Liu et al., 2002). In a meta-analysis of data from several European populations, this region reached genome-wide significance, leaving little doubt that a susceptibility gene exists in this region (Babron et al., 2003). There is also accumulating evidence for a susceptibility factor on chromosome 11q (Greco et al., 1998) and chromosome 19p13 (van Belzen et al., 2003).

ENVIRONMENTAL INFLUENCES

Wheat Gluten and Similar Proteins of Barley, Rye, and Oats

Due to their high content of proline and glutamine residues, the proteins of wheat gluten are collectively referred to as prolamines. They are usually classified into α-, γ- and ω-gliadins and high and low molecular weight (HMW and LMW) glutenins (Shewry et al., 2003). The number of unique prolamine proteins is enormous due to the hexaploid nature of the wheat genome, multiple encoding loci, and allelic variation. A single wheat cultivar may express more than 100 different gliadin proteins (Anderson, 2001). The high content of proline residues makes the prolamines particularly resistant to gastrointestinal digestion. This has important implications for their immunogenicity for T cells.

Clinical observations suggest that the prolamins of barley and rye are also toxic for celiac disease patients (Farrell and

Kelly, 2002). Given the similarities between the prolamine genes of barley, rye, and wheat this is to be expected (Vader et al., 2003). With the oat prolamins the situation is more complex. Several feeding studies have suggested that oats are safe for celiac disease patients (Janatuinen et al., 1995; Srinivasan et al., 1996; Hoffenberg et al., 2000; Janatuinen et al., 2002; Størsrud et al., 2003), but it is now clear that some celiac patients are oat intolerant (Lundin et al., 2003). Interestingly, the celiac lesions of these patients harbor T cells specific for modified peptides derived from oat prolamins (Arentz-Hansen et al., 2004). These oat epitopes closely resemble gliadin T-cell epitopes (see below).

Other Environmental Factors

A possible role of infections in the development of celiac disease was indicated in a recent report from Sweden. In children younger than 2 years, a positive correlation was found between celiac disease risk and being born during the summer, which may be related to the fact that children born in the summer are first exposed to dietary gluten during the winter when infections are more prevalent (Ivarsson et al., 2003a). In addition, case–control data were presented which indicated that celiac patients experience 3 or more episodes of infection more than referents. Adenovirus 12 was proposed as a candidate factor because one of its proteins displays partial linear homology over 12 amino acids with an α-gliadin (Kagnoff et al., 1984). Subsequent epidemiologic studies have, however, not confirmed this hypothesis.

ANIMAL MODELS

Different approaches have been taken to establish an animal model of celiac disease, but none have demonstrated mucosal immunopathology and genetic features mimicking the human disorder. So far, it has not been possible to induce gluten-sensitive enteropathy in mice made transgenic for the HLA-DQ2 (Chen et al., 2002; 2003) or HLA-DQ8 (Black et al., 2002). Possibly, the failure of gluten to induce enteropathy in mice may relate to nonpermissive background genes of the mouse strains used so far. Notably, a fraction of HLA-DQ8 transgenic mice on a nonobese diabetic (NOD) background develops a dermatitis herpetiformis-like skin disorder after systemic immunization with gluten, but no apparent enteropathy (Marietta et al., 2004). Food-induced enteropathy can, however, be induced also in rodents, as demonstrated in hen egg lysozyme TCR transgenic mice orally fed with hen egg lysozyme and a Cox-2 inhibitor (Newberry et al., 1999). Of interest for celiac disease, transgenic mice overexpressing human IL-15 in intestinal epithelial cells develop intestinal inflammation confined to the proximal small intestine with reduced villus length, marked infiltration of lymphocytes, and vacuolar degeneration of the villus epithelium (Ohta et al., 2002).

PATHOGENETIC MECHANISMS

Effects of Gluten Challenge on the Intestinal Mucosa

Co-culturing celiac biopsies with gluten proteins has, over the past 30 years, provided useful insights into the pathogenesis of celiac disease. The first of these organ culture studies demonstrated that the small intestinal epithelium of untreated celiac patients improved in the absence of gluten (Townley et al., 1973; Browning and Trier, 1969). Later, the model was used to link gluten exposure directly to T-cell activation when Halstensen et al. (1993) showed that gluten challenge of biopsies from treated celiac patients induced CD25 (IL-2 receptor α chain) expression on lamina propria T cells (Figure 51.5). One advantage of the organ culture system is that it has allowed semikinetic analyses on the effects of gluten. These studies have suggested two different waves of immune activation: a rapid wave that occurs within hours, including overexpression of HLA-DR molecules on enterocytes, and a later wave dominated by activation of resident T cells (Maiuri et al., 1996). Peptide 31–43 of a particular α-gliadin, A-gliadin, which prevents the increase in enterocyte height seen during culture of intestinal biopsies from untreated celiac disease patients (De Ritis et al., 1988), was recently demonstrated to rapidly activate factors in the innate immune system in biopsies of treated celiac disease patients (Maiuri et al., 2003).

Studies of biopsies taken from patients following oral challenge with gluten proteins have also provided important results. Marsh (Marsh, 1992; Marsh and Crowe, 1995) orally challenged a large number of well-treated patients with gluten and sampled biopsies at several time points thereafter. Morphologic changes were induced in all patients, and the mucosal response was directly related to the amount of gluten given. At higher doses, mucosal damage was severe but the mucosa recovered rapidly (within 24–72 h).

Gluten-Reactive $CD4^+$ T Cells

T cells specific for various gluten proteins can be isolated from the small intestinal biopsies of the majority of celiac disease patients (Lundin et al., 1993; Molberg et al., 1997; Troncone et al., 1998; van de Wal et al., 1998b; Ellis et al., 2003), but not from biopsies obtained from disease controls (Molberg et al., 1997). In contrast, both patients and many control subjects have gliadin-reactive T cells in their peripheral blood. These T cells use many different HLA molecules for antigen presentation (DR, DQ, and DP) (Gjertsen et al., 1994; Jensen et al., 1995), and their reactivity is not enhanced by deamidation of the gliadin (Molberg et al., 1998). This implies that many individuals can be immunologically sensitized to gluten without having small intestinal

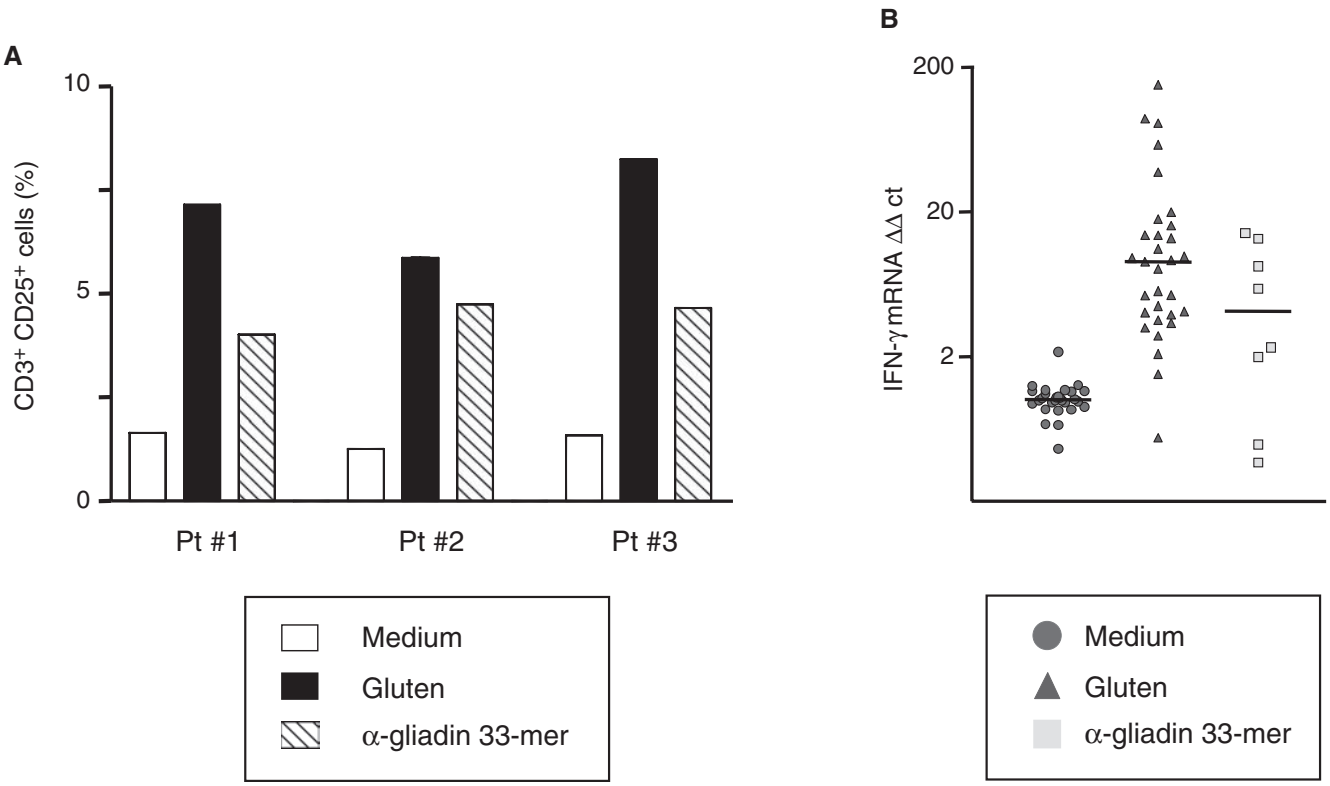

FIGURE 51.5 Gluten-induced activation of T cells within intestinal biopsies of celiac disease patients. *A*, T-cell activation, as evaluated by induction of CD25 expression, following a 24-h *ex-vivo* stimulation of celiac biopsies with a chymotryptic digest of bread wheat gluten with the immunodominant 33-mer peptide fragment of the α-2 gliadin. The figure shows data from three treated adult celiac disease patients with good T-cell reactivity (S. Tollefsen et al., unpublished data). *B*, Immune activation, as evaluated by induction of IFN-γ mRNA, following a 24-h *ex-vivo* stimulation of celiac biopsies with the same antigens as in *A*. Each point represents one individual biopsy specimen. All the biopsies were collected from treated celiac disease patients (S. Tollefsen et al., unpublished data).

pathology. The gluten-specific T cells derived from the intestinal celiac lesions display a remarkable feature; they are invariably restricted by the disease-associated DQ2 or DQ8 molecules (see Figure 51.2A) (Lundin et al., 1993; 1994). Most gluten proteins, including α-gliadins, γ-gliadins, and LMW and HMW glutenins appear to be recognized by these DQ2- and DQ8-restricted T cells, although with variable frequency (Lundin et al., 1997; Sjöström et al., 1998; van de Wal et al., 1999; Anderson et al., 2000; Arentz-Hansen et al., 2000; 2002; Vader et al., 2002b; Ellis et al., 2003; Molberg et al., 2003). The intestinal T-cell responses to gluten are thus characterized by their heterogeneity. The existence of multiple epitopes is related to the enormous heterogeneity of gluten proteins (see above).

Role of Tissue Transglutaminase

The role of the TG2 enzyme in the pathogenesis of celiac disease is not completely understood, but clearly encompasses more than simply being the target of the autoantibodies in the disease. There are high levels of active TG2 in the inflamed lesions of untreated celiac disease patients (Bruce et al., 1985) and the gluten proteins are excellent substrates for TG2 (Larre et al., 1993). Most importantly, however, the T cells within the celiac lesions predominantly recognize gluten peptides modified by TG2 (van de Wal et al., 1998a; Molberg et al., 1998; 2001; Arentz-Hansen et al., 2000; Vader et al., 2002b).

TG2 catalyzes a post-translational transamidation or deamidation of specific glutamine residues within its substrate proteins (Folk, 1983; Lorand and Graham, 2003). In the transamidation reaction, the glutamine becomes cross-linked to a protein-bound lysine or a polyamine, whereas the deamidation reaction results in conversion of the glutamine to glutamic acid. The enzyme displays regional selectivity for particular glutamine residues in the gliadin peptides, and the spacing between the targeted glutamine and proline residues seems particularly important for the specificity. Good targets are QXP and QXXF (Y, W, M, L, I, V), whereas a Q followed directly by a P will not be targeted (Fleckenstein et al., 2002; Piper et al., 2002; Vader et al., 2002a). The enzyme is thus involved in the selection of

DQ2-restricted T-cell epitopes. The fact that the glutamic acid residues created by TG2-mediated deamidation play a crucial role in DQ2/DQ8 binding and T-cell recognition provides indirect evidence that TG2 is involved in the mucosal deamidation of gluten peptides (see Figures 51.2A and B). Direct evidence for the *in situ* deamidation of gluten proteins by TG2 was provided by a study of celiac biopsies challenged with digests of gliadin (Molberg et al., 2001). The T-cell lines derived from these biopsies displayed only weak reactivity to gliadins, but responded efficiently to the TG2-treated variants of the same proteins.

T-Cell Epitopes of Gluten Proteins

There exist multiple T-cell epitopes in gluten proteins (Table 51.1), and T cells with several distinct specificities can be isolated from small intestinal biopsies of a single patient. Notwithstanding, there is a hierarchy within the epitopes that have been characterized. For instance, among the α-gliadins there are epitopes that are immunodominant and are recognized by T-cells from almost all patients (Arentz-Hansen et al., 2000), whereas reactivity to other epitopes can only be found in a minority of patients. T cells specific for these α-gliadin epitopes become detectable in the peripheral blood of treated celiac disease patients following an *in vivo* challenge with gluten (Anderson et al., 2000). Interestingly, a total of 6 copies of 3 of the immunodominant epitopes of α-gliadin (DQ2-α-I, DQ2-α-II, and DQ2-α-III) are expressed in some gliadins within a 33-mer fragment that is resistant to degradation by all gastric, pancreatic, and intestinal brush border membrane proteases (Shan et al., 2002). This 33-mer fragment is superstimulatory to T cells. We believe that a final and unambiguous definition of all DQ2- and DQ8-restricted gluten epitopes recognized by gut T cells will be difficult. While many of the epitopes are dissimilar when aligned according to their DQ2-binding motif, some have high degrees of similarity. In fact, T-cell clones exist that cross-react with similar sequences of α- and γ-gliadins, and with sequences of LMW glutenins and γ-gliadins (Vader et al., 2002b).

Recent experiments using organ culture assays have demonstrated that the gluten epitopes recognized by the intestinal T-cells from DQ2- and DQ8-positive patients induce immune activation *in situ* (Martucci et al., 2003; Mazzarella et al., 2003). Recently, *in vivo* instillation of a peptide containing the DQ2-α-I and DQ2-α-II epitopes has been shown to induce morphologic changes in the intestinal mucosa (Fraser et al., 2003). These changes were more pronounced than those seen in a previous *in vivo* challenge study that used a peptide derived from a distinct α-gliadin (A-gliadin 31–49) (Sturgess et al., 1994).

Despite the absence of a single pathogenic motif, the gluten epitopes recognized by gut T cells are generally very rich in proline and glutamine residues (see Table 51.1). In

several of the epitopes, proline residues are found in four of the nine residues in the core region (Sollid, 2000). The key role of prolines in the epitopes is underscored by the observation that DQ2-restricted T-cell epitopes in α- and γ-gliadins often cluster in regions with the highest density of proline residues (Arentz-Hansen et al., 2002). This clustering probably reflects the resistance to gastrointestinal digestion by proline, the importance of proline for the fine specificity of TG2, and the increased immunogenicity imposed by multivalency.

Presentation of Gluten Peptides by DQ2 or DQ8

Stable binding of peptides in the membrane distal groove of the HLA molecules is achieved by multiple hydrogen bonds between the amino acids of HLA and the peptide main chain atoms. Amino acid residues that differ between the polymorphic variants of HLA molecules contribute to the formation of specific binding pockets that can accommodate side chains of peptide amino acids, so-called anchor residues. The peptide interactions with HLA mainly take place in a core region of nine residues. Within this region, side chains of peptide amino acids in positions P1, P4, P6, P7, and P9 dock into pockets of the class II binding site. DQ2 has a unique preference for binding peptides with negatively charged side chains at the three middle anchor positions (Johansen et al., 1996; van de Wal et al., 1996; 1997; Vartdal et al., 1996). The recently solved X-ray crystal structure of DQ2 complexed with the DQ2-α-I epitope (QLQPFPQPELPY) provides a clue to explaining why DQ2 is predisposing to celiac disease by presenting gluten peptides (Figure 51.6) (Kim et al., 2004). The glutamic acid at P6, which is formed by tissue transglutaminase catalyzed deamidation, is an important anchor residue as it participates in an extensive hydrogen-bonding network involving Lys-β71 of DQ2. It is likely that Lys-β71 is important for the binding preference of negatively-charged residues at the P4 and P7 pockets in other peptides by electrostatic interactions (Kim et al., 2004). The α-I peptide–DQ2 complex retains critical hydrogen bonds between the HLA molecule and the peptide backbone despite the presence of many proline residues in the peptide that are unable to participate in amide-mediated hydrogen bonds. The positioning of proline residues so that they do not interfere with backbone hydrogen bonding results in a reduction of available HLA binding registers for gluten peptides, and impairs the likelihood of establishing favorable side chain interactions. The HLA association in celiac disease can thus be explained by a superior ability of DQ2 (and DQ8) to bind the biased repertoire of proline-rich gluten peptides that have survived gastrointestinal digestion and that have been deamidated by TG2. It is also known that MHC molecules are important for determining the repertoire of peripheral T cells during maturation in the thymus. A thymic effect of the same DQ molecules on the TCR repertoire selection is, however, not excluded by these results.

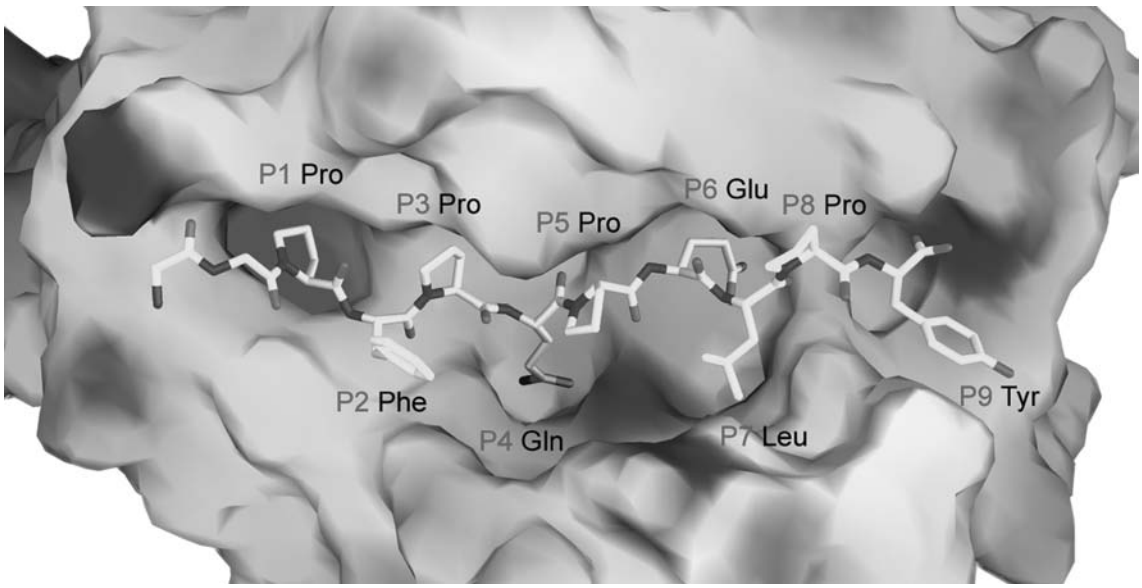

FIGURE 51.6 Three-dimensional structure of the binding site of HLA-DQ2 complexed with a deamidated gliadin peptide (DQ2-α-I epitope—carbon, yellow; nitrogen, blue; oxygen, red). The electrostatic potential surface of DQ2 is shown as red (negative) and blue (positive). Courtesy of the Proceedings of the National Academy of Sciences of the United States of America.

Musosal Antigen-Presenting Cells

The activation of gluten-reactive T-cells by stimulating biopsies with gluten implies that antigen-presenting cells (APCs) exist within the biopsy, but the nature of these cells has not been identified. Just beneath the epithelium in the normal mucosa is a high number of macrophage/dendritic-like cells that stain positive for CD68. It is conceivable that these cells are involved in sampling of luminal antigens. The expression of HLA class II, ICAM-1, and CD25 molecules is increased in these macrophage/dendritic-like cells, suggesting that they are activated in the disease state (Sturgess et al., 1990; Halstensen et al., 1993).

Effector Mechanisms Leading to Mucosal Alterations

The celiac lesion is characterized by increased enterocyte proliferation in the crypts, partly driven by keratinocyte growth factor (KGF) produced by stromal cells (Salvati et al., 2001) and apoptotic loss of surface epithelial cells (Moss et al., 1996; Maiuri et al., 2001). The apoptosis of the epithelium can be secondary to the mucosal inflammation and can involve cytotoxic IELs.

Despite the lack of detailed knowledge of the effector mechanisms involved in the creation of the celiac lesion, there is a large body of evidence that suggests that inflammatory cytokines, particularly interferon (IFN)-γ, are involved. Messenger RNA for IFN-γ is abundant in biopsies taken from untreated patients and is rapidly induced when biopsies from treated patients are challenged *ex vivo* with gluten (Nilsen et al., 1998) (see Figure 51.5B). IFN-γ is also produced by the intestinal, gluten-specific $CD4^+$ T cells (Nilsen et al., 1998), and by IELs (Forsberg et al., 2002; Olaussen et al., 2002). The induction of IFN-γ is probably mediated by IL-18 and IFN-α rather than IL-12 (Nilsen et al., 1998; Monteleone et al., 2001a; Salvati et al., 2002). Interestingly, there are several reports on the occurrence of clinical celiac disease in patients receiving IFN-α therapy for malignancy or viral hepatitis (Bardella et al., 1999; Cammarota et al., 2000; Monteleone et al., 2001a). IFN-α has also been shown to induce activation of Th1 cells in a fetal gut explant model of T-cell-driven enteropathy (Monteleone et al., 2001b).

IL-15 appears to be another important cytokine in celiac disease. In active celiac disease there is increased expression of IL-15, both in the lamina propria (Maiuri et al., 2000) and in the epithelium (Mention et al., 2003). Enterocyte-bound IL-15 can activate and expand IELs (Mention et al., 2003). In addition to the effect on IELs, IL-15 has been shown to induce epithelial CD95(Fas) expression promoting apoptosis of epithelial cells (Maiuri et al., 2000). The expression of IL-15 increases following *in vitro* gluten challenge of celiac biopsies, and it has been demonstrated that certain gluten peptides can directly activate the innate immune system, leading to IL-15 production (Maiuri et al., 2003). This innate effect of gluten is only seen in celiac disease patients, questioning whether some part of the adaptive immune system may be involved in the production of IL-15.

The activation of Th1 cells, which recognize gluten peptides presented by DQ2 or DQ8 molecules, can be considered to be a key event in the development of celiac disease, and this could explain the dominant genetic role of HLA. The products of the other predisposing genes may participate in pathway(s) that lead to lesion formation. The minor genetic effects of the non-HLA genes may indicate a lack of critical checkpoints along these pathways in susceptible individuals, or that there are several different pathways that lead to lesion formation. The role of the innate immune system and whether there are genetic polymorphisms in any innate immune genes that predispose to celiac disease development need to be studied further.

IMMUNOLOGIC MARKERS IN DIAGNOSIS

Serologic Markers

Accumulating evidence suggests that more than 95% of untreated celiac disease patients have high titers of serum IgA antibodies directed against the human TG2 enzyme (Dieterich et al., 1998; Sulkanen et al., 1998; Sblattero et al., 2000; Hansson et al., 2002; Wong et al., 2002).The development of enzyme-linked immunosorbent assays (ELISAs) with human recombinant TG2 as antigen has allowed both the routine detection of anti-TG2 antibodies in clinical practice and large population-based screening for celiac disease. These ELISA tests are now rapidly replacing the laborious detection of anti-endomysium IgA antibodies (i.e., anti-TG2), which was based on immunofluoresence staining of endomysial TG2 in tissue sections. In addition to the anti-TG2 antibodies, untreated celiac disease patients also have increased titers of IgA antibodies against gluten and gliadin, but these antibodies are less disease specific.

Some celiac disease patients undoubtedly present with negative serologies (Dahele et al., 2001; Kaukinen et al., 2002b), and an intestinal biopsy should therefore always be taken when there is high clinical suspicion of celiac disease (Farrell and Kelly, 2002). Notably, false-positive anti-TG2 tests do also occur, particularly in patients with inflammatory bowel disease (Carroccio et al., 2002; Dahele et al., 2001). A recent report from Finland identified some children who were positive for anti-TG2 in archival serum samples but who later were seronegative (Mäki et al., 2003). It is not known if these children had transient celiac disease, but this is clearly a possibility. Anti-TG2 antibodies of the IgG

isotype are useful in evaluating patients with selective IgA deficiency, but should otherwise not be tested for (Collin, 1999; Murray, 1999; Fasano and Catassi, 2001).

Other Immunologic Markers

As almost all celiac disease patients carry DQ2 or DQ8, HLA typing can thus be used to exclude the diagnosis with high probability. However, as these HLA variants are also present in a large proportion of the healthy population, this test has low positive predictive value (Kaukinen et al., 2002a). Immunohistochemical staining of intestinal biopsies with antibodies against TCR γδ and other T-cell markers are of clinical benefit in selected cases (Jarvinen et al., 2003).

TREATMENT AND OUTCOME

The current treatment for celiac disease is a life-long gluten exclusion diet. The disease is largely a benign disorder, particularly in patients detected by screening (West et al., 2003). Although celiac disease patients overall have an increased relative risk for non-Hodgkin lymphoma of the gastrointestinal tract, the absolute risk is low and lower than previously anticipated (Askling et al., 2002; Catassi et al., 2002). A large Italian study it was found that the overall mortality rate in celiac disease patients was twice that in controls (Corrao et al., 2001). This increased mortality was accounted for by increased death rates in the first 3 years after diagnosis. The gluten-free diet has been considered to be protective against the development of malignancy, but this notion was not supported by a recent study from the US (Green et al., 2003).

The most frequent reason for no or incomplete clinical improvement is poor dietary compliance (Ciacci et al., 2002), but it is clear that some patients do have refractory disease that does not respond to an adequate diet. The clinical evaluation and treatment of such patients are difficult (Ryan and Kelleher, 2000). A majority of patients with refractory celiac disease have monoclonal expansions of IELs, which in some patients progress to overt enteropathy-associated T-cell lymphoma (Cellier et al., 2000).

Novel Therapeutic Options

Many patients cope easily with the gluten-free diet. Others find that the dietary restrictions are laborious and have negative impact on their quality of life. Better alternatives are thus called for. It is promising that the greater insight into the molecular mechanisms involved in the intestinal T-cell reactivity to gluten seems to be uncovering novel targets for therapy. There are already some attractive possibilities. The activation of $CD4^+$ gluten-reactive T cells is a critical checkpoint in the development of celiac disease, and interference with this step should be an effective way to control the disease. One possibility, which is basically an extension of today's treatment with a gluten-free diet, is to produce cereals with bread-making properties but that are devoid of T-cell epitopes, either through breeding programs or transgenic technology. Another possibility is enzyme supplementation with the aim of either destroying T-cell epitopes directly or facilitating their gastrointestinal proteolysis (Figure 51.7A) (Hausch et al., 2002; Shan et al., 2002). Prolylendopeptidases are particularly attractive enzymes as they target the proline-rich regions of gluten that harbor the T-cell epitopes. TG2 is a target for intervention because of the critical role it plays in generating gluten T-cell epitopes (Figure 51.7B). Analogs of gluten peptide-containing "warheads" that function as irreversible inhibitors of human TG2 have been designed (Hausch et al., 2003). One possible problem with this approach is that TG2 inhibitors may have unacceptable side effects, as TG2 is involved in many different physiologic processes, including programmed cell death (Aeschlimann and Paulsson, 1994). TG2 inhibitors may also not be specific for TG2, but may affect the function of other transglutaminases. Another strategy would be to aim directly at the gluten-reactive T cells and eliminate or anergize them *in situ* by coadministering gluten and agents that alter the outcome of T-cell activation, such as antibodies to CD154 (Monk et al., 2003) or CD3 molecules (Chatenoud, 2003) (Figure 51.7C). Alternatively, it may be possible to silence gluten-specific T cells directly using soluble dimers of HLA–peptide complexes, as such dimers have been shown to induce the apoptosis of antigen-specific T cells as a result of inappropriate stimulation (Appel et al., 2001). However, the increasing number of characterized gluten epitopes would complicate this approach. The central role of DQ2 and DQ8 in presenting gluten peptides offers yet another target for intervention. Blocking the binding-sites of these HLA molecules would prevent presentation of disease-inducing gluten peptides (Figure 51.7D). The challenge with this approach will be to find an efficient way to target and block the binding sites of DQ molecules, which are continuously synthesized by APCs. Whatever new therapeutic modality is introduced in celiac disease, it will have to prove better than the current gluten-free diet regime with regard to its long-term safety and outcome. This fact must be taken into consideration when devising new treatments.

CONCLUDING REMARKS AND FUTURE PROSPECTS

Considerable progress has been made in recent years in the understanding of the molecular basis for celiac disease, but several new questions have emerged. Many of these

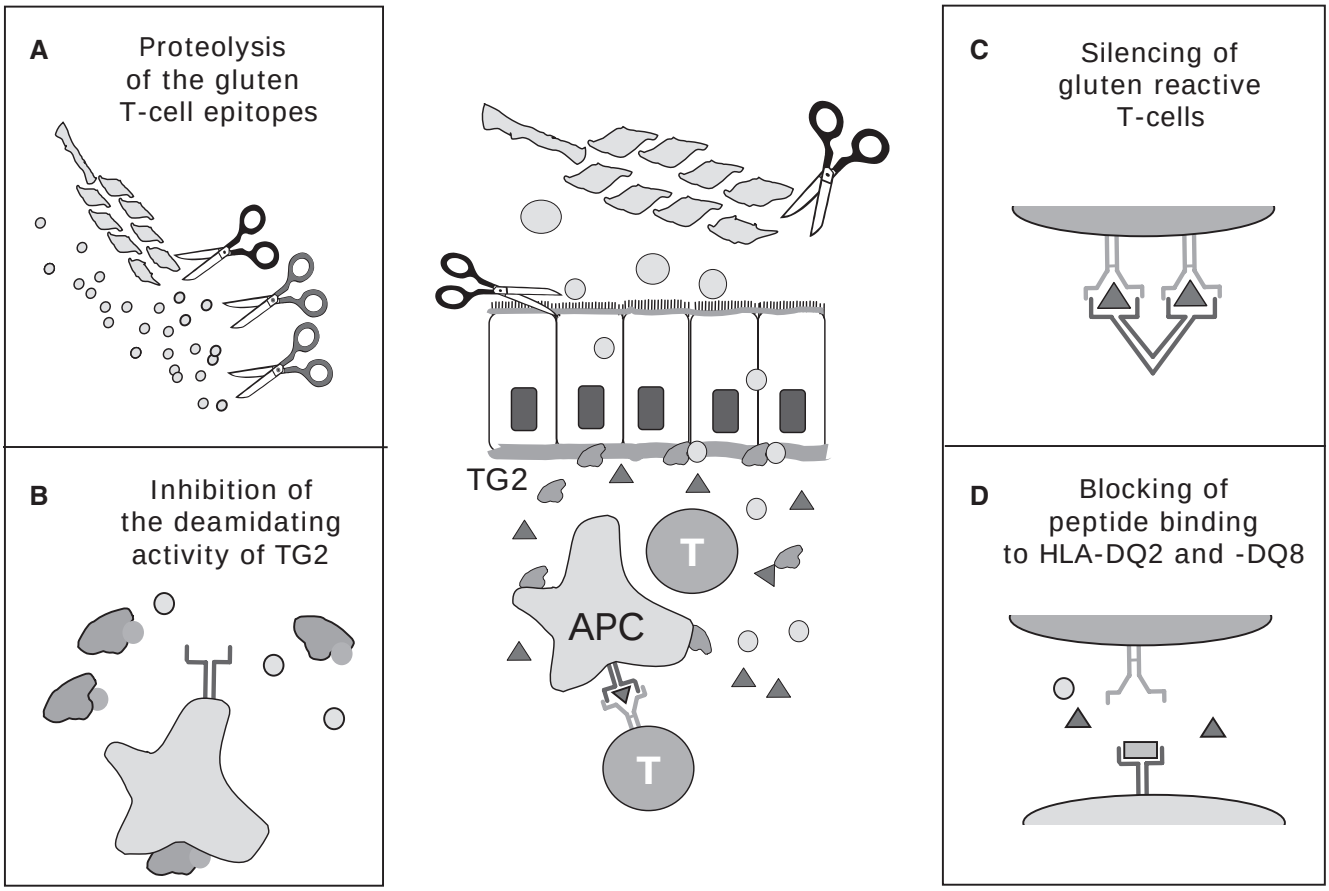

FIGURE 51.7 New insight into the pathogenesis of celiac disease provides rational targets for interfering with the disease process. *A*, Peptidase supplementation can prevent immunogenic peptide from being presented to T cells by direct destruction or by facilitating the gastrointestinal proteolysis. Prolylendopeptidases that cleave adjacent to proline residues are particularly attractive as these enzymes will target proline-rich peptides that are especially resistant to proteolysis and which often contain HLA-DQ2-restricted T-cell epitopes. *B*, Inhibition of the deamidating activity of tissue transglutaminase (TG2). Inhibitors of TG2 will prevent formation of the deamidated gluten peptides that are particularly stimulatory to T cells. *C*, Silencing of gluten-reactive T cells. This can be done in a variety of ways from oral challenge with gluten together with infusion of antibodies to CD154 or CD3 or the generation of multivalent and soluble HLA–peptide complexes (depicted) that are unable to provide all signals required for T-cell stimulation and which induce T-cell apoptosis. *D*, Blocking of peptide presentation by HLA molecules to gluten reactive T-cells by compounds that fill up the binding sites of DQ2 and DQ8 molecules without activating T-cells. This will prevent binding of gluten peptides to these HLA molecules and thereby T-cell activation. APC, Antigen-presenting cell.

relate to the autoimmune aspects of the disease. Is celiac disease an autoimmune disorder? To what extent are the autoimmune components of celiac disease involved in the disease development? How relevant are the findings of T-cell recognition of post-translationally-modified peptides and autoantibody formation driven by an exogenous food antigen for other autoimmune disorders? Can it be that other autoimmune disorders are driven by immune responses to foreign, not yet identified, antigens? Finally, is it true that a gluten-free diet can protect against development of associated autoimmune diseases, and if so, can this knowledge be used to understand autoimmunity in general? We are sure that studies of celiac disease will continue to provide interesting answers.

Acknowledgments

Studies in the authors' laboratory are funded by grants from the Research Council of Norway, the European Commission (BMH4-CT98-3087, QLRT-1999-00037, QLRT-2000-00657), the Norwegian Cancer Society, Medinnova, Freia Chokolade Fabriks Medicinske Fond, the Jahre Foundation, and EXTRA funds from the Norwegian Foundation for Health and Rehabilitation.

Inflammatory Bowel Diseases: Ulcerative Colitis and Crohn's Disease

RON PALMON AND LLOYD F. MAYER
Mount Sinai School of Medicine, New York, NY

Inflammatory bowel disease (IBD) is divided into 2 distinct but related entities: Crohn's disease (CD) and ulcerative colitis (UC). While the two diseases share some features, there are important clinical differences between them, and so they will be presented separately for part of this discussion. It should also be noted that the etiology and pathophysiology of IBD is not yet clearly established; furthermore, the degree to which these diseases are truly autoimmune in nature is increasingly unapparent.

HISTORY

Numerous case reports exist from the 19th century describing inflammatory diseases of the small and large intestine that may have represented CD (Baron, 2000). Ileocecal inflammation as seen in CD is also characteristic of intestinal tuberculosis, which was the most commonly recognized disease of the small intestine at that time. As microscopy evolved, case series exist of patients with inflammation and strictures of the ileocecal region that were determined to be neither tuberculous nor malignant. These strongly suggest that CD, as we presently know it, existed at least as far back as the 19th century. In fact, the first real report of terminal ileitis (later termed CD) was made by a Scottish physician, Dalziel, in 1824.

The seminal work describing CD, however, was a paper from the Mount Sinai Hospital in New York by Burrill B. Crohn's, Leon Ginzburg, and Gordon D. Oppenheimer (1932) entitled *"Regional Ileitis: A Pathologic and Clinical Entity."* The authors described a series of 14 patients operated upon by Dr. A. A. Berg with granulomatous inflammation of the terminal ileum. The title of the paper reflected Crohn's belief that the disease affected only the ileum (Wells, 1952) despite evidence, presented by Ginzburg and Oppenheimer (1932) and others, of cases affecting the small and large intestine. Interestingly, the disease came to be known as Crohn's disease only because the authors agreed to list their names alphabetically and because the surgeon Berg humbly declined to be included as an author (Baron, 2000).

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

Early work on UC was also complicated by difficulty in distinguishing it from infectious colitides such as bacillary dysentery. Credit for the discovery of UC as a distinct entity has been given to Samuel Wilks (1859) who termed it "idiopathic colitis." The term "ulcerative colitis" was first used by Hale-White (1888), although in retrospect these patients may not have had UC but rather irritable bowel syndrome (Baron, 2000). Further work was facilitated by the introduction of the electric sigmoidoscope; studies by Sir William Hurst (1909) and also Lockhart Mummery (Mummery, 1907) helped to clarify the appearance of the colon in UC.

EPIDEMIOLOGY AND ENVIRONMENTAL FACTORS

The highest rates of IBD are found in northern Europe, the United Kingdom, and North America (Loftus, 2004). However, it is increasingly recognized that IBD can occur in persons from other areas such as Africa, Latin America, and Asia. Extrapolation of incidence and prevalence rates for North America as presented by Loftus (2004) and suggest the following: approximately 780,000 persons in the U.S. and Canada have UC and 630,000 have CD. Between 7,000 and 46,000 new diagnoses of UC are made yearly and between 10,000 and 47,000 new diagnoses of CD are made. Similar to multiple sclerosis, IBD does appear to be more frequent in the northern latitudes (Blanchard et al., 2001; Sonnenberg et al., 1991).

Inflammatory bowel disease may present at any age; however, it is most commonly diagnosed in the second or third decade of life. There does not seem to be a major gender preference in IBD. Other than genetic risk factors, which will be addressed in a separate section, several environmental risk factors have been hypothesized to predict the development or course of IBD. Cigarette smoking is an important risk factor with divergent effects on CD and UC. Numerous studies have confirmed that smoking is associated with a higher risk of developing CD (Calkins, 1989), an earlier need for surgery for CD (Sands et al., 2003), and earlier relapse after surgery (Timmer et al., 1998). Conversely, cigarette smokers are less likely to develop UC (Calkins, 1989) or to require colectomy for UC (Boyko et al., 1988). In numerous case–control studies as well as a meta-analysis by Koutroubakis et al. (2002), appendectomy has been shown to protect against the subsequent development of UC. The pathophysiologic and protective effects of smoking and appendectomy are as yet unclear. Numerous other environmental factors have been studied, including breastfeeding, diet, measles vaccination, oral contraceptives, and various infectious agents. However, none of these have been conclusively shown to affect the development or course of IBD.

CLINICAL AND PATHOLOGIC FEATURES

Disease Presentation

Crohn's Disease

A hallmark of CD is its ability to involve any part of the gastrointestinal (GI) tract from mouth to anus. Multiple sites in the intestine can be affected in the same individual. The inflammation in CD, as distinct from UC, is discontinuous; diseased bowel is separated by areas of healthy bowel (so-called "skip lesions"). The location of CD in the bowel usually falls into one of three patterns: isolated small bowel disease, combined small and large bowel disease, or isolated colitis. The most commonly affected segment of bowel is the terminal ileum, which is diseased in two-thirds of patients (Munkholm and Binder, 2004). Colonic involvement in CD typically does not involve the rectum, which is always involved in UC. A small percentage of patients have disease of the duodenum, jejunum, or esophagus only.

Crohn's disease can also be divided into 3 types of disease behavior: pure inflammatory, stricturing, or fistulizing. These behavior types are not mutually exclusive; however, the combination of disease behavior and location can nonetheless often dictate clinical presentation. For example, a common presentation of CD is inflammatory disease of the terminal ileum with symptoms of pain, diarrhea, and weight loss. When inflammatory disease involves the colon, a more UC-like syndrome ensues with diarrhea and occasional rectal bleeding. Stricturing disease can be more subtle in development, with a long time course of relatively normal bowel function before symptoms of pain, bloating, and eventually obstruction ensue.

The ability of CD to cause fistulae reflects its transmural nature. Ulcerative colitis involves only the mucosal layer of the GI tract while CD can involve all layers from mucosa to serosa. When inflammation is severe enough to extend from mucosa to serosa, fistulae result such that the contents of the intestinal tract spill out into an adjacent space. The perianal region is the most common site of fistula development in CD. Approximately 20% of patients with CD will have perianal fistulae (Schwartz et al., 2002) which present clinically with perianal abscesses that may spontaneously drain. Fistulas can also arise in the bowel and invade other parts of bowel, bladder, vagina, or psoas muscles causing abscesses or frank drainage of stool.

Another characteristic feature of CD is its capacity to recur following surgery. Resection of an affected segment of bowel followed by reanastomosis of the histologically uninflamed margins invariably (98% by endoscopy) leads to the development of recurrent disease at the anastomosis, generally on the proximal side, although other sites can develop disease. The predilection for this site of recurrence may relate to the presence of an overgrowth of luminal micro-

organisms or potentially to vascular factors. In contrast, surgery for UC is associated with a "cure." Since UC is a colonic disease, the surgery—total proctocolectomy and end ileostomy—completely removes the site where disease can exist. However, this concept has had to be reassessed in recent years. A new surgical approach, restorative proctocolectomy, eliminates the ileostomy and involves the creation of a reservoir, fashioned from the terminal ileum, which resides within a denuded rectal muscular tube. Up to 50% of UC patients develop a syndrome called pouchitis within the ileal reservoir that is clearly bacterially driven i.e. it responds to antibiotic therapy. Interestingly, patients with familial polyposis, a premalignant non-inflammatory disease of the colon, rarely if ever develop pouchitis following a similar procedure. This clinical observation provides evidence for a broader mucosal immune defect in UC patients that is only exposed following the "colonization" of the pouch flora.

Ulcerative Colitis

Ulcerative colitis affects only the colon. As a result, its presentation is more consistent than that of CD. It usually presents with symptoms of diarrhea and rectal bleeding. Abdominal pain and constitutional symptoms (fever, weight loss) are less frequent than in CD, except in severe UC flares. The amount of colon that is involved in UC can vary from the entire colon (pan-colitis) to just the most distal part (left-sided colitis or proctitis). As a rule, the more proximal colon will only be affected when the more distal area is as well. Thus the endoscopic findings of isolated right-sided colitis (in combination with other features such as rectal sparing) argue strongly for a diagnosis of CD as opposed to UC. Isolated proctitis can present as tenesmus or rectal bleeding in the absence of diarrhea given the normal proximal colon. Infrequently, pan-colitis can progress to toxic megacolon, a massively dilated colon with accompanying fever and tachycardia; immediate surgery is most often indicated for this condition.

Pathology

Microscopy of specimens from endoscopic mucosal biopsies or surgical resections can help ascertain the diagnosis of IBD and occasionally distinguish between UC and CD. Common features of IBD include ulceration, acute and chronic inflammatory infiltrate, crypt abscesses, and crypt distortion. Though suggestive of IBD, these changes can sometimes be seen in other conditions such as infectious colitis. The findings of transmural inflammation (usually discernible only in surgical specimens) or of non-caseating granulomas suggest a diagnosis of CD as opposed to UC. Unfortunately, granulomas may be identified in as few as 15% of endoscopic biopsies (Okada et al., 1991), and therefore the absence of granulomas does not rule out CD. The cellular infiltrate in the CD mucosa is one of activated lymphocytes (mostly T-cells) and macrophages. In UC, neutrophils and mast cells predominate although activated lymphocytes and macrophages are present as well.

There are characteristic gross features of CD and UC that can be seen by the naked eye at surgery or during endoscopy. The propensity to have normal areas interspersed with areas of active inflammation in CD ("skip lesions") favors the development of a classical gross feature called cobblestoning. Longitudinal fissures dissect normal mucosa, leading to this finding. Furthermore, the transmural nature of the inflammatory process in CD is seen as "creeping fat" with envelopment of the bowel with fat starting from the mesenteric border. Stricturing is also a common feature of CD with fixed fibrotic stenotic segments interspersed throughout the bowel. Areas of the bowel proximal to the stenotic segment are dilated and, therefore, subject to bacterial overgrowth, potentially worsening the malabsorption seen in this disease. In contrast, UC is characterized by an ulcerated, edematous, and friable mucosa with frank bleeding. The continuous nature of the inflammatory process allows a reasonable assessment of the degree of disease activity at all sites just by looking at the rectum (unless the patient is on topical medications).

Colorectal Cancer and Inflammatory Bowel Disease

The most feared complication of IBD is the development of colorectal cancer (CRC). Numerous studies have confirmed the increased risk of CRC in UC as well as Crohn's colitis. A meta-analysis by Eaden (2001) found the prevalence of CRC in patients with UC to be 3.7%. In anatomically extensive Crohn's colitis, the risk of colon cancer is similar (Sachar, 1994). The factors that increase risk of CRC in patients with IBD include duration and extent of disease, family history of CRC, and presence of primary sclerosing cholangitis (Itzkowitz and Harpaz, 2004); the most important of these is duration of disease. Colorectal cancer is rarely found in patients with less than 7 years of colitis. After 10 and 20 years of disease, the risk of CRC is 2% and 8%, respectively (Eaden, 2001).

The molecular mechanisms of CRC development in the sporadic population (those without IBD) have been extensively studied. In sporadic CRC, there is a sequence of mutations that leads to carcinogenesis. For example, a mutation in the *APC* gene is the initiating event, while mutations in p53 occur late in carcinogenesis. In colitis-associated CRC, the p53 mutations occur earlier and *APC* mutations occur late if at all (Itzkowitz, 2004). Clinically, mutations that appear earlier in the pathway are reflected in the development of dysplasia, precancerous changes that can be detected on mucosal biopsy. Colonoscopic surveillance

programs are recommended for patients with long-standing colitis to detect early evidence of malignancy and then perform colectomy before the development of CRC.

Extraintestinal Manifestations

Although IBD is considered a primary disease of the bowel, it is a systemic disease. The most commonly involved organs outside the gut are the skin, joints, eyes, and liver. Many of the extraintestinal manifestations of IBD are associated with other autoimmune and inflammatory disorders or can exist as primary disorders.

The most common skin manifestation of IBD is erythema nodosum (EN), which typically presents as painful red nodules on the pretibial region. It occurs in 5–10% of patients with IBD (Greenstein et al., 1976), is more frequent in women, and both flares and resolves along with the underlying bowel disease. Erythema nodosum also occurs with sarcoidosis, post-streptococcal infection, and oral contraceptive use. Pyoderma gangrenosum (PG) is less common but more troublesome than EN; it begins as a fluctuant nodule on the skin with eventual ulceration and central necrosis. It is most commonly observed on the trunk and extremities. Unlike EN, PG does not parallel the activity of underlying IBD. It can frequently occur in the absence of IBD or precede the development of IBD.

The joint manifestations of IBD include both axial and peripheral arthropathies. The axial arthropathies of IBD are ankylosing spondylitis (AS) and isolated sacroiliitis (see Chapter 33). Both present with back pain as a result of inflammation of the sacroiliac joint, but only in AS is there progressive involvement of the spinal column with severe limitation of mobility. Between 50% and 80% of patients with IBD-associated AS are HLA-B*27 positive (Orchard and Jewell, 2004); presumably, possession of this allele affects the presentation of an as yet unknown bacterial antigen. The course of AS is independent of the bowel disease. The most common peripheral arthropathy of IBD is the type I or pauciarticular arthritis, which can present as pain and swelling of the knees, wrists, ankles, or other joints. The arthritis is typically asymmetric, involves fewer than four joints, and does not cause destruction or erosion of the joints. This form of arthritis usually resolves with improvement of the underlying bowel disease.

Ocular involvement in IBD ranges from inflammation of the more superficial layers, such as the conjunctiva and sclera, to the inner layers such as the uvea. Superficial involvement can cause redness and irritation, but the development of pain or blurry vision suggests uveitis and warrants prompt ophthalmologic evaluation with a slit-lamp exam. Treatment with topical steroids is usually effective, and permanent loss of vision is rare.

The major extraintestinal manifestation of IBD in the liver is primary sclerosing cholangitis (see Chapter 55). This is a chronic cholestatic disease, which can present initially with abnormal liver chemistries, with the subsequent development of jaundice and then cirrhosis.

Differential Diagnosis

Common examples in the differential diagnosis of IBD are presented in Table 52.1. There is no pathognomonic clinical feature or test that allows one to make a diagnosis of CD or UC with absolute certainty. However, a careful examination of clinical, endoscopic, radiographic, laboratory, and pathologic data will usually allow the clinician to make a diagnosis (Figures 52.1 to 52.3). Features of the disease may change over time, occasionally even requiring a modification of the original diagnosis. In approximately 10% of patients with colitis, a distinction between UC and CD cannot be made; this is termed indeterminate colitis. Serologic tests may be helpful in this situation (see Serologic Markers).

Genetics

Several factors point to a genetic contribution to the etiology of IBD. Rates of IBD are considerably higher in certain ethnic groups such as Ashkenazi Jews compared with others living in the same geographic area. Relatives of patients with IBD also have a higher rate of developing

TABLE 52.1 Examples of the major categories in the differential diagnosis of inflammatory bowel disease

Category	Examples
Infectious	Bacterial (*Salmonella*, *Shigella*, *Escherichia coli*, *Yersinia*, *Clostridium difficile, Campylobacter*) Viral (Cytomegalovirus) Mycobacterial (*M. tuberculosis*, *M. avium-intracellulare*) Parasitic (*Entamoeba histiolytica*, *Strongyloides*, *Giardia*)
Vascular	Vasculitis (polyarteritis nodosa, Henoch-Schönlein purpura) Radiation-induced enteritis Ischemia
Oncologic	Lymphoma, adenocarcinoma, carcinoid, metastatic disease
Inflammatory	Microscopic colitis, diverticular colitis, diversion colitis, celiac disease
Functional	Irritable bowel syndrome
Drug-induced	Nonsteroidal anti-inflammatory drugs

the disease. For monozygotic twins, the concordance rate is approximately 40–60% for CD and 5–20% for UC (Halfvarson et al., 2003; Orholm et al., 2000; Subhani et al., 1998). This suggests that CD may have more of a genetic basis, but, clearly, since both rates are much less than 100% the environment must play a role as well. Between 5% and 10% of patients with IBD will have an affected first-degree relative, and the subtype (CD vs. UC) will be the same in 75–80% of cases (Binder, 1998). This corresponds to about a 15-fold increased risk of disease if one has a first-degree relative with IBD (Peeters et al., 1996; Satsangi et al., 1994). Lastly, certain rare genetic syndromes include IBD or an IBD-like component; these include Turner syndrome, Hermansky-Pudlak syndrome, and glycogen storage disease type Ib.

Much effort has been directed towards identifying the specific genes involved in IBD. Genome-wide screening using microsatellite markers have identified seven loci, named *IBD1–7*, that meet criteria for linkage to *IBD* (Ahmad et al., 2004). In 2001, the first CD susceptibility gene was identified within the *IBD1* locus on chromosome 16q12 (Hugot et al., 2001; Ogura et al., 2001a; Hampe et al., 2001). This gene, named *CARD15* (formerly called *NOD-2*), encodes an intracellular protein containing two C-terminal caspase recruitment domains (*CARDs*), a nuclear binding domain, and a leucine-rich repeat (LRR) region (Ogura et al., 2001b). All of the described CD mutations are in the LRR. The LRR appears to be involved in recognition of peptidoglycans (muramyl dipeptide) from gram-positive bacteria (Chamaillard et al., 2003). *In vitro* evidence suggests that mutations in the LRR region may affect innate immunity by decreasing the ability of intestinal epithelial cells and macrophages to clear luminal and intracellular bacteria (Hisamatsu et al., 2003). Normal activation of *CARD15* results in the activation of NFκB, which promotes an inflammatory response (Ogura et al., 2001b). *CARD15* mutations

appear to affect this pathway but the exact mechanisms are still unclear.

There are three common mutations within or near the LRR region on *CARD15* that are associated only with CD and not UC. Of patients with CD, 10–30% are heterozygotes for these mutations, and 10–15% are homozygotes or compound heterozygotes (Hugot et al., 2001; Ogura et al., 2001a; Hampe et al., 2001). In controls without CD, 8–15% are heterozygotes and 0–1% are homozygotes. Carrying one of these mutations increases the relative risk of CD significantly, although the absolute risk remains small (Table 52.2). Numerous studies have shown that *CARD15* variants are associated specifically with younger age of onset, ileal disease, and stricturing phenotype (Lesage et al., 2002; Ahmad et al., 2002). Of note, the contribution of *CARD15* to CD is strongest in whites; studies of African-Americans populations show weaker associations (Bonen et al., 2002), while *CARD15* mutations have not been found in Asians (Inoue et al., 2002).

The identification of *CARD15* as a CD susceptibility gene is an important development in IBD research. However, only a minority of cases of CD worldwide are associated with *CARD15* mutations. The relevant genes on other loci are beginning to be elucidated. *IBD3* on chromosome 6 contains the major histocompatibility complex (MHC) regions; numerous studies have shown various HLA associations with CD and UC (Stokkers et al., 1999). *IBD5* on chromosome 5 has recently been shown to contain the organic cation transporter (*OCTN*) gene cluster. Homozygosity for two linked single-nucleotide polymorphisms in the *OCTN* gene cluster confers a 3- to 5-fold increase in the risk of CD (Peltekova et al., 2004). Furthermore, possessing both the *OCTN* and *CARD15* mutations increases the risk of CD much more. The *OCTN* genes are expressed in the intestinal epithelium, but their function has not yet been explored. Variation in *DLG5*, a newly discovered gene on chromosome 10, appears to increase the risk of both UC and CD (Stoll et al., 2004). *DLG5* may be important in the pathogenesis of IBD as it encodes a protein involved in maintenance of epithelial integrity. Clearly, there is much that remains to be learned about the genetic basis of IBD.

TABLE 52.2 Relative and absolute risk of Crohn's disease based on *CARD15* genotype variants*

	Relative risk	Absolute risk
No variant	1	7×10^{-4}
Simple heterozygote	3	2×10^{-3}
Homozygous	38	3×10^{-2}
Compound homozygous	44	2×10^{-2}

*Data from Hugot et al. (2001).

ANIMAL MODELS OF INFLAMMATORY BOWEL DISEASE

Probably the greatest advance in the study of IBD has been in the identification of a number of animal models (Table 52.3). These models have enabled investigators to test hypotheses regarding the pathophysiology and treatment of IBD. Initial animal models were based on the induction of intestinal inflammation by a chemical agent. These chemically induced models are limited in that acute, rather than chronic, inflammation is usually the result. In addition, there does not appear to be a convincing role for T-lymphocytes in the majority of these models. Recently, genetically engineered mice and rats have been developed whereby chronic models of T-lymphocyte-mediated injury, more consistent with the human disease, can be tested.

Chemically-Induced Models

A representative example of a chemically-induced model of IBD is the dextran-sodium sulfate (DSS) model. Administration of 5% DSS in drinking water can induce an acute colitis in most mice with symptoms such as bloody diarrhea and weight loss (Cooper et al., 1993). Repeated administration of DSS can also induce chronic inflammation. Histologic changes ensue such as inflammatory cell infiltration and ulcerations (Sartor, 2004). However, the role of intestinal bacteria is questionable as germ-free mice are also susceptible to DSS-induced colitis (Kitajima et al., 2001). The effects of DSS appear to be directed at the intestinal epithelium (?direct toxic injury/effect). Furthermore, it does not appear that T-lymphocytes are important in this model as SCID mice will also develop colitis in response to DSS (Axelsson et al., 1996). Several other chemical agents have been used in mice and rats such as acetic acid, indomethacin, trinitrobenzene sulfonic acid (TBNS), and oxalazone (the latter 2 involving different sub-populations of T-cells, Th1 and Th2, respectively). These models appear to be more useful in studying epithelial response to injury rather than true chronic immune-mediated injury. However, they have been used extensively in drug discovery.

TABLE 52.3 Commonly used animal models of inflammatory bowel disease

Category	Examples
Chemically-induced	Dextran-sodium sulfate, acetic acid, indomethacin, trinitrobenzene sulfonic acid, oxalazone, peptidoglycan-polysaccharide
Genetic	IL-$2^{-/-}$, IL-$10^{-/-}$, TCR$\alpha^{-/-}$
Transfer	$CD45RB^{high}$ T-cell to SCID mice
Spontaneous	C3H/HeJ Bir, SAMP-1/Yit, cotton-top tamarin

An interesting variant of the induced model is the peptidoglycan-polysaccharide (PG-PS) enterocolitis model. Peptidoglycan-polysaccharide is a component of bacterial cell walls that stimulates inflammation via activation of NFκB. Injection of PG-PS directly into the wall of the ileum and colon induces a chronic enterocolitis, peripheral arthritis, and anemia in Lewis rats (McCall et al., 1994; Sartor et al., 1996). This chronic inflammation is T-lymphocyte mediated and reversed by corticosteroids (Herfarth et al., 1998).

Genetic Models

A common theme for the development of these models is the deletion of a gene encoding a cytokine or its receptor. Interleukin 2 (IL-2) is necessary for T-cell replication, regulatory T-cell activation, as well as programmed cell death. Mice deficient in IL-2 actually have increased numbers of activated T cells early in life, perhaps from defective apoptosis (Kneitz et al., 1995). The IL-$2^{-/-}$ mouse develops pancolitis, diarrhea, weight loss, and eventual death (Sadlack et al., 1993). Histologic changes resemble those of IBD. In this model there is also evidence of autoimmunity as they develop autoimmune hemolytic anemia at an early age. In fact many mice fail to survive long enough to develop the IBD due to the profound anemia seen at an early age. Evidence suggests that T cells secreting a Th1 cytokine profile are the mediators of colitis in this model (Ehrhardt et al., 1997). Germ-free mice develop only a mild colitis, if any (Schultz et al., 2001). The dominant T-cell nature of this and other models has been underscored by the finding that IBD is still seen in the $IL2^{-/-}$ mouse even in B-cell deficient mice. In fact, in some models the absence of B cells is associated with an even more aggressive course (i.e., $TCR\alpha^{-/-}$ mouse). Thus the animal models of IBD have helped to raise further doubt regarding the autoimmune nature of these diseases.

Interleukin 10 is an important inhibitory cytokine that can cause a decrease in T-cell activation. SPF IL-$10^{-/-}$ mice develop a progressive pan-colitis with weight loss (Kuhn et al., 1993). The ability of antibodies to interleukin 12 (anti-IL-12), interferon-γ (anti-IFNγ) and tumor necrosis factor (anti-TNF) to block colitis highlights the importance of the Th1 response, as in the IL-$2^{-/-}$ model (Davidson et al., 1998). As in the $IL2^{-/-}$ mouse, B-cells do not appear to play a positive role in the development of intestinal inflammation in the $IL10^{-/-}$ model. However, the role of commensal bacteria in pathogenesis of the colitis is suggested by observations that germ-free mice do not develop colitis, and that subsequent introduction of such bacteria will induce a rapid inflammatory response (Sellon et al., 1998). Furthermore, probiotics and antibiotics prevent or ameliorate colitis (Madsen et al., 2000). Interestingly, administration of nonsteroidal anti-inflammatory drugs (NSAIDs) to IL-$10^{-/-}$ mice results in a much more rapid development of colitis (Berg et al., 2002). Inhibition of prostaglandins by NSAIDs may hasten colitis by interfering with important immunomodulatory functions and by disrupting the intestinal epithelium, leading to an abnormal inflammatory response to intestinal bacteria.

The $TCR\alpha^{-/-}$ mouse also develops colitis spontaneously around 10–14 weeks of age but the immune response in the gut is more Th2 in nature (Mombaerts et al., 1993). These findings support the concept that an immune imbalance of any type (Th1 or Th2) is poorly tolerated by the mucosal immune system and that tight regulation is critical for normal mucosal homeostasis. T-cells are the major regulators of this mucosal homeostasis; B-cells and antibodies, while present in abundant quantities, play a regulatory rather than an inflammatory role in disease development.

Transfer Models

Adoptive transfer of $CD45RB^{high}$ $CD4^+$ T cells from normal mice to SCID mice induces non-bloody diarrhea, weight loss, and death within 4–8 weeks (Morrissey et al., 1993). $CD45RB^{high}$ is a marker of naïve T cells (as well as Th1 cells), and expression decreases once T cells are activated. Interestingly, co-transfer of $CD45RB^{low}$ $CD4^+$ T cells prevents colitis, suggesting that these cells have an important regulatory function. Evidence suggests that colitis in this model is induced by naïve T cells in the presence of commensal enteric bacteria (Sartor, 2004). This model was the first to truly document the role of regulatory cells in mucosal homeostasis. This has led to the concept that the defect in IBD is related to an overzealous immune response due to a defect in immune regulation.

Spontaneous Models

There are two inbred strains of mice, the C3H/HeJ Bir mouse (Sundberg et al., 1994) and the SAMP-1/Yit mouse (Matsumoto et al., 1998), that develop a Crohn's-like phenotype with ileocolonic and perianal disease. These spontaneous models are presumed to be genetic mutations but have yet to be fully elucidated. Some gene candidates have been identified and are similar to disease modifying genes in the IL-$10^{-/-}$ model. The cotton-top tamarin in captivity will spontaneously develop a chronic colitis with periodic flares of disease and ultimately colonic adenocarcinoma (Chalifoux and Bronson, 1981). This model is used less frequently due to limited access to the animals.

IMMUNOPATHOGENESIS

Since the mid-1990s there has been an explosion in our knowledge of IBD pathogenesis. Such advances have directly contributed to the growing number of specific

biologic therapies for IBD. These advances have come from the identification of a large number of animal models, genome-wide scans leading to the identification of a gene *NOD2/CARD15* (Hugot et al., 2001; Ogura et al., 2001a) associated with CD (as well as two other genes *OCTNI/II* and *DLG5*) (Peltekova et al., 2004; Stoll et al., 2004), and a renewed appreciation of the existence of regulatory cells. We have also learned from the successes and failures of available targeted biologic therapies in humans. The overall hypothesis guiding the current advances is that IBD occurs as a result of a dysregulated $CD4^+$ T-cell response to a number of bacterial antigens (normal flora) in a genetically susceptible host. The animal models have served to underscore the role of the luminal flora. In virtually every model identified to date (over 50 described), the animals fail to develop disease when reared in a germ-free environment (Podolsky, 1997). When normal flora are added, disease ensues rapidly. In some studies, addition of as few as one nonpathogen is sufficient to initiate the disease process. Furthermore, more recent studies from Sartor's group (Rath et al., 2001) suggest that specific bacteria trigger disease in different locations. Such a finding goes a long way towards explaining the segmental nature of CD. The models have also provided validation of the hypothesis regarding the concept that CD is a multigenic disorder and that the input of different genes provides the substrate for specific disease expression. For example, an $IL\text{-}10^{-/-}$ mouse on a C57BL/6 background develops disease early, but if the same defect in IL-10 is bred onto other backgrounds there is a modification of the disease expressed (ranging from more severe to protected from disease) (Powrie, 1995). Therefore, IBD is clearly a multigenic disorder providing a rationale for the variability in disease expression. We have also learned that the animal models are not really classical IBD. The overwhelming majority of models have colonic disease only and respond to therapies that have no effect on human disease (e.g. IL-10) (Lindsay and Hodgson, 2001). However, most importantly, we have learned that multiple distinct immune defects can result in overt clinical and histologic disease. Defects in innate immunity (targeted STAT3 knockout in macrophages) (Welte et al., 2003) as well as in Th1 and Th2 immune responses can lead to inflammation.

The take-home message is that too much of any type of immune response is poorly tolerated in the mucosal immune system. This makes immunologic sense since the mucosal immune system is continuously challenged by bacterial and dietary antigens, but a state of suppressed and controlled immunity is the norm. Disruption of this control in any way results in inflammation. Failure to regulate the inflammation results in its persistence. Oxazalone colitis occurs because of an overproduction of IL-13 by NK T cells (Heller et al., 2002). TNBS colitis is Th1 driven (Neurath et al., 2000). How these correlate to human CD or UC has yet to be defined.

The genetic defects described have a common feature in that the gene products are expressed in the epithelium. *NOD2/CARD15* is an intracellular pattern-recognition receptor recognizing muramyl dipeptide on gram-positive organisms (Girardin et al., 2003). The mutations result in a failure to signal and may be related to a loss of regulation of TLR2 signaling, or the persistence of intracellular bacteria in intestinal epithelial cells (IECs) or macrophages (Watanabe et al., 2004). Persistent intracellular infection is associated with granuloma formation similar to that seen in CD. *OCTNI* and II are cation transporters found in IECs (Peltekova et al., 2004) and in part may contribute to permeability or integrity of the mucosal barrier.

The identification of genes associated with IBD has served to clarify some of the pathogenetic issues, but the major focus of various laboratories studying these diseases has been on the role of the immune system. While there are several "camps" focused on a given cell type or component of the immune system responsible for development of disease (epithelial cell, T cell, innate immunity, adaptive immunity, macrophage/DC), the final outcome will likely be some mixture of the various models. Defects in permeability have been described for years, but a specific defect has not been identified (Meddings, 1997). Epithelial cells are at the interface between the outside world and the enormous lymphoid mass that is the Gut-associated lymphoid tissue (GALT). Epithelial cells can sample antigen, present it to T cells, form a tight barrier, transport IgA, and secrete pro- and anti-inflammatory cytokines and chemokines (Mayer and Shlien, 1987; Kaiserlian et al., 1989; Mostov, 1994; Jung et al., 1995; Allez et al., 2002). Due to the normal differentiation process of the IEC these properties may differ from the crypt to the surface. The IEC also expresses a large number of nonclassical class I molecules embedding its role as a bridge between innate and adaptive immunity (Campbell et al., 1999). Dendritic cells and macrophages also communicate with both arms of the immune system, and each has been implicated in human disease and murine models.

As alluded to above, there is increasingly less evidence that B cells and antibodies play a role in the disease process of IBD. This may be different in CD or UC: in CD, classic Th1-mediated immunopathology is seen (i.e. granulomas, T-cell, and macrophage activation); in UC, the pathology is more reminiscent of an Arthus reaction, where neutrophil emigration and mast cell degranulation are commonplace. Immune complexes might form in the tissues and activate the complement cascade. However, the initial description of anti-epithelial cell antibodies has yielded to the increasing evidence that many of these antibodies are cross-reactive with anti-bacterial antibodies. In addition, there is limited evidence to support the concept that these antibodies actually play an active role in the disease process other than potentially as a complement-activating immune complex as suggested above. The perinuclear antineutrophil cytoplas-

mic antibody (pANCA) associated with UC is a marker of the disease and persists even after colectomy (see below). Its titer does not correlate with disease activity and transfer of these antibodies from mouse models fails to transfer disease. Similarly the anti-40 kDa epithelial antibody described by Das that has been shown to recognize tropomyosin V does not vary with activity of disease. The TCR$\alpha^{-/-}$ mouse does develop these antibodies, and they have been shown to co-localize with terminal complement components, but no-one has been able to document that they can either trigger or foster the disease. The finding that colitis can develop in B cell deficient mice as well as in humans with hypogammaglobulinemia raises doubts as to whether these diseases are classically autoimmune. More persuasive are the findings that both T and B cells react inappropriately to the patient's own gut flora, contributing to the persistence of the inflammatory process.

However, the greatest focus relating to disease pathogenesis has been on the $CD4^+$ T cell. Studies from a large number of groups have documented the enhanced activation status of these cells in the lamina propria in IBD patients (Pallone et al., 1987). Isolated lamina propria mononuclear cells (LPMCs) from inflamed areas secrete high levels of cytokine (IFN-γ, IL-12, TNF-α in CD; IL-5, IL-13 in UC) (Colpaert et al., 2002; Monteleone et al., 1997). They also demonstrate a defect in apoptosis (Boirivant et al., 1999). Once activated, the cells persist. This is in direct contrast to normal lamina propria lymphocytes (LPLs) where there is easy induction of apoptosis after activation. This activation is inappropriate in an immune system that is highly regulated and tolerant of luminal antigens in the normal state. Duchmann et al. (1995) reported that patients with IBD fail to demonstrate tolerance to their own flora. Kraus et al. (2004) extended this to show that tolerance to a soluble protein antigen (oral tolerance) was defective in both UC and CD. Direct evidence for a defect in regulatory T cells (Tregs) in the gut of human IBD patients is lacking. It is becoming increasingly apparent that a large number of distinct Treg populations exist in the GI tract. In fact, all of the Tregs described to date have been identified in the gut (oral tolerance and Th3 cells) or as a component of an intestinal inflammatory disorder (Tr1 cells and graft-versus-host disease [GvHD], $CD4^+CD25^+foxp3^+$ Tregs and autoimmune gastritis in the mouse). If anything, there appears to be an increase in the amount of suppressive cytokines present in the lamina propria of IBD patients (increased TGF-β in CD, increased IL-10 in both UC and CD, and recent studies showing an increase in $CD4^+CD25^+$ Tregs in IBD tissues—areas of active disease) (Makita et al., 2004; Kelsen et al., 2005). Whether these are functional and/or appropriately placed within the mucosal immune milieu has not been addressed. Studies in mice strongly suggest that defects in Tregs provide the substrate for murine IBD. However, in all cases, the number of Tregs required to abrogate disease in these models (i.e. in a transfer model) is consistently greater than would be expected to exist *in vivo* in the normal state. The concept remains that it is the inability of the mucosal immune system to regulate an active mucosal immune response that allows for disease persistence.

Thus the current model provides a number of therapeutic insights. These have been exploited providing valuable therapies for the intractable patients.

SEROLOGIC MARKERS

A variety of serologic markers have been identified in patients with IBD. The best-described markers include pANCA, and anti-*Saccharomyces cerevisiae* antibodies (ASCA); pANCA is associated with ulcerative colitis and is distinguished from the ANCA associated with Wegener and other vasculitides in that the target antigen is located in the perinuclear region and is sensitive to degradation by DNase I (Targan and Karp, 2004). The exact target of pANCA in UC is thought to be the histone H1 protein. The ASCA is associated with CD and targets mannose sequences in the cell wall of the yeast *S. cerevisiae* (Sendid et al., 1996). The prevalence of pANCA and ASCA in patients with and without IBD is listed in Table 52.4. These prevalence data can be used to devise serologic strategies for diagnosing CD and UC. However, the utility of these strategies is debatable as no combination of serologies can make the diagnosis

TABLE 52.4 Prevalence, measured by three different groups, of perinuclear antineutrophil cytoplasmic antibody (pANCA) and anti-*Saccharomyces cerevisiae* antibody (ASCA) positivity in patients with Crohn's disease (CD), ulcerative colitis (UC), and controls

	UC		CD		Controls

of UC or CD with absolute certainty. Serology may be particularly helpful in the 10% of IBD patients with indeterminate colitis, in which the distinction between UC and CD cannot be made on clinical grounds (Joosens et al., 2002).

Serology has been used not only for diagnostic purposes but also for prediction of disease course. The subset of CD patients who are $pANCA^+$ uniformly have a more UC-like disease with left-sided colonic involvement, bleeding, mucus discharge, urgency, and the requirement for topical therapy (Vasiliauskas et al., 1996). These patients may be less likely to respond to infliximab therapy than the pANCA-CD patients (Taylor et al., 2001). This suggests that CD and UC may not be as much distinct diseases as they are two ends of a spectrum of disease. Patients with UC who have high titers of pANCA may be more likely to develop the complication of pouchitis after ileal pouch-anal anastomosis (Fleshner et al., 2001).

Several new antibodies have been discovered in CD patients. The first is the outer membrane porin C antibody (Omp-C). Anti-Omp-C is directed against a protein in the outer membrane of *Escherichia coli* and has been recently shown by Landers et al. (2002) to be present in 55% of patients with CD. The same group has identified another antibody, I2, which recognizes a bacterial protein associated with *Pseudomonas flourescens*. I2 antibodies were found in 50% of CD patients. The presence of anti-Omp-C and I2 in CD patients suggests that loss of tolerance to microbial antigens may in fact be important in the pathogenesis of IBD.

TREATMENT

The medical treatment of IBD involves a growing armamentarium of medications, as a fundamental knowledge of disease pathogenesis expands. Many of these drugs are used for both UC and CD. Clinical trials are hampered by a consistent finding of placebo response rates of about 30%. Some of the major classes of medication will be presented here, with specific mention of their use in CD and UC.

Aminosalicylates

The first aminosalicylate used in IBD was sulfasalazine, which consists of 5-aminosalicylic acid (5-ASA) bound to the antibiotic sulfapyridine via an azo-bond. This bond is split by enzymes present in colonic bacteria. It is the free 5-ASA that is released into the colon that exerts the therapeutic effect. 5-ASA has multiple anti-inflammatory properties including inhibition of production of IL-1 (Mahida et al., 1991), interference with binding of TNF (Shanahan et al., 1990), and as a free radical scavenger (Ahnfelt-Ronne et al., 1990). These effects appear to be mediated in part by inhibition of the activation of NFκB (Bantel et al., 2000). The most commonly used aminosalicylate in the treatment of IBD today is mesalamine. Various mesalamine preparations exist including coated drugs designed to delay release until the terminal ileum or colon, and topical enemas or suppositories for treatment of the distal colon and rectum.

Glucocorticoids

Corticosteroids are used extensively in the treatment of IBD. Glucocorticoids are steroid hormones that bind to cytosolic receptors and are then translocated to the nucleus where they affect transcription of various genes. This leads to inhibition of various proinflammatory mediators such as cytokines, leukotrienes, adhesion molecules, and nitric oxide synthase (Sands, 2002). Most patients with active UC or CD will respond to courses of oral glucocorticoids, although occasionally the intravenous route is required for severe disease. In many patients, however, tapering the drug will lead to a flare; this phenomenon is termed steroid-dependence. The well-known side effects of chronic steroid use are common and troublesome; these include diabetes, bone loss, acne, moon facies, and adrenal suppression. Attempts to limit these side effects have resulted in other formulations such as topical foam and enemas, which can be effective for left-sided colonic disease. Budesonide is an oral glucocorticoid that undergoes extensive first-pass metabolism in the liver. As a result, high topical levels are achieved in the GI tract with only about 10% systemic absorption and thus less steroid side effects (Edsbacker et al., 1999). Budesonide has been shown to have some efficacy as a treatment for mild-to-moderately active CD (Greenberg et al., 1994; Tremaine et al., 2002).

Thiopurines

The thiopurines include azathioprine and 6-mercaptopurine (6-MP). Azathioprine is metabolized to 6-MP, which can eventually be converted into a number of metabolites including 6-thioguanine nucleotides (6-TG). The therapeutic effect is thought to be due to induction of apoptosis of activated T-cells. The beneficial effect of thiopurines is generally not seen until after 3–6 months of use. The ideal use of thiopurines is as so-called "steroid-sparing" agents: to allow for the discontinuation of steroids in the patient who requires chronic or frequent use. Clinical studies have confirmed the utility of the thiopurines as steroid-sparing agents effective in inducing and maintaining remission in CD and UC (Present et al., 1980; George et al., 1996). The side effects of thiopurines are far less than those of glucocorticoids but include leukopenia, pancreatitis, and hepatitis. Interestingly, genetic variations in the enzyme thiopurine methyltransferase increase the risk of leukopenia by increasing 6-TG levels.

Infliximab

An exciting development in IBD is the approval of the first so-called "biological" agent. Infliximab is a chimeric monoclonal antibody against TNFα. The exact mechanism of action of infliximab is unknown. It appears that neutralization of soluble TNF is not the primary mechanism, since the soluble TNF-receptor etanercept is not effective in CD (Sandborn et al., 2001). Recent data suggest that binding of infliximab to membrane-bound TNF on inflammatory cells leads to apoptosis (Lugering et al., 2001; Van Den Brande et al., 2003) or reverse signaling resulting in the inhibition of cytokine synthesis by tissue macrophages.

For moderate-to-severe luminal (non-fistulizing) CD that is resistant to other therapies, an intravenous infusion of infliximab will lead to clinical response in more than half of patients within 2–4 weeks (Targan et al., 1997). Infliximab is also effective in the treatment of perianal fistulae due to CD (Present et al., 1999). After initial treatment with infliximab for luminal or fistulizing CD, a regimen of infliximab given every 2 months is effective in maintaining remission (Hanauer et al., 2002; Sands et al., 2004). Antibodies to infliximab (ATIs) are of concern in that they appear to increase the risk of infusion reactions and limit effectiveness (Baert et al., 2003); maintenance dosing and concomitant immunomodulator use will decrease the formation of these ATIs. The safety profile of infliximab is excellent. The major side effects are infusion reactions, which are generally mild and easily managed. Inhibition of TNF with infliximab can cause reactivation of latent intracellular infections (e.g. tuberculosis) and, therefore, all patients need to be screened for tuberculosis prior to treatment.

New Biologic Therapies

Inhibitors of Inflammatory Cytokines

As mentioned, the use of infliximab is limited by the formation of ATIs. Several other antibodies to TNF have been developed in an attempt to reduce immunogenicity. CDP571 is an IgG4 humanized monoclonal antibody to TNF. The largest placebo-controlled study of CDP571 in CD showed benefit only in the subgroup of patients with elevated baseline serum C-reactive protein (CRP) (Sandborn et al., 2004). The use of the marker CRP may be important in the future in identifying patients whose disease is truly inflammatory in nature and, therefore, would benefit from anti-TNF therapy. CDP870 is an anti-TNF Fab fragment conjugated to polyethylene glycol (PEG). The conjugation to PEG is used to prolong the half-life of the Fab fragment and reduce immunogenicity. However, an exploratory randomized study of CDP870 in CD failed to show a significant effect on clinical response (Winter et al., 2004). Adalimumab is a fully human IgG1 antibody to TNF that is already approved in the USA for the treatment of rheumatoid arthritis. Preliminary open-label studies suggest that adalimumab is safe and effective in the treatment of CD in patients who have had attenuated responses to infliximab (Papadakis et al., 2005). Further studies with adalimumab are underway.

Etanercept is a fully human fusion protein of the p75 TNF receptor with the Fc portion of IgG1. Although efficacious in rheumatoid arthritis, a placebo-controlled trial in CD failed to show any benefit (Sandborn et al., 2001). The lack of efficacy may be related to the fact that unlike infliximab, etanercept does not bind to membrane-bound TNF to induce apoptosis of inflammatory cells.

IL-12 has been shown in various animal models to be an important component of the Th1-mediated immune response in CD. A study of a weekly subcutaneous injections of human monoclonal antibody to IL-12 in patients with CD provides preliminary evidence for the efficacy of this new drug (Mannon et al., 2004).

Adhesion Molecule Inhibitors

Natalizumab is a humanized monoclonal antibody against α4 integrin. The integrins are a family of adhesion molecules on the cell surface of leukocytes that bind to endothelial cells. This binding is upregulated at sites of inflammation and leads to recruitment of leukocytes to these tissues. A large study of natalizumab in CD showed some improvement in clinical response (Ghosh et al., 2003); further studies are underway. Another antibody against the more specific target α4β7 integrin, LDP-02, has shown efficacy in induction of remission in UC. However, the recent description of 3 cases of progressive multifocal leukoencephalopathy (PML) in patients with multiple sclerosis or CD have resulted in the removal of this agent from the therapeutic armamentarium.

T-Cell Inhibitors

The ability to directly modulate the T-cell response could lead to benefit in the treatment of CD and UC. Monoclonal antibodies have been developed against the T-cell surface molecule, CD-3. CD-3 is associated with the T-cell receptor and is expressed on all T cells. Visiluzimab binds to CD-3 and is thought to induce apoptosis of T cells; it is presently being studied as a treatment for severe, steroid-resistant UC. Visiluzimab has been noted to cause a profound but temporary depletion in peripheral T cells limiting concerns regarding development of opportunistic infections.

Apheresis Procedures

Photochemotherapy involves *ex vivo* exposure of autologous peripheral blood mononuclear cells to 8-methoxypsoralen and long-wavelength ultraviolet A light. The cells are subsequently re-infused into the patient. Photoactivation leads to an immune response against pathogenic

T-cell clones. This has been used successfully against T-cell lymphomas, and appears to be promising in the treatment of steroid-dependent CD (Reinisch et al., 2001).

Another technique involves exposure of blood to an extracorporeal filter containing cellulose acetate beads or woven fiber filters, which provide selective adsorption of granulocytes and monocytes or granulocytes and monocytes and lymphocytes, respectively. This leads in turn to a decrease in the number of inflammatory cells in the blood and eventually to a decrease in such cells in the intestine. Japanese investigators have demonstrated that weekly treatments with this device has efficacy in the treatment of UC (Hanai et al., 2004; Yamamoto et al., 2004).

Hematologic Strategies

Several rare immunodeficiencies involving neutrophils, monocytes, or macrophages have CD-like intestinal inflammation, suggesting that defects in innate immunity are important. This has led to the use of growth factors such as granulocyte-monocyte colony-stimulating factor (GM-CSF) to treat CD. A recent open-label study of GM-CSF was very promising (Dieckgraefe and Korzenik, 2002).

In a different approach, a preliminary study of autologous hematopoietic stem cell transplant for the treatment of CD reported a sustained remission in 11 of 12 patients (Oyama et al., 2005). Although encouraging, it is as yet unclear if the improvement is secondary to the transplant itself or to the intense immune ablative pretransplant conditioning regimen.

SUMMARY

Inflammatory bowel disease is a complex, multifactorial disease with a wide range of clinical presentations and complications. Great strides have been made recently in understanding the immunopathology and genetics of the disease. The pathogenesis of IBD appears to represent an abnormal response by T-cells to normal gastrointestinal flora on a genetically susceptible background. Advances in our understanding of IBD have already led to an explosion of new targeted therapies. Further research will undoubtedly lead to better treatment and perhaps even cure or prevention of disease.

In the 1940s, the first reference to "chronic active hepatitis" was in relation to protracted viral hepatitis in soldiers (Barker et al., 1945). In the 1950s, there was recognized from Walderström in Sweden, Kunkel in the USA, and Wood and colleagues in Australia, a "malignant" chronic hepatitis affecting mainly young women, marked by systemic features and pronounced hyperglobulinemia (Mackay and Tait, 1994). Persisting high aminotransferase activities in blood and inflammation in the liver justified its designation as chronic active hepatitis (CAH). An immunologic basis for CAH was proposed, based on antinuclear antibodies (ANA) first detected by the test for lupus erythematosus (LE) cells, and a complement fixation (CF) reaction for anticytoplasmic antibodies (Mackay and Gajdusek, 1958). In the 1960s, ANA were detected more readily by indirect immunofluorescence (IIF) (Holbrow et al., 1963), and a further serologic reactivity was described by IIF as smooth muscle antibody (SMA) (Johnson et al., 1965; Whittingham et al., 1966). Also, efficacy of treatment with corticosteroid drugs alone, or with 6-mercaptopurine/azathioprine, became established (Mackay, 1968). These discoveries prompted replacement of the initially coined term *lupoid hepatitis* (Mackay et al., 1956) by autoimmune hepatitis (AIH) (Mackay et al., 1965). In the 1970s, efficacy of immunosuppressive treatment was substantiated by placebo-controlled trials (Cook et al., 1971; Soloway et al., 1972; Murray-Lyon et al., 1973; Kirk et al., 1980) that indicated greatly enhanced survival. Another autoantigenic reactivity was recognized by IIF to liver and kidney microsomes (LKM1) (Rizzetto et al., 1973). In the 1980s, anti-LKM1 was seen to distinguish two serologically distinct but otherwise similar forms of AIH (Homberg et al., 1987), type 1 (ANA and SMA) and type 2 (anti-LKM1). The identity of the LKM1 autoantigen as a cytochrome P450 isoform (2D6) was established biochemically and by gene cloning and, hereby, the relatively infrequent AIH type 2 differs strikingly from AIH type 1 for which a definitive disease-specific autoantigen has not yet been identified.

Until the late 1960s, CAH had been used generically for all types of chronic hepatitis, with cases mostly segregating into *autoimmune* and *cryptogenic* groups. However,

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

identification of viruses responsible for acute and chronic hepatitis, viruses A, B and later C (HAV, HBV, HCV), led to the recognition, in the 1970s, of chronic viral hepatitis (due to viruses B and C). The realization that "CAH" comprised multiple entities (Mackay, 1972) led to disuse of the term CAH, and a need was seen for a clearer identification of AIH. Consensus reports in 1993 and 1998 were prepared by a representative expert panel of hepatologists, the International Autoimmune Hepatitis Group (IAIHG), with diagnostic criteria and a scoring system that weighted the net strength of the diagnosis for research purposes (Johnson and McFarlane, 1993; Desmet et al., 1994; Alvarez et al., 1999).

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Clinical Features

Autoimmune hepatitis is a female-predominant disease with reported female-to-male sex ratios ranging from 4–6:1. Although AIH has a bimodal age distribution with peak occurrences between 10 and 30 years and 40 and 50 years (Mackay, 1975), current experience suggests that AIH can occur across all age ranges (Parker and Kingham, 1997; Schramm et al., 2001). Nevertheless, among the Japanese an elderly presentation is more common (Toda et al., 1997). In sharp contrast, AIH type 2 occurs mostly in children between the ages of 2 and 14 years, with severe inflammatory activity (Homberg et al., 1987), but some 5% of cases in Southern Europe are in older men, often in association with HCV infection (Lunel et al., 1992; Michel et al., 1992; Vergani et al., 2004). Elsewhere than in central Europe, AIH type 2 seems infrequent (Mackay, 2004). Additionally, outside of Europe, the presence of anti-LKM1 in chronic hepatitis C is likewise infrequent (Reddy et al., 1995). And further, epitope reactivities of anti-LKM1 in Europeans with chronic hepatitis C differ from those of anti-LKM1 in spontaneous AIH type 2.

Autoimmune hepatitis presents in 50% of cases as an indolent non-resolving hepatitis, in 25% as acute or even fulminant hepatitis (Crapper et al., 1986; Desmet et al., 1994; Porta et al., 1990, Nikias et al., 1994), and in 25% as an asymptomatic illness with incidentally discovered abnormal laboratory indices (Hay et al., 1989). The symptoms and signs are those for any form of hepatitis, and include anorexia, fatigue, jaundice, right upper abdominal discomfort, and enlargement of the liver and spleen. A former requirement for a 6-month observation period to define chronicity is now dispensable (Johnson et al., 1993; Alvarez et al., 1999). Approximately one-third of those affected are asymptomatic, but most become symptomatic during follow-up (Kogan et al., 2002). As the disease advances, features that are generic to cirrhosis of the liver supervene. Various extrahepatic expressions pointing to an autoimmune background include coexisting autoimmune thyroiditis, ulcerative colitis, thrombocytopenias, rheumatoid arthritis, or systemic lupus erythematosus (SLE). Considerable discussion is generated by the coexistence of features of AIH with those of other autoimmune liver diseases (see Chapters 54 and 55), called overlap syndromes (Mackay 2000; Woodward and Neuberger, 2001). Perhaps the greater proportion of cases of the usual overlap, that of AIH with primary biliary cirrhosis (PBC), actually represents the latter disease (Lohse et al., 1999; Kinoshita et al., 1999).

Pathologic Features

The characteristic histologic lesion, first called *piecemeal cirrhosis* (Popper et al., 1965) and later *interface hepatitis*, consists of lymphoid accumulation and hepatocellular destruction at junctions of liver lobules and portal tracts (Figure 53.1). In acute phases, mononuclear cells are seen invading liver lobules, in close contiguity with damaged hepatocytes, described as *lobular (panacinar) hepatitis* (Wilkinson et al., 1978). Kupffer cells are prominent in liver sinusoids. Zones of necrosis between portal tracts tend to coalesce, called *bridging necrosis*, a pattern of injury regarded as a forerunner of the scarring that initiates macronodular cirrhosis (Schalm et al., 1977). Hepatocytes appear ballooned or necrotic or as shrunken eosinophilic remnants, formerly known as Councilman bodies, and now as apoptotic cells (Searle et al., 1987). The lymphoid infiltrates show prominence of plasma cells, consistent with an earlier disease designation as plasma cell hepatitis (Page and Good, 1960). Notably, these florid necro-inflammatory changes are "wiped clean" with use of prednisolone (Czaja et al., 1984). Other manifestations of AIH include 1) perivenular (zone 3) necrosis with or without inflammation of the portal tracts (Pratt et al., 1997; Te et al., 1997; Singh et al., 2002; Misdraji et al., 2004); 2) giant syncytial multinucleated hepatocytes (Phillips et al., 1991; Devaney et al., 1992); and 3) coincidental bile duct injury (Ludwig et al., 1984). More detailed descriptions are available elsewhere (International Group of Pathologists, 1977; Dienes, 1989).

Epidemiology

Autoimmune hepatitis is cited as more prevalent among populations of Northern European extraction, and may share the polar–equatorial gradient characteristic of many autoimmune diseases. However, actual prevalences have been ascertained only for populations of Norway, Iceland, Alaska, and Japan, with these being rather lower than for many other autoimmune diseases (Mackay and Toh, 2002). Even so, AIH has been described in African Americans, Brazilians,

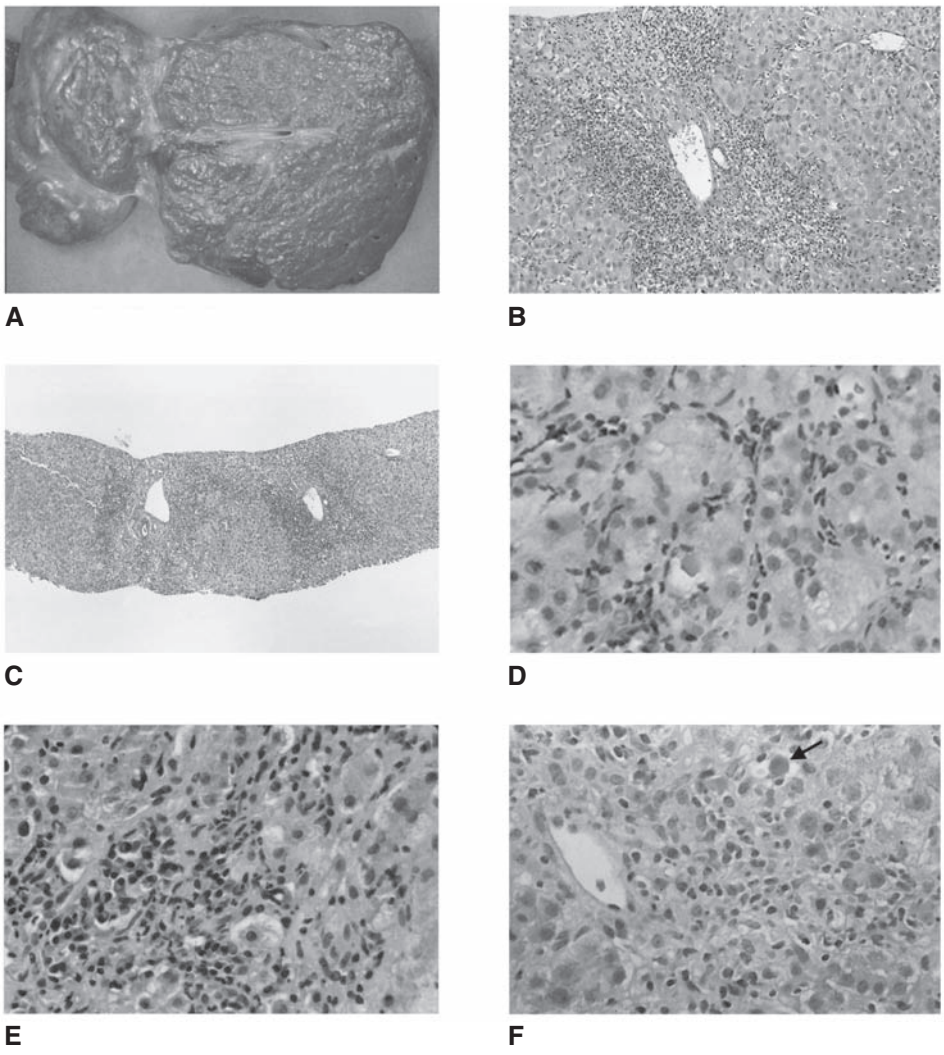

Figure 53.1 Pathological features of autoimmune hepatitis (AIH) *A,* An autopsy specimen of a liver in advanced AIH illustrating coarse nodular cirrhosis and shrunken left lobe (Case reported by Joske and King, 1955). *B–F,* photomicrographs from cases of AIH type 2. *B, Interface hepatitis* illustrating lymphocytic infiltrate in portal trail of liver abutting an adjacent liver lobule. *C, Bridging necrosis* illustrating necroinflammatory infiltrates connecting portal tracts and a likely forerunner to fibrosis and cirrhosis. *D, Lobular hepatitis* illustrating extra lobular lymphocytic infiltrates, damaged hepatocytes and prominence of (spindle-shaped) Kupffer cells. *E, Lobular hepatitis* illustrating severely degraded liver cells surrounded by lymphocytes, and prominence of plasma cells. *F, Periportal hepatitis* illustrating *(arrow)* a shrunken eosinophilic remnant of a hepatocytic that has undergone apoptosis (Councilman body). (See color plate section.)

Argentinians, Arabs, and subcontinental Indians. The incidence of AIH among Norwegians was 1.9 in 100,000 persons per year with a point prevalence of 16.9 in 100,000 (Boberg et al., 1998). A higher prevalence was reported among Alaskan natives, 43 in per 100,000 population (Hurlburt et al., 2002). In the USA, AIH may effect some 100,000 to 200,000 persons (Jacobson et al., 1997), although precise incidence and prevalence data are not available.

Genetic and indigenous risk factors probably affect disease occurrence in different regions and ethnic populations; the prevalence of AIH among Northern European white groups accords with a high frequency of HLA-DR3 and -DR4 and, expectedly, AIH occurs with a similar frequency in the derivative populations of North America and Australia (Donaldson et al., 1991). HLA-DR3 is rare in Japan, and there AIH is associated with HLA-DR4 (Seki et al., 1992). Overall, the prevalence of AIH type 1 appears greatly to exceed that of AIH type 2. Accepting some degree of case selection bias in earlier reports, the contribution of AIH to all cases of CAH in the 1960s was high—e.g., 60% in Melbourne, Australia, and 30% in Mainz, Germany (Mackay, 1985). Subsequently, this contribution has been

strikingly reduced by waves of chronic hepatitis due to HBV and HCV. There is a perception that the incidence of AIH may be decreasing, although one of us (IMcF) believes that in the UK it may be increasing, perhaps because of greater awareness. Whatever the case, AIH was not represented among causes of mortality from all types of liver disease in the USA (Vong and Bell, 2004), either because of its actual rarity, certification errors, or efficacy of contemporary therapy.

AUTOIMMUNE FEATURES

Autoimmune hepatitis belongs to that puzzling group of autoimmune disorders in which there is a disease-specific target organ yet non-organ-specific serologic markers, and it remains one of the less well understood in regard to both inductive and effector processes. This section provides an analysis of the range of antigenic reactants in the context of the defined serologic types, 1 and 2.

Autoimmune Hepatitis Type 1

In AIH, hypergammaglobulinemia reaches levels up to 10 g/L, which is seen in few other autoimmune diseases. The high serum levels of immunoglobulin G (IgG) are not explicable by a response to any single antigen or autoantigen and may reflect polyclonal B-cell activation as one of the pathogenetic components of the disease. Patterns of serologic reactants in AIH by IIF are shown in Figure 53.2. Fluctuations in level reflect the degree and duration of inflammatory activity, and a decrease marks efficacy of treatment.

Nuclear Antigens

In AIH type 1, there are multiple nuclear reactants. Antinuclear antibodies in untreated cases give homogeneous labeling by IIF, but this tends to fade during remission, revealing other coexisting patterns and reactants. The sensitivity of ANA for diagnosis of AIH type 1 (allowing for technical variations) would be 70%, but its specificity is low.

Nucleosome

As much by analogy with SLE as by direct observations, the reactant for ANA in AIH is taken to be the nucleosome (Mackay, 2001), an octamer with two coils of DNA (each of 146 bp), wrapped around the small nuclear proteins, the histones of which there are five main classes, H1, H2A, H2B, H3, and H4. A linear array of nucleosomes forms the primary chromatin fiber, which condenses into a quaternary protein structure and could generate an autoepitope for both T and B lymphocytes (Czaja et al., 2003). There is accompanying reactivity to histones, occasionally to native double-stranded DNA, and also to a variety of characterized and uncharacterized non-nucleosomal nuclear proteins (Czaja et al., 1994; 1995; 1997a) that may result from epitope spreading. On a "wheat and chaff" analogy, certain antibodies (wheat) seem pathogenetically relevant, while others (chaff) seem an incidental and irrelevant consequence of inflammatory activity and cellular degradation.

Double-stranded (ds) DNA

Studies on the frequency of anti-dsDNA in AIH have given divergent results. In two representative studies, employing either radioimmunoprecipitation (RIP) (Smeenk et al., 1982), or RIP together with IIF on *Crithidia luciliae* (Leggett et al., 1987); positivity rates were 10% and 16% (transient 8%, persisting 8%), respectively. Technical factors, case selection, and disease activity would materially influence results.

Others

The variety of ANA reactivities in AIH type 1 (Czaja and Norman, 2003; Mackay, 2004) resembles that in other multisystem autoimmune diseases, and does not provide additional diagnostic assistance nor pathogenetic clarity.

Cytoplasmic Antigens

Various anti-cytoplasmic reactivities in AIH have been characterized at the molecular level.

Soluble Liver Antigen/Liver Pancreas Antigen

A *liver-pancreas antigen* (LP) was identified by complement fixation (Berg et al., 1981) and reactivity to it in AIH reported by Stechemesser et al. (1993). Independently, a *soluble liver antigen* (SLA) was detected by inhibition enzyme-linked immunosorbent assay (ELISA) (Manns et al., 1987), which later became co-identified with LP. The SLA was successively nominated as cytokeratins 8,18 (Wächter et al., 1990) and glutathione S-transferase (Wesierska-Gadek et al., 1998), but cloning from cDNA expression libraries identified SLA/LP as the UGA-serine transfer RNA-protein complex ($tRNP^{(Ser)Sec}$) (Wies et al., 2000; Costa et al., 2000; Volkmann et al., 2001; Torres-Collado et al., 2004), and a member of the family of serine hydroxymethyl transferases (Gelpi et al., 1992; Kevenbeck et al., 2001). Anti-SLA/LP initially appeared to define a novel (third) serologic type of AIH, because it occurs in some cases that are otherwise seronegative (Baeres et al., 2002). However anti-SLA/LP coexists with other autoantibodies, in AIH type 1 particularly (Kanzler et al., 1999), but also occasionally in AIH type 2 and autoimmune sclerosing cholangitis (Vergani et al., 2004). Anti-SLA/LP is closely associated with HLA DR3, with relapse after corticosteroid withdrawal (Czaja et al., 2002), and with greater severity (Ma et al., 2002). However, all of the autoantibodies, and also serum IgG, are

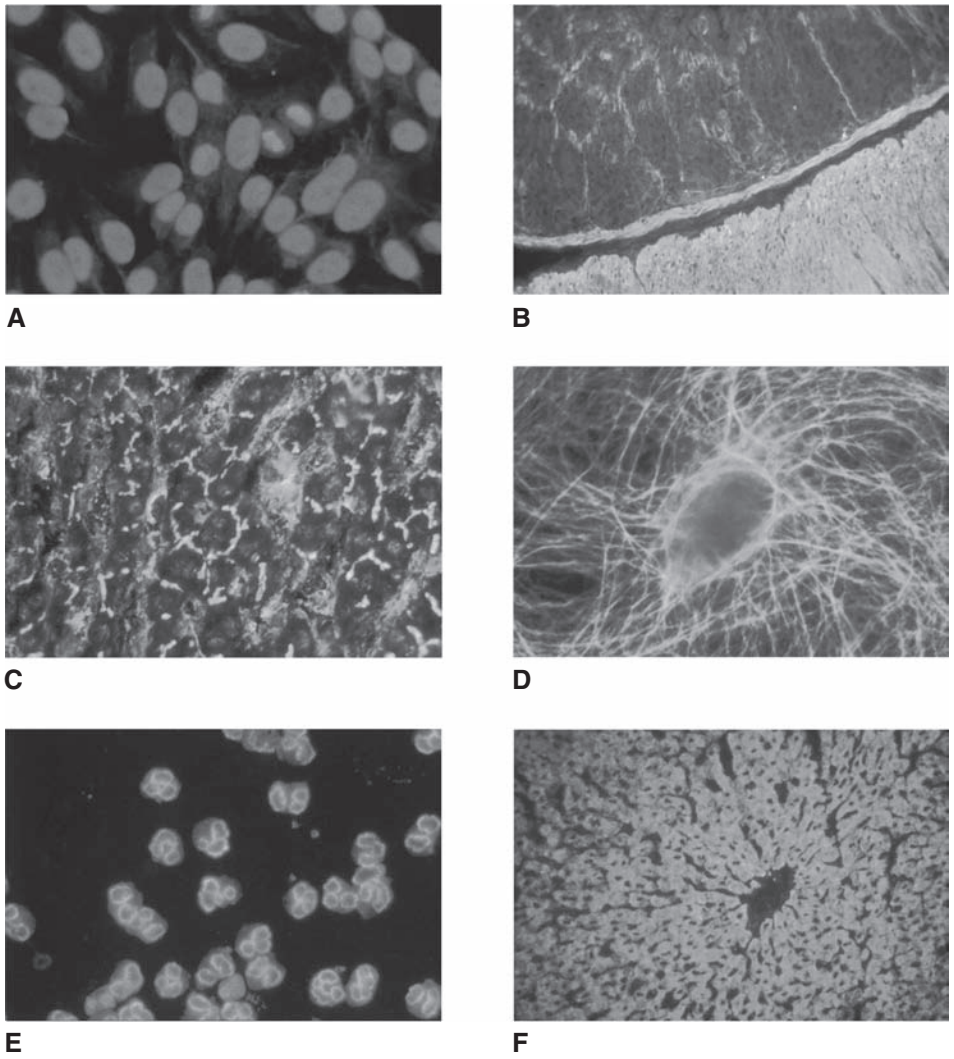

Figure 53.2 Serologic expressions of autoimmune hepatitis (AIH) by indirect immunofluorescence. *A,* Antinuclear antibody (ANA) from an AIH type 1 serum on cells of HEp2 cell line illustrating typical homogeneous pattern of labeling. *B,* Smooth muscle antibody (SMA) on mouse from an AIH type 1 serum illustrating labeling of submucosal smooth muscle layer, muscularis mucosal (thin band), and thin vertical strands in mucosa suggestive of anti-actin reactivity. *C,* Antiactin reactivity on mouse liver by an AIH type 1 serum illustrating polygonal pattern due to labeling of submembranous actin of hepatocytes. *D,* Anti-intermediate filament reactivity on cultured fibroblast of an SMA-positive but anti-actin-negative serum; this reactivity is not specific for AIH. *E,* Antineutrophil cytoplasmic antibodies (ANCA) reactivity on granutocytes exposed to an ANCA-positive serum, as seen in vasculitic and other diseases (see Chapter 65); note that the perinuclear ANCA seen in AIH may be a true antineutrophil nuclear autoantibody (see text). *F,* Anti-LKM1 reactivity on mouse liver by an AIH type 2 serum illustrating evenly granular labeling of cytoplasm of hepatocytes throughout the lobule. (See color plate section.)

present at higher levels in more severe types of AIH, and so anti-SLA/LP is not unique in this respect.

Ribosomal P Proteins

Antibodies to ribosomal P proteins (RPP) occur mostly in the setting of SLE (16% of cases), but were earlier described in "SLE and liver dysfunction" (Koren et al., 1993).

Ribosomal P proteins are present in the cytoplasm of all cells and comprise a set of three phosphoproteins, P0, P1, and P2, of molecular weight 38, 19, and 17 kDa, respectively. Natural RPP exists as a pentamer of P0 and two copies of P1 and P2 (Zampieri et al., 2003) with each polypeptide sharing a C-terminal 22-residue (C22) immunodominant epitope that is detectable on the surface of cultured hepatoma cells. Anti-RPP are cited as a particular example

of autoantibodies that penetrate living cells, with possible adverse intracellular effects (Koscec et al., 1997). There has been no systematic analysis of the frequency or epitope specificity of anti-RPP in AIH, and this is needed.

Neutrophil-specific Cytoplasmic Proteins

High titers of "granulocyte-specific" ANA in AIH were described in the 1960s (Smalley et al., 1968). They were later identified with antineutrophil cytoplasmic antibodies (ANCA), the cytoplasmic reactants for which clump with a perinuclear distribution and so simulate ANA. The two well-characterized species of ANCA, cytoplasmic (c) and perinuclear (p) that have particular disease associations and molecular identity (see Chapters 59 and 65), but the ANCA of AIH are not directed at either of the two main ANCA antigens, proteinase 3 or myeloperoxidase (Targan et al., 1995). The reactant in AIH has been ascribed to lactoferrin, elastase, a 50 kDa nuclear envelope protein restricted to neutrophil-myeloid lineages, or a high mobility group (HMG) protein (Mackay and Toh, 2002). Currently, the AIH-associated pANCA are cited as "atypical," and appear to react with nuclear lamina proteins, thereby justifying their earlier designation as "granulocyte-specific ANA," and current designation as antineutrophil nuclear antibodies (ANNA) (Terjung et al., 2001).

Hepalaminin

A recently described novel protein specific for the cytoplasm of hepatocytes and cholangiocytes, and called hepalaminin, consists of laminin p-2 fused to an unknown polypeptide (Fukuda et al., 2004). Responses to hepalaminin were postulated to exacerbate hepatic inflammation in chronic viral hepatitis.

Cytoskeletal Elements (Enriched in Smooth Muscle)

Cytoskeletal autoantibody was initially detected on gastric mucosal smooth muscle (SMA) (see Figure 53.2) and was validated as a marker for AIH by Toh (1979) and Kurki and Virtanen (1984). The reactant is cytoskeleton comprising abundant filamentous proteins that support cellular organization, contractility, locomotion, and pseudopod extrusion. Cytoskeletal proteins include 6 nm microfilaments (actin), 15 nm intermediate filaments (vimentin, desmin, and others), and 30 nm microtubules (tubulin) (Toh, 1979). Testing for SMA on different tissues by IIF showed particular patterns with vessels (SMA-V), glomerular mesangium (SMA-G), and renal tubular brush borders (SMA-T) (Bottazzo et al., 1976). SMA-T signifies actin microfilaments, as seen by testing sera on cultured cells on which SMA-positive sera label actin "cables" spanning the long axis of the cell (Toh, 1979; Muratori et al., 2002). Non-actin SMA are attributable to incidental antifilament reactivity after infections, particularly viral (Toh, 1979). Whether actin is the exclusive cytoskeletal autoantigen in AIH is debated (Vergani et al., 2004). The specificity and sensitivity of anti-actin for the diagnosis of AIH is high (~80%); however, some 16% of patients with AIH and SMA lack anti-actin (Czaja et al., 1996a). Since anti-actin positivity is associated with a worse overall outcome, it has prognostic as well as diagnostic utility.

Actin as an Autoantigen

Actin is a fascinating autoantigen. It is a globular protein found as one of the most abundant proteins, only in eukaryotic cells. The extreme conservation of actin structure in eukaryote evolution is attributed to the large number, some 70, of actin binding proteins including myosin that would exert high selective pressure (Galkin et al., 2002; Dos Remedios et al., 2002). These are three isoforms α, β, and γ, with minor differences in sequence. Monomeric G actin protein (mw 46 kDa) readily polymerizes to form helical filaments, so providing force-generating effects for cellular movement. Various actin-binding proteins regulate the multiple-step polymerization–depolymerization cycle, whereas others cross-link polymeric (filamentous, F) actin into bundles or networks. Autoantigenicity resides in the polymerized F-actin state. Surprisingly, given the advanced structural knowledge of actin and its binding partners (Dos Remedios et al., 2003), there has been rather meager dialog between cell biology and immunopathology in the context of actin autoimmunity. All cells contain actin, and hepatocytes are richly endowed, evident by the "polygonal" IIF labeling pattern when liver is used as substrate for anti-actin antisera (Mackay and Toh, 2002). Two populations of anti-actin autoantibodies (AAA) were described in AIH sera, natural (N)AAA and disease-associated (D)AAA. The latter were shown to have undergone isotype and subclass switching, were likely antigen-driven, and may recognize a different and disease-specific epitope (Zamanou et al., 2003).

Liver Membrane Antigens

Non-identified Membrane Components

The liver cell membrane has been long-suspected as a site of an autoantigenic reactant (Meyer zum Büschenfelde et al., 1980). Analysis by immunoblot of AIH sera on partially purified liver membrane preparations shows multiple reactants of widely differing molecular weight. However, none appears promising, since the intensity of immunoblot signal fades when sera are diluted beyond 1:1000 or when remission stage antisera are tested, and weakly reactive counterparts of many of the components are seen with sera from other inflammatory liver diseases (Frazer et al., 1987; Swanson et al., 1990; Matsuo et al., 2000). Hence, these multiple reactants may be consequential to hepatocellular degradation.

Anti-190 kDa Molecule

A human IgM monoclonal autoantibody generated from blood lymphocytes of a patient with AIH type 1 reacted specifically with the hepatocyte surface membrane (190 kDa molecule) and had complement-dependent cytotoxicity for hepatocyte-derived cell lines (Yamauchi et al., 2004). This observation redirects attention to humoral cytotoxicity as an immunopathogenic element in AIH.

Asialoglycoprotein Receptor

The asialoglycoprotein receptor (ASGPR) was identified in 1984 as a component of liver membrane protein preparations used as antigenic substrates for studies with AIH sera (McFarlane et al., 1984a; McFarlane, 1996). It is a highly conserved hepatocyte-specific glycoprotein involved in the binding and endocytosis of serum glycoproteins for disposal by the liver. A multinational study on anti-ASGPR reactivity by radioimmunoassay and ELISA, using the purified receptor as antigen, showed a 76% positivity rate in AIH, but positive results in 7.6–11% of cases with other liver diseases, indicating limited specificity (Treichel et al., 1994). However, anti-ASGPR was strongly and quantitatively associated with severity of interface hepatitis in these conditions (McFarlane et al., 1984b; Czaja et al., 1996b), and may become useful in defining end points of therapy. The structure and function of the ASGPR, its antibody and T-cell responses to it in disease, and potential autoepitopes are described by Treichel and Meyer zum Buschenfelde (1998).

Autoimmune Hepatitis Type 2

Microsomal Antigens

According to different pathogenetic backgrounds, several liver and kidney microsomal (LKM) antigens have been described and designated as LKM1, LKM2, LKM3 and LM. Studies by immunoblot (Waxman et al., 1988; Zanger et al., 1988; Guegen et al., 1988) revealed that most were isoforms of the cytochrome P450 oxidase (CYP) enzyme family, and function as autoantigens in various autoimmune liver disorders (Bogdanos and McFarlane, 2003).

Cytochrome P450 2D6—LKM1 Antigen

Anti-LKM1 react by IIF with liver cells and the proximal P3 segment of renal tubules (Rizzetto et al., 1973) (see Figure 53.2). Definitive identification of the target as CYP2D6 was achieved by molecular cloning from a gene expression library (Manns et al., 1989; Guegen et al., 1989). Anti-KLM1 antibodies inhibit CYP 2D6 enzyme function *in vitro* (Zanger et al., 1988). Epitope analysis using candidate synthetic peptides and ELISA identified five CYP2D6 antigenic regions recognized by anti-LKM1, located at the amino acid (aa) ranges 193–212, 257–269, 321–351, 373–389, and 410–429, with other minor regions as well (Obermeyer-Straub et al., 2000) (Figure 53.3). Mostly the antibodies reacted either with a main antigenic site, aa257–269 (DPAQPPRD) (Manns et al., 1991), or a second major site, aa321–351 (Yamamaoto et al., 1993a; Kerkar et al., 2003), whereas in chronic hepatitis C epitopes for anti-LKM1 were located at aa208–273 (Yamamoto et al., 1993b; Ma et al., 1994; Dalekos et al., 1999; Bogdanos and McFarlane, 2003). However, a differing antigenic site, aa181–245, was described by Kitazawa et al. (2001). According to the latest data, antibody-binding sites on a three-dimensional structure of CYP450 2D6 are shown in Figure 53.3 (Sigimura et al., 2002).

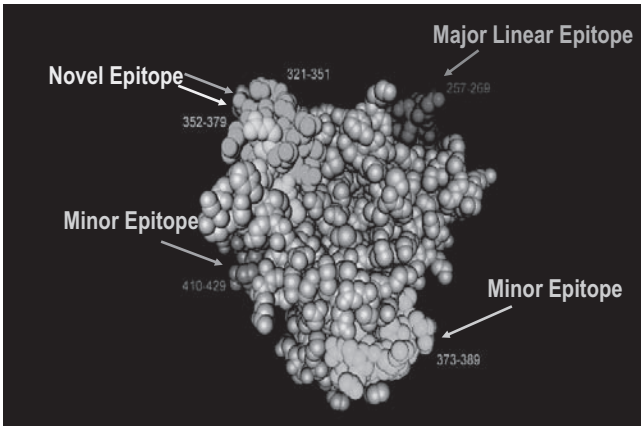

Figure 53.3 A three dimensional representation of cytochrome P450 2D6 showing various epitope regions. A major epitope region *(red)* at amino acids 257–269 is a reactant for autoantibodies in autoimmune hepatitis (AIH) type 2, and it has sequence homology with the intermediate-early protein IE 175 of herpes simplex virus type 1 (Manns et al., 1991). An epitope region *(green/yellow)* is a reactant for autoantibodies in AIH type 2 and chronic hepatitis C. Minor epitopes at amino acids 373–389 and amino acids 410–429 are shown in light blue and dark blue, respectively. (See color plate section.)

Cytochrome P450 2C9. 2E1, 3A—LKM2 Antigen

Anti-LKM2 reactivity was recognized by Beaune et al. (1987) in acute and chronic hepatitis induced by exposure to tienilic acid, a drug which is no longer marketed, and called LKM2. The autoantigenic reactant was identified as the CYP450 isoform, 2C9. There are various other drugs or toxins that can induce an immune-mediated hepatitis with LKM2-type reactivities, and remarkably each is associated with the particular CYP isoform that hydroxylates the drug, as described in detail by Manns and Obermeyer-Straub (1997), and shown in Figure 53.4. Examples include reactivity to CYP450 2E1 in halothane hepatitis or occasionally alcohol-induced hepatitis, or to CYP450 3A in anticonvulsant hepatitis; in general, for drug-induced types of

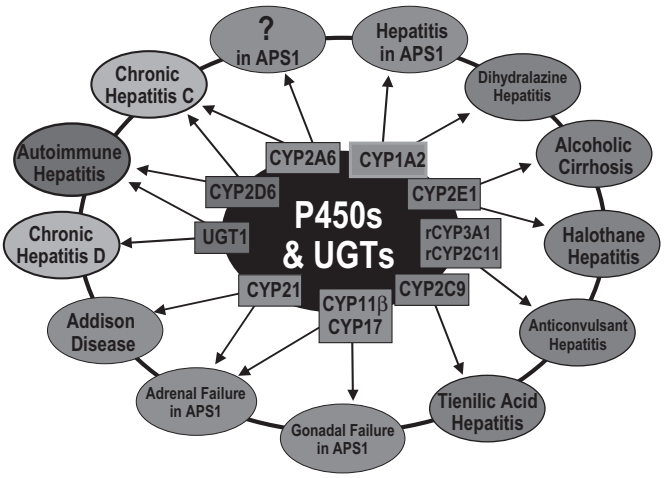

Figure 53.4 Cytochrome P450 isoforms (CYPs) and uridine-5′-diphosphate glucuronosyl transferase 1 (UGT1) as autoantigenic targets in various types of hepatitis, occurring in spontaneous autoimmune hepatitis (AIH) type 2 *(red)*, or associated with drug reactions *(blue)*, or hepatitis virus infection *(green)*, or other spontaneous autoimmune conditions *(orange)*. (APS1, autoimmune polyendocrine syndrome type 1.) (See color plate section.)

hepatitis, disease and serologic expressions fade when the provocative agent is withdrawn.

Cytochrome P450 1A2—LM Antigen

In drug-induced hepatitis provoked by the anti-hypertensive medication dihydralazine, serologic reactivity by IIF is organ-restricted to the CYP450 1A2 isoform in liver microsomes (LM) (Bourdi et al., 1990). These also occur in children with AIH as part of the autoimmune polyendocrine syndrome type 1 (APS1).

Cytochrome P450 2A6 Antigen

In the APECED/APS1 syndrome antibodies to another liver-expressed cytochrome P450, CYP2A6 were described, but in contrast to anti-CYP1A2, these were not exclusively associated with liver disease (Obermayer-Straub et al., 2001). Interestingly, molecular mimicry involving T-cells between CYP2A6 and epitopes of the hepatitis C core protein was described by Kammer et al. (1999) but, in regard to B cells, anti-CYP2A6 occur only rarely in chronic hepatitis C (Dalekos et al., 2003).

UDP glucuronosyl transferase—LKM3 Antigen

Anti-LKM-like reactivity was recognized in 1983 in hepatitis delta (D) virus infection (Crivelli et al., 1983). The reactant, identified as the bilirubin-conjugating enzyme uridine-5′-diphosphate glucuronosyl transferase (UGT) rather than a CYP450 isoform (Philipp et al., 1994), was called LKM3. A B-cell epitope is common to several members of family 1 UDP-glucuronosyl transferases. Sera from 3 of 18 cases of AIH type 2 reacted mainly against UGT 1A1, the principal isoform required for the glucuronidation and disposal of bilirubin (Strassburg et al., 1996).

Liver Cytosol Antigen Type 1 (LC1)

Autoantibodies were recognized by Martini et al. (1988) to a soluble, organ-specific *liver cytosolic* antigen LC1 in cases of spontaneous AIH type 2. Anti-LC1 was said to be more specific for AIH type 2 than anti-LKM1, but it has since been demonstrated in chronic HCV infection (Lenzi et al., 1995), and occasionally in AIH type 1 (Vergani et al., 2004). Anti-LC1 elutes from liver cytosol as a protein of 240–290 kDa but, since there is a 62 kDa signal by denaturing immunoblot, the protein likely exists as a tetramer (Abauf et al., 1992). LC1 can be detected by IIF on liver by a progressively decreasing homogeneous labeling of hepatocytes towards the central vein of the lobule, by immunoblot, and by counter-immunoelectrophoresis (Muratori et al., 1995). Molecular cloning revealed LC1 to be the enzyme forminotransferase cyclodeaminase (FTCD) (Lapierre et al., 1999), which has two domains—a globular FT domain containing conformational epitopes joined by a short linker to the CD domain (Muratori et al., 2001).

T-Lymphocyte Reactivity to Hepatic Autoantigens

Details on the participation of T-cells in the pathogenesis of AIH are scanty because of the lack of experimental models, the non-availability (for AIH type 1) of identified or recombinant autoantigens, and, perhaps, the relatively "lower profile" of AIH among the autoimmune disorders. Immunohistochemical studies indicated that T lymphocytes predominated among cells in the intrahepatic infiltrates (Frazer et al., 1985), but their antigenic specificity is undefined. Various earlier studies on cytotoxic activities of blood T cells on hepatocellular targets might not withstand contemporary scrutiny, but might bear repeating with modern technologies, given that they pointed to the possibility in AIH of antibody-dependent cellular cytotoxicity (ADCC) as a mechanism of liver cell damage (Mackay, 1985). The cellular immune responses to ASGPR described by Treichel and Meyer zum Buschenfelde (1998) could be relevant here.

GENETIC FEATURES

Evolving methods for identification of the multiple loci for genetic risk for autoimmunity promise much (see Chapters 20 and 21). It will be interesting to know, when

data from genome-wide screening for AIH types 1 and 2 do become available, which loci are AIH-specific, and which are generic for autoimmunity.

Human Leukocyte Antigen (Major Histocompatibility Complex) Alleles

Risk Alleles

Associations were recognized between AIH type 1 and HLA alleles A1 and B8 by Mackay and Morris (1972), and then DR3. Family studies revealed that HLA A1-B8-DR3 was inherited as a haplotype, with DR3 as the likely primary risk allele (Mackay and Tait, 1980); the estimated relative risk conferred by DR3 was 6–7. Included in the DR3 haplotype were null alleles (gene deletion) for complement (C4A) (Tait et al., 1989), implicating C4 deficiency as an additional risk factor. A weaker association with HLA-DR4 was recognized by Donaldson et al. (1991). Two immunogenetic subsets of AIH type 1 include the DR3 subset (younger age of onset, more severe disease, and higher requirement for liver transplantation), and the DR4 subset (older age more benign disease) (Czaja et al., 1997b). Molecular genotyping has revealed a high representation (52% vs. 19% in controls) of the *DRB1*0301-DRB3*0101-DQA1*0501-DQB1*0201* haplotype, and an association in *DRB3*0101*-negative subjects with the DR4 allele, *DRB1*0401* (54% vs. 23% in controls). *DRB1*0301* and *DRB1*0401* each encode a shared motif, amino acids LLEQKR, at positions 67–72 in the DRβ polypeptide chain of the HLA DR, with the presence of lysine (K) at DRβ 71 proposed as a determinant of susceptibility (Strettel et al., 1997).

The genetic determinants of AIH type 2 are uncertain. HLA DR7 and the allele *DRB1*0701* were implicated in cases from Germany by Czaja et al., (1997b) and South America by Bittencourt et al. (1998), but with insufficient case numbers for a confident association.

A Disease Susceptibility Motif

Explanations for HLA-disease associations (see Chapter 5) include the presence, within the antigen-binding groove of MHC class II molecules, of a *disease susceptibility motif* (DSM) that efficiently presents an autoantigenic peptide to responder T cells. The observations in AIH type 1 are that *DRB1*1501*, which encodes ILEQAR at DRβ 67–72, is protective in white Northern European and North American patients (Doherty et al., 1994), and this motif differs from the presumed DSM, LLEQKR, at two positions, isoleucine (I) at DRβ67 and alanine (A) at DRβ71. The substitution of I for L at DRβ67 is neutral whereas A for K at DRβ71 replaces a highly charged polar amino acid with a non-polar amino acid, so likely influencing antigen binding and immunocyte recognition, and in turn susceptibility to disease (Czaja and Donaldson, 2000). Converse to this argument, the DSM could function by inefficient presentation of self antigens by dendritic cells during negative selection in the thymus, and so impair deletional tolerance.

Ethnic Differences

Different ethnic groups have different susceptibility alleles. Those for AIH type 1 are *DRB1*0405* for Japanese (Seki et al., 1992), *DRB1*0405* in Argentine adults (Pando et al., 1999), *DRB1*1301* in Argentine children (Fainboim et al., 1994), *DRB1*13* and *DRB1*03* for Brazilians (Goldberg et al., 2001), and *DRB1*0404* for Mestizo Mexicans (Vazquez-Garcia et al., 1998). This multiplicity of different MHC-encoded risk alleles suggests that different alleles can encode one or more common determinants (shared motifs) which are critical for disease expression or that, in different geographic regions, the genes which promote AIH are selected by region-specific etiologic factors. Protracted infection with HAV has been associated with *DRB1*1301*, which is implicated in the occurrence of AIH type 1 (Fainboim et al., 2001). Perhaps children with *DRB1*1301* in South America are naturally selected to have prolonged exposure to virus and liver antigens during HAV infection, so conferring increased risk of developing AIH. In this fashion, the susceptibility allele for the disease within a geographical region may be a clue to an etiologic agent.

Non-MHC Alleles

TNF-A

Various non-MHC alleles have been identified, or suspected, as risk elements for AIH type 1. The tumor necrosis factor-α (TNF-α) gene promoter *TNF-A* results in high constitutive and induced levels of TNF-α (Cookson et al., 1999; Czaja et al., 1999) and has a weak effect on risk.

CTLA-4

The cytotoxic T-lymphocyte antigen-4 (CTLA-4) is a molecule that normally downregulates T-cell responses. The CLTA-4 G allele, representing a polymorphism in exon 1 (position 49 A/G), is at higher frequency in AIH type 1 than in controls (Agarwal et al., 2000a; Djilali-Saiah et al., 2001).

SLE1

The *sle1* gene region identified in murine models of SLE has a likely ortholog in humans at 1q22-22, and includes multiple genes that contribute to production of antibodies to nuclear (chromatin) antigen, and hence is a suspect locus for AIH type 1.

Fas

The Fas gene (*tumor necrosis factor receptor super family-6* or *TNFRSF6*) encodes the apoptosis-related molecule CD95 (Fas), noting that apoptosis is critically involved in immune regulation (see Chapter 70). There are high constitutive levels of CD95 expression on hepatocytes, Kupffer cells, and sinusoidal endothelial cells, and hence the liver may be an important site for apoptosis-mediated immunocyte destruction (Galle et al., 1995). CD95 is abundantly expressed on activated lymphocytes, and the ligand CD178 (FasL) can be expressed on liver cells after oxidative stress. If enhanced apoptosis were to contribute to collateral damage in AIH type 1, this could lead to abnormal display of autoantigen (see Chapter 15); conversely, impaired apoptosis may extend the effects of activated immunocytes and so perpetuate disease (see Chapter 70). Patients with AIH with the *TNFRSF6*G,G* or **A,G* genotype have higher serum levels of aspartate aminotransferase and IgG at presentation than do patients with the TNFRSF6*A,A genotype (Agarwal et al., 2000b).

MHC Class I Chain-Related A Gene

The MHC class I chain-related A gene (MICA) is highly polymorphic, and encodes a stress-inducible protein that interacts with the NKG2D receptor of various immune effector cells, including cytotoxic T cells and natural killer (NK) cells (Molinero et al., 2002; Vivier et al., 2002). As sensors of cell stress, the MICα molecules identify cells that can be targeted and destroyed by cytotoxic immunocytes including $\gamma\delta$ T lymphocytes. Furthermore, they act as restriction elements for NK and NK T-cells, which constitute a large resident population within the liver. Homozygosity for the *MICA*008* allele confers an increased risk of AIH (OR = 2.2), but the association may be simply due to linkage with the ancestral 8.1 haplotype and *DRB1*0301* (McKiernan et al., 2002). Homozygosity for the *MICA*008* allele may lead to the activation of $CD4^+$ and $CD8^+$ T lymphocytes that are not readily targeted by cytotoxic immunocytes bearing the NKG2D receptor; reduced clearance of these activated T-lymphocytes may in turn increase the risk and severity of hepatocyte injury.

Vitamin D Receptor

The polymorphic gene encoding the vitamin D receptor (VDR) can modulate immune responses (Adorini, 2002). Vitamin D receptors are expressed on blood monocytes and activated T-lymphocytes, and 1,25 hydroxyvitamin D can inhibit lymphocyte activation, prevent dendritic cells from differentiating into antigen presenting cells, decrease production of type 1 cytokines, and increase expression of interleukin 4 (IL-4) and transforming growth factor-β (TGF-β). Polymorphisms of the VDR gene occur more commonly among patients with AIH type 1 than in controls, and Fok polymorphisms of the VDR distinguish patients with AIH from those with PBC who have mainly BsmI polymorphisms (Vogel et al., 2002).

AIRE

An AIH type 2-like disease with anti-LKM antibodies is inherited as an autosomal recessive disease, APS1, marked by autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy (APECED) (Manns et al., 1990; Sacker et al., 1980; Clemente et al., 1997; Gebre-Medhir et al., 1997; Obermeyer-Straub et al., 2001). This disease is associated with a recessively inherited mutation on chromosome 21q22.3 (see Chapter 38). The nonfunctional gene product is the autoimmune regulator (AIRE), a transcriptional factor. Deficiency of AIRE causes impaired intrathymic negative selection/deletional tolerance to various tissue-specific autoantigens. CYP1A2 and CYP2A6 are the autoantigens described in associated with AIRE-deficiency liver disease (Clemente et al., 1998). Curiously, these particular autoantigenic reactants differ from the CYP2D6 isoform characteristic of classical AIH type 2 (Obermeyer-Straub et al., 2001).

Analysis of Genetic Risk for Autoimmunity

We suggest that predisposition to autoimmunity in general is attributable to the inheritance, together with MHC risk alleles, of a large "package" of immune response genes of low potency or penetrance acting through any one of four pathways. *First*, by influencing overall immunologic responsiveness and/or tolerance, as judged by clustering of multiple autoimmune expressions in patients and/or their families, and exemplified by genes particular to female sex, or genes influencing apoptosis. *Second*, by directing immune responses to particular tissues or autoantigens, exemplified by effects of class II HLA (MHC) alleles, or perhaps genes involved in the assembly and structure of T- and B-cell antigen receptors. *Third*, by influencing events during and after immune activation, including expression of costimulatory molecules such as CTLA-4, pro-inflammatory cytokines, or chemokines or their receptors. *Fourth*, by conferring vulnerability on a particular target tissue, as so-called "end-organ" genes.

ENVIRONMENTAL INFLUENCES

It is dogma that environment contributes substantially to autoimmunity, but the nature of the agents, and the way these operate, remain cryptic (see Chapters 22 and 23). Virus infection ranks highly, and candidates have included measles virus (now dismissed), Epstein–Barr virus, hepati-

tis viruses, and others. Interestingly, the surge of case reports on autoimmune-type CAH in the 1960s coincided in time with the last major endemic wave of HAV infection. But even if virus infections were to be implicated, what might be their mode of action? One explanation is simply "spillage" of autoantigenic cellular fragments in a genetically predisposed host, perhaps abetted by the cytokine-rich milieu of the antiviral response in which potentially self-reactive T cells can, as "bystanders," become coincidentally activated. A popular explanation is molecular (epitope) mimicry, with the evidence strongest in the case of initiation of AIH type 2 by HCV, although most childhood cases of AIH type 2 occur "spontaneously" in the absence of infection with HCV, and the mimicry sequences between CYP2D6 and the HCV polyprotein (Manns et al., 1991) are not particularly impressive.

Medicinal drugs induce acute or chronic hepatitis occasionally with serologic expressions that may simulate those of AIH type 1 or type 2, but these syndromes typically recede after the offending drug is withdrawn. Such drugs include α-methyl dopa and minocycline that provoke AIH type 1-like disease, but act in an undefined way, perhaps by causing interference with peripheral tolerogenesis. Drugs that provoke AIH type 2-like disease (anti-LKM2 or other cytochrome P450 enzymes) appear to act by generation of drug-associated neoepitopes in the course of enzymatic disposal, thereby inducing autoimmune reactions (Liu and Kaplowitz, 2002).

ANIMAL MODELS

Close animal models of AIH have proven difficult to generate by conventional procedures (Mackay and Toh, 2002). Those that have been developed are reviewed by Vierling (2003). Acute and, under certain conditions, chronic hepatitis can be induced by injection of the plant lectin, concanavalin A (Tiegs et al., 1992), and illustrate effector pathways for hepatocellular damage dependent on pro-inflammatory cytokines (Howell, 2002); however, since autoimmune features do not supervene, the model does not address the inductive phases of AIH.

There are well-exploited models of autoimmunity dependent on transgenically introduced proteins (see Chapter 26), wherein the encoded proteins elicit natural self-tolerance but, on suitable provocation, are induced to function like autoantigens. One example is the introduction of the transgene under a promoter that can be activated in postnatal life, illustrated by the metallothionine (Met) promoter that is activated by exposure to heavy metals. Mice with a transgene construct comprising Met-ovine growth hormone (Met-oGH) could be induced by exposure to a heavy metal (zinc) to express oGH extracellularly and secrete it as a foreign protein; the outcome was a giant mouse, which developed a characteristic interface and lobular hepatitis with oval cell proliferations and, terminally, hepatocellular carcinoma (Orian et al., 1990; Hardy et al., 1997). Another illustrative system in mice was based on transgenic allo-MHC class I molecules (H-2K^b), which, after activation of the transgene (Met-K^b), caused a severe CD8 T-cell driven hepatitis. The inflammatory process, however, dissipated in time as a result of intrahepatic tolerogenesis and/or activation-induced cell death of lymphocytes (Bertolini et al., 1995). In a further development of similar transgenic technology, in which the transgene was expressed in both liver and lymph nodes, Bowen et al. (2004) found that when naïve CD8$^+$ T cells were activated in lymph nodes hepatitis ensued, but not so when naïve T cells were activated in the liver.

Various other genetic manipulations are cited by Lapierre et al. (2004). Moreover, these authors developed a model of AIH type 2 by DNA immunization in mice with a construct comprising coding sequences for the antigenic regions of CYP2D6 and FTCD, leading to development of a T-cell predominant hepatitis with autoantibodies to CYP2D6 (LKM1) and FTCD (LC 1).

PATHOGENIC MECHANISMS

Autoimmune hepatitis belongs to a family of autoimmune diseases in which there is organ-directed pathology to the liver, but multisystem-type autoantibodies. The added complexity is that the liver is a lymphoid organ with an abundant resident population of cells of the innate and adaptive immune systems (Kita et al., 2001), and an intrahepatic milieu tilted towards tolerogenesis. Notwithstanding, intrahepatic immune responses can be long sustained, as illustrated by the persistently destructive pathologies seen in chronic viral and autoimmune hepatitis. Autoimmune hepatitis could be regarded as a genetically biased immune response to products of apoptotic or necrotic hepatocellular breakdown with ensuing self-perpetuating damage after the initial injury. Such products would undergo endocytosis by intrahepatic dendritic or other antigen-presenting cells that express MHC risk alleles, and would be transported to regional lymph nodes where there is presentation of self peptide-MHC and induction of reactive T cells. However, the actual peptide that is presented is still a mystery, perhaps an epitope sequence derived from F-actin in AIH type 1, or an epitope sequence derived from CYP2D6 in AIH type 2. Effector processes are just as poorly defined as are inductive processes, with both T-cell or antibody-dependent cellular cytotoxicity seen as credible mechanisms.

Finally, there is occurrence of *de novo* AIH in transplanted human liver allografts for diseases other than AIH (Mieli-Vergani and Vergani, 2004; Miyagawa-Hayashino et al., 2004). Sounding first a cautionary note on whether these cases are actual AIH or merely rejection, the possible

occurrence of AIH *de novo* merits serious investigation for clues to the pathogenesis of the naturally occurring disease.

IMMUNOLOGIC MARKERS IN DIAGNOSIS

The specification of, and agreement on, criteria for diagnosis by the IAIHG was a distinct advance (see earlier). These criteria include results for autoimmune serologic assays, which, unfortunately, are not always ideally performed. A recent report from a Serology Subcommittee of IAIHG regarded traditional IIF as the mainstay for diagnosis and discrimination of the two major types of AIH (Vergani et al., 2004) (Table 53.1). The initial screening should be performed on frozen unfixed sections from a composite tissue block that includes kidney, liver, and stomach, with a secondary screening if needed on a cell-line (HEp2) for patterns of ANA reactivity. The distinction of SMA and anti-actin reactivities can require special tissue substrates (Mackay and Toh, 2002), and sera should be preheated (56°C, 30 min) to eliminate interfering serum factors (Cancado et al., 2001). Arbitrary cut-off titers for IIF positivity were set at 1:40, but should be lower for children (Vergani et al., 2004). Practicalities may dictate the use of commercially available sections, for which mild fixation is usually used to improve shelf-life, but with attendant loss of clarity of IIF patterns. In commercial laboratories, there will be a preference for semiautomated assays, usually an ELISA, using recombinant or purified native antigens. Those currently available include anti-SLA-LP, SMA, and anti LKM1, but so far these have been validated only "in-house."

The lack of well-standardized assays has led to a poorly founded perception of unreliability (low specificity) of routine serologic procedures for the diagnosis of AIH, even to the degree that these were seen as dispensable for diagnosis (Pratt and Kaplan, 2000). The hope is that, following the lead of the diabetes community (see Chapter 74), standard reference sera can become available, that international serum exchange workshops can be inaugurated to validate existing assays, and that evaluation of new substrates can be undertaken as these come on stream, based on the autoantigens described earlier.

TREATMENT AND OUTCOME

The treatment of choice for AIH is immunosuppression, comprehensively reviewed by Heneghan and McFarlane (2002). The preference is for prednisolone monotherapy in children and young females, in combination with azathioprine in adults. This standard regimen has been in use worldwide for many years since its introduction in the 1960s (Mackay, 1968), and evidence-based treatment guidelines have been promulgated by the American Association for the Study of Liver Diseases (Czaja and Freese, 2002). Immunosuppression markedly improves the clinical status, bio-

TABLE 53.1 Methods, associations, and reactants for autoantibodies in liver diseases

Autoantibody	Conventional method of detection*	Molecularly based assays	Disease association	Molecular target(s)
ANA	IIF	N/A	AIH-1; overlap syndromes	Multiple targets, particularly chromatin
SMA	IIF	N/A	AIH-1; overlap syndromes	Microfilaments (actin?); intermediate filaments (vimentin, etc.)
Anti-LKM-1	IIF†	ELISA, IB, RIA	AIH-2; HCV infection (5%)	Cytochrome P450 2D6
Anti-LC1	IIF, DID, CIE	ELISA, RIA	AIH-2	Formiminotransferase cyclodeaminase
SLA/LP	Inhibition ELISA	ELISA, IB, RIA	AIH-1; AIH-2 & AIH-negative for other reactivities	tRNP(Ser)Sec (see text)
Atypical pANCA (pANNA)	IIF	N/A	AIH-1; sclerosing cholangitis	Unidentified antigen(s) at nuclear periphery
AMA	IIF	ELISA, IB, RIA	primary biliary cirrhosis	E2 subunits of 2-oxo-acid dehydrogenase complexes, particularly PDC-E2

AIH, autoimmune hepatitis; AMA, anti-mitochondrial antibody; ANA, anti-nuclear antibody; CIE, counter-immuno-electrophoresis; DID, double dimension immunodiffusion; ELISA, enzyme linked immunosorbent assay; IB, immunoblot; IIF, indirect immunofluorescence; LC1, anti-liver cytosol type 1 antibody; LKM-1, anti-liver/kidney microsomal antibody type 1; pANCA, perinuclear anti-neutrophil cytoplasmic antibody; pANNA, perinuclear anti-neutrophil antibody; SLA/LP, anti-soluble liver antigen/liver pancreas antibody; RIA, radio-immunoprecipitation assay; SMA, anti-smooth muscle antibody.

*IIF—recommended cut-off titer for positivity is 1:40 except in children (see text). †Anti-LKM-1 and AMA both stain renal tubules and are frequently confused (see text).

From Vergani et al. (2004), reproduced with permission from *Journal of Hepatology*

chemical indices of liver dysfunction, and histologic abnormalities, and greatly influences survival (Soloway et al., 1972; Roberts et al., 1996). Corticosteroids may also decrease hepatic fibrosis or prevent its progression by reducing inflammatory activity (Czaja and Carpenter, 2004). More than 90% of patients with AIH experience an initial clinical, biochemical, and histologic remission, and only 2% fail to show some response. Response is usually evident within days or weeks at the most, and the induction doses of prednisolone of 40–60 mg daily can be tapered after 2–4 weeks to maintenance daily doses of 10 mg or even less. Liver functional indices and serum IgG levels should be assessed monthly for 3 months and thereafter at 3-month intervals. Autoantibody titers decrease during remission, often to negative, but are not useful markers of disease course (Czaja, 1999). Repetitive liver biopsies are unnecessary.

Treatment should be continued for at least 2 years. Thereafter some 80% of treatment responders will relapse whereas, if maintenance treatment is continued for four years, fewer (only 33%) will relapse (Kanzler et al., 2001; Heneghan and McFarlane, 2002). Post-treatment relapse requires reintroduction of immunosuppression and maintenance for an indefinite period on either low dose (5–15 mg/day) of prednisolone (Czaja, 1990) or azathioprine monotherapy at 2 mg/kg body weight (Johnson et al., 1995); azathioprine as monotherapy does not induce, but can sustain, remission. Recent data have shown that long-term azathioprine confers less risk for oncogenic and teratogenic complications than previously suspected. Relapse and retreatment do not preclude the possibility of ultimately sustaining a long-term remission without therapy. Patients with HLA DR3 less frequently experience full remission, and relapse rates are higher than for others, so that HLA DR3 is more prevalent among transplanted patients with AIH (González-Koch et al., 2001).

There are certain situations where the decision to treat AIH must be debatable. The first is AIH that appears biochemically, serologically and histologically "definite" yet the patient is asymptomatic, the diagnosis having been made incidentally and functional indices are only mildly deranged: does one commit such patients to a 2-year course of prednisolone or simply maintain surveillance. Evidence-based medicine does not help here but, considering the risk of slow evolution to "cryptogenic" cirrhosis, we lean to therapy. The second is "treatment-resistant" AIH, a relative term since it includes patients that require drug doses above accepted safety ranges, and also patients (of uncertain number) who are non-compliant with prescribed regimens. Small trials have been made of numerous alternative immunosuppressive agents, cyclosporine A, FK506, mycophenolate mofetil, cyclophosphamide, and budesonide, but outcomes have not been encouraging enough to warrant formal evaluations. Hence, a modified standard regimen is recommended, with a watch for effects of drug overdose, and liver transplantation a medium-term option. The serologic type of AIH, 1 or 2, does not influence treatment except for the some 5% of cases of type 2 that carry markers for HCV infection, wherein antiviral regimens may be preferable.

Notwithstanding the efficacy of "standard therapy," some cases of AIH undergo slow evolution to cirrhosis and liver insufficiency. Autoimmune hepatitis is among the best indications for transplantation with long-term (5-year) survival rates over 90%. Recurrence of disease after liver transplantation is managed by post-transplant immunosuppression, and does not prejudice long-term outcome (Manns and Bahr, 2000).

CONCLUDING REMARKS, FUTURE PROSPECTS

Hepatologists who are keen for a (much needed) better understanding of etiopathogenesis of AIH are, in a sense, victims of their successes! The disease is infrequent relative to the 0.1–1% prevalence for various other autoimmune disorders but, added to this, contemporary protocols for diagnosis and therapy are so well accepted and effective that research into the basic nature of AIH lacks the profile that pertains for the more prevalent and less successfully treatable autoimmune diseases. Increasingly, it is being ascertained, based particularly on autoantibody prevalences in long-archived serum samples, that autoimmune diseases have a prolonged subclinical phase (incubation period) before disease becomes overt, and AIH is likely no exception. If so, an initiating event to pathogenesis would be undetected. The problems relating to AIH remain abundant. What initiates the disease? What (for type 1) is the true autoantigen? Why (for type 1) is anti-actin such a striking marker? How (for type 2) does reactivity to CYP2D6 participate in pathogenesis? How does the special "lymphoid milieu" of the liver influence the expression of intrahepatic autoimmunity? What role do T cells play in either type of AIH? How earnestly should we seek to develop models based on transgenic systems? Will Treg cells intrude into AIH as for so many other autoimmune conditions? And so the list goes on. Supporters of research in hepatoimmunology should be sustained by the thought that lessons learned from the liver could have implications extending well beyond the capsule of this large, multifunctional, and immunologically interesting organ.

FIGURE 53.1 Pathological features of autoimmune hepatitis (AIH) *A,* An autopsy specimen of a liver in advanced AIH illustrating coarse nodular cirrhosis and shrunken left lobe. *B–F,* photomicrographs from cases of AIH type 2. *B, Interface hepatitis* illustrating lymphocytic infiltrate in portal trail of liver abutting an adjacent liver lobules. *C, Bridging necrosis* illustrating necroinflammatory infiltrates connecting portal tracts and a likely forerunner to fibrosis and cirrhosis. *D, Lobular hepatitis* illustrating extra lobular lymphocytic infiltrates, damaged hepatocytes and prominence of (spindle-shaped) Kupffer cells. *E, Lobular hepatitis* illustrating severely degraded liver cells surrounded by lymphocytes, and prominence plasma cells. *F. Periportal hepatitis* illustrating *(arrow)* a shrunken eosinophilic remnant of an hepatocytic that has undergone apoptosis (Councilman body).

A, from Joske and King, (1955).

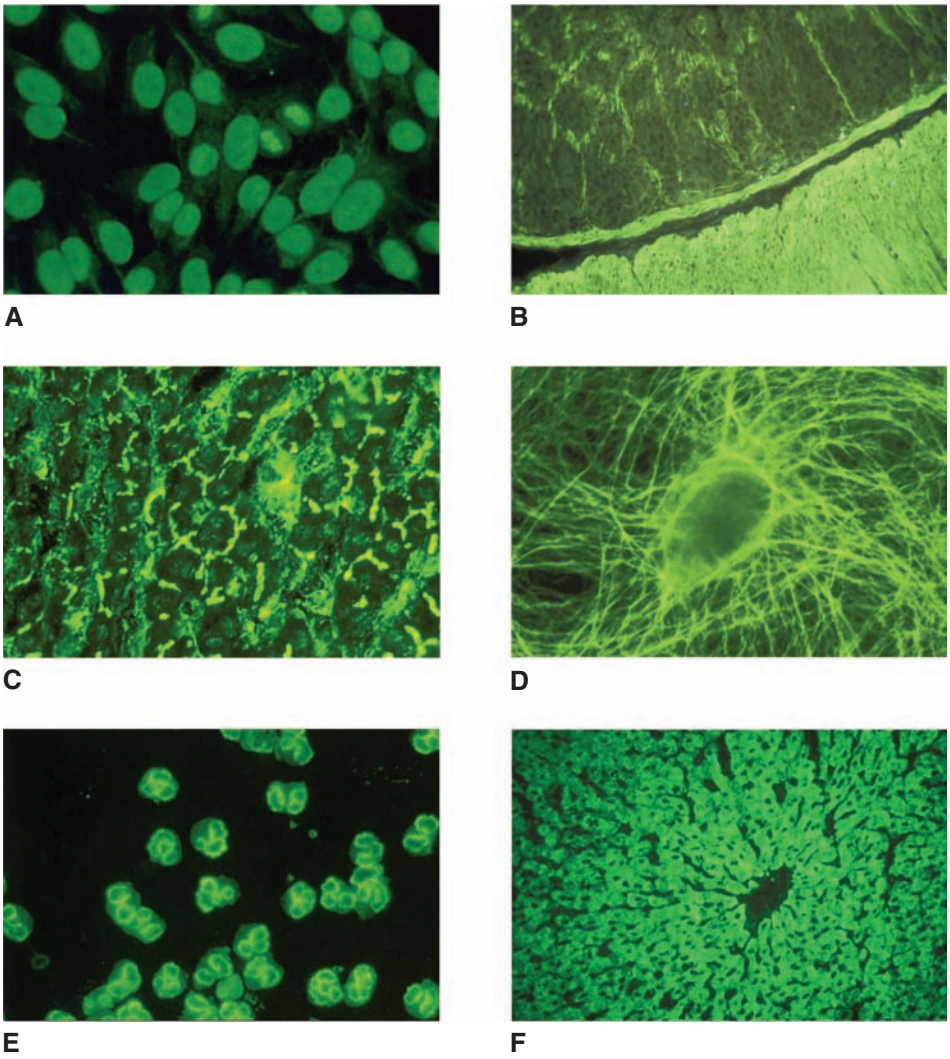

FIGURE 53.2 Serologic expressions of autoimmune hepatitis (AIH) by indirect immunofluorescence. *A,* Antinuclear antibody (ANA) from an AIH type 1 serum on cells of HEp2 cell line illustrating typical homogeneous pattern of labeling. *B,* Smooth muscle antibody (SMA) on mouse from an AIH type 1 serum illustrating labeling of submucosal smooth muscle layer musculares mucosal (thin band) and then verticle strands in mucosa suggestive of antiactin reactivity. *C,* Antiactin reactivity on mouse liver by an AIH type 1 serum illustrating polygonal pattern due to labeling of submembranous actin of hepatocytes. *D,* Anti-intermediate filament reactivity on cultured fibroblast of an SMA positive but antiactin negative serum; this reactivity is not specific for AIH. *E,* Antineutrophil cytoplasmic antibodies (ANCA) reactivity on granutocytes exposed to an ANCA-positive serum, as seen in vasculitic and other diseases (see Chapter ••); note that the perinuclear ANCA seen in AIH may be a true antineutrophil nuclear autoantibody (see text). *F,* Anti-LKM1 reactivity on mouse liver by an AIH type 2 serum illustrating evenly granular labeling of cytoplasm of hepatocytes throughout the lobule.

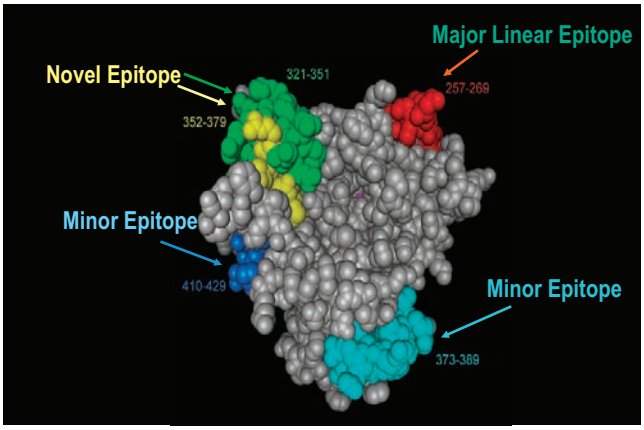

FIGURE 53.3 A three dimensional representation of cytochrome P450 2D6 showing various epitope regions. A major epitope region *(red)* at amino acids 257–269 is a reactant for autoantibodies in autoimmune hepatitis (AIH) type 2, and it has sequence homology with the intermediate-early protein IE 175 of herpes simplex virus type 1 (Manns et al., 1991). An epitope region *(green/yellow)* is a reactant for autoantibodies in AIH type 2 and chronic hepatitis C. Minor epitopes at amino acids 373–389 and amino acids 410–429 are shown in light blue and dark blue, respectively.

Primary Biliary Cirrhosis

CARLO SELMI,*† ROSS L. COPPEL,‡ AND M. ERIC GERSHWIN*

**Division of Rheumatology, Allergy, and Clinical Immunology, University of California at Davis, Davis, CA. †Division of Internal Medicine, San Paolo School of Medicine, University of Milan, Italy. ‡Department of Microbiology, Monash University, Clayton, Victoria, Australia*

The first description of biliary cirrhosis, albeit possibly secondary, can be traced back to the work of the Italian pathologist Giovanni Battista Morgagni in 1761, while the first report of non-obstructive biliary cirrhosis was by Addison and Gull in 1851. For this reason, the entity was then known as the Addison–Gull syndrome (Reuben, 2003) until the term primary biliary cirrhosis (PBC) was finally accepted in medical literature (Ahrens et al., 1950). In 1959, Sherlock presented the first series of patients affected by PBC who had been followed over the previous decade and noted that patients presented with pruritus as well as with signs and symptoms of endstage liver disease including jaundice (Sherlock, 1959). In most cases, the diagnosis was made after laparotomy, once the physical examination or the referred symptoms had suggested the presence of cholestasis. The association between serum antimitochondrial antibodies (AMA) and PBC was first recognized in 1965 by Walker and colleagues who described the specific fluorescence pattern due to reactivity with antigens present in cytoplasmic organelles; such reactivity was found almost exclusively in sera from affected individuals (Walker et al., 1965). In 1987, the AMA antigens were cloned and identified as subunits of the pyruvate dehydrogenase complex (PDC) located on the inner mitochondrial membrane (Gershwin et al., 1987). This discovery led to the development of more sensitive assays for the determination of AMA, although indirect immunofluorescence remains the method of routine testing in most clinical centers.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Diagnosis

The diagnosis of PBC, although in some cases suggested by symptoms or clinical signs (see below), is based on three objective criteria. This triad consists of detectable serum AMA (titer >1:40), increased enzymes indicating cholestasis (i.e. alkaline phosphatase) for longer than 6 months, and a compatible or diagnostic liver histology (Heathcote, 2000). A classification proposed by a British group (Metcalf et al., 1997) indicates a "probable" diagnosis when two out of the three criteria (most often AMA-positivity and compatible liver histology, but normal liver enzymes) are present. Accordingly, a "definite" diagnosis can be made in the presence of all three states. This classification may be overly strict as the vast majority of asymptomatic AMA-positive individuals will eventually develop a classical picture of PBC during follow-up. Moreover, patients lacking detectable AMA (especially when indirect immunofluorescence is used) but otherwise presenting signs of PBC should be regarded as affected by "AMA-negative PBC" (or "autoimmune cholangitis"), as they appear to follow a similar natural history when compared to their AMA-positive counterparts (Invernizzi et al., 1997). Although it remains critical for the assessment of the histologic stage, the issue of whether a liver biopsy is still needed for the diagnosis of PBC is still highly debated. Currently, performing a liver biopsy seems not to be indicated when the other two diagnostic criteria are met. However, histology should be pursued to establish the diagnosis of PBC in the presence of serum AMA and serum alkaline phosphatase less than 1.5 times the upper normal level (Zein et al., 2003) or in the absence of detectable AMA.

Asymptomatic/Symptomatic Primary Biliary Cirrhosis

In a large number of cases (20–60%) the diagnosis of PBC is established in the absence of symptoms indicating a liver condition or cholestasis (Inoue et al., 1995). The number of asymptomatic patients at the time of diagnosis has been increasing with time since the earlier series descriptions when the majority of patients were diagnosed when jaundice was already present (Ahrens et al., 1950). The increasing number of symptomless patients most likely also represents the growing awareness of the syndrome as well as, perhaps more importantly, the availability of more sensitive noninvasive tests. Interestingly, however, symptomless patients are commonly older than symptomatic ones, thus possibly implying differences in the progression of PBC in these two groups (Howel et al., 2000). We note, however, that during extended clinical follow-up most AMA-positive patients will eventually develop PBC-associated symptoms, such as fatigue, pruritus, or right upper abdominal pain (Metcalf et al., 1997). In the later stages of the disease, when liver cirrhosis appears, symptoms of advanced liver disease, such as complications of portal hypertension or jaundice, may also develop. The most common symptoms accompanying PBC are fatigue and pruritus. Physical findings may include skin hyperpigmentation, hepatosplenomegaly, and xanthelasmas (caused by deposition of cholesterol). Jaundice may appear in advanced stages and is now less common than described in early reports (Sherlock and Scheuer, 1973), where patients were diagnosed when severe liver impairment had already developed. Endstage symptoms are those of all liver cirrhosis and include ascites, encephalopathy, and upper digestive bleeding. In some cases, however, endoscopic signs of portal hypertension, such as varices or gastropathy, can be encountered during what is apparently early stages PBC—i.e., without histologic evidence of liver cirrhosis—and appears to be secondary to presinusoidal fibrosis and inflammation induced by granulomas (Navasa et al., 1987).

Clinical features

Fatigue

Fatigue, roughly defined as reported severe distress and disability, may affect up to 70% of patients with PBC. The symptom may be overlooked by patients, particularly middle-aged women, who might believe it a consequence of aging. Similar prevalence rates can be observed in other autoimmune conditions including systemic lupus erythematosus in which, however, fatigue often correlates with depression rather than with immunologic markers or inflammation. In PBC, the severity of fatigue is also independent of the severity of liver disease or its other symptoms (pruritus or severe cholestasis) and independent of psychiatric factors. Impairments in central neurotransmission (Jones and Yurdaydin, 1997) or corticotropin-releasing hormone response (Swain and Maric, 1995), and, more recently, morphologic abnormalities of the central nervous system due to accumulation of manganese have been postulated as putative causes of fatigue in PBC (Forton et al., 2004). No medical treatment has been shown effective in alleviating this symptom, although fatigue has never been included as an endpoint in any of the large controlled clinical trials.

Pruritus

Pruritus is considered the second most common symptom of PBC, affecting 20–70% of patients with PBC and jaundice. Longitudinal data show that the vast majority of

patients will experience this symptom during progression of the disease, and its appearance most commonly precedes jaundice by months or years. Pruritus can be localized or diffuse, but at the time of onset it is more frequently localized to specific areas. Typically, the symptom worsens at night, following contact with certain fabrics (wool), or in warm climates. However, the pruritus of cholestasis is not mediated in the skin. The two main hypotheses to explain the pathogenesis of pruritus implicate either serum bile-acid retention secondary to chronic cholestasis, or alternatively but not exclusively, an amplified release of endogenous opioids (Bergasa et al., 2000).

Treatment of pruritus in PBC is often challenging for the clinician. Trials of antihistamines or phenobarbital for the treatment of the symptom have proven these medications to be ineffective, whereas the use of cholestyramine (4 g before and after the first meal) ameliorates pruritus. In selected cases poorly responsive to resins, rifampicin has been used to achieve rapid symptom relief; its prolonged use, however, is not recommended. Since experimental evidence indicates that the opioid neurotransmitter system, rather than bile acid retention alone, might mediate pruritus in chronic cholestasis, a central mechanism has been proposed. This hypothesis is supported by data (Jones and Bergasa, 1999) demonstrating that opioid receptor ligands with agonist properties mediate pruritus and that endogenous opioid-mediated neuromodulation in the central nervous system is increased in chronic cholestasis. For these reasons, treatment with opiate antagonists such as naltrexone 50 mg/day is currently being used for pruritus in PBC. The efficacy of naltrexone has been assessed in one controlled clinical study that has also indicated that side effects were temporary and usually did not require specific treatment (Terg et al., 2002). Studies of the behavioral consequence of the pruritus of cholestasis, scratching activity, allow for the design of clinical trials with objective and well-defined endpoints. The efficacy of sertraline, so far evaluated only in one clinical study (Browning et al., 2003), is promising but warrants further evaluation. In patients with intractable pruritus, liver transplantation is the ultimate therapeutic option.

Portal Hypertension

As mentioned above, portal hypertension is a common finding in patients with PBC, but significantly fewer patients now present with acute digestive bleeding or other signs of portal hypertension compared with the first reported series of affected individuals. Interestingly, portal hypertension in PBC does not imply the presence of liver cirrhosis. Longitudinal studies indicate that approximately 58% of untreated patients will eventually develop endoscopic signs of portal hypertension over a 4-year follow-up (Lindor et al., 1997). Signs of portal hypertensions should be monitored in individuals affected by PBC but the phenomenon should be regarded as less life-threatening than if it occurred in the context of other chronic liver conditions.

Reduction in Bone Density

A metabolic bone disease is found in PBC with accelerated bone loss due to reduced bone deposition being noted in patients compared with sex- and age-matched healthy individuals. These findings are still somewhat contentious and conflicting data have been reported. A mild reduction of bone density (osteopenia) is present in about 30% of patients while frank osteoporosis is diagnosed in 10% of patients. The bone loss can, moreover, worsen after liver transplantation, possibly due to the administration of specific immunosuppressive drugs. The mechanisms leading to metabolic bone alterations are not completely understood as no significant changes in the metabolism of calcium and vitamin D can be found in patients with PBC. Current treatment of bone loss includes oral calcium supplementation, weight-bearing activity, and oral vitamin D replacement (if a deficiency is present). Post-menopausal hormone replacement therapy should be considered as effective and as prone to cause side effects in women with PBC as in the general population. However, as estrogens have been associated with worsening of the cholestatic pattern, jaundice and signs of liver failure should be monitored closely particularly during the first months of treatment. Efficacy and safety of treatment with calcitonin, sodium fluoride, alendronate, and etidronate are under evaluation or have provided limited efficacy.

Hyperlipidemia

Alterations in the blood lipid profile are a common finding in PBC (up to 85% of patients present with hyperlipidemia) and often precede the diagnosis. Both serum cholesterol and serum triglyceride levels can be raised. Interestingly, however, such alterations do not correlate with increased incidence of cardiovascular events or atherosclerosis (Longo et al., 2002). Of note, the degree of hyperlipidemia does not correlate with the presence of cutaneous xanthelasmas. Treatment with ursodeoxycholic acid (UDCA) may reduce blood lipid levels via unknown mechanisms.

Steatorrhea and Malabsorption

Long-standing cholestasis leads to steatorrhea by inducing bacterial overgrowth syndrome in the gut. The mechanism is mediated by the impaired flow of bile acids to the small intestine and is commonly found in advanced stages of PBC (Lanspa et al., 1985). Oral replacement of medium-chain triglycerides for long-chain compounds, along with an overall reduction of fat in the diet can be offered as the treatment for symptoms. Pancreatic enzyme replacement

medications can also improve the symptoms when pancreatic insufficiency is suspected. Empirical antibiotic regimens can treat the bacterial overgrowth but their use, particularly when prolonged, should be carefully evaluated.

Malabsorption of fat-soluble vitamins is commonly found in advanced stages of PBC (Phillips et al., 2001). The most common deficiency, involving vitamin A, although almost always symptomless, is present in 20% of cases. Oral replacement therapy can overcome impaired absorption, and monitoring of serum concentrations is recommended after 6–12 months to avoid potential hepatotoxicity or overcorrection. In less common deficiencies such as vitamin E (potentially leading to ataxia), vitamin K (influencing coagulation), and vitamin D (see metabolic bone loss), oral or parenteral supplementations are safe and effective.

Associated Conditions

Various disorders, particularly other autoimmune syndromes, have been reported as associated with PBC. As many as 70% of patients with PBC will present another autoimmune disease (Talwalkar and Lindor, 2003). Table 54.1 lists the most commonly associated diseases and conditions and their prevalence in PBC. Some degree of impaired alveolar function and renal tubular acidosis, in both cases rarely burdened by symptoms or clinical significance, were found in 39% and 50% of PBC cases, respectively (Costa et al., 1995; Pares et al., 1981). Among autoimmune conditions, keratoconjunctivitis sicca and Raynaud phenomenon are most commonly associated with PBC but also systemic sclerosis is not uncommon. Among autoimmune diseases rarely associated with PBC, cases have been reported for systemic lupus erythematosus and multiple sclerosis, while the prevalence among PBC cases of inflammatory bowel diseases and pulmonary fibrosis is in both cases below 5%.

Malignancies

Similarly to other chronic liver conditions that lead to cirrhosis, PBC at the stage of cirrhosis can be complicated by the occurrence of hepatocellular carcinoma (HCC) and patients should be periodically monitored (Findor et al., 2002). From the clinical perspective, therefore, this implies that in PBC patients with cirrhosis, the screening for HCC should be performed using ultrasonography (and computed tomography in selected cases) twice a year to estimate the prognosis and to choose among therapeutic alternatives, particularly when orthotopic liver transplantation (OLT) is being evaluated. Apart from liver cirrhosis, there seem not to be any PBC-specific risk factors for the development of HCC (Findor et al., 2002). The treatment of HCC in PBC should follow the same guidelines as in other chronic liver diseases. No association with cholangiocellular carcinoma or other malignancies has been identified.

Natural History

The clinical course of PBC presents a very wide range of progression rates, with some patients remaining stable and asymptomatic for decades and others rapidly advancing towards endstage liver disease in just a few years. For descriptive purposes, however, the natural history of the disease can be divided into three time periods. First, patients experience an asymptomatic stage, lasting up to 20 years, in which the diagnosis is usually made based on occasional tests or referral for investigation of non-specific symptoms. Later on, a symptomatic phase, lasting up to 5 years, can be observed in which mild jaundice may also appear. Ultimately, patients show a rapid pre-terminal stage characterized by severe jaundice and complications of liver cirrhosis. Although the diagnosis is now made more frequently within the first stage, it is clear that the high variability of presentation time-points militates against the development of

prognostic models or the reaching of definitive conclusions about the natural history of the disease. Studies on patients followed over a long period of time, however, have provided indications on the progression of PBC.

Asymptomatic/Symptomatic Primary Biliary Cirrhosis

The presence of symptoms at the time of presentation, as indicated above, should be regarded as a major factor determining survival rates of patients with PBC.

Initial studies indicated that symptomless PBC is accompanied by survival rates over 10 years similar to the sex- and age-matched general population. However, longitudinal studies indicate that 67% of precirrhotic patients will develop liver cirrhosis over a 7-year period (Roll et al., 1983), while up to 70% of asymptomatic patients will develop symptoms over a longer follow-up (Mitchison et al., 1986). Further, regression models indicate that asymptomatic patients with PBC present significantly lower survival rates during long-term observation when compared with the general population. At the present state of knowledge, it appears reasonable to conclude that, among asymptomatic patients, survival should be considered shorter than the general population once symptoms develop during follow-up, while patients with PBC who remain symptomless over a 5-year follow-up have a survival rate equal to same-sex unaffected individuals of similar age (Springer et al., 1999). We also note that a recent report has suggested that the shorter survival of asymptomatic patients over time might be due to a higher prevalence of nonhepatic causes of death in such groups, compared with deaths related to PBC (31% vs. 57%, respectively) (Prince et al., 2004). These observations, albeit interesting and possibly compatible with data on comorbidity in PBC, present potential implications in the clinical management that need further study.

Patients with symptomatic PBC show a more rapid progression to late-stage disease and a worse prognosis than their asymptomatic counterparts. It should be noted, however, that such progression is to be considered slow as the symptomatic phase may last for several years. The mean survival time among these patients is estimated in the 6–10 year range (Pares and Rodes, 2003). Multivariate analysis among symptomatic patients with PBC has indicated several factors that can negatively influence the prognosis including clinical features (older age, presence of ascites, edema, or hepatic encephalopathy), analytical features (hyperbilirubinemia, hypoalbuminemia), and histologic features (presence of fibrosis or cirrhosis) (Pares and Rodes, 2003).

Mathematical Prognostic Models

Several prognostic models have been proposed for PBC over the past decades, but convincing validation has been obtained for only a few. Currently, the model based on the Mayo score is the most widely accepted and utilized for estimating expected survival (Grambsch et al., 1989). The formula takes into account clinical (age, presence of ascites), as well as biochemical variables, based on cholestasis (bilirubin levels) and liver function (prothrombin time, albumin). It should be noted that the major limitation to wide clinical application of this as well as other models is the fact that they rely on single-point measures and variables, thus providing a static representation of a dynamic entity. Attempts have been made to remove this limitation by deriving a numerical factor for the yearly increase in a risk score for PBC, but this often fails to account for the highly variable course of the disease. It is also debatable whether pharmacologic therapies, such as UDCA, actually influence the natural history of the disease over long periods (see below).

HISTOLOGY

The utility of histologic assessment in PBC has been widely debated. We believe that obtaining a liver biopsy specimen provides important data to determine the stage of the disease, both at presentation and during the follow-up (Heathcote, 2000). As a compatible histology is one of the three internationally accepted diagnostic criteria, it should be pursued in those in whom the diagnosis is suspected but AMAs are negative and alkaline phosphatase levels normal. The possibility of a sampling error should be considered and, in case of variable staging within a single biopsy, the highest stage should be accepted (Ludwig, 2000).

According to Ludwig's classification (Ludwig et al., 1978), histology identifies four stages of PBC. Morphologically, stage I shows portal-tract inflammation with predominantly lymphoplasmacytic infiltrates, resulting in vanishing septal and interlobular bile ducts (diameter $<100\,\mu m$). At this stage, the diagnosis of PBC should be regarded as highly probable if duct obliteration and granulomas are observed, in the absence of sarcoidosis or tuberculosis. In stage II, a periportal inflammatory infiltrate is observed. Signs of cholangitis, granulomas, and florid proliferation of ductules are typical in this stage. Stage III is characterized by the appearance of septal or bridging fibrosis, with ductopenia (over half of the visible interlobular bile ducts having vanished). As in other cholestatic conditions, copper deposition in periportal and paraseptal hepatocytes can be present at this stage. Stage IV corresponds to frank cirrhosis. Peculiar characteristics of PBC that can be found at any histologic stage include epithelioid granulomas with no signs of caseous necrosis such as in tuberculosis. A large retrospective study has demonstrated that 23.8% cases of granulomas encountered in unselected liver biopsies were to be attributed to PBC. The mechanisms leading to granuloma

formation are still largely unknown, although experimental findings suggest that gram-positive bacteria through lipoteichoic acid might initiate the process (Tsuneyama et al., 2001) while osteopontin might also mediate the recruitment of mononuclear cells (Harada et al., 2003). The observation of eosinophils in the portal tract is a specific finding in PBC histology (Goldstein et al., 2001), although its significance, alongside a peripheral hypereosinophilia, is currently poorly understood (Neuberger, 1999).

AUTOIMMUNE FEATURES

Several clinical and experimental findings strongly imply an autoimmune pathogenesis for PBC (Selmi et al., 2004). Common features of other autoimmune conditions seem to apply only in part to PBC. First, autoantibodies should be present in patients with the disease. Primary biliary cirrhosis is characterized by the presence of detectable AMA in approximately 90% of affected individuals (Mackay et al., 2000), although we note that patients lacking AMA can present with a similar disease picture and progression as found in AMA-positive subjects (Invernizzi et al., 1997) seemingly arguing against a pathogenic role for these autoantibodies. Autoreactive T cells, both $CD4^+$ and $CD8^+$ have been identified in AMA-negative PBC and such lymphocytes and AMA recognize overlapping epitopes within the mitochondrial antigens (Ishibashi et al., 2003). Second, autoantibodies should interact with the target antigen, the passive transfer of autoantibodies should reproduce the clinical features, and experimental immunization with the antigen should produce a model disease. As mentioned above, no direct proof has yet been provided for a direct pathogenic role of AMA in the bile duct injury observed in PBC. Similarly, no convincing animal model has been described (see below), although AMA can be generated in experimental animals following immunization. Thirdly, in autoimmune diseases the reduction of autoantibody levels should ameliorate the disease; this criterion is poorly fulfilled in PBC, where there is no correlation between the pattern or titer of AMA and progression of the disease (Bogdanos et al., 2003). Finally, it is well-established that most autoimmune diseases are responsive to immunosuppressive therapy. In PBC, all immunosuppressive agents have proven relatively ineffective (see below).

Antimitochondrial Antibodies

Antimitochondrial antibodies are directed against components of the 2-oxoacid dehydrogenase (2-OADC) family of enzymes within the mitochondrial respiratory chain (Gershwin et al., 2000). Specifically, the main recognized antigens are the E2 and E3 binding protein (E3BP) components of the pyruvate dehydrogenase complex PDC (frequently presenting cross-reactivity) and the E2 components of the 2-oxoglutarate dehydrogenase and branched-chain 2-oxoacid dehydrogenase complexes (OGDC and BCOADC). The mapping of AMA epitopes within such molecules has been achieved using partial constructs and combined peptides. Data indicated that AMA recognize closely-related conformational epitopes including the inner lipoylated domain of PDC-E2, BCOADC-E2, and OGDC-E2 (Gershwin et al., 2000). In all three molecules, in fact, contact sites contain the three amino acid motif DKA, with lipoic acid covalently bound to the lysine (K) residue. It is not clear whether lipoic acid participates in the epitope recognition by AMA; apparently conflicting results indicated that AMA bind to both the lipoylated and unlipoylated forms of PDC-E2 (Quinn et al., 1993), while they can also bind to lipoic acid attached to a non-2-OADC peptide (Bruggraber et al., 2003).

Antinuclear Antibodies

As many as 50% of patients with PBC present serum antinuclear antibodies (ANA). The pathogenic role of ANA in PBC is still poorly understood, or perhaps it could be said that their pathogenic role is no better understood than that of AMA. The two immunofluorescence patterns most often encountered in PBC are "nuclear rim" and "multiple nuclear dots," based on the recognition by the autoantibodies of gp210 and nucleoporin 62 (within the nuclear pore complex) and of Sp100 and promyelocytic leukemia protein (PML), respectively. Interestingly, the presence of serum reactivity against proteins from the nuclear pore complex (gp210, p62) in PBC was found associated with a more severe disease in a cross-sectional study (Invernizzi et al., 2001). On the other hand, the nuclear body proteins Sp100 and PML have been shown to be complexed with small ubiquitin-like molecules (SUMO) for cell transport regulation, and SUMO are in turn independent antigens specific for ANA-positive PBC (Janka et al., 2005).

Autoreactive T cells

A number of mononuclear cells can be found in the area surrounding damaged bile ducts in PBC. T-helper ($CD4^+$), $TCR\alpha\beta^+$, and $CD8^+$ T cells are most commonly seen among such cells, perhaps secondary to high levels of IFN-γ acting as a chemotaxic stimulus. Autoreactive T cells have been well characterized in PBC from both the liver and peripheral blood of affected patients. PDC-E2-specific autoreactive $CD4^+$ T-cell (T-helper) clones were isolated by *in vitro* stimulation of intrahepatic or peripheral lymphocytes to PDC-E2 (Van de Water et al., 1991; 1995). The autoepitope for T cells overlaps with the B-cell (AMA) epitope and includes the lipoyl-lysine residue located at amino acid residue 174 of the inner lipoylated domain of the protein (Shimoda et al., 1995). Interestingly, a specific increase of between 100- and 150-fold in the frequency of PDC-

$E2_{163–176}$-specific $CD4^+$ T-cells in the hilar lymph nodes and liver when compared with that in periphery is observed in PBC (Shimoda et al., 1998). Autoreactive cytotoxic T lymphocytes (CTLs) are also well characterized in PBC and currently considered major effectors in the tissue injury encountered in PBC. The MHC class I restricted epitope for CTLs, namely amino acids 159–167, also maps in close vicinity to the epitopes recognized by $CD4^+$ cells and by AMA (Kita et al., 2002b) . Similarly to $CD4^+$ cells, moreover, the recent use of tetramer technology has shown a 10-fold higher prevalence of PDC-$E2_{159–167}$-specific CTLs in the liver compared with peripheral blood of patients with PBC (Kita et al., 2002c). Figure 54.1 illustrates the structure of tetramers used for MHC-peptide coupling in cell-immunity studies.

EPIDEMIOLOGY

Epidemiology and Geoepidemiology

Most of the epidemiologic data used to determine the incidence and prevalence rates of PBC are descriptive, with some studies containing methodological flaws such as non-uniform case definition. The performance of a population-based study to ascertain the prevalence of PBC is challenging, as a noninvasive highly sensitive marker is not currently available (the most specific candidate, AMA, being negative in 5–10% of patients) and the absence of a register of patients does not allow the recognition of all cases. Primary biliary cirrhosis is considered to be most prevalent in England, Scandinavia, and specific areas of the United States, although a factitious prevalence due to more exhaustive epidemiologic studies from these countries compared with other areas cannot be excluded. Table 54.2 indicates a synopsis of the epidemiologic data available (Selmi et al., 2004). Prevalence rates for PBC vary widely in different geographic areas and have been reported to be as high as 402 in 1 million.

Sex Differences and Gravidity

Similarly to other autoimmune diseases, women, primarily middle-aged, outnumber men by as much as 10 : 1 among patients with PBC (see Table 54.2). The prevailing expla-

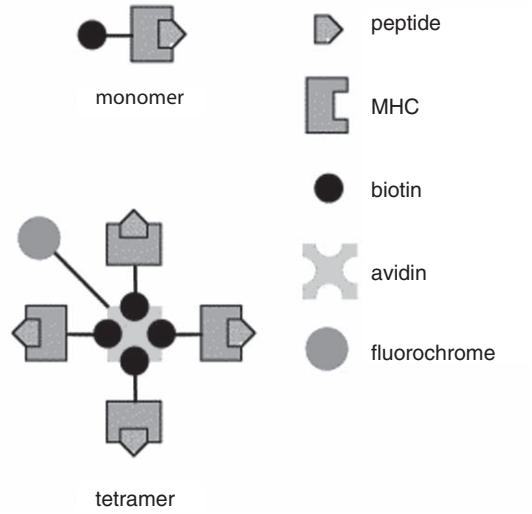

Figure 54.1 Structure of peptide-MHC tetramers used for the isolation of specific autoreactive T cells. The tetramer based on streptavidin-biotin is the most widely used and is represented. Recombinant MHC molecules (HLA class I, II, or non-typical II can be used), are incubated with peptide to form peptide-MHC complex, which is biotinylated. Only autoreactive T cells specifically reacting with the presented peptide recognize the tetramer, and the presence of a fluorochrome allows detection of such cells by flow cytometry.

TABLE 54.2 Synopsis of population-based epidemiologic studies of primary biliary cirrhosis

Year	Location	No of cases	Annual incidence (per million)	Prevalence (per million)	Gender ratio (M/F)
1980	Sheffield, UK	34	5.8	54	1 : 16

Modified from Selmi et al. (2004b).

nation for the striking predominance of disease in females is the effects of sex hormones on the immune system, although conclusive data are not available. It has also been reported that female PBC cases have significantly more pregnancies than controls, although no explanation is available for this observation (Parikh-Patel et al., 2002).

GENETIC FEATURES

Familial Primary Biliary Cirrhosis

Primary biliary cirrhosis is more frequent in relatives of affected individuals and the term "familial PBC" has been coined to indicate families that have more than one case. Variable rates of familial PBC are seen in different geographic areas, possibly due once again to different methods of case definition. In general, data indicate that 1–6% of PBC cases have at least one family member presenting the disease (Selmi et al., 2004). Such familial prevalence rates are significantly higher than general population prevalence estimates (see Table 54.2), thus indicating a genetic predisposition to the disease. However, the difficulty in evaluating these data is that prevalence rates in the general population are still uncertain, and control groups are not always included in the family studies.

Twin Studies

The concordance rate observed among monozygotic twins for PBC is 63%, among the highest reported in autoimmunity, reinforcing the idea of an important role of genetics in disease susceptibility (Selmi et al., 2004).

Association Studies

Several studies have attempted to identify genes associated with PBC. No family study of genetic linkage has been performed, possibly because PBC is a relatively rare disease and it is, therefore, difficult to obtain DNA samples from a large number of representative families. All available studies were designed in a controlled, cross-sectional fashion but were prone to multiple sampling errors and biases of incorrect estimations. A multi-hit genetic model seems to apply to PBC, with different genetic variants conferring susceptibility (first hit) and others influencing disease progression (second hit). For this reason, most authors investigating genetic factors in PBC have studied the role of such factors in susceptibility to the disease (comparing allele and genotype frequencies in patients and controls), as well as in its severity (through the analysis of clinical characteristics of patients carrying different genotypes or alleles). No definitive association of PBC susceptibility or progression could be identified in these studies (Jones and Donaldson, 2003). When an association has been found, it has proven to be weak or limited to specific geographic areas. We note, moreover, that this also applies to the study of the variants of MHC (including type I, II, and III loci) in which, different from most autoimmune diseases, reported associations were often weak or limited to specific geographic areas (Invernizzi et al., 2005). Similar findings were also reported from the study of the genetic variants of immunomodulatory molecules, enzymes producing vasoactive compounds, bile-acid transporters. Among immunomodulatory molecules, we note that weak associations have been reported with polymorphisms of genes coding for chemokines IP-10 and MIG and chemokine receptors CXCR5 and CXCR3, toll-like receptor 9, and cytotoxic T lymphocyte associated antigen-4 (CTLA-4). In the future, definitive indications on the genetics of PBC may be obtained by methods based on inheritance by descent techniques on large series of affected and unaffected family members and should be encouraged. Such an approach will lead to more reliable findings compared with the use of cross-sectional association studies based on the comparison of allelic frequencies in cases and controls.

Sex Chromosomes

Similar to other autoimmune diseases more commonly diagnosed in women following reproductive years (Lambert and Nelson, 2003), fetal microchimerism has been suggested in PBC, with the hypothesis of a higher prevalence of small amounts of fetal (paternal) DNA found in mothers with PBC. First, it was suggested that the presence of fetal DNA in the liver of affected women years after pregnancy might predispose to PBC (Fanning et al., 2000); independent findings, however, have not confirmed such hypothesis (Invernizzi et al., 2000; Tanaka et al., 1999a).

Genes mapping on the X chromosome are critical to the maintenance of physiological sex hormone levels and, more importantly, of immune responsiveness. Invernizzi and colleagues reported an age-dependent enhanced monosomy X in the peripheral white blood cells of women with PBC (Invernizzi et al., 2004b). This observation seems to indicate a polygenic model for PBC with an X-linked major locus of susceptibility in which genes escaping inactivation are the major candidates. On the other hand, it can also be hypothesized that susceptibility to PBC is the result of a multigenic complex inheritance model where Y-linked genes might exert a protective role.

ENVIRONMENTAL INFLUENCES

Risk Factors

Although genetics should be regarded as the major determinant in susceptibility to PBC, several other factors have

Box 54.1
Proposed risk factors and their association with primary biliary cirrhosis (PBC)

Significant associations

- Female gender
- Non-PBC autoimmune disease (particularly autoimmune thyroiditis)
- Vaginal or urinary tract infection
- Previous tonsillectomy
- Chronic bronchitis

Doubtful associations

- History of shingles
- Previous hepatitis A infection
- Previous surgery (particularly appendectomy, uterine surgery)
- Former smoking habit

No association

- Dietary fat intake
- Childhood diseases

Modified from Parikh-Patel et al. (2001).

Deficient sunlight/vitamin D
Pregnancies/microchimerism

been proposed, including a history of previous infections, comorbidity with other autoimmune diseases, and lifestyle factors, such as smoking and a high-fat diet. Most evidence was obtained from large questionnaire-based studies, which showed associations of PBC with past smoking habit, the presence of other autoimmune diseases, previous tonsillectomy and a history of vaginal or urinary tract infection in females only (Parikh-Patel et al., 2001). Box 54.1 lists the proposed risk factors for the development of PBC.

Proposed Environmental Factors

The lack of strong genetic associations for PBC has meant that environmental factors have received attention as possible triggers of autoimmunity in PBC. A list of proposed factors is given in Box 54.2. Attention has focused on two main agents, infectious (bacteria and viruses) and chemical (xenobiotics).

The ability of infectious agents, particularly bacteria, to induce autoimmune responses in experimental settings has been documented, and molecular mimicry is the most widely studied mechanism explaining these observations (Van de Water et al., 2001). Briefly, this paradigm suggests that microbes present peptides sharing different degrees of homology with self-proteins, thus leading to a promiscuous antibody and cell-mediated immune response capable of reacting with both microbial and self-epitopes. T-cell activation produces cross-reacting T cells leading to self-tissue destruction, thus perpetuating the autoimmune response, possibly through the degeneracy of the T-cell receptor and cross-priming. Of the bacterial strains suggested to lead to PBC through molecular mimicry (Selmi and Gershwin, 2004), most evidence has been reported for *Escherichia coli*, mostly based on the reports of an increased prevalence of urinary tract infections in patients with PBC (Parikh-Patel et al., 2001). We also note that, based on serum cross-reactivity, several infectious agents have been proposed for the initiation of PBC, including *Klebsiella pneumoniae*, *Proteus mirabilis*, *Staphylococcus aureus*, *Salmonella minnesota*, *Mycobacterium gordonae*, *Neisseria meningitidis*, and *Trypanosoma brucei* (Van de Water et al., 2001). More recently, the common commensal yeast *Saccharomyces cerevisiae* has also been investigated in PBC, based on the expression of AMA antigens in extra-mitochondrial sites (Ghadiminejad et al., 1988) but serologic studies indicated that the reactivity against the yeast (anti-*Saccharomyces cerevisiae* antibodies; ASCA) was not specific for the disease (Muratori et al., 2003). Interestingly, contrasting evidence has been collected on the role of *Chlamydia pneumoniae* in the pathogenesis of PBC. Abdulkarim and colleagues detected the bacterial antigen and RNA in 100% of PBC explanted liver sections compared with 8.5% of controls (Abdulkarim et al., 2004) while a different immunologic and molecular approach could not confirm this hypothesis (Leung et al., 2003a). Finally, our group has recently provided serologic data suggesting that a ubiquitous xenobiotic-metabolizing gram-negative bacterium, *Novosphingobium aromaticivorans*, is the best candidate yet for the induction of PBC, as it elicits a specific antibody reaction (estimated to be 100- to 1000-fold higher than against *E. coli*) and its 16S rRNA-specific sequences were detected in human fecal samples (Selmi et al., 2003). For completeness, we also note that a novel human beta-retrovirus has been identified in lymph nodes and other samples from patients with PBC (Xu et al., 2003), thus suggesting that this mouse mammary tumor (MMTV)-like virus might play a role in the patho-

genesis of PBC. However, our laboratory failed to confirm this hypothesis using a different molecular and immunologic approach on a large series of patients and controls (Selmi and Gershwin, 2004), therefore discouraging the use of any anti-retroviral therapy in PBC (Gershwin and Selmi, 2004).

Xenobiotics are foreign compounds that may either alter or complex to defined self or non-self proteins, inducing a change in the molecular structure of the native protein sufficient to induce an immune response. Such immune responses may then result in the cross-recognition of the self form, which could in turn perpetuate the immune response, thus leading to chronic autoimmunity. A role for specific compounds has been proposed in a number of autoimmune conditions (Table 54.3). Figure 54.2 depicts the proposed pathogenic pathway by which xenobiotics may induce PBC in genetically susceptible individuals. Interestingly, most xenobiotics are metabolized in the liver, thereby increasing the potential for liver-specific alteration of proteins. Experiments showed that specific organic structures attached to the mitochondrial antigens were recognized by sera from PBC patients with a higher affinity than native forms of such antigens (Long et al., 2001). Such findings indicated for the first time that an organic compound may serve as a mimotope for an autoantigen, thus further providing evidence for a potential mechanism by which environmental organic compounds may cause PBC. One halogenated compound was capable of inducing AMA production in animal models (Leung et al., 2003b). This model did not lead to production of liver lesions; however, it appeared to simulate the stage of the disease in humans where AMA is present prior to the appearance of liver damage. The AMA-positivity, moreover, was reversible after the immunization ceased (Amano et al., 2004).

It is of note that the vast majority of data on molecular mimicry in PBC were obtained from the study of humoral immunity (i.e., AMA), either in patient sera or animal models, while the study of cellular autoimmunity is limited. An extensive study of autoreactive $CD4^+$ T-cell clones by Shimoda et al. (2003) has demonstrated that molecular mimicry takes place between T-cell epitopes of PDC-E2 and gp210 (an ANA antigen in PBC), thus suggesting that immunospreading may occur from mitochondrial proteins to nuclear proteins, similar to that hypothesized for bacterial antigens. Supporting evidence was obtained by our group also for autoreactive $CD8^+$ T cells. Results indicated that a peptide derived from the gram-negative *Pseudomonas aeruginosa* (belonging to the same family as *N. aromaticivorans*) showed a higher binding affinity to the T-cell HLA than PDC-E2 (Kita et al., 2002a).

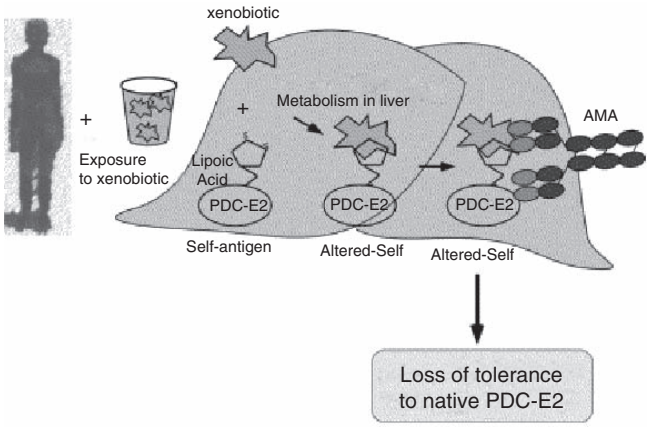

Figure 54.2 Proposed pathway by which xenobiotics might break tolerance and give rise to primary biliary cirrhosis (PBC). According to such theory, xenobiotics are transported to the liver through the portal circulation. In the liver, xenobiotics are then metabolized (possibly through the cytochrome P450 pathways) and their metabolites form adducts with the lipoylated domains of the mitochondrial antigens (PDC-E2). Such adducts in turn induce changes in the structure of the native proteins, which are now recognized as non-self, thus raising a humoral response (AMA) against both the modified and the unmodified forms and perpetuating the autoimmune response.

TABLE 54.3 The role of xenobiotics in autoimmune disease

Compound	Associated autoimmune condition
Mercury (Bagenstose et al., 1999; Yoshida and Gershwin, 1993)	Immune complex formation Glomerulonephritis
Iodine (Rose and Burek, 2000)	Autoimmune thyroiditis
Vinyl chloride (D'Cruz, 2000)	Scleroderma-like disease

6-bromohexanoate (Selmi et al., 2003)	Primary biliary cirrhosis

ANIMAL MODELS

The development of an animal model would be extremely helpful in elucidating the undoubtedly multifactorial causation and progression of PBC. Several models, mostly murine, have been proposed. The first reported animal model for PBC was observed in an inbred rabbit strain with spontaneous nonsuppurative cholangitis. However, the AMA response was weak (Tison et al., 1982). In later attempts, PBC epithelial cells and purified PDC-E2 with lipopolysaccharide (LPS) or recombinant polypeptides of PDC-E2 were injected intravenously into neonatally thymectomized A/J mice (Kobashi et al., 1994) and C57BL/6 mice (Hayashi et al., 1989), respectively. Antimitochondrial antibodies were induced in both these models, but no PBC-like pathologic changes in the liver were observed. A graft-versus-host disease (GvHD) model has also been developed based on the observation that the histology of PBC shared some characteristics with human GvHD, but no specific serologic response was generated against mitochondrial antigens (Vierling et al., 1989). The injection of PBC cell repertoire into human severe combined immunodeficient (SCID) as well as knockout murine models, has also been pursued, with conflicting and non-definitive results (Krams et al., 1989). In 2000, a British group reported that the immunization of SJL/J mice with PDC-E2 led to autoimmune cholangitis associated with T cells that display a mixed cytokine profile similar to that observed in PBC. Such findings were later proven to be nonspecific, as bile duct inflammation was found also after immunization with control peptides under the same conditions (Sasaki et al., 2002). More recently, our group has reported that immunization of rabbits with a specific halogenated compound coupled with albumin could elicit AMA development (Selmi et al., 2003), but not liver lesions.

A number of obstacles still militate against the development of a consistent and reliable animal model for PBC. An important one is likely to be the long latent period between AMA and liver pathology appearance (as observed in humans), which is at odds with the short life expectancy of the animals used (particularly mice). Moreover, and possibly more importantly, we need to take into account that an enormous "constellation" of genetic conditions must be met in order to produce a specific phenotype, as indicated by the growing experience with the non-obese diabetic (NOD) mouse model for type 1 diabetes (Johansson et al., 2003).

PATHOGENIC MECHANISMS

Several theories have been proposed for the pathogenesis of the immune-mediated tissue injury observed in PBC. In all cases, such theories should not be regarded as independent from other etiologic factors leading to PBC susceptibility (i.e., genetic background, environmental triggers), but rather as effector mechanisms leading to the clinical manifestations.

Expression of PDC-Like Antigens on Cell Membranes

The highly selective destruction of biliary epithelial cells (BEC) is one of the unique features of PBC. As all nucleated cells in the body contain at least some mitochondria, the target antigens are continually being presented in association with MHC class I in all tissues. Why then are BECs singled out for destruction? An explanation for this comes from the observation that certain anti-PDC-E2 antisera react not only with PDC-E2 in mitochondria but also additional material located at the apical end of the BEC in close apposition to the surface (Van de Water et al., 1993). The degree of staining is quite intense, suggesting large amounts of this apically located material. Such a staining pattern is not seen in any other cells of the body, other than salivary duct epithelial cells, which are frequently a target of immune attack in PBC. Thus, there appears to be aberrant expression of a molecule that shares epitopes with PDC-E2 exclusively in the cells targeted by the immune system (Joplin et al., 1997). Further, this apical staining occurs very early in the natural history of PBC, even before the appearance of MHC class II on BECs (Tsuneyama et al., 1995a), and it is not detected in other liver diseases such as autoimmune hepatitis or primary sclerosing cholangitis. Finally, this aberrant apical staining is detected in liver samples from patients with AMA-negative PBC (Tsuneyama et al., 1995b). What is the identity of this apically and surface-located material in the BECs of PBC patients? This is still mysterious, and the difficulty of obtaining liver samples has significantly slowed progress. Livers from patients obtained at the time of transplantation have very few intact intrahepatic bile ducts so that laser dissection of BECs yields very few cells. Studies that have been performed have shown that the material is not immunologically identical to PDC-E2 as only some murine anti-human PDC-E2 monoclonal antibodies react with it. However, it may be a truncated product or it may be PDC-E2 that is complexed with other molecules (perhaps xenobiotics) in a way that masks epitopes. There is no significant difference in the amount of PDC-E2 transcript present in PBC liver compared with normal liver, suggesting that the observation may not be secondary to overexpression of PDC-E2. However, there is seldom a good correlation in eukaryotic cells between mRNA transcript levels and abundance of protein in the cell. Mass spectrometric studies of BECs from PBC suggested that the material had a different molecular mass to PDC-E2, making it either a breakdown product or a molecular mimic (Yip et al., 1996). The matter

rests there at present but the increasing sensitivity of proteomics methods may eventually provide a means to sequence or otherwise fingerprint the material. In the interim it is only possible to speculate. If the material is derived from PDC-E2, perhaps there are sequence variants common in PBC patients that lead to an altered turnover of the molecule, thus leading to the accumulation of PDC-E2 only in specific BECs. In this scenario, moreover, chemicals (xenobiotics) metabolized by the liver could significantly modify PDC-E2, possibly leading to the production of such variants (Long et al., 2002). Perhaps abnormal splicing during synthesis of PDC-E2 mRNA could result in an endoplasmic reticulum targeting signal instead of a mitochondrial targeting signal at the N-terminus of PDC-E2. This mechanism would be responsible for the delivery of PDC-E2 into the endoplasmic reticulum and Golgi apparatus via the secretory route. Although fascinating, this theory is currently supported only by observations using transmission electron microscopy (Jorge et al., 2002). The other alternative is that it is a molecular mimic perhaps associated with microbial infection or left over from prior infection. Whatever its identity, it is noteworthy that the material is found in association with IgA and the polymeric Ig receptor (Fukushima et al., 2002; Migliaccio et al., 1998) on the cell membranes of BECs.

The Role of Immunoglobulin A

The IgA isotype of immunoglobulin is the most common form found on all epithelial surfaces, including the biliary epithelium. It is, therefore, possible that the selective injury in PBC is mediated by AMA-IgA binding to the mitochondrial antigen, thus inducing cell dysfunction and death. Our group has demonstrated that IgA from PBC patients co-localizes with the PDC-E2 (or cross-reactive material) both in the cell cytoplasm and on the apical membrane of BECs, whereas no co-localization could be observed with antibodies from healthy subjects (Fukushima et al., 2002). The IgA that is found on the mucosal surface arrives there by uptake and trafficking across the BEC in association with the polymeric Ig receptor. It is possible that during this transport process, IgA with antimitochondrial specificity may contact its cognate antigen and that the complex may lead to deleterious effects. Evidence for this is provided by a study in which IgA was purified from PBC patient sera and incubated with canine kidney cells transfected with the human polymeric Ig receptor. Uptake of IgA into the cells led to a significant activation of caspases suggesting that apoptosis was being induced. Incubation with control IgA did not lead to caspase stimulation, providing evidence for a direct pathogenic role of anti-PDC-E2 IgA. IgA titers were directly correlated with the degree of caspase activation. (Matsumura et al., 2004). Presumably, in PBC patients, further cellular damage arises with time as AMA IgA transcytoses the BEC.

Molecular Mimicry by Infectious Agents

The cross-reactivity of AMA with prokaryotic antigens (particularly with the microbial respiratory-chain enzymes) has been reported for a number of microbes, including *E. coli*. This cross-reactivity is not particularly surprising given the conserved sequence of PDC-E2 across all species, from eubacteria to mammals (Van de Water et al., 2001). Indeed it is proposed that mitochondria originated following uptake of bacteria into the precursors of eukaryotic cells and maintenance as intracellular symbionts. Thus, it becomes difficult to tease out a causal role for microbial proteins in pathogenesis given their phylogenetic relationship to the human autoantigen. One line of argument that we have taken is that the breaking of tolerance and induction of autoimmunity would be more likely to occur when the microbial protein is extremely similar in sequence. We have recently suggested that a gram-negative ubiquitous bacterium, *N. aromaticivorans*, sharing the highest homology with human PDC-E2 yet described and capable of metabolizing xenobiotics, is the best candidate so far identified for the induction of PBC via molecular mimicry (Selmi et al., 2003). A necessary requirement of such a scenario would be the exposure of the patient to the candidate bacteria, either accompanied by overt signs of infection or not. A number of studies have tried to search for bacterial species within the liver and biliary tract of patients with PBC, but data have so far failed to define bacteria specific only to PBC liver (Tanaka et al., 1999b). *A priori* however, it is not clear that the bacteria would necessarily need to be present in these tissues as infection, and tolerance breakdown may occur anywhere including the urinary tract. Further the bacteria may well have disappeared by the time the patient presents with PBC, further complicating the search.

Researchers from one group have reported the presence of a beta-retrovirus in the liver and the lymph nodes of some patients with PBC, and that the culture of normal BECs in the presence of an homogenate of such PBC lymph nodes induced the expression of a PDC-E2-like antigen on cell membrane (Xu et al., 2003). Although intriguing, this latter observation has not been confirmed (Selmi et al., 2004).

Briefly, we can summarize our theory on molecular mimicry in PBC as follows. The microorganism (possibly the ubiquitous *N. aromaticivorans*) enters the human system through the digestive mucosa. Bacterial mimics containing lipoic acid residues at this point might be modified by xenobiotics to form immunoreactive adducts. This modification would be then sufficient to trigger the innate immune system to initiate a cascade of local inflammatory events, via Toll-like receptors, for example, thus resulting in local dendritic cell activation and antigen processing. Mucosal antigen-presenting cells (APC) in turn activate autoreactive T and B cells that are directed to the liver through the portal system.

T cells participate directly in the autoimmune injury and/or further recruit autoreactive lymphocytes. B cells, on the other hand, secrete AMA, particularly of the IgA type. These antimitochondrial IgA are then transported to the vascular side of the bile duct cell, where they react with the PDC-E2-like molecules located on the luminal surface cell membrane. This binding then initiates the apoptotic signaling cascade. Ultimately, the immune complexes of post-apoptotic PDC-E2 and IgG-AMA and the direct cytopathic effects of autoreactive T cells (and possibly AMA) contribute to the tissue injury observed in PBC.

IMMUNOLOGIC MARKERS FOR DIAGNOSIS

Antimitochondrial Antibodies

Antimitochondrial antibodies are highly specific for PBC and can be detected in up to 95% of patients, depending on the diagnostic methodology used. In most cases, indirect immunofluorescence techniques are used for initial screening of cases. It should be noted, however, that such methods have a limited sensitivity and, particularly at lower dilutions of sera, low specificity for PBC, with the latter probably responsible for the encountered cases of non-PBC AMA positivity. Commercially available enzyme-linked immunosorbent assays (ELISAs) can also be used to detect AMA, although such assays are less sensitive than immunofluorescence. When AMA are tested with more recently developed techniques, based on the use of recombinant mitochondrial antigens (with immunoblotting), the sensitivity and specificity of the test are significantly higher, approaching 100% (Miyakawa et al., 2001). However, these methods are currently only performed at selected centers and are not readily available to the physician for diagnostic purposes. Accordingly, immunofluorescence continues to be available as the main diagnostic test for use in commercial laboratories.

Antinuclear Antibodies

In a subset of patients with PBC approaching in some cases 50%, autoantibodies are directed at nuclear antigens. Patients who are ANA-positive are more frequently AMA-negative, possibly because of the lack of a masking effect of these latter antibodies in such sera. Antinuclear antibodies are currently tested by immunofluorescence, although commercial ELISA kits for individual antigens are becoming available. Cumulatively, such "nuclear rim" and "nuclear dots" patterns should be considered as highly specific for PBC (Worman and Courvalin, 2003), thus being an important diagnostic tool particularly in AMA-negative patients. Finally, we note that patients with PBC and CREST syndrome (but not overt systemic sclerosis) present anticentromere antibodies (ACA) in 10–15% of cases (Bernstein et al., 1982).

TREATMENT AND OUTCOME

Several medical treatments have been investigated in patients with PBC. Currently, ursodeoxycholic acid (UDCA) is the only accepted therapy and has received US Food and Drug Administration approval.

Ursodeoxycholic Acid

Ursodeoxycholic acid accounts for 4% of the bile acid pool in human bile. Compared with other bile acids, such as chenodeoxycholic and deoxycholic acids, UDCA is more hydrophilic. Its absorption (3–60% following oral dose) occurs mainly in the small intestine, and its presence decreases cholesterol secretion into bile, possibly lowering its conversion to bile acids. Cumulatively, the proposed mechanism of action of UDCA in PBC is based on modification of the bile-acid pool, reduction in pro-inflammatory cytokines, effects on apoptosis and on vasoactive mediators (Lazaridis et al., 2001). However, since UDCA anti-inflammatory effects are found only in bile ducts, it has been assumed that its effect is mediated by the modification of the bile acid pool. Doses of UDCA ranging from 13–20 mg/kg lead to optimum bile enrichment. Long-term survival with UDCA therapy has been noted to be higher than predictions based on mathematical models for PBC and an extensive meta-analysis of published trials indicated that such increased survival is obtained only when an adequate dose (>13 mg/kg) is used (Gluud and Christensen, 2002). A complete biochemical response to UDCA (normalization of serum liver tests in absence of cirrhosis) is achieved in approximately 40% of treated patients (Leuschner et al., 2000).

Other Drugs

Based on success rates observed in other autoimmune diseases, the use of immunosuppressive drugs was attempted in PBC; however, efficacy was poor (Oo and Neuberger, 2004). Corticosteroids, azathioprine, cyclosporine, methotrexate, penicillamine, and colchicine have not been shown to influence the severity or progression of the disease or are associated with serious side effects. Their use should be considered only in combination with UDCA in selected cases (i.e., when features of autoimmune hepatitis overlap with PBC). In the event of an unsatisfactory response to UDCA alone, these drugs are still considered, but the lack of efficacy and the risk of serious side effects makes their use highly debatable. Inconclusive

results from pilot studies or case reports of single or UDCA-combinations of bezafibrate (Itakura et al., 2004), mycophenolate mofetil (Talwalkar et al., 2005), and tamoxifen (Invernizzi et al., 2004a; Reddy et al., 2004) require future long-term studies, possibly not limited to patients unresponsive to UDCA treatment.

Orthotopic Liver Transplantation

Orthotopic liver transplantation is considered the ultimate treatment for end-stage PBC, and PBC is among the most common indications for transplantation worldwide (MacQuillan and Neuberger, 2003). Post-OLT survival rates are 92% and 85% at 1 and 5 years, respectively. A retransplantation is needed in fewer than 10% of patients. Orthotopic liver transplantation appears to be beneficial also with regard to PBC symptoms of fatigue and pruritus, as well as bone loss. The AMA status does not change after OLT, and recurrence of PBC following OLT is found in 25% of patients after 5 years (Liermann Garcia et al., 2001). Interestingly, however, this seems to reproduce a new start of the disease with a long latency between AMA appearance and clinical manifestation of the disease (Balan et al., 1993). Recurrence rates could be influenced by the use of specific immunosuppressive post-OLT regimens. Interestingly, the frequency of OLT for PBC in a large series from the United Kingdom was reported as decreasing over the past decades, alongside an increased age at the time of transplantation (Liermann Garcia et al., 2001). Cumulatively, such data could once again indicate that the natural history of PBC might be influenced by earlier diagnosis or medical treatment. The use of UDCA in transplanted patients is currently considered safe, and no contraindications have been identified so far.

CONCLUDING REMARKS AND FUTURE PROSPECTS

Primary biliary cirrhosis should be considered a unique disease within the range of autoimmunity. Future efforts should be dedicated to overcoming some of these conceptual and logistic difficulties. First, only study of a very large number of representative families will unravel the genetic basis of PBC. Given the relatively rare prevalence of the disease, only a worldwide effort will allow the collection of a population of families large enough (and with two or three generations available) to guarantee enough statistical power for a linkage analysis. Second, the role of xenobiotics and infectious agents in the onset of PBC should be further probed, particularly with respect to the efforts for the development of an animal model and using detailed epidemiologic studies to ascertain the exposure to specific environmental factors. Third, it is crucial to determine the pathogenic role of AMA in the bile duct damage of PBC. Once again, the development of an animal model appears to be the only way to provide a clear demonstration of such pathogenic mechanism. Finally, from a clinical standpoint, new clinical trials are needed to identify novel therapies in the long-term treatment of PBC. Together with the already present trend towards an earlier diagnosis of the disease, a better efficacy of medical treatment, possibly using specific monoclonal antibodies or hematopoietic stem cell transplant, will be the cornerstone to reducing the need for OLT in patients affected by PBC.

Primary Sclerosing Cholangitis

DIEGO VERGANI AND GIORGINA MIELI-VERGANI
Institute of Liver Studies, King's College Hospital, London, UK

Sclerosing cholangitis (SC) is a chronic cholestatic disorder of unknown etiology, characterized by inflammation and progressive obliterative fibrosis of the intrahepatic and/or extrahepatic bile ducts. It progresses slowly and often asymptomatically to biliary cirrhosis, liver failure, and/or cholangiocarcinoma. The latter can occur any time during the course of the disease.

HISTORIC BACKGROUND

Sclerosing cholangitis was first described in 1924 by a Parisian surgeon, P.L.E. Delbet (Delbet, 1924), who reported a patient with "irregular fibrosis and stenosis of the biliary tree." In 1927, R.T.J. Miller referred to a similar condition as a "benign stricture of common bile duct" (Miller, 1927). Until the 1960s, SC remained largely undiagnosed, with only few cases reported in the literature (Delbet, 1924; Lafourcade, 1925; Judd, 1926). In 1964 (Holubitsky and McKenzie, 1964), the condition was called for the first time "primary sclerosing cholangitis" to distinguish it from SC secondary to lesions of the bile ducts or systemic disease like primary or secondary immunodeficiencies. Until the advent of endoscopic retrograde cholangiopancreatography and percutaneous transhepatic cholangiography, recognition was rare, being made at laparotomy in patients with persistent jaundice. With the availability of cholangiography the disease is now recognized in anicteric patients, and its reported prevalence in both adults and children is increasing. The association of SC with ulcerative colitis (UC) was first clearly established in 1966 (Warren et al., 1966), though inflammatory involvement of the liver parenchyma in inflammatory bowel disease (IBD) had been described as early as 1899 by Lister (Lister, 1899).

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Clinical Features

Primary SC has long been considered a disease confined to adulthood, but it is now clear that it occurs in all age groups, with some features being unique to children. In adult primary SC, the majority of patients are male. They are often initially asymptomatic, and identified on the basis of abnormal liver function tests, in particular elevated levels of alkaline phosphatase (AP) and/or γ-glutamyltransferase (GGT). These patients may also have increased levels of immunoglobulins G and M (IgG, IgM) and positive auto-

antibodies. Some patients may present with entirely normal AP (Balasubramaniam, et al., 1988). Further investigations are usually prompted by the persistence of laboratory abnormalities. Cholangiography shows the characteristic changes of SC, i.e., multifocal strictures and dilatations, usually involving both the intrahepatic and extrahepatic bile ducts (Figure 55.1). In early stages, ulcerations of the common bile duct similar to those seen in the colon in early ulcerative colitis may be seen. Some patients, usually with associated IBD, have chronic cholestasis and hepatic histology compatible with primary SC but normal findings on cholangiography. This condition, called "small duct SC" (Wee and Ludwig, 1985), may represent an early stage of classic primary SC and is associated with a significantly better long-term prognosis. Patients with primary SC may have advanced radiologic and histologic disease without overt symptoms. Increase in serum bilirubin with a decrease in serum albumin heralds impending liver failure. The most common symptoms of decompensation are jaundice, fatigue, itching, and weight loss. Fever and acute cholangitis are uncommon, being present in 10–15% of the cases (Kaplan, 1991). Primary SC is a risk factor for the development of colorectal adenocarcinoma that is independent with or without the presence of IBD.

In childhood, idiopathic SC is characterized by florid autoimmune features, including elevated titers of autoantibodies, in particular antinuclear antibodies (ANA) and anti-smooth muscle antibodies (SMA), elevated IgG, and interface hepatitis (Figure 55.2) (Gregorio et al., 2001). Since these features are shared in common with autoimmune hepatitis (AIH), in the absence of cholangiographic studies, many of these children are diagnosed with and treated for AIH, though the diagnosis of SC may become apparent during follow-up. To ascertain the relative prevalence of SC and AIH in childhood, a prospective study was conducted over a period of 16 years, in which all children presenting with liver disease and elevated levels of aspartate aminotransferase (AST) and IgG and positive autoantibodies underwent cholangiography and liver biopsy both at presentation and follow-up (Gregorio et al., 2001). Approximately 50% of the patients had alterations of the bile ducts characteristic of SC at presentation, though less advanced than in adult SC (Figure 55.3), often in the absence of histologic features suggesting bile duct involvement. Fifty-five percent were female. Presentation ranged from symptoms indistinguishable from those of acute hepatitis to a prolonged history of liver dysfunction or the incidental finding of abnormal liver function tests. Inflammatory bowel disease was diagnosed in 44%, but also in 18% of the children with AIH. Cholestatic biochemistry was rare, with most children having normal GGT and AP. A laboratory index significantly different between SC and AIH was an increased AP/AST ratio in SC. Ninety seven percent of the children with SC had ANA and SMA. One child with normal cholangiography at presentation progressed to severe SC 8 years later.

Overlap between primary SC and AIH has been described also in adult patients (Rabinovitz et al., 1992; Lawrence, 1994; Schrumpf and Boberg, 2001), who similarly to children have elevated levels of circulating immunoglobulins and non-organ-specific autoantibodies and interface hepatitis on liver biopsy. In these patients, treatment with corticosteroids may, at least temporarily, induce biochemical and clinical improvement in selected cases. (Boberg et al., 1996).

Figure 55.4 'Onionskin' fibrosis around a damaged bile duct. This is the characteristic lesion of sclerosing cholangitis, but is rarely seen in percutaneous liver biopsies.

Histological Features

Histologically, primary SC has been divided into four stages, though this classification is used more as a research tool than for clinical management (Ludwig et al., 1986). In Stage 1, there is degeneration of the bile duct epithelial cells and infiltration of the bile ducts by mononuclear cells, with occasional neutrophils. The portal tracts may be expanded because of fibrosis and edema, and may show proliferation of bile ducts, vacuolization of ductular epithelial cells, and concentric layers of connective tissue surrounding individual bile ducts (onionskin fibrosis). Stage 2 is characterized by more widespread fibrosis and inflammation, which infiltrates the periportal parenchyma with damage of periportal hepatocytes (interface hepatitis). A prominent feature is bile ductopenia. This becomes more severe in Stage 3, where bile ducts may be absent and porto-portal bridging fibrosis prominent, with cholestasis in periportal and paraseptal hepatocytes. Stage 4 is characterized by frank biliary cirrhosis.

The typical onionskin fibrosis lesion (Figure 55.4) is rarely seen on a percutaneous liver biopsy, where paucity of normal bile ducts with nonspecific portal tract fibrosis and inflammation are the most common findings. In view of the variable and largely nonspecific histologic lesions, the diagnosis of SC rests on cholangiographic imaging.

Epidemiologic Features

Adult primary SC affects mainly patients in their third to fourth decade of life with a male-to-female ratio of 2:1 (Lee and Kaplan, 1995). There is a strong association between primary SC and IBD, particularly ulcerative colitis (Fausa et al., 1991; Olsson, 1991). Patients with primary SC and without IBD are more likely to be female (Rabinovitz, 1990) ranging from 21% in Japan to 82% in Northern Europe (Schrumpf and Boberg, 2001). Of the primary SC patients with IBD, some 85% have UC, and the remainder have Crohn's colitis. Conversely, approximately 4% of patients with IBD will either have or develop primary SC.

An early Norwegian population study showed an incidence of primary SC of 1.3 and a prevalence of 8.5 for 100,000 inhabitants (Boberg et al., 1998). These values were considered higher than for the rest of Europe and the United States. However, a recent report from Minnesota, USA (Bambha et al., 2003), shows an incidence of primary SC in men of 1.25 and in women of 0.54 per 100,000 person-years. The prevalence of primary SC in 2000 was 20.9 per 100,000 men and only 6.3 per 100,000 women.

Little is known of the epidemiology of childhood SC, though genders appear to be equally represented (Gregorio et al., 2001).

AUTOIMMUNE FEATURES

A high proportion of patients with primary SC have circulating autoantibodies, including ANA, SMA, and antineutrophil cytoplasmic antibodies (ANCA) (Cullen and Chapman, 2003). Possibly of pathogenic relevance is the observation that sera from two-thirds of patients with primary SC have circulating autoantibodies against amino acid sequences shared in common by colon and biliary epithelial cells (Mandal et al., 1994). Other autoantibodies described in primary SC include anti-endothelial cell

antibody (35%; Gur et al., 1995), anticardiolipin antibody (4–66%; Angulo et al., 2000), antithyroperoxidase (7–16%; Angulo et al., 2000), antithyroglobulin (4%; Gur et al., 1995), and rheumatoid factor (15%; Angulo et al., 2000). The presence of these autoantibodies in association to abnormalities of the complement system (Senaldi et al., 1989) and elevated circulating immune complexes (Bodenheimer et al., 1983; Minuk et al., 1985) suggest a possible immune pathogenesis in primary SC. This is supported by the early histologic findings of a mononuclear inflammatory infiltrate in the portal tracts—comprising lymphocytes, macrophages, and plasma cells—with interface hepatitis. This histologic picture, particularly evident in the juvenile form of SC, is undistinguishable from that of AIH (Gregorio et al., 2001).

GENETIC FEATURES

The occurrence of primary SC in members of the same family suggests a genetic predisposition (Quigley et al., 1983). Immunogenetic studies have contributed towards the understanding of the influence of the immune system on the development and progression of primary SC. Small, early studies identified significant associations with both HLA B8 and DR3 (Schrumpf et al., 1982; Chapman et al., 1983; Shepherd et al., 1983). Subsequent investigations (Donaldson et al., 1991; Farrant et al., 1992; Mehal et al., 1994; Chapman, 1995; Olerup et al., 1995; Spurkland et al., 1995; Moloney et al., 1998; Bernal et al., 1999; Mitchell et al., 2001b; Norris et al., 2001; Wiencke et al., 2001; Donaldson and Norris, 2002) in different European populations uncovered three potential susceptibility haplotypes: the first being *A1-Cw*0701-B8-MICA*008-TNFA*2-DRB3*0101-DRB1*0301-DQA1*0501-DQB1*0201*, the second *DRB3*0101-DRB1*1301-DQA1*0103-DQB1*0603*, and the third *MICA*008-DRB5*0101-DRB1*1501-DQA1*0102-DQB1*0602*, and three different protective haplotypes, the first encoding *DRB4*0103-DRB1*0401-DQA1*03-DQB1*0302*, the second *DRB4-DRB1*0701-DQA1*0201-DQB1*0303*, and the third the *MICA*002* allele. A key role in conferring susceptibility and resistance appears to be played by specific amino acids at position DQβ-87 and DQβ-55, respectively (Donaldson and Norris, 2002).

A range of non-major histocompatibility complex (MHC) immunoregulatory genes have been studied in relation to primary SC, including cytotoxic lymphocyte antigen-4 (Saarinen et al., 1998; Agarwal et al., 2000), tumor necrosis factor-α (Bernal et al., 1999; Mitchell et al., 2001b), and interleukins 1 and 10 (IL-1 and IL-10) (Donaldson et al., 2000), with controversial results. Since the end result of inflammation in primary SC is periductal fibrosis, the reported association between a polymorphism of *MMP*-3 (stromelysin) (Satsangi et al., 2001), a gene involved in the regulation of the production and destruction of extracellular matrix, and susceptibility to primary SC and its progression is of interest. Susceptibility and resistance to primary SC are likely not to be linked to individual loci, but to the contribution of different alleles according to the model of a "complex genetic disease" (Nepom, 1990).

ENVIRONMENTAL INFLUENCES

A number of environmental factors have been proposed in the pathogenesis of the bile duct injury typical of SC, including chronic portal bacteremia (Brooke et al., 1961), toxic bile acid metabolites produced by the enteric flora (Carey, 1964), toxins produced directly by the enteric bacteria (Palmer, 1972), chronic infections (Finegold and Carpenter, 1982; Fox et al., 1998; Ponsioen et al., 2002), and ischemic vascular damage (Ludwig et al., 1989). The close association between primary SC and UC has led to the hypothesis that the initiating step in primary SC is the access of intestinal bacteria, through an inflamed and leaky bowel wall, to the portal circulation (Boden et al., 1959; Warren et al, 1966). Though one study did demonstrate portal bacteremia in patients with UC after colonic surgery (Brooke et al., 1961), this observation has not been confirmed. The role of toxic bile acid metabolites generated by the gut flora is also uncertain, since no major abnormalities in the composition and concentration of bile acids have been found in the bile and portal blood of patients with either primary SC or chronic IBD (Siegel et al., 1977).

ANIMAL MODELS

Several animal models of SC have been developed, none, however, faithfully mimicking the human condition. They include models involving: 1) bacterial cell-wall components or colitis; 2) biliary epithelial and endothelial cell injury; and 3) toxic intraluminal injury of the biliary tract.

Bacterial Cell Wall Components or Colitis

Bile duct lesions similar to SC have been reproduced in rats with small bowel bacterial overgrowth (Lichtman and Sartor, 1990; 1991; Lichtman et al., 1991a; 1991b; 1991c; Sartor et al., 1996) The disease develops only in susceptible strains of rat, suggesting a crucial influence of the genetic make up. The innate immune response appears to play a major role, with production of IL-12, interferon-γ, macrophage and natural killer cell activation, and secretion of proinflammatory cytokines.

Focal strictures of intrahepatic bile ducts follow intraperitoneal injection of peptidoglycan-polysaccharide prepared

from the cell wall of group A streptococcus in rats (Cromartie et al., 1977).

Pericholangitis and periductular fibrosis can be induced in rabbits by injecting muramyl dipeptide (MDP), a bacterial cell-wall fragment, into the submucosa of the rectum and colon (Kuroe et al., 1996a; 1996b). If MDP is injected with complete Freund's adjuvant the rabbit develops granulomatous colitis (Kuroe et al., 1996a), while if it is injected with long-chain fatty acid the animal develops colitis without granulomas (Kuroe et al., 1996b).

Cholangitis is induced by *N*-formyl L-methionine L-leucine L-tyrosine (fMLT) in rats with colitis. In this model, colitis is induced in rats by intrarectal administration of 15% acetic acid, followed by daily intrarectal infusion of fMLT (Yamada et al., 1994), a pro-inflammatory peptide secreted by *Escherichia coli*, which undergoes enterohepatic circulation and is a strong chemo-attractant for neutrophils and macrophages. The fMLT appears in bile within 3 hours. One day after injection, the portal tracts are infiltrated by macrophages and neutrophils. By day 4, $CD4^+$ and $CD8^+$ T cells are present in the peribiliary infiltrates and are attached to the biliary epithelia (Yamada et al., 1999). Carageenan treatment, which reduces the number of macrophages, also reduces the cholangitic lesions, suggesting that bacterial chemotactic peptides, normally sequestered in the gut, can cause small duct cholangitis if they gain access to the portal circulation through an inflamed colonic mucosa.

Biliary Epithelial and Endothelial Cell Injury

Ueno et al. showed that immunization with highly purified cholangiocytes leads to the development of nonsuppurative cholangitis (Ueno et al., 1996). Immunohistochemical studies revealed that portal tract infiltrates around bile ducts consisted of $CD3^+$ T-lymphocytes, some expressing MHC class II antigen, a sign of activation.

Induction of experimental graft-versus-host disease across minor histocompatibility antigens in the mouse results in a severe involvement of both intrahepatic and extrahepatic bile ducts, with features of nonsuppurative cholangitis (Ueno et al., 1998; Vierling et al., 1989) 2–3 months post-transplantation, which persists long term.

Intra-arterial infusion of floxuridine in dogs or rhesus monkeys causes fibrous inflammation and diffuse focal stricturing of intra- and/or extrahepatic bile ducts (Dikengil et al., 1986). Similarly, infusion of ethanol into the hepatic arteries of rhesus monkeys induces diffuse focal strictures and dilatation of intrahepatic bile ducts, lymphocytic infiltration of the portal tracts, and portal fibrosis (Doppman and Girton, 1984), with cholangiographic features similar to those of human SC. These experiments corroborate the clinical observations in humans that direct injury of the hepatic arterial branches or capillary plexi can trigger mechanisms leading to SC, as seen in periarteritis nodosa of the hepatic artery (Le Thi Huong et al., 1989) or in the bile duct damage after infusion of floxuridine into the hepatic artery (Ludwig et al., 1989).

Hepatobiliary injury has been induced in female Lewis rats by portal vein injection of 2,4,6-trinitrobenzene sulfonic acid (TNBS), a chemical hapten that binds to lysine residues and facilitates immune responses against haptenated proteins. The histopathology is characterized by periportal inflammation and bile ductular proliferation. In addition, ANCA with perinuclear and cytoplasmic staining is observed in 40% of the rats (Orth et al., 1999).

Toxic Intraluminal Injury of the Biliary Tract

In both male Sprague-Dawley rats (Mourelle et al., 1995) and in female Lewis rats (Orth et al., 2000) retrograde instillation of TNBS into the distal biliary tract stimulates inflammatory and immunologic events culminating in portal tract inflammation and fibrosis, cytokine production, diffuse focal stricturing of the intra- and extrahepatic bile ducts, and development of ANCA and SMA reactivities.

Histologic and cholangiographic features suggestive of SC are seen in male Sprague-Dawley rats fed with α-naphthylisothiocyanate (ANIT), a substance toxic to intrahepatic bile ducts (Lichtman et al., 1995; Tjandra et al., 2000). Portal tract inflammatory infiltrate with macrophages and lymphocytes appears by day 4, progression of portal inflammation by day 7, and extensive fibrosis by day 14.

Summary

While no animal model fulfils the attributes of an ideal primary SC model, those induced by bacterial cell-wall components and biliary infusion of the hapten TNBS exhibit several characteristics of primary SC and recapitulate the strong association between primary SC and IBD and the production of pANCA.

PATHOGENIC MECHANISMS

Primary SC is associated with a variety of immunologic changes. Early findings showed that T cells were decreased in the circulation but increased in the portal tract (Whiteside et al., 1985; Lindor et al., 1987; Snook et al., 1989) and that the $CD4^+/CD8^+$ lymphocytes ratio and the B-lymphocytes in the circulation were increased (Lindor, 1997). A sensitization to biliary antigens and enhanced expression of class II antigens on biliary epithelial cells were described (McFarlane et al., 1979; Chapman et al., 1988; Broome et al., 1990). The relevance of these mainly descriptive findings has been questioned. For example, the mere ligation of bile ducts in rats enhances the expression of class II antigens on bile-duct cells (Hu et al., 1996). The strong associ-

ation between primary SC and IBD has led to the hypothesis that the initial insult in primary SC is the reaction of a genetically susceptible host to bacterial cell-wall products entering the portal circulation through a permeable gut wall, either due to colitis or during episodes of intestinal infection (Vierling, 1998). This may lead to activation of Kupffer cells in the liver, with the consequent production of peribiliary cytokines and chemokines that attract inflammatory cells. As a result of this peribiliary inflammatory process, concentric fibrosis around the bile ducts would ensue, with consequent ischemia and atrophy of the biliary epithelial cells. Bile duct loss would then lead to progressive cholestasis, and eventually to biliary cirrhosis. Primary SC, however, exists also in the absence of IBD, may present several years before IBD or after colectomy, and colectomy does not alter the course of the disease (Cangemi et al., 1989; Fausa et al., 1991).

An interesting recent hypothesis, supported by some experimental evidence, proposes a role for an enterohepatic circulation of lymphocytes, whereby intestinal lymphocytes produced in the gut mucosa during active inflammation recirculate as memory cells through the liver (Grant et al., 2002). Activated intestinal lymphocytes express $\alpha 4\beta 7$, a gut-specific homing receptor that binds its coreceptor mucosal addressin cell adhesion molecule-1 (MAdCAM-1), which is gut specific. The liver endothelial cells in primary SC express aberrantly MAdCAM-1, providing a docking station for lymphocytes originating from the gut. Thus, it would not be the microorganism or product thereof that triggered the immune-mediated liver inflammation of primary SC, but memory T cells activated in the gut and capable of microbe/self cross-reactivity. This process would initiate in the colon, since primary SC is associated with UC and Crohn's colitis. The long life of memory T cells would explain why the disease may occur a long time after colectomy and why colectomy does not affect the course of primary SC. This hypothesis is attractive, but does not explain why primary SC can exist without IBD, though subclinical intestinal inflammation may be sufficient to trigger the process.

IMMUNOLOGIC MARKERS IN DIAGNOSIS

Patients with primary SC often have elevated levels of IgG and IgM and circulating autoantibodies, in particular ANA, SMA, and ANCA. The relevance of these autoantibodies in the diagnosis of primary SC is a matter of debate. The presence of ANA has been described in 7–77% (Wiesner and LaRusso, 1980; Chapman 1986; Zauli et al., 1987; Klein et al., 1991; Gur et al., 1995; Angulo and Lindor, 1999), SMA in 13–20% (Wiesner and LaRusso, 1980; Chapman et al., 1986; Klein et al., 1991), and ANCA in up to 88% (Cullen and Chapman, 2003) of the patients. In the juvenile form of autoimmune SC, 97% of the patients are positive for ANA and/or SMA (Gregorio et al., 2001). The variability of the reported prevalences is almost certainly due to the lack of standardization in autoantibody detection. It would be advisable to apply to primary SC the same guidelines used in the diagnosis of AIH, where ANA and SMA are considered positive at a titer of more than 1:40 in adults (>1 : 20 in children) when tested on frozen composite sections of rodent liver, kidney, and stomach (Johnson and McFarlane, 1993; Alvarez et al., 1999).

Antineutrophil cytoplasmic antibodies are a fairly consistent feature of primary SC, but are also detected in a high proportion of patients with other autoimmune diseases, in particular UC (Frenzer et al., 1998) and type 1 AIH (Targan et al., 1995; Zauli et al., 1997). The ANCA associated with primary SC and AIH type 1 are distinct from cytoplasmic ANCA (c-ANCA) and classical perinuclear ANCA (pANCA) (Terjung and Worman, 2000), which are diagnostic seromarkers for Wegener granulomatosis and microscopic polyangitis, respectively. Primary SC, UC, and AIH are associated with "atypical pANCA," which have a distinct staining pattern on indirect immunofluorescence microscopy (Terjung et al., 2001). Recent evidence indicates that the target of "atypical pANCA" is located within the nuclear membrane, and for this reason it has been proposed to rename it perinuclear antineutrophil nuclear antibody (p-ANNA) (Terjung et al., 2000).

TREATMENT AND OUTCOME

Several choleretic, immunosuppressive, and antifibrotic agents have been used to treat adult primary SC, but no drug has been shown to alter its natural history. Ursodeoxycholic acid (UDCA) is a hydrophilic bile acid that stabilizes liver cell membranes exposed to toxic concentrations of the naturally occurring chenodeoxycholic acid. A prospective randomized double-blind placebo-controlled trial in adult patients with primary SC showed an improvement in laboratory tests in patients receiving 13–15 mg/kg/day UDCA, but this was not accompanied by long-term beneficial changes (Lindor, 1997). It has been suggested (Mitchell et al., 2001a), and some evidence provided (Harnois et al., 2001), that higher doses of UDCA (25–30 mg/kg/day) can be of benefit.

Despite anecdotal reports of improvement with glucocorticoids and azathioprine in adult patients with primary SC (Myers et al., 1970; Javett, 1971), their use is controversial. Other drugs that have not been found effective include penicillamine, methotrexate, colchicine, cyclosporine, cholestyramine, nicotine, and pentoxifylline. Tacrolimus was reported to improve liver function tests in a small pilot study, which, however, was uncontrolled, of short

duration, and lacked histologic and cholangiographic data (Van Thiel et al., 1995).

In the juvenile form of SC, which has strong autoimmune features, treatment with steroids and azathioprine akin to that used in AIH, has been reported to be beneficial in abating the parenchymal inflammatory lesion, but to be less effective in controlling the bile-duct disease (Gregorio et al., 2001). The positive response to immunosuppression observed in these young patients contrasts with the disappointing results reported in adult primary SC, possibly because the latter present with a much more advanced disease.

The median reported survival in adult patients with primary SC is 10–12 years from diagnosis (Wiesner et al., 1989; Farrant et al., 1991). The disease runs a progressive course, and most asymptomatic patients eventually develop symptoms of chronic cholestasis and biliary cirrhosis (Porayko et al., 1990). Older age, high serum bilirubin and AST, low albumin, hepatosplenomegaly, variceal bleeding, presence of IBD, and advanced histologic stage are independent predictors of a poor prognosis (Angulo and Lindor, 1999).

For patients with advanced SC, liver transplantation is the only effective therapeutic option, and, for optimal results, it should be offered when the disease is not too advanced. Current 3-year survival rates are 85–90%. Interestingly, patients transplanted for SC have a significantly higher rate of developing non-anastomotic biliary strictures after surgery (Sheng et al., 1993; Feller et al., 1996). This, together with the frequent finding of histologic features consistent with SC in post-transplant biopsies (Harrison et al., 1994; Narumi et al., 1995), has suggested that the disease can recur in the graft, though diagnosis of recurrence is made difficult by other post-transplant complications that can affect the bile ducts. A definition for recurrent SC has been proposed by the Mayo Clinic (Graziadei et al., 1999) and includes: 1) diagnosis of SC before transplant; 2) cholangiographic features of SC less than 90 days after surgery or histology showing fibrous cholangitis and/or fibro-obliterative lesions with or without ductopenia, biliary fibrosis, or biliary cirrhosis; 3) exclusion of hepatic artery thrombosis, chronic ductopenic rejection, anastomotic stricture, non-anastomotic stricture less than 90 days from surgery, donor/recipient ABO incompatibility. Using this definition, SC recurrence has been reported in 20% of transplanted patients (Graziadei et al., 1999). In general, recurrent SC does not appear to have a major negative impact on medium-term patient or graft survival. The activity of IBD after transplantation is variable, but has been reported to be more severe, especially in units where steroid immunosuppression is withdrawn early (Papatheodoridis et al., 1998; Gow and Chapman et al., 2000). Colorectal cancer affects 5–7% of patients with primary SC after liver transplantation, in particular those with a long history of ulcerative colitis and pan-colitis (Loftus et al., 1998; MacLean et al., 2003; Vera et al., 2003). To prevent this life-threatening complication, annual surveillance and colectomy in selected high-risk patients with longstanding severe colitis have been advocated (Loftus et al., 1998; Gow PJ, Chapman, 2000; Vera et al., 2003).

CONCLUDING REMARKS— FUTURE PROSPECTS

There is a large body of evidence suggesting that primary SC is an immune-mediated disease. Yet, the consensus among physicians is that adult primary SC does not respond to immunosuppressive treatment. It can be argued that the juvenile form of SC, characterized by unambiguous serologic and histologic features of autoimmunity, and responsive to immunosuppression, represents the early stage of adult primary SC. In contrast to juvenile SC, adult primary SC has an insidious onset, being often completely asymptomatic, and could represent a late "burnt out" stage of the same condition, too advanced to respond to treatment. The discrepancy in sex distribution between juvenile SC, which is slightly more common in females, and adult primary SC, which has a male preponderance, could be due to the fact that the disease is more progressive in males. A plausible alternative is that the course of the disease, more aggressive and symptomatic in young females frequently diagnosed as having AIH, is favorably modified by early immunosuppressive treatment.

Both SC and AIH could lie within the spectrum of the same disease process. Future studies should determine how frequently AIH evolves to SC and what is the ultimate outcome of juvenile SC treated with immunosuppression. The composition of the mononuclear cell infiltrate should be analyzed in both AIH and SC, and the possible intestinal origin of the liver-infiltrating lymphocytes investigated. In view of the strong association of SC with UC, a condition deemed to have a T-helper 2 profile (Bouma and Strober, 2003), the T-helper profile of adult primary SC, juvenile SC, and AIH should be determined. Moreover, regulatory T cells that are key to preventing manifestations of autoimmunity should be analyzed, also in view of an early report indicating that $CD4^+CD25^+$ regulatory T-cells are decreased in both juvenile SC and AIH (Longhi et al., 2004).
