THE AUTOIMMUNE DISEASES, FOURTH EDITION
ISBN-13: 978-0-12-595961-2
ISBN-10: 0-12-595961-3

Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

ISBN-13: 978-0-12-595961-2
ISBN-10: 0-12-595961-3

IAN R. MACKAY†

†Department of Biochemistry and Molecular Biology, Monash University, Clayton, Victoria, Australia

With this, the 21st year since the first edition of The Autoimmune Diseases in 1985, we turn to some historical reflections. The term "immunity" as used in Roman times had a legal sense (*immunitas*, exemption from duty), but came into common parlance to describe the observation that people recovering from certain infectious diseases became resistant to those diseases. Immunity was given biologic sense by Pasteur in the late 19th century to describe the protection conferred by the use of vaccines, a term Pasteur coined in deference to Jenner. Immunity took on a more precise meaning in 1891 when Behring and Kitasato showed that this protection depended upon the serum. Serologic science developed hand-in-hand with bacteriology, and Metchnikoff and Ehrlich promulgated their alternative views, cellular versus humoral, on the provision of immunity against infection. Indeed, even then, around the year 1900, views were current on the possibility (or impossibility) of autoimmunity, followed by a long period of neglect and eventual reawakening 50 years later, as recounted by Silverstein in Chapter 1. During this eclipse the science of immunology itself, and its associated pathologies in the form of hypersensitivity, anaphylaxis, and allergy, flourished and spread rapidly and far afield from Europe. For example, The American Association of Immunologists was established in 1913 largely to promote the use of vaccines, as recounted in the first presidential address by Gerald B. Webb. The Journal of Immunology began publication in 1916, edited by Arthur F. Coca, a pioneer in allergy. Immunology had its "second coming" after the 1950s with the beginning of a clearer recognition of the cellular basis of immune responsiveness, and the complex inner workings of the immune system, in both health and disease, became even more evident.

This brief prospectus to introduce our fourth edition cannot claim to demystify contemporary immunology, but rather seeks to annotate a few of the landmarks in the transition from immunity as a mechanism of protection to autoimmune disease, the pathologic consequence of an autoimmune response.

I. AN IMMUNOLOGIC ROADMAP

The same immune system that guards the body against infection can also cause autoimmune disease. Whether directed against self-antigens or foreign antigens, the immune system follows the same rules of the road, once natural immune tolerance has failed. Our growing knowledge of the intricate highways and byways of the immune response helps us to understand the seamless transition from protection to pathogenic autoimmunity.

The present vertebrate immune system represents a melding of two evolutionarily distinct systems. The earliest immune response descends from the major defense mechanisms passed down from our invertebrate ancestors. It was adopted and modified in vertebrates to form the natural or innate immune response. This response depends upon broad patterns of recognition of noxious agents and can be set into motion with little delay. Since the patterns that prompt the innate immune system appear mainly on invading microorganisms we would not expect this innate immune response to react against self-antigens. Yet, naturally occurring autoantibodies and their precursor cells are a component of the innate immune system, and indeed in some circumstances have beneficial functions, including the "sanitary" disposal of waste and debris accruing from cell turnover. Although the origin of natural autoantibodies is still uncertain, they provide a measure of initial protection against infection because of their broad cross-reactivity. But might they represent the precursors of later, injurious autoimmune responses? The evidence is not in.

Most of the cells of the adaptive immune system are recycled by vertebrates from the earlier innate immune system. The distinctive components of the adaptive immune

system include thymus-derived T lymphocytes and bone marrow-derived B lymphocytes, the major histocompatibility complex (MHC), and the antigen-processing and antigen-presentation systems. Over many millennia, these elements have been further adapted by evolutionary modification to include cell–cell collaboration, secretion of cytokines for cell-to-cell signaling, chemokines to control cell trafficking, and cellular adaptations for provision of immunologic memory. The adaptive immune system recognizes specific antigens through precisely structured receptors on lymphocytes generated by a unique system of genetic recombination and reassortment. The more focused and potent immune response of adaptive immunity requires the generation of a galaxy of different antigen receptors, each tailored for optimal affinity of reactivity with a specific antigen. Inevitably many of these receptors on B cells and T cells will react with constituents of the host, albeit in most cases at lower affinity.

The mounting of an efficient immune response involves cooperation of the two immune systems; the ancient innate system and the more recent adaptive system. To achieve this goal, three major cell populations must participate; antigen-presenting cells (APCs) that take up, prepare and present antigen, and T cells and B cells that alone have the ability to recognize specific antigenic determinants (epitopes). Cells capable of serving as APCs come in many guises; the prototypic APC is the dendritic cell (DC), but macrophages are also capable as well as B cells, which, in their role as APCs, can strongly promote the persistence of autoimmunity. Lymphocytes of either T or B lineage can exist functionally as naïve, activated (antigen-experienced and antigen-reactive) or memory cells, a distinction of relevance to autoimmunity.

Repeated stimulation of the adaptive immune system raises the possibility of infinite expansion of constituent T and B lymphocytes. This outcome is obviously untenable and indicative of the requirement that the immune system be carefully regulated by processes that restore homeostasis among the constituent cell populations. Immune responses to invading pathogens typically continue for only a limited period of time because the antigen driving them is eliminated; thus, immunity wanes unless refreshed or restimulated. Processes intrinsic to the immune system itself also regulate the immune response. In fact, the failure of any of the intrinsic control mechanisms could lead to unchecked lymphoproliferation with dire consequences, including autoimmunity and malignancy. Metaphorically, the immune domicile requires efficient housekeeping to ensure that it is neither underpopulated with consequent immunodeficiency (and possible responses to self-proteins developed to "fill the gap"), nor overpopulated with insufficient flexibility for new responses. Finally, in the process of winding down after an antigenic encounter, there is a crucial need for a lasting imprint in the form of immunologic memory to provide for a prompt response on the next encounter. This anamnestic response can produce great benefits (witness the medical triumph of wide-scale vaccination) but has the potential for great harm if, somehow, a nascent autoimmune response cannot be snuffed out before memory cells develop.

Although immunity proceeds as a continuum we can, for discussion purposes, consider four distinct stages: initiation, maintenance, termination, and memory, as shown schematically in Figure 1.

The immune response begins when a particulate antigen is ingested by a macrophage and degraded so that peptide fragments can be presented at the cell surface in conjunction with molecules of the MHC to CD4-bearing lymphocytes expressing the appropriate antigen receptor. DCs, which are richly present at mucosal surfaces as well as in other tissue sites, stand ready to endocytose, prepare, and present soluble antigen, as described in Chapter 4. If the antigen engages a toll-like receptor (TLR) on the DC, it transduces an activation signal that stimulates production of facilitating cytokines by the DC. Upregulation of MHC further enhances the capacity for presentation of antigen.

The activated DC migrates to a regional lymph node or to the splenic white pulp. There the DC may encounter a naïve or memory T cell with the corresponding receptor. This event sets into motion the formation of germinal centers to serve as factories for production of additional antigen-specific lymphocytes and sites that maximize the chance of an encounter between antigen-reactive T and B cells with the APCs, as described in Chapter 2.

Germinal center formation is a critical step in the development of a robust immune response. The reaction depends upon a subset of $CD4^+$ T cells, follicular homing T cells (Tfh), which are chemotactically attracted to the germinal center. These T cells, in turn, direct naïve B cells that have received an antigenic signal (called signal 1) to respond to this second T-helper signal (signal 2) by proliferation and affinity maturation of their immunoglobulin-like antigen receptor. Second signals involve costimulatory molecules on the participating APC and T cells such as CD80/86 and CD28, and between participating T and B cells, such as CD40 and CD154 (CD40L). Affinity maturation of B cells occurs in germinal centers by the process of somatic hypermutation among genes that encode the B-cell receptor.

The immune response naturally terminates after the elimination of the provocative antigenic stimulus following removal of antigen, assisted by the regulatory processes intrinsic to the immune system mentioned above. These include expression of the molecule CD152 (CTLA-4) by activated T cells which, when engaged by CD80/86 (B7-1/2) on APCs, transduces a negative signal to the T cell. Other downregulatory events include activation-induced cell death (AICD), production of particular cytokines such as trans-

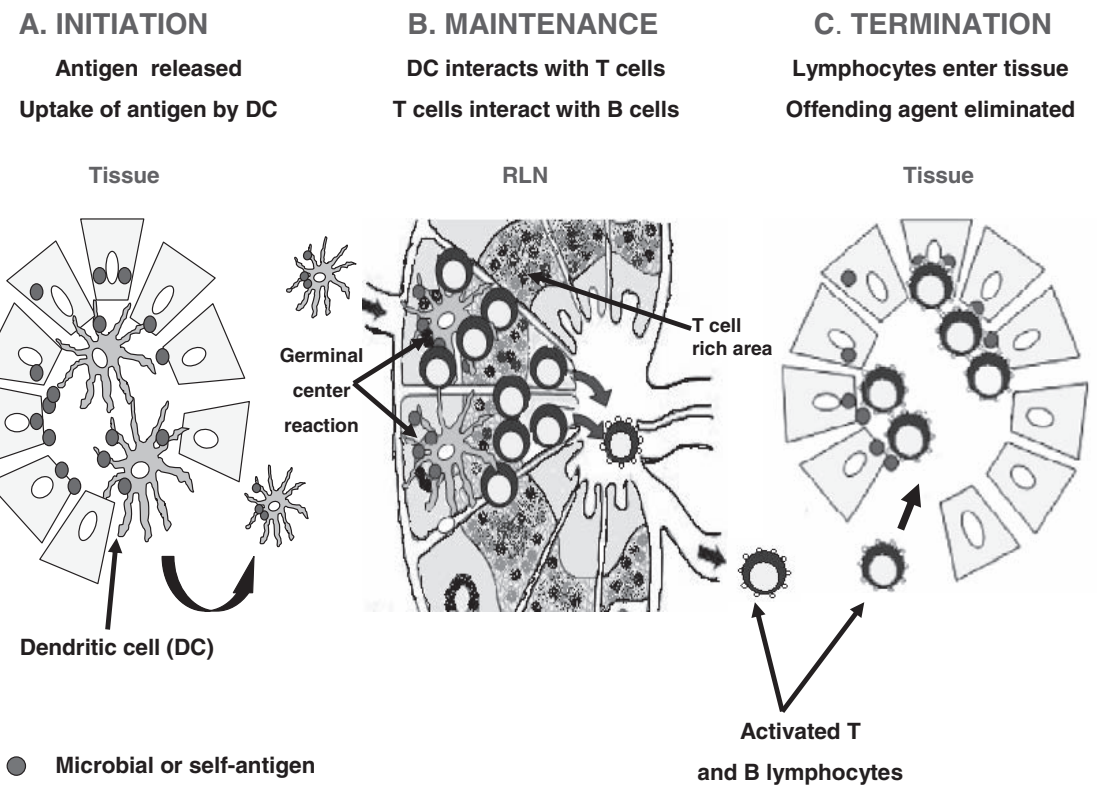

FIGURE 1 *A, Initiation*. The immune response begins with uptake of microbial antigens and self-antigens from degraded tissue by dendritic cells (DCs) that undergo maturation and migrate to regional lymph nodes (RLNs). *B, Maintenance*. The DC enters the primary follicle of the lymph node and may meet a cognate $CD4^+$ T cell, whereupon the germinal center (GC) reaction develops. T-cell proliferation and activation provide helper signals for $CD8^+$ T and B cells. Activated cells exit the RLN. *C, Termination*. Activated lymphocytes specific for microbial antigens enter the infected tissue, eliminate the offending agent, and the immune response winds down. But, if the incoming lymphocytes are specific for self-antigens, and tolerance is weak, self-sustaining autoimmunity ensues. Not shown are the accompanying development of immunologic memory, the costimulator cytokine- and chemokine-dependent events that are essential to the above processes, and the variety of processes that operate in the termination phase.

Reproduced from Seminars in Liver Disease (2005), with permission of Dr Paul Berk, Columbia University, New York, NY, and Thieme Medical Publishers, Norwalk, CT.

forming growth factor (TGF)-β, and the mobilization of suppressive types of regulatory T cells, as described in Chapter 9.

Memory confers major advantages on the adaptive immune system by providing a more efficient and effective response on second encounter with a particular pathogen. Yet, the basis of immunologic memory is still not fully understood, as discussed in Chapters 6 and 12. It was first studied in relation to B-cell function, being discernible after antigen challenge by conversion of a delayed low-titer primary response to an early higher-titer secondary response. Later the memory B cell was characterized by the conversion of variable regions of the immunoglobulin gene from a germline to a mutated sequence. Memory T cells express antigen-specific receptors with higher affinity for the peptide–MHC complex and have a particular phenotype that confers the capacity for ready egress from the lymphatic circulation, as described in Chapter 18.

The immune system is endowed with a wide range of effector elements designed to combat infections. These same agents come into action in unison in autoimmune reactions. They include soluble antibody, which in combination with complement, can effect target-cell destruction. $CD4^+$ T cells secrete a variety of cytokines, some of which can be cytotoxic, including lymphotoxin (LT) and tumor necrosis factor (TNF)-α. $CD8^+$ T cells may themselves be directly cytotoxic to target cells that express the requisite peptide–MHC complex on their surface. In addition, both $CD4^+$ and $CD8^+$ T cells may produce cytokines that activate phagocytic cells. Any of these mechanisms can be called upon under certain circumstances depending largely upon the accessibility and vulnerability of a particular antigenic target.

II. IMMUNE TOLERANCE

With an immune system poised to respond to a nearly infinite number of antigens, specialized regulatory devices are required to minimize the harmful effects that may occur as the result of the concomitant autoimmunity that would seem inevitable, given the similarities in constituents of mammalian and microbial cells. These processes involve tolerance to self-antigens in both the T- and B-cell compartments, as described in Chapters 8, 9, and 13. For convenience, as much as logic, these mechanisms are generally grouped as central or peripheral.

Central tolerance develops during the generation of the immune repertoire in primary lymphoid tissues. It requires specific deletions of nascent lymphocytes that undergo high-affinity interaction with their cognate antigen. In the thymus, developing lymphocytes encounter stromal cells that can express a self-antigen associated with an appropriate MHC molecule. If the affinity of the interaction is sufficiently high, the nascent lymphocyte experiences a lethal signal and undergoes apoptosis. This purging tilts the T-cell repertoire strongly away from self-reactivity. The process is, however, necessarily imperfect, because the repertoire of "self" is so large and complex that complete purging of the antiself repertoire might well leave almost no remaining specificities to react with nonself. Accordingly, it would appear inevitable that the developing lymphoid system must make compromise decisions concerning survival versus death based on affinity, where clones with sufficiently low affinity for self are allowed to survive. The threshold for these decisions has presumably been made over evolutionary timespans to give a reasonable compromise between threats from outside the body versus the threat to the body posed by autoreactivity.

In addition, it is conceivable that such an affinity-based selection system in primary lymphoid organs could occasionally fail and let a high-affinity antiself clone escape to the periphery, perhaps because of a failure to encounter the relevant self-antigen while developing. Efficient thymic deletion of self-reactivity requires that the greatest possible array of autoantigens be available in the thymus for presentation by specialized cells in the thymus to antigen receptors of developing T cells. Sources of self-antigens might include constituents of the blood that pass through the thymus, as well as antigens of the thymus tissue itself, along with cell debris that may happen upon the scene.

General self-tolerance also requires that self-antigens of tissue-specific character be presented in the thymus. A number of years ago, one of us (IRM) suggested that the thymus contains representatives of various other peripheral self-components that would initiate natural self-tolerance: in other words, the thymus might serve as an "immunologic homunculus." Recently, the concept of broad intrathymic representation of peripheral cells has been substantiated by an intriguing discovery in the clinic. It emanated from a disease of children, autoimmune polyendocrine syndrome type 1 (APS1) or, alternatively, autoimmune polyendocrinopathy-candidiasis-ectodermal dysplasia (APECED). This disease follows recessive inheritance of a mutated dysfunctional autoimmune regulator (*AIRE*) gene. The encoded AIRE protein, an E3 ubiquitin ligase, determines the intrathymic expression by thymic stromal cells of a wide variety of tissue-specific autoantigens, although exactly how this occurs has still to be worked out. In mice, homozygous disruption of *aire* by gene knock-out results in multiple and diverse autoimmune expressions depending upon the strain of mice. These features sometimes simulate APS1, as described in Chapter 38. Thus, intrathymic deletion of autoimmune T cells, based on ectopically expressed peripheral autoantigens, is an important mechanism for establishing tolerance to self. We now note that AIRE-based thymic deletion likely occurs in the periphery as well as in the thymus.

Central tolerance of B cells probably occurs by mechanisms of clonal deletion similar to those for T cells, although the details are less well known. Deletion, moreover, is accompanied by a process of receptor editing, such that engagement of an antigen receptor on the developing B cell by an autoantigen induces a signal to the immunoglobulin recombinase genes to express an alternative receptor molecule. Receptor editing operates in both the bone marrow and the periphery, and has been described in T cells as well as B cells.

The existence of self-reactive T and B cells in the periphery shows that central tolerance is indeed incomplete. Cells that escape central tolerance are controlled by multiple mechanisms. First, self-reactive "naïve" cells are kept in ignorance of their autoantigen by the absence of appropriate localization signals. In the case of T cells, they remain confined to the lymphatic circulation and lymphoid tissues. Second, self-reactive T or B cells do not receive the signals needed to ensure their survival, namely the necessary helper or costimulatory signals (signal 2) and so undergo anergy and eventually apoptosis. This could apply particularly to those B cells that are highly dependent on T-cell help. Third, there are mechanisms for tolerance that involve active suppression by regulatory cells. Quite a number of cells can provide downregulatory signals, including different types of T cells, and also APCs, as described in Chapter 9.

III. AUTOIMMUNITY: A FAILURE OF SELF TOLERANCE

As explained above, self-reactive T and B cells often avoid central deletion and take up residence in peripheral sites. The development of autoimmunity, therefore, presents a constant albeit generally low-grade hazard. DCs take up

self and foreign antigens alike, but foreign antigens such as microbial constituents are much more likely to engage a TLR and so transduce a vigorous activation signal. In previous publications, one of us (NRR) referred to the contribution to a self-antigen of a microbial product as the "adjuvant effect," recalling the significant role that complete Freund adjuvant plays in inducing experimental autoimmune disease. Spillage of autoantigens, during tissue damage or apoptopic cell death, should not normally activate a DC by a TLR and therefore should be less likely to engender a vigorous and therefore pathogenic autoimmune response. Yet, the diversity of molecules capable of binding a TLR or similar receptors is ever widening. There is no doubt that harmless autoantibodies frequently arise and may even help to mop up cellular debris. Perhaps endocytosis of autoantigens by DCs that are activated by an inflammatory stimulus does result in efficient presentation. In any event, activated DCs loaded with autoantigen can migrate in their usual pattern to the regional lymph nodes where they may encounter recirculating self-reactive T cells and B cells. Fortunately, such cells are greatly outnumbered in the recirculating pool by foreign-reactive cells.

Yet, when all is said and done, the occurrence of autoimmunity is a relatively common event. It is signified by the presence of broadly reactive T cells and of autoreactive antibodies of low affinity, often of the IgM class. Switching to high-affinity IgGs depends upon the active cooperation of B cells with corresponding T cells that have escaped mechanisms of self-tolerance. DCs, depending upon their state of activation, may provide stimulatory or suppressive signals. T cells themselves are constrained by the requirement for appropriate costimulatory signals. Furthermore, they must overcome the effects of suppressive regulatory T cells or other suppressive cells. A number of years ago, one of us (NRR) coined the term "clonal balance" to emphasize that an autoimmune response usually depends upon a subtle shift in the equilibrium between positive and negative factors, rather than the emergence of a somatically mutated "forbidden clone" as proposed in earlier days. However, we concede the possible emergence of harmful self-reactive clones as a result of somatic mutations in genes for antigen receptors or genes controlling thresholds for activation or apoptosis.

Unlike responses to foreign antigens, autoimmune diseases are concerned with antigens that have a continuing presence in the body. Therefore, termination of an autoimmune response due to the disappearance or masking of antigen is unlikely. Intrinsic downregulatory signals provide for AICD, which normally limits immune responses. Since AICD depends upon T-cell apoptosis, a defect in the apoptotic cascade can prevent AICD, prolong lymphocyte multiplication, induce lymphoproliferative disease, and enhance autoimmune responses, as described in Chapters 69 and 70. Cytokines generated during the immune response, like TGF-β (which inhibits T-cell activation) or interleukin (IL)-10 (which deviates the immune response toward Th2) also avert harmful, progressive self-responses. Since they are more easily stimulated than naïve cells, and are more resistant to ablative therapies, memory T cells are ranked highly among the components of unwanted autoimmunity that are targets of potential therapies.

IV. AUTOIMMUNE DISEASES

An autoimmune disease can be defined as a disease in which autoimmunity plays a directly causative or a significantly contributory role. It depends upon the induction and mobilization of immune effector mechanisms with the capability of injuring host cells. The effector mechanisms are the same as those associated with conventional immune responses to invading pathogens, including soluble antibody, $CD4^+$ T cells, $CD8^+$ T cells, macrophages, and other phagocytic cells and mast cells. Antibody can induce injury by binding directly to a cellular antigen and activating complement, by blocking or stimulating a receptor or by producing damaging immune complexes. The receptors for the Fc piece of antibody can variously modulate the course of immune and autoimmune responses, as described in Chapter 16. In organ-localized pathologies, $CD4^+$ and $CD8^+$ T cells are most often implicated because antibody would seem to be unable to reach the intracellular antigen in sufficient quantities. Frequently, however, it is difficult to sort out the relative roles of antibody- and cell-mediated damage in human autoimmune conditions. It should be remembered that B cells not only produce antibody but serve very effectively as antigen-capturing cells and APCs, particularly for activated/memory T cells, and thereby help to perpetuate the injurious autoimmune process.

A recurring problem, and one that confronted the Editors from the outset, was the definition of an autoimmune disease and the criteria for inclusion as such in this text. Unfortunately, since no set of criteria has succeeded in covering all the contingencies, we have simply adopted a listing of characteristics preparatory to a Bayesian type of solution when all the necessary data are in, as shown in Table 1.

The occurrence of autoimmune disease is associated with a confluence of genetic predisposition and environmental exposure combined with a large portion of chance. Mechanisms that could result in chance events include environmental influences, somatic mutations, and random receptor mutations. The importance of heredity in autoimmune disease is abundantly clear from human studies wherein familial aggregations of autoimmune diseases have been long recognized, and comparisons of genetically identical with nonidentical twins show increased frequencies in the former. In animals, the evidence is more direct and telling. Not only can animals be inbred so that they spontaneously

TABLE 1 Defining criteria for autoimmune diseases*

Level of evidence	Comments, caveats†
Level 1: Direct evidence	
1. Transfer of disease with autoreactive serum	
a. Person to person	
Experimentally	Autoimmune thrombocytopenic purpura is the classic example (42)
Naturally, transplacental transfer	Thyrotoxicosis (35), myasthenia gravis (48), congenital heart block (71), and others
b. Transfer with human antisera to animals	Pemphigus vulgaris (57), myasthenia gravis (48)
2. Autoantibody (aab) binding in vitro	Autoimmune hemolytic anemia (41)
3. Transfer of disease with autoreactive lymphocytes	Inadvertent transfer with bone marrow transplant (type 1 diabetes)
Level 2: Indirect evidence	
1. Animal model replicating human counterpart	
a. Spontaneous (genetic basis)	NOD mouse, NZB mouse, BB-W rat, OS chicken, and others (26)
b. Experimentally induced	
Immunization with culprit antigen	Experimental autoimmune encephalomyelitis, thyroiditis, orchitis, etc; adjuvants usually required (26)
Neonatal thymectomy	Gastritis, BALB/c mouse, illustrative of peripheral tolerance (39)
Genetic manipulation, transgenics, knock-outs	Numerous examples (26)
c. T-cell transfer of disease in animals	Type 1 diabetes in NOD mice (36), collagen-induced arthritis in mice
Level 3: Circumstantial evidence	
1. Other causes excluded, particularly chronic infection	Infection and autoimmunity may coexist!
2. Marker autoantibody (aab) to high titer	The basic pointer, but sometimes aab specificity "incongruent" with site of disease, e.g. primary biliary cirrhosis (54)
3. Female bias (25)	Some exceptions, e.g. type 1 diabetes, myocarditis
4. Disease clustering, within an individual or among family members, clinical and/or serologic	A long recognized feature (21)
5. Histopathology: lymphoid aggregates, germinal centers	Seen in some chronic infections as well
6. Responsiveness to immunosuppression	Characteristic feature—a diagnostic therapeutic! (76)
7. T-cell reactivity in vitro to putative autoantigen	Assays remain difficult (73)
8. MHC (HLA) associations	Usually class II, HLA-D (5 and 20)

*Modified from Rose, N. R. and Bona, C. (1993). Defining criteria for autoimmune diseases (Witebsky's postulates revisited). *Immunol. Today 14,* 426–430.

†Chapters citing relevant data are given in parentheses.

develop autoimmune disease, but more and more susceptibility genes are being identified and their functions defined. The dominant contributors to autoimmune diseases are susceptibility alleles at the MHC class II locus, as described in Chapters 5 and 20. It is generally believed, although it has never been clearly established, that the role of MHC class II depends on the presentation to T cells of a critical self-peptide. But does this involve hyperefficient presentation, which in the thymus would enforce the deletion of "rogue" T cells (or in the periphery favor their reactivity), or hypoefficient presentation with just the reverse effects? There remains much to be understood. Numerous other genes have more recently been implicated in affecting the susceptibility to autoimmune disease, as described in Chapter 21, including the *AIRE* genes and apoptosis genes, such as Fas and FasL. Often these turn out to be genes engaged in the regulation of the immune response, such as alleles at the CD152 (CTLA-4) locus, or allelic forms of genes or their promoters encoding cytokines involved in immune responses. And not to be overlooked are nonimmune genes of which the product is prejudicial to the integrity of the target tissue.

Despite the established role of genetic predisposition in virtually all autoimmune diseases, its total effect seems at first sight to be relatively minor, since rarely is more than a third of the risk of a human autoimmune disease attributable to inheritance. But this may change as knowledge of the genome increases. Alternatively, a major portion of remaining risk should be contributed by the environment, as described in Chapters 22 and 23. The most likely suspects include infectious organisms, although a direct connection has been firmly established only in a very few instances, such as some cases of Guillain–Barré syndrome or rheumatic fever, as described in Chapters 47 and 62. A virus that keeps popping up as a suspect without ever a direct conviction is the Epstein–Barr herpes type virus, of interest because this is lymphomagenic as well. Perhaps the best examples of environmental chemical causation can be found among the medicinal drugs that can induce signs and symptoms similar to classical autoimmune disease. Procainamide

and hydralazine are two drugs that can induce a "lupus-like" response with all the serologic concomitants, and their causative role can be substantiated by withdrawal of the drug inducing full remission, and by the autoimmune state recurring in an accelerated manner with rechallenge.

Finally, we must return to the role of chance in the development of autoimmune disease. Identical twins, after all, do not have identical immune systems because of the stochastic mechanisms integral to generating the diversity of the immune response. This randomness must certainly account for some measure of the nonconcordance of identical twins. Experimentalists are constantly reminded that even genetically identical mice immunized in exactly the same way show great variability in their responses. There are also strong suggestions that autoimmune diseases evolve in stepwise fashion, and that preclinical autoimmunity may lie dormant for long periods. Perhaps further environmental triggers and/or chance variations determine progression to symptomatic disease. We are reminded here of precancerous lesions that are on the way to, but may never reach, overt disease.

V. INTO THE FUTURE

Autoimmune diseases can affect virtually any site in the body and, accordingly, their clinical presentation varies widely. Therefore, each disease is usually considered separately. Only recently have the actual dimensions of the autoimmune disease problem become evident. Estimates suggest that 5–8% of people in developed countries (based on data from the USA) suffer from an autoimmune disease. To illustrate the breadth and depth of the autoimmune disease problem, in our first edition in 1985, we included some 25–30 disease entities, whereas in this fourth edition, 20 years later, there are over 60 well-credentialled examples. Moreover, for some, the population prevalence is notably high, e.g. rheumatoid arthritis, autoimmune thyroid disorders, and Sjögren syndrome; and the population morbidity is, for some others, extreme, particularly systemic lupus erythematosus, type 1 diabetes, and multiple sclerosis. Thus, we assert that in developed, and increasingly in developing countries too, autoimmune disease ranks well up with the major global health concerns of cancer, cardiovascular disease, chronic pulmonary disease, diarrhea, and obesity-related disorders. It is evident that autoimmune diseases are a substantial and increasing public health issue. In the past it may have been reasonable to approach each disease individually, but the magnitude of the autoimmune disease problem prompts us to emphasize the urgent need to look at the autoimmune diseases collectively. After all, many fundamental pathogenetic mechanisms link all of the autoimmune diseases and research on all will be strengthened if the common features are explored. Sometimes a new treatment of one autoimmune disease may be beneficial for another (although we do recognize, given the diversity of the immune response, a treatment benefiting one disease may be inert or even detrimental for another). Shared genetic traits dictate that individuals with one autoimmune disease are at risk of developing a second or even a third one, and that multiple autoimmune diseases may cluster in certain families. A deeper understanding of these fundamental principles will benefit all of the autoimmune diseases.

In Greek mythology, Aesculepius, the god of medicine, had two daughters, Panacea the goddess of cures and Hygeia the goddess of prevention. As we approach patients with autoimmune diseases in this millennium, we invoke blessings of both goddesses. Successful treatments will come from our better understanding of the mechanisms regulating the immune response and will undoubtedly encompass both antigen-specific and immunomodulatory approaches. Given our ultimate goal of prevention, we will garner our growing knowledge about genetic predisposition and early biomarkers to identify individuals and populations at inordinate risk. The diabetes community is showing the way in this respect, as described in Chapters 74 and 75. Separating the vulnerable person from the external, environmental trigger has already proved to be a highly successful strategy in celiac disease, as described in Chapter 51. But even for an established disease, there is growing optimism over the prospects for new biologic remedies, as described in Chapter 76. We may soon reach a point at which therapists can effectively arrest or even cure established autoimmune disease before there is full understanding of its cause. Early intervention may restore immunologic homeostasis and correct immunologic imbalance before disease produces irreversible destruction: this is a goal truly worthy of the effort.

Reviewers

The Publisher and Editors are indebted to the following individuals for their very helpful reviews of chapters in this book.

Gordon Ada Division of Immunology and of Cell Biology, John Curtin School of Medical Research, The Australian National University, Canberra City, New South Wales, Australia

Elaine Alexander Experimental and Clinical Research, Arena Pharmaceuticals, Inc., San Diego, California, USA

Mark Anderson Diabetes Center, University of California/San Francisco, San Francisco, California, USA

Acknowledgments

The editors are pleased to acknowledge the outstanding editorial assistance of Ms. Hermine Bongers. Ian R. Mackay would also like to thank Professor Christina Mitchell, Head of the Department of Biochemistry and Molecular Biology at Monash University Melbourne, for generous provision of facilities, Dr. Merrill Rowley and Professor Ban-Hock Toh for stimulating laboratory interactions and collegiality, and also Ms. Elaine Pearson for skilled secretarial assistance.

The editors are most appreciative of the sustained assistance and advice in the preparation of this book from Ms. Margaret MacDonald, Ms. Victoria Lebedeva, Mr. Stephen Packwood at the publishing office of Elsevier, London and Ms. Nora Naughton at Naughton Project Management.

The editors also thank their wives for their extraordinary patience.

Noel R. Rose

CHAPTER

1

Autoimmunity: A History of the Early Struggle for Recognition

ARTHUR M. SILVERSTEIN

Institute of the History of Medicine, Johns Hopkins Medical School, Baltimore, Maryland, USA

> ". . . 1955–1965 [was] the decade marked by the question, Does autoimmunity exist?"
>
> (Rose and Mackay, 1985)

It is one of the curious situations in science that certain well-demonstrated facts are refused entry into the body of accepted knowledge, and may become so effaced from the collective memory that they must be rediscovered many years later in order to gain acceptance. Such was the case in immunology with Donath and Landsteiner's (1904) discovery that paroxysmal cold hemoglobinuria is an autoimmune disease, or with Clemens von Pirquet's (1910) explanation of immune complex disease. Sometimes the cause of this selective amnesia is merely an earlier pronouncement by a respected leader in the field; sometimes it lies in an inability to fit the new finding into the working paradigm that guides thought in the field, as the historian of science Thomas Kuhn (1970) has suggested. In the end, it may be that Ludwik Fleck (1979) was right when he proposed that acceptance of a fact in science depends less upon its truth than upon its acknowledgment by the leaders in the discipline (whom Fleck called the *Denkkollektiv*). However, the truth in science ultimately emerges, although sometimes it takes a very long time.

The earliest discoveries in immunology were made in the context of the battle to ward off infectious diseases. These included Louis Pasteur's (1880) preventive vaccines, Ilya Metchnikoff's (1884) bacteria-eating phagocytes, and Behring and Kitasato's (1890) curative antidiphtheria and antitetanus sera. It seemed evident that these efficient mechanisms for the protection of the body were Darwinian adaptations designed to prevent or control infectious disease: a widespread view in the 1890s even after it was demonstrated that specific antibodies might be formed against such innocuous antigens as egg albumin, bovine serum proteins, and sheep red cells. It seemed unthinkable at the time that mechanisms designed to prevent disease might turn the tables and cause disease. So well established did this concept of a benign immune system become that demonstrations that antibodies might cause disease were either disregarded entirely, or else ascribed to "aberrant" antibodies acting under the influence of a "misdirected" immunity (Silverstein, 1989). This was how the early discoveries of serum sickness, hay fever, asthma, and a variety of immunopathologic phenomena were treated by mainstream immunology during the first half of the 20th century.

It is beyond the scope of this chapter to discuss the entire history of the unwillingness to accept that the immune response might lead to a variety of harmful outcomes (which we now describe under the rubric "immunopathology"). We shall limit the present discussion to the way that a subset of the whole, autoimmune diseases, was regarded (or rather disregarded) during the first half of the 20th century. This sample should provide an adequate representation of the way that early immunologists dealt with the paradox presented by the almost oxymoronic word *immunopathology*.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

THE SEARCH FOR AUTOANTIBODIES

Horror Autotoxicus

A new mechanism that functions to mediate immunity was discovered by Richard Pfeiffer (1894)—the destruction of bacteria by humoral antibodies. Jules Bordet (1899) showed that not only were bacteria lysed by thermostable antibody and a thermolabile substance that he called *alexine* (later termed *Komplement* by Paul Ehrlich), but that mammalian erythrocytes could be hemolysed specifically by the same two agents. Here was a technique that would see broad application in many areas of immunology (Silverstein, 1994), not least in connection with the question of whether the individual could form antibodies against his/her own self.

Two consequences of Bordet's report were immediately apparent. Karl Landsteiner (1900) became interested in red cells and discovered blood groups in humans (for which he received the Nobel Prize in 1930). Then Paul Ehrlich and Julius Morgenroth launched a series of studies of immune hemolysis in order to develop additional support for Ehrlich's side-chain theory of how antibodies are produced and how they function (Ehrlich, 1897; 1900). It is Ehrlich's interpretation of his hemolysis experiments that would play a major role in the early history of autoimmunity. These hemolysis experiments are described and analyzed in detail by Silverstein (2002).

During the course of these experiments, Ehrlich and Morgenroth immunized many different species with the red cells of other species. They also immunized animals with the red cells of other members of their own species, and even tried to immunize animals with their own red cells. In every case, they were able to demonstrate the production of xenohemolysins and isohemolysins, but autohemolysins were never observed. This led inexorably and logically to the conclusion that animals could not make autotoxic antibodies to any self-antigens, a postulate that Ehrlich named *horror autotoxicus*. Indeed, he would conclude that, "It would be dysteleological in the highest degree, if under these circumstances self-poisons of the parenchyma—autotoxins—were formed" (Ehrlich, 1902).

But Ehrlich was not the only one who responded to Bordet's publication on immune hemolysis. If red cells could stimulate an immune response, why not other tissues and organs? In no time, attempts were undertaken to immunize animals with all types of cells and tissue extracts, especially at the Pasteur Institute in Paris, where Bordet had worked. As expected, cytotoxic xenoantibodies against a variety of tissues were reported; indeed, volume 14 of the *Annales de l'Institut Pasteur* was largely devoted to these studies, including a review of antitissue antibodies by Metchnikoff (1900). Most surprising was the report by Metalnikoff (1900) that some animals were able to form antibodies against their own spermatozoa. But while these autoantibodies could destroy the sperm *in vitro*, they seemed to have no effect *in vivo* on the viable sperm in the immunized animal.

Ehrlich was not impressed. He commented that these are not "autocytotoxins within our meaning," since they do not cause disease (Ehrlich and Morgenroth, 1901). Here was the true meaning of *horror autotoxicus*: not that autoantibodies cannot be formed, but that they are prevented "by certain contrivances" from exerting any destructive action (Goltz, 1980). Due in part to Ehrlich's worldwide prestige and to the fact that an autoantibody seemed so obviously counterintuitive, *horror autotoxicus* found broad acceptance as a guiding principle. Indeed, so firm was the conviction that autoimmune disease was impossible that everyone soon forgot Ehrlich's suggestion that an autoantibody might exist without causing disease. It would be some 80 years before the important distinction would be made between autoimmunity and autoimmune disease (Rose and Mackay, 1985).

Nature of Ehrlich's "Contrivances"

Paul Ehrlich was nothing if not logical. He proposed one of his typical thought-experiments to examine the possible outcomes (Ehrlich and Morgenroth, 1900). Suppose the existence of a self-antigen α. Then, since antibody formation results from the interaction of antigen with preformed cell receptors according to the side-chain theory (the first selection theory), two possibilities are seen:

1. The host possesses no anti-α cell receptors. Therefore, no autoantibody response and thus no disease can occur. (Here is, in embryo, Burnet's later clonal deletion idea.)
2. The host does possess anti-α cell receptors on its cells. Therefore, autoanti-α is formed. But the host also possesses the self-antigen α on its cells, with which the anti-α may react to stimulate the formation of anti-anti-α. (Remember, Ehrlich knew nothing about lymphocytes, and conceived that all cells possess receptors and may form antibodies.) But the specific site on the anti-antibody should be identical with that on the original antigen, since they both should react specifically with the antibody combining site. Thus, Ehrlich proposed that a self-regulating equilibrium would be established between autoantibody and antigen (= anti-antibody) to suppress the development of autoimmune disease. [Here was a regulatory network theory 70 years before Niels Jerne's (1974) idiotype–anti-idiotype theory.]

CHALLENGES TO THE THESIS

Lens Autoantibodies

The initial flurry of interest in antitissue antibodies quickly subsided as the implications of *horror autotoxicus*

gained broad acceptance. But in 1903, Paul Uhlenhuth (1903) demonstrated the existence of organ-specific antigens by showing that the proteins of the lens are unique to that tissue; they are found nowhere else in the body. Moreover, these antigens are shared by the lenses of different species. Ophthalmologists seized upon this finding to suggest that an immune response to an individual's own lens might be responsible for the development of senile cataract (Römer, 1905). They showed further that an intraocular inflammation may be induced by the experimental rupture of the lens in the eye of a lens-immunized animal (Krusius, 1910).

Here were observations that would fascinate both ophthalmic clinicians and a later generation of immunopathologists interested in the possible workings of autoimmune disease. First, there was this early preview of what would later be called the "sequestered antigen" concept. Since "self"-antigens by definition cannot elicit an immune response, then such antigens as do must be "foreign," that is, isolated from the immunologic apparatus of the host, like sperm and lens. Secondly, Römer and Gebb (1912) concluded that if indeed disease does result from the formation of autoantibodies, this would represent a most unusual occurrence and must be considered as an aberration due to a malfunction of Ehrlich's "contrivances." Here they showed that, unlike a future generation, they understood Ehrlich's "law of immunity research" completely.

Interest in the possibility that autoimmunity to lens might lead to disease did not disappear in the years that followed. But whereas the initial studies had been done in the context of the new immunology and were known to all workers in the field, further work was restricted to ophthalmologists and eye departments. Thus a broad clinical study led Verhoeff and Lemoine (1922) to identify numerous cases of lens-induced inflammatory disease, to which they gave the name *phacoanaphylaxis*. Thenceforth, the description would appear routinely in textbooks of ophthalmic pathology, and clinical diagnoses would be made.

Paroxysmal Cold Hemoglobinuria

Fast on the heels of the lens antigen demonstration came an even more convincing case involving erythrocyte antigens. Paroxysmal cold hemoglobinuria (PKH) was a rare disease presenting with signs of intravascular red cell lysis and a resulting hemoglobinuria, following exposure of the patient to the cold. Donath and Landsteiner (1904; 1906) published reports that reproduced *in vitro* all features of the disease. They demonstrated beyond question that it was due to a peculiar autoantibody in the patient's serum that affixes to his/her own red cells only in the cold, and mediates hemolysis with complement when the sensitized cells are rewarmed.

It was clear from the outset that Landsteiner understood fully the implications of this discovery and its meaning for Ehrlich's *horror autotoxicus*. Indeed, even Ehrlich's student Hans Sachs (1909) gave a somewhat grudging acceptance of the phenomenon and its interpretation. But again, the implication seemed to be that this was an unusual exception to the regular scheme, and the implications of PKH as the prototypical autoimmune disease soon almost vanished.

Sympathetic Ophthalmia

It had always seemed odd to clinicians that after traumatic injury to one eye, the second eye might spontaneously develop a blinding inflammatory disease, even years later. Soon after the discovery of cytotoxic antibodies, the proposal was advanced that sympathetic ophthalmia might be caused by the formation of "autocytotoxins" (Santucci, 1906). This concept was picked up and given broad currency by one of the foremost ophthalmologists of the day, Elschnig (1910a; 1910b) of Prague. As with autoimmunity to lens, work on the immunology of sympathetic ophthalmia continued, but in ophthalmology departments. Woods (1921; 1933) reported the presence of antiuveal antibodies in patients with perforating injuries of the globe, and uveal pigment was implicated as the causative antigen (Woods, 1925; Friedenwald, 1934).

The Wassermann Antibody

The discovery of the role of complement in immune hemolysis was soon followed by the finding that *any* antigen–antibody interaction would fix complement nonspecifically (Bordet and Gengou, 1901). The ability to measure this uptake using a hemolytic assay meant that antibody could be titered if specific antigen were available. With the recent identification of *Treponema pallidum* as the cause of syphilis, a serologic test for this disease was sought. But since the organism could not be grown in culture, von Wassermann et al. (1906) and, independently, Detré (1906) used extracts of tissues from syphilitic patients as the antigen, and a valuable diagnostic test was born.

Most perplexing, however, was the report from many laboratories that positive tests for syphilis might be obtained also using extracts of normal tissues as antigen. This ran counter to the prevailing view that only *specific* antigen can interact with antibody to fix complement. It appeared necessary, therefore, to conclude that the "Wassermann antigen," being native, must be measuring an autoantibody rather than an antitreponemal antibody. This suggestion was made by Weil and Braun (1909) who speculated that the Wassermann antibody is an autoantibody specific for the tissue breakdown products generated in the syphilitic lesions. They suggested further that these autoantibodies exacerbate the disease, and that the brain lesions in tertiary

syphilis (paresis) may represent an autoimmune disease directed against neural antigens. (A century later, the antigen involved in the Wassermann reaction has been identified as a lipid, named cardiolipin, but why these antibodies are formed is still a mystery as is their role in the disease process.)

THE SHIFT TO IMMUNOCHEMISTRY

Despite all these hints that autoimmune diseases might exist, interest in the question waned in mainstream immunology—indeed almost disappeared—for some 40 years, from just before the First World War to the mid to late 1950s. This was due in part to the continuing sway of Ehrlich's *horror autotoxicus*. But there was another factor at play: the change in the overall direction of the field of immunology.

During the quarter century prior to the First World War, immunology had been concerned chiefly with medical problems, and was pursued almost exclusively by physicians. It had achieved notable successes in the prevention of infectious diseases (vaccine development), their cure (serotherapy), and their diagnosis (serology). It had even begun to define several immunogenic diseases (anaphylaxis, serum sickness, hay fever, and asthma). But most of the easy problems had been solved, and further successes in these areas became disappointingly rare. Vaccines were sought, generally unsuccessfully, for the remaining great scourges of mankind: syphilis, tuberculosis, typhus, and the many serious tropical diseases. Few diseases were caused by exotoxins like diphtheria and tetanus, and thus new serotherapeutic approaches were rare. Yet other forces were at work. The Wassermann test and its offshoots became so widespread for the diagnosis of disease that it moved from the immunologic research laboratory to the clinic. A new discipline, serology, arose and soon became independent of the mother discipline, immunology. In the same way, experimental anaphylaxis and its human disease relations, hay fever and asthma, stimulated the interest of clinicians, who soon took over work in this field and called their new discipline "allergy."

When in a science one research direction reaches the point of severely diminishing returns, its practitioners will usually move to more productive pursuits. So it was with immunology, beginning shortly after the end of the First World War. Karl Landsteiner (1962) started working with haptens, and soon devoted himself almost entirely to a chemically-oriented study of the structural basis of immunologic specificity and cross-reactions. Then, Michael Heidelberger (Heidelberger and Avery, 1923) studied the immunochemistry of pneumococcal polysaccharides and introduced a variety of quantitative methods for the estimation of antigens and antibodies, best typified by the popular text written by his students, *Quantitative Immunochemistry* (Kabat and Mayer, 1949). For more than three decades, the field was devoted largely to studies of structure, specificity, and the thermodynamics of antigen–antibody interactions. The texts and monographs were primarily chemically oriented, and the practitioners were either chemically trained or at least chemically oriented. Even the theories of antibody formation that guided the field, Breinl and Haurowitz's (1930) and Pauling's (1940) antigen-instruction concept, were chemical (i.e., nonbiologic and non-Darwinian) in spirit. It was easy to assume that a protein might be synthesized according to external instruction; for the chemist, molecules have no evolutionary history.

Given the continuing influence of Ehrlich's dictum, and the generally nonmedical orientation of the most prominent immunologic investigators, it is not surprising that autoantibodies and autoimmune diseases were not among the most popular topics in the research laboratory. This is not to say, however, that there was no work along these lines. As we have seen, ophthalmologists reported findings in lens-induced disease and in sympathetic ophthalmia, but these were published in specialty ophthalmic journals. In the early 1930s, Rivers et al. published a series of papers on the production of an experimental autoimmune encephalomyelitis (EAE) (Rivers et al., 1933; Rivers and Schwentker, 1935). While these studies are viewed today as important milestones in autoimmunity research, they attracted little attention at the time among immunologists.

The contemporary view of autoimmunity during the 1940s and early 1950s is perhaps best exemplified by the position of Ernest Witebsky, who was trained in immunology by Ehrlich's student Hans Sachs and was himself a disease-oriented physician. He could say as late as 1954 at the celebration of the centenary of the birth of Ehrlich that, "The validity of the law [sic] of *horror autotoxicus* certainly should be evident to anyone interested in blood transfusion and blood disease. Autoantibodies—namely, antibodies directed against receptors of the same individual—are not formed" (Witebsky 1954). This was said by the individual who, only 2 years later with his student Noel Rose, would help refocus interest on autoimmunity with the demonstration of the production of experimental autoimmune thyroiditis (Rose and Witebsky, 1956; Witebsky et al., 1957).

THE RETURN OF IMMUNOBIOLOGY

During the late 1930s and 1940s, a series of observations began to challenge the assumptions that had guided recent thought and experiment in immunology. How could the enhanced booster antibody response, or the change with time of the specificity and affinity of the antibodies formed,

be explained in chemical terms? How to explain the persistence of antibody formation in the apparent absence of antigen? Even more troubling was the lack of relationship between immunity to certain viral diseases and the titer of antiviral antibodies. Here were basic biologic questions that demanded answers—questions with which current theory was unable to cope, and for which it could not even provide experimental approaches. But even more difficult questions arising from biology and medicine would pose further challenges.

Peter Medawar's (1945) experiments showed that the rejection of tissue grafts was somehow mediated by immunologic mechanisms. Then, Ray Owen (1945) described the paradoxical situation in which dizygotic twin cattle might share one another's red cells without being able to mount an immune response to these foreign antigens. Macfarlane Burnet, biologist *par excellence*, called attention to all of these inexplicable phenomena and hypothesized the existence of a fundamental biologic mechanism to explain Owen's finding—an embryonic interaction that would suppress the ability of an individual to respond to his/her own native antigens (Burnet and Fenner, 1949). This was soon confirmed by Medawar's group (Billingham et al., 1953), and would be termed *immunologic tolerance*. Yet another observation to emphasize the awakening biomedical movement in immunology was the description of a group of immune deficiency diseases.

Taken together, these new questions and phenomena foretokened a radical change of direction—termed elsewhere the "immunobiologic revolution" (Silverstein, 1991). Not only did these questions challenge the accepted dogma but they also served to stimulate the entry of a new group of investigators into the field. These were basic scientists from such fields as genetics and physiology, and clinicians from a variety of medical disciplines. They were unfettered by any allegiance to earlier ideas and techniques, and thus could entertain iconoclastic ideas and design novel experiments.

Perhaps the best illustration of the long period during which immunologists showed little interest in disease is provided in Table 1.1. Here, for each organ or disease entity, the interval is given between the last significant study during the "classical" period and the first significant contribution of the "modern" era. The average hiatus, where both end and restart dates can be identified, is about 44 years. This is an extremely long interlude for a field that was only some 70 years old in 1950.

Thus, in the context of a growing interest in the more biomedical aspects of the immune response, work on autoimmunity became respectable. This was due also to the increasing use of Freund adjuvant, which made animal models of the various autoimmune diseases more readily available and more reproducible. Advances came rapidly.

TABLE 1.1 Dark ages of autoimmunity*

Disease/system	Last "classical" contribution	First "modern" contribution
Hemolytic disease	1909	1945 (Coombs et al.)
Sperm and testicular	1900	1951 (Voisin et al.)
Encephalomyelitis	1905	1947 (Kabat et al.)
Sympathetic ophthalmia	1912	1949 (Collins)
Phacoanaphylaxis	1911	1957 (Halbert et al.)
Thyroid	1910	1956 (Rose and Witebsky; Roitt et al.)
Wassermann antibody	1909	—
Platelet disease	—	1949 (Acroyd)

*Modified from Silverstein (1989).

Coombs et al. (1945), using the antiglobulin test, showed that many cases of acquired hemolytic anemia were due to the "incomplete" (nonagglutinating) antibodies, Kabat et al. (1947) refocused attention on the immunopathogenesis of "allergic" encephalomyelitis. Collins (1949) introduced a reproducible animal model of sympathetic ophthalmia. Voisin et al. (1951) showed how to produce an experimental allergic orchitis. Finally, Rose and Witebsky (1956) demonstrated in experimental animals and Roitt et al. (1956) in human Hashimoto's disease that some forms of thyroid disease might be based on autoimmune processes. In addition, an understanding of the pathogenesis of some of these diseases was made easier by the increasing appreciation of the fact that not all these diseases were mediated by circulating antibodies; some involved the action of subclasses of lymphocytes that originate in the thymus.

These new findings not only opened wide the floodgates of autoimmunity studies, but stimulated further interest in the more general field of immunopathology as well. This new movement was provided with a theoretical base with Talmage's (1957) suggestion and Burnet's (1959) clonal selection theory, emphasizing for the first time the biologically important role of cell dynamics in the antibody response. It is no accident that the late 1950s saw the first international conferences on immunopathology (Miescher and Vorlaender, 1958; Grabar and Miescher, 1959) and on the fundamentals of hypersensitivity (Lawrence, 1959; Shaffer et al., 1959). For the first time, in 1963, there appeared a textbook aimed at medical students (Humphrey and White, 1963), and then two comprehensive descriptions of immunologic diseases aimed at clinicians (Gell and Coombs, 1963; Samter et al., 1965). It was in the spirit of the new immunology that Mackay and Burnet (1963) could summarize contemporary knowledge in the increasingly active field of the autoimmune diseases.

CONCLUDING REMARKS

This, then, is the story of the early stirrings of interest in the possibility that disease might result from an immune response to an individual's own autochthonous antigens. Perhaps the initial reports were too premature to be incorporated into the received wisdom of the young field of immunology, just as the discovery of several allergic diseases could not at first be integrated. Certainly Paul Ehrlich's dictum of *horror autotoxicus* contributed to an unwillingness to recognize the full significance of the initial findings of a response to spermatozoa, erythrocytes, and retina. But the mounting challenges to the dogma would eventually prove irresistible and the field of autoimmunity would finally flourish, as the following chapters in this volume attest.

CHAPTER

2

Structural and Functional Aspects of the Innate and Adaptive Systems of Immunity

PETER J. DELVES

Department of Immunology and Molecular Pathology, Division of Infection and Immunity, University College London, London, UK

Most cells of the immune system are derived from self-renewing hematopoietic stem cells initially generated in the embryonic yolk sac, later in the fetal liver and spleen, and then by the time of birth onwards in the bone marrow. The stem cells give rise to both the lymphoid lineage, which produces lymphocytes, natural killer (NK) cells, and some types of interdigitating dendritic cells (IDCs), and to the myeloid lineage which generates polymorphonuclear leukocytes (neutrophils, eosinophils, and basophils), mast cells, monocytes and macrophages, megakaryocytes, erythrocytes, and IDCs. Development of the lymphoid and myeloid precursors is regulated by stromal cells (such as fibroblasts, endothelial cells, and macrophages) and by growth factors including stem cell factor and colony-stimulating factors.

The immune system can mount innate responses that occur to the same extent however many times the pathogen is encountered, and adaptive (acquired) responses that generate immunologic memory leading to quantitatively and qualitatively enhanced responses on subsequent encounters with the antigen. Innate responses exhibit broad specificity based on detection of pathogen-associated molecular patterns (PAMPs) by pattern-recognition receptors (PRRs) (Janeway, 1989), and the binding of complement- and/or antibody-coated antigens. Among the PRRs that have been described are a number of Toll-like receptors (TLRs), which recognize microbial components, such as lipopolysaccharide from gram-negative bacteria (TLR4), peptidoglycan (TLR2), and the CpG motifs (unmethylated cytosine–guanosine dinucleotide sequence flanked by two 5′ purines and two 3′ pyrimidines) (TLR9). Other PRRs include the mannose receptor, which binds to terminal mannose and fucose, and scavenger receptors that bind a variety of microbial components. Only the lymphocytes, the dedicated cells of the adaptive response, bear receptors permitting exquisitely refined recognition of individual antigens. Each lymphocyte possesses many thousand antigen receptors which all have identical specificity. While the B-cell receptor (BCR) recognizes structures (epitopes) on the surface of native antigen, the epitopes recognized by the T-cell receptor (TCR) are short peptides. The peptides are produced by proteolytic processing of antigen within cells and are then presented to T cells by highly polymorphic major histocompatibility complex (MHC) class I and class II cell-surface molecules. The human class I comprises HLA-A, -B, and -C, and the class II comprises HLA-DP, -DQ, and -DR, whereas mice bear the H2-D, -K, and -L class I molecules, and I-A and I-E class II molecules. MHC class II expression is restricted to IDCs, macrophages, and B lymphocytes, which present 8–30 amino acid long peptides to the TCR on helper T (Th) cells. In contrast, MHC class I molecules, which present peptides of only 8–9 amino acids in length, are expressed by nearly all nucleated cells in the body and are concerned with alerting cytotoxic T lymphocytes (CTL) to the presence of intracellular infections.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

INNATE RESPONSES

Cellular Components

Cells of the innate immune response are generally either phagocytic (neutrophils, monocytes, and macrophages) or act by releasing inflammatory mediators (basophils, mast cells, eosinophils). NK cells, also a component of innate responses, induce apoptosis in infected cells.

The immediate consequence of encounter with an antigen that is deemed to pose a threat is often the generation of an acute inflammatory response in which cells and molecules of the immune system are rapidly recruited to the site of the stimulus. Inflammatory mediators, such as gram-negative bacterial endotoxin [lipopolysaccharide (LPS)], and the cytokines interleukin (IL)-1β and tumor necrosis factor (TNF)-α lead to increased expression of vascular endothelial adhesion molecules, including P-selectin, E-selectin, and intercellular adhesion molecule (ICAM)-1. These alert inflammatory cells to the presence of a local infection. P- and E-selectin bind to P-selectin glycoprotein ligand (PSGL)-1 and ICAM-1 binds to the β_2 integrin CR3 on neutrophils (Ley, 2002). Initially the neutrophils are slowed down and roll along the blood vessel wall, eventually being brought to a halt by adhesion molecule interactions. The neutrophils undergo extravasation—squeezing between the endothelial cells—a process greatly facilitated by the deformable nature of the multilobed nucleus in these polymorphonuclear leukocytes. Histamine released from mast cells causes smooth muscle contraction and an increase in local vascular permeability, thus facilitating the passage of the neutrophil from the blood to the tissues. Activation of the complement system plays a central role in this process, triggering the mast cell degranulation and chemotactically attracting neutrophils. Chemokines (chemotactic cytokines) also induce the neutrophils to migrate to the site of the infection (Rot and von Adrian, 2004). The presence on the neutrophil cell surface of both Fc receptors for antibodies and complement receptors greatly facilitates phagocytosis if the antigen is opsonized (coated) with these agents (Underhill and Ozinsky, 2002). Engulfed microorganisms are killed by a plethora of toxic molecules, including superoxide anions, hydroxyl radicals, hypochlorous acid, nitric oxide, proteases, antimicrobial cationic proteins and peptides, and lysozyme.

Eosinophils are less phagocytic than neutrophils, but can kill large parasites by releasing cationic proteins and reactive oxygen metabolites. They also secrete leukotrienes, prostaglandins, and several cytokines (Wardlaw et al., 1995). Blood basophils and tissue mast cells are not phagocytic and share many features, although mast cells are probably not derived from basophils. Both cell types become sensitized with IgE antibodies bound to their high-affinity Fcε receptors (FcεRI) and, when antigen cross-links the IgE, release several preformed inflammatory mediators, including histamine, platelet-activating factor, neutrophil and eosinophil chemotactic factors, and TNF-α (Frossi et al., 2004). Newly synthesized leukotrienes, prostaglandins, and thromboxanes are also released. Two populations of mast cells have been described, those in the skin which contain both tryptase and chymase (MC_{TC}) and those in the lung and intestinal mucosa which do not contain chymase (MC_T) (Frossi et al., 2004). A number of immunoregulatory roles have been proposed for mast cells (Frossi et al., 2004), including the possibility that histamine release may regulate T- and B-cell responses via signaling through H1 and H2 receptors (Jutel et al., 2001).

The tissue macrophages and their circulating precursors, the blood monocytes, possess both Fc receptors and complement receptors, and they contain similar microbicidal substances to those present in neutrophils. However, they are not only much longer lived than neutrophils but are also able to process antigens for presentation to Th cells. An additional role of the macrophage is the removal of the body's own dead or dying cells. While tissue damage associated with necrotic cell death triggers inflammation, cells dying due to apoptosis are removed much more quietly. Loss of membrane symmetry is a feature of apoptotic cell death and exposes the molecule phosphatidylserine on the cell surface, marking the cell for phagocytosis by macrophages expressing phosphatidylserine receptors (Henson et al., 2001).

NK cells express sets of killer-activating receptors and -inhibitory receptors (Figure 2.1). The activating receptors, which can either possess immunoglobulin-like domains or be lectin-like, bind molecules ubiquitously expressed on the surface of nucleated cells, while the inhibitory receptors, which can also be either immunoglobulin- or lectin-like, recognize MHC class I molecules, which are also usually present on nucleated cells (Yokoyama et al., 2004). Loss of surface MHC class I expression can, however, occur in certain viral infections (e.g., herpesvirus) or sometimes as a result of malignant transformation. Any cell lacking MHC class I is therefore viewed by the immune system as being abnormal and signals from the NK-activating receptors are not blocked by the inhibitory receptors. Activation of NK cells leads to insertion of the pore-forming molecule perforin into the target cell membrane and subsequent injection of granzymes (serine proteases), which cause apoptosis in the target cell.

The IDCs, a heterogeneous population including the Langerhans cell in the skin, are bone marrow-derived cells that act at the interface of the innate and adaptive responses in that their recognition of antigen involves broadly-specific PRR, but their role is to present the antigen to the highly specific TCR on Th cells (Guermonprez et al., 2002) (Figure 2.2). IDCs constantly but quietly sample extracellular antigens by endocytosis and become activated to an

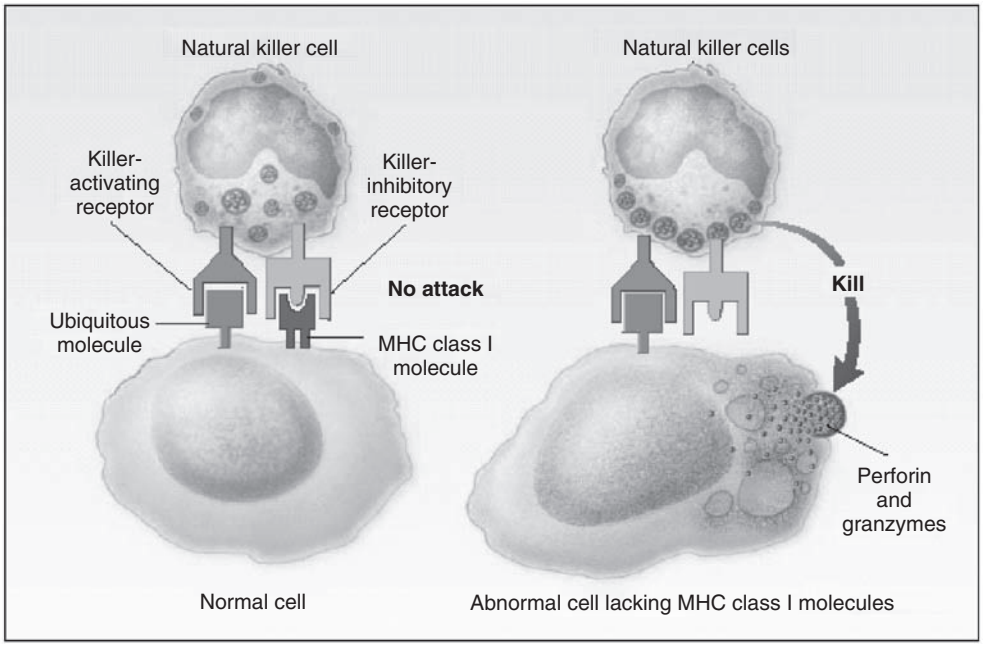

FIGURE 2.1 Natural killer (NK) cells can attack cells lacking MHC class I expression following recognition by killer-activating receptors in the absence of a downregulatory signal from killer-inhibitory receptors. The cytotoxic granules of the NK cells, which contain perforin and granzymes, become polarized to the interface between the cells and are then released into the target cell. See color plate section.

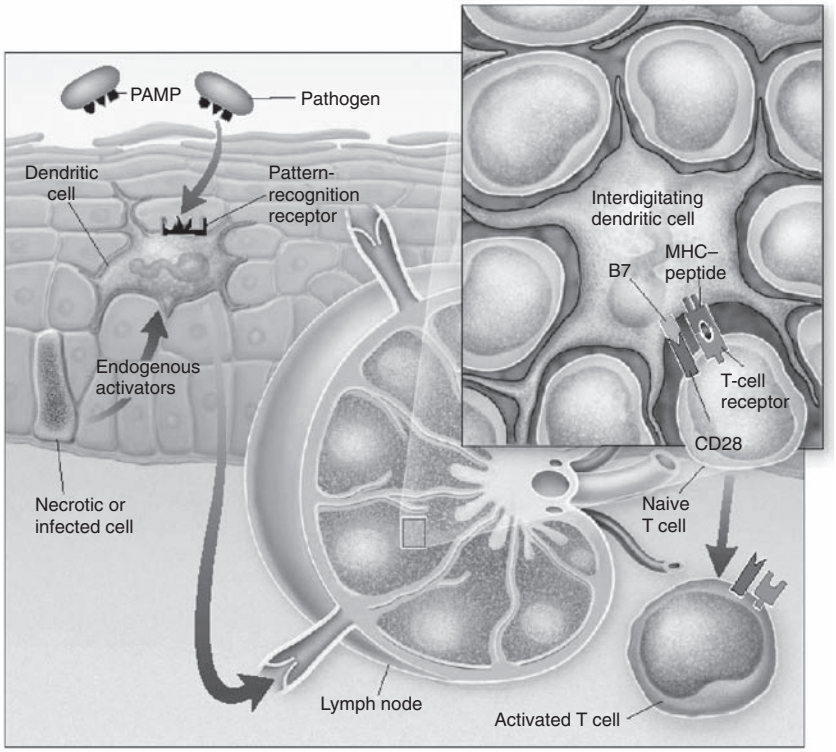

FIGURE 2.2 Pathogen-associated molecular patterns (PAMPs) allow the pattern-recognition receptors (PRR) on the interdigitating dendritic cells (IDCs) to differentiate between potentially harmful foreign microorganisms and self constituents. IDCs are also stimulated by endogenous activators such as interferon-α and heat-shock proteins released from infected or necrotic cells. The activated IDCs process the antigen to generate peptides that are presented by MHC molecules to the T-cell receptor (TCR) on T cells in the local draining lymph nodes. See color plate section.

antigen-presenting cell (APC) mode when their PRRs recognize PAMPs, such as LPS, terminal mannose, and microbial CpG motifs (Janeway and Medzhitov, 2002; Krieg, 2002). The activated IDCs then travel to the local draining lymph node where they present antigen to T cells. During their migration through the afferent lymphatics, they upregulate their cell-surface MHC class II molecules and CD80 (B7.1) and CD86 (B7.2) costimulatory molecules, which are ligands for CD28 on the T cell (Kroczek et al., 2004). Such costimulation is required, together with antigen, for the activation of naïve T cells. Within the dendritic cell (DC) the antigen is processed into short peptides and then expressed on the cell surface together with the MHC class II molecules for presentation to Th cells. IDCs are also able to "cross-present" exogenous antigens by transferring them into the MHC class I processing and presentation pathway for recognition by cytotoxic T cells (Ramirez and Sigal, 2004). T-cell interactions with immature DCs lacking CD80/CD86 expression lead to tolerance, often by inducing anergy (functional inactivation) in the T cell (Schwartz, 2003). Mature IDCs can also be tolerogenic in some cases, e.g., by suppressing T-cell proliferation via the production of indoleamine 2,3-dioxygenase (Mellor and Munn, 2003).

Although B cells are able to recognize antigen without the intervention of any other cell type, recognition is more efficient if multiple copies of the antigen are "presented" to the B cell, e.g., in the form of immune complexes held on the surface of follicular dendritic cells (FDCs) (van Nierop and de Groot, 2002). These are an entirely different cell type from the IDC, are not phagocytic, and lack MHC class II molecules. Furthermore, they are not bone marrow derived, probably arising from fibroblastic reticular cells in the B cell areas of lymphoid tissues. They can present immune complexes to B cells very efficiently by virtue of their FcγRIIB receptors for IgG, and CR1 and CR2 receptors for complement.

The role that erythrocytes perform in immune responses should not be overlooked. Their possession of CR1 complement receptors for C3b, C4b, and iC3b confers on these cells an important role in clearing immune complexes from the circulation to the liver and spleen, where they are destroyed by Küpffer cells and splenic macrophages (Birmingham, 1995).

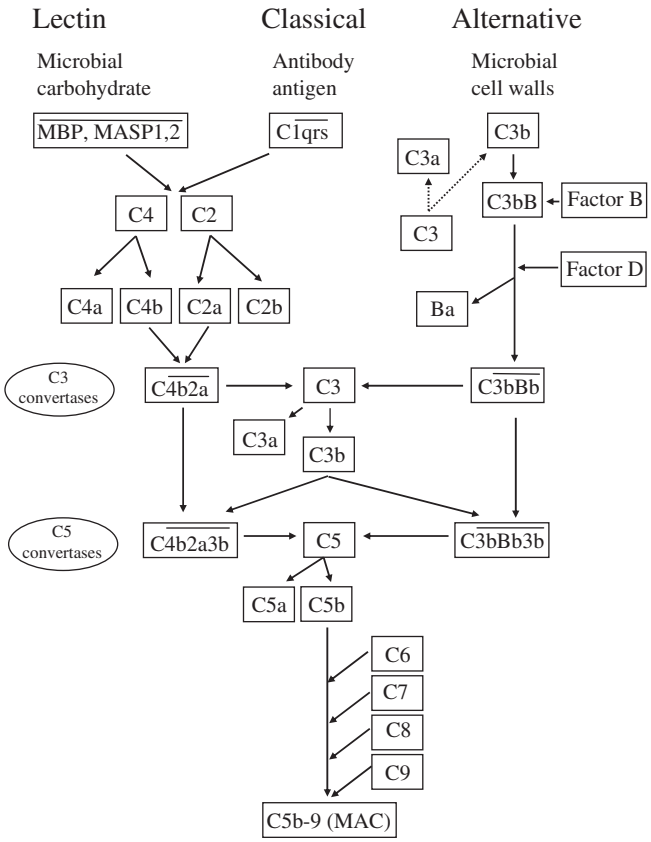

FIGURE 2.3 Complement system. For simplicity complement regulatory proteins have been omitted. For details see text. MAC, membrane attack complex; MASP, MBP-associated serine proteases; MBP, mannose-binding protein.

Soluble Mediators

The complement system is based on an enzymic amplification cascade that can be triggered using one of three pathways; classical, lectin, and alternative. These all lead to the cleavage of complement component C3 by a C3 convertase which "converts" C3 into C3a and C3b (Figure 2.3). The classical pathway is activated by IgG and IgM antibodies when they bind antigen, thereby creating an array of closely-associated immunoglobulin Fc regions to which complement component C1q binds, followed by C1r and C1s. This event initiates a series of enzymic reactions leading to the generation of the classical pathway C3 convertase, $C\overline{4b2a}$. The lectin pathway, which is essentially a variant of the classical pathway, leads to the generation of the same C3 convertase when microbial carbohydrates interact with mannose-binding protein (MBP) which then binds to the two MBP-associated serine proteases, MASP-1 and MASP-2. The initially quite separate alternative pathway is activated when complement component C3b becomes stabilized by binding to microbial cell walls. The C3b then combines with factor B which is cleaved by factor D, generating a different C3 convertase, $C\overline{3bBb}$. Both proteolysis and thioester hydrolysis of C3 constitutively generate very low levels of C3b. However, in the alternative pathway, it is only when $C\overline{3bBb}$ is generated that there is substantial splitting of C3 into C3a and C3b. Subsequently, a C5 convertase, either $C\overline{4b2a3b}$ (from the classical and lectin pathways) or $C\overline{3bBb3b}$ (from the alternative pathway), is produced by addition of C3b to the C3 convertase. This splits C5 into C5a

and C5b, ultimately leading to the generation of the membrane attack complex (MAC) composed of complement components C5b, C6, C7, C8, and C9. Because complement activation consists of a series of sequential enzyme reactions, there is a tremendous amplification of the initial response, and along the way a number of complement components with potent immunologic activities are generated.

The main function of C3b is to enhance the engulfment of antigens by phagocytic cells bearing the complement receptors CR1 and CR3. The C3a, C4a, and C5a components act as anaphylatoxins triggering the release of inflammatory mediators from mast cells. C5a is also a potent neutrophil chemoattractant. The MAC generates pores in cell membranes, ultimately leading to the demise of the target cell by apoptosis. Because of these many potent activities, the complement cascades are tightly controlled by a number of complement regulatory proteins, including C1 inhibitor, factor H, and factor I (both of which break down C3b in the alternative pathway); CD46 (membrane cofactor protein) and CD55 (decay accelerating factor), both of which limit the formation and function of the C3 convertases; and CD59 (homologous restriction factor, an inhibitor of MAC formation) (Morgan and Harris, 1999).

Complement components C3 and C9, and factor B are classed as acute-phase proteins. This diverse group of mediators, which includes C-reactive protein, serum amyloid A protein, proteinase inhibitors, and coagulation proteins, shares an ability to undergo a rapid change in plasma concentration in response to infection, inflammation, and tissue injury. Collectively, the acute-phase proteins facilitate host resistance to infection and promote the resolution of tissue damage (Gabay and Kushner, 1999).

Another group of proteins, which function in both the innate and adaptive response, are the cytokines (Fitzgerald et al., 2001). These soluble mediators facilitate communication both within the immune system and between the immune system and other cells of the body. To respond to a given cytokine a cell must express the relevant cytokine receptor. In addition to acting as communication molecules, some cytokines play a more direct role in immune defense. For example, the interferons produced by virally-infected cells establish a state of viral resistance in surrounding noninfected cells, thereby acting as a "firebreak" against the spread of the infection (Basler and Garcia-Sastre, 2002).

ADAPTIVE IMMUNE RESPONSES

The adaptive responses involve the clonal expansion of antigen-specific B and T lymphocytes. B cells produce the antigen-specific antibodies responsible for elimination of extracellular antigens. T cells kill virally-infected cells, secrete cytokines, and help B cells to make antibody.

T Cell Development

T-cell precursors migrate from the bone marrow to the thymus, an organ essential for the production of most T cells. T-cell development occurs in the thymus throughout life, despite the fact that it undergoes significant atrophy at puberty (Jamieson et al., 1999). The TCR on T cells comes in two versions, either a $\alpha\beta$ or a $\gamma\delta$ heterodimer; each chain of the dimer has one variable domain and one constant domain. T lymphocytes are capable of producing vast numbers of different TCR variable regions by recombining variable (V), diversity (D), and joining (J) gene segments from the pools of α, β, γ, and δ TCR genes. There are a number of different sequences for each segment and one of each set is utilized in the rearrangement event. The recombination-activating gene (RAG) products RAG-1 and RAG-2 mediate these processes following the recognition of recombination signal sequences (RSS) that flank the V, D, and J gene segments (Livak and Petrie, 2002). Splicing inaccuracies, and the insertion of additional nucleotides around the V–D–J junctions by the enzyme terminal deoxynucleotidyl transferase (TdT), further increase diversity (Benedict et al., 2000).

Rearrangement, and subsequent expression, of the TCR genes does not occur until the precursor T cells reach the thymus. For T cells that express an $\alpha\beta$ TCR, initially the TCR β chain gene segments are randomly rearranged and coexpressed with a nonrearranging pre-T α chain (which lacks a variable domain) to produce a preliminary version of the TCR. Subsequently the TCR α chain gene segments are randomly rearranged in order to generate the mature $\alpha\beta$ TCR. Both positive and negative selection of the T cells then occurs (Starr et al., 2003) (Figure 2.4). Positive selection ensures that the randomly generated TCR is able to interact with self MHC molecules. The T cells coexpress the cell-surface molecules CD4 and CD8 during their early development, allowing them to potentially interact with both MHC class I and class II molecules. CD4 binds to conserved (nonpolymorphic) residues on the MHC class II molecule, while CD8 binds to conserved residues on MHC class I. At this stage in their differentiation the T cells are programmed to undergo apoptosis and are only rescued from this default cell death if their TCR is capable of binding to MHC on the thymic cortical epithelium. Over 95% of the T cells fail at this first hurdle and are therefore eliminated. For the remaining cells the default pathway is switched to survival and apoptosis is induced in any lymphocytes capable of high-affinity binding to peptides presented by self-MHC on DCs, macrophages, and thymic epithelial cells. This clonal deletion process constitutes central tolerance of self-reactive T cells. Peptides are generated from the many organ- and tissue-specific self-antigens expressed in the thymus under the transcriptional control of the autoimmune regulator (AIRE) protein (Venanzi et al., 2004). Negative selection,

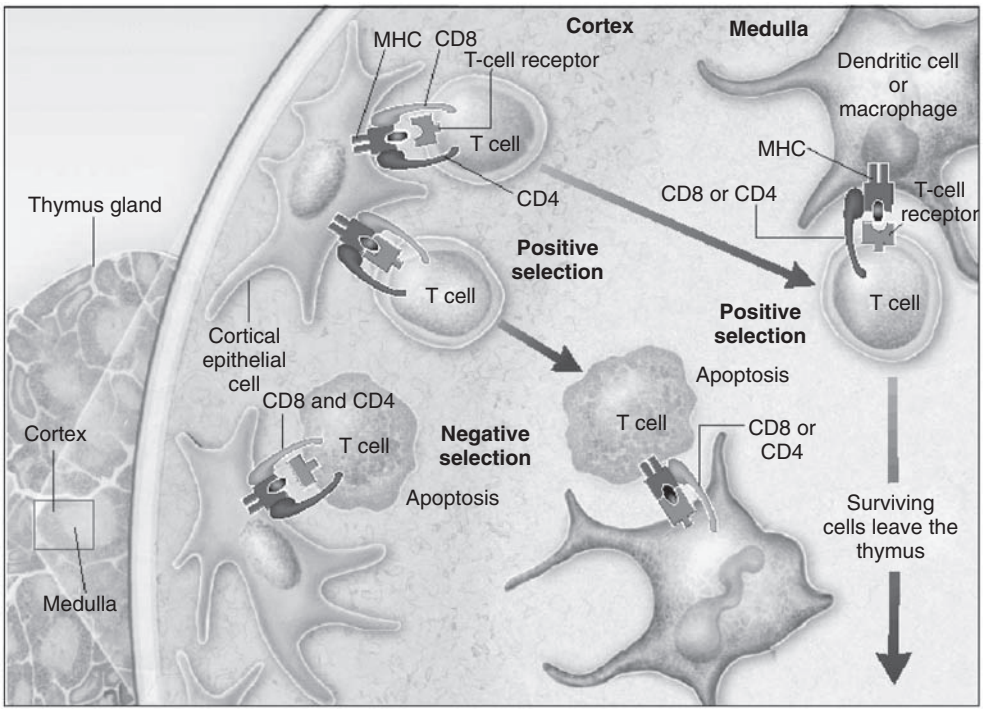

FIGURE 2.4 Positive and negative selection in the thymus. Cells with T-cell receptors (TCRs) of various affinities for self-MHC are positively selected on cortical epithelial cells. Any of these cells that bear a TCR with high affinity for self-peptide plus self-MHC (or even just MHC irrespective of the peptide contained) are subsequently eliminated by induction of apoptosis when they interact with dendritic cells, macrophages or epithelial cells in the thymic medulla (negative selection). This leaves T cells with only a weak affinity for self-MHC. These cells form the pool of T cells that are exported from the thymus as single $CD4^+$ or $CD8^+$ cells. In the periphery they have the potential to recognize foreign peptide plus self-MHC, and become activated if the affinity of the interaction is above a certain threshold and the recognition occurs in the presence of costimulatory signals. See color plate section.

like failure to be positively selected, results in extensive T-cell death within the thymus. The T cells lose expression of either CD4 or CD8 to become "single positive" CD4 or CD8 cells, and they exit the thymus and enter the periphery, a term used to denote any location outside of the primary lymphoid organs (bone marrow and thymus). These mature naïve T cells will be capable of recognizing foreign peptides presented by self-MHC.

Although γδ T cells also rearrange their TCR genes in the thymus, they do not undergo thymic selection and therefore leave the thymus early in their development. Indeed, the origin of some intestinal γδ T cells may be thymic independent (Carding and Egan, 2002).

Functional Activities of T Cells

The αβ and γδ TCRs are not themselves able to transmit activation signals to the cell nucleus, this function being assigned to the CD3 molecules (CD3γ, CD3δ, CD3ε) and the CD3-associated ζ chains (Figure 2.5). Receptor aggregation occurs within lipid rafts which also incorporate a number of adhesion and costimulatory molecules, including CD28, CD2, and CD43 (Dykstra et al., 2003), to form the immunologic synapse (Davis and Dustin, 2004). Stimulation through the synapse results in the phosphorylation of tyrosines within immunoreceptor tyrosine-based activation motifs (ITAMs) on the cytoplasmic tails of the CD3 complex and the ζ chains. A number of protein kinases, including Lck, Fyn, and ZAP-70, are involved, with Lck also binding to the cytoplasmic tail of the CD4 or CD8 molecule (Hermiston et al., 2003). Downstream signal transduction results in the transcriptional activation of several genes, including that for IL-2. The CD45 phosphatase also plays a critical role in both T- and B-cell activation by its ability to act as both a positive and negative regulator of Lck and Fyn (Hermiston et al., 2003).

Broadly speaking, $CD4^+$ T cells act as helper T lymphocytes, while $CD8^+$ T cells are usually cytotoxic. However, some $CD4^+$ cells can exhibit cytotoxic activity (Appay et al., 2002), while $CD8^+$ cells secrete cytokines that

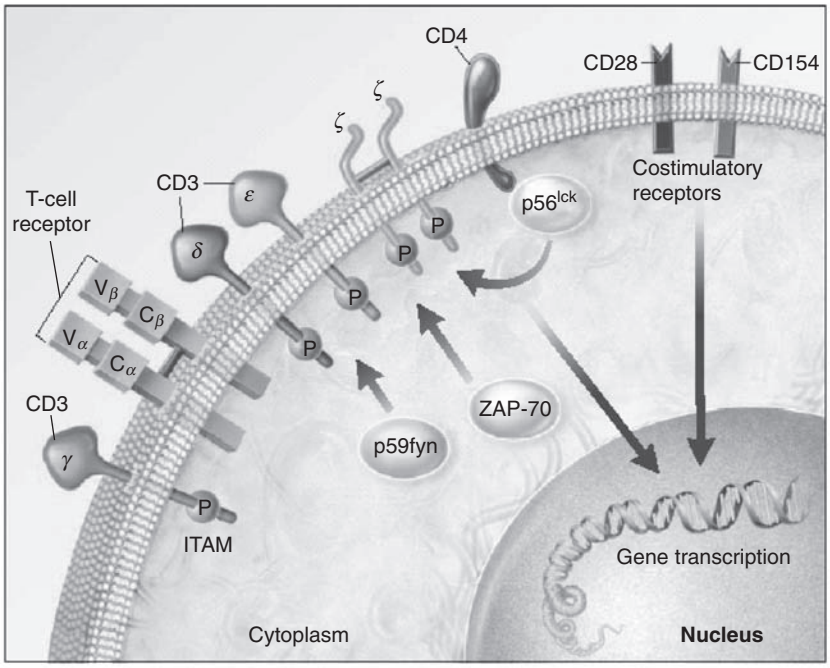

FIGURE 2.5 Lymphocyte activation involves a highly complex series of integrated events resulting from cross-linking of the antigen receptor on the cell surface. Because the antigen receptors have extremely short cytoplasmic tails they are associated with cell-surface molecules bearing cytoplasmic immunoreceptor tyrosine-based activation motifs (ITAMs), which are subject to phosphorylation by protein kinases. These events lead to downstream signaling involving a number of different biochemical pathways that result in the transcriptional activation of genes involved in cellular proliferation and differentiation. The presence of signals from costimulatory molecules, such as CD28 and CD154 (CD40 ligand), is obligatory if the lymphocyte is to be activated; signals from the antigen receptor signal-transducing molecules alone lead to anergy or apoptosis. TCR, T-cell receptor. See color plate section.

can either help in the generation of immune responses or be cytotoxic (Mosmann and Sad, 1996; Woodland and Dutton, 2003).

The TCR on $CD8^+$ CTL binds to peptide–MHC class I on target cells. Endogenous antigens, including self-antigens and viral proteins, are broken down into peptides by a proteolytic structure known as the immunoproteasome (Shastri et al., 2002). If the TCR recognizes the peptide–MHC combination the CTL can kill the target either by engaging the Fas molecule on the target cell with Fas ligand on the CTL or by using the perforin/granzyme pathway (Russell and Ley, 2002). The outcome of either of these events is apoptosis of the target.

In stark contrast to the ubiquitously expressed MHC class I, MHC class II is only present on a few specialized cells, which are referred to as professional APCs; namely IDCs, macrophages, and B cells. These cells generate peptides by proteolytic cleavage of engulfed antigens within endosomal vesicles and then present the peptide–MHC class II combination to $CD4^+$ T cells. Th cells can be divided into different populations based on the cytokines they produce. Cells secreting IL-2 and interferon (IFN)-γ, but not IL-4, IL-5, and IL-6, are designated Th1 cells, while those secreting IL-4, IL-5, IL-6, IL-10, and IL-13, but not IL-2 and IFN-γ, are classified as Th2 cells (Mosmann and Sad, 1996). In general, cytokine production by Th1 cells facilitates "cell-mediated immunity," including macrophage activation and T-cell mediated cytotoxicity; but can also assist in the production of some humoral responses (e.g., IgG2a in the mouse), while the cytokines produced by Th2 cells are mostly involved in humoral immunity by helping B cells to produce antibodies, particularly those of the IgE and IgA isotypes (Fitzgerald et al., 2001). IL-12 from IDCs drives T cells towards a Th1 phenotype (Moser and Murphy, 2000) and Th cell responses tend to become polarized because the IFN-γ from Th1 cells downregulates Th2 activity, whereas IL-4 and IL-10 from Th2 cells downregulate Th1 cells.

An additional population of $CD4^+$ lymphocytes exist that have some properties of NK cells and some of T cells. These NK cells express lower levels of the αβ TCR than do conventional T-cells, and these TCRs exhibit a very limited diversity (Pear et al., 2004). They can recognize antigen presented by the non-classical MHC molecule CD1 and secrete both IL-4 and IFN-γ (Kronenberg and Gapin, 2002).

The antigen-specificity and functions of γδ T cells is much less well characterized than those of αβ T cells, but some γδ TCRs recognize native antigen directly or

recognize lipids, glycolipids, and lipopeptides presented by CD1 (Brigl and Brenner, 2004). γδ T cells take up residence throughout the body, being particularly prevalent in the intestinal epithelium where they contribute to mucosal defenses (Chen et al., 2002). They may also play an immunoregulatory role, secreting proinflammatory IFN-γ early in an immune response and then later producing immunosuppressive cytokines, such as IL-10, and acquiring cytotoxic activity against activated macrophages (Carding and Egan, 2002).

B Cell Development and Functions

A minor population of B cells, B1 cells, develops early during ontogeny and often expresses the CD5 cell-surface molecule (Berland and Wortis, 2002). These cells secrete low- to moderate-affinity IgM antibodies that can exhibit polyreactivity, i.e., recognize several different antigens, often including common pathogens and autoantigens. Such antibodies are sometimes called "natural antibodies" because of their presence in the absence of an obvious antigenic challenge. Most B cells, B2 cells, lack CD5 and develop slightly later in ontogeny. Like T cells, these B cells are capable of producing a huge number of different variable regions on their antigen receptors using rearrangement of immunoglobulin heavy and light chain gene loci (Figure 2.6). Initially, they express a pre-BCR composed of an immunoglobulin μ heavy chain generated by gene rearrangement and a surrogate light chain encoded by two nonrearranging genes termed VpreB and λ5. Expression of this pre-BCR on the immature B cell is obligatory for interaction with the bone marrow stromal cells that drive B-cell differentiation towards the mature naïve B cell coexpressing conventional IgM and IgD antibodies on the cell surface (Bradl et al., 2003). Once the B cells express a mature antigen receptor their survival and further differentiation becomes antigen dependent.

The antigen receptor is associated with several molecules, including Igα (CD79a), Igβ (CD79b), CD19, CD21 (the CR2 complement receptor), CD81 (TAPA-1), and CD225, which collectively transmit activation signals into the cell when receptor aggregation occurs following cross-linking of the surface immunoglobulin by antigen. This signaling includes phosphorylation of ITAM sequences on Igα and Igβ by the Src family kinases Lyn, Fyn or Blk, and the subsequent recruitment of Syk kinase which initiates downstream signaling (Wang and Clark, 2003). On binding to the BCR, antigen is endocytosed and then processed for presentation by MHC class II to Th cells (Clark et al., 2004). In addition to an antigen-presenting role, B cells secrete a number of cytokines, including IL-10, IL-12, IL-13, TNF-α, TNF-β (lymphotoxin), transforming growth factor (TGF)-β and granulocyte-macrophage colony-stimulating factor (GM-CSF) (Fitzgerald et al., 2001). Following their activation, B cells undergo rounds of proliferation and differentiate into memory cells or plasma cells which produce high levels of soluble antibody. Most plasma cells have a half life of only a few days, but some survive for several weeks, particularly in the bone marrow (Slifka and Ahmed, 1998).

Antibodies

Antibodies are immunoglobulin molecules composed of two identical heavy polypeptide chains and two identical light polypeptide chains, held together by interchain disulfide bonds. All immunoglobulins are glycoproteins, containing between 3% and 13% carbohydrate, depending on the antibody class (Jefferis and Lund, 1997). The N-termini of the light and heavy chains are folded into a variable domain which contains three hypervariable loops, constituting the complementarity determining regions (CDRs) responsible for noncovalent binding of the antigen. Most epitopes recognized by antibodies are discontinuous, comprising amino acids that are only brought together on protein folding (Muller, 2000). The heavy chain C-terminal domains form the constant region, which specifies the class/subclass of antibody. The light chain constant domain determines the κ or λ isotype. The human antibody classes are IgG, IgA, IgM, IgD, and IgE, with four IgG (IgG1–4) and two IgA (IgA1, IgA2) subclasses. Each antibody can be produced either with a hydrophobic transmembrane sequence to anchor the molecule in the B-cell membrane, where it functions as the BCR, or as a secreted molecule lacking the transmembrane sequence.

The basic antibody monomer (biochemically a tetramer) is bivalent with two antigen-binding arms of identical specificity. Secretory IgA at mucosal surfaces is a tetravalent dimer, whereas circulating IgM is most frequently a decavalent pentamer with a minor proportion of hexamers and tetramers. IgA and IgM polymerization is stabilized by a polypeptide J (joining) chain (Johansen et al., 2000). Secretory IgA also includes a secretory component, a cleavage fragment of the poly-immunoglobulin receptor, which was used to transfer the IgA across epithelial cells to the mucosal surfaces (Johansen and Brandtzaeg, 2004).

Neutralizing antibody can inhibit the binding of microorganisms or biologic molecules (toxins, hormones, cytokines, and so forth) to their cellular receptors and thereby exert an effect independently of other immune system components. Usually, however, antibodies do not function in isolation but are employed to activate the classical complement pathway and/or link antigen to Fc receptor-bearing cells. Antigens opsonized with IgG, IgA or IgE bind to the appropriate Fc receptors (FcγR, FcαR or FcεR) on phagocytic cells (Underhill and Ozinsky, 2002). Alternatively, both IgG and IgE can mediate antibody-dependent cellular cytotoxicity (ADCC) in which NK cells,

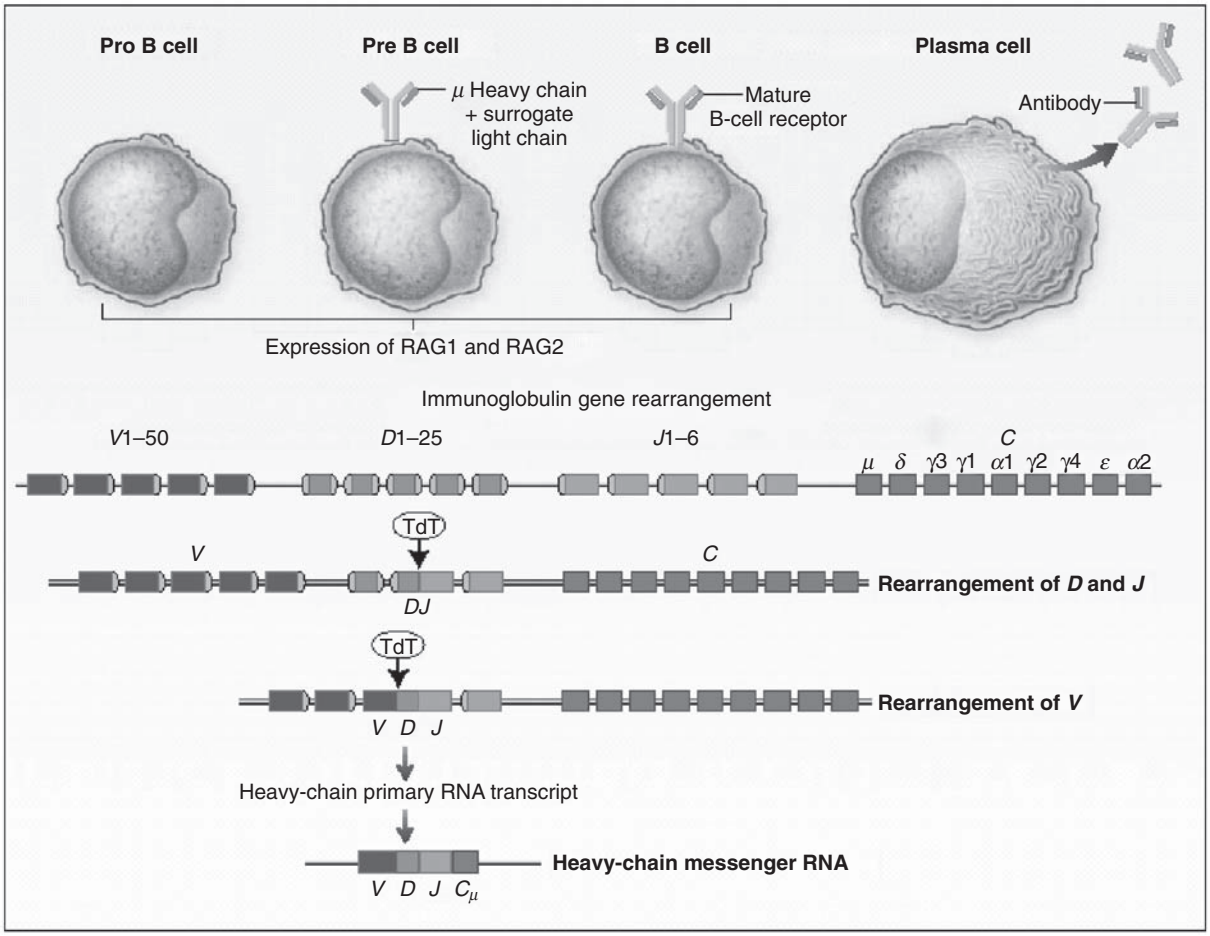

FIGURE 2.6 Diversity of antigen receptors. Early in B cell development, pro-B cells mature into pre-B cells, at which stage they express the recombination activating genes RAG-1 and RAG-2. Random rearrangement of any one of 25 diversity (D) gene segments next to any one of six joining (J) gene segments is followed by rearrangement of any one of approximately 50 variable (V) gene segments next to the already rearranged D–J segment. Different B cells will rearrange a different segment out of each pool, thereby creating one level of diversity. Additional diversity is brought about by junctional diversity due to splicing inaccuracies and by the incorporation of nucleotides mediated by the enzyme terminal deoxynucleotidyl transferase (TdT). The heavy chain primary RNA transcript is processed into messenger RNA (mRNA), with splicing of the rearranged V–D–J next to the Cμ constant region gene. This mRNA will encode a μ heavy chain which is placed on the surface of the pre-B cell together with the surrogate light chain V pre-B λ5. As the pre-B cell undergoes further maturation the immunoglobulin light chain V and J gene segments (for simplicity not shown) rearrange to produce a κ or λ light chain. This light chain replaces the surrogate light chain in order to produce a mature IgM B-cell receptor (BCR) on the cell surface. The BCR at this stage also usually comprises IgD antibodies of the same specificity, produced by alternative splicing of the rearranged V–D–J to either the Cμ or Cδ constant region genes. Expression of RAG-1 and RAG-2 is now switched off. Following encounter with antigen, and in the presence of costimulatory signals, the B cell further differentiates into either a plasma cell, which secretes high levels of the specific antibody, or into a memory B cell. The same general principles regarding the rearrangement process applies to the generation of αβ and γδ T-cell receptor. See color plate section.

monocytes, macrophages or neutrophils bearing Fcγ receptors or macrophages, eosinophils or platelets bearing Fcε receptors are focused onto antibody-coated target cells or parasites (Lucas, 1999). The target is destroyed by apoptosis using perforin and granzymes. IgE antibodies are also able to sensitize mast cells and basophils via the high-affinity IgE receptor FcεRI and, if cross-linked by antigen, will trigger the release of inflammatory mediators.

The epithelial cell poly-immunoglobulin receptor transports secretory IgA produced by plasma cells underlying mucosal surfaces (Johansen and Brandtzaeg, 2004). On the luminal side of the epithelium the IgA is released by proteolytic cleavage of the receptor and acts to prevent microbial adhesion to the epithelial cell wall. A second type of epithelial Fc receptor, FcRn, is present in both the placenta, where it transports IgG from the maternal to the fetal circulation

(Simister, 2003), and on the intestinal epithelium of the neonate where it is involved in the uptake of IgG from maternal milk (Ghetie and Ward, 2000).

Secondary Lymphoid Tissues

The primary lymphoid organs, bone marrow and thymus, are where fully differentiated mature naïve B and T cells are produced. However, activation of lymphocytes occurs in structurally-organized B- and T-cell compartments in the secondary lymphoid tissues; the lymph nodes, spleen, and mucosa-associated lymphoid tissues (MALT). Diffuse collections of lymphoid cells are also present throughout the lung and in the lamina propria of the intestinal wall. Only a handful of lymphocytes will be specific for a given antigen, requiring T and B cells to recirculate through the different lymphoid tissues. While responses to blood-borne antigens are usually initiated in the spleen, those to antigens in the tissues are stimulated in the local draining lymph nodes.

Lymphoid follicles within the secondary lymphoid tissues contain germinal centers where B-cell activation occurs within a meshwork of FDCs displaying immune complexes on their surface. Germinal centers are at the heart of the generation of adaptive responses for it is here that B cells proliferate, switch class, undergo affinity maturation, and differentiate into memory cells and plasma cell precursors (McHeyzer-Williams et al., 2001) (Figure 2.7). B cells can increase the binding affinity of their BCR by somatic hypermutation of the rearranged antibody variable genes. Higher affinity clones will then be preferentially selected by antigen. Class switching from IgM to IgG, IgA, and IgE involves switch sequences containing highly repetitive nucleotide motifs immediately upstream of each constant region gene (except Cδ). Both somatic hypermutation and class switching require the expression of activation-induced cytidine deaminase (AID) and of the heterodimeric protein Ku70/Ku80 (Sawchuk et al., 2004). Receptor editing, involving re-expression of RAG enzymes in the germinal centers, enables self-reactive B cells to replace the variable region gene in the rearranged VDJ sequence with a different variable region gene in order to eliminate autoreactivity.

Most pathogens enter the body through mucosal surfaces. The palatine tonsils and adenoids are the sites for induction of responses to intranasal and inhaled antigens (Brandtzaeg, 1999). Antigens from the gut are taken up by specialized epithelial microfold cells which transport the antigens across the epithelium for access to the Peyer patches where mucosal responses are induced (Kraehenbuhl and Neutra,

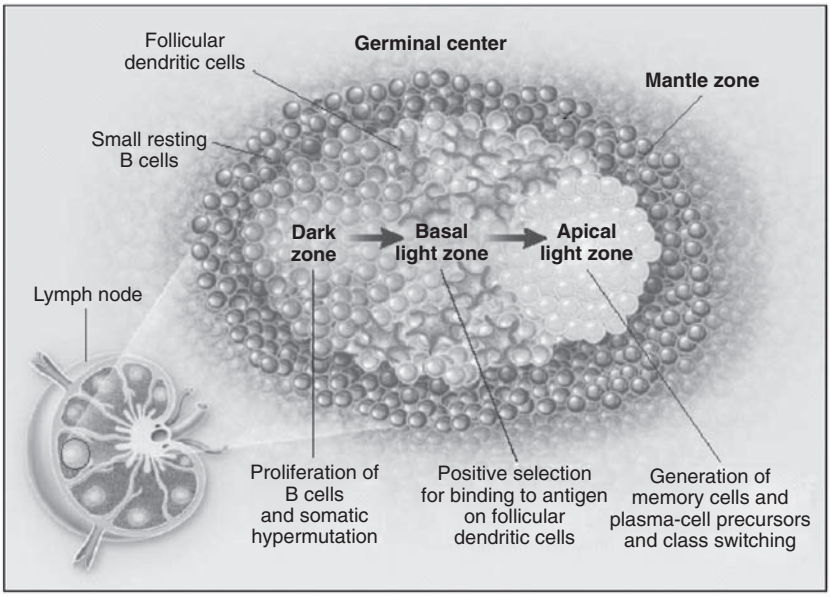

FIGURE 2.7 Germinal center. During the initiation of the acquired immune response, these structures form in the secondary lymphoid tissues in order to generate a microenvironment where all the necessary antigen-specific and innate antigen-presenting cells can interact. Antigen-stimulated B cell proliferation occurs in the dark zone and is accompanied by affinity maturation due to somatic hypermutation of the immunoglobulin variable region genes. Upon passage into the basal light zone, high-affinity antigen-specific B-cells are positively selected by interaction with antigen, which is present in the form of immune complexes on the surface of follicular dendritic cells. B cells which fail to be positively selected undergo apoptosis and are phagocytosed by tangible-body macrophages. The positively selected cells migrate to the apical light zone where proliferation continues, class switching occurs, and memory cells and plasma cell precursors are generated. See color plate section.

2000). Activated lymphocytes exit the Peyer patches via the efferent lymphatics, traffic through the blood, and then home to the lamina propria and other mucosal effector sites. Intraepithelial lymphocytes (IELs) interspersed between the gut epithelial cells also encounter antigens transported by microfold cells. Most IELs express CD8, can be either cytotoxic or immunoregulatory, and between 35% and 65% of murine IELs bear a γδ TCR (Hayday et al., 2001).

Lymphocytes enter lymph nodes, tonsils, and Peyer patches either via the afferent lymphatics or from the blood via high endothelial venules (HEV). L-Selectin is constitutively expressed on lymphocytes and constitutes a ligand for peripheral lymph node addressins (Ley, 2003). If expression of lymphocyte function-associated antigen (LFA)-1 is upregulated on the lymphocytes, their adhesion to HEV is enhanced and they migrate across the HEV into these lymphoid tissues. Although the spleen lacks HEV, circulating lymphocytes can directly access the marginal zone of this organ from the blood vessels. T cells locate mostly to the periarteriolar lymphoid sheaths, while B cells enter the lymphoid follicles. Lymphocytes leave the lymph nodes via the efferent lymphatics and the spleen via the splenic vein.

When naïve lymphocytes first encounter antigen in the secondary lymphoid tissues they mount a primary immune response, generating both effector and memory cells. The memory cells are responsible for the quantitatively and qualitatively superior secondary immune response that occurs on any subsequent encounters with the same antigen. Memory cells have a lower activation threshold than naïve cells and the secondary response is more rapid, involves larger numbers of lymphocytes, and, for B cells, produces higher levels of antibody with an improved affinity for antigen.

The term "T-independent antigen" refers to antigens that are capable of generating an antibody response without a requirement for Th cells. Polysaccharides, polymerized flagellin, and a number of other antigens have repetitive determinants which can extensively cross-link the BCR and thereby directly activate the B cell (Fagarasan and Honjo, 2000). Because they do not recruit T cells, T-independent antigens fail to provoke the formation of germinal centers and therefore are unable to induce B-cell memory, class switching to IgG, IgA or IgE production, or significant amounts of affinity maturation. Thus, low-affinity IgM antibodies are produced in response to T-independent antigens and, although involving B cells, the response does not go on to exhibit the characteristics of "adaptive" immunity. The majority of antigens that stimulate B cells are, however, T-cell dependent in that the B-cell response requires help from T cells. As mentioned earlier, the BCR on the surface of the B cell internalizes bound antigen which is then processed into peptides for presentation by MHC class II molecules. Upon recognition of the peptide–MHC complex by the T cells in the secondary lymphoid tissues, the costimulatory molecule CD154 (CD40 ligand) on the T cell engages CD40 on the B cell (Calderhead et al., 2000). In addition to cell surface molecules, cytokines play a key role in the mutual activation of the T and B lymphocytes. T-cell help can also be recruited by IDCs and macrophages presenting the relevant peptide–MHC class II combination to the Th cell.

Resolution of the Immune Response

Antigen stimulates the immune response and, therefore, for foreign antigen, its clearance by the immune system will naturally lead to a waning of the response. However, additional mechanisms initially amplify and subsequently downregulate the response. Once high levels of class-switched antigen-specific IgG are produced, the antibody can inactivate the antigen-specific B cells in a manner reminiscent of classical negative feedback loops in the endocrine system. Cross-linking of the BCR to FcγRIIB on B cells by immune complexes results in the transmission of inhibitory signals into the B cell (Leibson, 2004). A number of signals from cytokines and cell-surface molecules can also be inhibitory. Ligation of the T-cell surface molecule CTLA-4 by CD80 and CD86, in contrast to ligation of CD28, provides a downregulating signal (Carreno and Collins, 2002). Some $CD4^+CD25^+$ regulatory T cells secrete IL-10 and TGF-β, which can act in an immunosuppressive capacity, while others suppress responses by a cell-contact-dependent mechanism (Taams et al., 2003).

Neuroendocrine interactions with the immune system provide a further level of regulation (Webster et al., 2002). Lymphoid tissues are richly innervated and neurotransmitters, such as epinephrine from sympathetic neurons, acetylcholine from cholinergic neurons, and substance P and calcitonin gene-related peptide (CGRP) from pain fibers have immunomodulatory roles (Steinman, 2004). Among the many other interactions between these systems is the inactivation of chemokine receptors by vasoactive intestinal peptide (Grimm et al., 2003) and an influence on the Th1/Th2 balance by pituitary adenylate cyclase-activating polypeptide (Steinman, 2004).

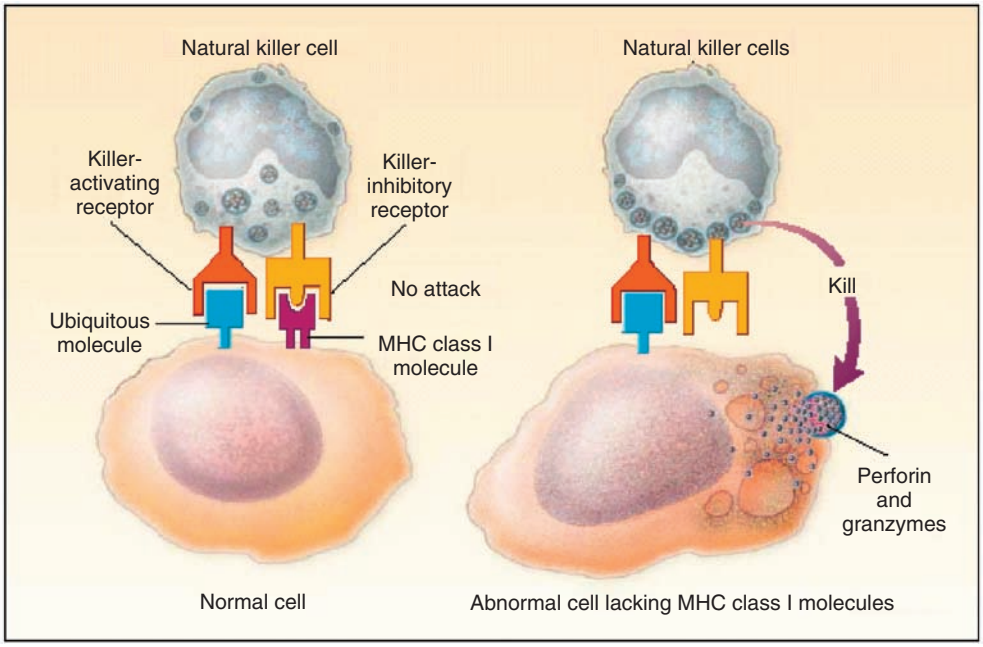

FIGURE 2.1 Natural killer (NK) cells can attack cells lacking MHC class I expression following recognition by killer-activating receptors in the absence of a downregulatory signal from killer-inhibitory receptors. The cytotoxic granules of the NK cells, which contain perforin and granzymes, become polarized to the interface between the cells and are then released into the target cell.

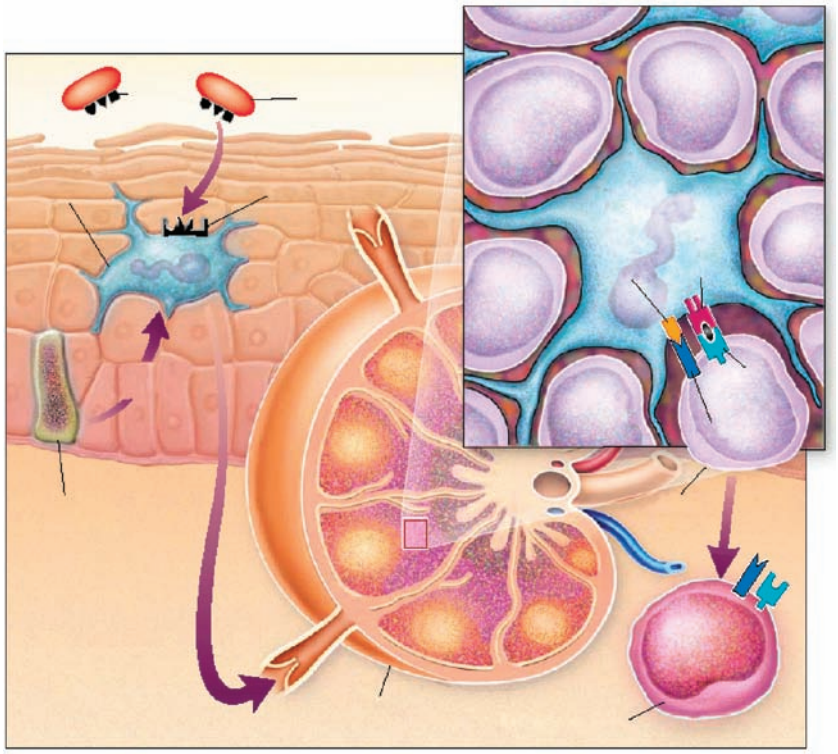

FIGURE 2.2 Pathogen-associated molecular patterns (PAMPs) allow the pattern-recognition receptors (PRR) on the interdigitating dendritic cells (IDCs) to differentiate between potentially harmful foreign microorganisms and self constituents. IDCs are also stimulated by endogenous activators such as interferon-α and heat-shock proteins released from infected or necrotic cells. The activated IDCs process the antigen to generate peptides that are presented by MHC molecules to the T-cell receptor (TCR) on T-cells in the local draining lymph nodes.

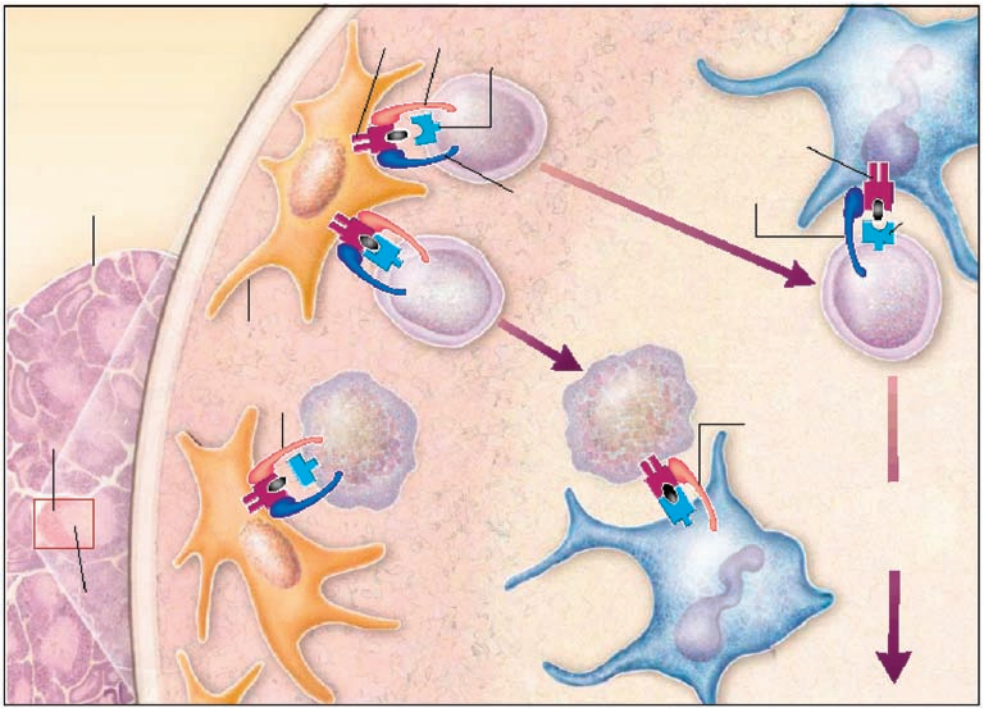

FIGURE 2.4 Positive and negative selection in the thymus. Cells with T-cell receptors (TCRs) of various affinities for self-MHC are positively selected on cortical epithelial cells. Any of these cells that bear a TCR with high affinity for self-peptide plus self-MHC (or even just MHC irrespective of the peptide contained) are subsequently eliminated by induction of apoptosis when they interact with dendritic cells, macrophages or epithelial cells in the thymic medulla (negative selection). This leaves T-cells with only a weak affinity for self-MHC. These cells form the pool of T-cells that are exported from the thymus as single $CD4^+$ or $CD8^+$ cells. In the periphery they have the potential to recognize foreign peptide plus self-MHC, and become activated if the affinity of the interaction is above a certain threshold and the recognition occurs in the presence of costimulatory signals.

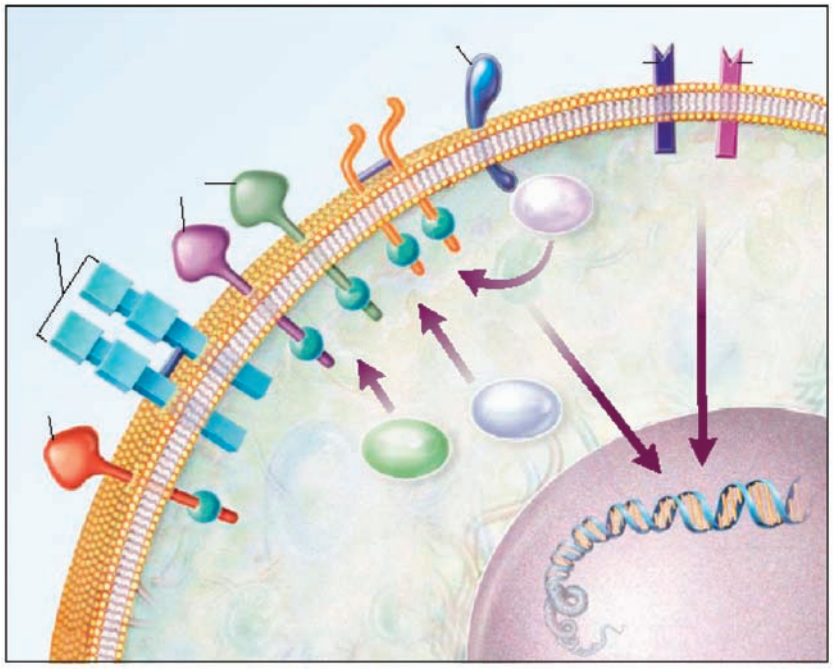

FIGURE 2.5 Lymphocyte activation involves a highly complex series of integrated events resulting from cross-linking of the antigen receptor on the cell surface. Because the antigen receptors have extremely short cytoplasmic tails they are associated with cell-surface molecules bearing cytoplasmic immunoreceptor tyrosine-based activation motifs (ITAMs), which are subject to phosphorylation by protein kinases. These events lead to downstream signaling involving a number of different biochemical pathways that result in the transcriptional activation of genes involved in cellular proliferation and differentiation. The presence of signals from costimulatory molecules, such as CD28 and CD154 (CD40 ligand), is obligatory if the lymphocyte is to be activated; signals from the antigen receptor signal-transducing molecules alone lead to anergy or apoptosis. TCR, T-cell receptor.

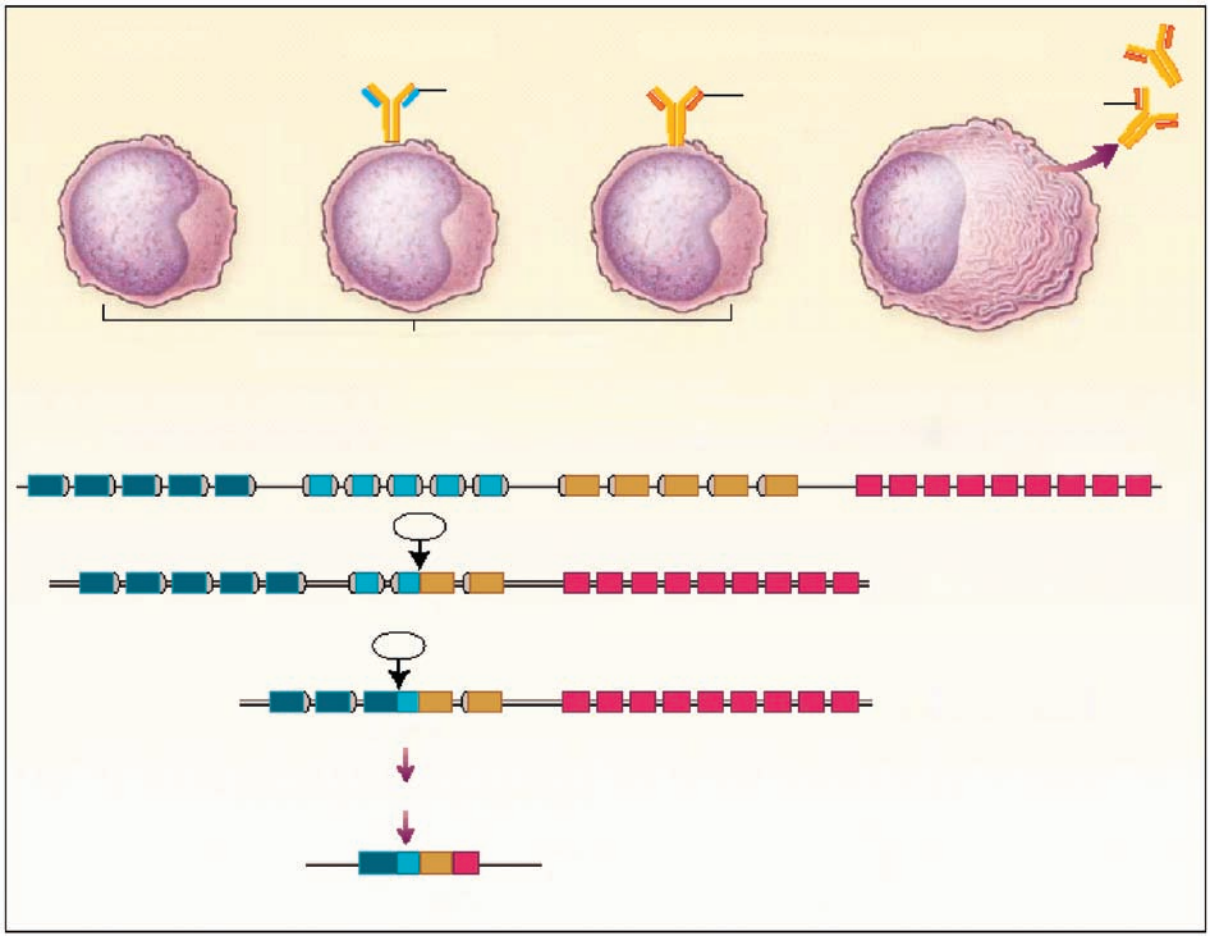

FIGURE 2.6 Diversity of antigen receptors. Early in B-cell development, pro-B-cells mature into pre-B-cells, at which stage they express the recombination activating genes RAG-1 and RAG-2. Random rearrangement of any one of 25 diversity (D) gene segments next to any one of six joining (J) gene segments is followed by rearrangement of any one of approximately 50 variable (V) gene segments next to the already rearranged D–J segment. Different B-cells will rearrange a different segment out of each pool, thereby creating one level of diversity. Additional diversity is brought about by junctional diversity due to splicing inaccuracies and by the incorporation of nucleotides mediated by the enzyme terminal deoxynucleotidyl transferase (TdT). The heavy chain primary RNA transcript is processed into messenger RNA (mRNA), with splicing of the rearranged V–D–J next to the Cμ constant region gene. This mRNA will encode a μ heavy chain which is placed on the surface of the pre-B-cell together with the surrogate light chain V pre-B λ5. As the pre-B-cell undergoes further maturation the immunoglobulin light chain V and J gene segments (for simplicity not shown) rearrange to produce a κ or λ light chain. This light chain replaces the surrogate light chain in order to produce a mature IgM B-cell receptor (BCR) on the cell surface. The BCR at this stage also usually comprises IgD antibodies of the same specificity, produced by alternative splicing of the rearranged V–D–J to either the Cμ or Cδ constant region genes. Expression of RAG-1 and RAG-2 is now switched off. Following encounter with antigen, and in the presence of co-stimulatory signals, the B-cell further differentiates into either a plasma cell, which secretes high levels of the specific antibody, or into a memory B-cell. The same general principles regarding the rearrangement process applies to the generation of αβ and γδ T-cell receptor.

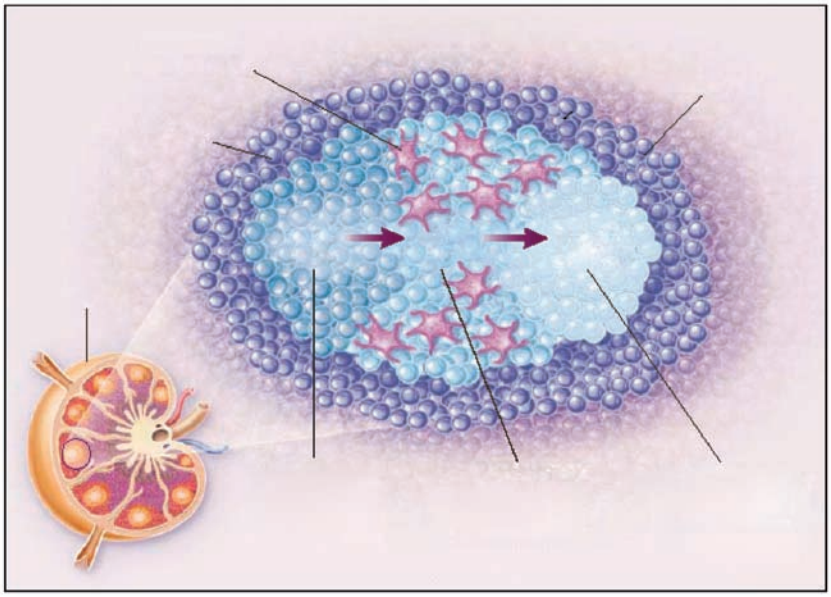

FIGURE 2.7 Germinal center. During the initiation of the acquired immune response, these structures form in the secondary lymphoid tissues in order to generate a microenvironment where all the necessary antigen-specific and innate antigen-presenting cells can interact. Antigen-stimulated B-cell proliferation occurs in the dark zone and is accompanied by affinity maturation due to somatic hypermutation of the immunoglobulin variable region genes. Upon passage into the basal light zone, high-affinity antigen-specific B-cells are positively selected by interaction with antigen, which is present in the form of immune complexes on the surface of follicular dendrite cells. B-cells which fail to be positively selected undergo apoptosis and are phagocytosed by tingible-body macrophages. The positively selected cells migrate to the apical light zone where proliferation continues, class switching occurs, and memory cells and plasma cell precursors are generated.

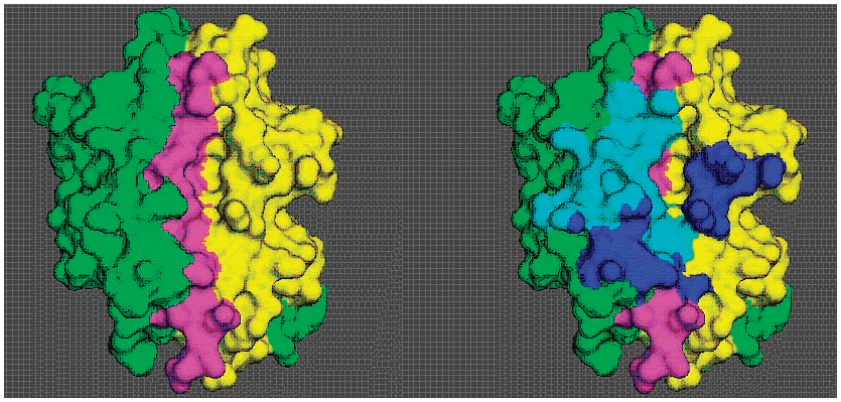

FIGURE 5.2 Trimolecular interaction between MHC, peptide, and T-cell receptor (TCR). The exposed molecular surface of an MHC class II molecule, containing a bound antigen peptide, is shown in the left panel. The MHC α chain is yellow, the β chain is green, and the peptide is shown in pink. Amino acid side chains on the underlying side of the peptide lie buried in the MHC groove, anchoring the binding interaction. This exposed surface forms the contact structure for TCR recognition; the image on the right is colored to show examples of the areas which contact the TCR, with the TCR α chain contacts shown in dark blue and the TCR β chain in light blue. Both peptide and MHC residues are involved in TCR recognition, and both contribute to the overall avidity of the interaction.

CHAPTER

3

General Features of Autoimmune Disease

ANNE DAVIDSON AND BETTY DIAMOND

Departments of Medicine and Microbiology, Columbia University Medical Center, New York, New York, USA

A host of diseases are characterized by activation of the immune system in the absence of an external threat to the organism. In these diseases, inflammation and tissue damage occur in the absence of infection, toxin exposure or tumor growth. These diseases can be characterized as those that display activation of the innate immune system and an excess of inflammatory mediators, but no evidence of an antigen-specific immune response; familial Mediterranean fever, Behçet disease, even atherosclerosis, can be considered to fall within this category. Alternatively, there are diseases characterized by an activation of the adaptive immune response with T and B lymphocytes responding to self-antigen in the absence of any detectable microbial assault or tumor invasion. These diseases constitute the vast majority of diseases considered to be autoimmune in origin, and they will be the focus of this chapter.

CELLS OF THE ADAPTIVE IMMUNE SYSTEM

There is a coordinated interplay among the cells of the adaptive immune system with dendritic cells (DCs), T cells, and B cells interacting to generate the effector response of the immune system. DCs activate T cells (Banchereau and Steinman, 1998; Granucci et al., 2004) and B cells (MacLennan and Vinuesa, 2002; Craxton et al., 2003). T cells activate DCs and B cells (Bishop and Hostager, 2003; O'Sullivan and Thomas, 2003). B cells activate T cells (Shlomchik et al., 2001). This cascade leads to an immune response that recognizes a broad spectrum of epitopes of microbial pathogens and enlists multiple effector mechanisms.

DCs are antigen-presenting cells (APCs) that are critical in initiating an immune response. Like essentially all cells, they display surface expression of class I major histocompatibility complex (MHC) molecules, which permit the presentation of intracellular antigens to T cells. DCs also express class II MHC molecules, which are present on a much more restricted set of cells and permit the presentation of extracellular antigens (Banchereau and Steinman, 1998). Multiple alleles of class I and II molecules exist and thus each individual has a unique set of MHC molecules (Beck and Trowsdale, 2000). DCs also express an array of nonpolymorphic receptors, termed Toll-like receptors (TLRs), and pattern-recognition receptors that bind microbial antigens (Geijtenbeek et al., 2004; Netea et al., 2004).

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Engagement of these receptors causes the DCs to upregulate expression of costimulatory molecules and to deliver an obligatory second signal for activation. It is important to note that each DC can recognize and respond to a broad spectrum of microbial antigens.

Each T cell and each B cell express a single receptor for antigen. These antigen receptors are acquired by gene rearrangements that occur in somatic cells (Gellert, 2002); thus, there is no inheritance of the T- or B-cell repertoire. T cells mature in the thymus. Each T cell expresses a unique receptor (TCR) that recognizes a molecular complex on the surface of an APC consisting of a class I or class II MHC molecule associated with a small peptide derived from an intra- or extra-cellular protein antigen, respectively. Signaling through both the TCR and costimulatory molecules is needed to effect activation of mature T cells (Bommhardt et al., 2004; Vallejo et al., 2004). B cells also express a single receptor for antigen, but the B-cell receptor (BCR) recognizes native antigen rather than processed antigen. B-cell activation also requires signaling through both the BCR and costimulatory molecules (Crow, 2004). Activated B cells not only secrete antibody, but can also function as APCs to engage a greater number of T cells in the immune response (Lipsky, 2001; Shlomchik et al., 2001).

A critical feature of both T and B cells is that they proliferate in response to antigenic stimulation to create clonal expansions of cells with a unique antigenic specificity and to develop cells with a memory phenotype (Bishop et al., 2003; Swain, 2003; Grossman et al., 2004). Memory cells have an accelerated and enhanced response following re-exposure to antigen. B cells have the added feature of undergoing random somatic mutation of the BCR and class switching of the immunoglobulin heavy chain gene (Li et al., 2004). Thus, there is a progression from low-affinity IgM antibodies to high-affinity IgG antibodies during the course of an immune response. The memory response reactivates the high-affinity IgG-producing B cells, whose repertoire is unique to each individual.

For the immune system to function effectively, there must be a sufficient number in both the naïve and memory repertoires of T and B cells that can respond to an enormous diversity of microbial antigens, and few, if any, cells that respond to self-antigen.

DEFINING AUTOIMMUNE DISEASE

An autoimmune disease is a condition in which tissue injury is caused by T-cell or antibody reactivity to self. The immune activation may be initiated by infection, but must persist in the absence of any detectable microbial antigen (Davidson and Diamond, 2001). It is important to state that although many diseases considered to be autoimmune diseases display antiself reactivity, evidence may still be lacking that the self-reactivity is, in fact, responsible for tissue damage. It is sometimes possible to determine whether autoantibodies are pathogenic by transferring them to a rodent host; however, T-cell reactivity is not transferable from humans to rodents because T-cell activation and T-cell effector function occur only in the context of self-MHC molecules. Thus, demonstrating the pathogenicity of the autoimmune response has not been accomplished in all autoimmune diseases. In some instances, a disease is presumed to be of autoimmune origin only because B- and T cells are present in affected tissue.

Animal models of autoimmune disease have been enormously useful in aiding our understanding of both disease inception and disease pathogenesis (Peutz-Kootstra et al., 2001; Howell, 2002; Lam-Tse et al., 2002; Hanninen et al., 2003; Wooley, 2004). Some models develop spontaneous disease. Others represent genetically modified mice that target a particular pathway in the immune response. Finally, some autoimmune diseases can be triggered in animals by immunization with self-antigen. While all these animal models have been very important in informing our understanding of autoimmunity, it is important to recognize that we do not know how closely they reflect human disease (Birmingham et al., 2001). Some of these models may be more similar to human disease in the effector mechanisms of tissue injury than in the mechanisms of induction of autoreactivity. Indeed, autoantibody-mediated tissue damage is probably most alike in human disease and animal models (Monach et al., 2004). It is also important to consider that there may be extensive heterogeneity in human disease and that the animal models we study intensively may reflect only a subset of individuals with a given disease. A challenge that confronts us is to understand which animal models are most similar to human disease, and can teach us most about the genetic predisposition to disease, disease pathogenesis, and effective therapy.

PREVALENCE OF AUTOIMMUNITY

It is striking that while each autoimmune disease individually affects only a small number of people, the prevalence of all autoimmune diseases is approximately 5% (Jacobson et al., 1997). Two critical facts about autoimmune disease are important in understanding the high frequency of these diseases. First, autoreactivity is an aspect of every normal immune system. In fact, the repertoire of immunocompetent lymphocytes that provides protective immunity is selected based on autoreactivity (Gu et al., 1991; Nobrega et al., 2002; Vallejo et al., 2004). Regulation of the autoreactivity helps shape the immune system (see below), so that it does not become the pathogenic autoreactivity associated with tissue damage, requires constant vigilance. The immune system maintains a precarious balance between the

two: too little response leads to potential neglect of danger, while an over-exuberant response can potentially lead to autoreactivity. How this balance is maintained is discussed below. Second, a genetic predisposition to autoimmunity exists in all individuals with an autoimmune disease and aspects of this predisposition may be similar for many different autoimmune diseases (Wakeland et al., 2001; Gregersen, 2003; Melanitou et al., 2003; Winchester, 2004). Autoimmune disease requires not just autoreactivity, but also target-organ vulnerability (Liao et al., 1995). Some of the recent studies of the genetic basis of autoimmunity show that the genetic factors governing specific organ vulnerability are distinct from those governing autoreactivity. Thus, individuals may share pathways promoting autoreactivity, yet present with different autoimmune diseases (Shamim and Miller, 2000; Henderson et al., 2000; Prahalad et al., 2002).

GENETICS OF AUTOIMMUNITY

It is clear from epidemiologic studies and studies of animal models of autoimmune disease that there is a genetic component to essentially every autoimmune disease. A few autoimmune diseases appear to be monogenic diseases. The human disease autoimmune-polyendocrinopathy-candidiasis-ectodermal-dystrophy (APECED), an autoimmune disease of multiple endocrine organs, is a consequence of a deletion in the AIRE gene that encodes a protein that causes tissue-specific genes to be expressed in medullary epithelial cells in the thymus (Pitkanen and Peterson, 2003; Gorman et al., 2004). These cells mediate negative selection of T cells reactive with peptides that derive from tissue-specific proteins. In the absence of AIRE expression, a spectrum of autoreactive T cells fails to be deleted; these cells mature to immunocompetence and mediate an immune attack on various organs. The absence of the AIRE gene appears sufficient for autoimmunity, although the phenotype of the disease that emerges, even within a single family, can be quite variable. Similarly, a defect in the Fas gene can also lead to autoimmunity. The Fas protein is expressed on activated lymphocytes. Engagement of Fas by Fas ligand leads to the death of the Fas-expressing cell, a process critical for downregulating the immune response. Individuals deficient in Fas expression have a disease called autoimmune lymphoproliferative syndrome (ALPS) characterized by an excess of T and B cells and by autoantibody production (Fleisher et al., 2001; Grodzicky and Elkon, 2002). Of note, not all individuals with deficient Fas expression display ALPS; thus, even in this disease other genes must modulate disease phenotype.

For most autoimmune diseases, multiple susceptibility loci must coexist for a disease phenotype to be apparent. Each locus is a region mapped by linkage analysis to the disease phenotype. Studies from mouse models of autoimmune disease have also revealed the presence of loci that suppress the autoimmune phenotype (Wakeland et al., 2001). Thus, an individual's risk of developing an autoimmune disease depends on a summation of susceptibility and resistance loci. It is possible that susceptibility to a particular autoimmune disease may be mediated by entirely distinct sets of genetic loci, although within the different loci there may be genes involved in the same or convergent cellular pathways. These considerations enormously complicate the genetic analysis of autoimmune disease.

Often the genetic basis of an autoimmune disease includes the expression of a particular HLA haplotype. For example, rheumatoid arthritis in the white population is highly associated with the expression of a set of DR4 alleles that have a particular structural motif, called the "shared epitope" (Winchester, 2004). Of note, other ethnic populations do not display this same association of DR4 alleles with rheumatoid arthritis (Gorman et al., 2004). A similar symptom complex can, therefore, arise from more than one etiopathogenic mechanism. Reactive arthritis occurs in individuals expressing B27 or, less commonly, B7 class I MHC molecules. Multiple sclerosis, systemic lupus, and diabetes display particular HLA associations, as do many other autoimmune diseases (Tomlinson and Bodmer, 1995; Wong and Wen, 2003; Winchester, 2004). While it is interesting to speculate that these HLA associations with autoimmune disease determine the antigens and antigenic peptides targeted by the autoimmune response, it is also clear that a number of non-MHC genes within or in linkage disequilibrium with the MHC locus help regulate the immune response (Djilali-Saiah et al., 1996; Gebe et al., 2002). These non-MHC genes also contribute to a genetic predisposition to autoimmunity.

Most susceptibility loci appear to represent extended disease-related haplotypes with a number of genes within each susceptibility locus contributing to the predisposition to autoimmunity (Djilali-Saiah et al., 1996; Morel et al., 2001). The identification of several loci and genes involved in autoimmunity has now been accomplished (Ueda et al., 2003; Russell et al., 2004). Evidence is emerging that genetic susceptibility can be a consequence of combinations of genes within each gene locus, and not the consequence of a single gene in each locus. In murine models, as susceptibility loci are analyzed, it is apparent that many genes within each locus affect pathways that promote autoimmunity. For example, a region on chromosome 1 is implicated in autoimmunity in systemic lupus erythematosus (Morel et al., 2001). Studies of murine lupus would suggest that certain alleles of Fc receptor genes, as well as non-Fc receptor genes in this locus, constitute a risk factor for disease (Tsao, 2003; Tarzi and Cook, 2003). Thus, while some epidemiologic studies have suggested that particular alleles of at least three genes contribute to the autoimmune diathesis in each individual, it is probable that many more genes are

in fact involved, but are positioned in a smaller number of distinct loci. Genes involved in lymphocyte survival, activation and downregulation have all been identified as risk factors for autoimmunity (Ravirajan and Isenberg, 2002). Thus, autoimmunity can result from a defect in almost any pathway of lymphocyte homeostasis, and many probably affect thresholds for negative selection of autoreactive lymphocytes.

Clinically, it has long been appreciated that autoimmune diseases cluster in families. The biologic basis for this observation is now clear; the same susceptibility genes can influence many different autoimmune diseases. For example, a polymorphism of CTLA-4, an inhibitory costimulatory molecule present on activated T cells, conveys risk for insulin-dependent diabetes, autoimmune hemolytic anemia, and Graves' disease (Ueda et al., 2003), while the CARD15 (NOD-2) gene is associated with both inflammatory bowel disease and psoriasis (Rahman et al., 2003; Russell et al., 2004). The differences in disease phenotype may lie in associated genes, those governing target organ susceptibility or those that modulate disease severity (Russell et al., 2004).

HORMONES AND AUTOIMMUNITY

Since many autoimmune diseases occur more commonly in women than in men, and autoimmunity in general is almost three times more common in women than in men, there have been several investigations of the role of sex hormones in autoimmune disease. It has been difficult to draw simple conclusions from these studies. Not all autoimmune diseases are more common in women. Some, such as ankylosing spondylitis, have a much higher incidence in men. Furthermore, the predisposition to autoimmunity can be sex determined or hormonally modulated; thus, the higher incidence of disease in women may not always reflect the influence of female hormones on the immune system. The evidence also shows that the effects of sex hormones differ in different diseases. While there is significant evidence that estrogen can exacerbate systemic lupus, estrogen seems to protect against rheumatoid arthritis. Additionally, estrogen or other sex hormones might affect target-organ antigen display or target-organ susceptibility to immune-mediated damage. Thus, there is no simple paradigm to explain the relationship between sex and autoimmunity (Grimaldi et al., 2005).

AUTOIMMUNITY AND CENTRAL TOLERANCE

The hallmark of autoimmune disease is the activation of self-reactive T and B lymphocytes. A major mechanism of self-tolerance is the elimination of self-reactive immature lymphocytes by antigen ligation of the TCR or BCR at critical stages of development. For autoimmunity to develop there must be a lack of stringency in the elimination of autoreactive cells. Because TCRs and BCRs are generated by random gene rearrangements that occur within the nucleus of the cell and are not determined by knowledge of the world of self or foreign antigen, autoreactive T and B cells arise routinely. To eliminate autoreactive cells and maintain self-tolerance, T and B cells routinely undergo a selection process during their maturation in primary lymphoid organs, the thymus and bone marrow, respectively (Rajewsky, 1996; Vallejo et al., 2004). B cells again undergo a second process of selection after somatic mutation of immunoglobulin genes, as somatic mutation routinely generates autoreactivity.

T cells that mature in the thymus and enter peripheral lymphoid organs must display TCRs with some affinity for self-peptide–self-MHC complexes in order to receive the necessary signals for survival, termed positive selection. T cells arising in the thymus that express TCRs lacking any affinity for the self-peptide–self-MHC complexes fail to undergo positive selection and die. T cells that are strongly reactive to self-peptide–self-MHC complexes are eliminated in a process termed negative selection. The threshold for both positive and negative selection represents a continuum. As the peptide–MHC complexes present in the thymus differ in each individual and the threshold for negative selection varies from individual to individual, each individual releases a different repertoire of antimicrobial and antiself reactive T cells to the periphery, each reflecting a different spectrum of foreign and self-peptide specificities (Werlen et al., 2003; Bommhardt et al., 2004; Vallejo et al., 2004). It is also probable that certain stimuli can rescue T cells.

B cells similarly undergo a process of negative selection prior to achieving immunocompetence. This process occurs in the bone marrow and continues in the spleen where B cells migrate as transitional cells after exiting the bone marrow (Davidson et al., 2002). Whether B cells require positive selection on self-antigen for survival and need to display some degree of autoreactivity remains an area of active investigation. It is clear, however, that highly autoreactive B cells are negatively selected on self-antigens encountered during early maturation, and again, the threshold for deletion is different for each individual (Monroe et al., 2003). Deletion occurs with the highest extent of BCR cross-linking; anergy occurs with less cross-linking. Thus, the degree of autoreactivity in the B-cell repertoire is also variable. Autoreactive B cells that have been signaled to undergo deletion can be rescued in a proinflammatory setting by engagement of costimulatory molecules on the B-cell membrane or by signaling through TLRs. Thus, the repertoire of naïve B cells will vary over time within an individual, with higher-affinity autoreactive B cells present

during times of infection or inflammation, and fewer, lower-affinity autoreactive cells present during times of immunologic quiescence.

AUTOIMMUNITY AND PERIPHERAL TOLERANCE

Negative selection of T and B cells occurs in the periphery as well as in primary lymphoid organs, permitting the removal of autoreactive cells that do not encounter autoantigen in the thymus or bone marrow. This process of negative selection is termed peripheral tolerance. Like central tolerance, it is mediated by engagement of the TCR or BCR in a noninflammatory setting (Defrance et al., 2002; Walker and Abbas, 2002). Although it has been traditional to debate whether autoimmunity results from a defect in central tolerance in the thymus or bone marrow, or in peripheral tolerance in secondary lymphoid organs, current knowledge of tolerance induction suggests that this may be an artificial distinction. Critical to both central and peripheral tolerance is engagement of the antigen receptor. While central and peripheral tolerance appear to differ in some features, it is likely that individuals with stringent negative selection have stringent negative selection in both central and peripheral lymphoid organs. Similarly, individuals with lax selection do not delete autoreactive cells effectively in either central or peripheral lymphoid organs. The idea that an autoimmune-prone individual has a general lack of stringency in tolerance might help explain why such individuals often have more than one autoimmune disease. In animal models, it is clear that poor negative selection in the naïve B- or T-cell repertoire is a condition for autoimmune disease (Ridgway et al., 1996; Lang and Bellgrau, 2002; Liossis and Zouali, 2004), and that laxity in negative selection can predispose to organ-specific autoimmunity of multiple organs. In summary, the thresholds for survival and deletion need to be set within appropriate limits. Too little deletion and autoreactivity ensues; too much deletion and the protective repertoire may be compromised. Any genetic change that reduces deletion may be a risk factor for autoimmunity.

ROLE OF ENVIRONMENTAL FACTORS

Environmental factors are also important triggers for expression of autoimmunity. Smoking, drug exposure, diet, chemical exposure, and sunlight have all been implicated as risk factors for particular diseases (Price and Venables, 1995; George et al., 1997; Knip and Akerblom, 1999; Steen, 1999; Cantorna, 2000; D'Cruz, 2000; Fournie et al., 2001; Moriyama and Eisenbarth, 2002; Debandt et al., 2003). Clearly, infection or antigen exposure can precipitate autoimmune disease. It has even been suggested that most autoimmune diseases represent the late sequelae of an infectious process (Pender, 2003; Varela-Calvino and Peakman, 2003). Proving this hypothesis has, however, been difficult. For some diseases, such as rheumatic fever, the causal connection between microbial infection, the antimicrobial response, and autoimmune disease is clearly established (Cunningham, 2003; Guilherme and Kalil, 2004). For other diseases, there is suggestive epidemiologic evidence in humans or evidence from animal models that autoimmunity can follow microbial infection, or T-cell or antibody cross-reactivity with both microbial and self-antigen has been identified (James et al., 2001; Kuon and Sieper, 2003; Strassburg et al., 2003). In general, researchers have sought to implicate particular infections in the pathogenesis of particular autoimmune diseases, but it is possible that for some autoimmune diseases there is more than one possible microbial trigger.

ACTIVATION OF THE IMMUNE SYSTEM

Activation of both T and B cells in the periphery requires that the cells receive two signals, one derived by ligation of the antigen receptor and the other by engagement of a co-stimulatory receptor. In general, when antigen enters the system, there is an activation of DCs, the critical APC in a primary immune response. This occurs because microbes express molecules that bind to pattern-recognition receptors or TLRs on the DC. The consequence of this binding is upregulation of the costimulatory molecules CD80 (B7.1) and CD86 (B7.2) on DCs, and transformation of the DC from resting, or tolerogenic (Steinman et al., 2003), to activated, or immunogenic (Hackstein and Thomson, 2004). T cells recognizing microbial peptide in either class I or class II MHC molecules on the immunogenic DC will be activated. Because some degree of autoreactivity is present in all T cells, each time a T cell is activated by a foreign-peptide–self-MHC complex, that activated T cell may also recognize a self-peptide–self-MHC complex. It is a feature of memory T cells that they can be activated by a lower-affinity interaction with the TCR than is required to activate primary T cells (Welsh et al., 2004). Thus, a T-cell that is not activated by a self-peptide–self-MHC complex while still a naïve cell may be activated by that complex once it becomes a memory T cell. Memory T cells may, therefore, be autoreactive in a proinflammatory setting.

There are many examples in the literature of a T-cell derived from an individual with autoimmune disease that recognizes both a microbial peptide and a self-peptide. This cross-reactivity is termed molecular mimicry, and represents a mechanism by which autoimmunity can be triggered by

infection (Albert and Inman, 1999; Wekerle and Hohlfeld, 2003). The hypothesis that molecular mimicry predisposes to autoimmunity clearly has validity in rodent models of autoimmune disease, and suggests that laxity in selection of the naïve T-cell repertoire can be a major contributor to autoimmunity. Those individuals with less stringent negative selection will have multiple T cells that can be activated by foreign antigen and will also display pathogenic autoreactivity.

The activated T cell provides T-cell help or costimulatory signals to B cells that are encountering microbial antigen. B cells that bind both microbial antigen and self-antigen will ingest, process, and present epitopes of self-antigen, which can then be recognized by T cells. Because B cells often process antigen to different peptides than do DCs, the B cells can present novel epitopes of self-antigen and activate T cells with novel autospecificities (Sercarz et al., 1993; Bockenstedt et al., 1995; Yan and Mamula, 2002). These cross-reactive B cells will, therefore, contribute to a cascade of autoreactivity, as they activate an expanded repertoire of T cells. The B-cell repertoire, therefore, critically influences the T-cell repertoire. The fewer autoreactive B cells present, the less presentation of self-antigen to T cells.

DOWNREGULATION OF AN IMMUNE RESPONSE

The induction of an immune response needs to be followed by a downregulation or elimination of many of the cells that have undergone clonal expansion. A major observation of recent studies of autoimmune disease is that a defect in the restoration of immune homeostasis, or in downregulation of an immune response, can be a risk factor for autoimmunity. Since all reactivity with foreign antigen includes reactivity to self-antigen, antiself responses are routinely generated in the process of mounting an immune response to foreign antigen. The potential pathogenicity of the autoimmune response will vary from individual to individual. In general, however, the mechanisms that exist to dampen the immune response also diminish the autoreactivity, and even potentially pathogenic autoreactivity is downregulated. B and T cells are routinely downregulated as soon as they are activated. For the B cell, this occurs, in part, by cross-linking of the BCR and FcRIIB by antigen–antibody complexes. When FcRIIB is absent or deficient, autoantibody production is poorly controlled (Ravetch and Bolland, 2001; Samuelsson et al., 2001). Multiple coinhibitory molecules are expressed on activated T cells. Interaction with their receptors transduces an inhibitory signal to the T cells, signaling them to downmodulate their response. There is also some evidence that engagement of CD80 (B7) on the APC by the T-cell coinhibitory molecule CTLA-4 transduces an inhibitory signal to the APCs. Mutations in two coinhibitory molecules, PD1 and CTLA-4, are associated with several autoimmune diseases (Chen, 2004; Khoury and Sayegh, 2004). Both B and T cells are also susceptible to activation-induced cell death mediated through Fas–Fas ligand interactions (Brunner et al., 2003; Li-Weber and Krammer, 2003). Defects in this process can lead to autoimmunity.

Thus, controlling the immune response is critical to normal homeostasis of the immune system and is mediated by multiple inhibitory pathways. A major component of autoimmune disease in some individuals may be a defect in the suppression of immune activation.

REGULATORY T CELLS

Another area of intensive study is the characterization and mechanisms of action of populations of regulatory cells. Many years ago, any discussion of autoimmune disease necessarily included a discussion of suppressor T cells. The study of suppressor T cells fell into temporary disrepute, but has been recently reinvigorated and several populations of regulatory T cells have now been identified, some of which arise during thymic development and others are induced by antigen exposure in the periphery (Cottrez and Groux, 2004). Natural killer (NK) T cells recognize lipid antigens in CD1 molecules (Brigl and Brenner, 2004). There is evidence in some diseases that a decrease in this population precedes the onset of autoimmunity. There is also evidence that a change in cytokine profile of this subset, particularly a loss of interleukin (IL)-4 production, associates with disease onset (Poulton and Baxter, 2001). In the nonobese diabetic (NOD) mouse model, it has been shown that activation of NK T cells with a synthetic ligand can prevent the progression to diabetes (Wang et al., 2001). There is also a population of $CD4^+/CD25^+$ (γ chain of the IL-2 receptor) T cells that mature in the thymus and appear to be critical in suppression of autoimmunity. These cells express the transcription factor Foxp3 and the cell surface receptor GITR, which distinguishes them from activated T cells that also express CD25. They suppress effector T cells in a cell contact-dependent but non-antigen-specific manner; it is possible that they also suppress APCs (Fontenot and Rudensky, 2004; Sakaguchi, 2004). They have been demonstrated to decline in number prior to overt diabetes in NOD mice and diabetes can be delayed by an infusion of these cells (Tang et al., 2004; Tarbell et al., 2004).

Other studies have identified a population of CD8 suppressor cells that may directly lyse autoreactive cells or may secrete immunosuppressive cytokines (Cortesini et al., 2001; Filaci and Suciu-Foca, 2002). Cells expressing the immunosuppressive cytokines transforming growth factor (TGF)-β (Th3 cells) (Weiner, 2001) or IL-10 (TR1 cells) (Roncarolo et al., 2001) arise under particular condi-

tions of antigen exposure and once activated, mediate non-antigen-specific suppression.

It is now apparent that a bias to the development of Th1 cells is present in most autoimmune diseases. Because Th2 cells control the activation of Th1 cells, the activation of Th2 cells can diminish autoimmunity in murine models of disease, regardless of whether the tissue damage is mediated by antibodies or by T cells (Dong and Flavell, 2001; Hill and Sarvetnick, 2002; Sugimoto et al., 2002; Szabo et al., 2003; Ghoreschi and Rocken, 2004; Gomez et al., 2004; Milani et al., 2003; Wurtz et al., 2004). There is some evidence that low doses of antigen preferentially activate Th2 cells (Boonstra et al., 2003). It is interesting to speculate that self-antigen is often presented in limiting amounts and leads preferentially to the activation of self-reactive nonpathogenic Th2 cells.

There are multiple populations of regulatory cells, any one of which may be deficient in autoimmune disease. The balance between effector cells and regulatory cells may determine whether an autoreactive response that arises in the course of microbial exposure is terminated or perpetuated. Since intense immunosuppression may inactivate both effector and regulatory T cells, new approaches to the therapy of autoimmunity may be directed at finding ways to inhibit effector cells, while allowing regulatory cells to expand.

ROLE OF ANTIGEN AS A DRIVER OF AUTOIMMUNITY

A major question in autoimmune disease is whether the process is autonomous or driven by antigen, and if the latter whether the antigen is self-antigen or foreign antigen. Animal models of disease definitively show that molecular mimicry following activation by microbial antigen can initiate autoreactivity (Cunningham, 2003; Kuwabara, 2004; Olson et al., 2004).

There are also data suggesting that self-antigen drives the autoimmune response. First, in animal models of systemic lupus, it appears that an excess of apoptotic cells or a problem in their clearance can result in a lupus-like serology with antichromatin reactivity (Liu et al., 2004). Current understanding would suggest that apoptotic debris can activate TLRs and transform tolerogenic DCs into immunogenic APCs, as well as activate B cells (Leadbetter et al., 2002; Lovgren et al., 2004).

Second, extensive tissue damage can lead to the presentation of normally sequestered self-antigen in a proinflammatory setting (Horwitz et al., 2002; Liu et al., 2002; Vezys and Lefrancois, 2002). The proinflammatory setting may be enhanced by apoptosis of cells following tissue insult. This can clearly lead to an autoimmune response. Whether in some individuals this response is perpetuated because of a lack of appropriate restoration to homeostasis is an important question.

Finally, polymorphisms in autoantigens may also constitute risk factors for autoimmune disease (Suzuki et al., 2003; Pauza et al., 2004). As the genetic susceptibility to autoimmune disease is further explored, it will become more apparent the degree to which molecular mimicry, aberrant expression of autoantigens, or exposure to previously sequestered antigen in an immunogenic setting contributes to disease.

MECHANISMS OF TISSUE DAMAGE

Studies over the past decade have clearly demonstrated that the mechanisms that incite autoimmune disease may differ substantially from the mechanisms that propagate tissue damage. Autoreactive T and B cells that are activated in secondary lymphoid organs and initiate disease may have a different cytokine profile from the effector cells that migrate into target organs and cause tissue fibrosis (Campbell et al., 2001). Thus, it is clearer and clearer that at each stage of autoimmune disease, induction of autoreactivity and tissue destruction need to be separately explored, and that the previous characterization of certain cytokines as proinflammatory and others as anti-inflammatory may be misleading. While TGF-β may dampen the induction of autoreactivity, it may hasten tissue fibrosis (Letterio and Roberts, 1998). Similarly, IL-10 is anti-inflammatory during disease initiation through its inhibitory effects on APCs, but can drive T-cell proliferation, immunoglobulin class switching, and antibody production later in disease (Mocellin et al., 2004). Even the proinflammatory cytokine interferon-γ can have anti-inflammatory properties in the early stages of some autoimmune diseases (Billiau, 1996; Grohmann and Puccetti, 2002; Rosloniec et al., 2002). It is perhaps important, as we move forward in studies of autoimmune disease, to consider the mechanism of both immune activation and tissue destruction, and to be aware that cytokines, hormones or other mediators may exhibit differential effects in each process. Studies of animal models have now clearly shown that it is possible to intervene in disease progression to protect organs from immune-mediated destruction, even while autoreactivity continues unabated (Clynes et al., 1998; Schiffer et al., 2002).

FLARES AND REMISSIONS DURING DISEASE

The vast majority of animal models of autoimmune disease represent chronic progressive disease activity. Once the autoimmune disease becomes manifest, it progresses to organ failure or death. Much human autoimmune disease, in

contrast, is characterized by periods of disease remission and flare. Little is known in human disease about the cellular events that lead to disease remission. It is also true that little is known regarding the cause of disease flares. A major area of ignorance concerns the cell type responsible for disease flares. It is not known whether flares represent a de-novo activation of naïve autoreactive cells or a reactivation of quiescent memory cells. Our ignorance in this regard derives largely from the difficulty of sampling a large repertoire of autoreactive T or B cells. Often, these cells are poorly represented in peripheral blood (Newman et al., 2003; Reddy et al., 2003; Reijonen et al., 2003, Bischof et al., 2004). Even when present in blood, and therefore accessible to analysis, they may be so infrequent that their analysis represents a major challenge.

THERAPEUTIC IMPLICATIONS

Current global immunosuppressive therapies remain overly toxic, and do not reflect our new understanding of autoimmune disease. Autoimmunity can result from defects either in repertoire selection or in immune regulation. The idea that autoimmune disease may be caused by excessive laxity in tolerance induction, either centrally or peripherally, or by inadequate downregulation of an immune response that has been engendered by microbial invasion or by tissue injury has therapeutic implications. The current therapies of autoimmune disease are based on a perceived need to institute immunosuppression and anti-inflammatory therapy at the time of autoimmune tissue destruction. Our most updated understanding of autoimmunity would suggest that it might be more appropriate to consider treating disease during times of disease quiescence. The goal of this therapeutic approach would be to alter T- and B-cell repertoire selection. One pathway to target for modulation of the repertoire is the TCR or BCR signaling pathway; increasing the signal delivered to naïve T and B cells may lead to greater stringency of negative selection with lower-affinity autoreactive cells maturing to immunocompetence. This might decrease autoimmunity without causing global immunosuppression. Currently, antigen-specific therapies remain a dream.

Multiple pathways of immune activation, including costimulatory pathways, and TLR and pattern-recognition receptor signaling pathways can be targeted to reduce activation of the immune system. Altering pathways involved in downregulation of the immune response is also an attractive therapeutic strategy. During periods of disease quiescence it may be possible to drive the expansion of regulatory cells. Maintaining an ample number and function of regulatory T-cell subsets either *in vivo* or through *ex vivo* manipulations of cells is a therapeutic approach poised to move soon from the realm of fantasy to that of reality.

Protecting target organs and preventing irreversible tissue damage will require different therapeutic strategies from blocking the induction of autoreactivity. These new therapeutic approaches offer the hope of maintaining immunocompetence while eliminating the consequences of pathogenic autoreactivity. The era of a uniform approach to therapy with intense immune ablation to treat autoimmunity may soon be over.

GOALS FOR THE FUTURE

Over the past several years, new technologies have been developed that will substantially increase our understanding of autoimmune disease. The development of microarray technology, which makes it possible to determine the level of expression of a very large number of genes or proteins in defined populations of cells, will provide new insights into disease pathogenesis and new ways to phenotype patients with autoimmune disease. These technologies are highly likely to provide sets of biomarkers that will help determine risk for developing a particular disease, characterize current activity of the disease and disease prognosis, and predict response to therapy. Already, data from microarray analyses of gene expression in peripheral blood cells suggest that systemic lupus and Sjögren syndrome share an "interferon signature" characterized by high expression of a number of interferon-inducible genes (Baechler et al., 2003; Bennett et al., 2003); rheumatoid arthritis, in contrast, is characterized by a different pattern of gene expression (van der Pouw Kraan et al., 2003). It is reasonable to predict that patterns of gene and protein expression will reveal differences and similarities among autoimmune disease. We can also look forward to the identification of subsets of patients within a given disease. Distinct patterns may distinguish patients with impending flares and may be an early marker of response to therapy.

The development of biomarkers will, undoubtedly, improve the therapy of autoimmune disease. It may be possible to identify early those patients whose disease is likely to be severe and to monitor disease activity without waiting for clinical symptomatology. Ultimately, it may be possible to customize therapy for each patient, thereby enhancing therapy and avoiding unnecessary toxicities.

CONCLUDING REMARKS

The past several years have witnessed a change in our understanding of autoimmunity and a clear new direction in our approach to the study of autoimmunity. It now seems most useful to consider autoimmunity as a failure in T- and B-cell repertoire selection or a failure in the regulation of activated T and B cells. It is also clear that autoimmunity

needs to be coupled to target-organ vulnerability to immune attack for autoimmune disease to be present. This understanding suggests new therapeutic targets, and new therapeutic strategies.

The focus on new technologies to provide biomarkers of immune function represents an exciting opportunity to treat disease prior to tissue damage and to customize therapy for each patient. Furthermore, studies of gene and protein expression will help elucidate those mechanisms of immune dysfunction that are shared among multiple autoimmune diseases and those that are unique to a particular disease. Thus, there are reasons to be optimistic, but acquiring the necessary new knowledge and translating that knowledge to therapy will take many years.

CHAPTER

4

Antigen Presentation, Dendritic Cells, and Autoimmunity

MURIEL MOSER

Laboratoire de Physiologie Animale, Institut de Biologie et Médecine Moléculaires, Université de Bruxelles, Gosselies, Belgium

Dendritic cells (DCs) were identified in the spleens of mice in 1973 and named after their branch-like projections (from δενδρεον, tree) (Steinman and Cohn, 1973). They were subsequently shown to be the most potent stimulators of the primary mixed leukocyte reaction. Their unique capacity to sensitize naïve T cells *in vitro* and *in vivo* was amply documented in the following years.

Although cells with a dendritic structure were visualized in the skin in 1868 by a young medical student, Paul Langerhans, it took more than a century before they were identified as cells from the dendritic family. The relationship between epidermal Langerhans cells and DCs was demonstrated when they were shown to mature into potent immunostimulatory DCs *in vitro*. Schuler and Steinman (1985) showed that Langerhans cells resemble spleen DCs when cultured for 2–3 days, and undergo a progressive increase in stimulatory capacity, becoming 3–10 times more stimulatory than spleen DCs.

The DC family includes many members which reside in most tissues of the body and display unique properties that have not been described for other antigen-presenting cells (APCs): 1) dendritic morphology on activation; 2) motility; 3) specialization of function over time—during a phenomenon called maturation, they shift from an antigen-capturing mode to a T-cell sensitizing mode; 4) elevated expression of major histocompatibility complex (MHC) molecules and intermediate-to-high expression of costimulatory molecules; and 5) production of cytokines.

DENDRITIC CELLS IN IMMUNITY

Immature DCs are ideally equipped to sensitize T lymphocytes specific for dangerous antigens encountered earlier in the periphery. They act as sentinels for infections in peripheral tissues and then migrate to the lymphoid organs where they transmit information regarding the nature of the pathogens and the lymphoid tissues, and activate lymphocytes specific for those microbial antigens. At the immature stage, DCs exhibit potent endocytic activity: they constitutively macropinocytose extracellular fluids, and express various receptors specific for non-self-antigens. DCs do not present antigen immediately after uptake but express the

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

immunogenic class II MHC–peptide complexes only after maturation. This delay in antigen presentation confers to DCs the capacity to display, in the lymphoid organs, antigens encountered earlier in peripheral tissues (Mellman and Steinman, 2001). Interestingly, DCs display some "fidelity" to the antigen encountered in inflammatory conditions (inducing their maturation) as they lose their capacity to capture and process antigens during this process.

The potent accessory properties of DCs appear to develop sequentially. In particular, the ability to process antigens and to sensitize naïve T cells develops in sequence during their maturation. This process is associated with upregulation of MHC restriction elements and costimulatory molecules, as well as production of stimulatory cytokines. The maturation of DCs is usually coupled to their movement to the zone where T cells are located in the lymphoid organs. The colocalization of fully competent DCs with lymphocytes is required for the engagement of membrane-bound ligand–receptor pairs required for optimal T-cell priming and is likely to represent the first step in the immune response.

It is noteworthy that the maturation of DCs is often induced by microbial constituents and inflammatory cytokines, thereby favoring the activation of T cells specific for non-self-infectious antigens. In particular, DCs express several receptors, including Toll-like receptors (TLRs), which recognize conserved pathogen-associated molecular patterns. It is interesting that TLRs control activation of the adaptive immune responses by inducing DC maturation (Schnare et al., 2001). However, it is likely that those mature DCs not only express antigens taken up at the site of infection but also self-antigens that are continuously processed and presented in the context of MHC class I and II molecules. This would imply that fully competent DCs may sensitize autoimmune T cells that have escaped negative selection in the thymus. Recent reports suggest that DCs trigger several lifeguard mechanisms that may prevent the onset of autoimmunity in peripheral tissues, including regulation of antigen presentation (DC lifespan), peripheral deletion or anergy of autoreactive T cells, induction/maintenance of regulatory T cells, and a novel mechanism which implies tuning of activation threshold (see below).

REGULATION OF DENDRITIC CELL LIFESPAN

The lifespan of new migrant dendritics in the lymphoid organs is a key issue in the induction of immunity. The imaging of T-cell–DC interactions in lymph nodes (Stoll et al., 2002) revealed that T cells form long-lived associations with a single APC and show evidence of activation only after 36–48 h. In agreement with these observations, the migration of DCs has been shown to strongly impact the magnitude and quality of $CD4^+$ T-cell responses, which are proportional to the number of antigen-carrying DCs that reach the lymph node (Martin-Fontecha et al., 2003). High numbers of DCs would increase the probability of a DC–T-cell encounter, favor a sustained stimulation through presumably monogamous interactions, and reduce competition among T cells.

The outcome of mature DCs in lymph nodes has long remained elusive. Injection of lipopolysaccharide (LPS) has been shown to induce the phenotypic and functional maturation of splenic DCs and their rapid (6 h) migration in the T-cell zone. Twenty-four hours after LPS injection, very few $CD11c^+$ cells remained in the spleen in contact with T-lymphocytes (De Smedt et al., 1996). The selective loss of $CD11c^+$ cells was found to correlate with the presence of apoptotic cells, as assessed by TUNEL staining on spleen sections. Injection of ovalbumin (OVA) peptide in OVA-specific, T-cell receptor (TCR)-transgenic mice strongly delayed the LPS-induced programmed cell death *in situ*, suggesting that T lymphocytes may rescue DCs presenting their own antigen (De Smedt et al., 1998).

The programmed cell death could be an autonomous mechanism or could be triggered by other cell populations. The hypothesis that DCs have discrete stages of life and that mature DCs are programmed to die is supported by the observation that growth-dependent long-term cultures of DCs display three stages of maturation: immature, mature, and apoptotic (Rescigno et al., 1998). Interestingly, a recent report (Hou and Van Parijs, 2004) indicates that mature DCs have a shorter lifespan than immature ones. Thus, TLRs and T-cell costimulatory molecules both triggered a DC survival pathway that was dependent on Bcl-x_L. However, TLR engagement later triggered DC apoptosis through upregulation of the proapoptotic Bcl-2 family member Bim. The ratio of Bim/Bcl-2 expressed in DCs treated with LPS or lipoteichoic acid (LTA) increased between day 1 and 4 in culture, resulting in an inversion of the ratio of antiapoptotic-to-proapoptotic proteins expressed by DCs stimulated through TLRs. The existence of a "molecular timer" set by TLR ligands shows that the apoptosis of mature DCs is an active process. Of note, DCs cultured with LPS ± agonistic anti-CD40 monoclonal antibodies similarly undergo apoptosis, suggesting that the timer is dominant over the expression of antiapoptotic molecule Bcl-x_L increased by T-cell signals. Which (if any) signal(s) from the adaptive immune response may rescue DCs from premature death induced by the innate system remains to be determined (Moser, 2004).

DENDRITIC CELLS IN TOLERANCE

T-cell tolerance to self-antigens is considered to reflect a combination of central and peripheral tolerance. Central tolerance leads to deletion of immature T cells in the thymus and is largely responsible for eliminating autoreactive T cells. However, the limited expression of tissue-specific antigens in the thymus suggests that additional mechanisms

may exist in the periphery that silence autoreactive T cells.

Thymic Dendritic Cells and Negative Selection

To evaluate the relative capacities of epithelial or bone marrow-derived cells in inducing apoptosis or positive selection, Brocker et al. (1997) generated a transgenic mouse model in which they targeted gene expression specifically to DCs. They used the CD11c promoter to express MHC class II I-E molecules specifically on DCs of all tissues (these mice will be referred to as B6CD11c-Eα^d). The selective expression of I-E on thymic DCs, but not cortical or medullary epithelial cells, B cells, or macrophages, allowed it to be tested whether thymic DCs *in vivo* would be capable of inducing clonal deletion. The frequency was measured of I-E reactive V$\beta5^+$ and V$\beta11^+$ T cells in C57BL/6 control mice, B6-Eα^d mice (a transgenic line expressing I-Eα^d under the control of a segment of the I-E MHC class II promoter) or B6CD11c-Eα^d mice. In B6-Eα^d mice, 65% of CD4$^+$ V$\beta5^+$ T cells and more than 95% of V$\beta11^+$ CD4$^+$ T cells were deleted. Of note, a similar degree of deletion was observed in the B6 CD11c-E_α^d strain, suggesting that the thymic DCs were the most potent cell type in eliminating self-reactive T cells, and that MHC class II expression on the epithelium or other bone marrow-derived cells was not necessary for complete clonal elimination of I-E-reactive T cells in the CD4$^+$ compartment. In addition, the same group demonstrated that thymic DCs *in vivo* were not able to induce MHC restriction of CD4$^+$ T cells, i.e., positive selection.

It remains to be determined, however, how thymic DCs express autoantigens, including tissue-restricted antigens. Although the transcription factor AIRE has been shown to promote ectopic expression of peripheral tissue-restricted antigens in the thymus, there is evidence that AIRE must be expressed in the stromal cells of the thymus (rather than in hematopoietic cells) in order to control autoimmunity in the periphery (Anderson et al., 2002). An interesting possibility would be that thymic epithelial cells may focus their self-antigen display on peripheral self, whereas DCs may be specialized to induce tolerance to hematopoietic self (Derbinski et al., 2001).

Peripheral Tolerance

For 25 years, immunologists have focused their attention on the role of DCs as adjuvant, and it was generally agreed that the principal function of DCs was to initiate T- and B-cell-mediated immunity. However, more recent observations convincingly suggest that DCs may play an active role in peripheral tolerance.

Heath and colleagues studied the outcome of constitutive class-I restricted exogenous presentation of self-antigens *in vivo* (Kurts et al., 1996). They used the rat insulin promoter (RIP)-mOVA transgenic mouse model, where a membrane-bound form of OVA was expressed by pancreatic β cells, kidney proximal tubular cells, the thymus, and the testis of male mice. Transfer of OVA-specific CD8$^+$ T cells led to the activation of these cells in the draining lymph nodes. This was due to class I-restricted cross-presentation of exogenous OVA on a bone marrow-derived APC population. To identify the cross-presenting cell, the authors created transgenic mice where MHC class I expression was driven selectively in DCs, and demonstrated that DCs were sufficient to cross-present self-antigens *in vivo* (Kurts et al., 2001). Interestingly, CD8$^+$ T cells activated by cross-presentation were deleted from the peripheral pool of recirculating lymphocytes. These observations suggested that APCs may be tolerogenic, and provided evidence for an extrathymic mechanism capable of inducing the loss of CD8$^+$ T-cells responding to self-antigens expressed in tissues outside the lymphoid compartment.

Although the nature of the tolerogenic DC population remains elusive, the role of potential candidates has been highlighted, including immature DCs, DCs maturing under noninflammatory conditions, specialized subsets of DCs, and DCs expressing indoleamine 2,3-dioxygenase.

Steady-State Dendritic Cells

A number of observations suggest that steady-state DCs may play a role in peripheral tolerance. First, several studies in mice and humans reported that injection of DCs exposed *ex vivo* to antigen but not to full maturational stimuli induces a state of hyporesponsiveness. In humans, Jonuleit et al. (2000) used immature DCs derived from monocytes cultured in granulocyte-macrophage colony-stimulating factor (GM-CSF) plus interleukin (IL)-4, which were induced to mature by providing a defined cytokine cocktail. As expected, mature DCs induced the expansion of T cells with a polarization towards Th1. In contrast, repetitive stimulation of naïve cord blood-derived T cells with allogeneic immature DCs resulted in the development of a population of non-expanding and IL-10-producing T cells. These regulatory T cells displayed suppressor function, in an antigen-nonspecific manner and independently of CTLA-4, IL-10, and transforming growth factor (TGF)-β. *In vivo*, Dhopdakar et al. (2001) analyzed the immune response induced after injection of immature DCs pulsed with influenza matrix peptide and keyhole limpet hemocyanin in two healthy subjects. A decline in matrix-specific interferon (IFN)-γ-producing T cells was observed, whereas such cells were detected before immunization as expected, because most adults have been exposed to the influenza virus. The decline in IFN-γ production was associated with the development of IL-10-producing cells specific for the same antigen.

Second, studies using inducible expression and presentation of lymphocytic choriomeningitis virus-derived epitopes

by resting or activated DCs *in vivo* confirmed that DCs may induce immunity and tolerance depending solely on their activation status. Probst et al. (2003) have used a Cre/LoxP-based system that allows inducible antigen presentation by DCs *in vivo* to study the immunologic consequences of antigen presentation by resting versus mature DCs without adoptively transferring DCs, and with physiologic numbers of endogenous, naïve responder T cells. The authors found that presentation of lymphocytic choriomeningitis virus (LCMV)-derived cytotoxic T lymphocyte (CTL) epitopes by steady-state DCs resulted in antigen-specific tolerance, whereas antigen presentation by activated DCs led to priming of endogenous CTL with expansion and development of protective effector function.

Third, antibodies directed against DEC-205 have been used to target an antigen on immature DCs. DEC-205 is an endocytic receptor highly expressed by DCs and which carries antigens into intracellular antigen-processing compartments. Early studies have shown that targeting hen-egg lysozyme (HEL) and OVA antigens to steady-state DCs *in vivo* (peptides were engineered into the heavy chain of the anti-DEC-205 antibody) resulted in tolerance (Hawiger et al., 2001). Injection of engineered anti-DEC-205 resulted in transient activation followed by a severe reduction in the number of antigen-specific T cells within 7 days, and the residual T cells became unresponsive to challenge with OVA in complete Freund adjuvant. By contrast, coinjection of the DC-targeted antigen and anti-CD40-activating antibody led to prolonged activation and immunity. Mahnke et al. (2003) subsequently reported that OVA protein coupled to anti-DEC antibodies and injected into mice led to antigen presentation restricted to CD11c cells and initial expansion of antigen-specific T cells. However, these cells were subsequently anergized and expressed CD25 and CTLA-4 antigen, the phenotypic hallmark of regulatory T cells. Functional analysis of this cell population showed that $CD25^+$ T cells could suppress proliferation and IL-2 production of conventional T lymphocytes in a cell–cell contact-dependent way.

Targeting DCs in the steady-state (at least through DEC-205) can induce peripheral tolerance not only for $CD4^+$ but also for $CD8^+$ T cells. Bonifaz et al. (2002) reported that anti-DEC-205 chemically coupled to full-length OVA delivered the protein selectively to DCs *in vivo* and mediated presentation of protein antigen via the exogenous but TAP-dependent MHC I pathway. Subcutaneous injection of anti-DEC-205:OVA induced four to seven cycles of division of transferred TCR transgenic $CD8^+$ cells, but the cells were then deleted, leading to a state of antigen-specific tolerance.

Using a similar antigen-delivery system for an autoantigen, Hawiger et al. (2004) described a novel mechanism whereby DCs induce unresponsiveness associated with dynamic inhibition of secondary rather than primary responses. Targeting a peptide of myelin oligodendrocyte glycoprotein (MOG) through anti-DEC antibodies (engineered to express MOG) induced profound T-cell tolerance to MOG and prevented induction of experimental autoimmune encephalomyelitis (EAE). Of note, a novel mechanism of tolerance has been shown to account for the lack of responsiveness: indeed, the authors found that T cells tolerized by steady-state DCs remained highly responsive to TCR stimulation *in vitro* but failed to respond to antigen *in vivo*. Also of note, expression of CD5 was found to be enhanced on antigen-specific peripheral T cells in these mice and the tolerance appeared to be CD5 dependent. CD5 is a negative regulator of TCR signaling, which directly influences the threshold of activation of thymocytes, suggesting that tolerance may result from a "tuning" of signaling thresholds in the periphery. Therefore, autoimmune T cells may lose their reactivity following exposure to persistent self-antigens. $CD5^{hi}$ T cells did not inhibit activation of naïve T cells to the same antigen *in vivo* and could not regulate naïve cells in cotransfer experiments.

The physiologic role of immature DCs in peripheral tolerance *in vivo* (through T-cell anergy or differentiation of regulatory T cells) is challenged by the general acceptance that DC migration to lymphoid organs is necessarily coupled to their maturation. The chemokine receptors CCR6 and CCR7 are inversely regulated during maturation, and CCR7 has been shown to direct maturing DCs to the T-cell zone of lymphoid follicles which expresses MIP3β (Dieu-Nosjean et al., 2000). However, there is increased evidence that DCs capture and transport tissue-specific self-antigens even in the steady-state. Veiled cells transport tissue-specific antigens to the lymph nodes (Bujdoso et al., 1989), migrating Langerhans cells contain melanosomes (Mishima, 1966), and DCs of the gastric lymph nodes constitutively present parietal cell-restricted H^+/K^+-ATPase in healthy mice (Scheinecker et al., 2002). Huang et al. (2000) have identified a DC subset that constitutively transports apoptotic intestinal epithelial cell remnants to T-cell areas of mesenteric lymph nodes *in vivo*. These cells are weak APCs and contain cytoplasmic apoptotic DNA and epithelial cell-restricted cytokeratins. In the lung, Vermaelen et al. (2001) reported a steady-state flux of DCs that transport macromolecules from the airways to the thoracic lymph nodes. Collectively, these observations suggest that immature DCs are good candidates as tolerogenic DCs capable of inducing peripheral T-cell unresponsiveness.

(Semi)-Mature Dendritic Cells

Although the tolerogenic potential of DCs was first proposed to correlate with their immature state, several reports have described populations of (semi)-mature DCs that induce tolerance *in vivo*. Menges et al. (2002) showed that

repetitive injections of semi-mature DCs, pulsed with an autoantigenic MOG peptide, could induce protection from EAE in mice. Maturation by TNF-α induced high levels of MHC class II and costimulatory molecules on DCs, which remained weak producers of proinflammatory cytokines. The protection was antigen specific and partially dependent on IL-10. Of note, immature DCs (generated in the presence of IL-10) did not influence the score of the disease under the same conditions. Similarly, mature pulmonary DCs induce the development of regulatory T cells in the bronchial lymph nodes of mice exposed to respiratory allergen. This process required T-cell costimulation via the inducible costimulator (ICOS)-ligand pathway and regulatory T cells produced IL-10 and blocked the development of allergen-induced airway hyperreactivity. Similarly, McGuirk et al. (2002) reported that the filamentous hemagglutinin (FHA) of *Bordetella pertussis* modified cytokine production and costimulatory molecules (increased CD86 and moderately enhanced CD40) expression on DCs drove DCs into a phenotype that could selectively enhance the induction of type 1 regulatory T (Tr1) cells *in vitro* (see below). Tr1 cells specific for FHA and pertactin were induced at the mucosal surface in the lungs of mice during acute infection with *Bordetella pertussis* (McGuirk et al., 2002). These Tr1 cells secreted high levels of IL-10 and inhibited protective type 1 helper T (Th1) cell responses against *Bordetella pertussis in vitro* and *in vivo*. Of note, the authors reported that FHA interacted directly with DCs to induce IL-10, and inhibit IL-12 and inflammatory chemokine production.

Lutz and Schuler (2002) have proposed that the semi-mature DCs correspond to the steady-state DCs which constitutively migrate to the lymphoid organs. This developmental stage would be considered as mature according to their surface marker analysis (high expression of MHC II and costimulatory molecules), but immature since they do not release high levels of proinflammatory cytokines. In some cases, the production of IL-10 may participate in their tolerogenic properties. This hypothesis postulates that tissue-resident DCs (immature) and steady-state migrating DCs are different, and that some degree of maturation would be required for mediating homeostatic DC migration. The respective role of immature and partially mature DCs in peripheral tolerance remains unclear and deserves further attention.

Indoleamin 2,3-Dioxygenase-Expressing Dendritic Cells

The role of indoleamin 2,3-dioxygenase (IDO) in the regulation of immune responses has been highlighted by Munn et al. (1998) who demonstrated that IDO expression at the maternal–fetal interface was necessary to prevent immunologic rejection. Thus, treatment of pregnant mice with a pharmacologic inhibitor of IDO resulted in rapid T-cell-induced rejection of all allogeneic concepti, suggesting that the fetus suppresses maternal T-cell immunity by catabolizing tryptophan.

It was subsequently reported that one mechanism by which APCs may regulate T-cell responses is through the expression of IDO. In particular, a subset of human monocyte-derived DCs has been shown to use IDO to inhibit T-cell proliferation *in vitro* (Munn et al., 2002). Although maturation has no effect on the basal expression of IDO protein, activation of mature DCs with IFN-γ resulted in downregulation of IDO, which could be prevented by the presence of IL-10 during maturation. Of note, a few IDO^+ cells were detected in normal lymphoid tissue, whereas accumulation of IDO^+ cells was found in lymph nodes from patients with melanoma, breast, colon, lung, and pancreatic cancers.

Additional studies showed that mouse $CD4^+CD25^+$ regulatory T cells (see below) could initiate tryptophan catabolism in DCs, through a CTLA-4-dependent mechanism. Long-term survival of pancreatic islet allografts was induced by the soluble fusion protein CTLA4-Ig and depended upon effective tryptophan catabolism (Grohmann et al., 2002). This process required CD80 (B7) expression and cytokine production by the DCs. Various types of APCs, and in particular the $CD8\alpha^+$ fraction in the spleen, have been shown to inhibit the generation of T-cell responses *in vivo* by the expression of IDO, through the generation of specific tryptophan catabolites in the kynurenine metabolic pathway, which act as apoptotic agents in T cells. To study the mechanism of action of IDO, the human IDO gene was inserted into an adenoviral vector and expressed in DCs. Kynurenine, 3-hydroxykynurenine, and 3-hydroxyanthralinic acid, but no other IDO-induced tryptophan metabolites, were found to suppress the T-cell response, the suppressive effects being cumulative (Terness et al., 2002). The cytotoxic action on T cells preferentially affected activated T cells. Of note, in addition to T cells, B cells and NK cells were also killed, whereas DCs were not affected. The activity of IDO appears tightly regulated in DCs that express IDO constitutively: in particular, triggering of functional IDO required ligation of CD80 (B7) molecules on the DCs. The ability to trigger active IDO is confined to the $CD4^+$ T-cell subset through the engagement of CTLA4/B7 molecules (Munn et al., 2004).

Collectively, these observations suggest that localized control of tryptophan catabolism in specific tissue microenvironments may contribute to the induction and maintenance of peripheral tolerance.

A Specialized Dendritic Cell Subset?

A few studies have suggested that tolerogenic DCs may represent a specialized lineage.

$CD8\alpha^+$ Dendritic Cell Subset

Initial studies by Shortman's group demonstrated that splenic $CD8\alpha^-$ DCs induced a vigorous proliferative response in $CD4^+$ T cells, whereas $CD8\alpha^+$ DCs induced a weaker response that was associated with T-cell apoptosis (Suss and Shortman, 1996). This programmed cell death appeared to result from interaction of Fas on T cells with FasL on $CD8\alpha^+$ DCs. This observation was the first evidence for a tolerogenic function of DCs expressing a $CD8\alpha\alpha$ homodimer. This notion was consistent with the reduced phagocytic capacity of $CD8\alpha^+$ DCs, their localization in T-cell zones of lymphoid organs, as well as their expression of high levels of self-peptides–MHC complexes expressed by DCs in the T-cell area. The tolerogenic capacity of $CD8\alpha^+$ DCs was demonstrated *in vivo* using a model of tumor/self-peptide (P815AB) presentation for induction of class I-restricted skin test reactivity. It should be noted that the negative regulatory effect was found to be restricted to P815AB and was not observed with other antigens. More recent studies suggest, however, that the $CD8\alpha^+$ DC subset may produce elevated levels of IDO and display tolerogenic properties (see above).

$CD8\alpha^-CD4^+$ Dendritic Cell Subset

Legge et al. (2002) have shown that an immunoglobulin-chimera carrying the encephalitogenic myelin proteolipid PLP1 peptide was presented to T cells 100-fold better than free PLP1. Of note, aggregation of immunoglobulin–PLP1 facilitated cross-linking of Fcγ receptors on APCs and induced IL-10 by macrophages and DCs without upregulating costimulatory molecules. Aggregated immunoglobulin–PLP1 induced a strong reduction in paralytic severity and promoted full recovery from EAE in mice with ongoing disease. IL-10 production on triggering of the Fcγ receptor was confined to the $CD8\alpha^-CD4^+$ subset, which supported suppression of autoreactive T cells and reversal of EAE in the FcγR-deficient mice (Legge et al., 2002).

$CD11c^{low}$ $CD45Rb^{high}$ Dendritic Cells

A population of DCs with specific expression of CD45RB was identified that induced tolerance and Tr1 cell differentiation *in vivo*. $CD11c^{low}$ $CD45Rb^{high}$ DCs could be generated *in vitro* from bone marrow cells in the presence of IL-10 and were detected in the spleen and lymph nodes of normal mice (Wakkach et al., 2003). This $CD11c^{low}$ $CD45Rb^{high}$ DC subset displayed plasmacytoid morphology and an immature phenotype even after activation, and secreted high levels of IL-10. Transfer of $CD11c^{low}$ $CD45Rb^{high}$ DCs, pulsed with antigen *in vitro*, induced the differentiation of specific type 1-regulatory cells leading to antigen-specific tolerance *in vivo*. A single injection of 3×10^5 OVA peptide-pulsed cells was sufficient to strongly decrease the ability of the treated mouse to mount a T- and B-cell-mediated immune response directed against the whole OVA protein in the presence of different adjuvants.

DENDRITIC CELLS AND REGULATORY T CELLS

In the late 1970s, Gershon and his collaborators provided evidence for the existence of "suppressor cells" (Calkins et al., 1976). The authors showed that spleen cells could be educated *in vitro* to induce thymus-dependent help or suppression of the immune response to sheep red blood cells. After a long eclipse, suppressor cells have taken center stage in studies of immune responses and were renamed regulatory cells.

Essentially, three populations of cells exhibiting suppressive mechanisms have been described: naturally occurring $CD4^+CD25^+$ T cells and induced Tr1 and Th3 cells. The $CD4^+CD25^+$ regulatory T (Treg) cells arise spontaneously during ontogeny, are present in the periphery of normal mice, and are associated with protection from a number of autoimmune processes. They express CD25 and Foxp3 constitutively and suppress immune responses via direct cell–cell interactions, although IL-10 and/or TGF-β seem(s) to be partially involved in suppression *in vivo*. By contrast, Tr1 cells differentiate in the presence of IL-10, produce high levels of IL-10 and TGF-β, and suppress via the production of these immunosuppressive cytokines (Levings et al., 2002). Th3 cells were identified in studies of oral tolerance and produce TGF-β as well as variable amounts of IL-10 and IL-4. IL-4 was shown to be a key factor for the differentiation of Th3 cells, whereas TGF-β seems to mediate the immunosuppressive effect of Th3 cells.

There is some evidence that DCs, at some stage of maturation or restricted to a specialized lineage, may induce peripheral tolerance indirectly, through the induction and/or activation of regulatory T cells.

Dendritic Cells as Inducers of $CD4^+CD25^+$ Regulatory T Cells

Although it was initially believed that these $CD25^+$ Treg cells inhibited immune responses against self-antigens, subsequent reports clearly demonstrated that these cells also suppressed immune responses against microbes and innocuous foreign antigens. During infection by *Leishmania major*, $CD4^+CD25^+$ T cells have been shown to accumulate in the dermis, where they suppress by both IL-10-dependent and -independent mechanisms and so inhibit the ability of effector T cells to eliminate the parasite from the site (Belkaid et al., 2002). Several reports have shown that Treg cells

proliferate in response to immunization with antigen in adjuvant (Walker et al., 2003) or loaded on DCs (Oldenhove et al., 2003;Yamazaki et al., 2003). In particular, development of Th1-type responses was enhanced in mice depleted of $CD25^+$ T cells and immunized by injection of antigen-pulsed mature DCs, suggesting that Treg cells naturally exert a negative feedback effect on Th1 responses.

The essential role of $CD25^+$ Treg cells in the maintenance of peripheral tolerance has been further documented by a few reports showing alterations of $CD4^+CD25^+$ Treg function in patients suffering from autoimmune diseases. Viglietta et al. (2004) reported a significant decrease in the effector function of $CD4^+CD25^{hi}$ T cells from peripheral blood of patients with multiple sclerosis. These cells poorly inhibited responder T-cell proliferation as well as IFN-γ production. Similarly, $CD25^+$ Treg cells were found to be defective in their suppressive capacity in patients suffering from autoimmune polyglandular syndrome type II (Kriegel et al., 2004).

Of note, a recent report demonstrates that $CD4^+CD25^-$ T cells can convert into $CD4^+CD25^+$ T cells *in vivo* (see Chapters 9 and 10). The converted $CD25^+$ T cells exhibit characteristics of the naturally occurring $CD25^+$ T cells, and in particular were anergic *in vitro*, suppressed proliferation of responder cells, and expressed high levels of the transcription factor Foxp3 mRNA (Liang et al., 2005). CD80 (B7) costimulation was found to be an absolute requirement for this conversion, suggesting that DCs, which express CD80 (B7) *in vivo* in the absence of intentional stimulation, may be involved in this phenomenon.

Dendritic Cells as Targets of $CD4^+CD25^+$ Regulatory T Cells

DCs may not only be inducers but also targets of Treg activity. Indeed, one report suggests that $CD4^+CD25^+$ cells could alter the phenotype and function of DCs *in vitro*. Thus, DCs exposed to $CD4^+CD25^+$ cells expressed low levels of MHC and costimulatory molecules, and were less efficient at eliciting IFN-γ secretion by $CD8^+$ cells than were DCs cultured alone (Serra et al., 2003). Mature DCs are refractory to suppressive activity of Treg cells, suggesting that Treg cells may serve to keep DCs in the off-mode in steady-state conditions.

Another mechanism of action of Treg cells involves the regulation of immunosuppressive tryptophan catabolism in DCs, as discussed above.

Dendritic Cells as Inducers of Type 1 Regulatory T Cells

As stated above, several reports have demonstrated that DCs may induce a state of tolerance by triggering the IL-10-dependent development and function of Tr1 cells. Although there is ample evidence that immature or semi-mature DCs may trigger Tr1 cells, this activity has also been reported for mature DCs (see above).

MECHANISMS OF TOLERANCE

Direct and indirect mechanisms may be involved in the induction of peripheral tolerance by DCs. In particular, DCs may induce deletion of autoreactive T cells, through the production of tryptophan metabolites or signaling through CD95. Tolerogenic DCs may also act indirectly through the activation of Treg cells, a mechanism that would be more effective in promoting a memory for tolerance and a long-term, antigen-specific hyporesponsiveness. Although the respective role of DC subclasses and of regulatory T-cell populations remains unclear, we believe that immature and mature DCs act through distinct regulatory T-cell subsets. Steady-state DCs (semi-mature or immature) would present mainly self-antigens and either themselves produce, or induce the production of, IL-10 and thereby drive the differentiation of IL-10-producing Tr1 cells. By contrast, DCs that have matured in an inflammatory/infectious environment would undergo maturation and present self- as well as microbial antigens. These mature DCs would promote the survival/activation of naturally occurring $CD4^+CD25^+$ T cells by expressing costimulatory molecules and inducing IL-2 production. These Treg cells would therefore control the immune responses directed to microbial, self- and environmental antigens presented by mature DCs.

If this is true, the repertoire to self-antigens would be regulated at three checkpoints: 1) by thymic DCs through negative selection; 2) by immature DCs through Tr1; and 3) by mature DCs through activation of $CD4^+CD25^+$. By contrast, the repertoire to foreign antigens would be under the control only of $CD4^+CD25^+$ Treg cells, which would prevent an excessive immune response which can be deleterious to the organism.

A report by Pasare and Medzhitov (2003) suggests, however, that microbial induction of the Toll pathway may block the suppressive effect of $CD4^+CD25^+$ Treg cells, allowing activation of pathogen-specific adaptive immune responses. This would suggest that TLR-mediated recognition of pathogen signatures controls the induction of T-cell responses at two levels: through the induction of costimulation and through the release of suppressive activity by naturally occurring T cells. Production of IL-6 by DCs in response to TLR engagement was found to be critical to overcome the inhibition by Treg cells. Of note, the authors postulate that during chronic infection, blockade of suppression of self-reactive T cells may occur, which would explain the link between infection and some autoimmune diseases.

Kurts and colleagues (Hamilton-Williams et al., 2005) recently addressed the question whether TLR ligands would break tolerance to self-antigens. They mimicked a potent temporary infection by injecting a single large dose of TLR ligands into transgenic RIP-mOVA mice, which express the model antigen OVA in pancreatic islet β cells and in kidney proximal tubules. They showed that administration of TLR ligands resulted in DC activation and increased proliferation of cytokine production by T cells. However, coinjection of TLR ligand and OVA did not break tolerance in the absence of specific help, suggesting that cross-tolerance can prevent autoimmunity even when DCs are activated by microbial products.

DENDRITIC CELLS AND AUTOIMMUNITY

Nonobese Diabetic Mouse Model

Studies of autoimmune diabetes are facilitated by mouse models such as nonobese diabetic (NOD) mice which develop diabetes spontaneously. During the first stage of insulitis in this biphasic disease, the islets are invaded by DCs, macrophages, and B and T cells. This insulitis remains essentially static, and progression to diabetes occurs only at a later stage, in a proportion of mice, when the islet infiltrate converts to a destructive process, resulting in destruction of β cells and eventually loss of insulin and glucose homeostasis (see Chapter 36). Turley et al. (2003) have underscored the role of DCs in this process: they have shown that the stimulus initiating insulitis appears to be a ripple of β-cell death and that APCs that ferry cell debris from the pancreas to the pancreatic lymph nodes is a DC of $CD11c^+CD8\alpha^-$ phenotype.

There is evidence that the predisposition of NOD mice to develop autoimmune disease can be attributed to defects in central and peripheral tolerance mechanisms. Kishimoto and Sprent (2001) presented evidence that NOD mice display a defect in negative selection of thymocytes, an effect associated with upregulation of the antiapoptotic molecule cFLIP. Similarly, Lesage et al. (2002) tracked the fate of high-avidity $CD4^+$ T cells that recognize a self-antigen expressed in pancreatic islet β cells on autoimmune-susceptible or -resistant genetic backgrounds, and showed that these cells escaped clonal deletion in the thymus in NOD mice.

Unexpectedly, it was found that spontaneous diabetes was exacerbated in CD80/CD86-deficient and CD28-deficient NOD mice compared with control animals (Salomon et al., 2000). These data contradicted previous studies showing that antigen-induced models of autoimmunity could be reduced when CD28 costimulation was blocked during the priming with the relevant self-antigen. The CD80/CD86- and CD28-deficient mice were found to present a profound decrease in function of the $CD4^+CD25^+$ Treg cell subset and the transfer of this subset from control NOD animals into CD28-deficient mice delays/prevents diabetes, suggesting that Treg cells control autoimmune diabetes (Salomon et al., 2000).

Regulatory T cells appear to coexist in balance with aggressive effector cells directly in the autoimmune infiltrate during the stage of static insulitis (Herman et al., 2004). Loss of this balance leads to rapid onset of diabetes, suggesting that effector T cells capable of transferring disease are actively suppressed by regulatory T cells during the nondestructive period of static insulitis. These $CD25^+CD69^-$ cells express high levels of IL-10, glucocorticoid-induced TNFR family-related protein (GITR), and inducible costimulator (ICOS). Of note, blockade of costimulatory signals, such as CTLA-4 or ICOS, led to a rapid onset of diabetes and to a change of the ratio of effector-to-regulatory T cells in the pancreatic infiltrate.

Of note, these $CD25^+$ Treg cells essentially expressed the clonotypic TCR BDC2.5 (specific for a diabetogenic $CD4^+$ T-cell clone), implying that TCR specificity for antigens in the target organ may be important for their effectiveness. In agreement with these studies, Tang et al. (2004) reported that small numbers of antigen-specific Treg cells, expanded *in vitro* from autoimmune NOD mice, could reverse diabetes after disease onset. The islet autoantigen-specific BDC2.5 Treg cells were more efficient than polyclonal NOD Treg cells in regulating autoimmune responses *in vivo*. Steinman and colleagues (Tarbell et al., 2004) have shown that DCs from NOD mice could expand $CD4^+CD25^+$ suppressor T cells from transgenic mice specific for a natural pancreatic islet β cell antigen, and that these expanded T cells exhibited increased suppressive activity as compared to nontransgenic cells and suppressed autoimmune disease *in vivo*.

Dendritic Cells in Human Diseases

The role of DCs in the induction of autoimmune diseases in humans is still poorly defined. A few reports suggest that members of the DC family may determine reactivity to self-antigens. Banchereau and colleagues (Jego et al., 2003) have underscored the role of two DC subsets in patients suffering from systemic lupus erythematosus. They have shown that the plasmacytoid DCs release large amounts of IFN-α which induce the maturation of classical DCs. These mature DCs, which have captured autoantigens from apoptotic cells (see Chapter 15), activate autoreactive T and B cells. The same authors have reported a reciprocal regulation between TNF and IFN-α, two cytokines regarded as essential elements of autoimmunity and importantly as regulators of DC function (Palucka et al., 2005). A recent report suggests that DCs may be involved in the early steps of autoimmune uveitis (Howard et al., 2005). The authors showed that two retinal autoantigens, S-antigen and interphotoreceptor retinoid-

binding protein, which are associated with uveitis in humans and rodents (see Chapter 49), can attract immature DCs and lymphocytes expressing CXCR3 and CXCR5.

CONCLUDING REMARKS: REGULATION OF IMMUNITY TO SELF AND NONSELF

DCs express several receptors that enable them to recognize self from nonself. They also display a unique phenotypic and functional maturation process, often associated with their migration. Of note, this specialization of function over time and location helps to focus the immune response on antigens likely to be delivered under inflammatory conditions.

In addition to their immunostimulatory properties, DCs have the capacity to induce T-cell deletion and/or anergy, to trigger expansion of naturally occurring $CD4^+CD25^+$ regulatory T cells, and to activate the development of Tr1.

Collectively, these observations suggest that DCs favor immunity to nonself antigens by orchestrating the positive and negative regulation of immune responses. The mechanisms by which DCs display the opposite functions, i.e., induction of immunity and tolerance, are still unclear and will be an essential focus for future studies.

CHAPTER

5

Major Histocompatibility Complex and Autoimmunity

MINDI R. WALKER AND GERALD T. NEPOM

Benaroya Research Institute at Virginia Mason, Seattle, Washington, USA

Discrimination between self- and nonself-recognition is a fundamental role of the adaptive immune system, and is accomplished through mechanisms linked to the major histocompatibility complex (MHC), known in humans as the human leukocyte antigen (HLA) genes. Immune responses to pathogens take many forms, broadly categorized as including innate pattern recognition and adaptive antigen recognition. In the latter mechanism, T and B lymphocytes utilize different strategies: B-cell recognition is mediated by immunoglobulins, which bind conformational epitopes exposed on pathogen-associated molecules, while the T-cell response pathogens are not recognized directly, but are first processed into peptide antigens and then presented to T cells by specialized antigen-presenting cells (APCs). This antigen-presentation pathway generates thousands of peptide fragments from pathogen targets and displays these peptide fragments bound to MHC molecules, offering them to T cells for recognition by antigen-specific receptors.

This MHC-associated immune recognition mechanism is unfortunately error prone. In fact, not only are pathogen-associated peptide fragments presented by MHC molecules, but most of the time the same MHC molecules are occupied by presentation of self-peptides, products of normal cellular function and degradation. Thus, when not directing immunity to pathogens, MHC molecules on APCs are engaged in an active form of self-antigen expression, which appears to play a key role in homeostatic mechanisms, such as maintenance of pools of circulating memory cells capable of rapid recall immune responses and of fairly fixed numbers of circulating lymphocytes under normal, healthy conditions.

These two diverse functions—protection from pathogens and maintenance of homeostasis—are accomplished by closely related immune recognition pathways, using many of the same MHC genes and molecules. The evolution of the vertebrate immune system has been an ongoing effort to strike a balance between these functions, which poses a fundamental issue in our understanding of the MHC in autoimmunity: e.g., genetic mechanisms for the expansion and diversification of the T-cell receptor (TCR) repertoire allow for extremely broad potential reactivity. This is advantageous in the context of immune responses to rapidly changing infectious pathogens, but is potentially harmful in the context of recognizing molecules associated with normal tissues. Similarly, potent regulatory mechanisms are necessary to control T-cell expansion and inappropriate activation, but these regulatory mechanisms run the risk of being utilized during pathogen responses, with deleterious outcome.

Thus, the need for sophisticated sensing mechanisms and regulatory mechanisms is paramount, and a large number of immunologically-related genes are devoted to this task. In this chapter we will discuss these genes, and the functional consequences of structural diversity within the MHC gene products that participate in this pathway.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

MAJOR HISTOCOMPATIBILITY COMPLEX DIVERSITY

The principle function of MHC molecules is to bind and present peptides to the antigen-specific TCR on T lymphocytes, and to sets of receptors on natural killer T (NKT) cells which also control activation and inhibition of this effector lymphocyte population. There are two types of MHC molecules responsible for presentation of antigen to T cells; MHC class I and class II, which direct antigen recognition to the $CD8^+$ and $CD4^+$ subsets of T lymphocytes, respectively. An illustration of the evolutionary pressures to diversify the immune system comes from a comparison of T-cell and NKT-cell recognition of MHC molecules. Several pathogens invoke molecular mechanisms to inactivate MHC class I molecules, apparently to aid escape from immune attack by T cells. NKT receptors also recognize MHC class I molecules, but by utilizing inhibitory receptors for this recognition provide an immune response to target cells which lack MHC expression, thereby countering this pathogen escape strategy.

The genes for MHC molecules in humans are located on chromosome 6 in the HLA region, and are known as HLA-A, HLA-B, HLA-C, HLA-E, HLA-F, and HLA-G. When complexed with another molecule, β2 microglobulin, products of these genes form the MHC class I molecules. The MHC class II gene is divided into three loci, HLA-DR, HLA-DQ, and HLA-DP, and each locus contains a class II α gene and one or more β genes, which together encode the class II αβ heterodimer molecules. The most important functional property of the MHC genes is an extremely high degree of polymorphism in the human population. Hundreds of alleles exist, and there is tremendous variation both within and between different ethnic backgrounds.

The MHC class I and class II genes are the most polymorphic genes in the human genome. Within the MHC class II gene most of the allelic diversity is localized to the second exon. In the MHC class I gene, the sequence diversity is located within exon 2 or 3. These regions of each gene are responsible for coding the peptide-binding grove for each molecule. The allelic diversity at these regions is generated by recombinational events, such as gene conversions or reciprocal recombination (Erlich and Gyllensten, 1991), and by numerous point mutations which cluster within the peptide-binding regions.

Other genes important for immune system function are also found within the MHC. Located between the HLA-DR region (class II) and the HLA-B locus (class I), the class III region contains genes that encode members of the complement family, C2 and C4, members of the tumor necrosis factor (TNF) family (TNF-α and -β), the MHC class I-associated chain A (MICA) and MICB loci, and several others. Examples linking these genes to autoimmunity include deficiencies in C4 which are associated with systemic lupus erythematosus, and overproduction of TNF-α, which has been associated with the development of several autoimmune diseases. Elsewhere in the MHC, the transporter associated with antigen-processing (TAP) genes encode transporter proteins which facilitate the loading of peptides into newly synthesized MHC class I molecules, and the nearby LMP2 and LMP7 genes, which encode interferon (IFN)-γ-inducible subunits of the proteosome complex. HLA-E and HLA-G are MHC class I loci, with a more limited tissue distribution and polymorphism than the HLA-A, -B, and -C genes, and are important in NKT-cell recognition.

EVOLUTION OF THE MAJOR HISTOCOMPATIBILITY COMPLEX

Evidence from allelic frequency distribution, patterns of nucleotide substitution in coding exons, phylogenetic analysis of sequences, and differences in the evolutionary pattern between exons and introns of MHC genes all suggest that natural selection is responsible for generating and maintaining MHC polymorphism. In addition to the large number of alleles present in the MHC, MHC genes have several features that distinguish selection from random mutation, including the presence of rare alleles found at similar frequencies in different populations, and the distribution of regions of variation closely tied to the functions exhibited by those regions. Hughes and Nei (1988) noted that if MHC molecules were undergoing selection, then the selection or amino-acid altering substitutions would be greatest in the peptide-binding region. This is indeed the case and these substitutions preferentially lead to coding changes, as opposed to changes that are silent, and merely reflect a higher mutation rate in this area. The genetic variation also results in frequent heterozygosity at the sites involved in peptide presentation, providing a link between functional diversification and population variation.

Pathogens may be the major source of selective pressure to drive diversification of MHC alleles. The way pathogens drive selection of MHC diversity has been explained in three major hypotheses. In the first, individuals with heterozygous MHC alleles would have an advantage over those with homozygous MHC alleles because they would have the ability to present a wider range of peptides. The range of peptides an individual could present would depend on the degree of overlap between the ranges of peptides the two MHC alleles could present. This method of selection would therefore favor individuals with the greatest divergent range of peptide-binding specificities. This hypothesis is consistent with observations that MHC class I homozygous autoimmune deficiency syndrome (AIDS) patients have a faster progression to late-stage AIDS (Carrington et al., 1999; Tang et al., 1999), and MHC class II heterozygosity

has been advantageous for hepatitis B virus infection (Thursz et al., 1997).

The second hypothesis is based on a presumption of rare allele advantage. In this hypothesis individuals with rare alleles would have an advantage over those with common alleles because of the coevolution of pathogen diversity to target common alleles. An example comes from studies of malaria, associated with an increase in the frequency of HLA-B*53 in the Gambian population (Hill et al., 1991).

In the third hypothesis, HLA variation would fluctuate with pathogen variation. As pathogens change, MHC alleles would change in response, albeit at a much slower rate. This model differs from the second one in that allelic differences change with the frequency of the pathogen, whereas in the second model the frequency of the allele dictates how well a given individual will respond to a particular pathogen.

MAJOR HISTOCOMPATIBILITY–PEPTIDE INTERACTIONS

The specificity of the MHC–peptide interaction relies on structural complementarity between the antigenic peptides and the binding groove of the MHC molecule. The binding groove is bordered by α-helical loops that form a canyon, inside which binding pockets are formed by different combinations of amino acids, which determine the types of peptides able to bind. These pocket variations in amino acid sequence in MHC molecules are due to allelic variations in the MHC gene. Subtle differences in the peptide-binding groove correspond to varying abilities of different peptides to bind different MHC molecules, and in turn result in the differences in ability of individuals to respond to different peptides. Atoms of the bound peptide backbone form hydrogen bonds with the nonpolymorphic MHC residues, while bound peptide side chains interact with the side chains of the polymorphic MHC.

MHC molecular interactions with both peptide main chain and side chains are critical for maintaining the structure and stability of the MHC–peptide complex. Thus, the overall strength of binding is also determined directly by the nature of specific HLA genetic variation. As discussed below, the strength of binding controls the duration of signals transduced between the MHC–peptide complex and the antigen-specific TCR, a variable with important ramifications for T-cell selection and autoimmunity. In some cases, multiple binding registers may occur within the peptide-binding groove, which would greatly increase the opportunities to recognize specific antigens, but which could possibly also contribute to the masking of autoantigens during thymic selection (Goverman, 1999; He et al., 2002).

MHC class I molecules are loaded when proteins within the cytosol are degraded into small peptides by a proteosome. The proteosome is a multifunctional protease with several catalytic subunits. These peptides are then transported into the endoplasmic reticulum by the TAP and are then loaded into the MHC class I molecules with the help of chaperone proteins and translocated to the cell surface. On the other hand, MHC class II molecules are typically used to present extracellular peptides to $CD4^+$ helper T (Th) cells. First, extracellular proteins are endocytosed by the APC. At the same time, newly synthesized MHC class II molecules are being exported through the Golgi. Newly synthesized MHC class II molecules bind the invariant chain within the endoplasmic reticulum. The invariant chain serves two purposes: to prevent binding of endogenous peptides within the endoplasmic reticulum lumen and to direct the export of MHC molecules to endosomes. Within the endosome, proteolytic processing of the endocytosed peptide and invariant chain occurs. Proteolytic processing of the invariant chain leaves a small peptide, class II-associated invariant chain peptide (CLIP), within the MHC class II peptide groove. Dissociation of CLIP is facilitated by specialized MHC molecules, DO and DM. Removal of the CLIP peptide allows loading of the extracellular peptide into the peptide-binding groove of the MHC class II molecule. The MHC molecule is then exported to the plasma membrane where it presents the bound peptide to TCR molecules on $CD4^+$ Th cells.

T-Cell Selection

T cells develop and mature during the process of thymic selection. During this process, self-peptides within the thymus are presented on MHC molecules to T-cells. The interaction between TCR and MHC–peptide complexes involves intermolecular, and therefore intercellular, contacts. The specificity of the TCR binding is controlled by both peptide contacts and MHC contacts. Both the peptide and the MHC contribute to the overall avidity of the trimolecular interaction and, therefore, to activation of the T cell. The MHC therefore controls not only the interaction between peptide and MHC, but also the interaction between TCR and MHC. This MHC-controlled TCR recognition is termed MHC restriction and is a key checkpoint in the genetic control of a T-cell immune response. HLA genetic polymorphism therefore controls interaction with the T cell and T-cell activation through three structural mechanisms: directly through binding the antigenic peptide, directly through binding the TCR, and indirectly by altering the conformation of the bound peptide and influencing the interaction between peptide and TCR.

Positive selection of thymocytes is mediated in the thymic cortex by epithelial cells presenting antigen to immature T cells, whereas negative selection occurs predominantly in the medulla and is mediated by medullary epithelial APCs and dendritic cells (DCs). T cells that do not

recognize peptides within the thymus die from neglect. This rids the T-cell repertoire of nonreactive T cells, while T cells that recognize self-peptides during negative selection as agonists or with high affinity are also deleted from the T-cell repertoire. This form of central tolerance is a major physiologic barrier that should delete T cells that are highly reactive to self-antigens. However, this deletion mechanism is inefficient, and T cells that are autoreactive often escape negative selection and can be found in the periphery of normal healthy individuals. When these cells are unregulated and become activated, autoimmune diseases are a likely outcome. Figure 5.1 illustrates this progression: autoantigen-specific $CD4^+$ T cells are not detected in assays utilizing unfractionated peripheral blood from normal individuals; however, removal of regulatory cells unmasks the autoreactive potential, and self-responsive $CD4^+$ T cells are now evident. These cells are very similar in phenotype and TCR repertoire to activated autoreactive T cells, which are frequently found in the peripheral blood of patients with active autoimmune disease.

There are several maturation phases wherein mistakes in T-cell selection may lead to autoimmunity. This is most clearly evidenced by the fact that animals undergoing thymectomy between day 2 and 5 of life succumb to severe autoimmunity (Taguchi and Nishizuka, 1980; Sakaguchi et al., 1994). This autoimmunity can be directed against several organs and is characterized by the infiltration of T cells into the affected organs and organ-specific antibodies in the serum (Taguchi et al., 1980). Thymectomy-induced autoimmunity is typically explained by a lack of regulatory T cells (Tregs) because selection of these cells is delayed until the second week of life (Sakaguchi et al., 1994). Similarly, animals that undergo irradiation along with cyclosporine A (CsA) treatment have disrupted T-cell selection and unbalanced Th1 versus Th2 responses in the periphery, which lead to autoimmunity. This autoimmunity is also believed to be caused by a defect in negative selection resulting in an increase in the output of autoreactive cells (Sorokin et al., 1986; Beijleveld et al., 1995; Damoiseaux et al., 1997). Mice deficient in Zap-70, a signaling molecule that receives signals from the TCR, also have defects in both positive and negative selection (Negishi et al., 1995; Sakaguchi et al., 2003).These mice have autoreactive T cells in the periphery which mediate a syndrome resembling rheumatoid arthritis.

It has become clear over the past several years that thymic stromal cells, medullary epithelial cells in particular, express several peripheral tissue-specific antigens, which are important in negative selection (Kyewski et al., 2002). Expression of these tissue-specific antigens is controlled by the autoimmune regulatory (AIRE) gene. Mutations in the AIRE gene have recently been shown to result in the multiorgan autoimmune disease, autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) (Nagamine et al., 1997), which is also known as autoimmune polyglandular syndrome-type 1 (APS-1). AIRE knockout mice also have lymphocytic infiltrates and autoantibodies against several peripheral organs and tissues (Anderson et al., 2002; Ramsey et al., 2002). Studies in nonobese diabetic (NOD) mice suggest that the level of expression of tissue-specific antigens within the thymus and thus clonal deletion controls the response to these antigens in the periphery (Kishimoto and Sprent, 2001; Chentoufi and Polychronakos, 2002; Dubois-Lafforgue et al., 2002; Lesage et al., 2002; Moriyama et al., 2003; Thebault-Baumont et al., 2003; Villunger et al., 2003).

Mistakes in T-cell selection also occur when the number of peptides presented in the thymus is reduced or is not controlled. For example, mice that lack the MHC class II invariant chain have substantial loss of MHC class II expression and $CD4^+$ T-cell selection (Bikoff et al., 1993; Viville et al., 1993; Elliott et al., 1994). In addition, $DM^{-/-}$ mice have about one-quarter the number of normal circulating T cells, and the majority of the APCs within these mice present CLIP because of the lack in DM-mediated catalysis of the release

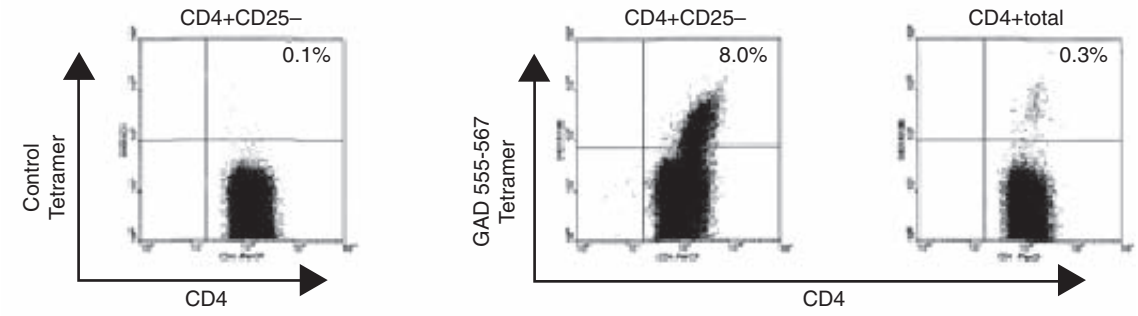

FIGURE 5.1 Autoreactive T cells are present in human peripheral blood, under regulatory control. $CD4^+$ T cells specific for GAD65, an autoantigen associated with autoimmune diabetes, are visualized by fluorescent flow cytometry using MHC tetramers. Removal of regulatory T cells (middle panel) unmasks a robust proliferative response which results in an expansion of tetramer-positive cells. The left panel shows the same cell population analyzed using an unrelated control tetramer. Adapted from Danke et al. (2004), with permission.

of this peptide (Fung-Leung et al., 1996; Martin et al., 1996; Miyazaki et al., 1996; Grubin et al., 1997; Surh et al., 1997; Tourne et al., 1997). A large percentage of T cells in these mice respond to syngeneic APCs from normal mice, a characteristic of unregulated autoreactivity. Similar observations have been made in I-A^bE_α (aa52–68) mice in which the class II I-E_α (52–68aa) peptide is covalently linked to the β chain of the I-A^b heterodimers; APCs in these animals display I-A^b where nearly all molecules contain the I-E_α (52–68) peptide (Ignatowicz et al., 1995; Fukui et al., 1997). Autoimmunity in these mice may therefore be due to the low number of self-peptides being presented within the thymus and thus a lack of negative selection.

Differences in MHC alleles may contribute to autoimmunity during thymic selection either by presenting autoantigens for positive selection or by inefficiently performing negative selection, such as by limiting the amount of self-peptides presented. T cells that undergo positive thymic selection normally react to self-peptides presented in the thymus with weak agonistic or low-affinity responses. However, there are methods to escape negative selection if T cells are too highly reactive to self; e.g., T cells have the ability to permanently downregulate the coreceptors CD4 and CD8, or T cells may mature under the influence of activation blockade or Tregs as a way of escaping negative selection. In addition, many human T cells express multiple TCR α chains, and it is conceivable that T cells selected for one specificity may acquire other specificities after maturation. Examples where certain MHC alleles contribute to susceptibility due to binding of autoantigens with poor affinity to that particular MHC, in which a lack of negative selection of the autoimmune T cells within the thymus leads to autoimmunity, are found in several animal models (Fairchild et al., 1993; Liu et al., 1995; Carrasco-Marin et al., 1996; Ridgway et al., 1998).

T-Cell Activation

The functional outcome of the TCR–MHC–peptide interaction is complex and variable. The T-cell response is strongly influenced by lineage commitment, maturation stage, cytokine environment, and the nature of the APCs and costimulators. However, a key determinant in this interaction is the TCR–MHC–peptide signal itself. Variation in the strength of signal mediated through this interaction leads to alteration of T-cell responses, both naïve and memory responses. Essentially, variation in the strength of signal through the TCR–MHC–peptide complex changes the threshold for activation responses and modulates the commitment to specific response pathways. At the molecular level, the interface between MHC–peptide complexes and the TCR occupies an approximately 10×20 Å interface with 40 or more specific intermolecular contacts (Figure 5.2). Seemingly minor variations within this interface can lead to a profound difference in functional outcome. For example, in the HLA-A2-tax system, four different crystal structures derive from single amino acid substitutions at the TCR–peptide contacts, which lead to very subtle shifts in the three-dimensional complex but correspond to a range of functions from agonist to antagonist (Ding et al., 1999).

While the affinity of an individual TCR–MHC–peptide interaction is quite low, the overall avidity of the interaction is greatly enhanced during the intercellular interaction between T cell and APC by the clustering and multimerization

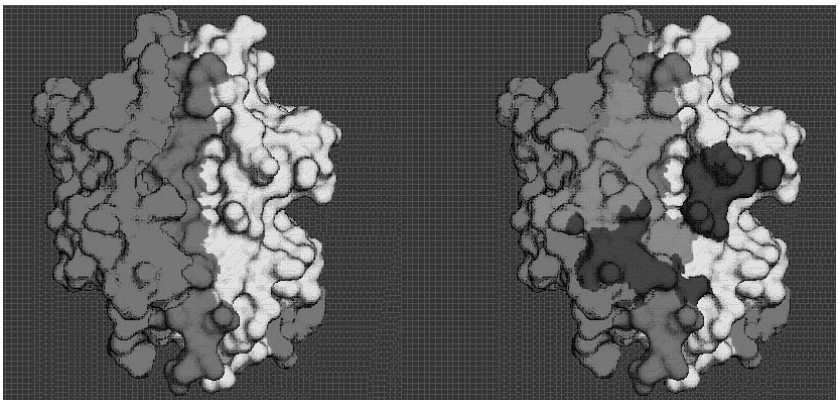

FIGURE 5.2 Trimolecular interaction between MHC, peptide, and T-cell receptor (TCR). The exposed molecular surface of an MHC class II molecule, containing a bound antigen peptide, is shown in the left panel. The MHC α chain is yellow, the β chain is green, and the peptide is shown in pink. Amino acid side chains on the underlying side of the peptide lie buried in the MHC groove, anchoring the binding interaction. This exposed surface forms the contact structure for TCR recognition; the image on the right is colored to show examples of the areas which contact the TCR, with the TCR α chain contacts shown in dark blue and the TCR β chain in light blue. Both peptide and MHC residues are involved in TCR recognition, and both contribute to the overall avidity of the interaction. See color plate section.

of the complex due to multiple site interactions. Strength of signal is a function of the density and duration of these complexes at the cellular interface, in combination with accessory molecules and membrane structure effects. As summarized by van der Merwe (2001), there is no evidence for change in structural interface of TCR–MHC–peptide interactions, which correlate with the functional outcome of binding, and many data consistent with the hypothesis that signal duration or strength is the key element.

While there is still considerable uncertainty and controversy about the mechanisms by which signal duration determines outcome [i.e., the serial triggering model (Lanzavecchia and Sallusto, 2001) or oligomerization in lipid rafts acting as signal amplifiers (Drake and Braciale, 2001; Viola, 2001) or time-dependent assembly of tyrosine kinase-dependent protein interactions (Pacini et al., 2000)], regardless of mechanism, the outcome of T-cell stimulation is strongly dependent on the strength of signal. T-cell polarization (Iezzi et al., 1999), anergy induction (Appel et al., 2001), and commitment to memory or regulatory responses (Lanzavecchia and Sallusto, 2000) all differ in their "weak" and "strong" TCR–MHC peptide interactions.

Studies using murine models and soluble class I–peptide multimers to analyze CD8 responses have observed a range of functional avidities among cells with differential activation properties (Derby et al., 2001; Rosette et al., 2001). Functional avidity in such studies depends not only on the affinity of the TCR–peptide–MHC complex, but on the density of these complexes, and their assembly or "packing" on the T-cell surface, potentially as a response to activation (Hesse et al., 2001; Margulies, 2001; Slifka and Whitton, 2001). The importance of these functional avidity differences is crucial not only for determining T-cell response on a single cell basis, but also for inducing major shifts in the population of T cells elicited in a polyclonal response. Within a complex polyclonal response, T cells of different avidity will be selected for differential activation and lineage commitment for effector pathways, with profound functional consequences. For example, selection of high-avidity responses has been suggested to underlie a mechanism for sensing low-density antigen (Fahmy et al., 2001), for determining the hierarchy of peptide epitopes recognized during determinant spreading (Tian et al., 2001), and for eliminating high-avidity autoreactive cells (Anderton et al., 2001).

During the process of thymic selection, T cells that are highly reactive to self-proteins should be deleted from the T-cell repertoire; however, post-translational modifications of proteins can occur that lead to new epitopes, which can now be recognized by positively selected T cells. Evidence of the creation of neoepitopes in disease exists in celiac disease, rheumatoid arthritis, and atherosclerosis. Celiac disease is characterized by autoantibodies to tissue transglutaminase. This enzyme converts glutamine to asparagine within gluten proteins in the intestine to generate neoepitopes that preferentially bind DQ2 class II molecules for antigen presentation (Quarsten et al., 1999). In rheumatoid arthritis, the presence of citrullated proteins is highly predictive of the onset of disease with neoepitopes of matrix proteins, such as vimentin created by conversion of arginine to citrulline (van Boekel et al., 2002). Oxidized low-density lipoproteins (LDLs) are markers for coronary atherosclerosis and may similarly contribute to neoepitopes for immunologic responses in the inflammatory response associated with the progress of coronary artery disease (CAD) (Holvoet et al., 1998a; 1998b).

Other environmental influences also can change the threshold for MHC–peptide–TCR triggering. Differences in pH at the site of inflammation may cause MHC structural changes that may lead to high-affinity interaction (Hausmann et al., 1999), or differences in Toll-like receptor (TLR) molecules may cause maturation of DCs, which will provide an immune stimulatory signal even when self-peptides are presented. In addition, the level of costimulation may be different within the thymus and periphery. CD80 (B7) levels have been shown to be low on thymic cortical epithelial cells, which are the APCs that induce positive selection. Indeed, expression of CD80 (B7) molecules within the pancreas of transgenic animals is sufficient to promote diabetes in the context of susceptible MHC alleles (Wen et al., 2000). Molecular mimicry or cross-reactivity with bacterial and viral antigens have also been shown to both accelerate and protect from autoimmunity (Zhao et al., 1998; Katz-Levy et al., 1999; Brehm et al., 2002; Christen and von Herrath, 2004).

T-Cell Regulation

MHC–peptide interactions regulate T-cell homeostasis. Just as self-peptide–MHC complexes mediate positive selection in the thymus, continual recognition of self also seems to play a key role in the survival of T cells in the periphery (Janeway et al., 1984; Ernst et al., 1999; Freitas and Rocha, 1999; Goldrath and Bevan, 1999). $CD4^+$ T cells quickly die in the periphery of mice that lack MHC class II molecules (Takeda et al., 1996; Brocker, 1997), even when MHC class II molecules are expressed selectively in the thymus (Rooke et al., 1997). This requirement for MHC apparently fosters the maintenance of low-level proliferation in memory T-cell compartments and a similar function for Treg homeostasis may influence autoimmune disease predisposition.

Because T-cell selection in the thymus is an imperfect process, there are several mechanisms in place to help ensure that aberant activation of autoreactive cells that escape negative selection do not proliferate out of control. One mechanism to control autoreactive cells is through Tregs. Table 5.1 summarizes the properties of Tregs and their relationship to autoimmunity. Three types of Tregs

Table 5.1. MHC interactions in regulatory T-cell generation and function

Functional property	Immune compartment	Role in autoimmunity
Selection of Treg	During thymic development	Establishing an avidity threshold for regulatory T–cell maturation
Activation of Treg	During antigen exposure in the periphery	Treg require TCR signals for expression of their regulatory program
Homing of Treg	During an ongoing immune response	Requirement for MHC–antigen interaction directs Treg function to specific sites
Persistence of Treg	Normal physiology	Maintains a homeostatic level of Treg function, probably essential for prevention of autoimmunity
Induction of Treg	Post-thymic development	Provides for generation of Treg in the periphery, may aid in controlling autoimmunity

have been described, $CD4^+CD25^+$ (T_R), type 1 regulatory T (Tr1) cells, and Th3 cells. Studies in mice have shown that $CD4^+$ T_R, which are characterized by the expression of CD25 and Foxp3, are derived from the thymus and exert their suppressive activity in a cell-contact-dependent, cytokine-independent manner (Sakaguchi et al., 1995; Baecher-Allan et al., 2001; Dieckmann et al., 2001; Jonuleit et al., 2001). Tr1 and Th3 cells are thought to be peripherally derived and exert their suppressive activity via IL-10 and transforming growth factor (TGF)-β, respectively (Chen et al., 1994; Groux et al., 1996). Both types of regulatory T cell have to be activated through the TCR in order to be suppressive. The Tregs have recently been categorized based on their source as either "natural" thymically derived cells, such as $CD4^+CD25^+$ T_R, or "adaptive" Tregs, which can be generated in the periphery, including Tr1 and Th3 cells (Bluestone and Abbas, 2003).

The nature of the antigen specificity of Tregs is controversial. Freshly isolated unmodified $CD4^+CD25^+$ T cells have been able to suppress proliferation in assays using peptides to stimulate cells rather than polyclonal anti-CD3 stimulation (Kohm et al., 2002; Taams et al., 2002). T-cell clones that express CD25 and exhibit *in vitro* suppressive activity when given cognate antigen have recently been described (Levings et al., 2002b; Wang et al., 2004). Repeated alloantigen stimulation of $CD4^+CD25^+$ T cells (Jiang et al., 2003) or priming mice with alloantigen (Dai et al., 2004) has also resulted in antigen-specific Tregs. Most notably, two recent reports show that *in vitro* expanded antigen-specific $CD4^+CD25^+$ T cells can suppress the development of diabetes in NOD mice even after injection of diabetogenic T cells (Tang et al., 2004; Tarbell et al., 2004). These two reports also suggest that the antigen-specific regulatory T cells once activated have the ability to control responses to other antigens present at the site of inflammation, which would be particularly useful in therapy for autoimmune diseases where multiple autoantigens are present. Similar human Tregs have been described, generated *in vitro* following TCR activation (Walker et al., 2003; 2005).

Selection of Tregs may be controlled by the affinity of the TCR for a peptide–MHC complex. $CD4^+CD25^+$ Tregs have been shown to preferentially express endogenous α chains in transgenic mice and are severely decreased in transgenic mice lacking TCRα expression, whereas $CD4^+CD25^-$ cells develop normally (Suto et al., 2002). This suggests an affinity difference in selection of Tregs. It has been suggested that Tregs may be the T cells with the highest affinity for peptides presented in the thymus, just below the threshold for negative selection (Jordan et al., 2001; Apostolou et al., 2002; Kawahata et al., 2002). Transgenic animals created with a high-affinity TCR preferentially select $CD4^+CD25^+$ T cells as opposed to low-affinity TCR transgenic animals (Jordan et al., 2001). Thus, Tregs may be the cells within the thymus with the highest affinity for self-peptides, a property that could contribute to the ability of these cells to regulate aberrant responses to self in the periphery.

Regulation of immune responses in the periphery has been the objective of many new therapies. In particular, current trials involving the use of anti-CD3 antibodies aim to control peripheral T-cell responses through a combination of T-cell activation-induced cell death (AICD), Th2 polarization and secretion of IL-10, and the induction of TGF-β producing Tregs (Masteller and Bluestone, 2002; Belghith et al., 2003; Chatenoud, 2003). Alternatively, to avoid general immune suppression, several promising experimental therapies utilize the MHC–peptide complex to provide specificity. In particular, the soluble peptide–MHC class II chimeras has been used to prevent autoimmune diabetes onset and restore normal glycemia in mice (Casares et al., 2002; Masteller et al., 2003), reduce the relapse rate of experimental autoimmune encephalomyelitis (EAE) (Huan et al., 2004), or reduce the severity of and delay the onset of collagen-induced arthritis (Zuo et al., 2002). *In vitro* studies using human cells have also shown promise with MHC–peptide dimers. Soluble dimeric DR2–IgG fusion protein with a bound peptide from myelin basic protein (MBP) has been shown to cause anergy in MBP-specific

T cells (Appel et al, 2001). All these methods of inducing peripheral tolerance to self-antigens are thought to occur by induction of anergy or production of immunoregulatory cytokines. Immunoregulatory cytokines such as IL-10 and TGF-β have also been implicated in producing Tregs (Yamagiwa et al., 2001; Dieckmann et al., 2002; Jonuleit et al., 2002; Levings et al., 2002a; Zheng et al., 2002; Chen et al., 2003a; 2003b; Horwitz et al, 2003). As mentioned above, this method of preventing peripheral immune responses may be particularly promising due to the lack of antigen specificity of these cells once activated. Tregs could be activated selectively by antigen at the site of autoimmunity, but may control the response to other epitopes present at that site through bystander suppression, which is of particular importance in autoimmune diseases where pathology is directed against several antigens.

Another way to manipulate the MHC–peptide interaction with TCR for immunotherapy is through the use of altered peptides which act as TCR antagonists. T-cell epitopes can be altered by one or more amino acids to become an altered peptide ligand (APL). APLs elicit reduced or partial responses in contrast to their fully antigenic wild-type counterparts. Some APLs not only fail to elicit certain T-cell responses, but can also inhibit T-cell responses in mice (Basu et al, 1998). TCR antagonists are usually clone specific and require excess antagonist over agonist in order to suppress the response to the agonist (De Magistris et al., 1992; Jameson et al, 1993), although some general antagonists have been described (Anderton et al., 1999; Toda et al., 2000). However, the use of APLs as a therapy has led to responses to the APL itself and also to cross-reactive responses to disease-associated autoantigens (Bielekova et al., 2000; Kappos et al., 2000). This latter property makes it unlikely that APL therapies will fulfill the necessary safety profiles for most clinical applications.

From the perspective of disease pathogenesis, however, antagonistic self-peptides may play a significant role in many immune responses. The T-cell repertoire is selected from partially agonistic self-peptides and therefore, fully mature T cells in the periphery may recognize modified self-peptides as partial agonists or antagonists. The ability of certain MHC alleles to bind and present antagonistic self-peptides likely differs with different alleles, and could explain why some HLA types have inhibitory effects on autoimmune responses.

CONCLUDING REMARKS

Selection, activation, and regulation of autoreactive T cells, as outlined above, represent fundamental features which condition the immune system for pathogen responses and for homeostatic properties. The error-prone nature of these essential functions leads to altered functional thresholds, which predispose to autoreactivity and autoimmunity. Many different MHC genes are implicated in human disease; e.g., several class II MHC molecules are associated with the development of type 1 diabetes, with *DRB1*0302* being the principal risk allele (Bertrams and Baur, 1984; Nepom and Erlich, 1991; 2002; Nepom, 1993; Thomson et al., 1988). On the other hand, *DQB1*0602* is associated with protection from disease (Baisch et al., 1990). *DRB1*0401* and *DRB1*0404* are both associated with rheumatoid arthritis (Nepom et al., 1987; Nepom and Nepom, 1992; Ollier and Thomson, 1992; Winchester et al, 1992); however, a closely related allele *DRB1*0402* is associated with pemphigus vulgaris (Scharf et al., 1988). *DRB1*1501* and *DRB5*0101* are highly associated with the development of multiple sclerosis (Tiwari and Terasaki, 1985) and *DQB1*0201* has been associated with celiac disease (Sollid et al., 1989). HLA transgenic mice have been successfully designated containing DR2, DR3, DR4, DQ6, and DQ8, and have allowed the study of several autoimmune conditions, including diabetes, rheumatoid arthritis, systemic lupus erythematosus, EAE, and experimental autoimmune uveitis (EAU) (Taneja and David, 1998; Abraham et al., 2000; Das et al., 2000). In each case, it is likely that unique allelic polymorphisms confer subtle variation on peptide or TCR interactions and these establish the thresholds which ultimately determine autoreactive T-cell selection, activation, and regulation. In this sense, the MHC contribution to autoimmunity is permissive for disease susceptibility, creating an error-prone framework which, in combination with non-MHC genes and environmental variables in specific end organs, leads to the overall clinical spectrum manifest as MHC-associated autoimmunity.

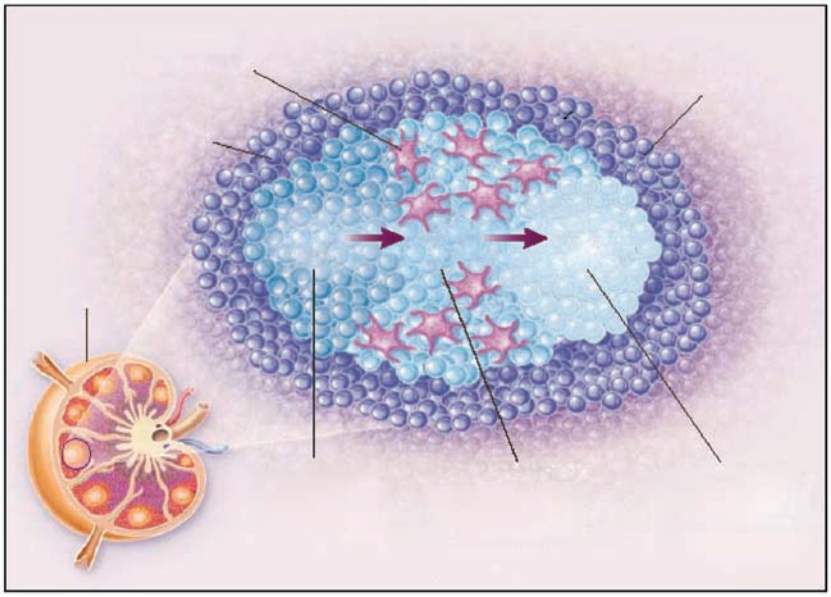

FIGURE 2.7 Germinal center. During the initiation of the acquired immune response, these structures form in the secondary lymphoid tissues in order to generate a microenvironment where all the necessary antigen-specific and innate antigen-presenting cells can interact. Antigen-stimulated B-cell proliferation occurs in the dark zone and is accompanied by affinity maturation due to somatic hypermutation of the immunoglobulin variable region genes. Upon passage into the basal light zone, high-affinity antigen-specific B-cells are positively selected by interaction with antigen, which is present in the form of immune complexes on the surface of follicular dendrite cells. B-cells which fail to be positively selected undergo apoptosis and are phagocytosed by tingible-body macrophages. The positively selected cells migrate to the apical light zone where proliferation continues, class switching occurs, and memory cells and plasma cell precursors are generated.

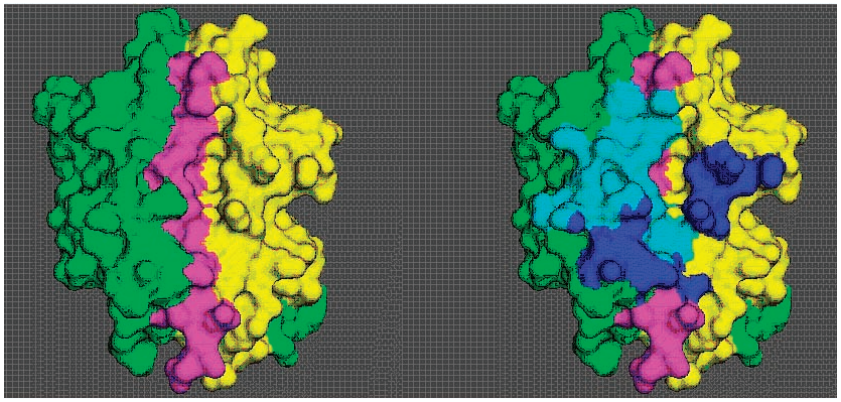

FIGURE 5.2 Trimolecular interaction between MHC, peptide, and T-cell receptor (TCR). The exposed molecular surface of an MHC class II molecule, containing a bound antigen peptide, is shown in the left panel. The MHC α chain is yellow, the β chain is green, and the peptide is shown in pink. Amino acid side chains on the underlying side of the peptide lie buried in the MHC groove, anchoring the binding interaction. This exposed surface forms the contact structure for TCR recognition; the image on the right is colored to show examples of the areas which contact the TCR, with the TCR α chain contacts shown in dark blue and the TCR β chain in light blue. Both peptide and MHC residues are involved in TCR recognition, and both contribute to the overall avidity of the interaction.

T cells play a fundamental role in most, if not all, adaptive immune responses, including those executed by antibody-producing B lymphocytes. The most fundamental difference between T- and B-cell responses lies in major histocompatibility complex (MHC) restriction. Whereas antigen-specific T cells recognize ligands presented by "self"-MHC molecules on the surface of antigen-presenting cells (APCs), B cells recognize linear or conformational epitopes on antigens in a non-MHC-restricted manner. T cells can be divided into different subpopulations based on surface markers and functional behavior. $CD4^+$ helper T (Th) cells are those capable of promoting B-cell and $CD8^+$ T-cell responses. Cytotoxic T cells, which include cells belonging to both the $CD4^+$ and $CD8^+$ lineages, are those capable of killing target cells. The functions of $CD4^+$ Th cells are predominantly determined by the cytokines they produce, and these T cells are further subclassified into subsets depending on their cytokine profiles (Th0, Th1, Th2 or Th3). Upon antigen stimulation, some $CD4^+$ and $CD8^+$ T cells suppress, rather than drive, immune responses. Evolutionarily speaking, these T cells [also known as regulatory T cells (Tregs)] likely arose out of the immune system's need to control the magnitude of inflammatory reactions against microbial infections, to prevent collateral damage to healthy, noninfected tissue. Disruption of the delicate balance that exists among all these cell types of the adaptive immune system (in health) thus has the potential to cause autoimmunity, which, by definition, results from a loss of tolerance to self. Because of the central role that T cells play in adaptive immune responses, it is not surprising that they, too, play a fundamental role in most, if not all, autoimmune disorders, including those mediated by autoantibodies. This chapter provides a general overview of the roles of MHC, self-antigens and tolerance, T–T interactions, cytokines, T–B collaboration, and T-cell-mediated regulation in autoimmunity.

MAJOR HISTOCOMPATIBILITY COMPLEX POLYMORPHISM AND T-CELL-MEDIATED AUTOIMMUNITY

Imprinting of self-MHC restriction and tolerance to self on the mature T-cell repertoire occurs during thymocyte development. In the thymus, MHC molecules instruct maturing T cells how to discriminate between self- and non-self-antigens. Whereas thymocytes expressing T-cell receptors (TCRs) recognizing self-antigen–MHC with high affinity perish (a process also referred to as negative selec-

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

tion), those expressing low-affinity TCRs (for the same complex) differentiate into the mature T cells that populate the peripheral lymphoid organs (Figure 6.1A). In addition to playing a key role in shaping the peripheral TCR repertoire, MHC molecules present cognate antigenic molecules, including self-antigens, to mature T cells in the periphery.

Human MHC molecules are encoded in several closely linked genes that comprise the HLA system on the short arm of chromosome 6. Murine MHC molecules are encoded in the H-2 complex, located on chromosome 17. HLA and H-2 genes encode MHC class I (A, B, or C in humans, and K, D and L in mice) and class II molecules (DR, DQ or DP in humans, and I-A and I-E in mice). The structure and function of human and murine MHC molecules are very similar. The N-terminal domains of class I heavy chains or class II α and β chains form a molecular pocket with peptide-binding properties. In general, MHC class I and II molecules present antigenic moieties (predominantly peptides) to $CD8^+$ and $CD4^+$ T cells, respectively. HLA and H-2 genes (A, B, C, DRB1, DRB3, DQA1, DQB1, DPA1, and DPB1; and K, D, L, I-Aα, I-Aβ, I-Eα and I-Eβ) are highly polymorphic, such that specific alleles at a given locus may be expressed

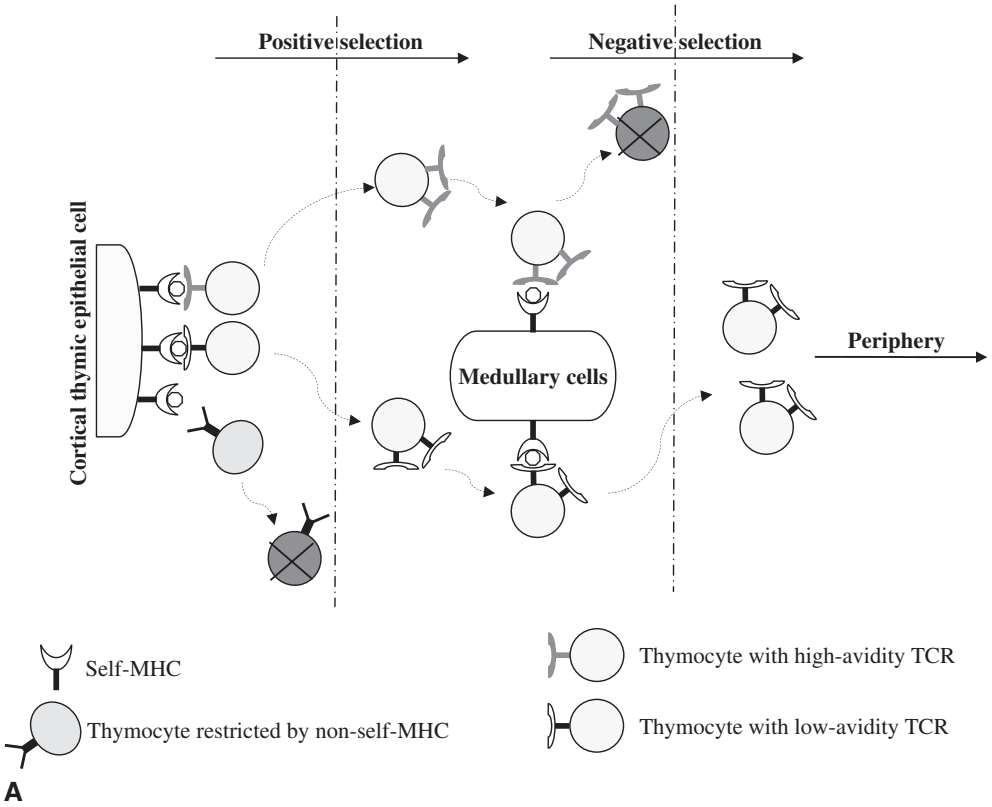

FIGURE 6.1 Hypothetical relationships among proautoimmune and protective MHC molecules, T-cell avidity (for peptide–MHC) and development of diabetogenic or regulatory autoreactive T cells. *A*, Central tolerance versus T-cell receptor (TCR) affinity. *B*, Central tolerance by antidiabetogenic MHC–peptide complexes. *C*, Central tolerance by autoantigen versus avidity. *D*, Developmental fate of autoreactive thymocytes. $CD4^+CD8^+$ thymocytes expressing autoreactive TCRs undergo positive selection by engaging diabetogenic, but not antidiabetogenic, MHC molecules on cortical thymic epithelial cells (*A*, *B*, and *D*). In the thymic medulla, the positively selected $CD4^+CD8^-$ or $CD4^-CD8^+$ thymocytes may or may not recognize proautoimmune or protective MHC molecules. Proautoimmune MHC molecules on medullary thymic epithelial cells or bone marrow-derived antigen-presenting cells (APCs) (i.e., dendritic cells) may or may not present the target autoantigenic peptide that the autoreactive T cells recognize in the periphery. This depends on whether the autoantigen is expressed by the APC or captured by the APC in the periphery and then ferried to the thymus (*B–D*). In some instances, the autoantigen is presented by medullary APCs but the target epitope is a cryptic one (*C* and *D*). High-avidity interactions between thymocytes and APCs will promote deletion, anergy of the thymocytes, and/or their differentiation into regulatory T cells (*B–D*). Low-avidity interactions will tune the activation threshold of the autoreactive thymocyte without inducing tolerance. Absence of autoantigen presentation will allow the migration of high-avidity, and hence potentially pathogenic, mature autoreactive T cells to the periphery (*C* and *D*). We have proposed that these high-avidity autoreactive thymocytes are inherently cross-reactive with protective MHC molecules in a peptide-, but not autoantigen-specific manner (see text and corresponding references). These interactions will selectively promote central tolerance of highly pathogenic autoreactive T cells, sparing low-avidity autoreactive T cells, which may not be pathogenic. See color plate section.

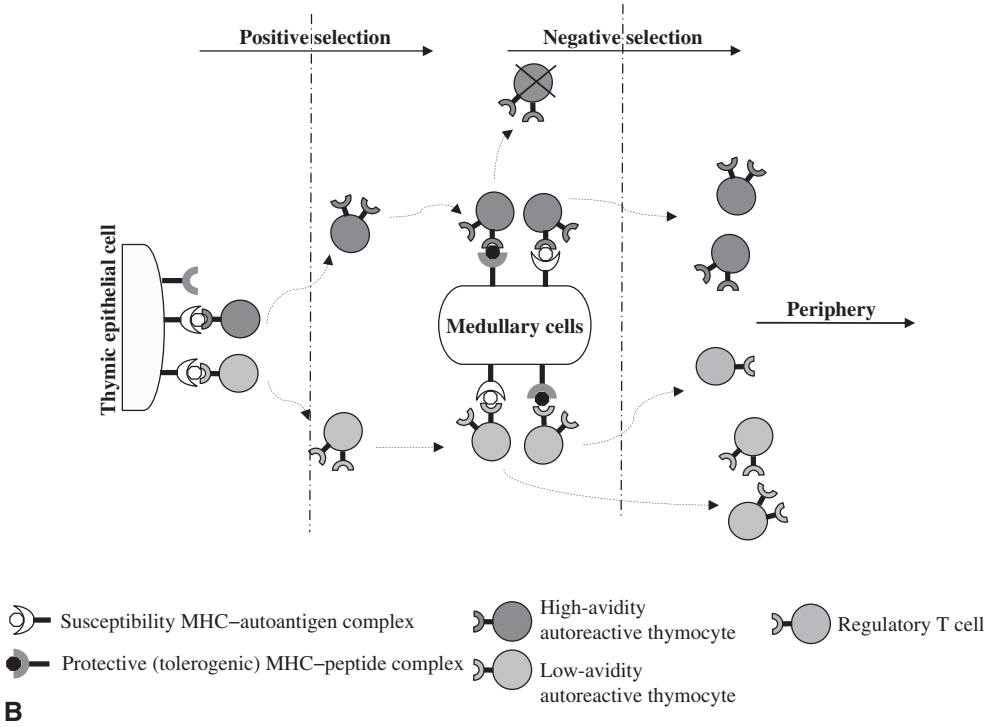
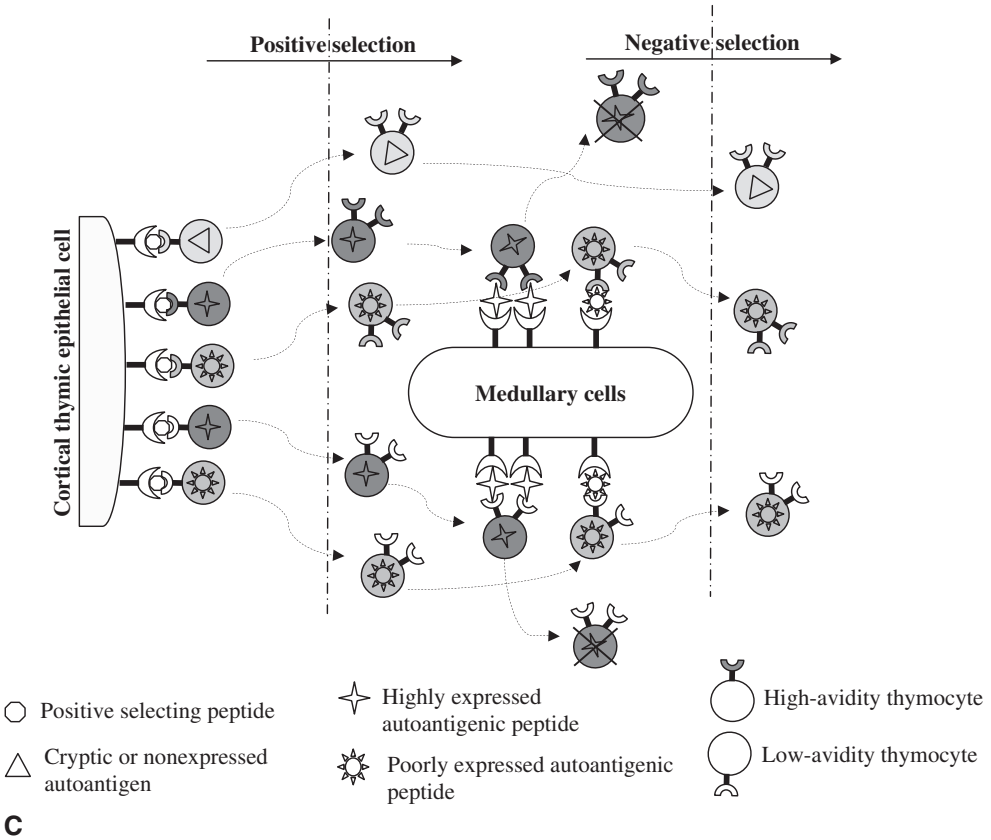


B



C

FIGURE 6.1 (*Continued*)

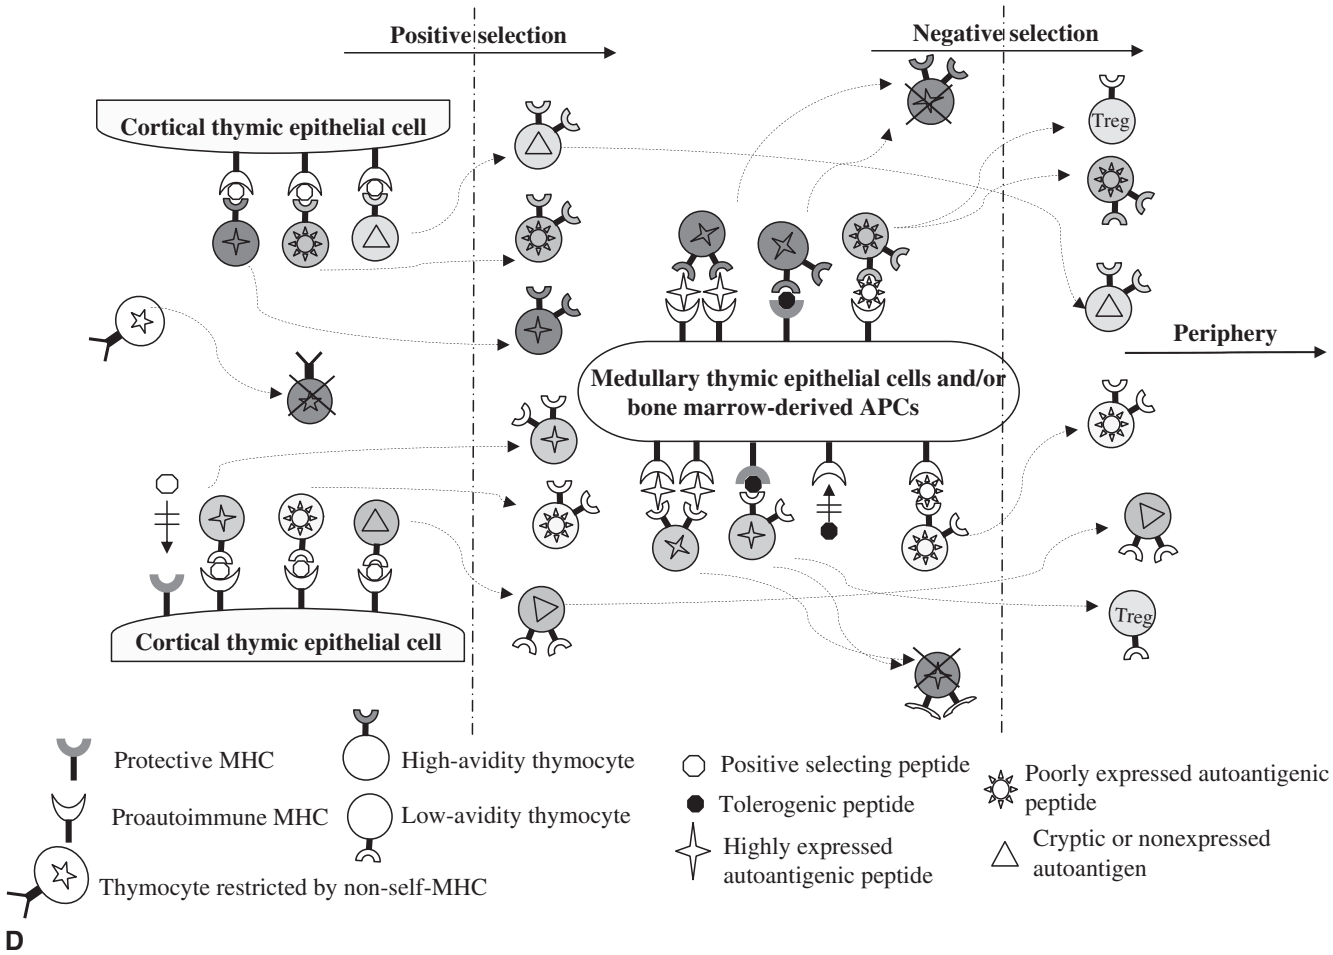


FIGURE 6.1 (*Continued*) (*D*). The balance (in the peripheral T cell repertoire) between high- and low-avidity autoreactive clonotypes and regulatory T cells will determine the overall risk of the individual to a given autoimmune disorder. In diseased individuals, the self-reactive T cells that escape central tolerance undergo activation in the lymph nodes draining the target tissue by recognizing target antigen–MHC complexes on APCs in the presence of proinflammatory signals. See color plate section.

in the context of several different alleles at most other loci. The issues of transcomplementation, whereby α or β chains encoded on alleles of one haplotype can pair with the corresponding partners encoded on the second haplotype, add yet another level of complexity of potential import in genetic susceptibility and/or resistance to autoimmune disorders. Obviously, the extraordinary diversity of the MHC at the population level impacts on an individual's ability to present specific self-antigens, and thus to control the development of autoreactive thymocytes, or the activation of their mature counterparts in the periphery. It is therefore not surprising that susceptibility and/or resistance to specific autoimmune diseases are associated with certain HLA/H-2 alleles and/or haplotypes.

Most autoimmune diseases are primarily associated with MHC class II polymorphisms, but some are almost exclusively associated with polymorphisms at MHC class I loci. To cite a few examples, there are associations between HLA-DR4 and rheumatoid arthritis (RA); between HLA-DR2 and systemic lupus erythematosus (SLE) or multiple sclerosis (MS); between HLA-DR3 and celiac disease, SLE, Graves' disease, myasthenia gravis, and Addison's disease; between HLA-DR8 and juvenile idiopathic arthritis; between HLA-DR3/DR4 and type 1 diabetes (T1D); between HLA-B27 and ankylosing spondylitis, reactive arthritis or anterior uveitis; between HLA-B35 and subacute thyroiditis; and between HLA-Cw6 and pemphigus vulgaris. The MHC class II–disease associations are predominantly accounted for by sequence polymorphisms in the second exon of DQB1, DRB1, and/or DPB1 genes. The MHC-associated susceptibility to T1D, for example, is mostly determined by polymorphisms at the DQB1 locus, particularly at the codon encoding position 57. The presence of alanine, valine or serine at this position affords susceptibility, whereas the presence of aspartic acid affords resistance. RA, on the other hand, is primarily associated with DRB1

alleles encoding DRβ molecules sharing key amino acids between positions 67 and 74. Similar MHC class II–disease associations have been described in the mouse. Susceptibility to T1D in nonobese diabetic (NOD) mice, for example, is associated with a unique I-A allele (I-Aβ^{g7}) in which the histidine and aspartic acid located at positions 56 and 57 in most murine I-Aβ chains (the counterparts of human DQβ chains) are replaced by proline and serine, respectively.

To examine the molecular bases of HLA–disease associations, a number of human MHC genes have been transgenically expressed in rodents lacking endogenous MHC genes (Geluk et al., 1998). When DQ8 molecules (positively associated with T1D) were expressed in mice also expressing a costimulatory CD80 (B7.1) transgene in β cells, the mice became intolerant to islet antigens and developed diabetes (Wen et al., 1998; 2000; 2002). Interestingly, coexpression of DR4 or DQ6 molecules in these animals modulated the diabetes susceptibility provided by the DQ8 transgene (Wen et al., 2001; Kudva et al., 2002). Likewise, whereas expression of DQ8 or DR4 molecules in mice afforded susceptibility to collagen-induced arthritis (CIA), expression of DR2 molecules (negatively associated with RA) afforded disease resistance (Nabozny et al., 1996; Taneja et al., 1998). DQ8 expression also provided susceptibility to experimental autoimmune encephalomyelitis (EAE), an animal model of MS (Das et al., 2000). Expression of DR3 or DR2 molecules in transgenic mice rendered them susceptible or resistant, respectively, to severe experimental autoimmune thyroiditis (EAT), a model of Graves' disease and Hashimoto's thyroiditis in humans (Kong et al., 1996; Flynn et al., 2004). The observations in HLA-B27 transgenic rats and mice are particularly interesting, given the well-established association that exists between HLA-B27 and the spondyloarthropathies (SpA), a group of inflammatory conditions affecting the skeleton, skin, and mucous membranes. These HLA-B27 transgenic animals spontaneously develop autoimmune syndromes that closely mimic SpA, provided that human β2 microglobulin (hβ2M) is coexpressed (in rats) or that the endogenous mβ2M gene is absent (in mice) (Taurog et al., 1999). Interestingly, HLA-B27 molecules can form homodimers in the absence of β2M (Allen et al., 1999) and can support the development of both $CD8^+$ and $CD4^+$ T cells (Roddis et al., 2004). In fact, a role for $CD4^+$ T cells in HLA-B27-associated autoimmunity has been proposed (Breban et al., 1996). Taken together, the above studies strongly support the idea that MHC genes themselves (as opposed to other linked genetic elements) afford autoimmune disease susceptibility and/or resistance.

The roles of murine MHC molecules in autoimmune disease susceptibility and/or resistance have also been explored in MHC-transgenic or -congenic mice. NOD mice have been widely used in these studies because they spontaneously develop a form of autoimmune diabetes that resembles the human condition and is strongly associated with a particular MHC haplotype (H-2^{g7}). Studies of congenic NOD mice expressing non-NOD MHC haplotypes, and of NOD mice expressing I-Eα^d, I-Eα^k, I-Aα^k/I-Aβ^k, I-Aβ^d or modified I-Aβ^{g7} transgenes, provided strong evidence supporting a role for class II molecules in providing susceptibility or resistance to T1D (Tisch and McDevitt, 1996). Although the underlying mechanisms remain unclear, experiments in bone marrow chimeras have shown that the MHC-linked resistance to diabetes is mediated by an hematopoietic cell type, possibly an APC [B lymphocytes, macrophages, and/or dendritic cells (DCs)]. Crystallographic studies have shown that I-A^{g7} molecules have a unique structure that supports the preferential binding of peptides bearing acidic residues at their C-terminal (Chao et al., 1999; Corper et al., 2000). It has been proposed that structural differences resulting from polymorphisms around the I-Aβ chain position 57 account for the ability of I-A^{g7} and protective MHC class II molecules to afford susceptibility or resistance to diabetes, respectively. Evidence for this comes from studies of transgenic mice expressing a diabetogenic TCR. Thymocytes expressing the islet-specific 4.1-TCR, which is highly diabetogenic when expressed in the NOD background (I-A^{g7} homozygous), undergo deletion in NOD mice that coexpress antidiabetogenic MHC class II molecules (Schmidt et al., 1999; Thiessen et al., 2002). Central deletion of 4.1-thymocytes is exclusively mediated by hematopoietic cells and requires the presentation of a specific, but as yet unknown, peptide(s) (Schmidt et al., 1999; Thiessen et al., 2002). Notably, 4.1-thymocyte-deleting class II molecules could restrict neither the positive selection of 4.1-thymocytes on the thymic cortex nor the presentation of their target autoantigen in the periphery, suggesting that the deleting peptide(s) is(are) exclusively expressed by a thymus-resident, tolerogenic APC, possibly a DC. Figure 6.1B represents the interpretation of the data. Namely, the MHC-promiscuous autoreactive T cells undergo central tolerance by engaging protective MHC–peptide complexes on thymic medullary APCs. In the absence of protective MHC molecules, these autoreactive T cells evade central tolerance and migrate to the periphery. Whether these observations account for the MHC-linked resistance of wild-type mice to autoimmune diabetes or are a peculiarity of 4.1-like $CD4^+$ T cells remains to be determined. What is known is that this phenomenon does not target all autoreactive T cells. For example, antidiabetogenic MHC class II molecules, such as I-A^b, I-E^k and I-A^{g7PD} (encoding proline and aspartic acid at positions 56 and 57, respectively), did not trigger deletion of thymocytes expressing another islet antigen-specific, I-A^{g7}-restricted TCR (BDC2.5). Whereas I-A^{g7PD} rendered 4.1-$CD4^+$ thymocytes partially unresponsive to antigen (Thiessen et al., 2002), it fostered the positive selection of BDC2.5 $CD4^+$ thymocytes (Kanagawa et al., 1998). Neither 4.1 nor BDC2.5 $CD4^+$ T cells could recognize islet antigen in the

context of this MHC molecule (Kanagawa et al., 1998). Since the BDC-2.5 TCR is not diabetogenic when expressed as a transgene in immunocompetent NOD mice, it is tempting to speculate that protective MHC class II molecules selectively (or preferentially) target certain highly pathogenic T-cell specificities, rather than all self-reactive T cells regardless of pathogenic potential.

An alternative, albeit certainly not mutually exclusive possibility, is that protective MHC class II molecules act by promoting the selection of non-autoreactive T cells with regulatory properties (Bohme et al., 1990; Parish et al., 1993; Singer et al., 1993) (Figure 6.1B). For example, NOD mice expressing an I-A^k transgene developed a significantly reduced incidence of diabetes, yet T cells from the spleens of these mice could adoptively transfer diabetes into NOD.scid recipients (Slattery et al., 1993). Thus, protective MHC class II molecules need not delete all islet-autoreactive T cells to afford diabetes resistance. Nevertheless, these observations do not prove a contribution of Tregs to disease resistance, or rule out a tolerogenic effect of I-A^k on T-cell specificities that might play key roles in the natural history of the spontaneous disease. Whatever the mechanism, it is clear that MHC class II molecules contribute to diabetes susceptibility and resistance by promoting the development of different TCR repertoires.

TOLERANCE VERSUS BENIGN AUTOREACTIVITY OR PATHOGENIC AUTOIMMUNITY

Not all self-proteins are immunogenic or capable of driving autoimmune responses. Autoreactive T-cell responses preferentially target certain self-proteins, such as thyroid-stimulating hormone receptor in Graves' disease; myelin basic protein (MBP), proteolipid protein (PLP), and myelin oligodendrocyte glycoprotein (MOG) in EAE/MS; H^+/K^+ ATPase in autoimmune gastritis; or insulin, glutamic acid decarboxylase (GAD), and islet-specific glucose-6-phosphatase catalytic subunit-related protein (IGRP) in T1D. Surprisingly, many of these antigenic T-cell specificities are tolerized during T-cell development, at least partially, even in disease-susceptible genetic backgrounds. For example, although NOD mice mount T-cell responses to various GAD65 epitopes, thymocytes expressing a transgenic GAD65-reactive TCR ($GAD65_{286–300}$) underwent negative selection (Tian et al., 1997; Tisch et al., 1999). A similar phenomenon was observed in transgenic mice expressing a TCR recognizing an H^+/K^+ ATPase β chain epitope (Alderuccio et al., 2000). In addition, whereas $MBP_{121–150}$-specific T cells developed normally in MBP gene-targeted mice, they succumbed to central tolerance in MBP-competent animals. Obviously, susceptibility of autoreactive thymocytes to tolerance depends not only on the affinity of the target autoantigenic peptide for self-MHC, but also on the abundance of the corresponding MHC–peptide complex on tolerogenic APCs. For example, $MBP_{1–11}$, which binds self-MHC with significantly lower affinity than $MBP_{121–150}$, did not delete TCR-transgenic thymocytes in MBP-competent mice (Harrington et al., 1998; Huseby et al., 2001b). However, when $MBP_{1–11}$'s affinity (for MHC) or concentration were increased (by introducing single amino acid substitutions in the peptide), deletion was observed (Liu et al., 1995; Pearson et al., 1997). Notwithstanding these observations, not all TCRs capable of recognizing potentially tolerogenic (stable and/or abundant) autoantigen–MHC complexes will necessarily undergo tolerance: the outcome of T-cell development is also a func-tion of the affinity/avidity with which individual TCRs engage specific MHC–peptide complexes. Thus, whereas TCR-transgenic thymocytes recognizing $IGRP_{206–214}/K^d$ with intermediate avidity developed normally, those recognizing the same complex with higher avidity did not (P. Santamaria, unpublished observations). Since high-affinity T cells can remove target MHC–peptide complexes from the surface of APCs (Kedl et al., 2002), high-affinity autoreactive T cells may spare lower-affinity T-cells with identical antigenic specificity from tolerance induction by downregulating the corresponding MHC–peptide complex on APCs (Perchellet et al., 2004). Autoreactive T cells may evade central tolerance if the target autoantigen is only expressed at low levels of tolerogenic APCs (Figure 6.1C).

Another important determinant of tolerance susceptibility is whether or not developing thymocytes encounter MHC–peptide complexes on medullary epithelial cells or bone marrow-derived APCs (Anderson et al., 2002; Ramsdell and Ziegler, 2003). In some cases, autoreactive T cells escape central tolerance because they target epitopes encoded on mRNA splice variants that are not expressed in tolerogenic APCs (Klein et al., 2000; Kuchroo et al., 2002). In other instances, such as appears to be the case for $IGRP_{206–214}/K^d$-reactive thymocytes, tolerance occurs despite the fact that the self-antigen is not expressed by thymic stromal cells (P. Santamaria, unpublished observation). Whether tolerance in this system is induced by delivery of $IGRP_{206–214}/K^d$ complexes to the thymus by autoantigen-loaded DCs, or by a different MHC–peptide complex remains to be determined.

Another important, albeit not always openly recognized, concept is that autoreactivity does not necessarily imply pathogenicity. Transgenic mice expressing TCRs specific for several MBP or MOG epitopes, including $MBP_{1–11}$, $MBP_{84–102}$, $MBP_{121–150}$, and $MOG_{35–55}$, did not spontaneously develop (or only did so with a low incidence) symptoms of EAE when housed in specific pathogen-free environments (Goverman et al., 1993; Lafaille et al., 1994; Madsen et al., 1999; Huseby et al., 2001b). In contrast, mice expressing $PLP_{139–151}$-reactive TCRs developed a high incidence of

disease, regardless of whether the TCRs came from encephalitogenic or non-encephalitogenic T cell clones (Waldner et al., 2000). Likewise, whereas T-cells recognizing an H^+/K^+ ATPase β subunit epitope barely induced autoimmune gastritis in TCR-transgenic BALB/c mice, those recognizing an H^+/K^+ ATPase α subunit epitope were highly gastritogenic (McHugh et al., 2001). Another example of incomplete correlation between autoreactivity and pathogenicity comes from studies of β cell autoreactive TCR-transgenic NOD mice. Whereas expression of the class II-restricted 4.1-TCR led to a dramatic acceleration of onset of diabetes (Schmidt et al., 1997), expression of the BDC2.5 TCR did not. In fact, the incidence of diabetes in BDC2.5 TCR-transgenic NOD mice is significantly lower than that seen in wild-type NOD mice (Kurrer et al., 1997; Luhder et al., 2000). Such effects of antigenic (and epitope) specificity on pathogenicity were also observed when a panel of GAD65-derived peptides were injected into young NOD mice. Certain epitopes protected the animals from T1D by inducing interleukin (IL)-4 producing Th2 cells (Tisch et al., 1999). Interestingly, T cells expressing a $GAD65_{286–300}$-specific TCR not only were nonpathogenic, but actually delayed the onset of diabetes in NOD.scid recipients of diabetogenic T cells (Tarbell et al., 2002).

Another factor that contributes to the expression of clinical autoimmunity is antigen processing. T-cell epitopes can be classified into at least two broad functional groups. The first group includes all naturally processed peptides capable of binding self-MHC molecules. The second includes the so-called cryptic epitopes, i.e., epitopes that are either not presented at all, or presented only inefficiently (See Chapter 14). T cells recognizing cryptic determinants that can be presented by APCs readily escape central tolerance because these determinants are presented at levels that fall below the threshold required for induction of tolerance (Figure 6.1C). Another example of crypticity is related to the ability/inability of autoreactive TCRs to recognize specific core sequences within larger epitopes. For example, MBP-pulsed APCs generate substantial amounts of $MPB_{1–17}$ and $MBP_{1–18}$, and these peptides bind MHC molecules with high affinity (Seamons et al., 2003). However, neither of these two peptides is recognized well by $MBP_{1–11}$-specific T cells. This phenomenon may account for both the lack of tolerance and the low incidence of disease in mice expressing $MBP_{1–11}$-specific TCR transgenes (Goverman et al., 1993; Brabb et al., 1997). Pathogenicity of such cryptic epitope-specific T cells may be enhanced by exposure to certain environmental factors, such as infectious agents capable of eliciting inflammation or molecular mimicry. Lastly, it is important to recognize the possibility that initiation of autoimmunity need not involve T cells recognizing the ultimate cellular target of the autoimmune response (i.e., pancreatic β cells in T1D). Initiation of T1D in both NOD mice and humans, for example, is associated with autoreactive T- and B-cell responses against peri-islet Schwann cells (Winer et al., 2003). Likewise, arthritis in a TCR-transgenic mouse model was triggered by recognition of a ubiquitous autoantigen (see below) (Kouskoff et al., 1996).

In summary, it is clear that pathogenic autoreactive T cells must "jump" through a number of "hoops" before they can establish themselves in the peripheral immune system. Factors such as presence or absence of anti- and pro-autoimmune MHC class II molecules, affinity of autoreactive TCRs for peptide–MHC, and levels of autoantigen expression will ultimately determine whether potentially pathogenic autoreactive T cells will develop. These factors are outlined individually in Figure 6.1A–C. Figure 6.1D attempts to integrate the contribution of each of these variables to the fate of autoreactive T cells.

T–T CELL INTERACTIONS AND SPONTANEOUS AUTOIMMUNITY

Most organ-specific, spontaneous autoimmune diseases require the contribution of $CD4^+$ and $CD8^+$ T cells. Both these T-cell subsets are found in the pancreatic or central nervous system (CNS) lesions of T1D and MS patients, respectively (Hauser et al., 1986; Somoza et al., 1994; Babbe et al., 2000; Skulina et al., 2004; Zang et al., 2004), and both recognize tissue-specific antigens (Tsuchida et al., 1994; Schmidt, 1999; Abiru and Eisenbarth, 2000). The same is true in animal models of these diseases. Unsorted splenic T cells from prediabetic NOD mice can transfer diabetes into NOD.scid or young nondiabetic NOD recipients, but splenic T cells depleted of $CD4^+$ or $CD8^+$ T cells cannot (Bendelac et al., 1987; Miller et al., 1988; Christianson et al., 1993). Since diabetes can be transferred by preactivated islet-specific $CD4^+$ or $CD8^+$ T-cell clones (Bradley et al., 1992; Peterson and Haskins, 1996), it is reasonable to suspect that T–T collaboration is required for activation of the pathogenic activities of autoreactive T cells. Alternatively, transfer of relatively large numbers of clonal T cells overwhelms the naturally-occurring immune-regulatory mechanisms that are responsible for keeping in check the limited numbers of naïve autoreactive T cells that are normally present in the circulation (see below). These considerations may account, at least in part, for the dramatic acceleration of disease that is normally seen in monoclonal TCR-transgenic NOD mice (Verdaguer et al., 1997; Graser et al., 2000; Gonzalez et al., 2001). $CD4^+$ and $CD8^+$ T cells also seem to play an equally important role in the pathogenesis of experimental autoimmune myasthenia gravis (EAMG) (Zhang et al., 1996). Although it has been generally held that EAE is a disease predominantly driven by $CD4^+$ T cells (Pettinelli and McFarlin, 1981; Jiang et al., 1992), recent studies have shown that MBP-specific $CD8^+$ T cells, while not necessary for the initiation of EAE,

contribute to its pathogenesis (Huseby et al., 2001a; Sun et al., 2001; 2003). $CD4^+$ T cells seem to be less critical for development of CIA, because CD4-deficient mice were significantly more susceptible to CIA development than their CD8-deficient counterparts (Tada et al., 1996).

Although there is compelling evidence to suggest that $CD4^+$ T cells are also required (Thivolet et al., 1991; Christianson et al., 1993), studies of $CD8^+$ T-cell-deficient NOD mice have shown that $CD8^+$ T cells are key to the initiation of the diabetogenic process (Wang et al., 1996; Serreze et al., 1997; DiLorenzo et al., 1998). Observations made in MHC class I-restricted, β cell autoreactive TCR-transgenic NOD mice are consistent with the idea that $CD4^+$ T cells contribute to the diabetogenic process by enhancing the recruitment, accumulation, and/or differentiation of Th-dependent autoreactive $CD8^+$ clonotypes. Recruitment of $CD8^+$ T cells expressing the 8.3-TCR, for example, is enhanced by endogenous (non-transgenic) $CD4^+$ T cells or by splenic $CD4^+$ T cells derived from non-transgenic NOD mice (Verdaguer et al., 1997). Not all diabetogenic $CD8^+$ clonotypes, however, require the assistance of $CD4^+$ Th cells to home to and/or accumulate into pancreatic islets. $CD8^+$ T cells expressing the AI4-TCR (recognizing a different antigen from the 8.3-TCR), for example, are as diabetogenic in the presence of $CD4^+$ T cells as they are in their absence (Graser et al., 2000).

Although the mechanisms underlying the helper-dependency or -independency of $CD8^+$ clonotypes remain unclear, there are some informative clues. Progression of diabetes in NOD mice is accompanied by avidity maturation of the $IGRP_{206–214}/K^d$-reactive $CD8^+$ T-cell subpopulation, such that low-avidity clonotypes predominating at the outset of insulitis are progressively replaced by high-avidity ones as the animals age (Amrani et al., 2000). Interestingly, studies employing TCR-transgenic NOD mice have shown that high-avidity $IGRP_{206–214}/K^d$-reactive $CD8^+$ T cells can trigger diabetes in a Th-independent manner (P. Santamaria, unpublished observations), suggesting that the requirement for T-cell help is a function of avidity. In this case scenario, the low-avidity clonotypes that prevail at the outset of the diabetogenic autoimmune response would only be able to differentiate into β cell killers in the presence of $CD4^+$ Th cells. With progressive recruitment of the less prevalent high-avidity clonotypes into islets, this Th-dependent response would evolve into a Th-independent one. This interpretation of the data is consistent with the observation that purified $CD4^+$ and $CD8^+$ T cells from nondiabetic NOD mice cannot transfer disease into NOD.scid mice unless they are transferred together (Bendelac et al., 1987; Miller et al., 1988; Christianson et al., 1993).

Collaboration between $CD4^+$ Th cells and precytotoxic $CD8^+$ T cells is usually bridged by DCs, which can process exogenous antigens through the endogenous pathway of antigen presentation. Engagement of CD40 on DCs by CD154 (CD40 ligand) on antigen-specific $CD4^+$ T cells upregulates the expression of costimulatory molecules on DCs, elicits the production of proinflammatory cytokines, and endows them with the ability to foster the differentiation of naïve $CD8^+$ T cells into cytotoxic effectors (van Essen et al., 1995; Yang and Wilson, 1996). In fact, blockade of the CD40–CD154 interaction prevents the development of several different autoimmune diseases in animal models, including EAE (Grewal et al., 1995; Gerritse et al., 1996; Howard et al., 1999; Girvin et al., 2002), thyroiditis (Carayanniotis et al., 1997), colitis (De Jong et al., 2000), lupus (Kalled et al., 2001), and T1D (Balasa et al., 1997; Green et al., 2000). In addition to triggering the activation of DCs, engagement of CD40 by CD154 is key to $CD4^+$ Th cell activation (Becher et al., 2001; Amrani et al., 2002). Furthermore, since CD40–CD154 interactions are dispensable for the development and function of regulatory $CD4^+CD25^+$ T cells, and since regulatory T cells inhibit DC maturation (Serra et al., 2003), CD40 blockade also prevents autoimmunity by promoting the active suppression of $CD8^+$ T-cell responses. Lastly, it is important to note that autoreactive $CD4^+$ T cells not only contribute to autoimmune responses by providing T-cell help; they, too, can differentiate into effectors capable of killing targets through a number of mechanisms (Bradley et al., 1992; Goverman et al., 1993; Lafaille et al., 1994; Peterson and Haskins, 1996; Verdaguer et al., 1997; Graser et al., 2000; Huseby et al., 2001a; Sun et al., 2001).

Figure 6.2A represents some of the processes underlying T–T collaboration in autoimmunity. Naïve $CD4^+$ T cells undergo activation by recognizing target MHC–peptide complexes on mature autoantigen-loaded DCs. Cytokines and chemokines produced by these activated $CD4^+$ T cells foster the recruitment of additional $CD4^+$ and $CD8^+$ T cells to the site of the autoimmune inflammation. High-avidity autoreactive $CD8^+$ T cells differentiate into effectors in the absence of Th cells. Activation of their low-avidity counterparts, on the other hand, requires the presence of $CD4^+$ Th cells. Such $CD4^+$ Th cells induce costimulatory activity on DCs by ligating CD40. Tissue damage in autoimmunity is ultimately caused by both T-cell types.

CYTOKINES AND T-CELL-MEDIATED AUTOIMMUNITY

Cytokines play pivotal roles in the development and regulation of immune responses in general, and T-cell-mediated autoimmunity in particular. According to their role in immune responses, cytokines can be categorized as being proinflammatory [e.g., interferon (IFN)-γ and TNF-α] or anti-inflammatory (e.g., IL-4 and TGF-β). Depending on the cytokines they produce, most $CD4^+$ T cells can be subclassified into Th1 and Th2 types (See Chapter 7). Th1 cells typ-

ically produce IFN-γ, TNF-α, and IL-2, whereas Th2 cells generally produce IL-4, IL-5, and IL-13. Cytokines secreted by autoreactive lymphocytes, particularly those with proinflammatory activity, can cause tissue damage either directly (i.e. by ligating proapoptotic receptors on target cells) or indirectly [i.e., by inducing the production of secondary mediators, such as nitric oxide (NO)]. Since an indepth discussion of the role of cytokines in autoimmunity is beyond the scope of this chapter, this section focuses on specific examples to illustrate the notion that cytokines often play paradoxical roles in autoimmunity, depending on the location, timing, and magnitude of expression.

Inflammatory lesions in the brains of patients with MS or in the pancreatic islets of patients with T1D contain significant levels of proinflammatory cytokines, such as INF-γ and TNF-α (Brosnan and Raine, 1996; Balashov et al., 1999). Peripheral T cells from both types of patients produce increased levels of IFN-γ, and the magnitude of this phenotype is associated with disease progression (Dettke et al., 1997; Begolka et al., 1998; Petereit et al., 2000; Karni

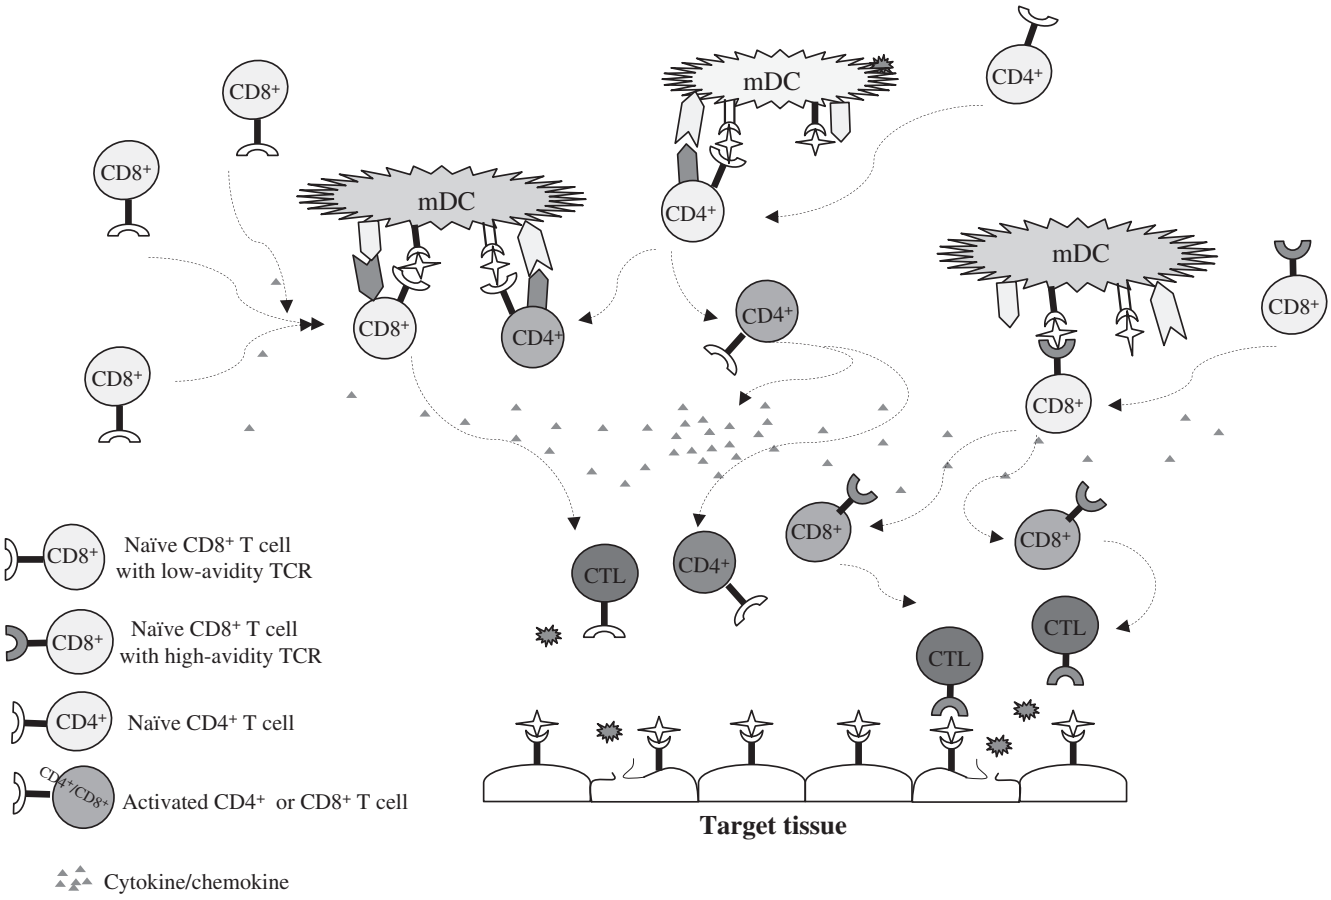

FIGURE 6.2 T–T and T–B interactions in the development of autoimmune responses. *A*, T–T collaboration in autoimmunity. *B*, Autoimmune reactions driven by collaboration between autoreactive T and B cells. *C*, Regulatory T cells suppress the activation of autoreactive T cells. In the steady-state, iDCs are kept in check by regulatory T cells (Treg) and, on capturing autoantigens, may have tolerogenic properties (TiDCs) against naïve autoreactive T cells. In the presence of activated helper T (Th) cells, Toll-like receptor ligands and/or proinflammatory (Th1) cytokines, iDCs are derepressed and differentiate into mature DCs (mDCs). Engagement of DCs by $CD4^+$ Th cells leads to CD154 upregulation and generation of effector $CD4^+$ cytotoxic T lymphocytes (CTLs). Ligation of CD40 on DCs by CD154 endows DCs with the ability to costimulate autoreactive $CD8^+$ T cells, and to foster their differentiation into $CD8^+$ CTLs (*A* and *D*). On capturing autoantigens via cell-surface immunoglobulins (BCR), B cells can activate autoreactive T cells and thus foster their differentiation into Th cells. Th2 cytokines produced by autoreactive $CD4^+$ Th can, in turn, promote the differentiation of naïve autoreactive B cells into autoantibody-secreting plasma cells. These autoantibodies may or may not have pathogenic significance, depending on the autoimmune disease (*B* and *D*). Tregs can suppress T-cell responses by inhibiting DC maturation, or by preventing T-cell activation or CTL differentiation (*C* and *D*). BCR, B-cell receptor; TCR, T-cell receptor. FIGURE 6.2 (*Continued*) *D*, Interactions that fuel or control autoimmunity in the periphery. Immunogenic antigens released from damaged tissues are captured and processed by B cells and immature dendritic cells (iDCs).

et al., 2002; 2004; Arif et al., 2004; Ott et al., 2004). In agreement with this, autoreactive T-cell clones and lines derived from patients and animal models of these two diseases produce large quantities of IFN-γ (Suarez-Pinzon et al., 1996; Bradley et al., 1999; Waldner et al., 2000; Huseby et al., 2001a; Pewe and Perlman, 2002; Bettelli et al., 2003). In addition, decreased production of IFN-γ by such cells correlated with clinical remission or delayed progression of disease (Kuchroo et al., 1995; Nicholson et al., 1995; Faust et al., 1996; Segal and Shevach, 1996; Trembleau et al., 1997). Furthermore, transgenic expression of IFN-γ in pancreatic islets or the CNS enhanced disease progression in animal models of these two diseases (Sarvetnick et al., 1990; Horwitz et al., 1997). Notably, patients with MS treated with IFN-γ displayed an exacerbated clinical course (Panitch et al., 1987). It should be noted, however, that, under certain circumstances, IFN-γ can also play a protective role in autoimmunity. In contrast to the outcome of clinical trials in patients with MS (Panitch et al., 1987), administration of IFN-γ to mouse models of MS and T1D decreased both the severity and incidence of these diseases (Voorthuis et al., 1990; Sobel et al., 2002). IFN-γ blockade with antibodies exacerbated the development of EAE in mice (Lublin et al., 1993; Heremans et al., 1996). Although genetic elimination of IFN-γ or its receptor had no significant effects on disease development (Ferber et al., 1996; Hultgren et al., 1996; Kanagawa et al., 2000; Serreze et al., 2000), animals lacking IFN-γ or IFN-γ receptor genes displayed increased susceptibility to EAE and T1D, depending on the genetic backgrounds that were studied or the disease induction protocols that were employed (Krakowski and Owens, 1996; Willenborg et al., 1996; Serreze et al., 2001; Trembleau et al., 2003). Some evidence suggests that the protective effects of IFN-γ on autoreactive responses are effected mainly in the periphery (Willenborg et al., 1999; Chu et al., 2000), although this remains to be demonstrated. Accordingly, the effects of certain cytokines (in this case, IFN-γ) on autoimmune responses are not always those expected. The timing

of expression is a very important consideration. For example, whereas early expression of TNF-α in pancreatic islets of transgenic mice accelerated diabetes, late expression prevented disease onset (Yang et al., 1994; Grewal et al., 1996; Green et al., 2000).

Th2 cytokines are thought to play a regulatory role in the development of T-cell–mediated autoimmunity. Peripheral autoreactive T cells from both MS and T1D patients expressed lower levels of IL-10 than autoreactive T cells derived from healthy controls (Ferrante et al., 1998; Rapoport et al., 1998; Kallmann et al., 1999). In addition, systemic treatment with, or transgenic expression of, IL-10 (Pennline et al., 1994; Rott et al., 1994) protected animals from EAE, autoimmune colitis, and T1D (Moritani et al., 1996; Bettelli et al., 1998; Nitta et al., 1998; Xiao et al., 1998, Cua et al., 1999; Pauza et al., 1999; Asseman et al., 2003). These observations are in agreement with the idea that many clonal T cells that regulate autoimmune diseases mediate their functions via IL-10 (Burkhart et al., 1999; Maron et al., 1999; Stohlman et al., 1999; Asseman et al., 2003; Bettelli et al., 2003; Frenkel et al., 2003). However, when IL-10 was specifically overexpressed in pancreatic islets, islet cells were destroyed rapidly (Moritani et al., 1994; Wogensen et al., 1994). It is likely that local expression of IL-10 accelerated the pathogenic process by fostering the recruitment of lymphocytes, possibly by upregulating the expression of intercellular adhesion molecule-1 (ICAM-1) (Wogensen et al., 1993; Balasa et al., 2000). In contrast, islet expression of viral–IL-10 mice protected from T1D (Kawamoto et al., 2001). Expression of IL-10 in the CNS also had a protective rather than a pathogenic effect (Cua et al., 2001), possibly because IL-10 expression was not sufficient to promote the recruitment of lymphocytes across the blood–brain barrier. IL-4 is another Th2 cytokine that has anti-inflammatory effects. Whereas increased production of IL-4 had protective effects against a number of autoimmune disorders, targeted disruption of the IL-4 gene had little or no effect on the natural history of these diseases (Rapoport et al., 1993; Mueller et al., 1996; Croxford et al., 1998; Samoilova et al., 1998; Pal et al., 1999; Martino et al., 2000; Serreze et al., 2001). When pathogenic T-cell clones were engineered to produce IL-4, they protected animals from EAE and T1D (Shaw et al., 1997; Maron et al., 1999). However, it was also reported that IL-4 producing autoreactive T cells could trigger EAE and T1D (Lafaille et al., 1997; Pakala et al., 1997; Poulin and Haskins, 2000; Durinovic-Bello et al., 2004). When taken together, these studies have revealed that the effects of cytokines in autoimmunity are more a function of the location and timing of expression than of their pro- or anti-inflammatory nature alone. Another important concept is that the effects of individual cytokines on autoimmune responses need to be studied in the context of all the other cytokines that are produced at the site of inflammation (Santamaria, 2003). Ultimately, it is the combined effects of all these cytokines that determine (or contribute to) the outcome.

B–T CELL COLLABORATION IN AUTOIMMUNITY

B cells often play important roles in the pathogenesis of organ-specific, T-cell-dependent autoimmune diseases. T1D patients and NOD mice produce autoantibodies against numerous islet antigens, including insulin, islet autoantigen-2 (IA-2) and GAD65, presumably as a result of defective B-cell tolerance to soluble autoantigens (Thomas et al., 2002; Silveira et al., 2004). Furthermore, B-cells are prevalent in the insulitis lesions of prediabetic NOD mice and T1D patients. Notwithstanding this, B cells or sera from diabetic NOD mice cannot transfer disease to healthy recipients. Although B cells are not sufficient in diabetogenesis, NOD mice do not spontaneously develop T1D, or do so with significantly reduced incidence and delayed kinetics if they lack B cells, suggesting that B cells play an essential role in diabetogenesis (Serreze et al., 1996; Akashi et al., 1997; Yang et al, 1997; Noorchashm et al., 1997 and 1999). It has been suggested that autoreactive B cells contribute to the disease process by capturing islet antigens via surface immunoglobulins (Falcone et al., 1998; Serreze et al., 1998; Noorchashm et al., 1999). In fact, the role of B cells in murine T1D seems to be restricted to early T-cell priming events, because NOD T cells can readily transfer diabetes into B-cell-deficient recipients if they are allowed to undergo priming in the donors (Charlton et al., 2001). Although monoclonal islet autoreactive TCR-transgenic NOD mice develop diabetes despite lacking mature B cells (Verdaguer et al., 1997; Graser et al., 2000; Gonzalez et al., 2001), the large frequency of circulating autoreactive T cells in these mice may overwhelm (artificially) the need for B cells. Alternatively, B cells are not necessary for the activation of naïve autoreactive T cells, but contribute to the maintenance and/or expansion of the peripheral autoreactive T-cell repertoire (Jaume et al., 2002; Dromey et al., 2004).

The recent description of a B-cell-deficient patient with T1D casts some doubts as to whether B cells are necessary for development of human T1D (Naserke et al., 2001). There is also some controversy as to whether autoantibodies contribute to the pathogenesis of T1D. Although the presence of islet antigen-specific autoantibodies in sera from T1D patients and NOD mice forecasts progression of clinically silent islet autoimmunity to overt T1D, these autoantibodies are generally considered to be nonpathogenic (Devendra et al., 2004). There is some evidence, however, that transplacental transfer of maternal autoantibodies in NOD mice affords risk of diabetes to the offspring (Greeley et al., 2002).

The role of autoreactive B cells in other T-cell-driven autoimmune diseases like MS seems to be different from that in T1D. Autoantibody-producing B cells are present in the CNS lesions of MS patients (Prineas and Wright, 1978; Genc et al., 1997), and in both MS and EAE, autoantibodies are associated with destruction of myelin (Storch et al., 1998; Genain et al., 1999). In EAE, B cells are only required when the disease is induced by immunization with intact protein antigens, but not when it is induced with peptides (Wolf et al., 1996; Lyons et al., 1999; Dittel et al., 2000; Svensson et al., 2002), suggesting that here, too, B cells contribute to the disease process by processing and presenting target autoantigens. Nevertheless, it has been shown that the presence of autoantibodies enhances the severity of EAE (Myers et al., 1992; Genain et al., 1995; Lyons et al., 2002). It has also been reported that autoreactive B cells may contribute to the regulation of EAE, possibly by producing IL-10 (Fillatreau et al., 2002).

T cells play an important role in the development of autoimmune diseases effected by pathogenic autoreactive B cells, such as SLE. Although SLE is characterized by the presence of high titers of pathogenic autoantibodies against several nuclear antigens, including dsDNA, Sm and Ro/SSA (Kotzin, 1996; Morrow et al., 1999), SLE-prone mice do not develop disease in the absence of T cells (Steinberg et al., 1980; Wofsy et al., 1985; Santoro et al., 1988; Jevnikar et al., 1994). Furthermore, disease severity correlates with the expansion of autoreactive T cells (Lang et al., 2003), which recognize the same antigens as antibody-producing B cells (Crow et al., 1994; Kaliyaperumal et al., 1996), and induce the production of autoantibodies by the latter through a CD40–CD154-dependent mechanism (Early et al., 1996; Peng et al., 1997; Voll et al., 1997; Kalled et al., 2001). Although there is evidence for dysregulated B-cell activation in animal models of SLE (Chang et al., 2004), this seems to result, at least in part, from defects in T-cell signaling (Jury et al., 2004, Xu et al., 2004).

Another example of a B-cell-mediated autoimmune disease that is driven by T cells is RA. RA is a chronic inflammatory disease of the joints that is usually associated with presence of rheumatoid factor, and involves cartilage destruction and bone erosion owing to infiltration of synovial tissue by leukocytes, T cells, macrophages, and autoantibody-producing B cells (Mellbye et al., 1990, Kraan et al., 2004). B-cell-deficient mice are refractory to RA-like disease induction (Svensson et al., 1998), and the disease can be transferred by serum or purified immunoglobulins (Stuart and Dixon, 1983; Matsumoto et al., 1999; Maccioni et al., 2002). Although clearly B-cell dependent, susceptibility to RA is associated with specific MHC class II genes (Wordsworth et al., 1989; Devereux et al., 1991), and T-cell depletion impairs disease development in experimental rodent models, demonstrating a key role for T cells in its pathogenesis (Pelegri et al., 1996, Corthay et al., 1999; Ehinger et al., 2001; Pohlers et al., 2004). A number of mice expressing collagen-specific TCR transgenes have been developed (Mori et al., 1992; Osman et al., 1998); these animals develop accelerated RA when immunized with collagen. Another animal model of possible relevance to human RA is based on transgenic expression of a TCR cloned from a disease-unrelated T-cell clone. These mice spontaneously develop RA (Kouskoff et al., 1996) because their transgenic T cells recognize a peptide derived from a ubiquitously expressed self-antigen, glucose-6-phosphate isomerase (G6PI), in the context of the NOD mouse MHC class II molecule I-A^{g7}, and elicit the production of arthritogenic immunoglobulins by B cells (Korganow et al., 1999; Matsumoto et al., 1999). Accumulation of extracellular G6PI on the surface of cartilage attracts autoantibodies from the circulation and triggers pathogenesis (Matsumoto et al., 2002; Wipke et al., 2002). Interestingly, immunization of normal mice with G6PI induced a T-cell-dependent RA-like syndrome (Schubert et al., 2004), and anti-G6IP antibodies were detected in RA patients (Schaller et al., 2001; Matsumoto et al., 2003). Therefore, autoreactivity against a non-tissue-specific autoantigen can result in a tissue-specific autoimmune disorder.

Figure 6.2B represents interactions between autoreactive T and B cells during the development of autoimmunity. On the one hand, B cells "concentrate" autoantigens for effective presentation to autoreactive $CD4^+$ T cells. On the other, activated $CD4^+$ T cells produce cytokines capable of fostering the activation and differentiation of autoreactive B cells into antibody-secreting plasma cells.

REGULATORY T CELLS AND AUTOIMMUNITY

Central (thymic) tolerance is responsible for removing potentially pathogenic autoreactive T cells from the repertoire. Some autoreactive T cells, however, escape central tolerance and harmlessly circulate in the periphery without posing a significant health threat to the individual (Yan et al., 1992; Wekerle et al., 1996). This is so, at least in part, because these cells are normally kept in check by regulatory T cells. The immunosuppressive power of regulatory T cells against autoimmunity is best documented by studies of mice expressing autoreactive TCR transgenes. Despite exporting overwhelmingly high numbers of autoreactive T cells to the periphery, some of these mice either do not develop autoimmunity or do so with very low incidence. However, when development of T cells expressing endogenous TCRs, including regulatory T cells, is abrogated, the mice rapidly develop spontaneous autoimmunity (Lafaille et al., 1994; Olivares-Villagomez et al., 1998; Gonzalez et al., 2001).

Tregs can be categorized into two major functional subgroups: inducible and naturally occurring. Inducible Tregs

arise from peripheral nonregulatory T cells under specific conditions, such as in the presence of cytokines like IL-4, IL-10 or TGF-β (Cobbold et al., 2004; Fantini et al., 2004). A number of experimental therapeutic strategies for autoimmunity exploit the existence of this type of Treg (Harrison et al., 1996, Panoutsakopoulou et al., 2004). In the steady-state, however, autoreactive T cells are predominantly kept in check by thymus-derived, naturally-occurring Treg types like $CD4^+CD25^+$ and natural killer T (NKT) cells. $CD4^+CD25^+$ T cells express heterogeneous TCRs, are thought to arise from autoreactive thymocyte precursors, and are kept (in the periphery) in a state of chronic activation (Bensinger et al., 2001; Jordan et al., 2001; Fisson et al., 2003). Development of these T cells requires IL-2 and CD28, and is controlled by expression of the transcription factor Foxp3 (Fontenot et al., 2003; Hori et al., 2003; Khattri et al., 2003). In fact, Tregs arising from conventional T cells in the periphery also express Foxp3 (Hori et al., 2003; Walker et al., 2003; Fantini et al., 2004). The regulatory activity of $CD4^+CD25^+$ T cells seems to be mediated by a poorly understood cell-contact-dependent mechanism that is capable of inhibiting IL-2 production by, and proliferation of, conventional T cells (Sakaguchi, 2004). CTLA-4 is thought to be necessary for this process (Boden et al., 2003; Fallarino et al., 2003; Liu et al., 2003). Recent work has shown that $CD4^+CD25^+$ T cells can inhibit diabetogenic $CD8^+$ T-cell responses indirectly, by suppressing DC maturation *in vivo* (Serra et al., 2003). It has also been shown that $CD4^+CD25^+$ T cells can, under certain circumstances, transform conventional (nonregulatory) $CD4^+$ T cells into inducible Tregs (Stassen et al., 2004, Zheng et al., 2004). Thus, as shown in Figure 6.2C, regulatory T cells may inhibit autoreactive T-cell responses directly by recognizing autoreactive T cells, or indirectly by suppressing DC maturation or by inducing tolerogenic activities in immature DCs.

Unlike $CD4^+CD25^+$ T cells, most NKT cells express an invariant TCR α chain (Benlagha et al., 2002, Kronenberg and Gapin, 2002, Sakaguchi, 2004) and recognize glycolipid antigens in the context of CD1d MHC molecules. Although their natural antigenic targets have not yet been identified, NKT cells can be activated by α-galactosylceramide (α-GalCer), a compound derived from a marine sponge. Like $CD4^+CD25^+$ T cells, NKT cells also arise in the thymus, but under the control of different signaling pathways. Development of NKT cells, for example, requires molecules such as Ets1, Fyn, cathepsin L, and RelB, which are dispensable for development of nonregulatory T cells (Gadue et al., 1999; Walunas et al., 2000; Honey et al., 2002; Elewaut et al., 2003; Sivakumar et al., 2003).

Although both $CD4^+CD25^+$ and NKT cells comprise a relatively small fraction of the peripheral T-cell repertoire, defective development of either subset promotes autoimmunity. For instance, IL-2-, CD80/CD28-, and Foxp3-deficient mice develop systemic or organ-specific autoimmunity, owing to the absence of $CD4^+CD25^+$ T cells (Almeida et al., 2002; Malek et al., 2002; Nelson, 2004). Notably, defective $CD4^+CD25^+$ T cells have been described in patients with specific autoimmune disorders (Kriegel et al., 2004; Ou et al., 2004). Early studies also found defective NKT-cell development in autoimmune-prone mice. In NOD mice, for example, there is impaired NKT-cell development, and NKT-cell transfer can inhibit T1D development (Mieza et al., 1996; Gombert et al., 1996; Hammond et al., 1998). In addition, NKT-cell deficiency enhances the development of T1D and EAE in NOD and C57BL/6 mice, respectively (Shi et al., 2001; Wang et al., 2001; Teige et al., 2004). Although abnormal NKT cell development has also been reported in humans, the contribution of this phenotype to human autoimmunity is less clear (Sumida et al., 1995; 1998; Wilson et al., 1998; Yanagihara et al., 1999; van der Vliet et al., 2001). Because NKT cells produce high levels of cytokines, such as IL-4 and IL-10, shortly upon activation, it is generally thought that these cytokines play a critical role in the suppressive activity of NKT cells (Miyamoto et al., 2001; Laloux et al., 2001; Sharif et al., 2001). These and other less well characterized populations of regulatory cells thus play a fundamental role in ensuring that the individual will respond vigorously to nonself, without mounting responses to self. Disruption of this balance surely has the potential to promote autoimmunity.

Figure 6.2D attempts to integrate the complex cellular interaction summarized in Figures 6.2A–C.

MEMORY T CELLS AND AUTOIMMUNITY

Antigen-primed naïve T cells proliferate and differentiate into effector cells. Upon undergoing clonal expansion, a fraction of these antigen-exposed T cells differentiate into long-lived memory cells. Memory $CD4^+$ and $CD8^+$ T-cells are responsible for the immune system's ability to mount recall responses against antigen re-encounters and thus are responsible for affording long-term protection against pathogens (Dutton et al., 1998). In mice, memory T cells arise from effector cells that exit the cell cycle and down-regulate activation markers, such as CD25 and CD69, while maintaining high levels of CD44 (Opferman et al, 1999; Hu et al., 2001). In humans, memory $CD4^+$ T cells are usually $CD45RA^-CD45RO^+$. Unlike effector cells, which are susceptible to activation-induced cell death, memory T cells can survive in nonlymphoid as well as secondary lymphoid organs without undergoing division (Sabbagh et al., 2004). Although generation and persistence of memory T cells do not always require MHC molecules (Murali-Krishna et al., 1999; Swain et al., 1999), their homeostatic survival is fostered by signals from the TCR and cytokines like IL-7 and

IL-15 (Kaech et al., 2003; Seddon et al., 2003). Importantly, upon antigen re-encounter, memory T cells are recruited rapidly to the site of inflammation, and expand and produce large amounts of cytokines, even in the presence of low levels of antigen and/or costimulatory signals (Pihlgren et al., 1996; Liu et al., 1997; Rogers et al., 2000; Veiga-Fernandes et al., 2000). Because memory T cells have increased functional avidities for ligand as compared to their naïve progenitors, and because the antigen-binding site of the TCR is conformationally flexible and potentially promiscuous, development of a sizeable population of memory T cells in response to an infectious agent bears a theoretical risk of eliciting autoimmunity.

Memory T cells can be categorized into central memory T (T_{CM}) cells, which migrate into secondary lymphoid organs, and effector memory T (T_{EM}) cells, which are recruited to inflamed nonlymphoid tissues (Sallusto et al, 1999; Iezzi et al., 2001; Masopust et al., 2001; Reinhardt et al, 2001). In humans, T_{CM} cells express CCR7 and CD62L, whereas T_{EM} cells are mostly CCR7- and CD62L-negative. T_{EM} cells express chemokine receptors characteristic of Th1 and Th2 cells, including CCR5 and CCR6 for Th1 cells and cytotoxic T lymphocytes, and CCR3 and CCR4 for both Th1 and Th2 cells. The expression pattern of chemokine receptors on T_{EM} cells parallels polarized cytokine profiles retained from effector cells. Indeed, $CD4^+$ T_{EM} cells produce Th1 or Th2 cytokines within hours of antigen stimulation, and $CD8^+$ T_{EM} cells express a large amount of perforin, allowing rapid effector function in response to antigen. T_{CM} cells proliferate vigorously and produce high levels of IL-2 in response to antigen, and differentiate into Th1- or Th2-like effector cells capable of producing abundant IFN-γ or IL-4 on antigen stimulation (Sallusto et al., 2004). In the absence of antigen, both T_{CM} and T_{EM} cells turn over, slowly, mostly in response to homeostatic cytokines. Whereas T_{EM} cells provide immediate protection against infectious agents, T_{CM} cells proliferate and differentiate into T_{EM} cells on secondary antigenic stimulation, ensuring the long-term retention of memory T-cell pools (Seder and Ahmed, 2003; Wherry et al., 2003).

Several lines of evidence suggest a role for memory T cells in autoimmune disease progression or recurrence. Murine T1D or EAE can be transferred to genetically susceptible recipients by splenic lymphocytes from affected individuals, consistent with the presence of autoreactive memory T cells in the spleen (Santamaria, 2001; Rossini et al., 2004). Since splenic memory T cells are probably T_{CM} cells, they likely undergo antigen-independent homeostatic expansion and antigen-dependent proliferation in the recipients before differentiating into effector cells. This may explain why transfer of T1D by splenocytes from diabetic NOD mice usually takes a few weeks. This contrasts with the rapidity with which pancreatic islet-associated T cells from prediabetic NOD mice, which presumably contain both effector and T_{EM} cells, transfer disease into NOD.scid hosts (Rohane et al., 1995). As noted above, homeostatic expansion of memory T cells involves cytokines such as IL-7 and IL-15, whose receptors share the common γ chain. Administration of a blocking anti-γ chain antibody to NOD mice effectively reduced the size of the memory T-cell population, and inhibited disease transfer, suggesting that expansion of memory T cells contributes to the progression of T1D (Demirci et al., 2003). It has also been shown that isolated $CD4^+CCR4^+CD44^{high}$ T cells can transfer insulitis into NOD.scid mice within a week of injection, underscoring their pathogenic potential. Furthermore, blockade of macrophage-derived chemokine (MDC), a ligand for CCR4, inhibited development of T1D in NOD mice (Kim et al., 2002). In addition, when the homeostatic turnover rate of the memory T-cell pool, which controls its size, was slowed by transfer of large numbers of syngenic T cells or by non-antigen-specific stimulation of endogenous T cells, NOD mice were protected from T1D (King et al., 2004). The formidable proclivity of diabetic NOD mice to disease recurrence following syngenic or allogenic islet transplantation provides additional evidence for the contribution of autoreactive memory T cells to the progression of this autoimmune disease. Another observation supporting the idea that memory T cells contribute to the progression of autoimmunity is that autologous hematopoietic stem cell transplantation in patients with severe multiple sclerosis can blunt disease progression in a subset of patients; in these patients, memory T cells are replaced by a diverse repertoire of naïve T cells that arise from new thymic emigrats (Muraro et al., 2005). Taken together, these observations suggest that development of autoreactive memory T cells fuels the progression of autoimmunity.

CONCLUDING REMARKS

In this chapter, we have provided a general overview on the role of T cells in autoimmunity. This is by no means a comprehensive review of the literature but rather a synopsis of recent developments in our understanding of the delicate balance that exists between autoreactive lymphocytes and their regulatory counterparts in both health and disease. Other chapters in this book deal in greater detail with some of the aspects we only touch upon here. Ultimately, we hope that the reader will gain a better understanding of how T cells contribute to autoimmunity, while maintaining an appreciation of the many complexities that remain unresolved.

Acknowledgments

The authors' work described in this review was supported by grants from the Canadian Institutes of Health Research, the Natural Sciences and

Engineering Research Council of Canada (to P. S.), the Juvenile Diabetes Research Foundation and the Canadian Diabetes Association (to Y. Y. and P. S.). P. S. is a Scientist of the Alberta Heritage Foundation for Medical Research. We thank all the members of our laboratories for excellent technical assistance and stimulating discussions. Y. Y. and P. CHAPTER

7

Role of Th1 and Th2 Cells in Autoimmunity

LORENZO EMMI AND SERGIO ROMAGNAMI

Center for Research, Transfer and High Education, MCIDNENT, University of Florence, Italy

DEFINITION AND FUNCTIONAL PROPERTIES OF HUMAN Th1 AND Th2 CELLS

Type 1 and type 2 T-helper (Th1 and Th2) cells do not represent distinct subsets, but rather are polarized forms of the $CD4^+$ Th cell-mediated immune response, which occurs under particular experimental or pathophysiologic conditions. In mice, Th1 responses are characterized by the prevalent production of interleukin (IL)-2, interferon (IFN)-γ, and tumor necrosis factor (TNF)-β, without production of IL-4, IL-5, IL-9, IL-10, and IL-13. By contrast, Th2 responses are characterized by the prevalent production of IL-4, IL-5, IL-9, IL-10, and IL-13, in the absence of production of IFN-γ and TNF-β. Th cell responses characterized by the conjunct production of Th1 and Th2 cytokines are commonly defined as type 0 Th (Th0) responses (Mosmann and Coffman, 1989). The Th1/Th2 polarization is clear-cut in murine models based on artificial immunization, whereas it is usually less restricted among human Th cell-mediated responses (Romagnani, 1995). Moreover, in humans, IL-10 is produced by both Th1 and Th2 cells (Romagnani, 1995). In general, Th1-polarized responses are highly protective against infections by the majority of microbes, especially the intracellular parasites, because of the ability of Th1 cytokines to activate phagocytes and to promote the production by B-lymphocytes of opsonizing and complement-fixing antibodies (phagocyte-dependent host defense) (Romagnani, 1995). However, when the microbe is not rapidly removed from the body, the Th1 response may become dangerous for the host, because of the strong and chronic inflammatory reaction evoked. By contrast, cytokines produced by Th2 cells induce the differentiation, activation, and *in situ* survival of eosinophils (through IL-5), promote the production by B-lymphocytes of high amounts of antibodies, including IgE (through IL-4 and IL-13), as well as the growth and degranulation of mast cells and basophils (through IL-4 and IL-9). Moreover, IL-4 and IL-13 inhibit several macrophage functions and IL-4 can suppress the development of Th1 cells (Romagnani, 1997). Thus, the phagocyte-independent Th2 response is usually less protective than the Th1 response against the majority of infectious agents, with the exception of some gastrointestinal nematodes (Finkelman and Urban, 2001). In addition to their protective activity against some nematodes, Th2 cells probably also play a regulatory role in the immune system, because a switch from Th1 to Th2 may provide a protective effect when the Th1 response threatens to become a dangerous event for the host (Romagnani, 1997) (Figure 7.1).

Besides the selective production of IL-4, IL-5, IL-6, IL-9, and IL-13, human Th2 cells also exhibit the preferential expression of some surface molecules, such as CD30, CCR4, CCR8, and the chemoattractant receptor of Th2 cells

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

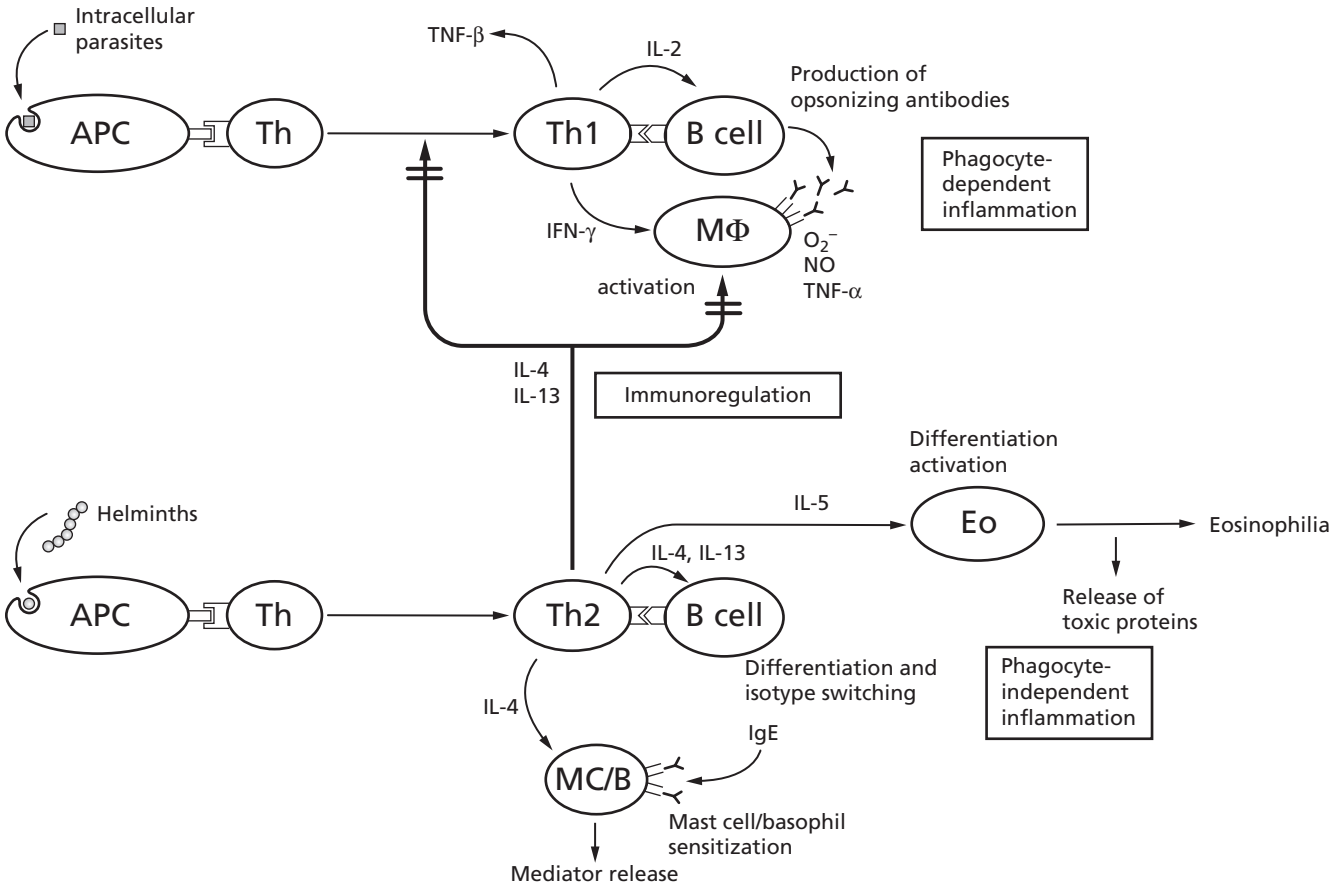

FIGURE 7.1 Th1/Th2 paradigm. Different infectious agents can polarize the helper T (Th)-cell-mediated immune response into different patterns of cytokine production. Intracellular microbes usually induce Th1 responses which are characterized by the production of interleukin (IL)-2, interferon (IFN)-γ, and tumor necrosis factor (TNF)-β. IFN-γ is the main activator of phagocytic cells, whereas IL-2 favors the production of opsonizing antibodies by B-cells, which together promote the removal of the infectious agent (phagocyte-dependent inflammation). Helminths usually induce Th2 responses, producing IL-4 and IL-13, which promote the production of high concentrations of antibodies, including IgE and IL-5, which activate eosinophil granulocytes. Moreover, IL-4 and IL-13 inhibit different macrophage activities (phagocyte-independent inflammation). APC, antigen-presenting cell; B, basophil; Eo, eosinophil; Mø, macrophage; MC, mast cell.

(CRTH2) (Romagnani, 1997), whereas human Th1 cells preferentially express the lymphocyte activation gene-3 (LAG-3), and the chemokine receptors CXCR3 and CCR5 (Romagnani, 1997). The chemoattractant receptors prevalently expressed on the surface of Th1 or Th2 cells are important for recruitment and homing in target tissues of effector Th cells.

Th1/Th2 POLARIZATION

Nature of Th1 and Th2 Polarizing Signals

Clear evidence suggests that Th1 and Th2 cells develop from the same Th cell precursor under the influence of both environmental and genetic factors acting at the level of antigen presentation. Suggested environmental factors include the route of antigen entry, physical form of the immunogen, type of adjuvant, and dose of antigen (Abbas et al., 1996; Romagnani, 1997). The genetic mechanisms involved in controlling the type of Th cell differentiation remain elusive. Genetic and environmental factors can influence, independently or in association, a series of modulatory factors, including: 1) ligation of the T-cell receptor (TCR); 2) activation of costimulatory molecules, such as B7/CD28, OX40/OX40L, and LAF-3/ICAM-1; 3) predominance of a given cytokine in the microenvironment of the responding Th cell, such as IL-4, IL-12, IL-18, IFN-γ, and IFN-α; and 4) the type of Notch ligands activated by the exogenous stimulus on the antigen-presenting cell (APC).

It has been known for many years that the production of IL-12, IL-18, and IFNs (γ and α) by cells of the natural immunity, such as dendritic cells (DCs) and natural killer (NK) cells, favors the development of Th1 cells. More recent data have allowed an understanding of why many microbial agents usually induce the production of IL-12 and IFNs (Maggi et al., 1992; Manetti et al., 1993). Both DCs and NK

cells possess receptors on their surface, named Toll-like receptors (TLRs) because of their homology with the archetypal *Drosophila* Toll protein. So far, 10 distinct TLRs have been identified, which are able to recognize constitutive and highly conserved pathogen-associated molecular patterns (PAMPs), such as lipopolysaccharide (LPS), double-stranded RNA, and flagellin, thus resulting in strong activation of, and cytokine production by, DCs and NK cells (Sabroe et al., 2003) (Figure 7.2).

IL-12 produced by DCs is the most powerful Th1-inducing agent and its production is upregulated by both CD40L–CD40 interaction and the production of IFN-γ by NK and Th1-polarized cells. Of interest, IFN-γ, but not IFN-α, promotes Th1 differentiation in mice, whereas both IFN-γ and IFN-α (which is also produced by a subset of DCs) play an important role in humans; IFN-α upregulates the expression of the IL-12 receptor (IL-12R) β chain. In contrast to the production of IL-12 and IFNs, early IL-4 expression during an immune response is critical for the development of Th2 cells. It has been suggested that naïve Th cells are able to produce small amounts of IL-4 from their initial activation, and the concentration of IL-4 that accumulates at the level of the Th cell response increases with increasing lymphocyte activation. The inducing effect of IL-4 dominates over other cytokines, so that if IL-4 levels reach a necessary threshold, differentiation of the Th cell into the Th2 phenotype occurs. Other possible sources of early IL-4 production may be NK T-cells, basophils, mast cells, and eosinophils, but IL-4 produced by these cells is certainly more important in the amplification rather than in the initiation of a Th2 response (Seder and Paul, 1994).

Signals through cytokine receptors elicit a complex series of molecular interactions in the naïve Th cell that culminate in the binding of cell-type-specific transcription factors to multiple regulatory elements in the promotors of cytokine genes, and their subsequent activation (Figure 7.3). At least five groups of transcription factor play an important role in Th2 differentiation. The interaction of IL-4 with its receptor on the surface of the naïve Th cell results in the activation of STAT6 (signal transducer and activator of transcription). Proteins of the NFAT (nuclear factor of activated T cells) family are also involved, since they bind specifically to the promotor region of the IL-4 gene and cooperate with activator protein (AP-1) factors, like Fra and Jun, to induce IL-4 transcription. However, NFAT and AP-1 are expressed by both Th1 and Th2 cells and their role in the selective Th cell differentiation appears to be very complex. By contrast, the proto-oncogene c-Maf is specifically expressed by Th2, but not Th1, cells and binds to a Maf response element (MARE) within the IL-4 proximal promotor. However, c-Maf is specific for IL-4 and is critical for high levels of IL-4 production, but is not sufficient for the initiation of IL-4 transcription. An even more important transcription factor for Th2 differentiation is GATA3, which is undetectable in Th1 cells. GATA3 inhibits the production of IFN-γ, increases the transactivation of the IL-4 promotor, and also directly regulates IL-5 and IL-13 expression (Rengarajan et al., 2000).

While the binding of IL-4 to its receptor activates STAT6, the IL-12–IL-12R interaction results in the activation of STAT4. This transcription factor, as well as IFN regulatory factor (IRF)-1, have been implicated in Th1 differentiation, because mice deficient for each of these factors lack Th1 cells. A substantial advance in elucidating Th1 lineage commitment and IFN-γ gene expression came with the isolation of the protein T-box expressed in T cells (T-bet).

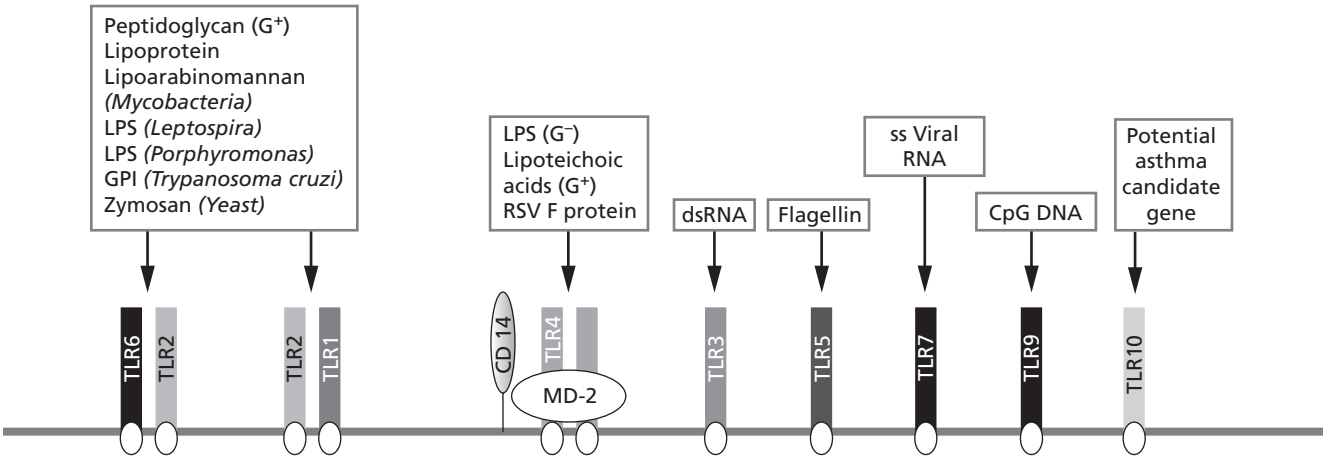

FIGURE 7.2 Schematic illustration of Toll-like receptors (TLRs) present on the surface of dendritic cells (DCs) and other cell types. Each of the 10 known TLRs can recognize constitutive and conserved microbial products. Interaction of TLRs with their respective ligands results in the activation of cells of innate immunity, such as DCs and natural killer (NK) cells, and the production of cytokines, including IL-12 and IFNs, which can influence the subsequent profile of the adaptive immune response. GPI, glycosylphosphatidylinositol; G^-/G^+, LPS, lipopolysaccharide; MD-2, an adaptor molecule required for TLR4 signaling; RSV, respiratory syncytial virus.

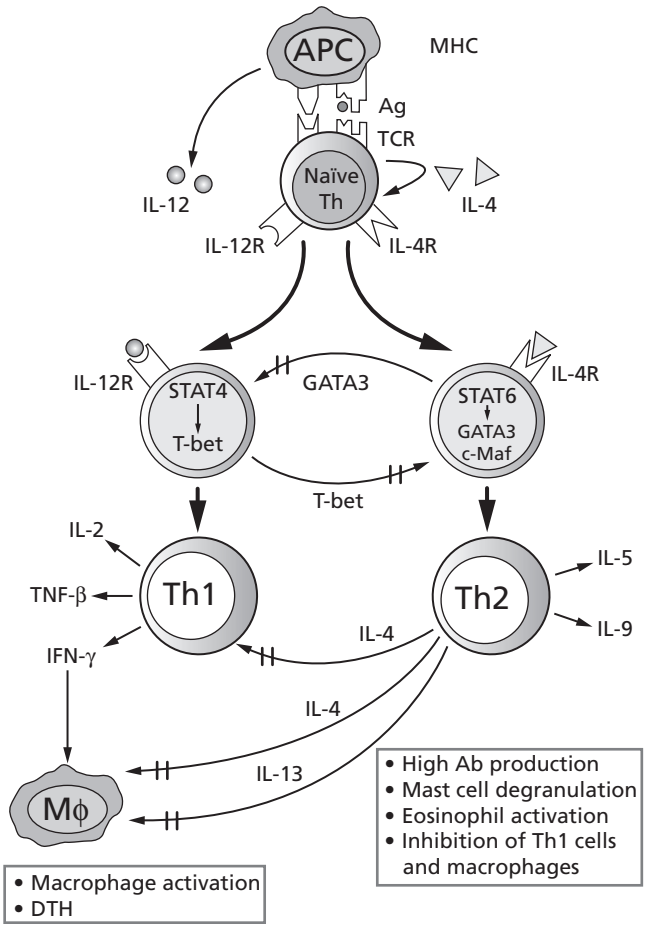

FIGURE 7.3 Main mechanisms involved in Th1 or Th2 polarization. The interaction of interleukin (IL)-12, produced by dendritic cells (DCs) in response to the stimulation of some Toll-like receptors, with its receptor (IL-12R) on the surface of the naïve Th cell, results in the activation of the transcription factors STAT4 and T-bet, which promote Th1 polarization. The early production of IL-4 and its interaction with its receptor (IL-4R) on the surface of the naïve Th cell results in the activation of the transcription factors STAT6, c-Maf, and GATA3, which promote Th2 polarization. Th2 polarization may also occur through the interaction of Jagged ligands expressed on DCs and the Notch receptors present on the naïve Th cell, resulting in the direct activation of the IL-4 promotor (see text). Of note, T-bet not only promotes Th1 polarization but also antagonizes Th2 polarization, whereas GATA3 promotes Th2 polarization and antagonizes Th1 polarization. APC, antigen-presenting cell.

T-bet expression strongly correlates with IFN-γ expression; it is specifically upregulated in primary Th cells differentiated along the Th1, but not the Th2, pathway, and it directly binds to the IFN-γ promotor. Thus, a model for Th1/Th2 polarization that involves a balance between the Th1-specific T-bet and the Th2-specific GATA3 transcription factors may presently be envisaged (Szabo et al., 2000) (see Figure 7.3).

A novel model of Th1/Th2 polarization recently has been described (Amsen et al., 2004). According to this model, APCs also use the Notch pathway to instruct T-cell differentiation. Notch is an evolutionarily conserved receptor involved in cell fate decisions. On binding ligand, its intracellular domain (ICD) is released from the membrane through proteolytic cleavages, enabling cytoplasmic and nuclear functions. A target of the Notch ICD is RBPJk, which is converted from a transcriptional repressor to an activator. Mammals express four Notch genes and, in addition, five genes encode ligands for Notch from two conserved families, Jagged and Delta. Strikingly, the Delta family of Notch ligands present on APCs induces Th1, while the Jagged family induces the alternate Th2 fate. Expression of these different Notch ligands on APCs is induced by Th1- or Th2-promoting stimuli. Interestingly, the Jagged-mediated signaling for Th2 differentiation appears to be independent of the IL-4/STAT6 pathway described above. Notch was indeed found to direct Th2 differentiation by inducing GATA3 upregulation and nuclear translocation, but also by directly regulating IL-4 gene transcription through RPBJk sites in a 3′ enhancer. These findings suggest that Th2 differentiation is not the result of a default pathway but, like Th1 polarization, is strictly controlled by cells of the natural immunity. Indeed, when DCs expressing the Delta family of ligands are stimulated, Notch receptors present on the naïve Th cell induce STAT6-independent upregulation of GATA3 and direct activation of the IL-4 gene. This early production of IL-4 by the naïve Th cell probably originates as an autocrine/paracrine circuit that then amplifies Th2 development via the previously described IL-4/IL-4R/STAT6 pathway (Amsen et al., 2004). By contrast, the role of Delta-mediated Th1 polarization is still unclear, although the Delta ligand on APCs does appear to stimulate Th1 responses.

Finally, it should be noted that the Th cell fate is regulated not only by differentiative signals delivered by early produced cytokines, contact-dependent factors, and the antagonism of transcription factors, but is also dependent on cell cycle expression, i.e., the number of postactivation cell divisions. Several studies suggest that there is an opportunity for a Th cell to initiate cytokine gene expression at each cell division and that the probability of this event varies between cytokines. It is of interest that these division relationships and probabilities of expression appear not to be heavily dependent on the genetic background of the T cells, but rather on epigenetic events that may control cytokine gene accessibility (Bird et al., 1998). Thus, in addition to a deterministic process related to the above-mentioned factors, a probabilistic process may influence the final cytokine pattern produced during the specific Th cell response.

Regulatory Mechanisms

Under some conditions, the T-cell effector response (either Th1- or Th2-polarized) may become dangerous for

the host and therefore, needs to be controlled. Under these conditions, the Th cell immune response can shift from a prevalent Th1 to a prevalent Th2 profile or vice versa. This switching process has been defined as "immune deviation." However, besides the mutual antagonisms at the level of cytokines and transcription factors mentioned above, Th1 and Th2 functions can also be regulated by other T-cell types, called regulatory T-cells (Tregs). Tregs are a highly heterogeneous family, which includes type 3 Th (Th3) cells, T regulatory 1 (Tr1) cells, and $CD4^+CD25^+$ T cells. Th3 cells mainly produce transforming growth factor (TGF)-β and their regulatory function is due to a TGF-β-dependent mechanism, whereas Tr1 cells mainly produce IL-10, with or without TGF-β. By contrast, $CD4^+CD25^+$ T cells do not produce cytokines and act via a contact-dependent mechanism, which probably involves the activity of both membrane CTLA (cytotoxic T-lymphocyte-associated antigen)-4 and TGF-β (Bluestone and Abbas, 2003). Another feature of $CD4^+CD25^+$ T cells is the expression of the products of FoxP3 and glucocorticoid-induced TNF receptor (TNFR)-related (GITR) genes (Fontenot et al., 2003).

Due to the heterogeneity of the Treg family, a distinction between "natural" and "adaptive" Tregs has recently been suggested (Bluestone and Abbas, 2003) (Figure 7.4). Natural Tregs are generated in the thymus and normally function to prevent the activation of other self-reactive T cells that have the potential to develop into effector cells. Indeed, both thymectomy and depletion of $CD4^+CD25^+$ T cells result in mice developing spontaneous autoimmune disorders, suggesting the important protective role of natural Tregs against autoimmunization. These natural Tregs act mainly by T–T-cell–APC contact in a cytokine-independent fashion. Similar to natural Tregs, adaptive Tregs also originate from the thymus, but they then further differentiate and acquire their suppressive activity in the periphery under certain conditions of antigenic stimulation. Their expression of CD25 is variable and their mechanism of suppression is mediated by the production of inhibitory cytokines, such as IL-10 and TGF-β. Natural and adaptive Tregs might function in different immunologic settings, depending on the context of antigen exposure, the nature of the inflammatory response, and the TCR repertoires of the individual cells. The relationship between microbial stimulation of the TLR pathway and Tregs is unclear. However, it has been shown that microbial induction of the TLR pathway can also block the suppressive effect of $CD4^+CD25^+$ Tregs, allowing activation of pathogen-specific adaptive immune responses (Netea et al., 2004). Thus, a complex and still partially unknown network of cells of innate immunity, Th1 or Th2 effector cells, and Tregs, seems to be operating (Figure 7.5).

Pathophysiologic Manifestations

Th1 and Th2 cells play a protective role against different infectious agents, but sometimes their wrong or exaggerated

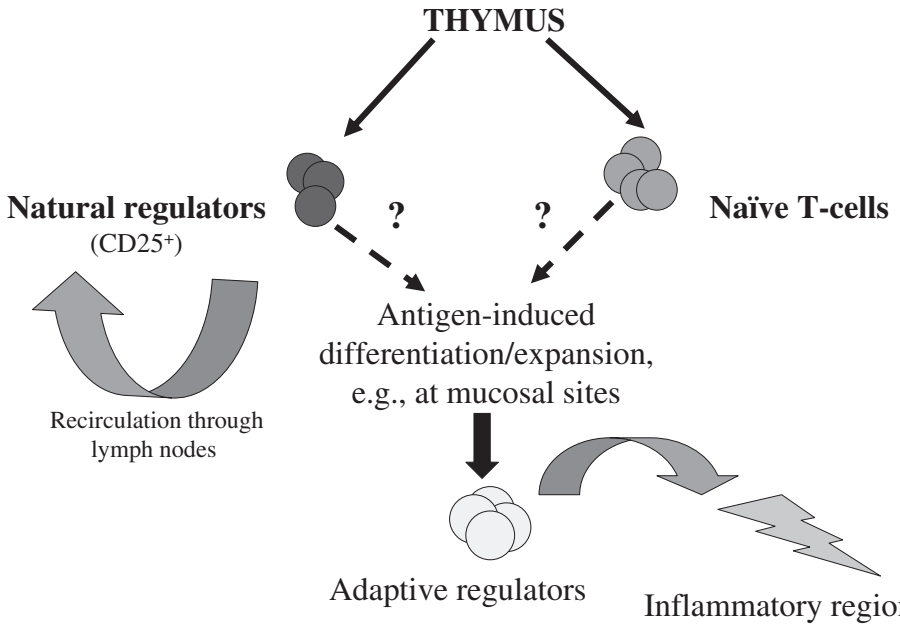

FIGURE 7.4 Regulatory T cells (Tregs). Natural Tregs originate from the thymus as $CD4^+CD25^+$ T cells and suppress the function of autoantigen-specific T cells not only in the thymus but also in the periphery. A proportion of the naïve T cell ($CD25^-$) population that originates from the thymus may encounter exogenous antigens in the periphery, which, under particular conditions, confer the ability to suppress the immune response with acquisition of CD25 positivity (adaptive Tregs) in an inflammatory site.

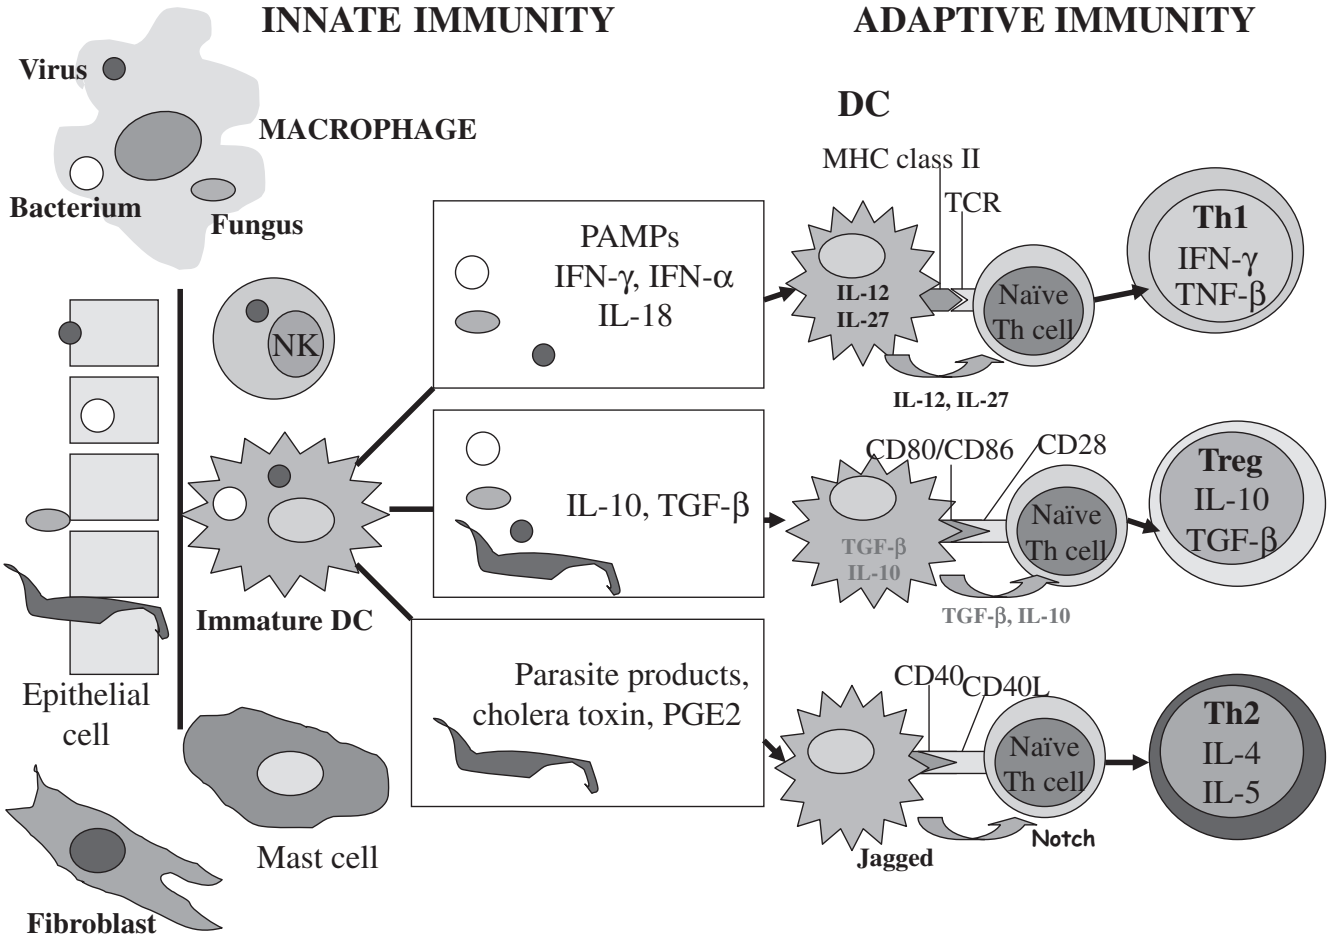

FIGURE 7.5 Complex bridge linking innate immunity, adaptive immunity, and immune regulation. Different pathogens can stimulate different types of dendritic cells (DCs) through interaction with the Toll-like receptors (TLRs) present on these cells, which may result in Th1 or Th2 polarization, as well as the development of regulatory T cells (Tregs), which are then able to suppress the Th cell effector responses. The production by DCs of interleukin (IL)-12 and interferon (IFN)-α, together with the production of IFN-γ by natural killer (NK) cells, promotes Th1 polarization. The production by DCs of IL-10 and tumor growth factor (TGF)-β promotes the development of Tregs. The production of IL-4 by mast cells, but mainly the interaction of Jagged ligands from DCs and Notch receptors present on the naïve Th cell, may promote Th2 differentiation. PAMPs, pathogen-associated molecular patterns; PGE2, prostaglandin E2; TCR, T-cell receptor.

response may cause an abnormal or chronic pathologic condition. Allergic disorders represent the prototypical immune-mediated conditions related to a polarized Th2 response against common environmental allergens. More often, however, Th1 cells are involved in the induction and maintenance of chronic inflammatory processes. These processes are usually initiated by an antimicrobial Th1 response that is unable to remove the invading agent, thus resulting in the perpetuation of an inflammatory response which is mainly sustained by the activation of phagocytic cells and the release of high concentrations of inflammatory cytokines. Under some conditions, and based on a particular genetic background, this may result in the accessibility of sequestered autoantigens and the aberrant expression of costimulatory molecules by APCs. This series of events is commonly known as "bystander activation." Infectious agents may also express antigens cross-reactive with self-determinants and this may trigger a Th1-mediated response against some peptide(s) shared by one or more autoantigen (epitope mimicry). These two possible events are now considered to be the most important mechanisms of autoimmunization that may follow a Th1 response triggered by a microbial agent, and are probably the main reason why the great majority of organ-specific autoimmune diseases have been found to be characterized by the prevalence of Th1 cells, their cytokines, and other Th1-related molecules.

Th1/Th2 BALANCE IN AUTOIMMUNE DISORDERS

Several clinical and experimental findings suggest that autoimmune diseases develop as a result of abnormalities in the immune response mediated by T cells and T-cell-derived lymphokines. Evidence is now accumulating in both experimental animal models and human pathologic conditions to suggest that the relative contribution of either Th1- or Th2-dominated reactions can determine not only the development of a particular autoimmune response, but also influence whether or not this response leads to clinical symptoms. Moreover, an important interplay with the activity of Tregs is also emerging.

Multiple Sclerosis

Multiple sclerosis (MS) is presumed to be an autoimmune disease of the central nervous system (CNS). Active lesions in the brains of patients with MS are characterized by lymphocyte (mainly $CD4^+$ T cells) and macrophage infiltration, but the relationship between these cells and the demyelinating process is still partially unclear. Although the etiology of the disease is unknown, it is thought to involve an autoimmune reaction against myelin antigens, such as myelin basic protein (MBP), proteolipid protein (PLP), and possibly other proteins, as shown in its classical animal disease counterpart, experimental autoimmune encephalomyelitis (EAE) (Windhagen et al., 1995).

Several features of MS lesions suggest that in the human disease the inflammatory process is mainly driven by a Th1-mediated autoimmune response. Several studies have suggested a primary pathogenic role for TNF-α and IFN-γ in MS. First, high levels of TNF-α were found in the cerebrospinal fluid (CSF) of patients with chronic progressive MS (Sharief and Hentges, 1991; Tsukada et al., 1991; Rieckmann et al., 1994; 1995). Most clones derived from both the peripheral blood and CSF of patients with MS showed a Th1 profile (Brod et al., 1991; Benvenuto et al., 1991; Correale et al., 1995). More recently, several Th1-type cytokine receptors (Fas, TNFR-1, and TNFR-2) have been described on oligodendrocytes (with ligands occurring on microglia) and show enhanced expression around MS lesions. Other studies have detected the presence of TRAIL-R2 and TRAIL-R4 on the same cells (Weber et al., 2004). Cytokine receptors on oligodendrocytes may play a role in both cell fate decisions and broader immunologic responses, a feature of particular relevance in a disease such as MS, where the oligodendrocyte is the major target. TNF-β expression was associated with T lymphocytes, whereas TNF-α was associated with astrocytes in all areas of the lesion (Selmaj et al., 1991). By using both semiquantitative reverse transcriptase-polymerase chain reactions (RT-PCRs) and immunohistochemistry, the cytokine IL-12p40 appeared to be predominantly upregulated in acute MS plaques in early disease, suggesting that an early event in the initiation of MS is the upregulation of costimulatory molecules and IL-12 (Windhagen et al., 1995). IL-18, another Th1-polarizing cytokine produced by DCs, has also been shown to be produced by activated microglia and may contribute to inflammation in the brain through synergism in a cascade of cytokines associated with the innate response, including IL-12 and IL-15. These probably represent the conditions that maximally stimulate T-cell activation and induce Th1-type immune responses. Finally, a high number of chemokines, such as CCL2, CCL3, CCL4, CCL5, CCL7, CXCL9, and CXCL10, produced by myelin-reactive T cells, macrophages, and glial cells have also been found to be expressed at the CNS level in MS. These factors can initiate a pathogenic cascade in the CNS, leading to inflammation, demyelination, and axonal damage, which contribute to the functional deficiencies. More importantly, in patients with MS, CXCL10 levels in the CSF are significantly higher than in controls (Franciotta et al., 2001; Sørensen et al., 2001), and Th1 cells expressing CXCR3 have been detected in the brain and CSF (Balashov et al., 1999; Sørenson et al., 1999; Misu et al., 2001).

However, there is evidence that cells other than classical Th1 cells contribute to the inflammatory response in MS lesions. Numerically, $CD8^+$ major histocompatibility complex (MHC) class I-restricted T cells outnumber $CD4^+$ T cells. Furthermore, class I-restricted $CD8^+$ T cells predominate at the site of tissue destruction in actively demyelinatimg lesions, whereas $CD4^+$ T cells are retained mainly in perivascular inflammatory infiltrates. Recent studies based on PCR analysis at the single-cell level show that clonal expansion is much more prominent in the $CD8^+$ than in the $CD4^+$ T-cell population. Finally, recent data based on the use of microarray analysis showed upregulation of the tryptase gene in MS plaques, suggesting a role for mast cell-derived products in the genesis of MS lesions (Pedotti et al., 2003). Thus, although the possible inflammatory role of Th2-related effector phenomena in MS is certainly less important than Th1 cell-triggered inflammation, the emerging picture is more complex than a pure Th1-mediated disorder (Lassmann and Ransohoff, 2004). It probably also includes a loss of functional suppression by $CD4^+CD25^+$ Tregs (Viglietta et al., 2004).

A hypothetical scheme illustrating the main immunologic events involved in the pathogenesis of MS is shown in Figure 7.6.

Autoimmune Thyroid Diseases

Autoimmune thyroid diseases include Hashimoto' thyroiditis (HT) and Graves' disease (GD). HT is an organ-specific autoimmune disease characterized by massive infiltration of lymphoid cells in the thyroid and parenchymal

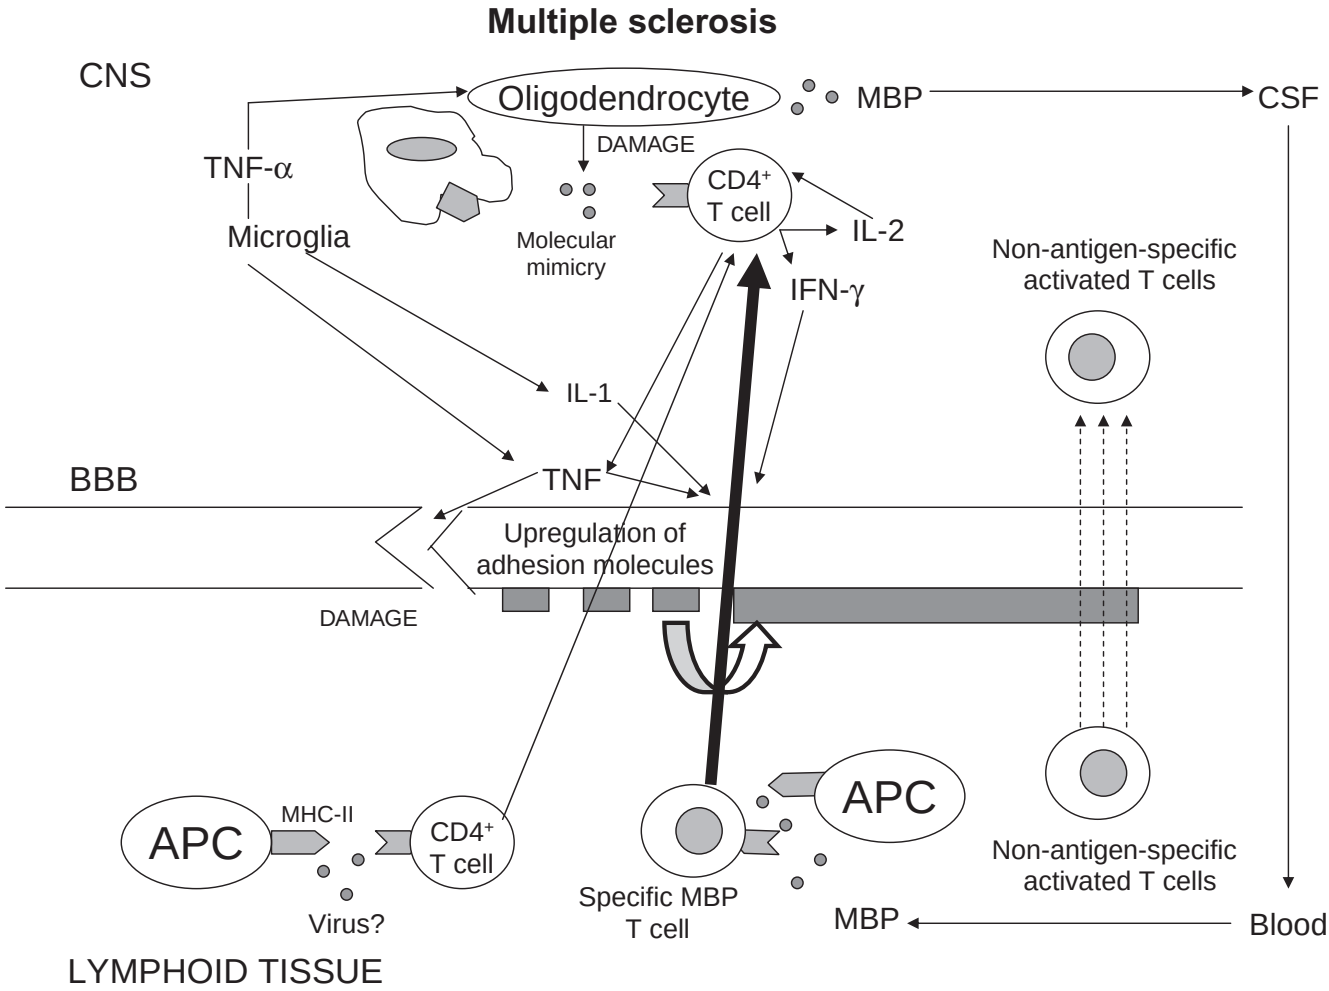

FIGURE 7.6 Possible events contributing to the development of multiple sclerosis. T-lymphocytes gain access to the central nervous system (CNS) by diapedesis through the blood–brain barrier. T-cell recruitment is a complex multistep process that can be influenced by several mediators, including those derived from macrophages, microglia, mast cells, and T cells themselves. Once within the CNS, T cells can release inflammatory cytokines in response to appropriate stimulation. Macrophages recruited by T cells and resident microglia cells also contribute to the tissue damage. In addition to promoting myelin sheath destruction through the direct effects of certain secreted mediators, T cells, macrophages, microglia, and mast cells can also contribute to the development of a local inflammatory response, in which additional recruited cells and mediators might also contribute to the destruction of the myelin sheath. Myelin basic protein (MBP) is shown as an illustrative autoantigen since it is operative in the experimental autoimmune encephalomyelitis (EAE) model. APC, antigen-presenting cell; CSF, cerebrospinal fluid; BBB, blood–brain barrier; IFN, interferon; IL, interleukin; TNF, tumor necrosis factor.

destruction leading to hypothyroidism. GD shows a histologic picture often indistinguishable from HT, but is characterized by both the production of thyroid-stimulating antibodies leading to hyperthyroidism and an associated ophthalmopathy.

Although the precise etiology of HT remains largely unknown, the role of infiltrating T-lymphocytes in the destruction of the target organ is generally accepted, and has been definitively proved in a "humanized" model of transgenic mice expressing a human TCR derived from the thyroid-infiltrating T cell of a patient with thyroiditis and specific for a cryptic thyroid-peroxidase epitope. These mice spontaneously developed destructive thryoiditis with histologic, clinical, and hormonal signs comparable with human autoimmune hypothyroidism (Quaratino et al., 2004). Accordingly, studies performed in humans by different laboratories showed that T cells from lymphocytic thyroid infiltrates of patients with HT or GD had a clear-cut Th1 lymphokine profile, with production of high TNF-α and IFN-γ concentrations, and exhibited strong cytolytic

potential (Del Prete et al., 1987; 1989). Moreover, quite a homogenous Th1 profile was also observed in $CD4^+$ T-cell clones derived from retroorbital infiltrates of patients with Graves' ophthalmopathy (De Carli et al., 1993). In contrast, either a Th1-like (Watson et al., 1994) or a more heterogenous cytokine profile (Grubeck-Loebenstein et al., 1994; McLachlan et al., 1994; Paschke et al., 1994; Roura-Mir et al., 1996) was found using PCR in both the thyroid gland and the retroorbital infiltrates of patients with GD (see Chapter 35). Th2 responses have been implicated in GD, which is caused by autoantibodies to the thyrotropin receptor (TSHR), which stimulates the thyroid [reviewed in Rapoport and McLachlan (2001)]. Indeed, a number of studies indicate that Th2 cytokines, or responses reflecting Th2 cytokines, are elevated in patients with GD. In addition, TSHR-specific clones derived from patients with GD secrete IL-4 and relatively little IFN-γ. Furthermore, elevated serum concentrations of eosinophil-derived neurotoxin (EDN) have been detected in GD, but not in HT. Moreover, the levels of EDN correlated with TSHR antibody activity measured by inhibition of thyrotropin (TSH) binding, suggesting that Th2-type responses are crucial for GD (Hidaka et al., 2003).

One explanation for the discrepancy between findings suggesting a Th1 predominance and those indicating a Th2 predominance in GD may emerge from recent experiments assessing the levels of the IFN-γ-induced chemokine CXCL10, as well as the presence of its receptor, CXCR3, in the thyroid gland and/or serum of patients examined at different times from the onset of GD. Both CXCR3 and CXCL10 were found to be expressed in the gland of patients in the early phases of GD, the former at the level of infiltrating cells and the latter at the level of follicular epithelial cells. Moreover, high CXCL10 levels were found in the sera of these patients. However, CXCL10 values declined in later phases and the CXCL10/CXCL22 (a Th2-related chemokine) ratio progressively decreased with time (Romagnani et al., 2002). These findings provide strong, although indirect, evidence that GD is initiated by a Th1-dominated inflammatory process, due to the recruitment of CXCR3-expressing Th1 cells by CXCL10 produced by follicular epithelial cells in response to some still unknown triggering agent (Romagnani et al., 2002). Then, Th1 cells produce IFN-γ, which further stimulates the production of CXCL10, thus contributing to the amplification of the inflammatory process. In subsequent phases, an immune deviation from Th1 to Th2 can occur to dampen the chronic Th1 inflammation, and this may account for the documented presence at glandular level of Th2-type cytokines. It is also of note that patients with MS treated with the Campath-1H antibody show a strong depletion of T cells, including those biased towards the Th1 profile, and the appearance of Graves' disease in a third of them (Coles et al., 1999). This finding suggests a possible major role for Tregs in controlling the breakdown in self-tolerance mechanisms that initiate thyroid autoimmunity.

Type 1 (Insulin-Dependent) Diabetes Mellitus

A cellular autoimmune process that selectively destroys the pancreatic islet β cells is thought to be responsible for the development of type 1 diabetes (T1D) in humans (Eisenbarth, 1986) and the spontaneous animal models, the Bio Breeding (BB) rat (Marliss et al., 1983) and the nonobese diabetic (NOD) mouse (Leiter et al., 1987) (see Chapter 36). A common histopathologic feature associated with the development of T1D is insulitis, characterized by the presence within and around the islets of mononuclear cells consisting predominantly of T lymphocytes and macrophages (Bottazzo et al., 1985; Foulis and Farquharson, 1986). The pathogenic role of Th1 cells in T1D in NOD mice is well established and seems to be related to a genetically controlled alteration intrinsic to T cells (Koarada et al., 2002). Disruption of the STAT4 gene, whose product mediates IL-12 signaling and regulates Th1 differentiation (Rengarajan et al., 2000), completely prevented the development of spontaneous diabetes in NOD mice (Yang et al., 2004). Accordingly, systemic administration of IL-18, a cytokine involved in Th1 polarization, promotes T1D development in young NOD mice (Oikawa et al., 2003). The role of Th1 cytokines in the pathogenesis of T1D in NOD mice is more complex than initially thought. Indeed, IFN-γ can have either a pathogenic or protective role for T1D development in NOD mice, since its deletion can allow alternative pathways to accelerate the establishment of diabetes (Trembleau et al., 2003).

The inflammatory cell infiltrate in insulitis lesions in human T1D has not been fully characterized. However, it appears that it is composed of both lymphocytes and macrophages (ratio 7–9:1) and that high proportions of lymphocytes (about 40%) contain IFN-γ (Foulis et al., 1991), thus suggesting a predominant Th1 phenotype. Interestingly, T-cell clones from peripheral blood of patients with recent-onset T1D had a Th1 cytokine profile, while those from prediabetic patients were of the Th2 subtype (Chang et al., 1995). Moreover, overwhelming IFN-γ production has been found in high-risk first-degree relatives of children with T1D, suggesting a Th1-like immune deviation in the prediabetic phase (Karlsson et al., 2000). Likewise, serum concentrations of CXCL10, a chemokine induced by IFN-γ are increased in patients with T1D, but only during the early and subclinical stage of the disease (Nicoletti et al., 2002). Recent observations also suggest a possible deficiency of $CD4^+CD25^+$ Tregs in patients with T1D (Kukreja et al., 2002).

A hypothetical scheme illustrating the main immunologic events in patients with T1D is shown in Figure 7.7.

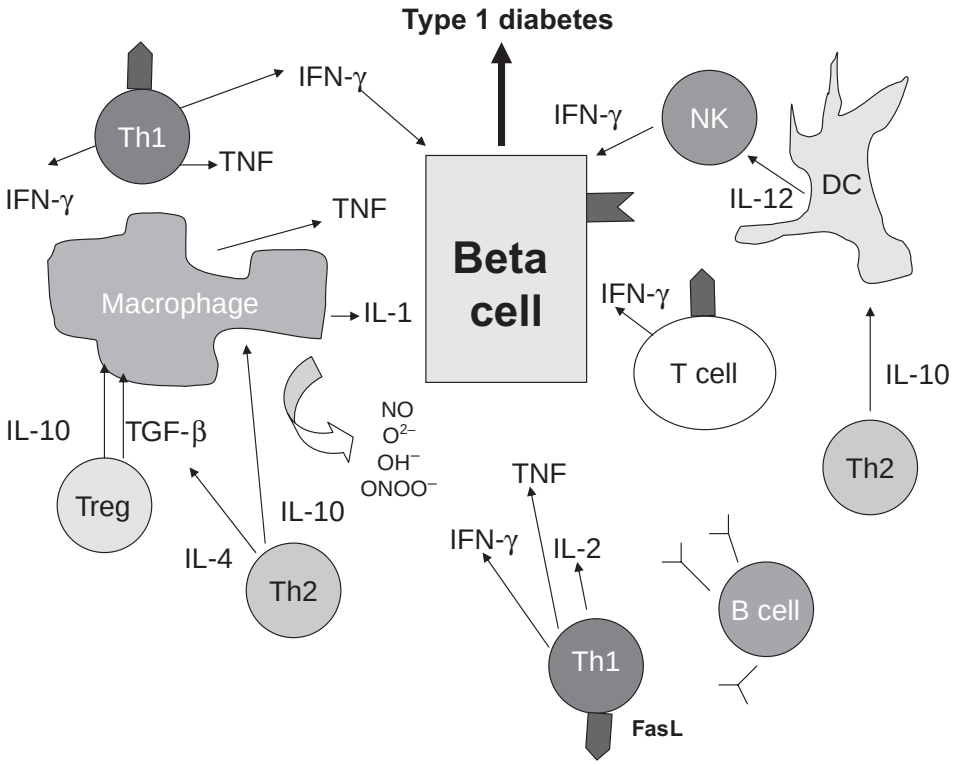

FIGURE 7.7 Possible events contributing to the development of type 1 diabetes (T1D). The hallmark is the selective destruction of insulin-producing cells (β cells) in the pancreas (insulitis). The islet tissue obtained by pancreatic biopsy from patients with recent-onset T1D shows insulitis, characterized by the infiltration of $CD4^+$ and $CD8^+$ T lymphocytes, B lymphocytes, and macrophages. An interaction between genetic and environmental factors is responsible for triggering an immune-mediated response, characterized by the appearance of autoantibodies as the first sign of β cell destruction by $CD4^+$ and $CD8^+$ T lymphocytes. A staged progression to overt diabetes through extensive beta cell destruction is related to various factors, including development of a more aggressive T-cell phenotype and a change in the Th1/Th2 balance towards a more proinflammatory milieu. The expression of FasL on cytotoxic T cells is also a marker of the progression to overt T1D. DC, dendritic cell; IFN, interferon; IL, interleukin; NK, natural killer cell; TGF, transforming growth factor; Treg, regulatory T cell.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an autoimmune disorder characterized by a chronic synovitis, which often leads to joint destruction (Harris, 1990) (see Chapter 32). Many studies have investigated the role of cytokines in the pathogenesis of RA. These studies have been performed both in patients and animals with collagen-induced arthritis (CIA), which is considered to be the best model of experimentally-induced RA. There is considerable and convincing experimental evidence for a dominant Th1 drive in murine CIA [reviewed by Schulze-Koops and Kalden (2001)]. When cytokine levels of cultured draining lymph node cells from mice with CIA are monitored during induction and throughout the time of clinical manifestation, IFN-γ can be detected very early, whereas production of Th2 cytokines is suppressed. Moreover, mice treated with IL-12 or IL-18, two powerful Th1-polarizing agents, develop a more severe disease. Finally, and most importantly, IL-12-deficient mice, as well as mice treated with an anti-IL-12 antibody, which have an impaired Th1 response and reduced IFN-γ production, manifest a significant reduction in both the incidence and severity of CIA. On the other hand, a beneficial effect of both Th2 and Treg cytokines, such as IL-4, IL-10, or TGF-β, has been reported (Schulze-Koops and Kalden, 2001).

The experimental evidence for a dominant Th1 drive in RA in humans is less clear, and categorization of a complex disease such as RA as "Th1" is probably too simplistic. It is well-established that pro-inflammatory cytokines, such as TNF-α, IL-1, granulocyte-macrophage colony-stimulating factor (GM-CSF), and IL-6 (Di Giovine et al., 1988; Hirano et al., 1988; Bucala et al., 1991; Haworth et al., 1991; Deleuran et al., 1992; Wood et al., 1992), as well as chemokines, such as CXCL8, CCL2, and CCL5 (Hosaka et al., 1994), are produced by the synovial membrane in RA and are considered to be important in the pathophysiology of the disease. Indeed, they can both induce bone resorption and cartilage destruction, and can stimulate prostaglandin

E2 release and collagenase production (Feldman et al., 1992). In contrast to the abundance of monocyte-derived cytokines, T-cell-derived cytokines have often proven difficult to detect in RA synovium (Firestein et al., 1988; Brennan et al., 1990), despite the fact that synovial membrane-infiltrating T cells appear to be phenotypically activated (Hovdenes et al., 1989). This has led to the suggestion that the pathogenesis of RA is mediated solely by macrophages and their effector cytokines (Firestein and Zvaifler, 1993).

An alternative view is that T-cell cytokines may be important, but are expressed at levels too low for detection by conventional methods (Panayi et al., 1992). In support of this possibility is the demonstration, by either PCR or *in situ* hybridization, of mRNA for IFN-γ and IL-2 in RA synovial tissue (Buchan et al., 1988; Firestein et al., 1990; Simon et al., 1994). Moreover, the majority of circulating mononuclear cells from RA patients show elevated expression of mRNA for Th1 cytokines, while elevated mRNA levels for IL-4 are present only in a few cases, which supports a predominant activation of Th1/Th0 cells (Schulze-Koops et al., 1995). Finally, T-cell clones derived from RA synovium produce predominantly IL-2 and IFN-γ, which suggests a Th1 profile (Miltenburg et al., 1992; Quayle et al., 1993). However, some rheumatoid inflammatory T-cell clones also exhibit a Th0-like or even a Th2-like profile (Quayle et al., 1993), which may represent the result of a disease-dampening immune deviation. Moreover, the number of IFN-γ-producing $CD4^+$ T cells is significantly increased in the synovial fluid compared to the peripheral blood (Davis et al., 2001), resulting in a markedly elevated Th1/Th2 ratio that correlates with disease activity (van der Graaf et al., 1999). In the synovial fluid of RA patients, IL-18 expression associates with the high levels of both IL-1β and TNF-α (Joosten et al., 2003), and seems to promote joint inflammation and cartilage destruction through a separate pathway (Joosten et al., 2004). Of note, progenitor cells and soluble factors in the synovial fluid of RA patients yield a subset of myeloid DCs that preferentially activate Th1 responses (Santiago-Schwartz et al., 2001). Increased numbers of peripheral blood cells secreting IFN-γ and IL-2 were also found in patients with new-onset synovitis (of under 1-year duration) and, more interestingly, the frequencies of IFN-γ-secreting cells in early arthritis correlated with disease activity, emphasizing the role of Th1 cells in the initiation of the disease (Kanik et al., 1998). Accordingly, analysis of subcutaneous nodules in RA patients revealed a classic Th1-like granuloma pathway (Hessian et al., 2003). The possible role of CXCL10 in the recruitment of Th1 cells from the bloodstream into the synovial joints has been suggested (Hanaoka et al., 2002). On the other hand, in addition to proinflammatory cytokines, a compensatory anti-inflammatory response has also been observed in RA synovial membranes. Thus, high levels of IL-1RA, soluble TNF receptors (both the 55- and 75-kDa receptors), IL-10, and TGF-β have been found in RA synovial fluid (Brennan et al., 1990; Deleuran et al., 1992). IL-10 was also found at both the mRNA and protein level in RA synovial membranes (Katsikis et al.,1994). This suggests that homeostatic immune system mechanisms exist in the rheumatoid joint to contain inflammation and limit joint destruction. Indeed, blocking IL-10 in synovial membrane cultures resulted in an increase in both TNF-α and IL-1β (Katsikis et al., 1994). Because IL-10 is a *powerful* inhibitor of both Th1 and macrophage cytokine production (Fiorentino et al., 1989; Del Prete et al., 1993), it is also possible that IL-10 may represent the factor, or one of the factors, responsible for the "elusiveness" of Th1-derived cytokines in RA. However, the possibility of a more heterogenous Th cell response cannot be excluded.

The complex immunologic events in patients with RA are shown in Figure 7.8.

Sjögren Syndrome

Sjögren syndrome (SS) is a chronic autoimmune disease with a clinical spectrum defined by the simultaneous presence of keratoconjunctivitis sicca and xerostomia in patients not fulfilling criteria for any other chronic inflammatory connective tissue disease (Skopouli et al., 1986) (see Chapter 31). The disorder is characterized by immune system hyperactivity expressed as hypergammaglobulinemia, multiple organ and non-organ-specific autoantibodies, and focal lymphocytic infiltration of the exocrine glands (Fox and Kang, 1992). Although not yet conclusive, the results of different studies suggest a predominant activation of Th1 cells in patients with SS. This has been observed in the IqI/Jic mouse model of primary SS, where the expression of IL-12 and IFN-γ associates with the presence of CD86-expressing DCs in the early development of sialodacryoadenitis (Konno et al., 2003).

In the human disease, the cytokines IL-1, IL-6, TNF-α, and IFN-γ were identified in defined parts of labial salivary gland specimens (Rowe et al., 1987; Oxholm et al., 1992). Increased serum levels of IL-6 and IFN-γ have also been reported (Al-Janadi et al., 1993). It has been suggested that virus-induced IFN-γ production may shift the distribution of the nuclear autoantigen La (SSB) from the nucleus to the cytoplasm and membrane of salivary cells, thus favoring the autoimmunization process (Clark et al., 1994). Indeed, spontaneous IFN-γ mRNA has been observed in freshly isolated unstimulated T cells from SS patients (Villarreal et al., 1995). Increased production of IL-10 by stimulated peripheral blood mononuclear cells and spontaneous IL-10 mRNA expression by freshly isolated mononuclear cells from SS patients have also been reported (Liorente et al., 1994; Villarreal et al., 1995), which may reflect a homeostatic attempt to contain the inflammation induced by the Th1

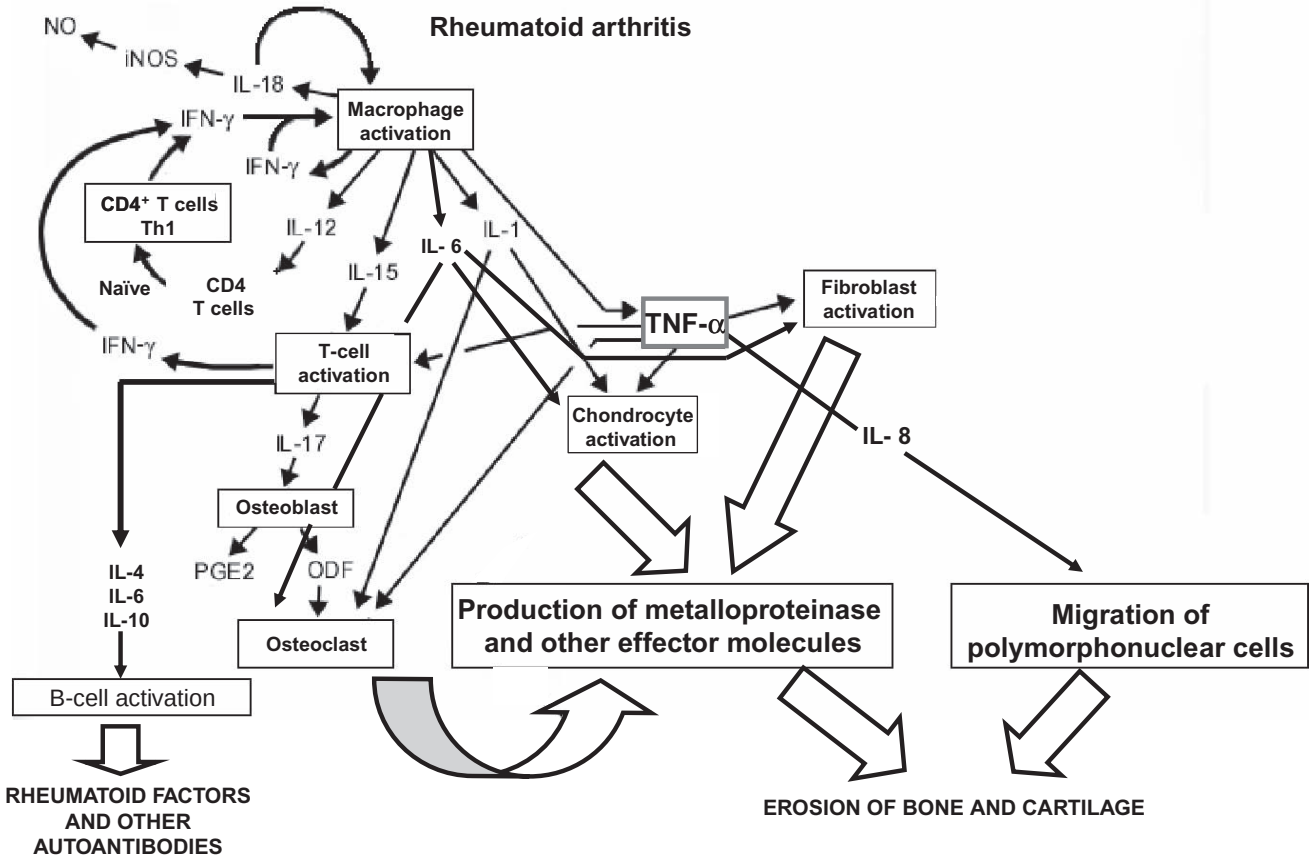

FIGURE 7.8 Possible events contributing to the development of rheumatoid arthritis (RA). Antigen-activated $CD4^+$ T cells stimulate macrophages and synovial fibroblasts to produce the cytokines interleukin (IL)-1, IL-6, tumor necrosis factor (TNF)-α, and matrix metalloproteinases. Activated $CD4^+$ T cells also collaborate with B cells in the production of immunoglobulins, including rheumatoid factor and other autoantibodies, and stimulate osteoclastogenesis. IL-1, IL-6, and TNF-α are the key cytokines in RA. TNF-α and IL-1 are potent stimulators of synovial fibroblasts, osteoclasts, and chondrocytes, which release tissue-destroying matrix metalloproteinases. IL-1 and TNF-α also inhibit the production of tissue inhibitors of metalloproteinases by synovial fibroblast. These dual actions are thought to lead to joint damage. In addition, TNF-α stimulates the development of osteoclasts, which are responsible for bone degradation. NO, nitric oxide; iNOS, induced nitric oxide synthase; ODF, osteoclast differentiation factor; PGE2, prostaglandin E2.

cytokines (see RA above). The possible role of IL-15 produced by macrophages in recruiting and activating T-lymphocytes into synovial membrane has also been suggested, but the pathogenic meaning of this finding remains unclear (Mcinnes et al., 1996). More recent data demonstrate the existence of both Th1 and Th2 cytokines in labial salivary glands (LSGs) of SS patients, with the balance between the two shifting in favor of Th1 in patients with a high LSG infiltration score (Mitsias et al., 2002). The predominance of the Th1 drive in SS patients has also been recently confirmed by the observation of increased circulating levels and salivary gland expression of IL-18 (Bombardieri et al., 2004).

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is an autoimmune disorder characterized by multiple immune abnormalities, culminating in the overproduction of a wide range of autoantibodies and a constellation of pathologic abnormalities involving the kidney, skin, brain, lungs, and other organs (Milis, 1994) (see Chapters 27 and 28). The imbalance between Th1 and Th2 cytokine production in SLE patients, which favors Th2 cytokines, may be critical to disease induction. It may contribute to the increased B-cell activation characteristic of SLE patients, and also to disease perpetuation. Moreover, the cytokine imbalance might underlie

the impaired self-tolerance, because several Th2 cytokines stimulate B cells. However, the immune alterations of SLE are likely much more complex than a Th1/Th2 imbalance alone, and the reasons for the defective Th1 responses in patients with SLE remain speculative. Downregulation by excessive Th2 cytokines, defective interaction between APCs, T cells, and NK cells, the presence of IL-2 inhibitors, and the downregulation of IL-2 receptors are possible mechanisms. Alternatively, the strong increase in IL-10 production may account for both the potent stimulation of B-cell proliferation and defective Th1 response (Csiszar et al., 2000). In contrast, IL-12 production was found to be inhibited in circulating mononuclear cells from SLE patients compared with matched controls (Horwitz et al., 1998). Thus, a dysregulation of the IL-10/IL-12 balance might play an important role in the impaired cellular immune responses seen in patients with SLE. However, multiple alterations in the immunoregulatory network (Figure 7.9) certainly play a more crucial role in SLE pathogenesis (Mok and Lau, 2003).

Systemic Sclerosis

Systemic sclerosis (SSc) is characterized by inflammatory, vascular, and fibrotic changes of the skin (scleroderma) and a variety of internal organs, most notably the gastrointestinal tract, lungs, heart, and kidney (see Chapter 29). In the skin, a thin epidermis overlies compact bundles of collagen, which lie parallel to the epidermis. Increased numbers of T cells may be present at the border of skin lesions, as well as in other organs in the early stages of the disease (Roumm et al., 1984). Furthermore, cellular autoimmunity to collagen and laminin (Fleischmajer et al., 1993), and the claimed development of scleroderma-like lesions after silicone mammoplasty (Endo et al., 1987) (see Chapter 23),

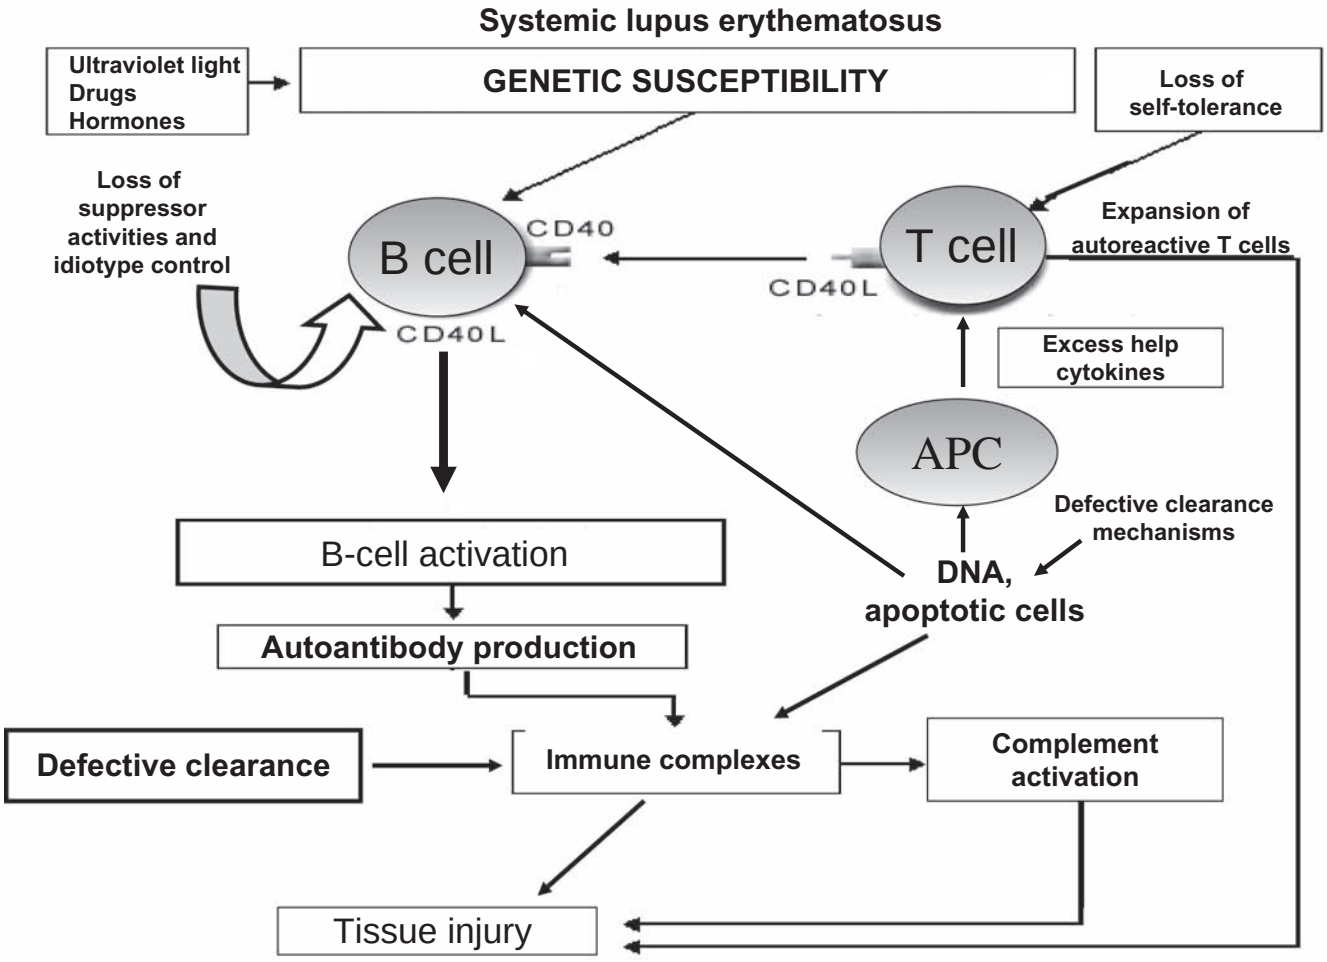

FIGURE 7.9 Possible events contributing to the development of systemic lupus erythematosus. Multiple genes confer susceptibility to the development of this disease. The interaction of sex-related factors, environmental factors, and defective immune regulation may predispose an individual to the expression of this susceptibility. Defective clearance mechanism, loss of immune tolerance, expansion of autoreactive T-cells, and defective B-cell suppression, lead to B-cell hyperactivity and the production of pathogenic autoantibodies. APC, antigen-presenting cell.

have suggested a role for activated T cells in the pathogenesis of SSc. Mice heterozygous for the tight-skin (Tsk) mutation develop skin fibrosis and are considered to be a good experimental animal model for the human disease. The administration of neutralizing anti-IL-4 antibodies to Tsk/$^{+}$ mice prevented the development of skin fibrosis in these mice, suggesting an important role for this Th2 cytokine in the pathogenesis of lesions. Accordingly, the development of skin fibrosis in Tsk/$^{+}$ mice was abrogated by the IL-4$^{-/-}$ or STAT6$^{-/-}$ mutation (Ong et al., 1999).

Interestingly, circulating mononuclear cells from patients with SSc produce higher amounts of IL-2 and IL-4 than controls (Famularo et al, 1990; Needleman et al, 1992; Sato et al., 1995). The great majority of SSc patients showed spontaneous IL-4, IL-5, and CD30 mRNA expression in peripheral blood T cells, and high numbers of CD4^{+} T cells in the perivascular infiltrates present in skin biopsy specimens obtained from SSc patients were CD30^{+} and expressed IL-4, but not IFN-γ, mRNA. These data strongly suggest predominant activation of Th2 cells in SSc and support the view that abnormal and persistent IL-4 production by the activated Th2 cells may play an important role in the induction of fibrosis and, therefore, in the pathogenesis of the disease.

A hypothetical scheme illustrating the possible immunologic events leading to the main pathophysiologic alterations characteristic of subjects with SSc is shown in Figure 7.10.

The origin of the Th2-dominated immune response in SSc is still unclear. The clinical features of SSc are similar to those of chronic graft-versus-host disease (GvHD) (Chosidow et al., 1992), a chimeric disorder in recipients of allogenic stem cell transplants and in whom Th2-type responses also predominate (de Wit et al., 1993). Identification of fetal DNA and cells in skin lesions and blood from women with SSc has been reported (Artlett et al., 1998), suggesting that a microchimerism established by fetal T

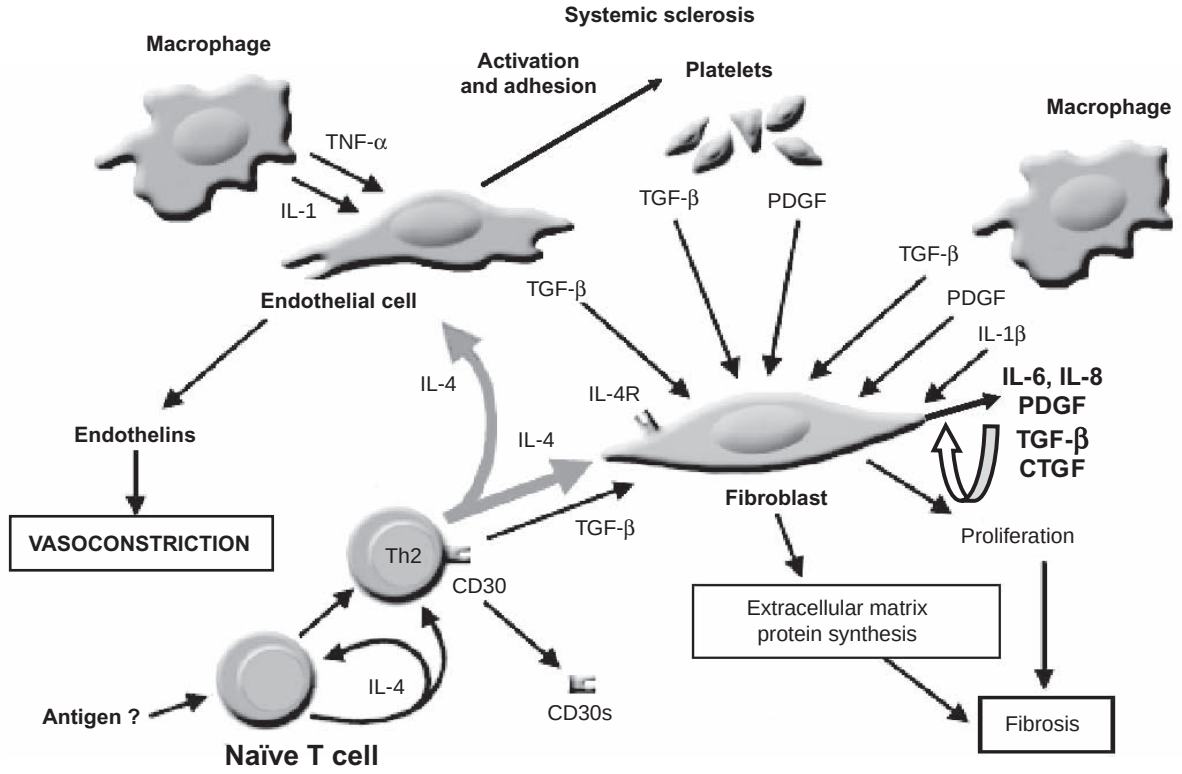

FIGURE 7.10 Possible events contributing to the development of systemic sclerosis (SSc). Extracellular matrix protein synthesis by fibroblasts is the hallmark of the disease. Collagen accumulation results from abnormal interactions between endothelial cells, lymphocytes, macrophages, and fibroblasts, leading to the production of fibrosis-inducing cytokines. Fibroblasts from subjects with SSc are activated and overproduce extracellular matrix proteins. Collagen synthesis is dependent upon tumor growth factor (TGF)-β, a cytokine produced by fibroblasts and endothelial cells, and connective tissue growth factor (CTGF), synthesized by fibroblasts under the influence of both TGF-β produced by fibroblasts and interleukin (IL)-4 produced by Th2 cells. PDGF, platelet-derived growth factor; TNF, tumor necrosis factor.

cells and the activation of such cells may induce a graft-versus-host response, manifesting as SSc. However, subsequent studies showed no difference in the frequency of microchimerism with fetal cells between healthy women and women with SSc; therefore, the casual link between microchimerism and disease pathogenesis remains uncertain (Evans et al., 1999). Seven maternal T-cell clones derived from women with SSc and one derived from a healthy woman proliferated in response to autologous non-T-cells and exhibited the Y chromosome, which demonstrated that they originated from male-offspring T cells. These data suggest that male-offspring T cells, which are present in blood and/or skin of women with SSc and are reactive against maternal MHC antigens, exhibit a Th2-oriented profile, thus supporting their possible role in the chronic GvHD occurring in women with SSc (Scaletti et al., 2002).

CONCLUDING REMARKS

It is now clear that the Th cell population contains functionally polarized subsets that are characterized by the patterns of cytokines they produce in response to different types of antigenic stimulation. Although Th1 and Th2 cells were first identified by *in vitro* analysis of murine T-cell clones, strong evidence now exists for similar subsets *in vivo* in mice, rats, and humans. Provided oversimplifications are avoided, these two extremely polarized forms of the specific cellular immune response, evoked by intracellular parasites and gastrointestinal nematodes, respectively, provide a useful model for explaining not only the different types of protection, but also the pathogenic mechanisms of several immunopathologic disorders.

Th1-dominated responses are very effective at eradicating infectious agents, including those "hidden" within the cell; however, if the Th1 response is not effective or is excessively prolonged, it may become dangerous for the host, due to both the activity of cytotoxic cytokines and the strong activation of phagocytic cells. In contrast, Th2 responses are not sufficiently protective against the majority of infectious agents, but they do provide an important downregulatory mechanism for exaggerated and/or excessively prolonged Th1 responses (Th1 to Th2 switch or immune deviation from Th1 to Th2).

Studies of autoimmune disorders in the context of Th1 and Th2 T-cell responses suggest the existence of a complex network of interactions that involves Th1 responses, counter-regulatory Th2 responses, and the defective intervention of Tregs. The majority of autoimmune diseases studied, especially organ-specific autoimmune diseases, appear mainly to be mediated by Th1-triggered inflammatory processes, the two clearest examples being MS and T1D. Interestingly, in these diseases, switching from a Th1 to a Th2 response can prevent Th1-mediated destruction of tissue in the experimental models of many conditions. However, a role for defective Treg activity is also emerging. In human SLE, a Thl/Th2 polarization is not apparent, and a more general imbalance of different immune mechanisms seems to be operating. In other autoimmune disorders, Th2 responses seem to predominate and can mediate tissue damage. Th2 cells are indeed involved in autoimmunity during chronic GvHD, in SLE induced by chemicals, and in SSc. It is of note that the chronic autoimmune diseases related to a prevalent Th2 response can in turn be prevented by switching from a Th2 to Th1 response. Taken together, these findings suggest that modulation of the relative contribution of Th1 or Th2 T cells to an autoimmune response, or suppression of the response that is prevalently involved in the inflammatory process, may allow clinical autoimmune disease to be regulated, thus opening the way for new therapeutic strategies.

Tolerance and Autoimmunity: T Cells

MATTHEW A. GRONSKI AND PAMELA S. OHASHI

University Health Network, Ontario Cancer Institute, Departments of Medical Biophysics and Immunology, University of Toronto, Canada

Autoimmune diseases generally develop as a result of an immune response against self-molecules. Insulin-dependent diabetes, multiple sclerosis, and myasthenia gravis are all examples of diseases that are believed to result from such a misdirected response. Immune tolerance mechanisms are normally in place to limit potential autoimmune responses. Self-reactive T cells, which often mediate autoimmune disease, are controlled through mechanisms of central tolerance that occur in the thymus during T cell development and peripheral tolerance that act on mature T cells after they leave the thymus.

THYMIC TOLERANCE

T-Cell Receptor Interactions Determine Thymocyte Fate

Differentiation of thymocytes is characterized by the cell-surface expression of proteins such as CD4 and CD8. Bone marrow progenitors that enter the thymus initially do not express CD4 or CD8 and are referred to as double-negative (DN) $CD4^-CD8^-$ thymocytes (Figure 8.1). Following T-cell receptor (TCR) β chain rearrangement, only thymocytes expressing a functionally rearranged TCR β chain are selected to continue maturation and upregulate both CD4 and CD8. At this $CD4^+CD8^+$ double-positive (DP) stage, TCR α chain rearrangement is initiated and functionally rearranged TCR α chains are expressed on the cell surface with the TCR β chain. Interactions between the TCR expressed by DP thymocytes and self-major histocompatibility complex (MHC) molecules mediate survival or death (Figure 8.1). Thymocytes expressing TCRs that do not interact with self-MHC molecules die within a few days. Thymocytes expressing TCRs that are able to interact with intermediate affinity with self-MHC molecules are rescued from death by a process called positive selection. Positive selection ensures that only T cells that are able to recognize peptides presented on self-MHC molecules are exported to the periphery. Thymocytes expressing TCRs recognizing class I MHC molecules downregulate CD4 and become cytotoxic $CD8^+$ single positive (SP) cells, while $CD4^+$ helper T (Th) cells arise as a result of interactions between TCRs and class II MHC molecules. A strong interaction between TCR and self-peptide–MHC leads to the elimination of thymocytes by a process called negative selection (Palmer, 2003; Starr et al., 2003).

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

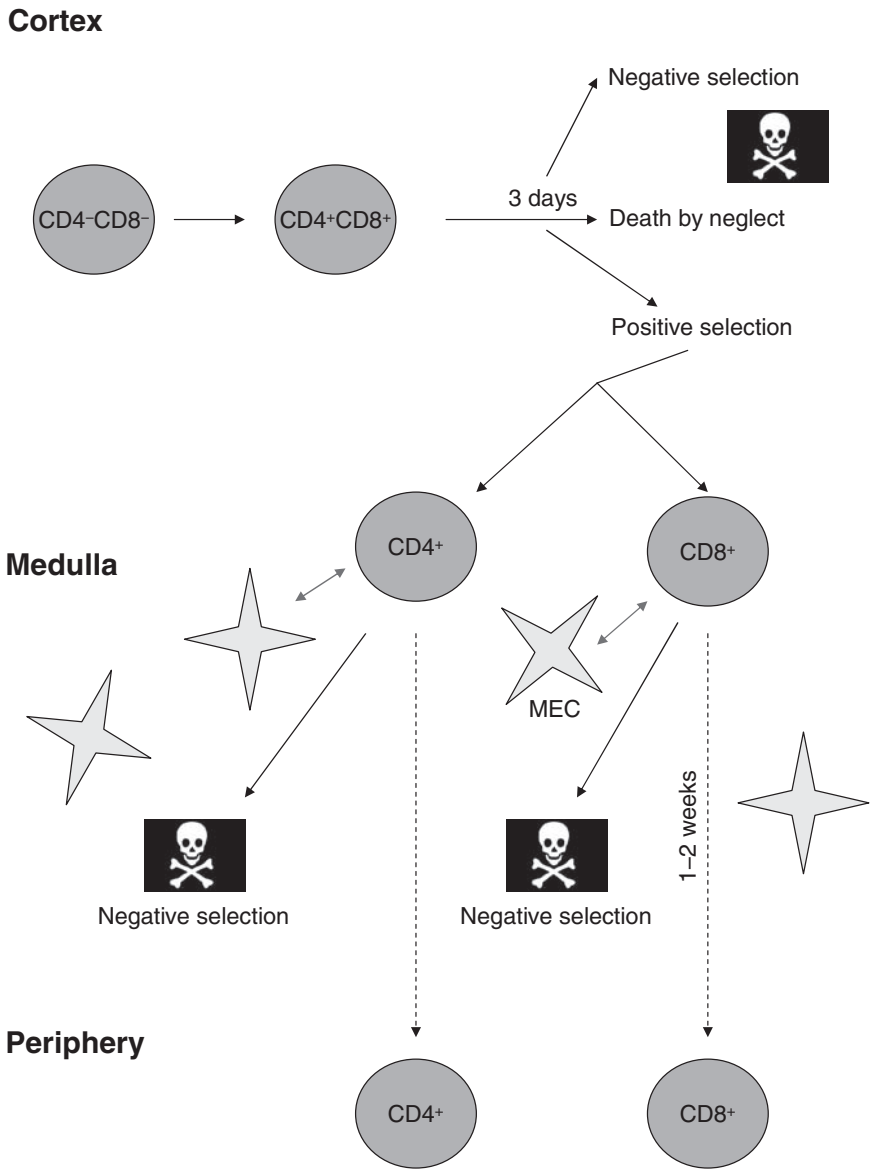

FIGURE 8.1 Thymocyte development and selection. Developing thymocytes follow a defined differentiation program in the thymus. Early progenitors are found in the cortex of the thymus as $CD4^-CD8^-$ double-negative (DN) thymocytes. Subsequently they upregulate the expression of the coreceptors CD4 and CD8 and become double-positive (DP) T cells. The DP thymocytes survive for approximately 3 days before undergoing programmed cell death. Intermediate-affinity interactions between the T-cell receptor (TCR) and self-peptide–MHC trigger differentiation and survival through a process called positive selection. Positive selection leads to the maturation of single-positive $CD4^+$ or $CD8^+$ thymocytes that transit into the medulla. A high-affinity/-avidity interaction between the TCR and self-peptide/MHC results in negative selection and central tolerance. Medullary epithelial cells (MECs) and other antigen-presenting cells contribute to negative selection.

Deletion of Autoreactive Thymocytes

What happens to the autoreactive thymocytes when they receive a strong signal through the TCR? Clonal deletion has been shown to be one of the main mechanisms that eliminate autoreactive cells (Kappler et al., 1987; 1988; MacDonald et al., 1988). This was first demonstrated by Kappler et al. (1987) using a monoclonal antibody that recognized the Vβ17 segment of the TCR. They found expression of Vβ17 in immature but not mature thymocytes of mice that expressed I-E, suggesting that the $V\beta17^+$ I-E reactive cells are deleted. Further evidence for clonal deletion as a

mechanism of negative selection was provided by TCR transgenic mice. H-Y TCR transgenic mice express TCRs that recognize the male H-Y antigen presented by MHC class I molecules. In male TCR transgenic mice, a striking reduction of the DP thymocytes and $CD8^+$ transgenic T cells was observed. In contrast, in female mice the H-Y TCR transgenic T cells were positively selected to the CD8 lineage (Kisielow et al., 1988; Teh et al., 1988). Together, these studies clearly demonstrate that thymocytes expressing self-reactive TCRs are clonally eliminated during development.

As an added level of protection from autoimmunity, thymic deletion appears to be more sensitive than mature T-cell activation. That is, stronger interactions with peptide–MHC are required for the activation of T cells in the periphery compared to deletion of immature thymocytes (Yagi and Janeway, 1990; Pircher et al., 1991; Vasquez et al., 1992; Davey et al., 1998; Lucas et al., 1999). The higher sensitivity in thymic selection creates a margin of safety by deleting T cells that would probably not receive strong enough signals to be activated by self-peptide–MHC in the periphery.

Clonal Inactivation of Autoreactive Thymocytes

In addition to thymic deletion, T-cell inactivation has also been proposed as a mechanism of thymic tolerance (Ramsdell et al., 1989; Speiser et al., 1990; Rellahan et al., 1990). This was originally shown by Ramsdell et al. (1989) using a chimeric model. They generated chimeric mice by transferring bone marrow cells from one mouse to an irradiated recipient mouse. Bone marrow cells are sensitive to irradiation while the thymic epithelial cells are resistant, allowing the selective depletion of bone marrow-derived cells. In this way, they generated animals that expressed the tolerizing superantigen Mls-1^a in the bone marrow cells or thymic stroma to study the effect on T cell development and tolerance. If Mls-1^a was expressed on bone marrow cells, deletion of $V\beta6^+$ Mls-1^a reactive T cells occurred. However, if the host expressed Mls-1^a and the donor bone marrow cells did not, clonal deletion did not occur. Instead, nondeleted mature $V\beta6^+$ T-cells were unresponsive to Mls-1^a or stimulation by monoclonal antibodies. Thus, it appears that under some circumstances thymocytes are inactivated rather than deleted.

Regulatory T-Cell Development

Some of the T cells that receive a relatively strong signal in the thymus, which is insufficient for negative selection, can develop immunosuppressive functions and negatively regulate responses by other T cells. Although the location and signals involved in the development of these regulatory T cells (Tregs) are unclear, evidence suggests that they are the result of relatively high-affinity interactions in the thymus (Itoh et al., 1999). At least one subset of $CD4^+CD25^+$ Tregs that express TCRs with self-reactive properties is produced in the thymus [reviewed in Fehervari and Sakaguchi (2004)]. Glucocorticoid signaling blockers, which effectively decrease the threshold for T-cell activation, result in the generation of more $CD4^+CD25^+$ Tregs in the thymus. Similarly, studies using double transgenic mice that express an ovalbumin (OVA)-specific TCR and a transgene-encoding OVA in the thymus, suggest that Tregs are the product of selection signals that are higher than those for positive, but lower than those for negative, selection (Jordan et al., 2001). However, a recent study has questioned the conclusions of these studies, suggesting that Tregs do not differentiate in the thymus as a consequence of high-affinity interactions. Rather, the observed increase in the percentage of these cells is a result of preferential deletion of $CD4^+CD25^-$ T cells (van Santen et al., 2004). Nonetheless, development of the Treg population in the thymus plays a key role in maintaining tolerance in the periphery.

Tissue-Specific Antigens and Negative Selection

A potential problem with central tolerance is the limited expression of peripheral tissue-specific antigens in the thymus. It has become clear, however, that certain cells of the thymic stroma express peripheral tissue-specific antigens that promote the elimination of self-reactive T cells (Smith et al., 1997; Kyewski et al., 2002). Studies have suggested that a putative transcription factor—the autoimmune regulator (AIRE) protein—is expressed in rare specialized cells called medullary epithelial cells (MECs). Interestingly, it was found that a mutation in this protein in humans led to the development of the multiorgan autoimmune endocrine disease, autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) (The Finnish–German APECED Consortium, 1997; Nagamine et al., 1997). Since both AIRE and peripheral antigens are expressed in MECs, it was speculated, and later confirmed by microarray technology, that AIRE controls the expression of these antigens (Anderson et al., 2002). To study the role of AIRE, AIRE-deficient mice were generated by two independent groups (Anderson et al., 2002; Ramsey et al., 2002). These mice developed lymphocytic infiltrates and autoantibodies directed against a number of peripheral organs and tissues, such as the salivary gland, retina, pancreas, ovary, stomach, and thyroid. Further analysis using bone marrow chimeras and thymic transplant experiments found that to prevent disease AIRE expression was only crucial in the non-hematopoietic cells of the thymic stroma (Anderson et al., 2002). Therefore, central tolerance includes mechanisms to

induce tolerance of T cells specific for tissue antigens expressed outside the thymus.

Other cell populations found in the thymus include dendritic cells (DCs) and macrophages. This is important because they expose thymocytes to antigens expressed on antigen-presenting cells (APCs) that activate T cells in the periphery. In this way, thymocytes become tolerant to "self"-antigens expressed by APCs, biasing the repertoire to respond to foreign antigens presented by these cells.

Negative Selection and Autoimmunity

If central tolerance were critical for eliminating autoreactive cells and preventing autoimmunity, it would be predicted that autoimmunity would develop if negative selection were impaired. Currently, the association between the loss of AIRE and autoimmunity in both humans and mouse models provides the best evidence for the importance of negative selection (The Finnish-German APECED Consortium, 1997; Nagamine et al., 1997; Ramsey et al., 2002; Anderson et al., 2002; Liston et al., 2003).

Other animal models of autoimmunity, however, have also been associated with impaired negative selection (Kishimoto and Sprent, 2001; Lesage et al., 2002). Since negative selection involves the death of self-reactive thymocytes, genes involved in apoptosis may be important for this process. As a result, mutations in apoptosis-related genes often result in autoimmune disease. An example of this is the proapoptotic molecule Bim, a Bcl-2 homology domain 3 (BH3)-only containing protein (Bouillet et al., 1999). Mice deficient in Bim accumulate lymphoid and myeloid cells, while older mice accumulate plasma cells and develop autoimmune kidney disease. Studies have suggested that defects in both central and peripheral tolerance contribute to these abnormalities (Bouillet et al., 2002; Davey et al., 2002; Hildeman et al., 2002).

This is not the only evidence for the importance of central tolerance in preventing autoimmunity. Many studies also support the corollary prediction: if central tolerance (clonal deletion) is induced to tissue-specific antigens, autoimmunity can be prevented (Herold et al., 1992; Posselt et al., 1992; Ally et al., 1995).

Escape of Autoreactive T Cells from Central Tolerance

Evidence suggests that central tolerance is incomplete because autoreactive cells can be found in the peripheral repertoire and autoimmune diseases do arise in humans and animal models (Haskins and McDuffie, 1990; Nagata et al., 1994; Verdaguer et al., 1997; Wong et al., 1999). Several factors have been identified to explain why self-reactive T cells may escape thymic deletion. Although the AIRE protein promotes expression of tissue-specific antigens in the thymus, it is likely that many are still not expressed at levels sufficient to induce T-cell tolerance. Models have suggested that many tissue-specific antigens are not expressed at sufficient levels for negative selection (Ohashi et al., 1991; Goverman et al., 1993; Katz et al., 1993; Pugliese et al., 1997; Vafiadis et al., 1997). Low levels of self-antigen expressed in the thymus would lead to deletion of only the high-affinity/-avidity autoreactive thymocytes, resulting in incomplete tolerance and allowing lower-affinity/-avidity, potentially self-reactive thymocytes to leave the thymus (von Herrath et al., 1994; Oehen et al., 1994). In addition, peptides that have a low affinity for MHC cannot induce negative selection of thymocytes expressing cognate TCRs (Liu et al., 1995). Weak binding to the MHC results in lower effective avidity that allows escape from deletion. T cells expressing TCRs with low affinity/avidity for peptide–MHC may also avoid negative selection (Morgan et al., 1998). These T cells could be activated in the periphery as a result of possibly higher levels of antigen expression. Finally, particular splice variants of proteins may not be expressed in the thymus and therefore specific T cells will not be tolerized (Anderton et al., 2002; Manoury et al., 2002). Thus, multiple factors alter the ability of self-peptides to be effectively presented in the thymus, limiting the efficiency of negative selection.

PERIPHERAL TOLERANCE

Because not all autoreactive thymocytes are deleted during development, peripheral tolerance mechanisms have been postulated to induce unresponsiveness in mature T cells that are specific for peripheral self-antigens. Four main mechanisms of peripheral tolerance play an important role in maintaining self-tolerance and preventing autoimmunity: deletion, anergy, ignorance, and regulatory cells.

Deletion

The mechanism of tolerance of mature T cells by clonal elimination was demonstrated *in vivo* using different approaches (Webb et al., 1990; Kawabe and Ochi, 1991; Rocha and von Boehmer, 1991). In the first report, injection of cells expressing the superantigen Mls-1^a into thymectomized Mls-1^b mice resulted in the expansion of Mls-1^a reactive $V\beta6^+CD4^+$ T cells, followed by deletion of these cells (Webb et al., 1990).

The relevance of clonal deletion as a mechanism of peripheral tolerance to tissue specific antigens was provided using transgenic mouse models (Chen et al., 1995; Kurts et al., 1996; Liblau et al., 1996). Kurts et al. (1996) utilized mice that expressed a membrane-bound form of OVA in the pancreas [rat insulin promotor (RIP)–OVA mice] and kidneys. Adoptive transfer of OVA-specific $CD8^+$ T cells

into RIP–OVA mice showed that in the lymph nodes draining the organs where the OVA antigen was expressed, the OVA-specific T cells divided and displayed an activated phenotype. The OVA-specific T cells detected antigen on bone marrow-derived APCs that picked up antigen and presented it in the context of MHC class I via an exogenous processing pathway. This activation and expansion in the draining lymph nodes, however, was only transient and was followed by deletion of the OVA-specific T cells (Kurts et al., 1997).

The importance of deletion as a mechanism of peripheral tolerance has also been suggested in mice deficient for genes involved in apoptosis, such as Fas and FasL. The natural mutant lpr mouse (lymphoproliferative), which carries a mutation in the TNF-family receptor Fas, and the FasL mutant gld mouse (generalized lymphoproliferative disorder), develop lymphadenopathy, splenomegaly, and spontaneous autoimmunity (Watanabe-Fukunaga et al., 1992; Takahashi et al., 1994). A similar phenotype and autoimmunity is seen in autoimmune lymphoproliferative syndrome (ALPS) patients (also known as Canale Smith syndrome), most of whom have a mutation in Fas (Fisher et al., 1995; Rieux-Laucat et al., 1995; Lenardo et al., 1999). However, the role of Fas in peripheral clonal deletion and autoimmunity remains controversial. While some studies have pointed to a role for Fas/FasL in activation-induced cell death of mature T cells but not thymocytes (Russell et al., 1993; Singer and Abbas, 1994), others have found Fas to be dispensable for peripheral deletion (Zhou et al., 1992; Sytwu et al., 1996; Hildeman et al., 1999; Nguyen et al., 2000; Reich et al., 2000). Numerous other examples exist of molecules involved in apoptosis whose dysregulation can result in autoimmunity (Field et al., 1996; Murga et al., 2001; Zhang et al., 2002).

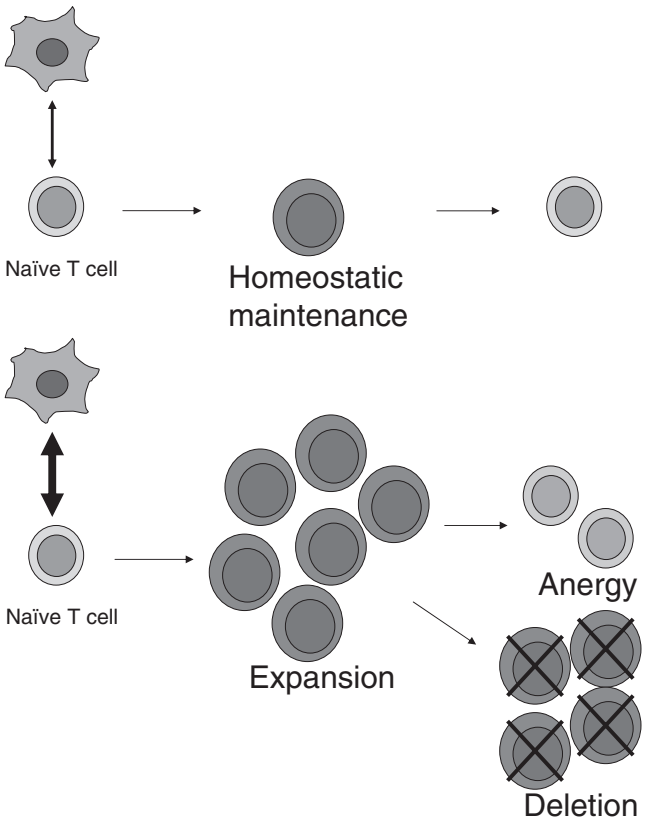

FIGURE 8.2 T-cell receptor (TCR) and peptide–MHC interactions govern homeostasis and peripheral T-cell tolerance. Weak-affinity/-avidity interactions with self-peptide–MHC are required for normal homeostatic T-cell survival as T cells that fail to receive TCR signals undergo programmed cell death. Strong-affinity/-avidity interactions with peptide–MHC on immature antigen-presenting cells result in T-cell expansion, followed by deletion of most of the clones, with the remaining ones being unresponsive to TCR stimuli (anergic).

T-Cell Inactivation

In some models, T-cell interaction with tolerizing antigen results in transient activation and eventual deletion. However, in some circumstances not all antigen-specific T cells are deleted; instead they become functionally inactivated, remaining alive for an extended period of time in a hyporesponsive state referred to as anergy (Figure 8.2) (Schwartz, 1990; 2003). Initial characterization showed that anergic cells were unable to proliferate or produce interleukin (IL)-2 upon stimulation.

The anergic state was first identified *in vitro* following activation of T cells with chemically fixed APCs (Jenkins and Schwartz, 1987; Mueller et al., 1989). Subsequently, other models have shown anergy induction *in vivo* (Lo et al., 1988; Burkly et al., 1989; Rammensee et al., 1989; Rellahan et al., 1990). *In vivo* anergy was first clearly shown by Rammensee et al. (1989) using superantigen Mls-1^a-positive cells that were injected into Mls-1^b mice. After the initial T-cell expansion and deletion of Mls-1^a-specific V$\beta6^+$ T cells, a population of V$\beta6^+$ T cells remained. These cells were unable to proliferate in response to Mls-1^a (Rammensee et al., 1989). Using a TCR transgenic mouse model, Rocha and von Boehmer (1991) have transferred H-Y specific transgenic T cells into nude male mice. This led to a rapid expansion and eventual deletion of the majority of T cells. The remaining T cells failed to proliferate in response to male cells and/or anti-TCR antibody.

Interestingly, there appears to be more than one type of anergy. Schwartz (2003) suggests that the *in vitro* induced clonal anergy is different from a state that is referred to as adaptive *in vivo* induced tolerance (Schwartz, 2003). Whereas clonal anergy can be reversed by the addition of IL-2, adaptive anergy cannot. Furthermore, adaptive anergy appears to depend on the continual presence of antigen. In the Rocha experiments with H-Y-specific T cells, if the anergic T cells were transferred into female mice that lacked the antigen, they recovered their ability to proliferate to

antigen (Rocha et al., 1993). This was also demonstrated in other models (Ramsdell and Fowlkes 1992; Migita and Ochi 1993). Further models have suggested that T-cell activation thresholds can be modulated; that is, the ability of T cells to be activated by antigens is affected by interactions with self-peptide–MHC encountered during development or in the periphery (Kawai and Ohashi, 1995; Sebzda et al., 1996; Mariathasan et al., 1998; Grossman and Paul, 2001). In addition, Tregs are generally believed to be anergic (Sakaguchi, 2004). Therefore, it appears that T lymphocyte unresponsiveness or anergy can be induced in multiple ways.

T-Cell Peripheral Tolerance Versus Activation

If mature T cells expressing TCRs that recognize self-peptide–MHC found in the periphery undergo clonal deletion and anergy, how is normal T-cell activation programmed to occur? Traditional models have suggested that T cells that are stimulated through the TCR (signal 1) together with a costimulatory signal 2 become fully activated effector T cells. In contrast, stimulation of T cells through the TCR in the absence of costimulation leads to the induction of anergy (Bretscher and Cohn, 1970; Lafferty and Cunningham, 1975; Schwartz, 1992). Costimulatory signals such as CD80 (B7.1) and CD86 (B7.2) are received from mature APCs. CD80 (B7.1) and CD86 (B7.2) bind to the costimulatory molecule CD28 that is constitutively expressed on the majority of T cells. Cytokines and chemokines also provide important signals that promote T-cell function and inflammation (Vella et al., 1997b; Curtsinger et al., 2003). Current models propose that the maturation state of the DC determines the outcome of T-cell tolerance versus activation. TCR-specific interactions between T cells and resting DCs result in tolerance (anergy and/or deletion), while interactions with activated DCs promote immunity (Steinman and Nussenzweig, 2002). Key signals that promote DC maturation *in vivo* include signals through Toll-like receptors (TLRs), which are triggered by various structural components of pathogens (Janeway and Medzhitov, 2002; Takeda et al., 2003).

T-cell function is also controlled through the actions of inhibitory receptors such as CTLA-4 and PD-1 on T cells (Greenwald et al., 2002). CTLA-4 is a molecule expressed on T cells that binds to CD80 (B7.1) and CD86 (B7.2) and is believed to be involved in the downregulation of T-cell responses, counteracting CD28 costimulation. CTLA-4 could do this by outcompeting CD28 for B7 ligands, antagonizing CD28-mediated signals, and/or antagonizing TCR-mediated signals; however, at this time the exact mechanism is unclear. CTLA-$4^{-/-}$ mice develop severe lymphoproliferative disorders ultimately resulting in death (Tivol et al. 1995; Waterhouse et al. 1995). Recently, a ligand-independent splice variant form of CTLA-4 (liCTLA-4) has been found and characterized as a negative regulator of signaling downstream of the TCR (Vijayakrishnan et al., 2004). It is more potent than the full-length CTLA-4 in inhibiting T-cell responses, and decreased levels of liCTLA-4 have been linked to susceptibility to diabetes, Graves' disease, and autoimmune hypothyroidism (Ueda et al., 2003).

Similarly, PD-1 (programmed death gene-1), which interacts with CD80/86 (B7) family members PD-L1 (B7-H1) and PD-L2 (B7-DC), has negative regulatory functions. PD-$1^{-/-}$ mice develop an autoimmune-like phenotype, although with delayed onset compared to CTLA-$4^{-/-}$ mice, with lupus-like glomerulonephritis and progressive arthritis associated with a high level of IgG_3 deposition, and increased numbers of myeloid and B cells (Nishimura et al., 1998; 1999). Thus, both the activation state of the APC and the inhibitory receptors affect T-cell tolerance and function, and regulate autoimmunity.

Ignorance

Many autoreactive T cells are not deleted or inactivated in the thymus or in the periphery. If tissue-specific self-antigens are not detectable by the immune system, potentially self-reactive "ignorant" T cells remain in the peripheral repertoire.

Ignorance was first demonstrated in an experimental model of diabetes (Ohashi et al., 1991; Oldstone et al., 1991). RIP-gp transgenic mice expressed the lymphocytic choriomeningitis virus (LCMV) glycoprotein under the control of the RIP, resulting in expression in the β cells of the pancreas. The LCMV-gp specific T cells from RIP-gp mice were not tolerized and yet, RIP-gp mice did not develop spontaneous diabetes. Lymphocytic choriomeningitis virus (LCMV) infection, however, resulted in the activation of gp-specific T cells that infiltrated and destroyed the insulin-producing islet β cells. Numerous examples exist where autoimmune diseases, such as experimental autoimmune encephalomyelitis (EAE), can be induced by immunizing animals with peptide in adjuvant, leading to the activation of self-specific T cells (Kuchroo et al., 2002). These studies suggest that T cells are not tolerized in the presence of antigen; rather they remain "ignorant" of the antigen expressed in the tissues.

Regulation by Other Cells

The existence of regulatory (suppressor) cells was postulated over 30 years ago following experiments using thymectomized mice and rats. These animals developed autoimmune destruction of the ovaries or thyroid gland, respectively, which could be prevented by adoptive transfer of normal $CD4^+$ cells (Nishizuka and Sakakura, 1969; Penhale et al., 1973). Sakaguchi et al. (1995) showed that the autoimmune disease induced by the transfer of $CD4^+CD25^-$ T cells into athymic nude mice could be pre-

vented by the cotransfer of $CD4^+CD25^+$ T cells. These $CD4^+CD25^+$ T cells occur naturally and act by suppressing immune responses. The molecular basis of $CD25^+CD4^+$ suppression remains controversial. *In vivo* studies with knockout mice and blocking antibodies suggested a role for the cytokines IL-10 and transforming growth factor (TGF)-β in some models [reviewed in Sakaguchi (2004)]. *In vitro* suppression requires direct cell–cell interactions but it is not clear if this is also true *in vivo* (Read et al., 1998; Takahashi et al. 1998; Thornton and Shevach, 1998). Interestingly, $CD4^+CD25^+$ T cells constitutively express CTLA-4 and its blockade abrogates Treg function *in vivo* (Read et al. 2000; Takahashi et al., 2000). Thus, it is possible that more than one mechanism of suppression exists.

Further evidence for the importance of Tregs is provided by both human and animal models. Immune dysregulation, polyendocrinopathy, enteropathy, and X-linked (IPEX) syndrome is an X-linked immunodeficiency syndrome associated with autoimmunity in multiple organs. The Scurfy strain of mice is an analogous disease model in mice displaying hyperactivation of $CD4^+$ T cells and overproduction of proinflammatory cytokines. The defective gene has been identified as Foxp3, a member of the forkhead/winged-helix family of transcription factors (Bennett et al., 2001; Brunkow et al., 2001; Wildin et al., 2001). Further studies have suggested a role for Foxp3 in the development and function of natural $CD4^+CD25^+$ Tregs (Fontenot et al., 2003; Hori et al. 2003; Khattri et al., 2003). For example, $CD4^+CD25^-$ T cells that were transduced with Foxp3 could suppress proliferation by other T cells *in vitro* and inflammatory bowel disease *in vivo* (Hori et al., 2003). Thus, Tregs appear to play an important role in the control of immune responses and autoimmunity.

AUTOIMMUNITY

In spite of the different tolerance mechanisms that exist, occasionally tolerance fails. This alone may not be sufficient to cause autoimmunity, but a variety of background genes may modulate disease susceptibility and contribute to the onset of autoimmunity in different ways. In the following section, we highlight potential mechanisms and discuss the requirements for the induction of autoimmune disease (Ohashi, 2002).

Aberrant T-Cell Homeostasis

T-cell homeostasis and survival in the periphery is controlled by several signals. The recognition of self-MHC ligand by naïve T cells is required for survival and thus is important in normal T-cell homeostasis (Figure 8.2) (Takeda et al., 1996; Tanchot et al., 1997; Jameson, 2002). These relatively weak interactions lead to partial tyrosine phosphorylation of the TCR ζ chain and upregulation of a subset of T-cell activation or memory markers, such as CD44 and CD122, respectively (Goldrath et al., 2002; Stefanova et al., 2003). Cytokines also play a crucial role in T-cell survival and homeostasis, particularly those that signal through the common γ chain. IL-4, IL-7, and IL-15 support homeostatic T-cell expansion *in vitro*, although only IL-7 has been shown to be crucial *in vivo* (Schluns et al., 2000; Goldrath et al., 2002). We suggest that dysregulation of lymphocyte survival may result in autoimmunity (Figure 8.3). Enhanced lymphocyte survival may occur as a result of altered lymphocyte cell survival signals. Semi-activated T-lymphocytes may constantly relay signals to APCs or B cells, promoting increased cytokine production and leading to the accumulation of lymphocytes in the secondary organs (splenomegaly and lymphadenopathy) and the production of antiself antibodies. Alternatively, enhanced TCR signaling could also lead to aberrant homeostasis. Weak interactions with self-peptide–MHC that normally lead to T-cell maintenance may actually lead to limited proliferation of certain clones, resulting in expansion and lymphoid hyperplasia (Figure 8.3).

Animal models have shown that altering the expression or regulation of cytokines important in homeostatic survival leads to autoimmunity. IL-7 functions as a crucial regulator of peripheral T-cell homeostasis by modulating the expansion of peripheral T-cell populations in lymphopenic animals (Schluns et al., 2000; Tan et al., 2001). It functions by increasing the proliferation of peripheral T cells in response to both low- and high-affinity antigens, in effect increasing peripheral homeostatic expansion. IL-7 potently inhibits programmed cell death by the upregulation of anti-apoptotic bcl-2 family members (Vella et al., 1997a; Fry and Mackall, 2001). Transgenic mice that expressed IL-7 under the control of the MHC class II promotor had a 10–20-fold increase in total T-cell numbers and $CD8^+$ T cells displayed a memory ($CD44^{hi}$ and $CD122^{hi}$) phenotype with enhanced production of IFN-γ after stimulation (Mertsching et al., 1995; Kieper et al., 2002). Some IL-7 transgenic lines developed dermatitis characterized by massive infiltration of mononuclear cells (Uehira et al., 1993). IL-7 administration also resulted in T-cell proliferation, although the upregulation of activation markers was not detected (Geiselhart et al., 2001).

IL-6 is a cytokine that regulates the immune response, hematopoiesis, and inflammation (Teague et al., 1997; Hirano, 1998). IL-6 transgenic mice developed a massive polyclonal plasmacytosis with autoantibody production and mesangial cell proliferative glomerulonephritis that resembled the autoimmune disease observed in systemic lupus erythematosus (SLE) patients (Suematsu et al., 1989). Hypergammaglobulinemia was also observed in mice who received a transplant of bone marrow cells infected with a retroviral vector expressing murine IL-6 (Brandt et al.,

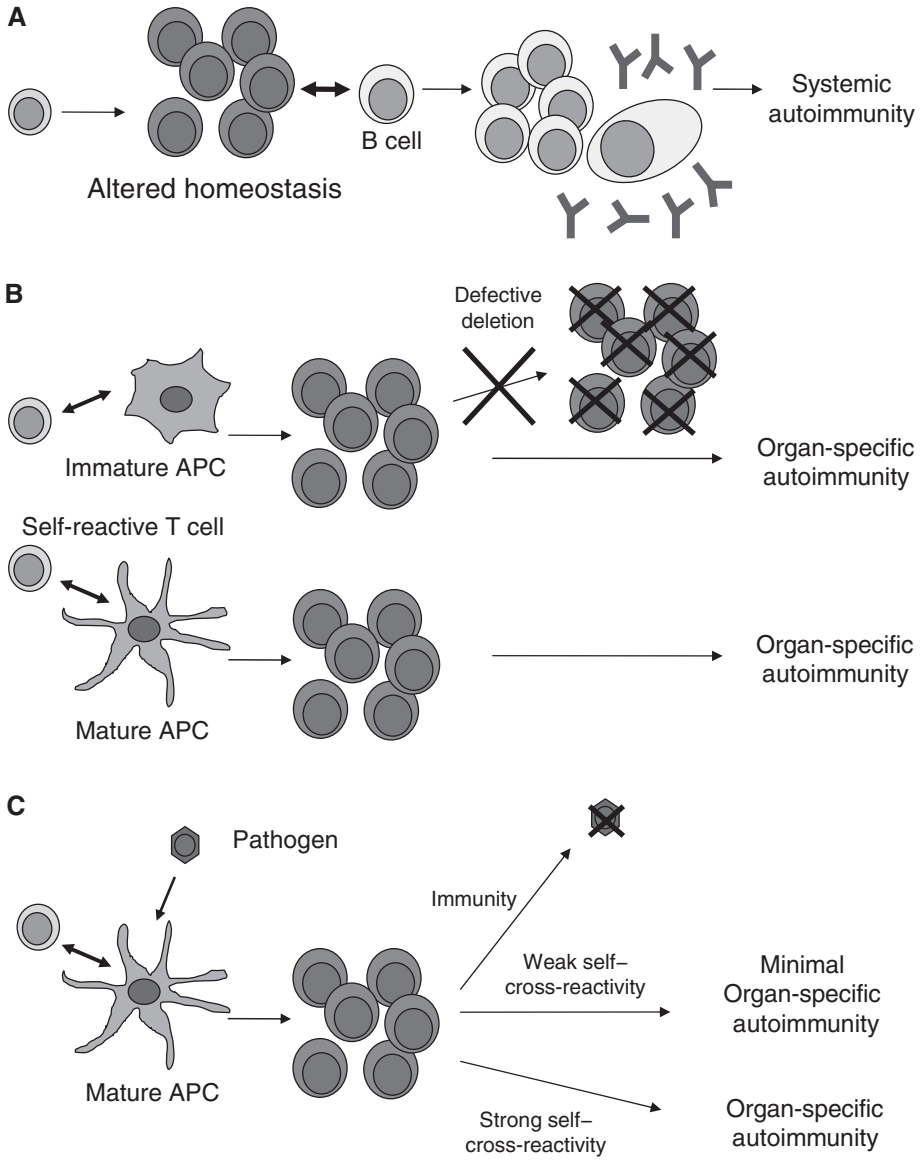

FIGURE 8.3 Potential mechanisms of autoimmunity. *A*, Weak interactions with self-peptide–MHC normally lead to homeostatic maintenance of T cells. If this process is disturbed by altering T-cell survival this can result in splenomegaly and lymphadenopathy. Over time, interactions between these partially activated T cells (dark cells) and B cells (light cells) can lead to systemic autoimmunity characterized by autoantibody production. *B*, T cells that encounter high-affinity/-avidity antigen on resting APCs would normally undergo a process of expansion followed by deletion or anergy. However, defects in apoptosis might lead to defective peripheral tolerance induction, either to the inability to directly delete the self-reactive cell or to the lack of cross-presentation of self-antigen, and result in autoimmunity. Alternatively, interactions with hyperactivated mature APCs may promote full activation of self-antigen-specific T cells instead of tolerance, and predispose individuals towards autoimmunity. *C*, Activation by pathogens results in the activation of a variety of T-cell clones specific for the foreign antigen. These clones proliferate and eliminate the pathogen. Weak cross-reactivity of these activated T cells with self-peptides may result in transient or minimal autoimmunity, i.e., organ infiltration but no destruction. On the other hand, T cells strongly reactive against self-antigen will cause organ-specific autoimmunity. It is not yet clear at which stage and by which of these mechanisms regulatory T cells act to prevent autoimmunity.

1990). Furthermore, high levels of IL-6 have been associated with a number of autoimmune diseases, like diabetes, inflammatory bowel disease, EAE, and rheumatoid arthritis (Ishihara and Hirano, 2002).

Cells have evolved important mechanisms to prevent excessive responses to cytokines. Suppressor of cytokine signaling (SOCS) proteins inhibit components of the cytokine signaling cascade via direct binding or by preventing access to the signaling complex. There are eight members of the SOCS family: CIS and SOCS1–SOCS7 (Alexander and Hilton, 2004). SOCS1 inhibits JAK-STAT signaling by many cytokines, including IL-2, IL-6, IL-7, and interferons. $SOCS1^{-/-}$ mice die by 3 weeks of age with monocytic infiltration, fatty necrosis of the liver, and inflammation of the pancreas and heart (Starr et al., 1998). The disease is thought to result from hypersensitivity to IFN-γ (Alexander et al., 1999). T cells in $SOCS1^{-/-}$ mice displayed an activated phenotype with increased cell size and expression of activation markers CD44, CD25, and CD69 (Marine et al., 1999). OT-I OVA-specific TCR transgenic $SOCS1^{-/-}$ $Rag1^{-/-}$ mice were used to determine if T cells would remain naïve in the absence of their antigen. These mice, however, still succumbed to disease in early adulthood and their T cells exhibited a blast-like activated phenotype with high levels of CD44 on the cell surface (Cornish et al., 2003). Studies by Hanada et al. (2003) examined the role of SOCS1 specifically in APCs by reintroducing SOCS1 as a transgene in lymphocytes. They provided evidence that SOCS1-deficient DCs are activated and promote autoimmunity. These experiments outline an important role for SOCS1 in directly regulating homeostasis of DCs, subsequently altering the homeostasis of lymphocytes.

Experimental evidence also suggests that altered T-cell survival via the phosphatidylinositol-3-kinase (PI3K) pathway can promote autoimmunity. Activation of PI3K catalyzes the formation of phosphatidylinositol-3,4-bisphosphate and phosphatidylinositol-3,4,5-triphosphate (PIP_3), which regulates many cellular events, including cell survival, division, and migration (Fruman et al., 1998; Scheid and Woodgett, 2001). The amount of PIP_3 is regulated by a lipid phosphatase known as PTEN (phosphatase and tensin homolog found on chromosome 10). The presence of PIP_3 on the membrane leads to recruitment and activation of a serine threonine kinase, protein kinase B (PKB/Akt). Perturbations in the activity of PI3K, PTEN or PKB lead to an autoimmune phenotype in mice characterized by activated $CD4^+$ cells, lymphadenopathy, a defect in Fas-mediated apopotosis, inflammation, and autoantibody production (Di Cristofano et al., 1999; Borlado et al., 2000; Parsons et al., 2001). Studies have shown that active PKB prevents Fas-induced death by inhibiting the formation of the death-inducing signaling complex, which is essential for the induction of apoptosis (Jones et al., 2002). These and other studies suggest that the primary role of Fas may be associated with homeostasis and not peripheral deletion (Markiewicz et al., 2003). Thus, evidence suggests that events that alter homeostasis or survival of lymphocytes may contribute to autoimmunity.

Defects in Peripheral T-Cell Tolerance

Strong stimulatory TCR signals that result from T-cell encounter with self-antigen on resting APCs generally lead to T-cell proliferation followed by deletion or anergy (Figure 8.2) (Kurts et al., 1997; Hawiger et al., 2001; Steinman et al., 2003). As discussed above, if the deletion of autoreactive clones is perturbed, autoimmunity might occur due to the presence of autoreactive cells (Figure 8.3). Aberrant peripheral tolerance may also occur if self-antigen is presented by activated APCs or if T cells circumvent the need for activated APCs to be fully stimulated (Diehl et al., 1999; Sotomayor et al., 1999; Garza et al., 2000).

Interaction of T cells with immature APCs normally results in tolerance. However, examples from genetically manipulated mice have shown that there are genes that influence the ability of APCs to induce tolerance versus activation. STAT3 is one of a family of cytoplasmic transcription factors that are key mediators of cytokine and growth factor signaling pathways. Disruption of STAT3 in mice resulted in generation of APCs that effectively primed rather than tolerized naïve T cells. Moreover, $STAT3^{-/-}$ DCs could restore the unresponsiveness of anergic $CD4^+$ T cells (Cheng et al., 2003). Studies have suggested that the absence of STAT3 leads to a proinflammatory environment, promoting inflammatory bowel disease (Takeda et al., 1999; Welte et al., 2003).

Tyro 3, Axl, and Mer (TAM) are receptor tyrosine kinases that are expressed by macrophages and DCs, but not T- or B cells. Upon receptor engagement, the Src family kinases are activated and signaling pathways downstream of Grb2 promote cell proliferation and protect against cell death (Schwartzberg, 2001). The Tyro 3, Axl, and Mer triple knockout mice contain large numbers of apoptotic cells in many tissues and have features associated with autoimmunity (Lu and Lemke, 2001). Beginning at 4 weeks of age, the spleen and lymph nodes of these mice expanded by up to 10 times those of wild-type mice. The aberrant growth of peripheral lymphoid organs was primarily due to hyperproliferation of B and T cells. All triple mutant TAM-deficient mice developed autoimmune disorders displaying lymphocytic invasion of multiple organs, autoantibodies to dsDNA, various collagens and phospholipids, as well as deposition of immune complexes in tissues. The triple knockout mice, as well as Mer^{kd} mutant mice that lack the cytoplasmic region of the molecule, have delayed clearance of apoptotic cells (Lu and Lemke, 2001; Scott et al., 2001; Cohen et al., 2002). This may result in failed tolerance, since there may be inefficient presentation of self-antigens from apoptotic

cells. $CD11c^+$ cells (DCs) from the knockout mice have upregulated levels of MHC II and CD86 (B7.2), markers of APC activation, while macrophages in these mice release larger amounts of TNF-α, a proinflammatory cytokine (Camenisch et al., 1999; Lu and Lemke, 2001). Therefore, the combination of an increase in tissue-specific T cells (due to the lack of peripheral tolerance) together with increased APC activation possibly results in autoimmunization and autoimmunity in these mice.

Although hyperactivated APCs can provide costimulation to T cells and predispose animals towards autoimmunity, studies have identified a genetic mutation that circumvents the requirement for costimulatory signals for full T-cell activation. Cbl, a family of E3 ubiquitin ligases, directs the ubiquitination of tyrosine kinases involved in signaling downstream of the TCR. Cbl-b-deficient mice have enhanced IL-2 production after TCR stimulation (Bachmaier et al., 2000; Chiang et al., 2000). The Penninger group described autoimmunity in the absence of Cbl-b characterized by multiorgan inflammation and autoantibody production (Bachmaier et al., 2000). Gu and colleagues showed that $Cbl\text{-}b^{-/-}$ mice were also more susceptible to antigen-induced EAE (Chiang et al., 2000). Both groups suggested that Cbl-b acts primarily by regulating the requirement for CD28 costimulation. Further studies have shown that T cells from Cbl-b-deficient animals cannot be anergized (Heissmeyer et al., 2004). Interestingly, Yokoi et al. (2002) mapped a diabetes-susceptibility locus in the Komeda rats to Cbl-b. These rats had a nonsense mutation that resulted in the transcription of a truncated form of the molecule. Transgenic expression of a full-length Cbl-b prevented diabetes in the rat model.

Other E3 ubiquitin ligases, such as Itch and Grail, have also recently been shown to play a role in the induction of T-cell tolerance. The expression of Itch, Cbl-b, and GRAIL is upregulated in anergic T cells and is crucial for the induction of anergy, suggesting the importance of these molecules in peripheral tolerance (Heissmeyer et al., 2004; Jeon et al., 2004). Like mice lacking Cbl-b, those lacking Itch also develop spontaneous autoimmunity characterized by inflammation of numerous tissues (Perry et al., 1998; Fang et al., 2002). Thus, in addition to Cbl-b, other E3 ubiquitin ligases are also crucial for the induction of anergy and tolerance by ubiquitinating downstream signaling molecules.

Collectively these studies suggest that the impaired induction of anergy due to the absence of E3 ubiquitin ligases, such as Cbl-b or Itch, promotes autoimmunity.

Molecular Mimicry

Potentially autoreactive T cells exist in the peripheral T-cell repertoire, but are not usually activated because APCs are normally not activated. Infections with pathogens usually lead to the generation of an effective immune response, because pathogens provide the necessary signals for APC maturation. If pathogens express antigens that are similar to host antigens, cross-reactive responses can lead to the destruction of host tissues. This process is called molecular mimicry and studies in various experimental models have shown molecular mimicry as a mechanism triggering autoimmunity (Damian, 1964; Fujinami and Oldstone, 1985; Ohashi et al., 1991; Oldstone et al., 1991; Jahnke et al., 1995; Oldstone, 1998; Olson et al., 2001). Examples of autoimmune diseases possibly induced by molecular mimicry are shown in Table 8.1. Although a number of studies suggest molecular mimicry as a mechanism for clinical autoimmune disease, it is still unclear whether this is a common way in which tolerance is broken (Benoist and Mathis, 2001).

Pathogenic infections have been associated with autoimmune diseases, which are believed to occur as a result of molecular mimicry (Table 8.1). Lyme arthritis results from an infection by the tick-borne spirochete *Borrelia burgdorferi*. In approximately 10% of patients with Lyme arthritis, joint inflammation continues even after bacterial DNA can no longer be detected in the joints of patients. The majority

TABLE 8.1 Autoimmune diseases that are associated with a pathogenic infection and where a candidate mimic and/or self-protein have been identified

Disease	Pathogen	Mimic protein	Self-protein	Reference
Antibiotic-resistant Lyme arthritis	*Borrelia burgdorferi*	OspA	hLFA-1	Gross et al. (1998)
Herpes stromal keratitis	HSV-1	UL6	Unknown (eye protein)	Zhao et al. (1998)
HTLV-1-associated myelopathy/tropical spastic paraparesis	HTLV-1	Unknown	hnRNP-A1	Levin et al. (2002)
Autoimmune gastritis	*Helicobacter pylori*	LPS biosynthesis protein	H+K+-adenosine triphosphate	Amedei et al. (2003)
Reactive arthritis	*S. typhimurium*	GroEL presented by class Ib molecule Qa1	mHSP60	Lo et al. (2000)

of patients with Lyme arthritis has HLA-DRB1*0401 or HLA-DRB1*0101. Patients also show immune reactivity to the outer surface protein A (OspA) of the spirochete. A study by Huber and colleagues identified the immunodominant HLA-DRB1*0401-restricted peptide of OspA (Gross et al., 1998). From this they identified human LFA-1 as a candidate autoantigen with homology to the OspA peptide. They also showed that synovial fluid T cells could respond to both the OspA and LFA-1 peptides that were identified. Although Lyme arthritis links human autoimmunity and molecular mimicry, whether molecular mimicry is truly the cause of Lyme arthritis remains controversial (See Chapter 33). The LFA-1 peptide acts only as a weak agonist in Lyme-resistant arthritis patients, mainly producing the Th2 cytokine IL-13 (Trollmo et al., 2001). Furthermore, a number of postulates have not been fulfilled to implicate molecular mimicry as the true cause of Lyme arthritis (Benoist and Mathis, 2001; Steere and Glickstein, 2004).

CONCLUDING REMARKS

Research over the past several decades has revealed a detailed understanding of T-cell tolerance mechanisms in the thymus and periphery. New insights into the mechanisms of breaking tolerance and factors that contribute to the induction of autoimmune disease are being unveiled with the generation of many different gene-deficient strains of mice. Ideally, the next few decades will bring a greater understanding regarding the molecular pathways and mechanisms that contribute to the different spectra of autoimmune diseases. This should provide insights and directions for specific therapy, targeting different autoimmune diseases.

CHAPTER

9

Regulatory T Cells

SIMON READ, KEVIN J. MALOY, AND FIONA POWRIE
Sir William Dunn School of Pathology, University of Oxford, Oxford, UK

Over the past three decades, advances in our understanding of how lymphocytes are activated at the molecular level have contributed to the discovery of several essential mechanisms involved in the maintenance of self-tolerance. These include clonal deletion of self-reactive immature lymphocytes during their development in the thymus and bone marrow (Kappler et al., 1987; von Boehmer, 1988; Cornall et al., 1995), as well as the deletion or functional inactivation (clonal anergy) of naïve lymphocytes in the periphery (Goodnow et al., 1989; Russell et al., 1991; Schwartz, 2003). While these recessive mechanisms are efficient, autoreactive T cells clearly constitute part of the normal T-cell repertoire and the occurrence of autoimmune disease is evidence of their pathogenic potential. More recently, it has become clear that dominant suppressive mechanisms also play an essential role in maintaining self-tolerance and controlling immune pathology, and that specialized populations of regulatory T cells (Tregs) are responsible for this activity (Piccirillo and Shevach, 2004; Sakaguchi, 2004). In this chapter, we describe a number of regulatory T cell types ($CD4^+CD25^+$, Tr1, Th3, NKT, and $CD8^+$) but with particular emphasis on $CD4^+CD25^+$ Treg cells.

Although the concept of T-cell-mediated suppression was first proposed over 30 years ago (Gershon and Kondo, 1970), it is only over the past decade that conclusive evidence has emerged to confirm the existence of a distinct T-cell phenotype. As will be discussed below, several complementary findings triggered this renaissance in Treg biology. Furthermore, reconstitution of immune-deficient mice with populations of normal T cells that lacked Tregs led to the development of a range of autoimmune and inflammatory pathologies (Sakaguchi et al., 1985; Powrie and Mason, 1990; Morrissey et al., 1993; Powrie et al., 1993). Second, disease development in these models was inhibited by reconstitution with Tregs from normal animals—a population that functionally resides primarily within the $CD4^+CD25^+$ T-cell fraction—the "naturally occurring" $CD4^+CD25^+$ Tregs (Read et al., 2000; Sakaguchi et al., 1995). Lastly, the identification of a transcription factor, Foxp3, which is expressed specifically in $CD4^+CD25^+$ Tregs, has been shown to play an indispensable role in their development (Fontenot et al., 2003; Hori et al., 2003; Khattri et al., 2003). Mutations in the human Foxp3 gene were shown to be the underlying cause of an X-linked immunodeficiency syndrome, the immune dysregulation, polyendocrinopathy, enteropathy, and X-linked (IPEX) syndrome (Bennett et al., 2001; Wildin et al., 2001), a fatal inflammatory disease characterized by multiple autoimmune disorders, allergies, and inflammatory bowel disease; the same spectrum of diseases is found in mice lacking a functional Foxp3 gene and therefore $CD4^+CD25^+$ Tregs (Fontenot et al., 2003; Khattri et al., 2003). Together,

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

these studies demonstrate that expression of Foxp3 is critical for the development of the unique regulatory phenotype of $CD4^+CD25^+$ Tregs. As outlined below, these cells can suppress a variety of experimental autoimmune diseases. In fact, they have been shown to impact on almost every type of effector immune response, from the suppression of allograft rejection to impeding antitumor immunity, from inhibiting the harmful immune pathology that accompanies many antimicrobial responses to augmenting T-cell memory in others [reviewed in Maloy and Powrie (2001), Sakaguchi (2004), and Shevach (2002)].

In this chapter we focus primarily on naturally occurring $CD4^+CD25^+$ Tregs, as their nonredundant role in maintaining self-tolerance has been the most clearly established. However, it should be noted that several other populations of $CD4^+$ T cells have been described to possess regulatory activity and can be exploited therapeutically. These include natural killer T (NKT) cells that also arise naturally during development, as well as "induced" $CD4^+$ Tregs that develop following stimulation of peripheral T cells. This chapter will cover the role of these additional Treg populations in autoimmunity; however, as the relationship between $CD4^+CD25^+$ Tregs and other Treg populations is still unclear, the reader is referred to more specialized reviews for a full description of their biology (Roncarolo et al., 2003; Godfrey and Kronenberg, 2004; Mills, 2004).

NATURALLY OCCURRING REGULATORY T CELLS

Ontogeny

One important characteristic of $CD4^+CD25^+$ Tregs is that, in contrast to conventional naïve $CD4^+$ T cells, they complete their functional maturation within the thymus and are exported as bona fide Tregs (Itoh et al., 1999). The production of differentiated $CD4^+CD25^+$ Tregs, which control potentially pathogenic self-reactive T cells that have escaped negative selection, has been described as the third function of the thymus (Seddon and Mason, 2000; Apostolou et al., 2002) (see Chapter 10). A number of studies have shown that $CD4^+CD8^-CD25^+$ thymocytes possess identical phenotypic and functional characteristics to peripheral $CD4^+CD25^+$ Tregs (Papiernik et al., 1998; Itoh et al., 1999; Stephens and Mason, 2000), including high levels of expression of the transcription factor Foxp3 (Hori et al., 2003). $CD4^+CD25^+$ Tregs do not develop in Foxp3-deficient mice (Fontenot et al., 2003), and retroviral transduction of Foxp3 into $CD4^+CD25^-$ T cells converts them into functional $CD4^+CD25^+$ Tregs (Hori et al., 2003). Studies with transgenic mice have shed some light on the unique thymic ontogeny of $CD4^+CD25^+$ Tregs. For example, enhanced development of $CD4^+CD25^+$ Tregs has been observed in transgenic mice expressing both a high-affinity transgenic T-cell receptor (TCR) and the peptide ligand recognized by that TCR on thymic stromal cells (Jordan et al., 2000; Kawahata et al., 2002). $CD4^+CD25^+$ Tregs did not develop when the affinity of the TCR was reduced or the transgenic peptide was expressed at a very high level, indicating that they are subject to positive and negative selection processes. Furthermore, the development of $CD4^+CD25^+$ Tregs was dependent on the expression of major histocompatibility complex (MHC) class II and the agonist peptide by thymic cortical epithelial cells (Bensinger et al., 2001). Taken together, these findings suggest that $CD4^+CD25^+$ Tregs develop as a result of a relatively high-avidity interaction of the TCR with self-peptide–MHC II complexes expressed by thymic cortical epithelial cells.

Further evidence that $CD4^+CD25^+$ Tregs exhibit enhanced self-reactivity was recently obtained through analysis of TCR-α gene rearrangements. This revealed that the $CD4^+CD25^+$ Treg subset possesses an equally diverse, but largely distinct, TCR repertoire to that of the $CD4^+CD25^-$ T cells, and that the former contains a high frequency of TCRs with a higher avidity for self-peptide–MHC II complexes (Hsieh et al., 2004). In addition to the higher avidity of $CD4^+CD25^+$ Tregs for self-peptide–MHCII complexes, these cells are able to mediate suppression in response to a lower concentration of agonist peptide than is required for activation of conventional T cells (Takahashi et al., 1998), thus providing a potent mechanism through which dominant tolerance towards self-antigens may be maintained.

While the thymus may be the primary site of $Foxp3^+$ Treg development, there is evidence that $CD4^+CD25^+Foxp3^+$ Tregs can develop from naïve peripheral $CD4^+CD25^-$ T cells (Thorstenson and Khoruts, 2001; Apostolou et al., 2002). Such conversion has been achieved through prolonged systemic infusion of agonist peptide *in vivo* (Apostolou and von Boehmer, 2004), as well as by activation in the presence of high levels of tumor growth factor (TGF)-β *in vitro* (Chen et al., 2003). Although the physiologic significance of this pathway remains to be established, it does offer the opportunity to generate antigen-specific $Foxp3^+$ Tregs that can be used in therapeutic approaches for autoimmune and inflammatory disease.

Functional Characteristics

Markers

Naturally occurring Tregs are enriched within the 5–10% of peripheral $CD4^+$ T cells in mice and humans who express CD25. Although a useful marker of Treg activity, CD25 expression is not specific, as many T cells upregulate CD25 following activation but do not express Foxp3. Conversely, cells expressing Foxp3 mRNA can also be detected in the $CD4^+CD45RB^{low}CD25^-$ pool (Hori et al., 2003), which may

explain the described Treg activity of this population (Olivares-Villagomez et al., 2000; Stephens and Mason, 2000). Like CD25, several other activation-associated surface molecules are expressed by Tregs, such as glucocorticoid-induced TNFR family-related receptor (GITR), CTLA4, and CD103, and these have been linked with Treg function (Read et al., 2000; Takahashi et al., 2000; Lehmann et al., 2002; Shimizu et al., 2002; Banz et al., 2003; Stephens et al., 2004;). However, like CD25, expression is not restricted to Tregs and is probably more related to the activation state of the cell. Currently, Foxp3 expression is used as the definitive marker of naturally occurring Tregs; however, as its expression is confined to the nucleus, it is of limited use for the isolation of Tregs. Identification of cell-surface proteins whose expression is linked to Foxp3 may identify more specific markers of naturally arising Tregs.

Activation and Costimulation

$CD4^+CD25^+$ Tregs exhibit an anergic phenotype *in vitro*, failing to proliferate or produce interleukin (IL)-2 following polyclonal or antigen-specific stimulation, although they can mount vigorous antigen-dependent proliferative responses *in vivo* (Klein et al., 2003; Walker et al., 2003). The T-cell growth factor IL-2 appears to play a crucial role in $CD4^+CD25^+$ Treg development and peripheral activity (Furtado et al., 2002; Malek and Bayer, 2004). Mice genetically deficient in IL-2, IL-2Rα or IL-2Rβ, have reduced numbers of $CD4^+CD25^+$ Tregs in the thymus and periphery, and develop fatal autoimmune and inflammatory disease. The inflammatory syndrome in these mice can be inhibited by restoration of normal $CD4^+CD25^+$ Treg numbers (Almeida et al., 2002; Malek et al., 2002). In addition to effects on the development and maintenance of $CD4^+CD25^+$ Tregs, IL-2 is also required for Treg cell activation and clonal expansion (Thornton et al., 2004; Setoguchi et al., 2005). The latter may play a key role in Treg function *in vivo* as suppression of autoimmune and inflammatory disease involves extensive proliferation of Tregs in the secondary lymphoid organs as well as locally in the inflamed tissue (Mottet et al., 2003; Peng et al., 2004). Even in the steady-state, a proportion of $CD4^+CD25^+$ Tregs are continually proliferating (Fisson et al., 2003; Klein et al., 2003). This physiologic proliferation, presumably in response to self-antigens, may be a crucial part of $CD4^+CD25^+$ Treg-mediated dominant tolerance as treatment of normal mice with a neutralizing anti-IL-2 monoclonal antibody (mAb) prevents $CD4^+CD25^+$ Treg proliferation, leading to a reduction in their number, and development of organ-specific autoimmune disease (Setoguchi et al., 2005). IL-2 is produced primarily by activated $CD4^+CD25^-$ cells, suggesting that $CD4^+CD25^+$ Treg numbers may be linked to the level of T-cell activation, providing a feedback mechanism that ensures an appropriate balance of regulatory and effector cell responses.

A reduction in CD28 signaling, either as a result of CD28 or CD80 (B7) deficiency, also leads to reduced numbers of $CD4^+CD25^+$ Tregs both in the thymus and periphery (Salomon et al., 2000). As CD28 costimulation induces IL-2 secretion by $CD4^+CD25^-$ cells, it is possible that the effects of CD28 are mediated via IL-2. However, high levels of CD28 costimulation abrogate suppression *in vitro* (Takahashi et al., 1998; Thornton and Shevach, 1998), suggesting that the level of CD28 signalling dictates $CD4^+CD25^+$ Treg function. CTLA4, which negatively regulates TCR/CD28-mediated signaling in T cells, is also involved in $CD4^+CD25^+$ Treg function as anti-CTLA4 mAb inhibits Treg activity *in vitro* and *in vivo* (Takahashi et al., 1998; Read et al., 2000). CTLA4 is expressed by a large proportion of $CD4^+CD25^+$ Tregs, as well as by activated $CD4^+CD25^-$ cells. As such, the effects of CTLA4 blockade may be to enhance effector responses, rendering them more resistant to suppression. Alternatively, CTLA4 signaling in $CD4^+CD25^+$ Tregs may play a functional role in their activation. Recently, CTLA4 binding to CD80 (B7) on dendritic cells (DCs) has been shown to induce indoleamine 2,3-dioxygenase, leading to local immune suppression as a consequence of tryptophan depletion and production of proapoptotic metabolites (Grohmann et al., 2002; Fallarino et al., 2003; Mellor and Munn, 2004). These results raise the possibility that CTLA4 acts as a direct mediator of $CD4^+CD25^+$ Treg suppression via the induction of an local immune suppressive pathway in DCs.

Costimulatory signals may also influence the susceptibility of $CD4^+CD25^-$ cells to suppression. Anti-GITR mAb abrogates $CD4^+CD25^+$ Treg suppression *in vitro* and induces organ-specific autoimmunity when administered to young BALB/c mice (Shimizu et al., 2002). Like CTLA4, GITR is expressed by a proportion of $CD4^+CD25^+$ Tregs, as well as by activated $CD4^+CD25^-$ T cells (McHugh et al., 2002; Shimizu et al., 2002; Tone et al., 2003). More recent studies suggest that anti-GITR mAb delivers a costimulatory signal to the effector cells, rendering them resistant to suppression (Stephens et al., 2004). $CD4^+CD25^+$ Treg activity can also be controlled by activation of the Toll-like receptor (TLR) pathway, which is involved in the detection of microbial infection and innate immune activation (Takeda et al., 2003). TLR-induced IL-6 production by activated DCs renders T cells resistant to suppression, providing a mechanism by which infection can overcome dominant $CD4^+CD25^+$ Treg activity (Pasare and Medzhitov, 2003). It has also been reported that $CD4^+CD25^+$ Tregs can express TLRs, raising the possibility that they respond directly to infection (Caramalho et al., 2003).

Together the data suggest that there is a dynamic equilibrium between effector and regulatory T cells that is dictated primarily by the activation status of the local

antigen-presenting cell (APC) population. Such a mechanism ensures that under physiologic conditions Treg responses will dominate, preventing the activation of low-affinity self-reactive T cells and development of autoimmunity. However, following infection, raised levels of costimulatory signals will override Treg activity, allowing the development of protective immune responses to microbial antigens.

Mechanism of Suppression

A cardinal feature of $CD4^+CD25^+$ Tregs is their ability to suppress a range of different responses mediated by both innate and adaptive immune systems [reviewed in Maloy and Powrie (2001), Sakaguchi (2004), and Shevach (2002)]. This activity is also apparent *in vitro*, as in co-cultures $CD4^+CD25^+$ Tregs suppress the activation of both $CD4^+$ and $CD8^+$ T cells in a dose-dependent manner (Thornton and Shevach, 1998; Takahashi et al., 2000; Piccirillo and Shevach, 2001). Suppression requires direct contact between responding and regulatory T cells, and leads to a block in IL-2 synthesis by the target T cells. Induction of suppression requires TCR-mediated activation and IL-2; however, once triggered, suppression operates in an antigen nonspecific manner allowing for bystander suppression (Thornton and Shevach, 2000). The molecular mechanism of *in vitro* suppression is poorly understood; there is evidence that membrane-bound TGF-β may play a role, although this is not an absolute requirement (Nakamura et al., 2001; Piccirillo et al., 2002). Suppression of antigen-specific T cells can also be visualized *in vivo*. In adoptive transfer of mixtures of antigen-specific clonally-related $CD4^+CD25^+$ and $CD4^+CD25^-$ cells, the former were found not to suppress the initial priming of the latter but did prevent their subsequent clonal expansion (Klein et al., 2003). These results suggest $CD4^+CD25^+$ Tregs do not prevent initial T-cell activation but act to inhibit a sustained response.

In contrast to *in vitro* suppression, there is good evidence that the immune regulatory cytokines IL-10 and TGF-β play a role in $CD4^+CD25^+$ Treg-mediated suppression *in vivo*. However, the requirement for one or both of these cytokines depends on the model system (Table 9.1). Thus, prevention and cure of colitis is functionally dependent on both IL-10 and TGF-β (Read et al., 2000; Asseman et al., 2003; Mottet et al., 2003). The latter also plays a role in the prevention of diabetes (Belghith et al., 2003), but neither cytokine appears to be required for suppression of gastritis (Thornton and Shevach, 1998; Suri-Payer and Cantor, 2001; Piccirillo et al., 2002). Together the data suggest that the nature and anatomic location of the inflammatory response dictate the mechanisms of Treg-mediated control. Thus, the requirement for IL-10 in Treg-mediated control of colitis may reflect the need to suppress the innate immune response that is a prominent feature of intestinal inflammation (Maloy et al., 2003). Further evidence that control of the innate immune response by IL-10 is important in intestinal homeostasis comes from the finding that selective disruption of IL-10 signaling in myeloid cells and neutrophils is sufficient to trigger colitis (Takeda et al., 1999).

In contrast to IL-10, TGF-β plays a more general role in immune homeostasis as TGF-$\beta1^{-/-}$ mice develop multiple organ inflammatory disease early after birth (Shull et al., 1992; Kulkarni et al., 1993). TGF-β may contribute to Treg activity in several ways; in models of diabetes (Green et al., 2003) and colitis (Fahlen et al., 2005), pathogenic T cells

that express a dominant negative TGF-β receptor RII (dnTGF-βRII) escape control by $CD4^+CD25^+$ T cells, indicating that TGF-β can act directly on T cells to suppress their effector function. $CD4^+CD25^+$ Tregs can express TGF-β on their surface and may focus it for presentation to effector T cells (Nakamura et al., 2001). However, there is conflicting data on whether Treg activity is dependent on TGF-β1 synthesis by $CD4^+CD25^+$ Tregs themselves (Nakamura et al., 2004; Fahlen et al., 2005). There is also emerging evidence that TGF-β can mediate positive effects on $CD4^+CD25^+$ Tregs, leading to their accumulation upon stimulation *in vitro* (Yamagiwa et al., 2001; Chen et al., 2003). This may also occur *in vivo*, as transient expression of TGF-β in the islets during diabetes inhibits disease through local expansion of Foxp3-expressing $CD4^+CD25^+$ Tregs (Peng et al., 2004).

OTHER REGULATORY T-CELL TYPES

A number of other T-cell populations have been shown to exhibit regulatory activity under some circumstances (Figure 9.1). These include other cell types that arise naturally during thymic development, like NKT cells, as well as several populations of inducible Tregs that are generated from naïve peripheral T cells.

Induced $CD4^+$ Regulatory T Cells

Naïve T cells can also be induced to differentiate into Tregs following encounter with antigen in the periphery. These induced Tregs are distinct from $CD4^+CD25^+$ Tregs in that they do not express Foxp3 and act primarily by the production of immune suppressive cytokines, such as IL-10 and TGF-β (Vieira et al., 2004). Different subsets of induced Tregs have been identified, including type 3 T-helper (Th3) and Tr1 cells, which are distinguished by their production of TGF-β and IL-10, respectively. Mucosal administration of intact proteins can induce TGF-β-secreting Th3 cells (Chen et al., 1994; Fuss et al., 2002). Tr1 cells were first generated *in vitro*; however, there is now evidence that antigen presentation by immature DCs and/or environments where high levels of immune suppressive molecules are present, such as at mucosal surfaces, can induce cells of a similar phenotype *in vivo* (Groux et al., 1997; Burkhart et al., 1999; Barrat et al., 2002; Cong et al., 2002). Induced Tr1-like cells can also develop during normal immune responses to infectious agents, especially those that cause

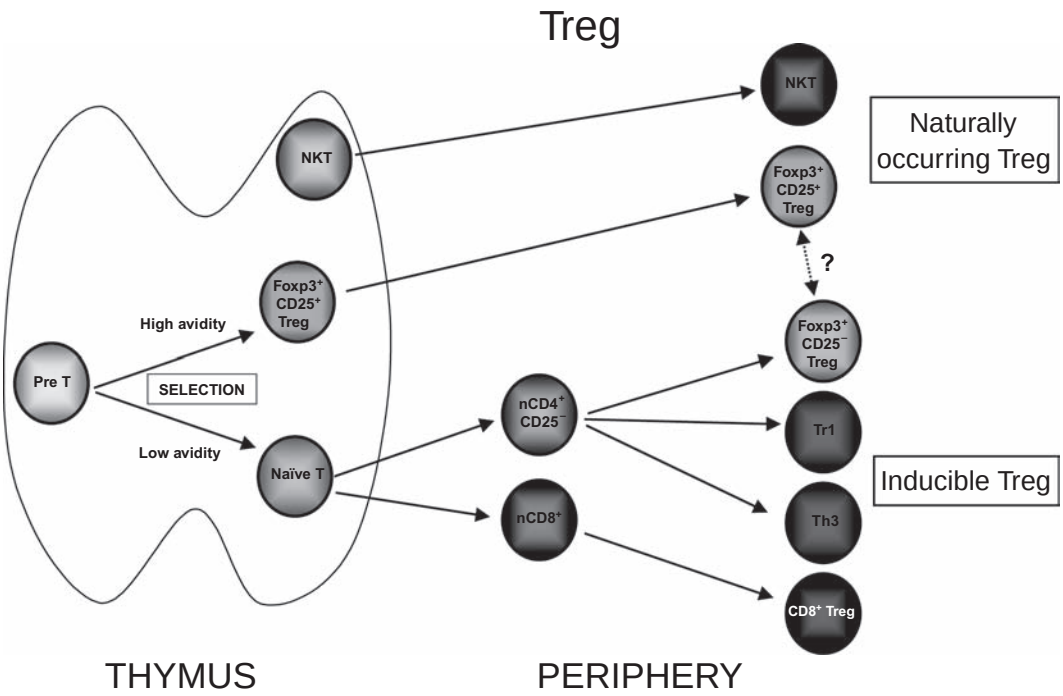

FIGURE 9.1 Major populations of regulatory T cells (Tregs). Naturally occurring Tregs ($CD4^+CD25^+$ T cells and natural killer T cells) arise during normal thymic development and do not require further differentiation in the periphery in order to mediate regulatory function. By contrast, inducible Tregs are exported from the thymus as naïve uncommitted T cells and acquire Treg function following activation and differentiation in the periphery. The precise interrelationships between the different Treg populations have not yet been fully defined.

persistent infections, and probably represent a host mechanism to limit pathology occurring as a consequence of chronic immune stimulation (Belkaid et al., 2002; Kullberg et al., 2002; Mills, 2004; Thompson and Powrie, 2004).

While the primary function of induced Tregs may not be to maintain peripheral tolerance, there is good evidence that they can be exploited therapeutically to prevent autoimmune and inflammatory diseases, where they offer the possibility of antigen-specific interventions. In autoimmune disease, Tregs responding to self-antigen have been shown to home specifically to sites where antigen is expressed and to suppress the inflammatory response via production of IL-10 and TGF-β (Barrat et al., 2002; Foussat et al., 2003). Furthermore, it may not be necessary to generate Tregs responding to all autoantigens targeted in a particular autoimmune disease. Rather it may be sufficient to generate Tregs to a single autoantigen as these cells should inhibit the response to other antigens expressed at the inflammatory site by bystander suppression.

Although the ontogeny of $CD4^+CD25^+$ Tregs and induced Tregs are different, their regulatory activity shares similar features. Indeed, recent findings suggest that the activity of these populations may be linked as $CD4^+CD25^+$ Tregs were able to induce the differentiation of cytokine-producing Tregs from $CD4^+CD25^-$ progeny *in vitro* (Dieckmann et al., 2002; Jonuleit et al., 2002; Zheng et al., 2004). While the significance of this *in vivo* has yet to be established, it would provide a mechanism to amplify the regulatory response.

$CD8^+$ T Cells

Recent evidence suggests that $CD8^+$ T cells may also mediate immune regulatory functions as several experimental systems have been described in which $CD8^+$ T cells can acquire Treg function [reviewed in Filaci and Suciu-Foca (2002) and Jiang and Chess (2000)]. These include repetitive stimulation with allogeneic APCs (Dhodapkar and Steinman, 2002; Gilliet and Liu, 2002) or presentation of self-peptides by the nonclassical MHC molecule Qa-1 (HLA-E) (Jiang et al., 1998; Sarantopoulos et al., 2004). $CD8^+$ Tregs have been implicated in the control of various experimental pathologies, including experimental autoimmune encephalomyelitis (EAE) (Jiang et al., 1992; Madakamutil et al., 2003; Hu et al., 2004), airway inflammation (Stock et al., 2004), and allograft rejection (Liu et al., 2001; Suciu-Foca et al., 2003). Although less well understood than their $CD4^+$ Treg counterparts, it appears that these induced $CD8^+$ Tregs may also utilize a variety of mechanisms to mediate suppression, including direct inhibition of autoreactive T-cell clones through cytolysis or cytokines (Jiang et al., 1998; Gilliet and Liu, 2002; Madakamutil et al., 2003; Sarantopoulos et al., 2004), as well as suppression of APC function via a cell-contact-dependent mechanism (Chang et al., 2002). Thus, it seems that induced $CD8^+$ Tregs may also contribute to immune regulation under certain circumstances, although further studies are required to precisely define their role within the regulatory cell network.

Natural Killer T Cells

NKT cells represent a distinct lineage of T cells (<1% of lymphocytes) usually identified by their expression of an invariant TCR (Vα14-Jα18 in mice, Vα24 in human), as well as characteristic NK cell markers. This invariant TCR does not recognize peptides presented in association with classical MHC molecules, but instead recognizes glycolipids presented by the nonclassical CD1d molecule (Jayawardena-Wolf and Bendelac, 2001; Godfrey and Kronenberg, 2004). The few NKT cell antigenic ligands thus far described include the synthetic glycolipid α-GalCer and the lysosomal glycosphingolipid iGb3 (Zhou et al., 2004).

NKT cells are best considered as a naturally occurring population of Tregs because, like $CD4^+CD25^+Foxp3^+$ Tregs, they are capable of immediate regulatory function following TCR stimulation. However, in contrast to $CD4^+CD25^+Foxp3^+$ Tregs, NKT cells are not always inhibitory—they may also act to exacerbate immune responses. This is due to their ability to rapidly produce both proinflammatory Th1 [interferon (IFN)-γ, tumor necrosis factor (TNF)] and/or Th2 (IL-4, IL-10) cytokines when activated. The regulatory functions of NKT cells have been most clearly demonstrated in studies of spontaneously diabetic nonobese diabetic (NOD) mice [reviewed in Godfrey and Kronenberg (2004)]. NOD mice have reduced numbers of NKT cells and increasing the size of this population by adoptive transfer (Hammond et al., 1998), by introduction of a Vα14-Jα18 transgene (Lehuen et al., 1998), or by repeated administration of α-GalCer (Hong et al., 2001; Sharif et al., 2001; Wang et al., 2001), all delay the onset of diabetes. Similarly, activation of NKT cells can prevent the development of pathology in models of EAE (Jahng et al., 2001; Singh et al., 2001; Furlan et al., 2003). However, it should be noted that some studies have reported conflicting results, with NKT-cell-derived IFN-γ exacerbating this disease (Jahng et al., 2001). Furthermore, a pathogenic role has also been attributed to IL-13–secreting NKT cells in a model of Th2-mediated colitis (Fuss et al., 2004; Heller et al., 2002). Thus, while it is clear that NKT cells can modulate autoimmune pathology, this may be either beneficial or detrimental for the host. The paradoxical functions of NKT cells mean that a greater understanding of the molecular signals that control their activation is necessary before their therapeutic potential can be fully realized (Mars et al., 2004).

Other Regulatory T-cell Populations

Additional minor subpopulations of cells with regulatory activity have been described. These include a population of $CD4^+DX5^+NK1.1^-$ T cells that were required to inhibit

diabetes in a transgenic model (Gonzalez et al., 2001), and DX5$^+$ NK cells that could suppress the expansion of autoreactive cytotoxic T lymphocytes (CTLs) (Lee et al., 2004). The spontaneous recovery from myelin basic protein (MBP) immunization-induced EAE in B10.PL mice was associated with the generation of CD4$^+$Vβ14$^+$ Tregs. These cells responded to a TCR Vβ8.2 peptide derived from the immunodominant MBP-reactive TCR, and were able to drive the deletion of activated Vβ8.2$^+$ MBP-reactive (pathogenic) T cells (Kumar and Sercarz, 1993; Kumar et al., 1996; Madakamutil et al., 2003). It is likely that under experimental conditions many cell types capable of producing suppressive cytokines or competing for survival factors may exhibit regulatory activity (Barthlott et al., 2003); however, they do not appear to be required for the maintenance of self-tolerance and prevention of autoimmunity in normal individuals.

CD4$^+$CD25$^+$ REGULATORY T CELLS IN AUTOIMMUNE DISEASE

Autoimmunity as a Consequence of a Lack of Regulatory T Cells

The roots of current thinking on naturally occurring Tregs go back to the 1960s and 1970s when two important observations were made. First, thymectomy at day 3 after birth was found to induce autoimmune oophoritis in mice (Nishizuka and Sakakura, 1969), and second, adult rats subjected to thymectomy followed by sublethal irradiation developed autoimmune thyroiditis (Penhale et al., 1973). In both cases, the autoimmune disease could be inhibited by infusion of normal lymphocytes, particularly CD4$^+$ T cells. In the 1980s attempts were made to identify the phenotype of these suppressive CD4$^+$ cells. Sakaguchi et al. (1985) found that following transfer of CD4$^+$ T cells depleted of the CD5^{high} fraction to BALB/c nude mice developed a wide spectrum of organ-specific autoimmune diseases, including gastritis, oophoritis, and thyroiditis. Similarly, transfer of CD4$^+$CD45RC^{high} cells to athymic nude rats in the absence of the CD45RC^{low} population, induced a multiorgan inflammatory disease (Powrie and Mason, 1990). Again, in both models, cotransfer of the depleted subpopulation was sufficient to prevent immune pathology, indicating that T cells capable of preventing destructive self-reactivity occur naturally in the CD4$^+$ T-cell pool in rodents. Transfer of CD4$^+$CD45RB^{high} T cells into severe combined immune deficient (SCID) mice induced an inflammatory bowel disease (IBD)-like syndrome as a consequence of immune recognition of the normal intestinal flora. Colitis was inhibited by infusion of CD4$^+$CD45RB^{low} cells, providing the first evidence that Tregs also control immune pathologic responses to environmental antigens (Morrissey et al., 1993; Powrie et al., 1993).

Pivotal studies by Sakaguchi et al. (1995) identified CD25 as a more specific marker for Tregs, as removal of the small number of CD25$^+$ cells from CD4$^+$ cells prior to their transfer to nude mice led to a higher incidence of autoimmune disease with a wider spectrum of affected organs than removal of CD5^{high} or CD45RB^{low} cells. Development of disease was prevented by restoring the CD4$^+$CD25$^+$ population. Suppression of colitis in the T-cell transfer model also enriches within the CD4$^+$CD25$^+$ pool (Read et al., 2000). However, it should be noted that Treg activity is not restricted to CD4$^+$CD25$^+$ cells as Tregs capable of inhibiting CD45RB^{high}-induced pathology in SCID mice and diabetes in ATX rats are also present in the CD45RB/C^{low}CD25$^-$ pool (Read et al., 2000; Stephens and Mason, 2000; Annacker et al., 2001; Alyanakian et al., 2003). Indeed, this may explain the observation that depletion of CD4$^+$CD25$^+$ Tregs in adult mice by administration of anti-CD25 mAb does not result in spontaneous autoimmune disease. By contrast, administration of anti-IL-2 mAb, which inhibits the functions of CD4$^+$CD25$^+$ and CD4$^+$CD25$^-$ Tregs, induces severe multiorgan autoimmune disease (Setoguchi et al., 2005).

Transfer of CD4$^+$CD25$^+$ Tregs also inhibits the development of organ-specific autoimmunity following day 3 thymectomy (d3Tx) (Asano et al., 1996). In this model, thymectomy between days 2 and 4 after birth is thought to prevent export of CD4$^+$CD25$^+$ Tregs from the thymus, allowing activation of autoreactive T cells in the periphery. However, a recent study has shown that adult d3Tx mice do retain at least some functional Foxp3$^+$ CD4$^+$CD25$^+$ Tregs (Dujardin et al., 2004), which may explain the finding that disease in these mice is considerably less severe than that in Foxp3$^{-/-}$ mice devoid of CD4$^+$CD25$^+$ Tregs.

Together these experiments suggest that a deficiency of Tregs is sufficient to allow activation of autoreactive T cells and induce autoimmune disease under conditions where there is presentation of physiologic amounts of self-antigen. However, it is likely that the presence of lymphopenia facilitates the development of autoimmunity in both T-cell transfer and d3Tx models by allowing the rapid expansion of low-affinity autoreactive T cells in the absence of clonal competition (King et al., 2004). As such, any cells that can efficiently compete with these autoreactive T cells may exhibit some suppressor function in these assays (Barthlott et al., 2003).

Recent studies on the T-cell transfer model of colitis have shown that infusion of CD4$^+$CD25$^+$ Tregs to mice with established colitis is sufficient to suppress the inflammatory response with restoration of normal intestinal architecture. The transferred Tregs homed to the site of inflammation and to the draining lymph nodes where they inhibited the proliferation of colitogenic effector T cells (Mottet et al., 2003). The ability of CD4$^+$CD25$^+$ Tregs to reverse an established inflammatory response, characterized by an accumulation of large numbers of activated effector T cells in the intestine,

strongly argues against simple clonal competition as the mechanism of suppression mediated by $CD4^+CD25^+$ Tregs. This is further supported by the fact that cure of colitis by Tregs is dependent on IL-10 and TGF-β (Liu et al., 2003; Mottet et al., 2003), arguing that $CD4^+CD25^+$ Treg-mediated suppression involves a functionally specialized response.

Furthermore, some studies suggest that protection from organ-specific autoimmunity is tissue specific, and that Tregs require continued exposure to tissue-specific antigens to mediate suppression. Thus, peripheral $CD4^+$ T cells isolated from athyroid rats were unable to suppress thyroiditis in susceptible rats, although they could prevent the development of type 1 diabetes (Seddon and Mason, 1999). By contrast, thymocytes obtained from athyroid rats could inhibit the development of thyroiditis, suggesting that maintenance of peripheral Treg activity is dependent on the presence of specific autoantigens. Similarly, in orchidectomized male mice, treatment with dihydrotestosterone induced not only the *de novo* development of a mature prostate, but also facilitated the concomitant development of $CD4^+$ T cells that inhibited prostatitis after transfer into d3Tx mice (Taguchi et al., 1994). Finally, using models of autoimmune ovarian disease, Tung et al. (2001) demonstrated that $CD4^+CD25^+$ Tregs prevented this disease in d3Tx mice and that the continuous presence of physiologically expressed autoantigen was required for the maintenance of self-tolerance in normal female mice. These experiments, together with others described below, suggest that $CD4^+CD25^+$ Tregs behave in a tissue-specific manner to prevent autoimmune disease.

Spontaneous Autoimmune Disease

Studies of the role of $CD4^+CD25^+$ Tregs in spontaneous autoimmune disease have complemented those in T-cell transfer models. In NOD mice, the destruction of insulin-producing β cells is preceded by insulitis, a nondestructive leukocytic infiltration of the islets. Strategies that reduce $CD4^+CD25^+$ Treg numbers, such as a lack of CD28, CD80, or blockade of CD80/CD86, accelerated the progression from insulitis to overt diabetes (Salomon et al., 2000). Similarly, delayed onset of diabetes induced by expression of TNF-α in the islets was found to involve enhanced recruitment of $CD4^+CD25^+$ Tregs, both to the draining lymph node and to the islets. Transfer of as few as 2000 $CD4^+CD25^+$ T cells from the pancreatic lymph node of protected mice was sufficient to prevent diabetes following adoptive transfer to young TNF-α transgenic NOD mice, providing direct evidence that $CD4^+CD25^+$ Tregs can inhibit spontaneous autoimmune disease in a lymphocyte-replete setting. $CD4^+CD25^+$ Tregs from the draining lymph node were more efficient than those from other lymph nodes, suggesting some antigen specificity in the regulatory response (Green et al., 2002). Antigen-specific $CD4^+CD25^+$ Tregs isolated from BDC2.5 TCR trangenic mice that recognize an islet antigen have also been used both to prevent and cure diabetes in NOD mice. These cells were expanded *in vitro* using either anti-CD3, anti-CD28, and IL-2, or a mimetope peptide and activated DC. Importantly, $CD4^+CD25^+$ Tregs taken from NOD mice lacked the ability to inhibit disease, again suggesting that Tregs of the appropriate specificity are required (Tang et al., 2004; Tarbell et al., 2004).

Induced Autoimmune Disease

MBP-specific TCR transgenic mice on a $RAG^{-/-}$ background develop spontaneous EAE, whereas those on a $RAG^{+/+}$ background do not (Lafaille et al., 1994). The protective effect of the RAG genes appears to involve the development of Treg populations, as $CD4^+CD25^+$ Tregs from TCR transgenic $RAG^{+/+}$ mice prevented the development of disease when transferred to TCR transgenic $RAG^{-/-}$ recipients. That Treg activity enriched within those $CD4^+CD25^+$ Tregs expressing the MBP-specific TCR provides further evidence for antigen specificity in the Treg response (Hori et al., 2002). Transfer of $CD4^+CD25^-$ T cells from TCR transgenic $RAG^{+/+}$ mice also prevented EAE in this model. In this case, suppression was found to be partially dependent on IL-10 (Olivares-Villagomez et al., 2000; Furtado et al., 2001).

A number of autoimmune diseases, including arthritis, gastritis, and encephalomyelitis can be induced by immunization with autoantigen in adjuvant. In each case, prior depletion of $CD25^+$ Tregs, although only partial, resulted in the development of significantly more severe pathology (Laurie et al., 2002; McHugh and Shevach, 2002; Morgan et al., 2003; Zhang et al., 2004). In EAE, these results suggest that $CD4^+CD25^+$ Treg activity may be involved in the spontaneous remission characteristic of this model. Consistent with this, transfer of $CD4^+CD25^+$ Tregs from normal mice into mice immunized with MBP was sufficient to ameliorate central nervous system (CNS) disease (Zhang et al., 2004). $CD4^+CD25^+$ cells isolated from $IL\text{-}10^{-/-}$ mice failed to provide any protective effect, suggesting that IL-10 production by Tregs is required to resolve CNS inflammation.

Human Autoimmune Disease

The finding that a reduction in $CD4^+CD25^+$ Treg activity is an important susceptibility factor for the development of autoimmune and inflammatory diseases in mice raises the possibility that alterations in this population, whether genetically or environmentally induced, may also contribute to polygenic autoimmune diseases in humans. In support of this there have been reports of reduced Treg activity among $CD4^+CD25^+$ cells from patients with multiple sclerosis, rheumatoid arthritis, and autoimmune polyglandular syn-

drome type II (Ehrenstein et al., 2004; Kriegel et al., 2004; Viglietta et al., 2004). Currently, it is not known whether changes in the functional activity of $CD4^+CD25^+$ Tregs are a primary cause of disease or a secondary effect. Furthermore, it cannot be excluded that the observed reduction in Treg activity is a consequence of an increase in effector cells within the activated $CD4^+CD25^+$ T-cell pool in patients with autoimmune disease as opposed to a reduction in Treg function per cell. Intriguingly, the less severe, self-remitting form of juvenile idiopathic arthritis, and in some cases remission of Goodpasture syndrome, have been associated with increases in $CD4^+CD25^+$ Treg numbers (Salama et al., 2003; de Kleer et al., 2004). Again, it is not clear whether this is the primary cause of remission or a secondary effect. However, this is an active area of interest and it is anticipated that answers to these questions will emerge with the development of better tools to track naturally occurring and other Treg population.

CONCLUDING REMARKS

During the past few years, interest in Tregs has reached unparalleled levels, culminating in the identification of the Foxp3 transcription factor that cements the link between Treg function and self-tolerance. Furthermore, there is a growing realization of the crucial physiologic role that Tregs play in maintaining the delicate equilibrium between immune responsiveness and immune pathology. Nevertheless, many important questions remain unresolved, including their precise mechanisms of action, their peptide specificities, and the interrelationships between the various subsets of Tregs. The complexities and disparities encountered in the various systems utilized to analyze Treg function are outweighed by the considerable therapeutic potential of these cells. With respect to autoimmune disease, key recent advances in mice at least include the characterization of Treg function in health and disease, the identification of more precise protocols for the generation and identification of Tregs, and the demonstration that Treg therapy can ameliorate established disease. Together, these findings strengthen the hope that continued study of Tregs will facilitate the transition from merely understanding their biology to exploiting their therapeutic potential in human disease.

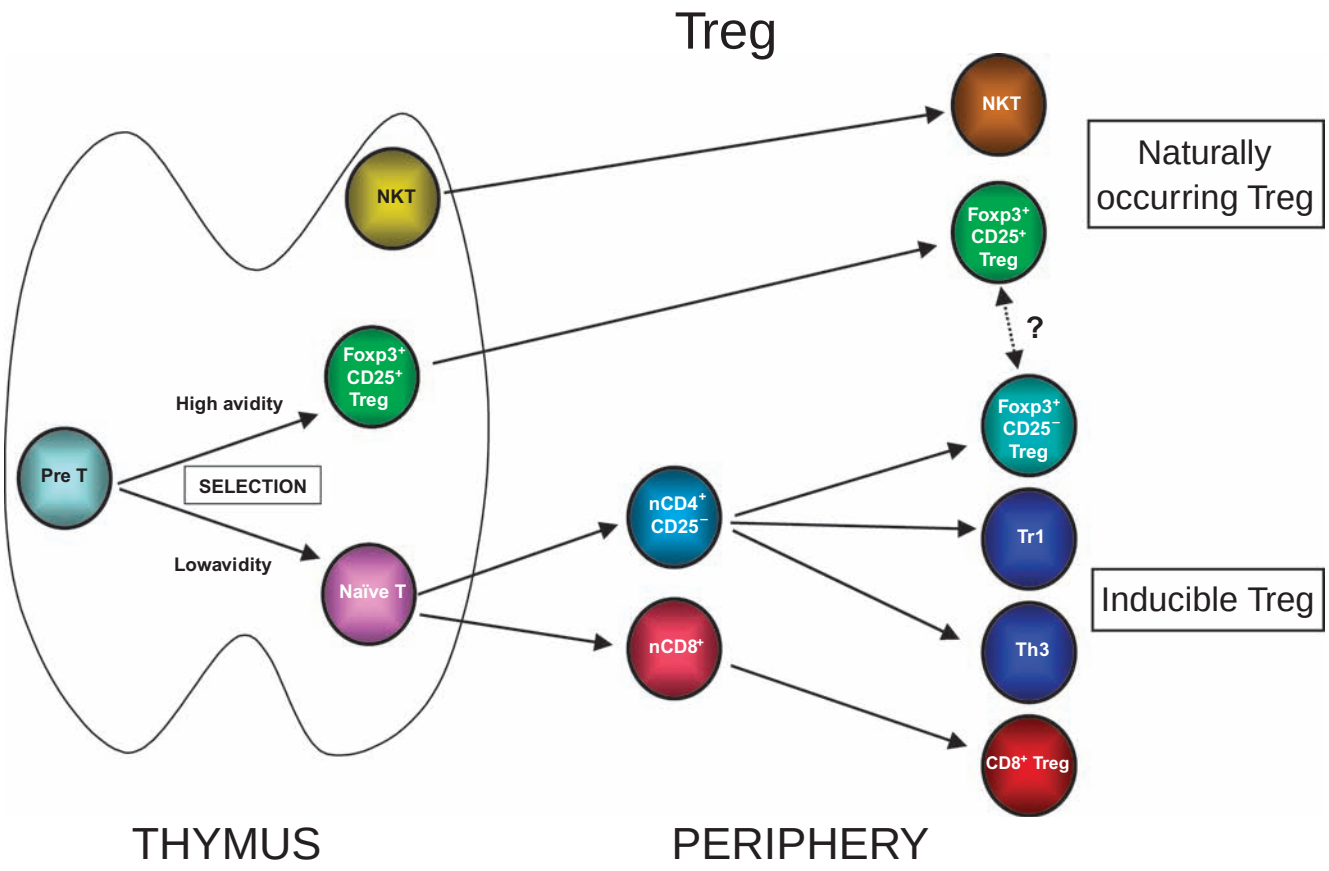

FIGURE 9.1 Major populations of regulatory T cells (Tregs). Naturally occurring Tregs ($CD4^+CD25^+$ T cells and natural killer T cells) arise during normal thymic development and do not require further differentiation in the periphery in order to mediate regulatory function. By contrast, inducible Tregs are exported from the thymus as naïve uncommitted T cells and acquire Treg function following activation and differentiation in the periphery. The precise interrelationships between the different Treg populations have not yet been fully defined.

CHAPTER

10

Peptide-Based Instruction of Suppressor Commitment in Naïve T Cells

IRINA APOSTOLOU, KARSTEN KRETSCHMER, AND HARALD VON BOEHMER

Harvard Medical School, Dana-Farber Cancer Institute, Boston, Massachusetts, USA

Recent years have witnessed the revival of suppressor T cells that control immunity by interfering with the generation of effector T-cell function *in vivo*. A major discovery was the identification of suppressor cells that expressed the α chain of the IL-2 receptor (CD25) on their surface and the fact that $CD25^+CD4^+$ T cells were highly enriched in suppressive activity (Sakaguchi et al., 1995). This enabled the phenotypic and functional analysis of so-called natural suppressor T cells. With regard to gene expression, it was found that such cells had upregulated several activation markers and downregulated proteins characteristic of naïve T cells (Sakaguchi et al., 2001; McHugh et al., 2002; Shimuzu et al., 2002; Caramalho et al., 2003). Of great significance was the observation that these cells express high levels of the transcription factor FoxP3, which, when defective, leads to the early onset of fatal autoimmune diseases (Fontenot et al., 2003; Hori et al., 2003; Khattri et al, 2003; Walker et al., 2003a). Experiments on T-cell receptor (TCR) transgenic mice revealed that coexpression of a class II major histocompatibility complex (MHC)-restricted TCR and its ligand drove the generation of suppressor T cells (Jordan et al., 2000; 2001; Bensinger et al., 2001), and that expression on thymic stroma was an effective (Bensinger et al., 2001; Jordan et al., 2001; Apostolou et al., 2002), but not exclusive, means of generating such cells (Apostolou et al., 2002).

In this chapter we are concerned with the generation of $CD25^+$ suppressor cells by exogenous antigens in the fully mature immune system, as well as with their *in vivo* stability and function. Evidence suggests that $CD25^+$ suppressor cells represent a suitable tool to induce antigen-specific immunologic tolerance in the fully mature immune system in the absence of general immune suppression, which often has undesired side effects ranging from increased risk of infection to development of life-threatening lymphoma.

GENERATING SUPPRESSOR CELLS BY EXOGENOUS ANTIGENS

There has been a long history of attempts to induce specific *in vivo* immune suppression by delivering exogenous antigens via the oral route, intranasally, intravenously or subcutaneously (Thorstenson and Khoruts, 2001; Chai et al., 2004; Nagler-Anderson et al., 2004), and thereby induce and/or expand suppressor cells (Chen et al., 2003; Horwitz et al., 2004; Tarbell et al., 2004; Zheng et al., 2004a; 2004b). There is no doubt that some of these experiments worked, but since the readout of most was immunosuppression rather than the generation of a well-defined class of suppressor cells, no consensus emerged on what might represent the most useful approach to specifically prevent unwanted immunity. "Chronic" antigenic stimulation could result in $CD4^+$ T cells that produced mostly interleukin (IL)-10 (Bacchetta et al., 1994; Lanoue et al., 1997; Buer et al., 1998). However, in some instances, these cells only suppressed certain immune reactions and had a phenotype that differed from the later described $CD25^+$ suppressor cells (Bacchetta et al., 1994). Before the recognition of FoxP3 expression as a marker for suppressor T cells, findings were

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

reported that the subimmunogenic presentation of proteins or peptides could result in the generation of $CD25^+$ T cells that, at least in some assays, qualified as suppressor cells (Chen et al., 1994; Weiner, 1997; Thorstenson and Khoruts, 2001; Sundstedt et al., 2003). Based on our own limited and initial studies in this direction (Apostolou et al., 2002), we pursued a larger study concerned with developing suitable protocols for the extrathymic generation of $CD25^+$ suppressors, and a comparative analysis of such peripherally-generated cells versus intrathymically-generated $CD25^+$ suppressor T cells (Apostolou and von Boehmer, 2004).

Initially, we attempted to mimic a situation that may occur *in vivo* when cell-specific proteins are expressed at low levels, broken down by proteases, and the peptides presented by steady-state (mostly nonactivated) dendritic cells. To this end we continuously infused relatively small doses of peptides with the aid of mini-osmotic pumps that were transplanted subcutaneously in mice, and monitored the appearance of cells with different phenotypes over time. Studies were first conducted in TCR-HA transgenic mice on the RAG-$2^{-/-}$ background that expressed a TCR specific for the peptide 107–119 of influenza hemagglutinin presented by E^d MHC molecules in naïve T cells. To exclude any influence of the thymus, these mice were thymectomized prior to implantation of the peptide-delivering osmotic pumps. The continuous supply of peptides, even at doses as low as 10^{-3} μg/day, resulted in downregulation (endocytosis) of the TCR on many T cells, as well as the appearance of $CD25^+$ T cells with suppressive activity at day 14 of peptide infusion in the absence of immunologic priming.

These experiments were then repeated by transferring pretreated naïve TCR-HA-expressing T cells into nu/nu recipient mice and then implanting the peptide-delivering pumps. The same result was obtained, arguing that it was possible to generate $CD25^+$ cells with suppressive activity *de novo* from $CD25^-$ naïve T cells in the absence of any "tutoring" by other intrathymically-generated T cells, the latter representing a phenomenon implicit in so-called "infectious tolerance" (Waldmann et al., 2004).

Finally, a similar approach was used to generate suppressors from small numbers of naïve $CD4^+$ T cells in normal mice, emphasizing that the protocol was suitable for generating suppressors from a small number of naïve T cells in a normal environment. In transgenic as well as nontransgenic systems, the induced $CD25^+$ cells prevented the development of antigen-specific effector T cell responses in various *in vivo* readouts (Apostolou and von Boehmer, 2004). The latter setting was then used to analyze whether continuous peptide infusion provided an advantage over single-dose injection of peptides, and whether targeting of peptide to steady-state dendritic cells (DCs) was suitable for inducing such cells. This approach was used because previous experiments using the DEC-205 antibody to target peptides to DCs had led to somewhat different outcomes in different laboratories: while in some studies this mode of peptide delivery resulted in moderate cellular expansion followed by deletion and/or anergy (Hawiger et al., 2001; 2004), in at least one experimental setting it also resulted in the generation of $CD25^+$ cells with suppressive activity (Mahnke et al., 2003). Our results using this approach showed that: 1) DEC-205 delivered peptide-induced dose-dependent proliferation; 2) the cells that proliferated most extensively did not acquire constitutive CD25 expression; and 3) cells that went through only a few divisions converted most efficiently into $CD25^+$ suppressor cells during 14 days from intraperitoneally delivery of the antibody–peptide fusion protein. Thus, there was an inverse relationship between cell division and CD25 conversion, but not in the sense, as previously reported, that those cells that did not divide at all converted best (Thorstenson and Khoruts, 2001). Instead, cells that were weakly activated and proliferated to some extent showed a better conversion rate than cells that had not divided at all.

Thus, in addition to intrathymic generation of $CD25^+$ suppressor cells by "self" agonist ligands of the TCR, recent information can be exploited to generate cells that are specific for exogenous antigens in the fully mature immune system and in the absence of a functioning thymus (Apostolou and von Boehmer, 2004). This opens new avenues for inducing specific immune tolerance, an old dream of immunologists that was experimentally addressed decades ago but resulted in erratic results, most likely due to the fact that protocols aiming to induce specific immunosuppression could not be optimized because the nature of suppressor cells was poorly understood.

"LIFESTYLE" OF SUPPRESSOR T CELLS

Naturally occurring suppressor T cells have been extensively characterized *in vitro*. These cells: 1) are intrinsically anergic, i.e., do not respond to antigenic stimulation with proliferation; 2) suppress other cells through a specific T–T-cell contact, resulting in inhibition of IL-2 gene transcription; and 3) do not require the production of IL-10 for their suppressive effect, whereas the involvement of tumor growth factor (TGF)-β is debated (Piccirillo and Shevach, 2004).

These experiments could not provide information on the question of whether $CD25^+CD4^+$ FoxP3-expressing T cells represent a lineage of irreversibly committed cells or an effector T-cell population that has acquired a suppressor phenotype when antigenically stimulated. This question was addressed using the TCR-HA transgenic system by transferring $CD4^+25^+$ T cells with a TCR of known antigen specificity into an antigen-free environment and following their fate or that of induced $CD4^+25^+$ cells of 14-day peptide-

infused mice over prolonged time periods (Klein et al., 2003). It was concluded that after their induction by cognate antigen, $CD4^+25^+$ suppressor cells could survive for long periods of time in a normal lymphoid environment without any requirement for antigenic stimulation by TCR agonist ligands. The cells had an intermitotic lifespan that in murine models lasted for months (Klein et al., 2003), an observation well compatible with the notion that some $CD4^+25^+$ cells in normal mice have an intermitotic lifespan of at least 70 days (Fisson et al., 2003). Whenever tested during the observation period, the activation of these cells by cognate antigen resulted in potent suppressor activity *in vitro* and $CD4^+25^+$ cells did not lose their anergic *in vitro* phenotype when maintained for long time periods in an antigen-free environment. Thus, by these criteria, $CD4^+25^+$ suppressor T cells represent a long-lived stable lineage of T cells committed to immunosuppression only.

DYNAMICS OF *IN VIVO* SUPPRESSION

Contrary to *in vitro* readouts, the effect of suppression by $CD4^+25^+$ T cells on the immune response of $CD4^+$ or $CD8^+$ cells *in vivo* is only observed at later stages when responses begin with a relatively low frequency of suppressor T cells and other T cells responding to antigenic challenge. *In vivo* suppressor T cells are not anergic and respond to antigenic challenge with strong proliferation (Cozzo et al., 2003; Fisson et al., 2003; Klein et al, 2003; Walker et al., 2003b; Yamazaki et al., 2003) as naïve or memory T cells do. Thus, both suppressor T cells and naïve $CD4^+$ T cells will initially expand in a similar fashion in antigen-draining lymph nodes to which both suppressor T cells and $CD4^+$ T cells home with similar efficacy. Later, the proliferation of $CD4^+$ T cells is selectively diminished and their cytokine secretion is suppressed, while the activated suppressor cells produce predominantly IL-10 (Klein et al., 2003). IL-10 is, however, not always essential for the observed suppression of $CD4^+$ T cells and the effector mechanism of the *in vivo* suppression is unknown. It is also worth mentioning that under these *in vivo* conditions, the commitment of $CD4^+$ T cells to produce IL-2 or interferon-γ is not prevented, i.e., these cytokines are produced in increased amounts when the suppressed $CD4^+$ T cells are separated from the suppressors and antigenically stimulated (Martin et al., 2004).

The suppression of $CD8^+$ T cells *in vivo* does not affect initially their proliferation, such that they accumulate at very similar frequencies whether suppressors are present or not (Lin et al, 2002). However, by about day 7 of a primary CD8 immune response in the presence of suppressors, the specific suppression of cytolytic activity of the expanded $CD8^+$ T cells can be observed (Chen et al., 2005). It is of particular interest that in some instances control of CD8 responses by suppressor cells was found to be entirely dependent on TGF-β signaling by $CD8^+$ T cells, as the cytolytic activity of $CD8^+$ T cells from mice expressing a dominant negative TGF-β receptor makes them resistant to suppression by $CD4^+25^+$ suppressor cells (Green et al., 2003; Chen et al., 2005). Thus, in this particular scenario, molecular pathways are emerging of how suppressors interact with $CD8^+$ T cells, but it is not clear whether under these circumstances TGF-β must be produced by the suppressors themselves.

INTERLEUKIN-2 DEPENDENCE OF SUPPRESSOR CELLS

It has become clear that IL-2- or IL-2-receptor-deficient mice lack $CD4^+25^+$ suppressor cells in their peripheral lymphoid tissue (Papiernik et al., 1998), and are therefore highly susceptible to autoimmune disease, which in IL-2-receptor-deficient mice can be cured by giving IL-2-receptor positive $CD4^+25^+$ suppressor T cells (Malek et al., 1991). Thus, these experiments challenge earlier notions that autoimmune disease in IL-2- and IL-2-receptor-deficient mice is due to a deficiency in activation-induced cell death (Leonardo 1991; Van Parijs et al., 1997). When analyzed in more detail, it became clear that the antigen-induced proliferation of suppressors *in vivo* is not dependent on IL-2 [IL-4 can substitute for IL-2 *in vitro* (Thornton et al., 2004)], but that suppressors that are stimulated by antigen in the absence of IL-2 lose their expression of CD25 and become less potent suppressors (unpublished results), a scenario likely to cause autoimmunity in IL-2- or IL-2-receptor-deficient mice that generate $CD4^+25^+$ cells in the thymus (Malek et al., 2002).

CONCLUSION

The fact that $CD4^+25^+$ FoxP3-expressing suppressor cells have an essential role in preventing the early onset of autoimmune disease in mammals, and the fact that these cells can be artificially induced through subimmunogenic presentation of TCR agonist ligands, opens new possibilities to exploit these cells to induce specific tolerance in the fully mature immune system. This may become a powerful tool in the prevention of allergies and transplant rejection. Inducing such cells by organ-specific antigens, such as insulin or myelin basic protein peptides, may become an effective means to prevent autoimmunity in patients at risk of developing such diseases. Such attempts have had success in animal models of disease (Daniel and Wegmann, 1996; Tarbekk et al., 2004) but not in clinical trials (Diabetes Prevention Trial–Type 1 Diabetes Study Group, 2002). There is hope, however, that our acquisition of knowledge on the "lifestyle" of suppressor T cells will help to develop more

suitable procedures that may be exploited for the induction of specific immunologic tolerance in the clinic without the use of dangerous general immunosuppression.

FABIENNE MACKAY†

†The Garvan Institute of Medical Research, Department of Arthritis and Inflammation, Darlinghurst, New South Wales, Australia

Systemic autoimmune diseases are debilitating conditions that often require lifelong therapies. Many of these conditions, such as systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), and Sjögren syndrome, are characterized by the production of autoantibodies. Furthermore, in recent times there has been much success in the treatment of RA by ablating B cells. Together, these findings highlight the significant contribution of B cells to the development and pathogenesis of autoimmune diseases. In this chapter, we detail recent advances in the understanding of B-cell differentiation, both in normal individuals and in those with autoimmune diseases, and the role of B-cell intrinsic and extrinsic factors to the progression of autoimmune conditions, and reveal how these findings have illuminated possible new therapies for improved treatment of such diseases.

NORMAL B CELL DEVELOPMENT AND FUNCTION

B Cell Development

B cell development occurs in two distinct stages: lymphopoiesis and immunopoiesis. Lymphopoiesis is initiated in the fetal liver and adult bone marrow (BM), and is the sequential differentiation of pluripotent hematopoietic stem cells → pro-B cells → pre-B cells → immature B cells (Figure 11.1) (Uckun, 1990; Banchereau and Rousset, 1992). Engagement of the B-cell antigen receptor (BCR) by high-affinity or multivalent self-antigen results in the deletion of potentially autoreactive B cell-clones in the BM. In contrast, exposure to monovalent or low-affinity self-antigen will result in the self-reactive B cells becoming recirculating anergic cells with a dramatically reduced half life (Goodnow et al., 1995). Immature B cells leave the BM and enter the spleen where they become transitional cells (Figure 11.1). Depending on the strength of the signals received through the BCR, as well as the receptor for BAFF [B-cell activating factor belonging to the tumor necrosis family (TNF) family; also called BLyS, zTNF4, TALL-1, THANK and TNFSF13b], these cells will undergo stimulation or deletion (Goodnow et al., 1995; Mackay et al., 2003). The end result of "productive" lymphopoiesis is a mature, naïve (i.e., antigen-inexperienced), immunocompetent B cell expressing a functional BCR (Banchereau and Rousset, 1992). Immunopoiesis continues in secondary organs and represents the antigen-driven differentiation of mature B cells into activated lymphoblasts, which further develop into antigen-specific plasma cells and memory B cells (Figure 11.2; see below) (Banchereau and Rousset, 1992; Liu and Banchereau, 1996).

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

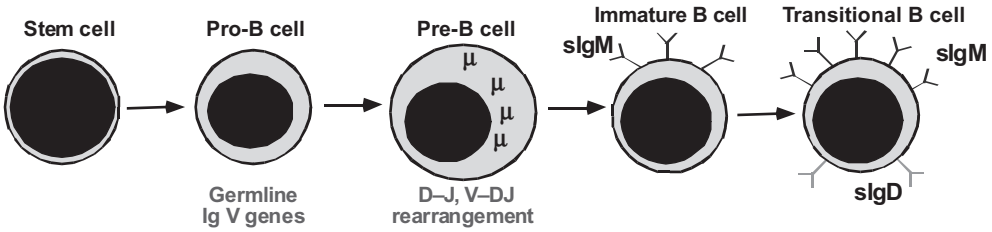

FIGURE 11.1 B-cell development. B cells arise from pluripotent stem cells present in the fetal liver and adult bone marrow. The stem cells progressively develop into pro-B cells, pre-B cells, and immature B cells, which are then exported to the periphery as transitional B cells, primarily localizing to the spleen, and undergo further maturation. Thus, the final product of this process is a mature B cell expressing a functional B-cell receptor. The different stages of B-cell development can be resolved according to the status of the immunoglobulin (Ig) genes expressed by the developing cells. Pro-B cells express unrearranged Ig genes that are in germline configuration, while D–J and V–DJ rearrangement occurs at the pre-B-cell stage. Pre-B cells also express cytoplasmic Ig μ heavy chains. Immature B cells express IgM on their surface, while transitional (and mature) B cells express both surface IgM and IgD.

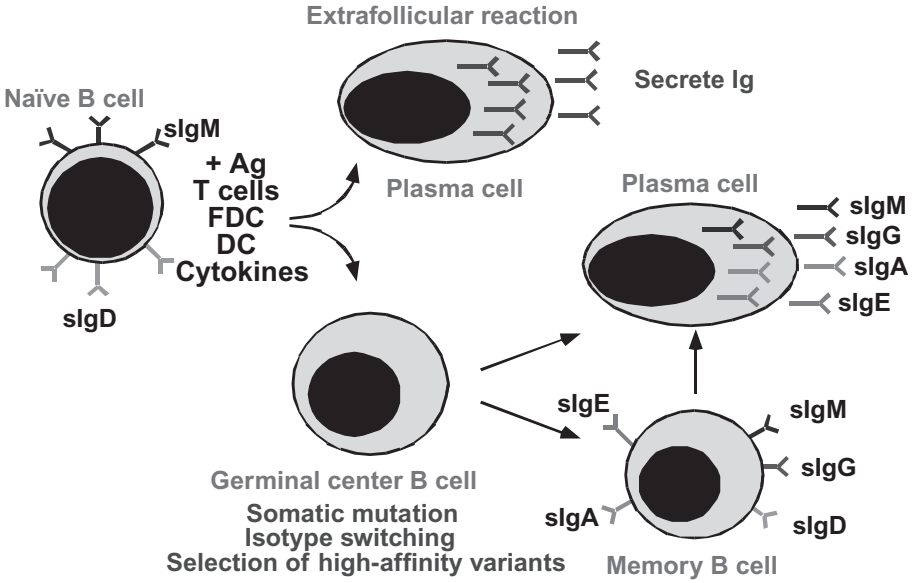

FIGURE 11.2 T-cell-dependent B-cell activation. Antigen (Ag)-specific T cells and B cells interact within secondary lymphoid tissues where, under the influence of additional signals provided by the lymphoid microenvironment in the form of dendritic cells (DCs) and follicular DCs (FDCs), B cells become activated and can enter either the extrafollicular reaction or seed a germinal center. The extrafollicular reaction yields short-lived plasma cells secreting predominantly low-affinity IgM. On the other hand, the germinal center (GC) generates long-lived cells responsible for long-term serologic humoral immunity—high-affinity memory B cells and plasma cells. On exposure to the same immunizing antigen, memory B cells can rapidly differentiate to become plasma cells. Memory B cells and plasma cells derived from a GC reaction have undergone somatic hypermutation, which results in an increase in affinity for Ag, and immunoglobulin (Ig) isotype switching, and thus express downstream Ig isotypes (IgG, A or E). However, some plasma cells and memory B cells can continue to express IgM.

T-Cell-Dependent Immune Responses: Development of Memory Cells and Plasma Cells

The differentiation of mature naïve B cells into effector memory B cells or plasma cells (PCs) in response to T-cell-dependent antigen is a complex procedure that occurs in peripheral lymphoid tissues and involves antigen, antigen-specific T cells, cytokines, and accessory cells, such as dendritic cells (DCs) and follicular dendritic cells (FDCs) (Liu and Banchereau, 1996; Liu et al., 1996b) (see Chapters 2 and 12). Interaction of naïve B cells with specific antigen in the T-cell-rich areas of lymphoid tissue induces activation and differentiation along one of two separate pathways. Antigen-specific B cells can remain in the T-cell-rich areas and rapidly differentiate to become PCs, and thus constitute the initial wave of the primary humoral immune response (the extrafollicular reaction; Figure 11.2). Alternatively,

some antigen-specific B cells become germinal center (GC) founder cells (MacLennan, 1994; Liu and Banchereau, 1996; Liu et al., 1996b).

Germinal Center Reaction

GCs are highly specialized immunologic microenvironments present within peripheral lymphoid tissues, such as lymph nodes, spleen, tonsil, and Peyer patches of the gut (see Figure 2.7). Within GCs, activated naïve B cells become centroblasts and undergo vigorous proliferation, somatic hypermutation (SHM) of the immunoglobulin V region genes, and immunoglobulin isotype switching (Liu et al., 1996a; 1996c). Histologically, proliferating GC B cells, termed centroblasts, constitute the dark zone of the GC. Centroblasts exit the dark zone and enter the FDC-rich light zone where they become nondividing B cells—centrocytes (MacLennan, 1994). It is within GCs that positive selection of antigen-specific B cells and apoptosis-mediated deletion of self-reactive or low-affinity B cells occurs. Specifically, a centrocyte expressing a mutated immunoglobulin that recognizes antigen on the surface of FDCs will undergo selection if it receives appropriate survival signals: engagement of the BCR by specific antigen, and of CD40 by CD40 ligand (CD40L), which is transiently expressed by antigen-specific T cells (Liu and Banchereau, 1996; Liu et al., 1996b). Centrocytes can then differentiate into either of two different populations of effector B cells—a memory B cell or a PC (Figure 11.2). PCs are terminally differentiated B cells that produce protective and/or neutralizing antibodies, and so maintain long-term serologic humoral immunity (Slifka and Ahmed, 1998; Manz et al., 2002), whereas memory B cells provide for an accelerated immune response upon re-exposure to the immunizing antigen (Ahmed and Gray, 1996; Rajewsky, 1996). Thus, the end product of GC reactions are populations of effector B cells that express high-affinity antigen-specific immunoglobulin and, occasionally, isotype-switched immunoglobulin heavy chain isotypes. GCs are therefore the major sites of production of memory B cells and PCs (Figure 11.2).

Phenotypic Delineation of Differentiating B Cells

The transition of naïve B cells into GC-derived effector or memory B cells has been well studied. In human tonsil, there are at least five identifiable distinct subpopulations of mature B cells (Bm1–Bm5) (Pascual et al., 1994). Bm1 cells are small resting B cells that express high levels of sIgD; Bm2 cells are activated Bm1 cells and, since both express unmutated immunoglobulin V region genes, represent naïve B-cells. Bm3 cells have a high proliferative capacity and have initiated the process of SHM, and thus represent centroblasts; Bm4 cells are centrocytes that have differentiated from Bm3 cells, and those with the greatest affinity for antigen develop into Bm5 cells, which are memory B cells (Liu et al., 1996a; Liu and Banchereau, 1996; Pascual et al., 1994). PCs can also be detected in human secondary lymphoid tissues and differ from other B cells by a $CD38^{++}CD20^{\pm}$ phenotype (Medina et al., 2002; Ellyard et al., 2004). In murine spleen, naïve B cells express sIgM, IgD, and CD38, whereas GC B cells are $CD38^{-}$ and are agglutinated by peanut agglutinin (PNA^{+}). Differentiation of naïve to memory B cells is demonstrated by loss of sIgD, expression of an antigen-specific IgG, and re-expression of CD38, whereas PCs have downregulated expression of several pan–B-cell molecules, such as B220, major histocompatibility complex (MHC) class II, and CD19, and become CD138 (Syndecan-1)$^{+}$ (Smith et al., 1996; Ridderstad and Tarlinton, 1998; Shinall et al., 2000).

Traditionally, the memory B cell has been defined as a B cell expressing a class-switched immunoglobulin isotype. However, a more reliable marker for human memory B cells is expression of CD27 (Klein et al., 1998; Tangye et al., 1998). Among human lymphoid tissues, CD27 is first expressed on B cells in the GC, and is retained by both memory B cells and PCs (Klein et al., 1998; Tangye et al., 1998; Jung et al., 2000; Ellyard et al., 2004). Thus, expression of CD27 by human B cells correlates with their involvement in a GC reaction and, when used in combination with other cell-surface markers, can accurately discriminate between multiple B-cell subsets: naïve B cells, GC B cells, memory (IgM-expressing as well as immunoglobulin isotype switched) B cells, and PCs.

Characteristics of Memory B Cells

Following the GC reaction, memory B cells acquire several characteristics that distinguish them from naïve B cells and therefore facilitate their ability to rapidly respond to antigen rechallenge (see Chapter 12).

Localization Within Lymphoid Tissue

Naïve and memory B cells differ from one another with respect to their anatomic distribution. In human tonsil, memory B cells colonize the mucosal epithelium, while naïve B cells localize to the follicular areas (Liu et al., 1995). In the spleens of humans and rodents, the white pulp is comprised of T-cell zones, B-cell follicles (the follicular zone), and marginal zones (MZs) (Liu and Banchereau, 1996). The splenic MZ surrounds the follicular zone and is adjacent to the red pulp. Much of the blood that enters the spleen traverses through the marginal sinus and MZ, and then into the red pulp, before it exits the spleen to re-enter the circulation. As a result, cells that are located in the MZ are exposed to high concentrations of blood-borne antigens (Mebius and Kraal, 2005; Pillai, 2005). Naïve B cells reside in the follicle while memory B cells colonize the MZ (Dunn-Walters et al., 1995; Liu et al., 1988; Tangye et al., 1998). The positioning of resident memory B cells within antigen-draining

sites of lymphoid tissue, especially the MZ, maximizes their exposure to circulating antigen so that specific memory B cells can rapidly respond to antigen. Similarly, circulating memory B cells disseminate immunologic memory throughout the secondary lymphoid tissues, providing a general surveillance for any sites of pathogen invasion.

Phenotype

By using the differential expression of switched immunoglobulin isotypes, and more recently CD27, the phenotype of human naïve and memory B cells has been determined. Naïve B cells present in human tonsil and spleen are morphologically small cells that express intermediate levels of IgM and CD21, high levels of IgD and CD23, and low to negligible levels of activation antigens such as CD80, CD86, and CD95. In contrast, memory B cells are larger cells, have downregulated IgD and CD23, and upregulated expression of CD21, CD40, CD80, CD86, and CD95 (Liu et al., 1995; Tangye et al., 1998; Ellyard et al., 2004). The elevated expression of the costimulatory molecules CD80 and CD86 allows memory B cells to act as efficient antigen-presenting cells (APCs) for $CD4^+$ T cells, which is of importance for autoimmunity (Liu et al., 1995). Similarly, increased expression of CD21 and CD40 on memory B cells over naïve B cells may provide them with the ability to respond to lower levels of stimulation received through immune complexes (CD21) and T-cell help (CD40). Lastly, the cytoplasmic domains of IgG and IgA significantly differ from that of IgM and are believed to facilitate a more robust response by memory B cells (Tangye and Hodgkin, 2004).

Differentiation to Plasma Cells

Naïve and memory B cells exhibit distinct responses following exposure to an activating stimulus. Memory B cells differentiate into PCs more rapidly than naïve B cells, and antigen-specific immunoglobulin was produced by human memory, but not naïve, B cells. Furthermore, this process does not require the memory B cells to enter a GC reaction, thus resulting in the rapid production of high-affinity immunoglobulin (Liu et al., 1988; 1991; Tangye and Hodgkin, 2004).

Characteristics of Plasma Cells

PCs are present in spleen, mucosal-associated lymphoid tissues, BM, and, in cases of disease, peripheral blood (Odendahl et al., 2000; Medina et al., 2002; Ellyard et al., 2004). Although similar with respect to surface phenotype, important differences have been noted between PCs isolated from different anatomic locations. For instance, the predominant immunoglobulin isotype produced is distinct in that IgM is secreted by splenic PCs, IgG by PCs in the BM, tonsils, and peripheral blood, and IgA by PCs in the gut (Merville et al., 1996; Medina et al., 2003; Ellyard et al., 2004). In contrast to GC-derived PCs, the immunoglobulin V_H genes of extrafollicular PCs typically remain in a germline configuration, having not undergone significant SHM. Furthermore, most extrafollicular PCs are short-lived, and die by apoptosis *in situ*, whereas the majority of GC-derived PCs are long-lived cells that migrate from the follicular areas of the lymphoid tissue to distant sites, or remain in the tissue of origin (Smith et al., 1996; McHeyzer-Williams and Ahmed, 1999; Calame, 2001). PCs themselves may not be intrinsically long lived, but rather depend on factors provided by particular niches to ensure their longevity (Sze et al., 2000). In other words, the local environment harboring the PCs can support only the survival of a finite number of effector cells (Sze et al., 2000). Mechanisms to support the survival and function of PCs include interactions with stromal cells within the BM or red pulp of spleen, which provides prosurvival factors such as cytokine [interleukin (IL)-6, chemokines (CXCL12), and cell-surface molecules (VLA-4)] (Manz et al., 2002; Ellyard et al., 2005).

Requirements for the Formation of Germinal Centers

Peripheral lymphoid tissues provide the appropriate environment for the formation and maintenance of a GC reaction. The microenvironment provided by DCs, FDCs, and T cells is critical for the formation of GCs, as demonstrated by the absence of GCs in mice deficient in T cells or FDCs (Liu et al., 1996b). In addition, the formation of GCs, and therefore the development of humoral immune responses to T-cell-dependent antigen, requires the expression of various cell-surface receptors, signaling molecules or transcription factors (see below).

CD40/CD154

One of the most important cellular interactions is between CD40, expressed on all B cells, and CD40L, transiently expressed by activated $CD4^+$ T cells (Van Kooten and Banchereau, 1996). GCs are absent from secondary lymphoid tissues of mice genetically deficient for CD40 or CD40L, as well as from patients with inactivating mutations in CD40L, which results in the immunodeficiency X-linked hyper-IgM syndrome (Van Kooten and Banchereau, 1996; Gulino and Notarangelo, 2003). These mice and patients fail to develop memory responses, with the lack of isotype switching to IgG (Van Kooten and Banchereau, 1996).

CD28/CD80, CD86

Another important receptor–ligand interaction for establishment of GCs is that between CD28, expressed by T cells, and CD80 or CD86, expressed by APCs. When this interaction is disrupted, mice respond poorly to specific antigen, with drastically reduced levels of specific immunoglobulin, an absence of GCs, and impaired SHM of immunoglobulin

V region genes of antigen-specific B cells (Han et al., 1995; Ferguson et al., 1996; Borriello et al., 1997).

ICOS (Inducible Costimulator)

ICOS is a CD28-like molecule expressed on activated T cells. Signaling through ICOS activates T cells and induces them to proliferate and produce IL-10, a potent growth and differentiation factor for human B cells. ICOS is expressed mainly on $CD4^+$ T cells within the light zone of GCs, while its ligand (ICOS-L) is on APCs, including B cells. Analysis of mice deficient in ICOS or ICOS-L revealed an inability to form GCs, undergo immunoglobulin isotype switching, and impaired production of IL-4 and IL-10 by $CD4^+$ T cells. ICOS-deficient humans develop common variable immunodeficiency and also fail to generate memory B cells and undergo immunoglobulin isotype switching *in vivo*. Thus, the ICOS/ICOS-L interaction, like CD28/CD80/86, is necessary for the generation of humoral immune responses (Grimbacher et al., 2003).

SAP (SLAM-Associated Protein)

SAP is encoded by the SH2D1A gene, which is mutated in X-linked lymphoproliferative disease. Affected individuals exhibit defective generation of memory B cells and hypogammaglobulinemia (Nichols et al., 2005). SAP-deficient mice exhibit a similar phenotype: they do not form GCs due to impaired $CD4^+$ T-cell help, and this results in a failure to generate a long-term humoral immune response following viral infection (Crotty et al., 2003).

Bcl-6

Bcl-6 is a transcriptional repressor expressed at the highest level in GC B cells. Mice deficient for Bcl-6 fail to form GCs (Calame et al., 2003). One function of Bcl-6 is to prevent the differentiation of activated B cells into PCs; this is achieved by the repression of the transcription factor BLIMP-1, which has been proposed as being a master regulator of PC differentiation (Calame et al., 2003).

Migration and Positioning of B-Cell Subsets

The positioning of PCs, as well as naïve and memory B cells, within different anatomic sites is regulated by the concerted actions of chemokines/chemokine receptors and adhesion molecules (see Chapter 18).

Developing and Mature B Cells

Chemokines and their cognate receptors that contribute to the localization of B cells are CXCL12-CXCR4, CXCL13-CXCR5, CCL19/CCL21-CCR7, and CXCL9/CXCL10/CXCL11-CXCR3. The responsiveness of B cells to lymphoid chemokines increases during B-cell development in both the spleen and BM, such that the greatest proportion of B cells that undergo chemotaxis towards CXCL12, CXCL13, CCL19, and CCL21 belong to the mature B-cell subset, while the least responsive cells correspond to pro- and immature B cells. This increased responsiveness correlated with the acquisition of expression of specific chemokine receptors during discrete stages of B-cell development (Bowman et al., 2000).

Plasma Cells

The majority of serum immunoglobulin is derived from PCs present in BM, to which they migrate from secondary lymphoid tissues. PCs have migratory properties distinct from mature B cells. Mature B cells migrate towards CCL19/21, CXCL12, and CXCL13, while PCs exhibit selective migration towards CXCL12 due to the downregulation of CCR7 and CXCR5, but not CXCR4. It was proposed that cells would home to particular lymphoid tissues in response to the production of a specific chemotactic factor by nonhematopoietic cells located within these tissues. Indeed, CXCL12 is produced by BM and splenic stromal cells, the latter being located in the red pulp (Ellyard et al., 2005). On the other hand, chemokines recognizing CXCR5 and CCR7 are produced by FDCs and DCs, respectively, located in lymphoid follicles. Thus, the chemotactic gradient established by the production of CXCL12 by stromal cells in the red pulp, and the inability of PCs to respond to follicular chemokines, would allow the emigration of antigen-specific PCs from the GC region to the red pulp. CXCR4 also has a pivotal role in the transit of PCs from lymphoid tissue to the BM. In the absence of CXCR4, antigen-specific PCs accumulate in the blood and are markedly reduced in number in the BM (Cyster, 2003; Kunkel and Butcher, 2003).

PCs that are located in mucosal tissues predominantly secrete IgA. This mucosal positioning appears to result from the selective expression of the chemokine receptors CCR9 and CCR10, and the mucosal homing receptor $\alpha4\beta7$ by IgA-secreting PCs, and the production of CCL25 and CCL28 (which interact with CCR9 and CCR10), and expression of MAdCAM-1, the counterstructure for $\alpha4\beta7$, by epithelial and endothelial cells located in the small intestine. Thus, expression of CCR9 and CCR10 on IgA-PCs appears to mediate the migration of these cells to specific regions in order to provide an appropriate mucosal immune response (Cyster, 2003; Kunkel and Butcher, 2003). Several inflammatory chemokines may also participate in the movement of PCs from their sites of generation to sites of inflammation. For instance, antigen-specific IgG-secreting PCs migrate towards CXCR3 ligands (CXCL9, CXCL10, and CXCL11), which are abundantly expressed by inflamed tissue resulting not only from a normal inflammatory response, but also from autoimmunity. Thus, the localization of PCs within inflamed sites may result from migration from lymphoid tissue guided by the production of such chemokines (Manz et al., 2002).

B CELLS IN AUTOIMMUNITY

Animal Models

A number of inbred mouse strains (NZB, NZW, NZM 2410, BXSB, NOD, and MRL) develop autoimmunity associated with the production of autoantibodies (Sakaguchi, 2000; see Chapter 26). Crosses of some of these mice, particularly the (NZB × NZW)F1 hybrids, are a classical model of SLE (Mohan, 2001). Understanding B-cell autoimmunity, even in these inbred models, has proven difficult due to the highly polygenic nature of the autoimmune process, since separate loci are responsible for separate aspects of the disease (Mohan, 2001). Therefore, immunologists have utilized induced and gene-specific models to understand environmental and genetic influences leading to B-cell autoimmunity.

Induced B-cell Autoimmunity

B-cell autoimmunity can be induced in mice in many ways, by hormones, environmental agents or dyregulation of various endogenous B-cell survival factors.

Hormones

Almost all B-cell-associated autoimmune disorders in humans, such as SLE, Sjögren syndrome, and RA, are more prevalent in women than men (Rider and Abdou, 2001), suggesting that sex hormones influence the susceptibility of women to autoimmunity (Castagnetta et al., 2002; see Chapter 25). Estrogen and prolactin have been shown to have pleiotropic effects on the immune system (Castagnetta et al., 2002). Clinical features observed in patients with autoimmune disorders during pregnancy also reinforced the idea of a strong effect of hormones in B-cell function and autoimmunity (McMurray, 2001). Recent work has provided some insight into the molecular basis for these effects. The functional estrogen receptors α and β are expressed on B cells and protect immature transitional B cells from BCR-mediated apoptosis (Grimaldi et al., 2002). As developing B cells normally receive an apoptotic signal when their BCR binds to self-antigen, abnormal production of estrogen at this stage may prevent this purging mechanism and allow the survival of autoreactive B cells. A role for excessive estrogen production during maturation is also suggested by the observation of an altered distribution of B-cell subsets, with a diminished transitional population and an increase in MZ B-cell numbers (Grimaldi et al., 2001). This picture is very similar to mice transgenic for BAFF (Mackay et al., 2003). BAFF transgenic mice have an altered distribution of B-cell subsets, such as an enlarged MZ B-cell compartment (Mackay et al., 2003). In addition, these mice develop severe autoimmune disorders similar to SLE and Sjögren syndrome (Mackay et al., 2003). The lactogenic hormone prolactin is also an immunomodulator involved in lymphocyte survival, activation, and proliferation (McMurray, 2001). Dysregulated prolactin production has been associated with the severity of B-cell–mediated autoimmune disorders, especially SLE (McMurray, 2001). Therefore, similar to BAFF, estrogen and prolactin may influence B-cell tolerance during maturation by altering the threshold of survival and activation of maturing B cells.

Heavy Metals

Heavy metals such as mercury are environmental pollutants which, when accidentally ingested, can lead to autoimmune disorders (see Chapter 23). These agents act on many cells, including B cells, and injection of mercuric chloride in rats and mice has been used as a model of B-cell autoimmunity leading to glomerulonephritis (Bagenstose et al., 1999; Nielsen and Hultman, 2002). However, this model only develops in susceptible rodent strains and is dependent on T-cell function (Nielsen and Hultman, 2002). The main feature of this model is the production of antinucleolar autoantibodies, with fibrillarin being the identified nucleolar reactant (Nielsen and Hultman, 2002). Modification of self-fibrillarin by mercury is thought to trigger the autoreactive response (Nielsen and Hultman, 2002).

Mineral Oils

Mineral oils are not normally toxic and are used regularly by humans. However, injection of hydrocarbon oil components such as pristane in mice can induce autoimmune disorders, notably arthritis in rats and lupus-like symptoms in mice characterized by the production of various anticytoplasmic and antinuclear autoantibodies (Holmdahl et al., 2001; Kuroda et al., 2004). Pristane has multiple effects on the immune system, including the induction of cytokines and lymphocyte activation. Pristane treatment leads to the emergence of autoreactive T cells and a reduction in regulatory T cells (Yang et al., 2003). The role of pristane on B-cell tolerance, however, is unclear. There is expansion of the MZ B-cell compartment in pristane-treated mice, which suggests a possible interference with B-cell tolerance during lymphocyte maturation, as described above (Yang et al., 2003).

Genetic Influences on B-Cell Tolerance and Autoimmunity

B-cell homeostasis results from the very fine balance between lymphocyte death and survival (Nemazee et al., 2000). This process is precise and discriminates between unwanted autoreactive cells that have to be eliminated and useful B cells that have to be positively selected for survival. Any defect of this process may either prevent the development of B cells or, conversely, allow the survival of harmful autoreactive B cells that are normally deleted. The immune

system has in place several checkpoints designed to eliminate or neutralize self-reactive B cells as they develop and emerge in the periphery (Goodnow et al., 1995; see Chapter 13). The nature of the signal delivered to B cells via their BCR is a critical factor controlling B-cell tolerance (Nemazee et al., 2000; Hardy and Hayakawa, 2001). Gene-targeting experiments have revealed numerous genes involved in B-cell tolerance. B-cell abnormalities and autoimmunity arising as the result of the absence or altered expression of B-cell-specific genes are described below.

Bcl-2 Family of Prosurvival/Proapoptosis Molecules

The Bcl-2 family of pro- and anti-apoptotic molecules plays an important role in the regulation of B-cell homeostasis (Chao and Korsmeyer, 1998; Marsden and Strasser, 2003; Strasser and Bouillet, 2003). One particular protein from this family, Bcl-2, is a central prosurvival molecule for B cells (Chao and Korsmeyer, 1998). Survival signals triggered by the BCR throughout the life of B cells are likely to involve upregulation of Bcl-2 in these cells (Strasser and Bouillet, 2003). Enforced Bcl-2 expression prolongs autoantibody responses and elicits autoimmune diseases (Strasser et al., 1991). Bim, another molecule from this family, has a proapoptotic function and has been shown to interact with Bcl-2, inactivating its survival effect in B cells (Bouillet et al., 1999). In the absence of Bim, mice have a large number of B cells and PCs (Bouillet et al., 1999). Many of these mice will die before 12 months of age from fatal immune complex-mediated glomerulonephritis (Bouillet et al., 1999). Therefore, molecules such as Bim play a critical role in preventing B-cell-mediated autoimmunity.

B-Cell Survival Factor BAFF

Expression of prosurvival molecules such as Bcl-2 in B cells can be triggered by prosurvival cytokines such as BAFF (Mackay et al., 1999), which is produced by T cells, monocytes/macrophages, neutrophils, and DCs, and is a very powerful soluble modulator of B-cell biology (Mackay and Browning, 2002; Mackay et al., 2003; Mackay and Tangye, 2004). BAFF can bind three separate receptors: BCMA (B-cell maturation antigen); BAFF receptor (BAFF-R); and TACI (transmembrane activator and CAML-interactor) (Mackay et al., 2003). BCMA is expressed at the surface of immunoglobulin-producing cells and is probably important for their survival in lymphoid tissues (Avery et al., 2003) and BM (O'Connor et al., 2004). BAFF transgenic mice have an excess of B lymphocytes in the periphery, secrete various autoantibodies, and develop an SLE-like condition marked by severe glomerulonephritis (Mackay et al., 1999; Gross et al., 2000; Khare et al., 2000), as well as a Sjögren-like syndrome characterized by the inflammation of the salivary glands, acinar cell destruction, and reduced saliva flow (Groom et al., 2002). Treatment of mice with BAFF inhibitors suppresses immune responses (Yu et al., 2000), reduces the lifespan of GCs (Rahman et al., 2003; Vora et al., 2003), prevents proteinuria and prolongs the life of mice with SLE-like disease (Gross et al., 2000). Such treatment also prevents disease in a mouse model of RA (Gross et al., 2001; Wang et al., 2001). These results suggest that excessive BAFF production may be a key factor promoting the development of autoimmunity. BAFF promotes B-cell survival *in vitro* and *in vivo* (Batten et al., 2000), suggesting a role for BAFF in peripheral B-cell homeostasis and maturation. This hypothesis was confirmed with $BAFF^{-/-}$ mice in which B-cell maturation is impaired beyond the transitional B-cell stage (Gross et al., 2001; Schiemann et al., 2001). Increased BAFF-mediated B-cell survival has also been shown to enhance humoral immune responses (Do et al., 2000). B cells in BAFF transgenic mice express higher levels of the prosurvival molecule Bcl-2 (Mackay et al., 1999). Combined, these findings suggested that abnormal BAFF production may be a key event in certain types of autoimmune diseases.

To best illustrate this, serum levels of BAFF are significantly higher in some patients with SLE or RA, and are particularly high in patients with Sjögren syndrome (Mackay and Tangye, 2004; Stohl, 2004), and levels of BAFF detected in the synovial fluid of patients with RA often exceed levels detected in the blood (Cheema et al., 2001). This suggests that BAFF is produced in inflammatory lesions *in situ* in response to inflammation and may further skew B-cell maturation towards an autoimmune-prone state by altering the threshold of B-cell survival, therefore feeding the immune system with more arthritogenic autoimmune B cells (Mackay and Mackay, 2002). The expanded MZ B-cell compartment may play some role in the autoimmune features of Sjögren syndrome because B cells with a MZ-like phenotype have been detected in inflamed salivary gland of BAFF transgenic mice (Groom et al., 2002), as well as inflamed salivary glands of patients with Sjögren syndrome (Hansen et al., 2002; Ochoa et al., 2001). The exact role of MZ B cells in autoimmunity is, however, still unclear (Lopes-Carvalho and Kearney, 2004). This population is known to include autoreactive B cells and MZ B cells are potent APCs for naïve T cells *ex vivo*, two aspects which may be important in autoimmunity in BAFF transgenic mice (Lopes-Carvalho and Kearney, 2004). Interestingly, one of the BAFF receptors, TACI, is a critical negative regulator of B-cell activation (von Bulow et al., 2001; Yan et al., 2001; Seshasayee et al., 2003). Lack of TACI leads to the expansion of the B-cell compartment, hyperreactivity, autoantibody production, and SLE-like autoimmune features, complicated by B-cell lymphomas as the mice age. Importantly, TACI is highly expressed on MZ B cells, suggesting these cells are potentially harmful and their repression via higher expression of TACI in normal animals is critical to maintain immune tolerance (Ng et al., 2004). BAFF may

promote B cell malignancies arising as a secondary problem in autoimmune disorders, and is a potent survival factor for malignant B-cells (Mackay and Tangye, 2004). Collectively, these observations suggest a possible critical role for BAFF in the pathogenesis of certain human autoimmune diseases, and BAFF inhibitors are currently being developed for the treatment of B-cell-mediated autoimmune pathologies (Mackay and Tangye, 2004; Stohl, 2004).

B-Cell Receptor Signaling and B-Cell Autoimmunity

BAFF is not the only element required for B-cell survival and development. Expression and signaling through the BCR is equally as important for B-cell survival, and engineered conditional suppression of BCR expression led to B-cell apoptosis (Lam et al., 1997; Nemazee et al., 2000; Niiro and Clark, 2002). Signaling through the BCR is very complex (see Chapter 19) and, depending on the strength of the stimuli and the stage of B-cell differentiation, the BCR can induce survival, death, anergy or activation (Nemazee et al., 2000). Signaling through the BCR is regulated by several signaling molecules and defect in these lead to B-cell autoimmunity (Yu et al., 2003).

Cell-surface BCR is formed of immunoglobulin heavy and light chains and is associated with two signaling molecules—Igα and Igβ. Following BCR ligation by antigen, the protein tyrosine kinase (PTK) Syk and the SRC-family PTK Lyn are activated [reviewed in Niiro and Clark (2002) and Chapter 19]. Lyn shares its function with other SRC kinases, Blk and Fyn. Lyn phosphorylates the immunoreceptor tyrosine-based activation motifs (ITAMs) in the cytoplasmic tail of Igα and Igβ, which serve as docking sites for the recruitment and activation of Syk and the TEC-family PTK Btk. Syk and Btk are then central in the activation of phospholipase Cγ2 and phosphatidylinositol 3-kinase (PI3K), two crucial enzymes in the BCR signaling pathway [reviewed in (Niiro and Clark (2002)]. However, Lyn has an important inhibitory feedback function that controls signaling through the BCR to prevent B-cell autoimmunity. $Lyn^{-/-}$ B cells are hyperresponsive to BCR cross-linking, and $Lyn^{-/-}$ mice develop SLE-like symptoms characterized by splenomegaly, high levels of serum immunoglobulin, antinuclear autoantibodies, and glomerulonephritis (Hibbs et al., 1995; Nishizumi et al., 1995; Chan et al., 1997). Several molecules participate in Lyn-mediated inhibition of BCR signaling: FcγRIIb, paired immunoglobulin-like receptor B (PIR-B), CD72, and CD22, which have immunoreceptor tyrosine-based inhibitory motifs (ITIMs) in their cytoplasmic domains (Smith et al., 1998; Pan et al., 1999; Ravetch and Lanier, 2000; Niiro and Clark, 2002). ITIMs can recruit the phosphatases SH2-domain-containing protein tyrosine phosphatase 1 and 2 (SHP-1, SHP-2) and SH2-domain-containing inositol 5′ phosphatase (SHIP), which can inhibit activation initiated through the BCR (Ravetch and Lanier, 2000; Niiro and Clark, 2002).

Surprisingly, while an absence of Lyn augments BCR signaling, this defect did not prevent anergy of B cells in various transgenic models (Cornall et al., 1998). Additional experiments suggest that, depending on the developmental stage of B cells and the anatomic site, Lyn may have different and opposite effects on BCR signaling (Cornall et al., 1998). CD19 and Btk play an important role in BCR signaling, and lack of CD19 or Btk in $Lyn^{-/-}$ mice has been shown to reverse the autoimmune phenotype seen in $Lyn^{-/-}$ mice (Hasegawa et al., 2001). FcγRIIb, activated by antigen–antibody immune complexes, can also negatively regulate BCR signaling. $Fc\gamma RIIb^{-/-}$ mice develop B-cell-dependent autoimmune symptoms (Yu et al., 2003), but this effect appears to be strain specific, suggesting that additional factors contribute to the autoimmune-prone state created by the absence of FcγRII expression (Bolland and Ravetch, 2000).

CD95/CD95L Death Mechanism

CD95L is another member of the TNF family that binds to CD95 and induces apoptosis in a variety of cells, including lymphocytes (Mizuno et al., 2003; Moulian and Berrih-Aknin, 1998). CD95 appears to play a critical role in activation-induced cell death (Siegel et al., 2000). Impaired apoptosis in autoimmunity is described in detail in Chapters 15 and 70.

CD40/CD154 System and B-Cell Autoimmunity

The CD40/CD154 system is essential for B-cell activation, isotype switching, GC formation, and affinity maturation of B cells (Van Kooten and Banchereau, 1996). CD154 is transiently expressed on activated T cells but is also detectable and functional on the surface of B cells in human SLE (Banchereau et al., 2004). In transgenic mice, expression of CD154 on B cells correlated with the production of various autoantibodies and the development of nephritis (Higuchi et al., 2002). Treatment with anti-CD154-blocking antibodies is an effective way to prevent the development of disease in both mouse models of lupus (Kalled et al., 2001), and humans with SLE (Grammer et al., 2003).

Role of Complement and Toll-Like Receptors in Activating Autoreactive B Cells

Complement receptors expressed on B cells are critical for the generation of normal antibody responses, but they also help maintain B-cell tolerance (Boackle and Holers, 2003). Deficiencies of complement receptor 1 (CR1) and CR2 have been associated with SLE (Ahearn et al., 1996; Croix et al., 1996; Molina et al., 1996). Using the hen-egg lysozyme (HEL) transgenic model for B-cell tolerance, deficiency in CR1/CR2 led to impaired immune tolerance of HEL-specific transgenic B cells and the emergence of B cells responding to the self-antigen (Prodeus et al., 1998). CR1/CR2 may, therefore, participate in lowering the

threshold for negative selection of autoreactive B cells. Defects in complement receptors and complement components may also result in autoimmunity because of impaired clearance of apoptotic cells and immune complexes, as well as the inability to generate C3-coated autoantigens for CR1/CR2 (Korb and Ahearn, 1997; Boackle and Holers, 2003). Impaired expression of CR1/CR2 alone has mild effects on B-cell immune tolerance, but combined with other disease-susceptibility genes, defects in this system may contribute to severe autoimmune disorders such as SLE (Boackle and Holers, 2003).

Toll-like receptors (TLR) and DNA–autoantibody immune complexes participate in the activation of autoreactive B cells (Leadbetter et al., 2003). Low-affinity autoreactive B cells can be detected in the periphery of normal individuals, however, they are often anergic (Souroujon et al., 1988; Wardemann et al., 2003). This observation was recently explored in detail using AM14BCR transgenic mice in which B cells recognize self-IgG2a$^{j/a}$ and produce rheumatoid factors (RFs) against this particular isotype (Boackle and Holers, 2003). RF^{+} B cells develop normally despite the presence of the self-antigen and are not deleted or rendered anergic. Interestingly, these RF^{+} B cells become activated if AM14BCR transgenic mice are back-crossed onto an autoimmune-prone background, such as MRL-lpr (Wang and Shlomchik, 1999). Further studies showed that RF^{+} B cells from AM14BCR transgenic mice were in fact activated by immune complexes formed by antinucleosome IgG2a$^{j/a}$ antibodies and chromatin (Leadbetter et al., 2002). In addition, coactivation of TLR9 on B cells with the nucleic acid present in these immune complexes was required for the activation of the autoreactive RF^{+} B cells, as lack of MyD88, which is required for TLR9 signaling, in AM14BCR transgenic B cells prevented their activation by IgG2a$^{j/a}$–chromatin immune complexes (Leadbetter et al., 2002). Activation of TLR9 also induces BAFF expression by DCs, potentially contributing to further survival of autoreactive B-cells (Boule et al., 2004). This mechanism of autoreactive B-cell activation may be particularly important when clearance of chromatin from apoptotic cells is impaired, as may occur in particular autoimmune conditions (Figure 11.3; see Chapters 15 and 18).

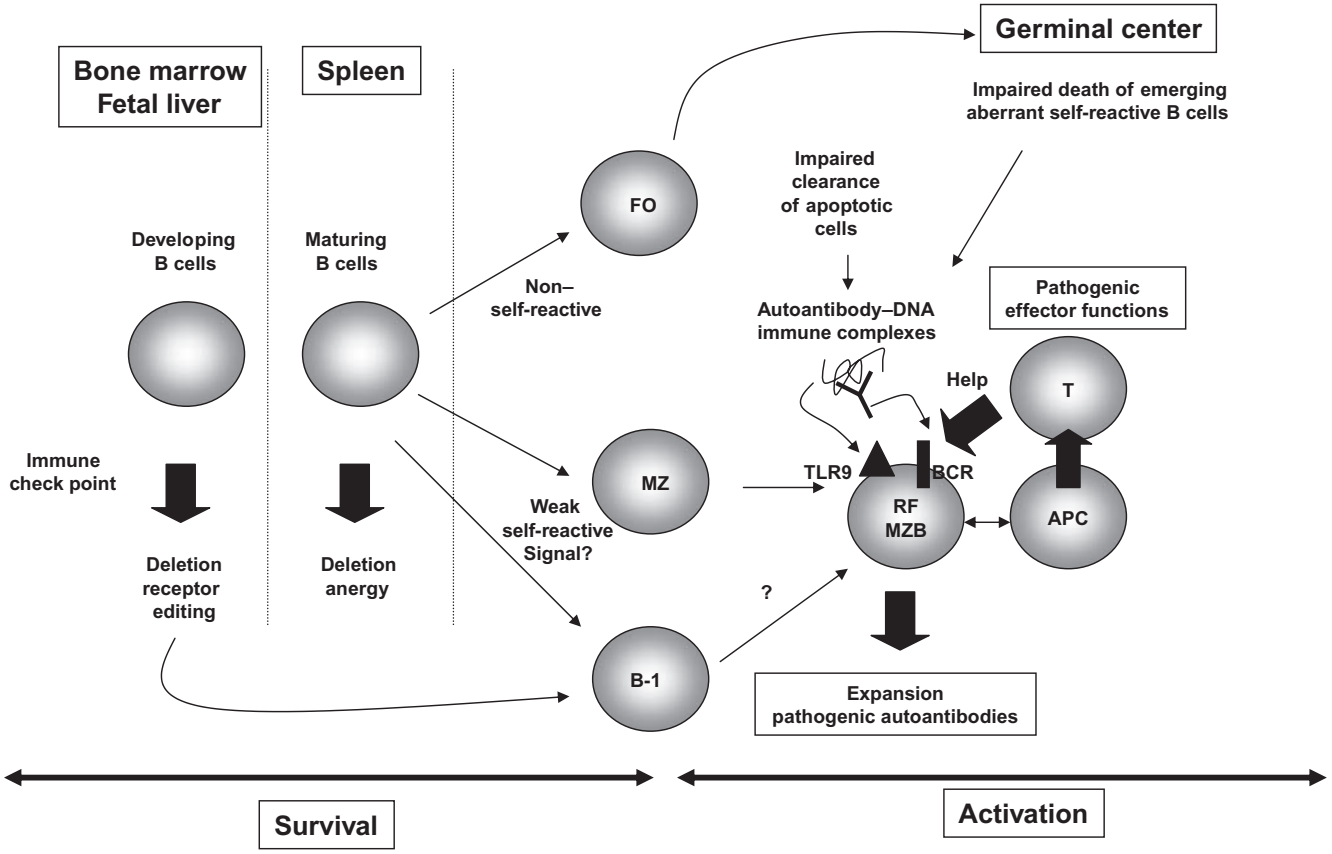

FIGURE 11.3 Mechanisms for the generation of autoreactive B cells and the development of autoimmunity. B-cells develop in the bone marrow and undergo further maturation in the spleen. Autoreactive B cells are censored at these stages either by deletion, receptor editing or anergy. If autoreactive B cells escape these checkpoints they can become activated in the periphery by aberrant signals delivered through the B-cell receptor (BCR), Toll-like receptor (TLR), or death receptor. As a result, autoreactive pathogenic antibodies will be produced. APC, antigen-presenting cell.

Pathogenicity of B cells in Autoimmunity

Over many years, scientists have questioned ways in which B cells trigger autoimmune disorders, and whether autoantibodies detected in the blood in various diseases have any pathogenic role. In human RA and SLE, levels of autoantibodies detected in the serum may correlate only weakly with disease severity and alternative pathogenic roles for B cells have been sought. Among the explanations, current diagnostic assays may not necessarily be detecting the "right" autoantibody in these patients, or truly relevant antibodies may be absorbed *in vivo* by the target tissue. However, recent studies in the mouse have shown that some autoreactive B cells do indeed secrete pathogenic autoantibodies, which alone can cause tissue destruction. This is certainly the case for arthritis in mice, illustrated by the K/BxN model developed by Mathis et al. (Kouskoff et al., 1996; Korganow et al., 1999) and to some extent in the collagen-induced arthritis model in mice. The K/BxN model resulted from mating a TCR-transgenic mouse onto a nonobese diabetic (NOD) background. The resulting progeny rapidly developed spontaneous and severe polyarthritis resembling human RA (Kouskoff et al., 1996). The autoreactive B cells in these mice secrete autoantibodies to glucose phosphate isomerase which, upon passive transfer, induce joint inflammation and destruction within 2–3 days (Korganow et al., 1999; Maccioni et al., 2002). These effects depended in part on mast cells and the C5a/C5a receptor complement system (Ji et al., 2001; Lee et al., 2002). This work shows that, in models of RA, damage to joint tissues can be caused solely by pathogenic autoantibodies. This may also be the case for SLE where immune complexes between DNA and anti-DNA autoantibodies can aberrantly activate autoreactive B cells via coactivation of the BCR and TLRs (Leadbetter et al., 2003).

However, in other diseases, including SLE, there is another role for autoreactive B cells. Here, B cells are required for the development of SLE on the MRL-lpr background (Chan et al., 1999); however, when MRL-lpr mice were engineered to produce B cells unable to secrete immunoglobulin, the mice still developed glomerulonephritis. Hence, B cells themselves, in the absence of autoantibodies, must have a pathogenic effect in this model (Chan et al., 1999). Finally, aside from producing autoantibodies, B cells can serve as APCs for T cells (Lanzavecchia, 1985; Roosnek and Lanzavecchia, 1991; Mamula et al., 1994; Liu et al., 1995; Attanavanich and Kearney, 2004). The MZ and memory B-cell subsets seem to be particularly efficient as APCs when compared to other B-cell subsets (Liu et al., 1995; Attanavanich and Kearney, 2004). As mentioned above, MZ B cells may play a role in autoimmunity and their autoimmune characteristics associated with their ability to activate T cells may be the key combination driving autoimmunity in some circumstances (Figure 11.3).

In summary, very few autoreactive B cells are present in normal mice and when they are, they are usually located away from T-cell help and are not normally activated. Increased B-cell survival may allow the emergence of autoreactive B cells and modified conditions of B-cell activation, including impaired clearance of apoptotic cells and hyperresponsive BCR signaling. Whether this participation occurs via the secretion of pathogenic autoantibodies and/or the indirect activation of self-reactive pathogenic T cells remains to be determined and may differ depending on the autoimmune condition.

Formation of Ectopic Lymphoid Tissue and Germinal Centers

In human autoimmune disease, the affected tissues are usually of nonlymphoid origin, and are thus devoid of immune cells. However, it has been known for over 40 years that the inflamed tissues of patients with diseases such as RA (synovial tissue), reactive arthritis (synovial tissue), Sjögren syndrome (salivary glands), myasthenia gravis (thymus) and Hashimoto's thyroiditis (thyroid) contain large numbers of infiltrating, and usually activated, lymphocytes (Berek and Kim, 1997). More recently, such structures have been detected in the cerebrospinal fluid (CSF) of patients with multiple sclerosis (MS), as well as in animal models of this disease, and this is often accompanied by the presence of oligoclonal antibodies in the CSF (Corcione et al., 2004; Magliozzi et al., 2004; Serafini et al., 2004). In RA patients, three distinct patterns of cellular infiltrates could be resolved: 1) diffuse infiltrates containing T cells, B cells, macrophages, and DCs (approximately 50% of patients); 2) T–B-cell aggregates (approximately 25%); or 3) B cells, T cells, DCs, and FDCs, which form GC-like structures (approximately 25%) (Berek and Kim, 1997; Takemura et al., 2001a). In these latter patients, the environment of the affected tissues could support the formation of GCs. Indeed, the concentration of ectopic follicle-like structures correlated with the levels of autoantibody in RA patients, suggesting that formation of GCs in inflamed tissues directly contributes to the levels of autoantibody (Weyand and Goronzy, 2003). PCs could also be detected within the affected tissues, and these were positioned surrounding the follicle-like structure formed by the infiltrating lymphocytes, rather than within the cluster (Kim et al., 1999). This parallels the exit of PCs from GCs formed within secondary lymphoid tissues. The detection of these ectopic GCs raises the possibility that production of inflammatory chemokines may retain PCs within these tissues rather than allowing their migration to other sites. Interestingly, synoviocytes

generated from synovial tissue have been found to support the survival and immunoglobulin production by activated B cells (Dechanet et al., 1995). This led to the proposal that synoviocytes within inflamed tissues could maintain PCs present within synovial tissue, analogous to stromal cells present in spleen and BM (Ellyard et al., 2005), and thus contribute to the accumulation of PCs within this tissue (Dechanet et al., 1995).

Examination of B cells in these nonlymphoid sites revealed them to be of GC origin, i.e., memory B cells and long-lived PCs. Similarly, B cells with a phenotype corresponding to predominantly memory cells, GC cells, and PCs were detected within the CSF, but not in peripheral blood, of MS patients (Corcione et al., 2004). Clonally-related immunoglobulin V region sequences were detected within these ectopic GCs in synovial tissue and salivary glands of patients with RA and Sjögren syndrome, respectively. The patterns of mutation within the memory B cells and PCs were characteristic of antigen selection (Berek and Kim, 1997; Stott et al., 1998; Kim et al., 1999). Furthermore, clonally-related sequences encoding TCR β chain V genes were microdissected from distinct follicles within the synovial tissue of the same patient, suggesting that these clonotypic cells may recognize the same (auto) antigen (Takemura et al., 2001b). Hence, antigen-driven B-cell diversification is occurring within these ectopic GCs, and the accumulation of B cells within the tissue is not simply due to migration of such cells formed at other (lymphoid) sites. Thus, it is likely that differentiation of (auto) antigen-specific B cells into memory B cells and PCs takes place within the GCs of inflamed tissues.

A xenogeneic animal model of RA was developed by transplanting human synovial tissue containing inflammatory infiltrates into NOD.scid mouse ("RA.scid mice"). This model has facilitated examination of the role played by B cells in the development and severity of RA. These studies suggested that B cells within the inflamed tissue may not only be responsible for secreting pathogenic or arthritogenic immunoglobulin, but also for maintaining the population of activated T cells by acting as efficient APCs. It was found that when T-cell clones were transferred into RA.scid mice they elicited production of increased levels of pro-inflammatory cytokines IL-1β, TNF-α, and IFN-γ, demonstrating that these $CD4^+$ T cells are important effector cells in the inflammatory process observed in RA. Strikingly, when B-cell-depleted synovial tissue was transplanted into SCID mice, the cotransferred synovial $CD4^+$ T cells did not become activated. Similarly, when RA.scid mice were established using GC-containing synovial tissue, and treated with depleting anti-CD20 monoclonal antibody, the ability of $CD4^+$ T cells to induce generation of inflammatory cytokines was reduced by up to 80–100% (Takemura et al., 2001b). These results indicated that activation of T cells in RA is B-cell dependent, and highlights the critical role of B cells in the pathogenesis of autoimmunity.

Disturbances to B-Cell Homeostasis

Several perturbations to B-cell homeostasis have been recognized in human autoimmune diseases. Sjögren syndrome patients have reduced numbers of circulating memory B cells, perhaps resulting from the retention or accumulation of these cells in the inflamed salivary glands (Bohnhorst et al., 2001; Hansen et al., 2002). Although SLE patients are typically lymphopenic, there is a striking increase in the number of circulating plasmablasts, as well as cells with a phenotype of pre-GC cells (Odendahl et al., 2000; 2003; Arce et al., 2001; Grammer et al., 2003), and there is a correlation between the number of circulating plasmablasts and the severity and duration of SLE (Jacobi et al., 2003). Lastly, the majority of B cells in peripheral blood mononuclear cells (PBMC) of RA patients are memory B cells and plasmablasts/cells (Lindenau et al., 2003). Together, these findings suggest that the presence of increased numbers of cells that are normally restricted to lymphoid tissue suggests further dysregulated control of the GC in autoantibody-mediated autoimmunity, and this may contribute to the generation of effector B cells with pathogenic autoantigen specificity.

Altered Cytokine and Chemokine Production: Relationship to Lymphoid Neogenesis and Exacerbated B-Cell Function

Elevated levels of some cytokines have been observed in both the serum and inflamed tissue of autoimmune patients. This has been most pronounced for serum TNF-α, IL-6, and IL-10, while these cytokines, as well as lymphotoxin (LT)-α/β, IL-1β and type 1 interferons (IFNs), have been detected at elevated levels in synovial tissue of RA patients (Brennan and Feldmann, 1996; Feldmann et al., 1996) and CSF of MS patients (Corcione et al., 2004). High serum levels of CD154, as well as expression on circulating pre-GC B cells, have been observed in SLE (Banchereau et al., 2004). These cytokines could contribute to the chronic inflammation observed in, and subsequent destruction of, the tissues affected by autoimmune diseases. Indeed, in RA, TNF-α appears to be the dominant cytokine that sustains inflammation, because *in vitro* culture of synoviocytes from RA patients in the presence of neutralizing TNF-α antibody reduced the spontaneous production of IL-1, granulocyte-macrophage colony-stimulating factor (GM-CSF), and IL-6, while blocking IL-1-reduced production of IL-6, but had no effect on TNF (Brennan and Feldmann, 1996; Feldmann et al., 1996; Feldmann and Maini, 2001). In addition to being

involved in the inflammatory response, some of these cytokines may contribute to the disease by facilitating and supporting the generation of ectopic lymphoid tissue, as well as by having a direct effect on the pathogenic B cells.

Lymphoid Neogenesis

TNF-α and LT are not only proinflammatory cytokines but also have fundamental roles in lymphoid neogenesis. Gene-targeting studies demonstrated that mice deficient in TNF, LT or their corresponding receptors have structural and functional defects in their secondary lymphoid organs (Fu and Chaplin, 1999). The mechanism by which TNF and LT mediate organogenesis is in part through regulating production of the lymphoid homeostatic chemokines CXCL13, CCL19, and CCL21(Ngo et al., 1999). Consistent with this, a correlation was observed between the level of expression of LT-α, LT-β, CXCL13, and CCL21, and the presence of FDCs and GCs within synovial tissue (Shi et al., 2001; Takemura et al., 2001a). Expression of these soluble mediators and the level of organization of the lymphoid cells in the synovium in RA suggested that the formation of GC was dependent on the concentrations of both CXCL13 and LT-β (Takemura et al., 2001a). CXCL13 is usually produced by FDCs in secondary lymphoid tissues. However, in RA, CXCL13-producing cells were identified as FDCs and also vascular endothelium and synoviocytes (Shi et al., 2001; Takemura et al., 2001a). Similar to normal lymphoid tissues, the predominant source of LT-β was the infiltrating B cells (Takemura et al., 2001a). Thus, within inflamed tissue, it could be that TNF-α produced by infiltrating inflammatory cells induces production of CXCL13 by vascular endothelium and synoviocytes. CXCL13 then recruits circulating B cells, and induces the expression of LT-β. LT-expressing B cells are required for the development of FDCs, which, once developed, would support the formation of GCs by acting as a repository for antigen. This model is consistent with the findings that treatment of RA patients with TNF-α antagonists resulted in reduced trafficking of leukocytes into, and reduced angiogenesis in, inflamed synovial joints (Feldmann and Maini, 2001). This model is also supported by the findings that transgenic expression of CXCL13 in murine pancreatic β cells causes infiltration of B cells, T cells, and DCs into the pancreas. Furthermore, pancreatic expression of CXCL13 resulted in the development of structures reminiscent of lymph nodes, and expression of CCL21, which probably mediates the recruitment of DCs and the majority of the T cells (Luther et al., 2000). B cells appear to be required for the establishment of pancreatic follicles, longevity of ectopic GCs, and lymphoid neogenesis because none of these features was observed in CXCL13 transgenic mice that were B-cell deficient (Luther et al., 2000). Thus, lymphoid neogenesis is secondary to the recruitment of B cells, consistent with the previous findings documenting the requirement for B cells in the development of follicles in secondary lymphoid tissues (Fu and Chaplin, 1999). The requirement for B cells in this process corresponds to the requirement for B cells in inducing activation of putative autoantigen-specific $CD4^+$ T cells in RA.scid mice, and suggests that in this animal model T-cell activation may be mediated by B-cell-dependent recruitment of T cells to the inflamed synovial tissue, or by B cells acting as potent APCs for pathogenic $CD4^+$ T cells (Takemura et al., 2001b).

It is of interest that lymphoid-like structures were demonstrable within the CNS of MS patients, and that there were high levels of CXCL12, CXCL13, LT-α, and BAFF within these structures (Corcione et al., 2004; Magliozzi et al., 2004; Serafini et al., 2004). Thus, in autoimmune disease of the CNS, LT-α and CXCL13 may contribute to the recruitment of B cells, and BAFF—produced by astrocytes (Krumbholz et al., 2005)—promotes the survival of B cells in these ectopic lymphoid tissues.

B-Cell Behavior

Cytokines such as IL-6, IL-10, IFN-α and CD40L are also elevated in the serum of patients with autoimmune diseases, and serum levels of IL-10 correlate with disease activity (Banchereau et al., 2004; Beebe et al., 2002; Llorente and Richaud-Patin, 2003). Notably, these have potent effects on the survival, growth, and differentiation of human B cells (Banchereau and Rousset, 1992; Banchereau et al., 2004).

IL-10

IL-10 may have a specific role in SLE. First, the cell types responsible for the production of IL-10 are B cells and monocytes, while T cells from SLE patients do not spontaneously produce significant levels of IL-10 (Beebe et al., 2002; Llorente and Richaud-Patin, 2003). Second, the increased levels of human IgG, as well as anti-dsDNA antibody, in the serum of SCID mice, observed following transfer of PBMC from SLE patients, was dramatically reduced in the presence of neutralizing anti-IL-10 monoclonal antibody (Llorente et al., 1995). Third, treatment of patients with anti-IL-10 monoclonal antibody resulted in a significant decrease in the SLE disease activity index for up to 6 months, as well as a reduced requirement for immunosuppression with corticosteroid drugs (Llorente et al., 2000). Similarly, using a pharmacologic approach, it was found that "lupus-like" symptoms of SCID mice reconstituted with mononuclear cells from patients with SLE and lupus-prone NZB/WF1 mice were ameliorated following treatment with the immunomodulatory drug AS101, whose effect is achieved by its ability to dramatically reduce production of IL-10 by SLE MNC (Kalechman et al., 1997). IL-10 is not only a powerful growth and differentiation factor for human

B cells, but it is also capable of protecting GCs B cells from apoptosis by increasing expression of Bcl-2 (Beebe et al., 2002). This may explain the increased number of GC-like B cells detected among PBL of SLE patients (Arce et al., 2001; Grammer et al., 2003). Thus, it is likely that IL-10 plays a complex role in SLE, rather than simply promoting the activation of autoantibody-producing B cells.

IFN-α

Another cytokine capable of inducing B-cell activation and differentiation that is overexpressed in SLE is IFN-α (Banchereau et al., 2004). Type 1 IFNs (α, β) are secreted in large quantities by plasmacytoid DCs (PDCs) activated through TLRs either by viruses or nucleic acid complexes (Banchereau et al., 2004). In SLE, these could take the form of immune complexes containing DNA or RNA. IFN-α/β can mediate the differentiation of activated human B cells into plasmablasts, which further develop into PCs in the presence of IL-6, another product of PDCs (Banchereau et al., 2004). *In vitro* studies have demonstrated that production of BAFF by DCs is increased in the presence of either exogenous IL-10 or IFN-α (Craxton et al., 2003; Litinskiy et al., 2002). It is possible that increased serum levels of IL-10 and IFN-α may act not only on the pathogenic B cell, but also on other effector cells, specifically DCs, by increasing their release of BAFF. Thus, neutralization of IL-10 and/or IFN-α may improve SLE by initially reducing circulating levels of these cytokines, and subsequently by reducing serum BAFF levels. It is presently unknown whether IL-10 induces the production of IFN-α by DCs or vice versa. Thus, it is possible that the increased production of BAFF by DCs stimulated with IL-10 or IFN-α is an indirect effect of each cytokine inducing the production the other.

DIFFERENT CYTOKINES—DIFFERENT AUTOIMMUNE DISEASES

Treatment of RA by neutralizing TNF-α has yielded great results. However, one notable side effect of this treatment has been the development of anti-DNA antibody in approximately 15% of patients (Feldmann and Maini, 2001). Interestingly, anti-TNF therapy is ineffective in SLE (and most other autoimmune diseases), suggesting that TNF has no role in the development and/or pathogenesis of such diseases (Banchereau et al., 2004). On the other hand, the immunomodulatory drug AS101 was found not only to decrease IL-10 production by mononuclear cells from patients with SLE, but also to increase production of TNF-α (Kalechman et al., 1997). These changes in serum cytokine levels of treated SCID mice were associated with reduced SLE-like pathology. Interestingly, polymorphisms in the TNF-α gene of NZW mice result in reduced production of TNF-α and increased susceptibility to the development of SLE-like disease (Jacob and McDevitt, 1988). Thus, reduced TNF-α production, or reductions in the relative amount of this cytokine due to either intrinsic or extrinsic regulatory mechanisms, may predispose individuals to autoimmune diseases such as SLE.

CONCLUDING REMARKS

Clinicians have long pondered over the association of evident B-cell overactivity and the genesis of autoimmune disease. One main reason for this is the frequently weak correlation between levels of autoantibodies and the severity of disease. However, current diagnostics may measure only a limited set of autoantibodies of which not all participate in pathologic processes. However, recent work on mice and humans has clearly identified pathogenic autoantibodies, which alone can cause tissue damage or adverse functional effects. In fact, these are probably the tip of an iceberg and tissue damage is likely triggered by several, if not different, autoantibodies, from patient to patient, with the challenge being to identify pathways by which they act. These ideas are fortified by the increasing range of autoimmune diseases alleviated by therapy with intravenous immunoglobulin for which the primary benefit depends on blocking of antibody-mediated effects (see Chapter 16). Immune cells clearly do not act alone and a mistake in the past has been to draw conclusions about autoimmune pathologies based on data from isolated subsets of lymphocytes, whether they be T cells, B cells or macrophages. Autoimmunity is a conspiracy involving the concerted misbehavior of many immune cell types. B cells play a major disruptive role in this plot as APCs and cytokine producers which, when inappropriately activated, will support the activation of harmful T cells and other cell types. The impressive efficacy of B-cell-depleting therapies in RA (e.g., anti-CD20 monoclonal antibody), which clearly spare PCs, is a strong indication that B cells as accessory cells are key elements driving autoimmunity. The challenge we face is to determine whether all B cell subsets are equal in that function and whether refined therapies targeting pathogenic B-cell subsets could be developed, sparing innocuous B cells, preventing toxicity and side effects due to prolonged and general B-cell deficiency.

CHAPTER

12

Memory B-Cell Development

LOUISE McHEYZER-WILLIAMS AND MICHAEL G. McHEYZER-WILLIAMS

The Scripps Research Institute, Department of Immunology, La Jolla, California, USA

Immune memory is a systemic phenomenon generated through the propagation and selective preservation of antigen-experienced memory cells in response to primary antigen exposure. Adaptive immunity to most foreign proteins requires the helper T (Th)-cell-regulated development of antigen-specific effector and memory B cells. This ordered cascade of cellular events progresses through multiple developmental checkpoints that serve to regulate immune function and limit self-reactivity. This chapter will outline what is currently understood of the temporally and spatially regulated development of antigen-specific memory B cells *in vivo*.

An adaptive immune response is a directed cellular program of development that progresses through distinguishable phases of change *in vivo*. The inflammatory context of initial antigen exposure primes the innate immune system to recruit naïve antigen-specific Th cells (phase I). Expanded effector Th cells prime antigen-experienced B cells to produce short-lived plasma cells and initiate secondary follicle formation (phase II). Secondary follicles are the microenvironmental precursors of the germinal center (GC) reaction, a cycle of somatic diversification and clonal selection that underpins affinity maturation and memory B-cell development (phase III). Multiple subsets of memory Th cells and memory B cells persist following primary antigen clearance in readiness for antigen rechallenge (phase IV). The cellular response to antigen rechallenge is substantially accelerated, resulting in the rapid and exaggerated production of memory response plasma cells and high-affinity antibody. This chapter will emphasize murine models of adaptive immunity to exemplify the emergent response to defined protein antigen. The extensive work that has been undertaken in humans is reviewed in Chapter 11.

During the primary immune response, expansion of self-reactive Th-cell or B-cell clonotypes and their differentiation into effector cells would reveal acute signs of autoimmunity. In contrast, the development and preservation of self-reactive clonotypes into the long-lived memory compartment assures a continued and self-replenishing cellular focus for chronic autoimmunity. Hence, avoiding the development of self-reactive memory is a fundamental property of the adaptive immune response to foreign antigen.

Exaggerated reactivity to antigen recall is the central defining characteristic of adaptive immunity (Burnet and Fenner, 1949). As early as 1957, Talmage (1957) and Burnet's (1957) postulates of clonal selection focused atten-

tion on the cellular organization of adaptive immunity. This powerful conceptual framework indicated that the cells of the immune system were the fundamental units of selection (Burnet, 1958). Early identification of cells that produced antibodies by Fragraeus (1948), and the assay of specificity with single-cell resolution by Nossal (1959), provided the initial experimental support for this model. Studies by Miller (1961) and Claman (1966) clearly indicated that mixtures of different cells were needed for efficient adaptive immunity. A series of transfer studies by Miller and Mitchell (1967) established that bone marrow produced the plasma cell precursors while the thymus-derived cells enhanced the antibody response. Subsequent studies of the hapten-carrier effect (Paul et al., 1966; Katz et al., 1970; Mitchison, 1971) began to probe the molecular basis of T–B-cell collaboration (Rajewsky et al., 1969). These classical studies also provide the experimental animal models so instrumental to our current appreciation of the cellular and molecular regulation of adaptive immunity.

PHASE I: RECRUITING SPECIFIC LYMPHOCYTES

Activating Innate Immunity

Local administration of oligovalent protein antigens without inflammatory stimuli will induce tolerance, largely due to inadequate costimulation of the adaptive system (Jenkins et al., 2001). Immune adjuvants provide the inflammatory stimulus necessary for effective protein vaccination strategies (Janeway and Medzhitov, 2002). Most adjuvants trigger cell activation through pattern-recognition receptors (PRRs), such as those of the interleukin (IL)-1R/Toll-like receptor (TLR) family (Aderem and Ulevitch, 2000). PRRs recognize conserved pathogen motifs, such as bacterial lipopolysaccharide (TLR4) or stretches of unmethylated DNA typically present in bacteria (TLR9). Dendritic cells (DCs) are uniquely efficient at protein antigen uptake and processing, and presentation of peptide major histocompatibility complexes (MHCs) *in vivo* (Banchereau and Steinman, 1998). At homeostasis, there are multiple varieties of DC resident in secondary lymphoid organs or trafficking there from regional tissue (Shortman and Liu, 2002). Upon vaccination, DCs at the site of injection produce large amounts of inflammatory chemokines, upregulate chemokine receptors and costimulatory molecules, and then relocate to the T-cell zones of regional draining lymph nodes (McHeyzer-Williams and McHeyzer-Williams, 2005) (Figure 12.1).

At sites of inflammation there will be concomitant local tissue damage. Hence, self-protein can also be processed and presented by the same activated DC population. Therefore, self-protein–MHC complexes will now be presented in the draining lymph node with adequate costimulation, providing a mechanism to activate and expand self-reactive T cells.

Immune Synapse I: Activated Antigen-Presenting Cells and Naïve Helper T Cells

In the regional lymph nodes, activated peptide–MHC II$^+$ DCs sample the naïve Th-cell compartment for T-cell receptors (TCRs) above a threshold for affinity of protein–MHC II binding (Malherbe et al., 2004). In the absence of agonist peptides, intercellular connections between antigen-presenting cells (APCs) and naïve Th cells are transient (Bromley et al., 2001). In contrast, immune synapse formation requires specific protein–MHC II recognition (Monks et al., 1998). TCR–protein–MHC II interactions, coreceptors, and intracellular signaling complexes focus centrally at the interface, surrounded by complementary adhesion molecule interactions. Exclusion of potentially negative signals, such as the receptor phosphatase CD45 or the large sialoprotein CD43, also appears to be part of the molecular rearrangement associated with immune synapsis. Longer-term immune synapsis can be visualized directly *in vivo* (Mempel et al., 2004), also requires TCR specificity (Huppa et al., 2003), and appears important for commitment to proliferation (Lee et al., 2002) and most likely differentiation of cell function.

Immune synapsis between an antigen-experienced protein–MHC II$^+$ DC and a naïve protein–MHC II-specific Th cell acts as the first critical developmental checkpoint in antiprotein immune responses (see Figure 12.1, phase I). Multiple DC subsets can be involved at this checkpoint, together with a variety of maturation states based on the quality of inflammation (Shortman and Liu, 2002; Pulendran, 2004). The route of immunization will influence the regional mix of DCs that can participate in this early phase of the response (Itano and Jenkins, 2003; Itano et al., 2003). Dose of antigen influences density of specific protein–MHC II complexes per cell, which may in turn influence Th-cell fate. We have also recently demonstrated a preexisting divide in the naïve Th-cell compartment based on differential Ly6C expression, which also divides the Th-cell repertoire and immune function (McHeyzer-Williams and McHeyzer-Williams, 2004). Hence, combinations of different cell types on either side of the immune synapse I can substantially impact Th-cell fate and function *in vivo*.

Activating Specific B Cells

To receive cognate T-cell help, naïve B cells must have first encountered a specific antigen. The epitope specificity of the two lymphocytes may differ; however, the antigen-experienced B cells must process and express the protein–MHC II complex specific for the Th cells. The B-cell receptor (BCR) can certainly recognize soluble antigen,

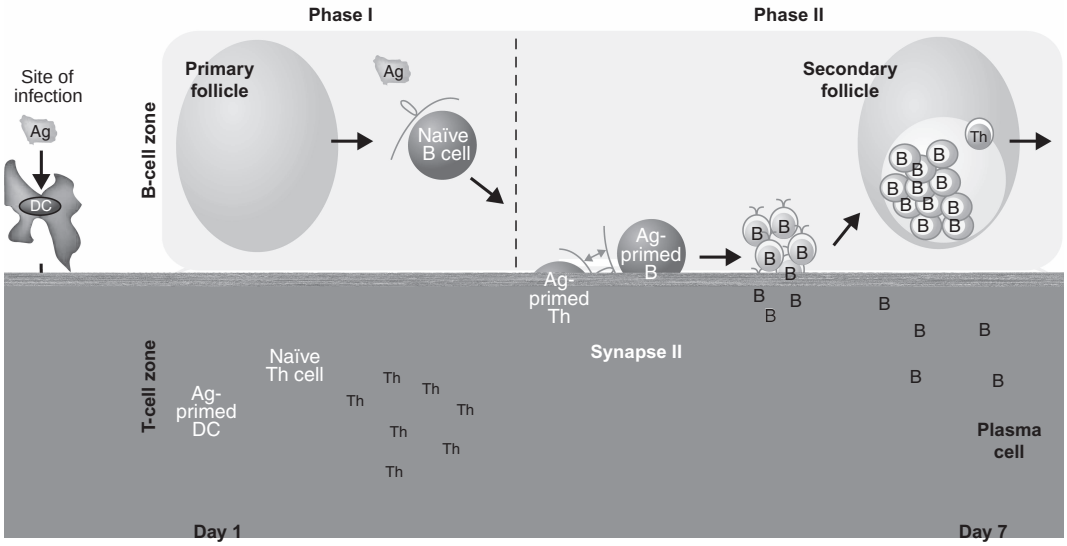

FIGURE 12.1 Initiating and regulating adaptive immunity. Phase I begins with activating antigen-presenting cells (APCs) at the site of vaccination and their migration into T-cell zones of draining lymph nodes. The formation of immune synapse I between antigen-experienced APC and naïve antigen-specific helper T (Th) cells is the first major developmental checkpoint in this pathway. Th cell clonal expansion and migration towards the T–B-cell borders initiates the search for antigen-experienced B cells. Phase II begins with immune synapse II between expanded effectors Th cells and antigen-primed B cells, the second developmental checkpoint in this pathway. A major division in B-cell development ensues with isotype switch and plasma cell differentiation or secondary follicle formation. Ag, antigen; DC, dendritic cell.

Reproduced from McHeyzer-Williams and McHeyzer-Williams (2005), with permission.

although the efficiency of B-cell responsiveness to APC-associated antigen can be 1000-fold higher (Batista et al., 2001). This cell-associated presentation has been demonstrated for Th-cell-independent B-cell responses to bacteria *in vivo* (Balazs et al., 2002), but may also be operative for protein antigens. Nevertheless, B cells must be primed with antigen prior to cognate Th-cell interactions.

PHASE II: REGULATING B-CELL FATE

Immune Synapse II: Effector Helper T Cells and Antigen-Primed B Cells

Clonal expansion precedes effector Th-cell differentiation and the delivery of cognate T-cell help to B cells (Malherbe et al., 2004). Temporal separation of these events serves to amplify low antigen-specific Th-cell precursors, increasing the probability of antigen-specific Th–B-cell contact. Upon activation and expansion, Th cells also progressively decrease CCR7 and increase CXCR5 expression as a means to relocate towards the B-cell-rich follicular regions (Ansel et al., 1999). Effector Th-cell function is delivered to B cells in a cognate manner, constituting the second major checkpoint in this emergent developmental pathway (see Figure 12.1, phase II). Immune synapse II between protein–MHC II-specific effector Th cells and antigen-primed B cells is qualitatively and quantitatively distinct from immune synapse I. The central focusing event remains the TCR–protein–MHC II interactions; however, the expression of secondary molecules capable of modifying cell fate at this juncture has substantially changed.

Diversity of effector Th-cell function in its microenvironmental context *in vivo* remains poorly resolved. Many cell-surface molecule pairs, such as CD154 (CD40L)/CD40 (Armitage et al., 1992) and ICOS/ICOSL (Dong et al., 2001; McAdam et al., 2001; Tafuri et al., 2001), play critical early roles in the delivery and reception of T-cell help to B cells. Antibody isotype switch and the GC reaction fail to develop in the absence of these key costimulator molecules. Many other members of these tumor necrosis factor (TNF)/TNF receptor (TNFR) and CD28/CD80 (B7) families have the capa-city to modify immune response outcomes (Bishop and Hostager, 2001). The production of cytokines, such as IL-4, interferon (IFN)-γ, and tumor growth factor (TGF)-β, by Th cells also have a major impact on B-cell fate by influencing isotype switch recombination (IgG1, IgG2a, and IgA, respectively) (Snapper and Paul, 1987; Cazac and Roes, 2000). Other cytokines, such as IL-5, IL-6, and IL-10, are thought to exert their influence more generally on survival and propagation of antigen-experienced B cells. Interestingly, the frequency of specific Th cells that express mRNA for any one cytokine *in vivo* is surprisingly low, with little change between primary and memory response (Panus et al., 2000). Nevertheless, the

diversity of effector Th cells serves to define a range of immune synapse II interactions that impact alternate B-cell fates *in vivo*.

The presentation of peptides from intracellular sources of self-protein in MHC II is inefficient. B cells are also poor phagocytes, thus non-BCR uptake of self-proteins is unlikely. Furthermore, if self-reactive B cells take up self-proteins and express self-protein–MHC II complexes, they still require cognate T-cell help before they can expand and differentiate into plasma cells. Low self-reactive B-cell precursor frequencies and the concomitant expansion of protein–MHC II effector Th cells for the same self-protein is another highly unlikely event. Hence, there are multiple practical barriers at the cellular, molecular, and biochemical levels that restrict exaggerated self-reactivity at this stage of the primary response.

Short-lived Plasma Cells and Secondary Follicle Formation

There is a major bifurcation in B-cell development following immune synapse II interactions during this first week after initial antigen exposure (MacLennan and Gray, 1986). Antigen-primed B cells that have received the requisite T-cell help either expand and differentiate into plasma cells or initiate secondary follicles (see Figure 12.1) (Jacob et al., 1991a). These alternate cell fates proceed separately in the T-cell zones and B-cell follicles, respectively. The early response plasma cells are characteristically short-lived with 3–5 day half lives (Ho et al., 1986) and express germline-encoded antibodies with no evidence of somatic diversification (Jacob et al., 1991b). Clonal expansion precedes plasma cell differentiation, which is considered to be the terminal event in this effector B-cell pathway. In contrast, some of the Th-cell-primed B-cell clonotypes move to the follicular area and expand rapidly. This cellular relocation, focal expansion, and regional exclusion of follicular B cells in the process establishes the secondary follicle as a dynamic new microenvironmental niche (MacLennan, 1994). These secondary follicles give rise to the GC reaction, providing the pathway to memory B-cell development.

BCR-based selection may drive this developmental decision with some evidence for the differential assortment of B-cell clonotypes into these two pathways (McHeyzer-Williams et al., 1993). Signature changes in transcription factor expression accompany differentiation to plasma cells. Transcriptional repression by Blimp-1 (Calame et al., 2003) and an XBP-1 requirement for antibody secretion (Reimold et al., 2001) are examples of these more intrinsic changes. Cognate Th-cell signals also clearly play a role in this developmental decision. Th signals that drive isotype switch in both pathways are also thought to originate at immune synapse II (Jacob et al., 1991a; McHeyzer-Williams, 2004). Combinations of Th-cell-expressed surface molecules and cytokines differentially regulate these key effector functions; however, it takes multiple cell divisions to reveal these cell fates *in vivo*. Thus, immune synapse II is the second pivotal checkpoint, controlling the quality of effector B-cell function and initiating memory B-cell development.

PHASE III: DEVELOPING B-CELL MEMORY

Germinal Center Reaction

Following initial clonal expansion, secondary follicles polarize. Continued expansion is relegated to the dark zone, always proximal to the T-cell areas, by antigen-specific GC B cells, now called centroblasts (MacLennan, 1994). The light zone at the opposite pole comprises many non-cycling GC B cells, now called centrocytes, dense processes of follicular DCs (FDCs) (non-bone marrow-derived stromal cells) (Szakal et al., 1988; Tew et al., 1990), and antigen-specific GC Th cells (Gulbranson-Judge and MacLennan, 1996; Zheng et al., 1996; Mikszta et al., 1999). This specialized microenvironment hosts a cycle of activity that underpins affinity maturation and the production of B-cell memory. As depicted in Figure 12.2, clonal expansion is accompanied by diversification of the antibody variable region genes by somatic hypermutation (SHM) (Rajewsky, 1996). The recent identification of activation-induced cytidine deaminase (AID) as an enzyme required for SHM provides a major breakthrough in understanding this multistep diversification mechanism (Honjo et al., 2002). Typically, one mutation is introduced per cell division, and cell cycle arrest then marks entry into the light zone and expression of the variant BCR (Kelsoe, 1996). Centrocytes are then selected for high-affinity BCRs and are filtered against self-reactivity (Linton et al., 1991). Although antibody production is not required for selection (Hannum et al., 2000), the FDCs and GC Th cells are thought to play a role in this critical selection event.

Immune Synapse III: Germinal Center Helper T Cells and B Cells

Positive selection in the GC cycle results in either reentry into the dark zone or exit into the long-lived memory B-cell compartment. Reiterative cycles of diversification and subsequent positive selection is the most conservative means to progressively mature the BCR affinity of the memory B-cell compartment. The precise role of the GC Th cell remains unclear; however, these cellular interactions most likely occur in a cognate manner and hence define a third and significant developmental checkpoint in the antiprotein adaptive response (Figure 12.3). Immune synapse III regulates the cellular outcome of the GC reaction

and thus controls the quality and quantity of the memory B-cell compartment.

Klinman (Linton et al., 1991) introduced the second window of tolerance to emphasize the capacity of the GC reaction to propagate self-reactivity. As SHM is random, if selection were inadvertently based on self-antigen, there would exist the potential to immortalize high-affinity neo-self-reactivity into the memory B-cell compartment. Flooding the system with soluble foreign antigen at the peak of the GC reaction interfered with normal GC development, providing some evidence that a protective mechanism was in place (Pulendran et al., 1995; Shokat and Goodnow, 1995). Importantly, the requisite self-reactive Th-cell compartment would also have to develop and be present in the GC reaction. Hence, a requirement for cognate GC Th-cell control in this process also provides a practical barrier to the development of self-reactive B-cell memory.

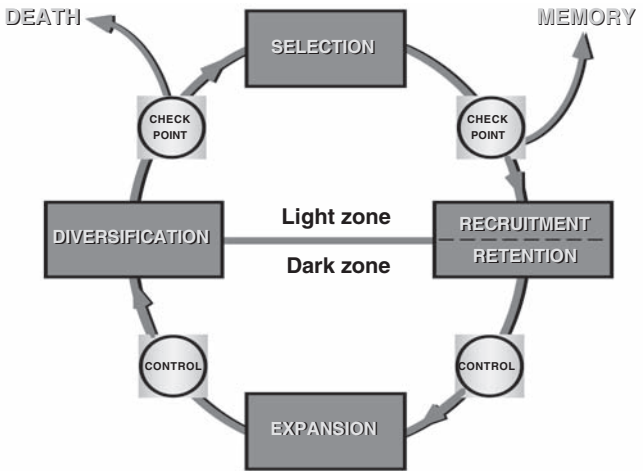

FIGURE 12.2 Germinal center (GC) cycle of activity. Antigen-specific B cells enter the follicular area and rapidly expand into secondary follicles that polarize into the light and dark zones of the GC reaction. Clonal expansion is accompanied by somatic diversification of the antibody variable region genes in the dark zone. Exit from the cell cycle and expression of variant B-cell receptors allows for antigen-specific selection of centrocytes in the light zones. Negative selection leads to apoptosis while positive selection of high-affinity variants results in GC cycle re-entry or exit from the GC into the memory B-cell compartment.

Memory B-Cell Subsets

Exit from the GC reaction is thought to signify entry into a long-lived memory B cell compartment (see Figure 12.3). Non-secreting precursors for the memory response and long-lived plasma cells are two separate subtypes of high affinity antigen-specific memory B cells that persist *in vivo* (McHeyzer-Williams et al., 2000). We have recently divided memory response precursors into two further subsets based on phenotype ***(6B2$^+$ versus 6B2$^-$ based on expression of a glycosylation variant of CD45),*** localization ***(6B2$^-$ preferentially home to BM)*** and capacity to produce antigen-specific plasma cells after adoptive transfer and antigen recall ***(6B2$^-$ have a greater propensity)*** (McHeyzer-Williams et al., 2000, Driver et al., 2001). ***We refer to these subsets as post-GC memory B cells and pre-plasma memory B cells in accordance with a proposed linear relationship in their development.*** Analysis of Blimp-1 conditional knockout animals (Shapiro-Shelef et al., 2003) indicates a novel requirement for Blimp-1 in memory B cell development. These genetic studies support a linear model of memory B cell development *in vivo* as outlined in Figure 12.3.

There is also evidence for continued antigen-based selection after the decline of the primary response GC reaction (Takahashi et al., 1998). This ongoing positive selection appears to be based on clonal competition with no further

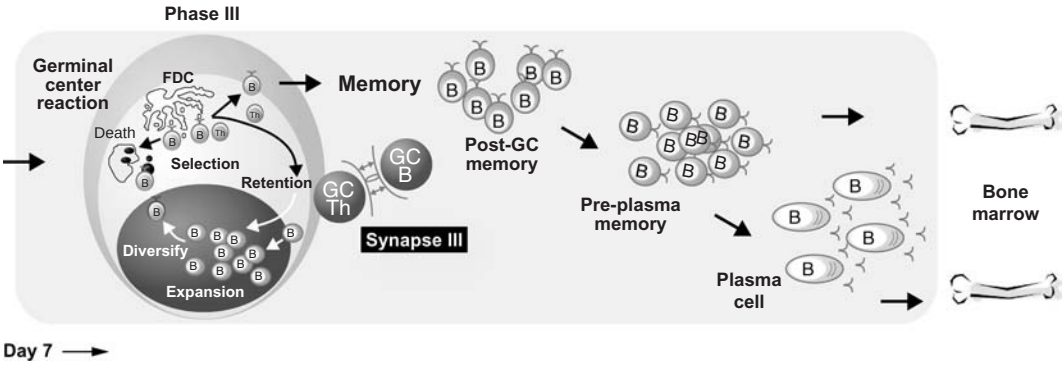

FIGURE 12.3 Memory B-cell subsets. Multiple subsets of memory B cells emerge from the germinal center (GC) reaction of the primary immune response. We propose that 6B2$^+$ post-GC memory B cells are the first cellular product to exit the GC. These cells can give rise to 6B2$^-$ preplasma memory B cells that are phenotypically and functionally distinct nonsecreting memory response precursors. The 6B2$^-$ pre-plasma memory B cells are the immediate cellular precursors of long-lived plasma cells that are a terminally differentiated antibody-secreting memory B cell compartment. Both PPM B cells and the long-lived plasma cells preferentially home to the bone marrow.

Reproduced from McHeyzer-Williams and McHeyzer-Williams (2005), with permission.

BCR diversification. Further, upon exit from the GC, memory B-cell survival is independent of BCR specificity (Maruyama et al., 2000). Individual memory B cells may not be long lived; however, the compartment persists even in the absence of the antigen-specific BCRs.

PHASE IV: RESPONDING TO ANTIGEN RECALL

Immune Synapse IV: Memory Helper T Cells and Memory B Cells

All three subsets of memory B cells persist without further antigen challenge (McHeyzer-Williams et al., 2000). The long-lived plasma cells preferentially home to the bone marrow and are the source of specific high-affinity serum antibody (McHeyzer-Williams and Ahmed, 1999). Upon antigen rechallenge, both subsets of memory response precursors expand rapidly in a Th-cell-dependent manner (McHeyzer-Williams et al., 2000). This memory response can manifest with minute quantities of soluble antigen in the absence of adjuvant. Hence, the innate system can be bypassed in the memory response. Nevertheless, effective antigen presentation and cognate Th-cell involvement are necessary for the memory response. The simplest model places the memory B-cell compartment as the APC and the elevated numbers of memory Th cells as the cognate regulators (Figure 12.4). Thus, immune synapse IV is the major developmental checkpoint for memory responses with exchanges of molecular information between memory Th cells and memory B cells.

The existence of memory Th cells and memory B cells to the same self-protein has disastrous consequences. In this scenario, inflammation would not be required to activate effector cell differentiation. There would be a potentially unlimited supply of antigen to trigger responsiveness to self. Finally, the self-replenishing characteristic of the memory compartment would broadly assure a continued supply of the precursors to damaging self-reactive effector cells. Hence, self-reactive memory is the true harbinger of unrelenting chronic autoimmunity.

Replenishment of the Memory Compartment

The number of persisting antigen-specific memory B cells of all subtypes increases following clearance of the secondary antigen challenge. The level of serum antibody specific for the antigen also increases with the secondary boost. Thus, replenishment of the memory compartment is a basic characteristic of the memory response (Traggiai et al., 2003). Self-replenishment allows continuance of

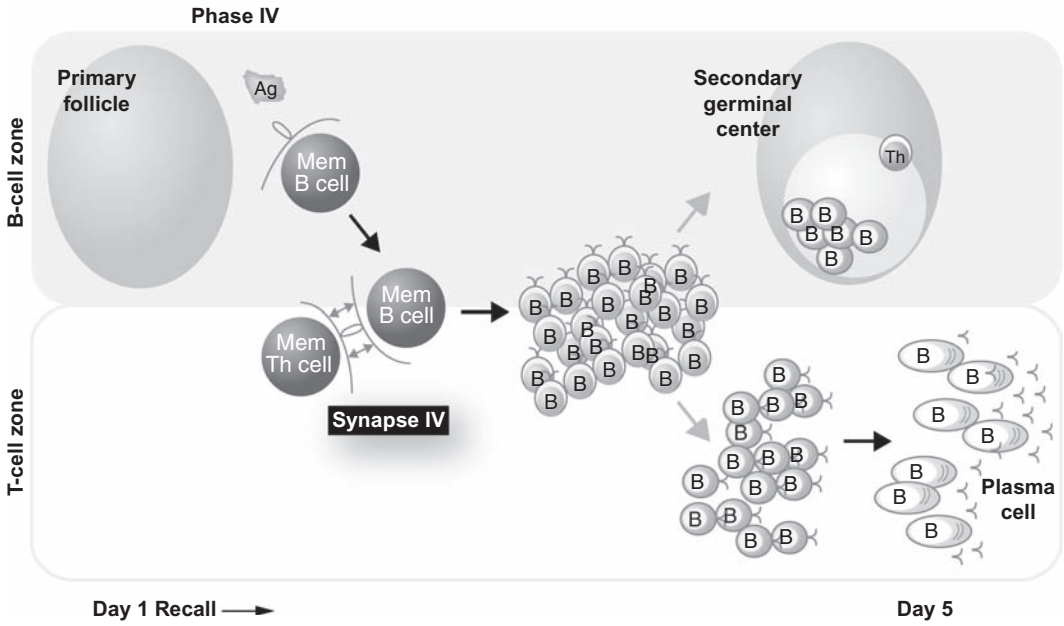

FIGURE 12.4 Response to antigen recall. Low-dose soluble antigen in the absence of adjuvant can induce a rapid and exaggerated humoral immune response. Hence, antigen-specific B cells are the most likely antigen-presenting cell (APC) for protein–MHC II complexes as immune synapse IV interactions between memory helper T (Th) cells and memory B cells are the critical developmental checkpoint for the memory response. Memory cell expansion is vigorous and produces large numbers of high-affinity memory response plasma cells as the dominant cellular outcome. Secondary germinal center (GC) reactions are also part of the memory response, although more a minor outcome than the primary response.

particular reactivity, but also heightens the basic capacity of the memory compartment to respond in the future.

Isotype-Specific Memory Cells

The spectrum of antibody isotype is the most clearly identifiable and differential functional characteristic of B-cell immunity. There is some information on the effector Th-cell control of isotype switch during the initial priming response, which has been discussed above. However, very little is known of the differential regulation of isotype-specific memory B cells into the memory response to antigen rechallenge. While IL-4 is a switch factor for some IgG1 and most or all IgE in B-cell responses (Snapper et al., 1988), it is not clear what $IgG1^+$ or IgE^+ memory B cells require for re-entry into the memory response. The distinct behavior of memory B cells expressing different isotypes *in vivo* has not been carefully studied. It seems likely that IgA memory B cells relocate to mucosal surfaces; however, it seems unlikely that TGF-β is required for their continued survival or re-entry into a memory response (Cazac and Roes, 2000). Hence, the developmental experience, resultant gene expression pattern, and intrinsic program of cellular behavior define memory B cells of different isotypes.

We have proposed the existence of functionally distinct memory Th-cell subsets that support the reactivation of isotype-specific memory B cells as one reasonable model of memory Th-cell organization. Unfortunately, the development of Th-cell memory itself remains poorly understood. How, where or even when Th-cell memory is developed during the primary responses is not clear. Direct experimental access to antigen-specific Th cells *in vivo* will help to resolve these issues (Altman et al., 1996); however, frequencies of responders remain quite low, even at the peak of the primary response, making functional assessment of effector and memory Th cells technically challenging. This is not the only organization proposed for Th-cell memory (see Chapter 6). Nevertheless, understanding functional diversity and developmental control of antigen-specific Th cells will be necessary to fully understand the control of antigen-specific B-cell memory.

CONCLUSION

The development and propagation of self-specific B-cell memory underpins many pathologic elements of autoimmune disease. The murine model provides access to the emergent properties of a developing adaptive response in secondary lymphoid organs that have been difficult to monitor in humans. The strategies that have been discussed in this chapter offer the means to analyze more directly the extent of antigen-specific immunity in humans. These strategies can potentially use peripheral blood to access memory lymphocytes and to quantify frequencies and qualify cellular diversity therein. Isolation and characterization of self-specific memory B cells and their memory Th-cell counterparts promise unique targets for immunotherapeutics at both the cellular and molecular levels.

CHAPTER

13

Tolerance and Autoimmunity: B Cells

ANTONY BASTEN AND ROBERT BRINK

Centenary Institute of Cancer Medicine and Cell Biology, University of Sydney, Sydney, NSW Australia

GROUND RULES FOR B-CELL SELF-TOLERANCE

Tolerance and memory constitute the two pillars on which the adaptive (specific) immune system is based. For self-antigens, tolerance or immunologic unresponsiveness is the appropriate outcome, whereas for foreign antigens, immunity and long-term memory are required.

The concept of self-tolerance can be traced back to the early 20th century when Ehrlich and Morgenroth [cited in Ehrlich and Morgenroth (1957)] described the production of hemolytic antibodies in goats following immunization with erythrocytes obtained from other goats, whereas autologous red cells failed to elicit a response. This and other findings on alloantisera led them to conclude that autoimmune responses "constitute a danger threatening the organism more frequently and more severely than all exogenous injuries." The fact that collectively autoimmune diseases are relatively uncommon is an indication of how effective the immune system normally is in distinguishing between self and nonself, or as Matzinger (1994) put it in her "danger" model, between harmless and dangerous entities.

Tolerance, like immunity, was shown early on to be somatically acquired as a result of exposure to antigen rather than being genetically pre-programmed into the germline [reviewed in Schwartz (1993)]. The simplest way of explaining how these two phenomena might be distinguished was on the basis of differences in the structure and properties of self- and foreign antigens. This proposition, however, was shown to be false by Traub (1938), Owen (1945), and Billingham et al. (1953) in their classic experiments demonstrating induction of tolerance to normally foreign antigens when introduced antenatally. Thus, the timing of antigen exposure appeared to be more important than the origin of the antigen per se. Based on these observations, Burnet (1959) encapsulated the concept of immunity and tolerance in his clonal selection theory, which states that: "self-not-self recognition means simply that all those clones which would recognize (that is produce antibody against) a self component have been eliminated in embryonic life. All the rest are retained." Thus every individual is born with a repertoire of "immunocytes," as Burnet called them, purged of self-reactive cells but still capable of mounting responses to foreign antigens. Clonal selection therefore paved the way for the concepts of positive and negative selection of cells recognizing nonself and self, respectively, although this thinking came to be applied more to the thymus than bone marrow.

Shortly afterwards, Lederberg (1959), while working in Burnet's laboratory, came to appreciate that tolerance could be imposed on developing lymphocytes, not just antenatally but throughout life, as they differentiate from precursor cells into mature immunocompetent cells. This line of reasoning

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

served to focus attention on primary lymphoid tissues (thymus and bone marrow) as the major sites for clonal elimination (deletion). In the event of a failure in self-tolerance, it was envisaged that a "forbidden clone" could emerge from these sites, resulting in onset of autoimmunity.

Cell–Cell Interactions and the Two-Signal Hypothesis

During the 20 years following promulgation of the clonal selection theory by Burnet, the immunologic function of the thymus was discovered (Miller, 1961), the lymphocyte was identified as the antigen-specific immunocyte (Gowans and Knight, 1964), the two-cell system of T and B lymphocytes was defined (Mitchell and Miller, 1968), and the phenomenon of major histocompatibility complex (MHC) restriction was described (Zinkernagel and Doherty, 1974). The picture of the immune system to emerge from these findings was one of an intricate set of cell–cell interactions initiated by exposure to antigen and regulated by multiple positive and negative signals derived from lymphocytes, antigen-presenting cells (APCs), and stromal cells located in primary and secondary lymphoid tissue. Thus, tolerance and immunity were no longer considered to be totally discrete entities, but rather the poles of a continuum of immune responsiveness, the former appropriate to self- and the latter to foreign antigens.

The ground rules for analyzing tolerance and immunity within this framework were first articulated by Bretscher and Cohn (1970) in their two-signal hypothesis. As originally applied to a generic antigen-responsive cell, the hypothesis envisaged that an immune response required associative recognition of two determinants (signal 1 and signal 2) on a given antigen, by two different cells. On the other hand, if the first recognition event (signal 1) occurred alone, then tolerance would ensue. For self-antigens, to which the immune system is exposed early in life, tolerance would be the most likely outcome since the frequency of cells with specificity for such antigens would be very low indeed and their chances of meeting remote. For foreign antigens, which are not continually present, precursors specific for multiple epitopes could accumulate prior to contact with antigen, thus allowing a cooperative immune response to proceed. Subsequently the two-signal paradigm was modified to accommodate collaborative interactions between T cells, B cells, and APCs (Lafferty and Cunningham, 1975; Schwartz, 1993).

For B-cell responses, the current thinking may be summarized as follows: signal 1 is provided by antigen binding to the B-cell receptor (BCR) (Figure 13.1). In the case of T-dependent antibody responses, B cells present antigenic peptides to adjacent activated helper T (Th) cells. These cells express cell-surface CD40L and release B-cell stimulatory cytokines like interleukin (IL)-4, and the binding of these ligands to their specific receptors collectively delivers signal 2 to the B cell (Hodgkin and Basten, 1995) (Figure 13.1). The efficacy of the interaction is enhanced by pairs of costimulatory molecules, like CD28/CD86 and ICOS/ICOSL, present on the surface of T and B cells, respectively. In the case of T-independent antibody responses, direct interaction of antigen with B cells can provide signal 2 as well as signal 1. For example, some antigens (signal 1) can form complexes with DNA-derived CpG motifs, thereby leading to cross-linking of BCR with TLR9 (signal 2) and a productive antibody response (Leadbetter et al., 2002). Also, certain multivalent antigens, such as polymerized flagellin (Basten and Miller, 1974), or complement-fixing polysaccharides, such as Ficoll and dextran (Thyphronitis et al., 1991), can not only bind to the BCR (signal 1) but costimulate the B cell through interaction with the complement receptor, CD21 (signal 2). A corollary to the two-signal hypothesis is that the immunogenicity of antigen, i.e., whether it is "strong" or "weak," influences the decision between tolerance and immunity; weak antigens are those that cross-link the BCR poorly and/or fail to generate a second signal, e.g., deaggregated immunoglobulin or anti-Fab, and tend to be tolerogenic. Strong antigens, on the other hand, cross-link the BCR and recruit second signals efficiently. Examples include viruses and bacteria that elicit T-dependent responses as well as the multivalent T-independent antigens mentioned above.

In addition to the nature of the antigen, the decision between tolerance and immunity may be influenced by the duration of antigen exposure and its timing during B-cell development. Immature (including transitional) B cells as opposed to mature B cells are thought to be hardwired to undergo tolerance (negative selection) on exposure to antigen, possibly due to differences in the balance between pro- and anti-apopotic molecules of the Bcl-2 family (Marsden and Strasser, 2002). Such a scenario can explain why congenital rubella is associated with a failure by the fetus to eliminate the virus. On the other hand, intrauterine infections other than rubella can elicit a positive immune response (Nossal, 1957; Buchmeier et al., 1980) and tolerance can be readily imposed on mature B cells (see below). The key factor in some instances may therefore be the duration of antigen exposure rather than its timing. Thus, persistent BCR stimulation by low levels of antigen appears to favor tolerance, whereas immunity would be the outcome of sudden BCR engagement, as proposed in the danger hypothesis (Matzinger, 1994; Jun and Goodnow, 2003). Thus, the latter rather than the former scenario is more likely to be associated with rapid delivery of signal 2.

Requirement for Tolerance in B-Cell and T-Cell Repertoires

The B-cell repertoire is generated in two waves by distinct mechanisms that shape and modify the genes encoding the antigen-binding site of immunoglobulin molecules. The

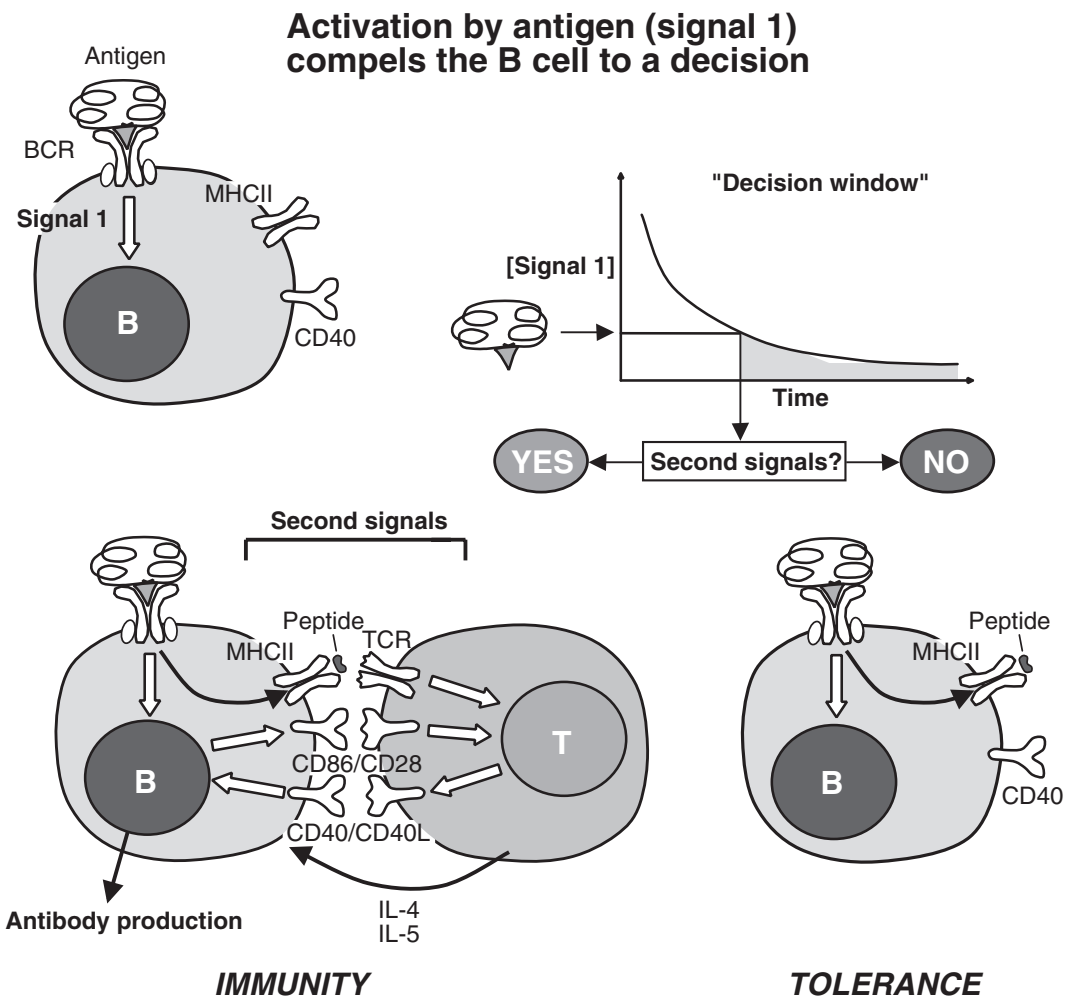

FIGURE 13.1 Two-signal hypothesis as it applies to B cells. Binding of antigen to the B-cell receptor (BCR) (signal 1) leads to primary activation. The B cell then has a finite amount of time to find a source of a second (costimulatory) signal. If it does, a productive response ensues. If it fails to do so, the cell will become tolerant and die. The time available for receipt of signal 2 is inversely proportional to the strength of signal 1. The case of a T-dependent B-cell response is shown here, where signal 2 is delivered collectively by multiple molecules expressed by activated T helper (Th) cells, such as cell-surface CD40L and the soluble cytokines IL-4 and IL-5. Effective collaboration with Th cells requires the B cell to both present peptide fragments of the antigen on class II MHC and to upregulate the costimulatory molecule CD86. Anergic B cells cannot upregulate CD86 in response to signal 1, which prevents them from receiving signal 2 from Th cells.

first is the process of VDJ gene recombination, which occurs in B-cell precursors within fetal liver and adult bone marrow. This process combines germline V, D, and J gene segments to form rearranged immunoglobulin heavy (VDJ) and light chain (VJ) genes. The products of these rearranged genes then combine to produce the nascent BCRs expressed on immature B cells and thus shape the primary B-cell repertoire. The second mechanism by which the B-cell repertoire is shaped is somatic hypermutation (SHM) of immunoglobulin variable region genes. This occurs largely in germinal centers (GCs) following B-cell activation and collaboration with Th cells, and generates what is referred to as the secondary B-cell repertoire. While the principal aim of both VDJ recombination and SHM is to diversify the B-cell repertoire in order to best deal with invading foreign antigens, the essentially random nature of both processes inevitably generates self-reactive B cells with the potential to produce pathogenic autoantibodies. The mechanisms whereby such clones are normally excluded from productive antibody responses represent the central issue in B-cell self-tolerance.

Following the discovery of the two-cell system and the demonstration of a helper function for T cells in antibody production by B cells in the late 1960s, it became apparent

that tolerance could be imposed on both T cells and B cells, although the threshold for its induction was lower in T cells (Chiller et al., 1970). This was accompanied by the notion of "low" and "high" zone tolerance in which small amounts of antigen led to T-cell unresponsiveness, whereas larger doses tolerized B cells as well as T cells. Moreover, the difference in the threshold of tolerance induction between T cells and B cells led Miller (1971) to suggest: "It may in fact turn out that tolerance to self components is a property confined exclusively to the T-cell population, tolerance in B cells being merely a laboratory artifice."

However, there are several reasons why an unpurged B-cell repertoire could pose a threat to the host. First, residual self-reactive B cells can be triggered by T-independent stimuli, such as the polyclonal activator CpG (type I T-independent antigen) or highly repetitive complement-fixing polysaccharides like those present on many capsulated bacteria (type II T-independent antigens). Moreover, self-reactive B cells play diverse roles in autoimmune responses; thus, the minority B1-cell subset is a major source of IgM autoantibodies with specificity for intracellular self-antigens (Casali et al., 1994), while class-switching B2 cells contribute to T-dependent autoimmune responses, either by secreting pathogenic IgG autoantibodies or by presenting self-antigens to activated $CD4^+$ T cells, which can then induce damage in target tissues. In nonobese diabetic (NOD) mice, for example, that spontaneously develop autoimmune (type 1) diabetes, B cells appear to play a direct role in disease pathogenesis, predominantly through the latter rather than the former mechanism (Silveira et al., 2004). There is also some evidence from animal models of rheumatoid arthritis that B cells may be directly pathogenic in joints. This may explain the efficacy of anti-CD20 monoclonal antibodies in treating this disease (Edwards et al., 2004).

Another reason why tolerance needs to be imposed on the B-cell as well as the T-cell repertoire is the situation where a self-reactive B cell may also recognize (cross-react with) a foreign antigen. Even if it is argued that T-cell self-tolerance alone would prevent self-reactive B cells from responding to endogenous antigens, cross-reactivity of such B cells with an epitope on an invading foreign antigen would effectively bypass T-cell self-tolerance by facilitating collaboration with nontolerant antiforeign T cells. A similar situation can arise when non-self-reactive B cells recognize a foreign antigen, collaborate with antiforeign T cells and undergo SHM of their immunoglobulin variable region genes in the GC. Because the nature of SHM is essentially random, B cells with new antiself specificities or increased affinity for self-antigens can appear in the GC and, if they still recognize the original immunogen, continue to receive T-cell help. The absence of self-tolerance mechanisms within either the primary or secondary B-cell repertoires would therefore significantly increase the potential for pathogenic autoantibody responses driven by antiforeign T cells. For all these reasons it is desirable for self-tolerance to be imposed on the B-cell as well as the T-cell repertoire.

MECHANISMS OF B-CELL SELF-TOLERANCE

Classification

Deletion as initially described by Burnet (1959) is not the only mechanism responsible for preventing autoimmunity. Rather self-tolerance has come to be regarded as a syndrome in which multiple mechanisms operate to polarize the immune response towards a negative outcome (Nossal, 1983). In addition to the landmarks in the evolution of the phenomenon of tolerance already mentioned, the past 30 years have seen the introduction of the idiotype regulation concept (Jerne, 1971), receptor editing (Gay et al., 1993; Tiegs et al., 1993), and the use of B-cell transgenic models for analyzing underlying mechanisms (see below). For convenience these mechanisms can be classified into *de novo* and regulatory (Tables 13.1 and 13.2). The former includes deletion and anergy, which operate throughout B-cell differentiation and contribute to the shaping of the repertoire, whereas regulatory mechanisms control the level of responsiveness in the mature B-cell pool without exerting a major effect on repertoire selection.

De Novo Mechanisms

The low frequency of antigen-specific B cells in the normal repertoire (approximately 10^{-3}–10^{-5}) made it difficult in the past to determine the relative importance of the various primary mechanisms of self-tolerance in the intact host. Although *in vitro* use of the surrogate antigen anti-immunoglobulin provided some clues about the normal fate of self-reactive B cells [reviewed in Nossal (1983; 1992)], definitive answers had to await the advent of transgenesis in the 1980s. By introducing transgene-encoded prearranged immunoglobulin heavy and light chain genes, mice were generated in which the majority of B cells expressed BCRs with a single defined specificity. These cells could therefore be tracked *in vivo* by flow cytometry using antiallotypic or anti-idiotype antibodies recognizing the transgenic BCR. Antigen-related as well as cellular variables in self-tolerance could therefore be studied by creating double transgenic mice consisting of a BCR transgenic line crossed with a second line expressing the corresponding self- or neo–self-antigen endogenously.

The overall conclusion from experiments in many such models is that B-cell self-tolerance is indeed mediated by a range of different mechanisms (Table 13.1). Among the most flexible and widely used double transgenic system is

TABLE 13.1 Primary mechanisms of B-cell self-tolerance

Mechanism	Site		Antigenic properties	Mode of action
	Central	Peripheral		
Deletion*	+	+	Multivalent high affinity	Activation of proapoptotic Bcl-2 family molecules
Receptor Editing*	+	–	Mulitivalent	Revised B-cell receptors (BCRs) with nonself specificities
Anergy*	+	+	Paucivalent soluble	BCR desensitization Lack of access to BAFF
Ignorance†	+	+	Low affinity Low concentration Poor access	No BCR recognition

*Result in exclusion of self-reactive B cells from mature B-cell pool.
†Self-reactive B cells present in mature B-cell pool.

TABLE 13.2 Secondary mechanisms of B-cell self-tolerance*

Mechanism	Examples	Mode of action
B-cell intrinsic	ITIM-containing motifs, e.g., FcγRIIb, CD22 Signaling molecules, e.g., Lyn, CD19	Increase threshold of B-cell receptor (BCR) activation and reduce B-cell expansion
B-cell extrinsic	Idiotype network	Neutralization of autoantibodies
	Classical complement pathway	Removal of apoptosing cells, guiding B cells to niches of negative selection
	Regulatory T cells	Reduce T-cell help for self-reactive B cells

*Operate mainly in peripheral lymphoid tissues.
ITIM, immunoreceptor tyrosine-based inhibition motif.

the hen-egg lysozyme (HEL)/anti-HEL BCR model originally developed by Goodnow et al. (1988) and recently modified such that the B cells can undergo switching from IgM to downstream isotypes (Phan et al., 2003). This, and other models where relevant, will be used to illustrate the various primary mechanisms of B-cell self-tolerance.

Deletion

Self-reactive B cells undergo negative selection on exposure to antigen at both immature and mature stages in their development within the bone marrow and peripheral lymphoid tissue, including the outer periarteriolar lymphatic sheath (PALS) of the T-cell zone and GCs (Russell et al., 1991, reviewed in Goodnow et al. 1995). Self-antigen in multivalent form favors deletion in the absence of signal 2, provided that a critical threshold of avidity is attained (Nemazee and Bürki, 1989; Hartley et al., 1991) (Figures 13.1 and 13.2). B1 cells as well as B2 cells are susceptible to deletion (Murakami et al., 1992). The molecular basis of B-cell deletion has yet to be fully worked out. However, the balance between pro- and anti-apoptotic members of the Bcl-2 family of molecules belonging to the classical mitochondrial pathway appears to be important for negative selection of B cells in the bone marrow and deletion of mature antigen-activated B cells in the periphery (Marsden and Strasser, 2002).

Receptor Editing

Self-reactive B-cell-expressing BCRs of medium to high affinity can also have their self-reactivity abolished by the process of receptor editing (Gay et al., 1993; Tiegs et al., 1993). Following engagement of BCR on immature B cells within the bone marrow, recombinase-activating genes (RAG 1 and 2) can be re-expressed, resulting in new VJ rearrangements at the immunoglobulin light chain loci. If a new light chain is successfully produced and the revised BCR loses self-reactivity, the B cell can then migrate to join the mature lymphocyte pool (Figure 13.2). During the past decade it has become apparent that receptor editing plays a more significant role in shaping the immature B-cell repertoire than deletion per se. Thus, in a recent study of B cells taken from patients with SLE, the relative contributions of the two mechanisms were found to be approximately 4 : 1, respectively (Wardemann et al., 2003).

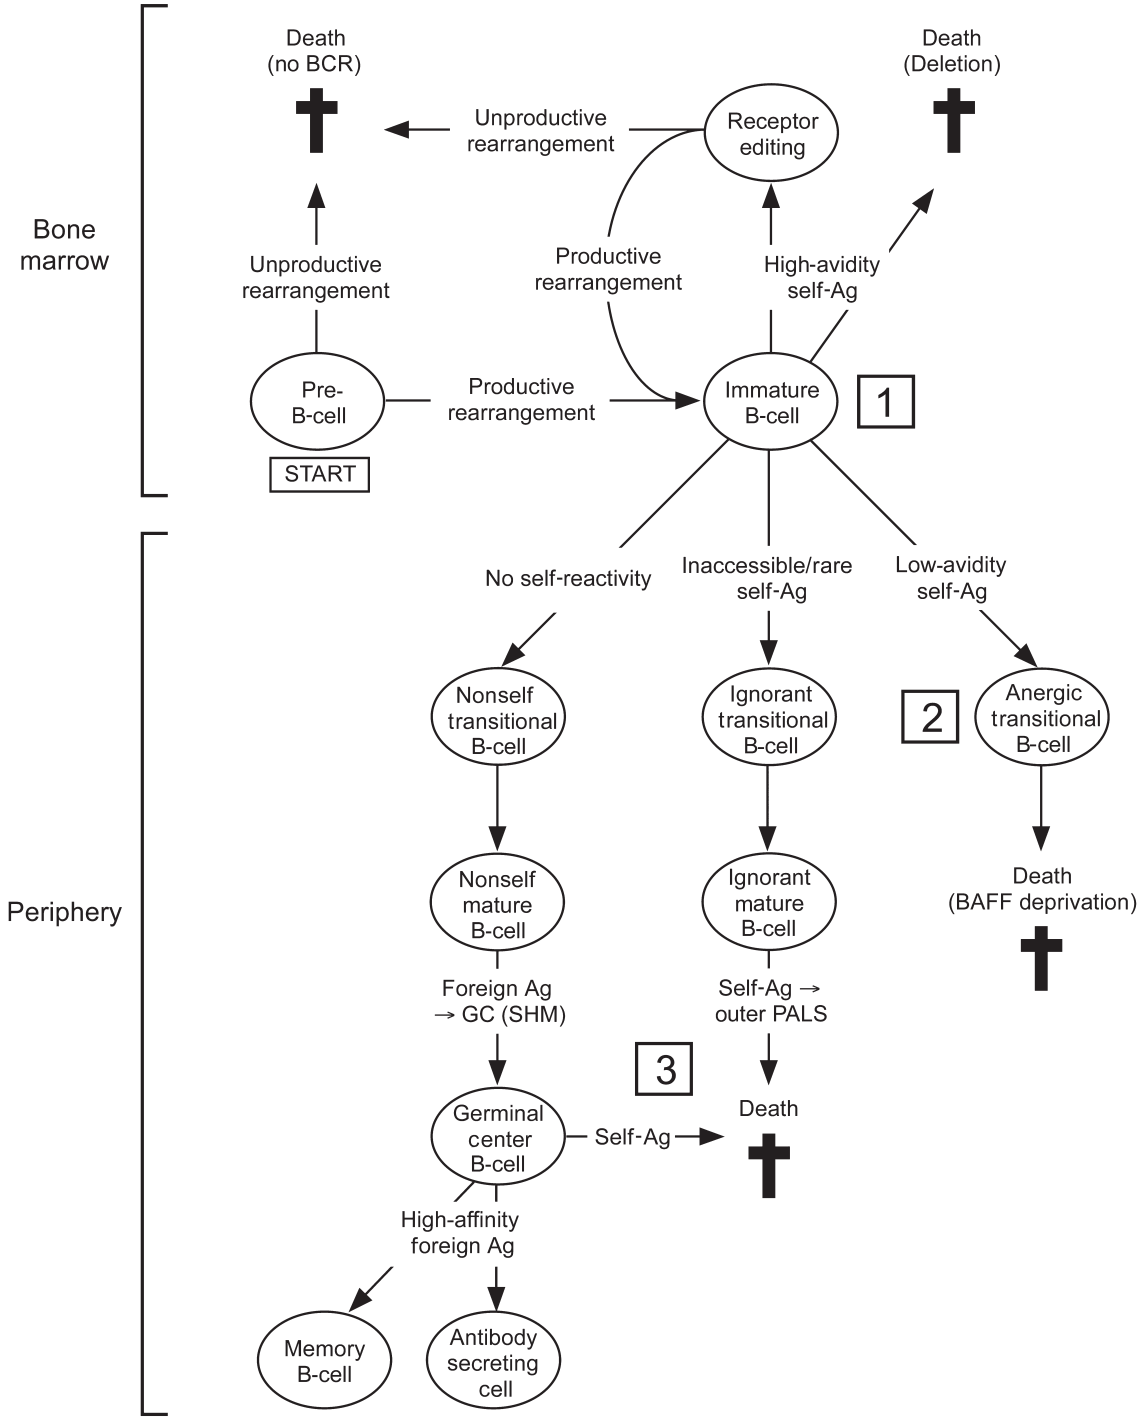

FIGURE 13.2 B-cell self-tolerance is enforced at multiple checkpoints during bone marrow and peripheral B-cell development. Self-reactive B cells are removed at three critical checkpoints during B-cell development: 1) following B-cell receptor (BCR) expression in the bone marrow (deletion or receptor editing); 2) at the immature transitional stage in the periphery (death of anergic B cells); and 3) following contact of mature B cells with antigen in the periphery (death of previously ignorant B cells and B cells that acquire self-reactivity in the germinal center (GC). See text for details. Ag, antigen; PALS, periarteriolar lymphatic sheath; SHM, somatic hypermutation.

Anergy

The term anergy was originally coined by Nossal (Nossal and Pike, 1980) to describe B cells which had *not been deleted but were functionally silenced* following *in vitro* cross-linking of BCR in the absence of second signals. Subsequently, anergy was clearly demonstrated *in vivo* in the HEL double transgenic model when transgenic B cells were exposed to soluble rather than multivalent neo–self-antigen (Goodnow et al., 1988). These anergic cells migrated from bone marrow to the splenic follicle to join the mature B-cell pool (Figure 13.2).

In the absence of competition from non-self-reactive B cells, anergic B cells survive in the periphery for several weeks. However, when normal levels of competition are present, the lifespan of anergic B cells drops to 2–3 days, effectively purging them from the mature B-cell pool. The reason for this effect is thought to be that anergic B cells do not compete efficiently for factor(s) required for B-cell survival and maturation. Recent studies using the HEL double transgenic model indicate that the factor in question is the B-cell survival factor, BAFF. Thus, anergic B cells respond poorly to BAFF and can be rescued from their normal early death when BAFF is overexpressed *in vivo* (Lesley et al., 2004; Thien et al., 2004). Increased expression of BAFF, as reported in patients with Sjögren syndrome and SLE, may therefore contribute to the pathogenesis of these autoimmune diseases by subverting the normal mechanisms of B-cell self-tolerance [reviewed in Mackay and Tangye (2004)] (See Chapter 11).

The principal biochemical lesion in anergic B cells is inactivation of signaling through the BCR (Cooke et al., 1994). In these cells there is a failure to activate the JNK and NF-κB pathways [reviewed in Jun and Goodnow (2003)] and to upregulate the costimulatory molecule CD86 required for antigen presentation to activated T cells, meaning that signal 1 is effectively inactivated. When this molecular lesion is taken in conjunction with the exclusion of anergic B cells from the long-lived B-cell pool, the outcome is a dramatic reduction in the risk of activation of such self-reactive clones by antigen-dependent or polyclonal stimuli (Phan et al., 2003).

Ignorance

Ignorance is not an active mechanism of self-tolerance; rather it refers to self-reactive B cells which are not anergic but persist in a potentially active state (Figure 13.2). This situation occurs if the binding of self-antigen to BCR is below a critical threshold (25–50% receptor occupancy) (Goodnow et al., 1988) or if self-antigen is expressed in a tissue not normally accessed by developing B cells (Akkaraju et al., 1997). The persistence of such cells poses a relevant threat to the maintenance of self-tolerance. For example, B cells reactive against vitreous-associated ocular antigens can produce autoantibodies if these normally inaccessible autoantigens leak into the circulation (Grisanti et al., 1994).

Regulatory Mechanisms

Superimposed on the *de novo* mechanisms of B-cell self-tolerance are a number of cellular and biochemical failsafe stratagems designed to control the level of B-cell responsiveness in peripheral lymphoid tissue once an autoimmune response has been initiated (Table 13.2). They can be divided into B-cell *intrinsic* and *extrinsic* mechanisms. Among the former are immunoreceptor tyrosine-based inhibitory motif (ITIM) surface molecules, such as FcγRIIb and CD22, which can reduce B-cell proliferation and/or raise the threshold of BCR signaling (Doody et al., 1996; Bolland and Ravetch, 2000). B-cell extrinsic factors comprise antibodies, complement, and its receptors, regulatory T cells, and an absence of T-cell help leading to "death by neglect."

In addition to feedback inhibition via FcγRIIb, antibodies may regulate ongoing B-cell responses through the *idiotypic network*, as originally proposed by Jerne (1971). The effect of this network was originally thought to be directed largely against B1 cells that produce polyreactive "natural" autoantibodies against a range of self-antigens, including nucleic acids, phospholipids, and cytoskeletal proteins (Casali et al., 1994). Recent work, however, has revealed significant levels of IgG anti-idiotypic specificities in normal human serum directed against pathologic as well as natural autoantibodies. Moreover, there is growing support for the concept that one of the modes of action of intravenous immunoglobulin (IVIG) in controlling autoimmune diseases like autoimmune thrombocytopenic purpura is related to the presence of anti-idiotypic antibodies capable of neutralizing the effects of antiplatelet autoantibodies (Kazatchkine and Kaveri, 2001).

The *classical complement pathway* appears to play an intriguing role in regulating autoimmunity by one of three mechanisms. The first and best known is related to the capacity of complement-binding immune complexes to be removed from the circulation. Depending on their size and charge, these complexes may either be rendered harmless, e.g., in the liver, or be deposited in the tissues, thereby causing damage. Secondly, complement fragments have been shown to enhance uptake and clearance, not just of soluble immune complexes but of apoptotic cells by phagocytes. The importance of this mechanism is related to the fact that blebs on apoptosing cells are highly immunogenic by virtue of their content of CpG-containing nuclear antigens. Thirdly, complement-containing self-antigen complexes may contribute to B-cell self-tolerance by guiding $CD21/35^{+}$ B cells to their stromal cell niches in bone marrow and spleen where negative selection normally takes place.

This mechanism may explain the enhanced susceptibility of C1q- and C4-deficient mice and humans to lupus, and of transitional B cells to tolerance, since the CD21/35 receptor complex is first expressed at this stage in B-cell differentiation and influences the threshold of BCR signaling [reviewed in Carroll (2004)].

Finally, T cells play an important role in the maintenance of B-cell self-tolerance in one of three ways. First, B2 cells, including those with antiself reactivity, have a finite lifespan in the absence of T-cell help and "die by neglect" following antigen encounter (Figure 13.1). Secondly, anergic self-reactive B cells are eliminated by a Fas-dependent mechanism should they be exposed to self-antigen and activated Th cells (Rathmell et al., 1995). Thirdly, and probably of greatest biologic significance for controlling antiself B cells as well as T cells, is the mechanism of *T-dependent regulation (suppression)*. After 20 years in the wilderness, regulatory T cells have re-emerged as important cells in preventing autoimmunity. Interestingly, B cells as well as T cells were originally thought to be the direct target of these cells (Adelstein et al., 1990). The current view, however, is that regulatory T cells appear to operate on B cells predominantly by interacting with other T cells, including $CD4^+$ Th cells, and are involved in the phenomenon of immune deviation or "split tolerance" (Parish, 1972). Like the other mechanisms in this category, regulatory T cells operate to control both antiforeign and antiself T-dependent responses.

Multiple Checkpoints of B-Cell Self-Tolerance

The diversification of the B-cell repertoire in two stages and at diverse anatomic sites highlights the necessity to have multiple "checkpoints" or filters for controlling self-reactivity in the B-cell lineage (Goodnow et al., 1995). This concept is illustrated in Figure 13.2. In brief, developing B-lineage cells that successfully express a BCR following VDJ recombination are subject to deletion or receptor editing in the bone marrow if they recognize a strongly cross-linking (e.g., cell surface) self-antigen (checkpoint 1). In conjunction with unsuccessful VDJ recombination, this results in the loss every day of approximately 75% of the 5×10^7 B-lineage cells generated by the mouse (Osmond, 1991). Of the remaining 25%, a further 15% die in the periphery at the sensitive transitional B-cell stage, including those recognizing more weakly cross-linking (e.g., soluble) self-antigens (checkpoint 2). The 10% of B cells that survive to become mature B cells again become susceptible to negative selection following exposure to antigens in the periphery (checkpoint 3). This occurs either at the outer PALS for previously "ignorant" self-reactive B cells due to lack of T-cell help, or in GCs where antiforeign B cells undergo SHM and potentially acquire self-reactivity for the first time. Superimposed on these deletional checkpoints, regulatory mechanisms operate to reinforce negative selection and to control the responsiveness of any residual B cells expressing antiself BCR.

AUTOIMMUNITY: A BREAKDOWN IN B-CELL SELF-TOLERANCE

A pool of self-reactive B cells comprising potentially responsive and anergic cells exists in peripheral lymphoid tissue (see above) with the capacity to generate pathogenic autoimmune responses in the event of a failure in self-tolerance. Broadly speaking, there are five situations that can lead to activation of this pool of self-reactive B cells, which are summarized here. Additional examples of autoimmunity are provided in Chapter 11.

In the first, T-cell self-tolerance is intact, but foreign antigen-specific T cells may interact with residual nontolerant self-reactive B cells. In other words, self-reactive (ignorant) B cells may present cross-reactive epitopes present on a foreign antigen (*molecular mimicry*) or a self-antigen modified by exposure to drugs or viruses to such antiforeign T cells [reviewed by Goodnow et al. (1990) and Hodgkin and Basten (1995)]. Examples of the former situation include rheumatic fever following Group A streptococcal infection and cold agglutinin disease following mycoplasma infection, while α-methyldopa-induced autoimmune hemolytic anemia and rubella virus-induced autoimmune thrombocytopenic purpura may represent instances of the latter [reviewed in Ebringer et al. (2003)].

Secondly, residual self-reactive B cells, even if they are anergic, can be stimulated directly by T-independent ligands such as lipopolysaccharide and DNA CpG motifs, which interact with TLR 4 and 9 on the B-cell surface, respectively [reviewed in Vinuesa and Goodnow (2002)]. Normally, such interactions lead to production of low-affinity IgM autoantibodies of little pathogenic significance. However, autoimmune-prone mice expressing large numbers of IgG2a self-reactive B cells, for example, contain IgG2a complexed with self-DNA or chromatin, which cross-link BCR with TLR9, resulting in high levels of circulating rheumatoid factor (Leadbetter et al., 2002). A similar mechanism may explain the occurrence of rheumatoid factors as well as contribute to "epitope spreading" in patients with systemic autoimmune diseases like rheumatoid arthritis, Sjögren syndrome, and mixed connective tissue disease.

In the third situation, T-cell tolerance is defective as it occurs, for example, in the autoimmune-polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome, which is due to mutations in the AIRE gene (Peterson et al., 2004). Since this gene regulates expression of self-peptides in the thymus, self-reactive T cells escape to the periphery where they can interact with nontolerant

(ignorant) self-reactive B cells, leading to secretion of multiple autoantibodies associated with a range of organ-specific diseases.

Fourthly, a primary defect may occur in self-reactive B cells per se, resulting in a breakdown in self-tolerance. For example, receptor editing is impaired in autoimmune-prone MRL mice and in some patients with lupus (Wardemann et al., 2003). Moreover, defective negative selection at the transitional stage of B-cell differentiation can also be a feature of lupus, while a P227A polymorphism in CD40 has been detected on B cells from members of several lupus families (Grammer and Lipsky, 2003). Superimposed on these B-cell-selective abnormalities are genetic defects in ITIMs, signaling pathways, and proapoptotic proteins, which further predispose to a breakdown in self-tolerance, often in T cells as well as B cells. The mouse models of autoimmune disorders associated with dysregulation of CD22 or FcγRIIb, lyn or CD19, and Bim, respectively, are all examples of this group of mechanisms (Cornall et al., 1998; see Chapter 11), as are the various types of human autoimmune lymphoproliferative syndrome (ALPS) characterized by mutations in Fas (or FasL) (Rieux–Laucat et al., 2003) (see Chapters 11 and 19). Of particular interest here is the recent finding that partial restoration of FcγRIIB levels on B cells from lupus-prone mice restores the tolerant state (McGaha et al., 2005) (See Chapter 70).

Finally, the defect may lie not in the primary but in the secondary mechanisms of B-cell self-tolerance related to complement-signaling pathways and regulatory T cells that control the level of responsiveness in peripheral lymphoid tissue (Table 13.2; see above). The association between autoimmunity and primary or acquired immunodeficiency states is one cogent piece of evidence supporting this possibility. Thus, in addition to the well-recognized linkage of SLE with primary complement deficiencies (Carroll, 2004) and of autoantibody-mediated hemolytic anemia with B-cell lymphomas, complicated by hypogammaglobulinemia, an increasing number of clinical situations as well as experimental models are being reported in which defective immune regulation predisposes to autoimmunity involving the B-cell lineage. Perhaps the most striking example is the immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome. In this primary immune deficiency, loss of function mutations in the FoxP3 gene expressed by natural $CD4^+CD25^+$ regulatory T cells can lead to certain organ-specific autoimmune diseases, inflammatory bowel disease, and allergy [reviewed in Nieves et al. (2004); see Chapter 9]. Moreover, about one-third of multiple sclerosis patients given the lymphocyte-depleting antibody, CAMPATH-IH, develop autoimmune thyroid disease (Coles et al., 1999). Collectively these examples lend strong support to the notion that immune dysregulation is of major importance in the development of autoimmunity.

This chapter focuses on the cellular strategy inherent in the creation of the self-determinants that become involved in autoreactivity. For an excellent and concise review of the biochemistry of T-cell receptor (TCR)–major histocompatibility complex (MHC)–antigen interaction, the reader is referred to Krogsgaard and Davis (2005).

NATURE OF AUTOANTIGENIC DETERMINANTS

Immunodominant, Subdominant, and Cryptic Determinants

Two decades ago, when T-cell determinant structures of model antigens were first characterized, a surprising observation was made: only a few regions of the intact pro-tein could elicit immune responses (Katz et al., 1982; Shimonkevitz et al., 1984). An initial theory to explain the unresponsiveness to other regions was simply that the T-cell repertoire was restricted and lacked receptors capable of responding to these other regions (i.e., holes existed in the T-cell repertoire). While examples of holes in the repertoire can be cited (Nanda et al., 1991; Moudgil et al., 1996), we favored the idea that a primary consideration for immunodominance was the competitive nature of the processing events within the antigen-presenting cell (APC).

The concept of dominance and crypticity was established with the use of T-cell proliferation assays. Dominant determinants were defined as regions of the protein molecule that could recall a strong *in vitro* proliferative response after the animal was primed with a whole-protein antigen. Cryptic determinants were defined as regions unable to recall such a response after the animal was primed with whole-protein antigen, but potentially excellent inducers of a proliferative response if used as the initial priming immunogen. Thus, outside their molecular context they were perfectly capable of initiating an immune response, but in the context of the intact protein antigen they were "invisible" to the immune system. It was hypothesized that dominant determinants were regions of the protein molecule readily processed by

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

the APC (Sercarz et al., 1993). In contrast, cryptic determinants were hypothesized to be poorly displayed after processing. However, certain cryptic determinants ("latent" or "facultative" cryptics) can be efficiently displayed under conditions of upregulated antigen processing and presentation (Lehmann et al., 1992; Moudgil and Sercarz, 1994; Opdenakker and Van Damme, 1994). Finally, there are determinants that fit between these extremes, "subdominant" determinants, which induce a weak-to-moderate level of T-cell response in comparison to the dominant determinants.

Thus, a determinant hierarchy exists on the surface of an APC. Determinant display hierarchies have now been confirmed by direct elution experiments. Unanue and colleagues (Viner et al., 1995) endogenously expressed hen-egg lysozyme (HEL) and then eluted the processed peptides from the surface of APCs, showing that relatively few regions of the intact molecule are presented by the APC. Since our original description of dominance and crypticity, other reasons for crypticity have been described (Grewal et al., 1995; Viner et al., 1995; Moudgil et al., 1996; 1998), and, although usually the case, there is not always a direct correlation between determinant display and T-cell proliferation.

Immunogenic, Dominant Self-Determinants, and the Self-Directed T-Cell Repertoire

Initially, it was thought that central and peripheral tolerance could effectively purge all self-reactive T cells. Although certain strains of mice were known to be susceptible to autoimmunity, self-reactive T cells were thought to be unique to these strains. It is now known, however, that all individuals harbor self-directed T cells capable of causing autoimmunity (Shaw et al., 1992; Abromson-Leeman et al., 1993; 1995). How do residual self-reactive responses remain if central and peripheral tolerances are so effective? Experimentally supported theories have arisen to explain how a potentially autoreactive T cell avoids tolerance induction. Most are centered on the principle that if presentation of a self-determinant in the thymus is too low (Gammon and Sercarz, 1989; Liu et al., 1995), negative selection will not occur and potentially autoreactive T cells will escape to the periphery (see Chapters 6 and 8).

Two types of sequestration can deny a determinant reasonable access to an MHC groove. In *geographic sequestration*, a self-determinant can be expressed in an immune-privileged site within the body (e.g., the eye) with no expression in the thymus (Griffith et al., 1995; Klein et al., 2000). However, several "geographically sequestered antigens" have now been shown to be expressed in the thymus. For example, the retinal antigen IRBP is expressed in the thymus at a low level, but consonant with inducing functional tolerance (Avichezer et al., 2003).

In fact, many other neuroproteins that had been thought of as sequestered can be found in the thymus (Pribyl et al., 1993; Feng et al., 2000; Klein et al., 2000). Interestingly, SJL mice mount a vigorous T-cell response to the self-peptide proteolipid protein (PLP) 139–151 due to a high precursor frequency of 139–151-specific T cells. This intact repertoire of self-reactive T cells exists because a splice variant (DM20) of PLP, which lacks the 139–151 portion, is the form of PLP expressed in the thymus. Thus, tolerance is achieved to all potential determinants on PLP with the exception of this region, leaving a 139–151 repertoire particularly poised to cause autoimmunity (Klein et al., 2000).

A similar situation exists with respect to a principal human HLA-DR2-restricted epitope, amino acids 85–99 of myelin basic protein (MBP), the display of which is inversely related to the level of a cysteine protease, asparaginyl endopeptidase (AEP). Since AEP is well expressed in the thymus, the presentation of 85–99 is low, allowing 85–99-specific T cells to escape tolerance induction (Anderton et al., 2002; Manoury et al., 2002). Thymic expression of self-antigens is also dependent in part on the AIRE (autoimmune regulatory element) protein, which is a transcription factor that promiscuously promotes expression of genes that are otherwise unique to other tissues (pancreatic antigens, thyroid antigens, myelin antigens). Lack of this factor results in multisystem autoimmunity (see Chapter 8). Nevertheless, as emphasized above, although many self-antigens are displayed, only some determinants on each antigen will become visible to ambient T cells.

In *molecular sequestration,* weakly displayed determinants: 1) are poorly processed from the native molecule; 2) have a poor binding affinity for the MHC molecules; 3) are out-competed for binding to the MHC class II molecules by a flanking determinant(s) (Maverakis et al., 2000b); or 4) are degraded by exopeptidases as a result of residing too close to another determinant that was successfully "captured" by a different MHC molecule.

The theory of molecular sequestration is based on the existence of hierarchies of determinant display for each self-protein, established by the processing and presentation mechanisms of the APCs' MHC class II pathways (Sercarz and Maverakis, 2003). It is essentially based on the affinity of the MHC molecule for different determinants within the protein and the location of these determinants with respect to antigen-processing sites within the protein (Schneider et al., 2000), and is subject to various secondary effects, such as hindrance by flanking residues (Grewal et al., 1995; Moudgil et al., 1996), competition by flanking determinants (Maverakis et al., 2003; Seamons et al., 2003; Sercarz and Maverakis, 2003), and effects contributed by the chaperone H-2M and H-20 proteins (Nanda and Sant, 2000).

Self-reactive T cells specific to well-displayed self-determinants are subject to the strongest tolerogenic pressures. With regard to well-displayed self-determinants,

tolerance generally eliminates the highest-avidity self-directed T cells, although with medium-to-poor determinant display, as is the case with subdominant and cryptic determinants, respectively, much of the available repertoire may remain intact. Thus, the self-directed T-cell repertoire will be deficient in high-affinity cells capable of responding to well-expressed determinants (Cibotti et al., 1994; Maverakis et al., 2000a), but will maintain a high-affinity repertoire to the cryptic self because the presentation of these determinants is insufficient to induce strong tolerance. The subdominant self-directed repertoire will be comprised of cells of intermediate affinity but should be deprived of most cells of high affinity for MHC–antigen.

The relationship between determinant hierarchies and tolerance induction has been supported experimentally. In studies with the model antigen, hen egg-white lysozyme, it was shown that B10.A (H-2^a) mice, when immunized with the intact protein, responded to certain codominant determinants, including HEL peptide 46–61. When animals were tolerized to whole HEL, responsiveness to the dominant peptide disappeared, but peptide responses to subdominant and cryptic determinants could still be elicited (Gammon and Sercarz, 1989). More interestingly, the degree of responsiveness to these subdominant/cryptic determinants was proportional to the amount of antigen used in the tolerance induction (Gammon and Sercarz, 1989). Likewise, when BALB/c (H-2^d) mice were made transgenic for HEL, making HEL a neo-self-antigen, the T-cell repertoire directed against the dominant I-E^d determinant, HEL:106–116, was functionally neutralized (Cibotti et al., 1992). By comparing the HEL-specific immune response of the HEL-transgenic mice to that of the nontransgenic H-2^d animals, it was discovered that T cells directed toward well-displayed "dominant" self-determinants are preferentially tolerized. Interestingly, the degree of tolerance induction was again found to be directly related to the amount of HEL expressed in the HEL-transgenic animal (Cibotti et al., 1992). Thus, although there was some residual responsiveness to HEL determinants in the transgenic animals, the HEL-specific T-cell repertoires of transgenic and wild-type animals were quite different. Likewise, the MBP-specific T-cell responses in MBP-deficient mice have been described as functionally different from those seen in MBP-expressing animals (Harrington et al., 1998; Targoni and Lehmann, 1998; Yoshizawa et al., 1998), as are self (mouse) lysozyme (ML) – specific T cell responses in the wild type versus ML knock-out mice (Sinha et al., 2004).

PROCESSING CREATES THE SELF

Antigen Processing

Antigen-processing events, both in the thymus and the periphery, influence the spectrum of determinants available to T cells, through influencing the display of dominant determinants, which either positively or negatively select the available repertoire. In the class II MHC processing program, both long and short peptides can bind to the open-ended groove. Whole molecules can bind to class II molecules, but some determinant(s) must be rendered available for binding, either by endopeptidases and/or disulfide bond reduction (Sercarz and Maverakis, 2003). The first endopeptidic cut provides mobility and availability to the stretches of peptide flanking the cut, and therefore, a determinant in this region is likely to be the first to bind to the MHC, and if the binding is of relatively high affinity, to become a dominant determinant on the antigen (Sercarz and Maverakis, 2003).

When a long peptide binds at a single site, the flanking ends will presumably become radically shortened, owing to exopeptidase action as well as some additional endopeptidase cuts, until peptide fragments of 13–22 amino acids are the majority remaining, with ends protruding from the MHC class II groove. Intriguing evidence for the binding of large fragments of HEL (Castellino et al., 1998) showed that many larger peptides with molecular weights between 3000 and 7000 Da could be eluted from either I-A or I-E molecules. Furthermore, complexes of 120 kDa could be found in the endocytic pathway, with a single HEL polypeptide chain of about 70 amino acids bound to two different MHC class II isotypes, I-A and I-E. This shows that binding of MHC class II molecules can occur before excessive antigen processing takes place.

Another set of experiments with HEL (Schneider et al., 2000) tested the proposition that a cryptic determinant could be rendered into a dominant one, if a processing site susceptible to an endopeptidase from the family of proprotein convertases (Seidah and Chretien, 1997) could be created adjacent to the determinant in question. This was accomplished by mutating a single residue on HEL to create a dibasic target site. The mutant HEL, with the extra processing site, induced a dominant response from a previously cryptic determinant. The importance of reductases was shown with the enzyme, interferon-γ-inducible lysozomal thiol reductase (GILT). A GILT knock-out mouse was able to respond to determinants with a single cysteine residue, but failed to respond to a tightly folded, double disulfide bond region of HEL which was immunogenic in the wild-type H-2^k mouse. Interestingly, the presentation of the dominant determinant of HEL, 46–61, was affected by GILT, even though it does not contain a cysteine, because in the absence of GILT there was a failure to reduce the nearby disulfide bond, cys64–cys80, and a consequent lack of response to 46–61 (Maric et al., 2001).

A final example with direct relevance for autoimmunity concerns MBP. The enzyme AEP was identified as the endopeptidase (Manoury et al., 1998) that could make the first cut in various proteins at a motif containing a crucial

asparagine. In the region between amino acids 89 and 101 of MBP, there are three overlapping determinants for the SJL mouse, MBP(89–94), MBP(92–98), and MBP(95–101), each binding to the same MHC molecule, and therefore subject to competition for the binding groove. In the absence of AEP the central determinant was dominant; however, AEP was shown to cleave MBP at position asn94, resulting in the destruction of this determinant, which allowed the flanking determinants to gain a degree of freedom from constraints of molecular rigidity and seclusion (Anderton et al., 2002). Accordingly, a flanking cryptic determinant indirectly achieved dominance in this situation.

Another site that is consequential in the race to be dominant concerns the removal of the invariant chain CLIP peptide from its position guarding the MHC class II groove. This is accomplished by two nonpolymorphic MHC molecules, DM and DO, which are special agents that supervise the occupation of the class II binding site. The DM/DO chaperone molecules play a crucial role in fostering the exchange for the CLIP peptide, and DM is also involved in a peptide-editing function, acting to favor the presentation of dominant epitopes and to disfavor recessive epitopes (Nanda and Sant, 2000). In DM knock-out mutants in H-2^d and H-2^k mouse strains, there is a selection away from dominant epitopes and toward the appearance of responses to novel epitopes (Nanda and Bikoff, 1995). There is also a DM-independent pathway which simply involves removal of Ii from MHC class II molecules (Wolf and Ploegh, 1995), followed by the binding of various large multideterminant fragments, which can be termed "prodeterminants" (Sercarz et al., 1993). The binding to class I MHC molecules is entirely different, following enzymatic activity by the proteosome, which cleaves the antigen into much smaller peptides, although these can be somewhat longer than the 8–10 amino acid length that fits snugly into the class I MHC, close-ended groove. Interestingly, a cytosolic pathway for MHC class II-restricted determinants has also been recently discovered (Tewari et al., 2005). This process is proteosome and transporter associated with antigen processing (TAP) dependent. Since the pathway may be restricted to virally infected dendritic cells (DCs), its role in the presentation of self-determinants is still uncertain.

The interactions of processing enzymes are quite complex, one example being the relative activities of cathepsin S and cathepsin L in controlling invariant chain degradation. The latter is active in thymic epithelial cells and kidney epithelium, but not in intestinal epithelium cells (IEC), while cathepsin S predominates in MHC class II maturation and presentation *in vivo* in professional as well as some nonprofessional cell types, such as IEC. Despite the dominance of cathepsin S in the IEC, cathepsin L is present, but is inhibited by cystatin F (Beers et al., 2005).

Thus, the nature of another hierarchy, that arising from the competition between processing enzymes, will determine the all important "first endopeptidic cut" that establishes in turn the hierarchy of peptide choice for the dominant determinant on the antigen. This determinant will be the one that, possibly among others, induces self-tolerance and in that sense, establishes which are the "self-determinants" (those which induce tolerance).

Influence of T-Cell and B-Cell Repertoires on Determinant Dominance

The T-cell repertoire can have a commanding role in the establishment of the dominant elements of a self-antigen. As one illustrative example, the dominant determinant on MBP in the B10.PL mouse strain is the N-terminal Ac1-9 or Ac1-11. This is the case despite the fact that other determinants on MBP (e.g., amino acids 7–16 or 121–140) bind with much higher affinity to the I-A^u MHC molecule. It is likely that those determinants induce tolerance in the complementary T-cell repertoire, but the poorly binding Ac1-9 does not, and because its neighboring, flanking determinants are of higher binding affinity, Ac1-9 is probably unable to compete at all for the I-A^u binding groove (Maverakis et al., 2003; Seamons et al., 2003). This permits the high-affinity clone, 172.10, to evade negative selection and to survive in the periphery to become the dominant clone after the administration of MBP. Accordingly, even though the MHC does play a role in this affair, the high-affinity T cell that evades tolerance is the direct agent that appears to contribute most to the dominance of Ac1-9; in fact, such high-affinity "escapees" are probably very influential in many autoimmune diseases.

In the above example, the strong encephalitogenic type 1 helper T (Th1)-cell response of the 172.10 Ac1-9–specific T-cell clone is likely dictated in part by the cell's high-affinity TCR. The 172.10 receptor is encoded by a Vβ8.2Jβ2.7 genetic recombination resulting in a CDR3 length of nine amino acids (Urban et al., 1988). This receptor has been shown to have a high affinity for the Ac1-9–I-A^u complex and the T cell responds to Ac1-9 in a Th1 fashion (Garcia et al., 2001). Other experimental systems have also investigated the role of the TCR in establishing a Th1 versus Th2 response. Janeway and colleagues (Blander et al., 2000) introduced a single amino acid substitution at a peptide-contacting residue within a TCR. The altered TCR had a 100-fold reduced affinity for the MHC peptide complex and responded in a Th2 fashion to antigenic challenge. Similarly, other investigators have shown that Th1 and Th2 populations can differ with respect to their TCRs (Foucras et al., 2000; Maverakis et al., 2000a). It is noteworthy that the class of T-cell response, Th1 versus Th2, can also be influenced by the antigen–MHC interactions. A very high-affinity ligand leads to a dense array of specific complexes on the APC surface, which favors a Th1 response. Changing a single amino acid on the ligand, to greatly

reduce its MHC-binding affinity, leads to a Th2 response (Kumar et al., 1995). These results are in accord with the idea that dense matrices and broad areas of contact between T cells and APCs strongly influence responsiveness in a Th1 direction.

The B-cell repertoire also can play a somewhat indirect role in the dominance of certain T cells. In this case, the scenario finds a rather predominant member of the B-cell repertoire directed against the self-antigen, which binds to the native antigen at a particular point, which can be called W, in the determinant sequence UVWXY. W, along with its flanking ends, UV and XY, are taken up by the B cell in question. The binding between the antigen and BCR can then lead, for example, to the enhancement of the reactivity of U or V, as well as the lessening of the reactivity of X or Y with the TCR. Such cases have been elegantly described by Watts and Lanzavecchia (1993), as well as in earlier studies (Manca et al., 1985).

STRUCTURAL FEATURES DETERMINING THE IMMUNOGENICITY OF ANTIGENIC DETERMINANTS

In an effort to define the molecular basis of dominance and crypticity of antigenic determinants, we have studied the pattern of immunodominance of determinants within HEL in mice of different MHC haplotypes, as well as in MHC-congenic strains. Results from 19 mouse strains bearing 11 different MHC haplotypes demonstrate that practically every 14–16-mer region within HEL could harbor an immunodominant determinant (Moudgil et al., 1997b). Furthermore, in mice with identical non-MHC genes but different MHC haplotypes, the pattern of dominance was quite different. These results suggest that despite presumably identical antigen-processing machinery, the display of dominant determinants within HEL was primarily determined by the MHC of the host. Thus, there are no inherent structural constraints in display of determinants in any region of HEL. In an earlier study from another laboratory on the relationship between MHC polymorphism and T-cell response to determinants within bacteriophage λ repressor protein, cI, it was observed that cI-reactive hybridomas raised in mice of different MHC haplotypes demonstrated reactivity to determinants spread all over the molecule (Roy et al., 1989). However, in most strains of mice, T-cell responses focused on only a few determinants of cI.

In a similar study, but based on self (mouse)-lysozyme (ML), we have determined the pattern of crypticity of determinants within ML in MHC-congenic mouse strains. Results again indicated that crypticity is MHC-associated and that there are no special structural features that render a determinant cryptic (Moudgil and Sercarz, 1994).

The above results on the association between MHC haplotype and dominance/crypticity of antigenic determinants have important functional significance with regard to induction of autoimmunity. The importance of this association is further underscored by the strong link between a particular MHC allele and the susceptibility to an autoimmune disease (see Chapters 5 and 20).

One of the chief prerequisites for initiation of a T-cell response is the availability and accessibility of the appropriate determinant. Factors that could compromise the immunogenicity of a potential determinant are described below.

Hindering MHC Interaction with Antigen

The presence of hindering residues within a product of processed native antigen was proposed by Brett et al. (1988) in their study on equine myoglobin (Emb). It was suggested that the flanking residues of an Emb determinant hindered its interaction with the Ak molecule but not with the As molecule. Similar observations of either inhibition or stimulation of T-cell reactivity by residue(s) flanking a minimal determinant or even far away from it have also been reported (Shastri et al., 1986; Bhayani et al., 1988; Vacchio et al., 1989; Liu et al., 1991; Kim and Jang, 1992).

In the case of a determinant within region 46–61 of HEL, we have observed that peptide 46–61 (p46–61) is immunogenic in C57BL/6 mice but only when the bulky C-terminal arginine residue (R61) is either deleted or replaced by an alanine residue (Grewal et al., 1995). Thus, p46–61 of HEL is nonimmunogenic in B6 mice, whereas p46–60 and p46–61(R61A) induce a good T-cell response in the same mouse strain. However, T cells primed by p46–60 cannot be recruited by native HEL and vice versa, suggesting that the immunogenic determinant within p46–60 is cryptic in nature. Unlike other cryptic determinants that are usually good immunogens in the peptide form, the cryptic determinant within p46–61 could only be revealed by using p46–60 instead of p46–61. Upon further examination of the mechanism of unresponsiveness of p46–61, we found that p46–61 did not bind at all to the A^b molecule, whereas p46–60 bound quite well. Thus, R61 hindered the binding of p46–61 to A^b. We have termed this determinant a "silent" cryptic determinant because even within the context of the peptide p46–61, it is cryptic in the C57BL/6 mouse.

Interestingly, another H-2^b strain, C3H.SW, could raise a strong proliferative response to p46–61 as well as to p46–60 following immunization with HEL. Thus, in this strain, the determinant within the region 46–61 behaved as a dominant determinant. We further observed that, unlike B6 mice, C3H.SW APCs could "fine-process" p46–61 to remove R61 and thereby display the immunogenic determinant. Thus, the inability of B6 mice to fine-process p46–61, possibly owing to absence of a carboxypeptidase, rendered

this determinant a nonimmunogenic, silent cryptic determinant. Extrapolating this model antigenic determinant to an autoimmune situation, it is conceivable that a defect in the antigen-processing machinery would preempt the induction and/or perpetuation of autoreactivity. On the contrary, if this determinant were involved in immune regulation, the same defect would compromise the host's ability to keep the autoreactive T-cell response under control, and thereby the host could succumb to a chronic, autoimmune disease.

Hindering MHC-Antigen Interaction with Cell Receptor

In another experimental system, we observed that p46–61 of ML, which binds well to the A^k molecule (but not to the E^k molecule), gave a strong proliferative T-cell response in CBA/J and B10.A mice (both A^k, E^k), but was nonimmunogenic in B10.A(4R) mice (A^k, E^o) (Moudgil et al., 1996). There are two arginine residues (R47, R61) in ML p46–61. This peptide could be rendered immunogenic in B10.A(4R) mice either by removal of arginine residues or by their substitution with alanine (or Phe, Leu, Lys, or Asn). Thus, in fact, B10.A(4R) mice have the T-cell repertoire to respond to the core residues between the arginine residues. From these results, we concluded that bulky arginine residues, flanking the core within ML p46–61, hindered the TCR-A^k–p46–61 complex interaction (epitopic hindrance), and thus, rendered this peptide nonimmunogenic in B10.A(4R) mice. Additionally, B10.A and CBA/J mice circumvent this hindrance by recruiting a subset of T cells whose TCRs can accommodate arginine residues within p46–61 bound to the A^k molecule. These T cells were presumably positively selected on peptides from the $E^k/D^d/D^k$ molecules encoded within the MHC E^kD^k region that was deleted in B10.A(4R) mice during the recombination event.

In another study on staphylococcal nuclease (Nase), it was similarly proposed that residues flanking a minimal determinant within Nase might be responsible for interfering with the interaction between the TCR and its complementary MHC–peptide ligand (Liu et al., 1991). The above results demonstrate that a self-/foreign determinant could be rendered nonimmunogenic owing to hindering residues flanking a minimal immunogenic determinant. In the context of autoimmunity, these results predict that susceptibility or resistance to induction of an autoreactive T-cell response could be determined by the availability of appropriate T cells, whose selection might be dependent on a particular MHC haplotype. In this regard, a particular MHC molecule would indirectly behave as a susceptibility allele. Furthermore, in the setting of inflammation, upregulated/altered antigen processing might result in removal of a hindering residue from an autoantigenic determinant, making the host susceptible to autoimmunity.

"Determinant Capture" During the Unfolding of Native Antigen

Another mechanism that could result in a lack of response to a potentially immunogenic determinant is based on preferential, strong binding of a determinant to one of the MHC molecules during unfolding of the native antigen, and concomitant, inadvertent capturing of the neighboring determinant restricted to another MHC molecule ("determinant capture") (Cogswell et al., 1988; Deng et al., 1993). Thus, the neighboring determinant is preempted from inducing a T-cell response. This concept of determinant capture is based on the role of the MHC in guiding processing of determinants within a multideterminant antigen (MHC-guided processing) (Sercarz, 1986; Sercarz et al., 1993; Ojcius et al., 1994a; 1994b; Sercarz and Maverakis, 2003). We gathered evidence for this hypothesis in an experimental system using nonobese diabetic (NOD) mice (I-A^{g7}, E^0) (Deng et al., 1993). We observed that NOD mice immunized with native HEL raised proliferative T-cell responses to determinants having the core sequences 14–20 (dominant determinant) and 95–102 (subdominant determinant), whereas BALB/c mice (A^d, E^d) responded to one immunodominant determinant having the core sequence 108–116, which is E^d restricted. Interestingly, (NOD × BALB/c)F1 mice immunized with HEL raised strong proliferative T-cell responses to determinants 14-20/I-A^{g7} and 108-116/I-A^d, whereas the T-cell response to determinant 95–102/I-A^{g7} was completely lost. We hypothesized that in (NOD × BALB/c)F1 mice, the unfolding HEL molecule bound strongly to the E^d molecule in the region 108–116. Consequently, the neighboring determinant 95–102 was carried along with the determinant 108–116, and thus, was preempted from binding to the A^{g7} molecule, presumably by exopeptidase trimming.

We tested the above hypothesis by using the cyanogen bromide (CNBr)-treated HEL molecule (Deng et al., 1993). CNBr cleaves HEL at positions 12 and 105 and thus, by separating determinants 108–116 and 95–102, should provide increased flexibility and availability for determinants near the cleavage point. Strikingly, we found that F1 mice challenged with CNBr-treated HEL not only responded to determinants 14–20 and 108–116, but also raised a potent response to the determinant 95–102. Thus, cleavage of HEL at position 105 allowed the neighboring determinant, 95–102, to bind freely to the A^{g7} molecule and thereby to induce a T-cell response that was much better in the F1 than that in the NOD mouse itself!

The above results provide a conceptual basis to explain the findings from several studies of protection from autoimmune diabetes in NOD mice by introducing an additional class II MHC molecule (Nishimoto et al., 1987; Slattery et al., 1990), as well as to demonstrate how diabetes-susceptibility/resistance alleles (Nepom, 1990a; 1990b;

1990c) could exert their influence. Presumably, the newly introduced MHC molecule could bind to the diabetogenic autoantigen at a site in close proximity to a major pathogenic determinant. As a consequence, a critical pathogenic determinant would be captured in this process and rendered unable to bind to the A^{g7} molecule for induction of a T-cell response. Projection of the above experimental observations to the heterogeneous human population predicts that one crucial factor in determining susceptibility or resistance to a particular autoimmune disease would be the *combination* of different MHC molecules expressed within the APCs of a given individual. In this context, the mere presence of a "susceptibility" allele might not be a real risk factor. Instead, the presence or absence of a suitable "protective" allele, operating through determinant capture, would determine the final outcome of events.

One mechanism underlying the association between MHC haplotype and particular diseases was recently shown in the case of two HLA-B27 subtypes, only one of which is associated with ankylosing spondylitis. The subtypes differ only at a single amino acid residue, position 116 in the peptide-binding groove. The susceptible one, B*2705, but not the resistant one, B*2709, can bind a disease-associated self-peptide in two distinct conformations, one of which particularly selects a disease-initiating T-cell repertoire. Thus, the differential binding pattern of a dangerous peptide to the two subtypes has a crucial influence on susceptibility to an autoimmune disease (Hulsmeyer et al., 2004).

PUBLIC AND PRIVATE T-CELL REPERTOIRES AND DRIVER CLONES

Public and Private Repertoires

The HEL-specific immune response in the BALB/c mouse is a classical example of T-cell determinant hierarchies and has proved to be an excellent model to characterize the antigen-specific T-cell repertoire. Kourilsky and colleagues (Cibotti et al., 1994) coined the term "public" clonotype to describe an expansion of T cells consisting of a clonotype that can be isolated from all individuals of a particular MHC haplotype after identical antigenic challenge. In contrast to the public response, a "private" repertoire is not found in every animal. For example, adult BALB/c mice immunized with HEL mount a T-cell response utilizing a "public" Vβ8.2Jβ1.5 T-cell clone characterized by a CDR3 length of eight amino acids, GTGNNQAP (Cibotti et al., 1994). [The complementary determining region 3 (CDR3) is a region of the TCR involved in antigen recognition.] The phenomenon of private and public responses has now been observed for several other model antigens and has been shown to exist also in humans and rainbow trout (Saubermann et al., 1999; Boudinot et al., 2001). Owing to the nature of junctional diversity, public responses, although identical at the amino acid level, can differ at the genetic level.

Concept of Driver Clones

The immune response to a particular determinant is usually heterogeneous, with several different clones expanding to a particular antigenic stimulus (Manca et al., 1984). Despite this heterogeneous response, a minority clonotype can play a role as a crucial "driver" in the initiation and propagation of autoimmunity. Our laboratory has been studying driver clones in the MBP B10.PL model of autoimmunity. In this system, experimental autoimmune encephalomyelitis (EAE) can be induced by immunizing B10.PL animals with MBP or its immunodominant determinant Ac1-9. By comparing the peripheral self-directed Ac1-9-specific T cells to those actually infiltrating the spinal cord, it was discovered that some self-directed clones played a more important role in the initiation and propagation of disease than others. For example, some clones that were expanded in response to Ac1-9 never infiltrated the spinal cord or did so only at very late stages of disease. The encephalitogenic potential of the driver response was suggested by: 1) their presence in the spinal cord during the acute phase of disease; 2) their positive reactivity in each animal to the inducing antigen; 3) a proinflammatory cytokine profile; and 4) the appearance of spontaneous disease when their TCR is expressed as a transgene (Menezes, J. et al., personal communication). Following the public "driver" repertoire through the induction and resolution of EAE demonstrates that during the natural process of recovery, the "driver" portion of the self-directed response is selectively purged, resulting in a repertoire shift which leaves behind a set of self-directed, non-central nervous system (CNS)-infiltrating T cells. During recovery, other private myelin-specific T cells remain available for antigen recognition, but they are unable to cause disease. When magnetic beads were used to separate the IFN-γ–secreting cells, the public (Vβ8.2Jβ2.7) response was exclusively found within the IFN-γ–secreting population (Menezes, J. et al., personal communication). Contrariwise, private members could be found secreting either IFN-γ or IL-4. Interestingly, the majority of the IFN-γ-secreting private repertoire never entered the CNS. Thus, not all self-reactive IFN-γ-secreting T cells are pathogenic.

We have identified public autoreactive T cells in other models of autoimmunity as well, including the PLP SJL model of EAE (A. Ametani, unpublished data) and the NOD model of type I diabetes (Quinn et al., personal communication). In addition, in both the SJL and B10.PL mouse models of autoimmunity, we have found self-directed public responses that do not play key roles in the disease process: self-reactive public T-cell clones are not always pathogenic.

Likewise, we have not excluded the possibility that a private response might play an accessory role in the induction and propagation of autoimmunity, although to date we have not found such an example.

In summary, of the vast number of self-reactive T cells, only a small fraction comprise the pathogenic population. In addition, recovery from an autoimmune episode correlates with a repertoire shift in which the pathogenic members of the self-reactive response are purged while a more benign set of T cells remains. It is worth noting that those dominant determinants, T cells specific for which have evaded negative selection, are often the inducers of driver clones.

MOLECULAR MIMICRY AND DEGENERACY

As pointed out earlier, there is a large repertoire in the normal animal specific for self-determinants, which fortunately is rarely successfully engaged for a pathogenic purpose. This repertoire can be activated following exposure to antigens of a pathogen, provided the foreign determinant mimics a self-determinant (molecular mimicry). This margin of safety which reduces the danger of unexpected mimicry might have been predicted because of the necessity for any cross-reactive determinant on a viral or microbial entity to be dominant so as to elicit a response in the first place, and concomitantly, for the self-determinant to be cryptic, so that a repertoire might still exist against it, and not have been negatively selected. But in addition to these ground rules, there is another overriding feature of immune recognition that must be understood with respect to mimicry, and that is degeneracy.

Within the past decade, it has become clear that T lymphocyte recognition is degenerate. Degeneracy, in contemporary immunologic usage, describes the ability of a single receptor to recognize and react to a heterogeneous assortment of ligands, with each lymphocyte clone having its own pattern of degeneracy (i.e., its own set of stimulatory ligands) (Bankovich et al., 2004; Christen and von Herrath, 2004; Cohen et al., 2004; Cunningham, 2004; Fae et al., 2004; Ford and Evavold, 2004; Fourneau et al., 2004; Holler and Kranz, 2004; Im et al., 2004; Judkowski et al., 2004; Nicholson and Wraith, 2004; Nino-Vasquez et al., 2004; Nishimura et al., 2004; Olson et al., 2004; Parnes, 2004; Sercarz and Maverakis, 2004; Shih and Allen, 2004; Shukaliak Quandt et al., 2004; Singh, 2004; Wilson et al., 2004; Wucherpfennig, 2004; Zhou and Hemmer, 2004). A reasonable estimate is that there may be 10^{18} such epitopes that need to be distinguished by the immune system. In a human, there is a finite number of lymphocytes, about 10^{12}, at any one time, so that each lymphocyte would have to recognize 10^6 epitopes in order to cover the universe of pathogenic epitopes (Mason, 2001). Current estimates, especially from combinatorial peptide libraries, suggest that each T cell can probably recognize from 10^6 to 10^8 ligands (Wilson et al., 1999). In the face of such a broad capacity for recognition, why is there not much more molecular mimicry and autoimmune disease?

Two requirements additional to those mentioned above can be suggested. First, it is far more difficult to activate a naïve cell than a primed one, and this feature alone would reduce the frequency of mimicry interactions. However, previous primings by other nonpathogenic cross-reactive stimuli could increase the frequency (Christen et al., 2004). Second, competition between the large number of T cells uniquely specific for the mimicking ligand, and T cells specific for the self-ligand, which are cross-reactive with the mimicking ligand (Maverakis personal communication), will protect the organism in large measure.

Historically, considerations of the relatedness of the mimicking determinant and the self-determinant have passed through three stages. In the first, it appeared that mimicry could occur if stretches of identical amino acids from the determinant on the mimic could be found on the self-determinant (Fujinami and Oldstone, 1985). Later, during the second stage, some studies showed that the determinants need not be identical, but only similar or homologous in several residues. Using a panel of 129 peptides derived from viral and bacterial antigens that matched a molecular mimicry motif, Wucherpfennig and Strominger (1995) showed cross-reactive recognition by MBP-specific T-cell clones from multiple sclerosis patients. Overlapping with this period, other experiments showed that there was no need for any identity between the two determinants, and emphasized the degeneracy of T-cell recognition (Bhardwaj et al., 1993). Several interesting examples of mimicry should be mentioned. Zhao et al. (1998) showed that the inducing mimic actually was processed and a mutational change in the mimic at the appropriate point eliminated the mimicry. In other work, it was shown that two entirely different regions within the same protein, human α-1-antitrypsin, could stimulate the same antigen-reactive T-cell lines and clones (Hagerty and Allen, 1995). Finally, we observed that a T-cell hybridoma directed against HEL could also recognize a determinant on the unrelated antigen, mouse albumin, as well as a third, but undefined, determinant: in this case, three different MHC class II molecules were involved, one for each antigen (H. Deng, unpublished results).

"DETERMINANT SPREADING" DURING THE COURSE OF AUTOIMMUNITY

A T-cell response to the dominant determinant, Ac1-9/Ac1-11, following immunization with whole MBP (Zamvil et al., 1986; Urban et al., 1988; Acha-Orbea et al.,

1988; Lehmann et al., 1992) is crucial for initiation of autoreactivity leading to induction of EAE in certain susceptible mouse strains like B10.PL, PL/J, and (B10.PL × SJL)F1 mice. We observed that when (B10.PL × SJL)F1 mice (Lehmann et al., 1992) were injected with this single dominant peptide of a pathogenic autoimmunogen, spreading of the T-cell response to previously cryptic determinants of MBP occurred, to 35–47, 81–100, and 121–140 ("determinant spreading"). This spreading was attributed to upregulated processing and presentation of MBP within the local inflammatory milieu, leading to efficient display of previously cryptic determinants (Lehmann et al., 1992; 1993). The above results are suggestive of a physiologic role of cryptic self-determinants in the propagation of autoimmunity induced by the dominant determinant of the same autoantigen.

Studies by the Miller laboratory (Weiner et al., 1994; McRae et al., 1995) have shown that both inter- and intramolecular determinant spreading occurred during the course of relapsing EAE. The phenomenon of recruitment of additional T-cell specificities during the course of chronic, relapsing EAE has also been reported by other investigators (Cross et al., 1993; Perry and Barzaga, 1987; Perry et al., 1991), although they initiated response with the native protein, so that intermolecular spreading may have been due to protein contamination. In another study by Tuohy and colleagues (Yu et al., 1996), a predictable, orderly determinant spreading involving determinants within PLP, MBP, and myelin oligodendrocyte glycoprotein (MOG) was observed during the course of EAE in (SWR × SJL)F1 mice. These studies provided functional evidence for the role of determinant spreading in the relapsing pathology of EAE.

The above results on determinant spreading have important implications for immunotherapeutic strategies in the treatment of EAE. In the face of determinant spreading, therapeutic approaches based solely on controlling T-cell responses to the initial disease-inducing determinant may not succeed once spreading has occurred. The timing of tolerization of the initial disease-inducing T cells is critical (McRae et al., 1995; Yu et al., 1996). Furthermore, strategies aimed at blocking the interaction between CD80 and CD28 molecules have also been found to be successful in blocking determinant spreading and thereby preventing relapses during the course of EAE (Miller et al., 1995).

From the viewpoint of initiation of autoimmunity, immunogenic, dominant, and subdominant determinants within an antigen (e.g., Ac 1-9 determinant of MBP) (Zamvil et al., 1986), which are responsible for the induction of autoimmunity, are of utmost importance. Nevertheless, latent cryptic determinants might play a critical role in the broadening of the autoreactive T-cell response and thereby, perpetuation of autoimmunity, e.g., in EAE (Lehmann et al., 1992; 1993; Watts and Lanzavecchia, 1993; Moudgil and Sercarz, 1994).

Diabetes and Arthritis

In another T-cell-mediated autoimmune disease, type 1 diabetes in NOD mice, the disease is characterized by early, spontaneous T-cell responsiveness to glutamic acid decarboxylase (GAD) (Kaufman et al., 1993; Tisch et al., 1993), with the initial response directed against C-terminal determinants. However, during the course of disease, there was spreading of the T-cell response not only to other determinants within GAD (intramolecular spreading), but also to other antigens, namely a mycobacterial hsp65 peptide, carboxypeptidase H, insulin, and others (intermolecular spreading). Interestingly, tolerization of GAD-reactive T cells in NOD mice successfully blocked the development of autoimmunity to the above-mentioned antigens as well as insulitis and clinical diabetes. This was not the case after treatment with the hsp65 peptide. Thus, in this case, understanding of the temporal pattern of appearance of the T-cell response to GAD and other β-cell antigens allowed development of an appropriate therapeutic regimen for prevention and treatment of diabetes.

Using the rat adjuvant-induced arthritis (AA) model of human rheumatoid arthritis (RA), we observed that arthritic Lewis rats in the late phase of AA raised T-cell responses to certain new determinants located at the C-terminus of Bhsp65 (Moudgil et al., 1997a). Furthermore, pretreatment of naïve Lewis rats with peptides comprising these C-terminal epitopes afforded significant protection from subsequently induced AA. These results suggest that diversification and intramolecular spreading of the T-cell response is involved in inducing natural remission or protection from AA ("regulatory diversification") (Moudgil et al., 1997a). Recently, we have shown that the C-terminal epitopes of Bhsp65 involved in this diversification of response are originally cryptic and cross-reactive with the corresponding self-epitopes within rat hsp65 (Rhsp65) (Durai et al., 2004a; 2004b); later, these regulatory determinants become available owing to enhanced processing. Interestingly, the self-homologs of the regulatory cryptic Bhsp65 epitopes are dominant in nature (Durai et al., 2004b). Our results suggest a model for epitope spreading in AA involving the upregulation of the cryptic C-terminal epitopes of Bhsp65, as well as enhanced cellular expression of self-hsp65, leading to display of its dominant C-terminal determinants during the acute phase of AA (Durai et al., 2004a).

CONCLUSION

In summary, there is no common structural characteristic describing antigenic determinants involved in autoimmunity. T lymphocytes directed against such determinants have managed to escape negative selection, and their emergence

into pathogenicity is contextual. The "dominant self" that *does* induce negative selection is created by the ordeal of antigen-processing events. The residual self-reactive potential, inherent in the "cryptic self," may erupt into autoimmune attack when fortuitously cross-reactive, dominant determinants are encountered, or upon interaction with environmental agents that excite Toll-like receptors, or provide unusual cell-activation stimuli (e.g., ultraviolet light). Deficiencies in regulation at a variety of points can alternatively unleash the available repertoire, largely directed against the cryptic self.

As a final word, autoimmune disease is an outcome dependent on a string of chance events, some genetically underwritten and others related to a series of immunologic events in the lifetime of the individual that prey upon the residual self-reactive repertoire. How to efficiently regulate these events is the goal of many current studies.

Apoptotic Cells as a Source of Autoantigens

LIVIA CASCIOLA-ROSEN*

*Department of Medicine, Johns Hopkins University School of Medicine

ANTONY ROSEN*‡§

‡Department of Cell Biology and Anatomy, Johns Hopkins University School of Medicine; and §Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Systemic autoimmune diseases are a heterogeneous group of genetically complex diseases in which the immune system targets a diverse, but very specific, group of molecules. Each disease is associated with the production of high-titer autoantibodies directed against a group of ubiquitously expressed, but phenotype-specific, autoantigens (von Muhlen and Tan, 1995; Hall et al., 2004). The autoantibody response in patients and animals with autoimmune disease exhibits clonal expansion, affinity maturation, and class switching, and provides evidence that the immune responses in these processes are antigen driven and T-cell dependent (Diamond et al., 1992; Burlingame et al., 1993; Radic and Weigert, 1995). Such studies have focused attention on the autoantigens that drive these immune responses, and the circumstances in which these molecules might have satisfied the criteria for initiation and propagation of a T-cell-dependent immune response. The most important criterion for initiation of a primary T-cell response is that the molecule targeted has not been previously presented in that form during development of T-cell tolerance.

Approximately a decade ago, we observed that the autoantigens targeted in systemic autoimmune diseases are unified by their clustering and concentration within surface blebs on apoptotic cells, and we proposed that such molecules were unified by their propensity to undergo structural modifications during some forms of cell death, generating novel structures not previously tolerized by the host (Casciola-Rosen et al., 1994a). Accumulating experimental evidence indicates that most autoantigens are indeed unified by their susceptibility to structural modification during cell death (Utz and Anderson, 1998; Rosen and Casciola-Rosen, 1999; Doyle and Mamula, 2002). Although autoantigens have been demonstrated to undergo several types of modification during cell death, we focus only on the proteolytic cleavage of autoantigens, and the mechanisms whereby such changes might lead to initiation of an autoimmune response.

APOPTOTIC CELLS MAY INDUCE TOLERANCE OR IMMUNITY

Apoptosis [reviewed extensively by Hengartner (2000)] is a sequence of morphologic and biochemical changes characterized by nuclear condensation and membrane blebbing (Kerr et al., 1972). During the apoptotic process, cleavage and activation of a series of cysteine proteases (called

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

caspases) results in the activation of a proteolytic cascade that cleaves downstream molecules that function in pathways essential to cell survival (Thornberry and Lazebnik, 1998; Green and Kroemer, 2004). Apoptotic cell death occurs throughout development and during tissue homeostasis; in these circumstances, the immune consequences are predominantly noninflammatory and tolerance inducing (Voll et al., 1997; Fadok et al., 1998; Gershov et al., 2000; Huynh et al., 2002). Furthermore, apoptosis occurs with great frequency during lymphocyte development and education in the thymus and bone marrow (Surh and Sprent, 1994). Significant experimental evidence indicates that apoptotic cells themselves constitute a prominent source of toleragen in these settings (Cocca et al., 2001; Li et al., 2003). A role of apoptotic cells in the establishment and maintenance of tolerance to peripheral tissues has also been established (Miller et al., 1998; Huang et al,. 2000; Belz et al., 2002; Hugues et al., 2002; Liu et al., 2002; Steinman and Nussenzweig, 2002), providing the immune system with the appropriate forms of autoantigens that will likely be encountered during homeostatic cell death of self-tissues. Consequently, abnormalities in the processes regulating clearance of, and tolerance induction by, apoptotic cells play important roles in rendering individuals susceptible to initiation of systemic autoimmunity (Botto et al., 1998; Scott et al., 2001; Cohen et al., 2002; Hanayama et al., 2004; Manderson et al., 2004). Furthermore, the structural changes that autoantigens undergo during various forms of non-tolerance-inducing cell death may be particularly relevant in selecting the molecular targets of such autoimmunity. An excellent construct within which to view such changes is that proposed by Sercarz et al. (1993), in which altered autoantigen structure modifies antigen processing and presentation such that previously cryptic epitopes are presented to the immune system and activate autoreactive T cells. This paradigm is reviewed in more detail below.

DOMINANCE AND CRYPTICITY

That the macromolecular structure of an antigen may influence its subsequent processing and presentation by MHC class II has become increasingly clear over the past two decades (Streicher et al., 1984; Lipham et al*.,* 1991; Mamula et al., 1992; Mamula, 1993; Schneider et al., 2000). Indeed, several studies have persuasively demonstrated this for various model antigens (see below). In Sercarz's construct of immunologic dominance and crypticity (Lanzavecchia, 1995; Sercarz et al., 1993; Sercarz, 2002), not all determinants on an intact protein antigen are equally immunogenic. Due to certain structural features of the antigen itself, specific determinants are preferentially presented. For a given antigen conformation and antigen-processing machinery, the processing pathway is relatively constant and predictable, and preferentially selects a few determinants that are effectively loaded onto major histocompatibility complex (MHC) class II molecules (dominant epitopes). Several recent studies demonstrating that intact antigens are also the preferential substrates for cross-priming suggest that a similar paradigm is possible for presentation of exogenous antigens on MHC class I (Norbury et al., 2004; Wolkers et al., 2004). Naïve T cells recognizing dominant epitopes of self-antigens in the thymus or periphery are deleted. In contrast, cryptic epitopes in self-antigens are not presented in significant amounts, and potentially autoreactive T cells recognizing such cryptic epitopes are therefore not deleted. Since the products of antigen processing are constant under homeostatic conditions, cryptic epitopes are not revealed under most circumstances. However, were they to be generated during some unusual antigen-processing event, autoreactive T cells recognizing these cryptic epitopes could conceivably be activated and drive the autoimmune response (Sercarz et al., 1993).

The dominance or crypticity of an epitope may be influenced by many intrinsic and extrinsic properties. For example, the sequence of unfolding and specific cleavage of antigens along the endosome/lysozome pathway strikingly influences which peptides finally get loaded onto a particular MHC molecule (Manoury et al., 1998; Antoniou et al., 2000). Also, the intrinsic affinity of a peptide for MHC class II proteins, as well as the properties of neighboring structural determinants, may influence the binding of this peptide to the binding groove (Sercarz et al., 1993; Sercarz, 2002). Understanding how the structure and processing of self-antigens might be altered during different physiologic and pathologic states is therefore significant. Of particular importance are early proteolytic events (Mamula, 1993; Bockenstedt et al., 1995; Manoury et al., 2002) and the effects of high-affinity binding of antibody or other molecules (Watts and Lanzavecchia, 1993; Salemi et al., 1995; Simitsek et al., 1995) on subsequent antigen processing.

Since potentially autoreactive T cells that recognize the cryptic self abound in the immune repertoire, they provide the capacity to respond to novel antigen forms generated through non-standard processing pathways. Changes in autoantigen structure that occur during cell death are therefore potentially of relevance.

MODIFICATION OF AUTOANTIGEN STRUCTURE DURING APOPTOSIS

Autoantigens in systemic autoimmune diseases are clustered and concentrated within the surface blebs on apoptotic cells (Casciola-Rosen et al., 1994a; Rosen et al., 1995; Korb

and Ahearn, 1997; Cocca et al., 2002; Caricchio et al., 2003). Whether structure (and potentially antigen processing) of naturally-selected autoantigens is altered during different forms of cell death has been a subject of significant experimental effort over the past several years. Such studies have demonstrated a striking susceptibility of autoantigens to structural modification, particularly specific proteolysis, during cell death (Utz and Anderson, 1998; Rosen and Casciola-Rosen, 1999; Doyle and Mamula, 2001). Recent studies have also demonstrated that membranes of cells undergoing apoptosis contain increased levels of biologically active oxidized phospholipids, which activate endothelial cells to induce monocyte adhesion. Furthermore, immunization of mice with syngeneic apoptotic cells induced high autoantibody titers to various oxidation-specific epitopes of oxidized phospholipids (Chang et al., 2004). Such structural changes during apoptotic cell death might play a role in the induction of autoimmune responses to apoptotic cells. The different forms of apoptotic proteolysis and some potential mechanisms whereby these changes may be relevant to human autoimmunity are reviewed below.

Cleavage of Autoantigens by Aspartic Acid-Specific Apoptotic Proteases

Proteases play a critical role in the apoptotic process through targeted cleavage of a limited group of downstream substrates that are functionally important in the maintenance of life (Nunez et al., 1998; Thornberry and Lazebnik, 1998). The caspases, a family of cysteine proteases with an absolute requirement for cleavage after aspartic acid, constitute the most prominent apoptotic protease family (Thornberry and Lazebnik, 1998; Boyce et al., 2004). In initial studies looking for modification of autoantigen structure in apoptotic cells, we and others noted that although caspases only have a limited number of substrates during cell death (perhaps a few hundred at maximum), autoantigens are highly represented among these molecules (Casciola-Rosen et al., 1994b; 1995; Casiano et al., 1996; Utz et al., 1998; Rutjes et al., 1999; Ayukawa et al., 2000; Malmegrim de Farias et al., 2003). In a minority of cases (e.g., NuMA, CENP-C), the cleaved form of the antigen is better recognized by patient autoantibodies than the intact protein, suggesting that cleavage may alter accessibility of the relevant epitopes (Schachna et al., 2002). There are also reports of some autoantibodies to U1-70-kDa, which specifically recognize the apoptotically modified form of this molecule. The observation that such antibodies are associated with distinct clinical features suggests that caspase-mediated cleavage may play a role in driving the immune response to U1-70-kDa in specific circumstances (Greidinger et al., 2004). To date, no persuasive experiments directly addressing the effects of caspase cleavage on immunogenicity of naturally-selected autoantigens have been performed. While it is possible that cleavage of autoantigens influences immunogenicity, it is equally likely that the presence and structural features of the cleavage site itself influence antigen processing and epitope selection, and that different mechanisms apply to different autoantigens.

In this regard, a series of experiments using tetanus toxin c fragment as a model antigen, which has demonstrated that a hierarchy of antigen-processing events exists, is relevant (Manoury et al., 1998; Antoniou et al., 2000). In these studies, processing of tetanus toxin is initiated upon cleavage by a lysozomal enzyme, asparaginyl endopeptidase (AEP), at a single defined site. There is an absolute requirement for this cleavage event, as elimination of the specific processing sites through mutagenesis dramatically alters the efficiency of epitope presentation to an antigen-specific T-cell clone. As a result of a single conservative mutation at the enzyme cleavage site, novel epitopes are generated during antigen processing. Inhibiting the AEP protease also alters processing of the whole antigen, resulting in different peptides being loaded onto MHC class II molecules. Thus, in this example, antigen processing occurs in a stepwise manner, with cleavage by a single, initial protease being necessary for the subsequent processing steps that generate the dominant T-cell epitopes. Subtle changes in antigen structure, which alter such key upstream processing sites, can dramatically alter processing of the intact antigen. Where such changes cause the revelation of epitopes not normally seen by the immune system, the subsequent development of an autoimmune response is enabled (Moudgil and Sercarz, 1993) (see Chapter 14).

Recent studies from Crow and colleagues (Chernysheva et al., 2002) have demonstrated the importance of caspase-dependent events in the initiation of an autologous mixed lymphocyte reaction (AMLR). Incubation of apoptotic non-T-cell stimulator cells with autologous T cells induces proliferation of the T cells, an event that is enhanced when apoptosis is promoted in the stimulator cell population by treatment with either γ-irradiation or staurosporine. This proliferation is almost completely abrogated when a number of different caspase inhibitors are preincubated with the apoptotic stimulator cell population. In contrast, preincubation of the responder T cells with caspase inhibitors did not alter T-cell proliferation, indicating that caspase activity is required in the stimulator population to initiate a response (Chernysheva et al., 2002). It remains unclear whether this effect is due to caspase-mediated cleavage of autoantigens themselves, or occurs indirectly, through pathways downstream of caspases that modify autoantigen structure (e.g., activation of kinases, nucleases) or otherwise enhance autoantigen presentation (e.g., enhanced phagocytosis or clearance).

Novel Autoantigen Structure during Cytotoxic Lymphocyte Granule-Induced Death

The initiation of a primary immune response is dependent upon the generation of suprathreshold concentrations of antigen with a structure not previously tolerized by the host, occurring within a proinflammatory environment. Since most forms of homeostatic apoptotic cell death are profoundly tolerance inducing (Voll et al., 1997; Fadok et al., 1998; Gershov et al., 2000; Huynh et al., 2002), it is likely that initiation of autoimmunity is associated with a more proinflammatory type of cell death. The killing of virally-infected or transformed cells is of particular relevance in this regard, both due to the proimmune context of such killing, as well as to alterations in autoantigen expression, structure, and conformation in such settings. For example, viral infection may directly alter the structure of self-antigens (Dong et al., 1994; Duncan and Nakhasi, 1997). It is also possible that viral infection initiates cytokine secretion and immune effector pathways that alter the expression and/or structure of self-antigens. Similarly, there is also significant evidence that autoantigen expression and conformation may be strikingly altered in transformed cells and tumors (Corradi et al., 1997; Zhang et al., 1999; Ulanet et al., 2003). Interestingly, both virus-infected and transformed cells are targets of similar immune effector pathways unleashed by cytotoxic T cells and natural killer (NK) cells (Russell and Ley, 2002; Trapani and Sutton, 2003).

Cytotoxic Lymphocyte Granule-Induced Death Pathways

Cytotoxic lymphocytes induce target cell death through several different pathways, including ligation of the Fas receptor on the surface of the target cell, as well as release of proteases contained in lytic granules within the cytotoxic cell (Andrade et al., 2004). Transduction of the Fas signal occurs through multiple protein–protein interactions that activate the caspase cascade by inducing processing of caspases-8 and -10 (Siegel et al., 2000). Thus, ligation of the death receptor Fas (CD95) results in recruitment of the adaptor molecule FADD. Death effector domains within FADD recruit and induce oligomerization of group 3 caspase precursors, which undergo autocatalytic cleavage and activation of the receptor complex known as DISC (death-inducing signaling complex) (Tibbetts et al., 2003). Cytolysis induced via the Fas pathway is thought to be predominantly associated with immune regulatory processes (Lenardo, 2003). Granzyme-mediated killing utilizes several granule components with unique activities. The most abundant components present in cytotoxic granules are perforin (a pore-forming protein) and a family of serine proteases termed granzymes (Henkart, 1994). Perforin has long been considered crucial for the entry of granzymes into the target cell, but the mechanisms underlying its activity remain controversial (Russell and Ley, 2002). Following release into the cytosol with the help of perforin, granzyme B (GrB), a rapidly-acting apoptotic enzyme, catalyzes the cleavage and activation of several downstream substrates, inducing apoptotic changes in the target cell. Prominent among the upstream mediators of the GrB effect are Bid and procaspases, which are directly cleaved by GrB to generate their active forms. Thus, through the early cleavage and activation of Bid, GrB rapidly recruits the mitochondrial amplification loop of caspase activation (Sutton et al., 2000; 2003; Pinkoski et al., 2001). GrB similarly cleaves and activates effector caspases that further amplify the apoptotic proteolytic cascade, resulting in cleavage of multiple downstream substrates, and generation of the apoptotic phenotype. In addition to the recruitment of caspase-dependent pathways, GrB also directly cleaves several downstream signature death substrates, constituting an important caspase-independent death pathway that can lead to cell death even in the absence of caspase activity (Andrade et al., 1998; Casciola-Rosen et al., 1999). For example, GrB directly cleaves and activates the apoptotic nuclease DFF45/ICAD; such cleavage is required for optimal granzyme-induced target cell death (Thomas et al., 2000). Additionally, autoantigens targeted in human autoimmune diseases are highly represented among these substrates (Casciola-Rosen et al., 1994a; 1996; 1999; 2001; Mancini et al., 2000; Nagaraju et al., 2001; Mahoney et al., 2002) (see Figure 15.1 for examples).

Granzyme B Cleavage of Autoantigens

The number of autoantigens known to be cleaved by GrB is steadily growing. The observation that many autoantigens targeted across the spectrum of human autoimmune diseases are directly and efficiently cleaved by GrB is remarkable for several reasons: 1) susceptibility to cleavage by GrB is a highly specific feature of autoantigens, and nonautoantigens are not similarly susceptible to cleavage by GrB at sites not cleaved by caspases (Casciola-Rosen et al., 1999); 2) a very similar group of autoantigens is cleaved by caspases and GrB, although at distinct sites, thus generating different fragments (Andrade et al., 1998); 3) the cleavage sites in autoantigens are uniquely suited to cleavage by GrB and are resistant to cleavage by the upstream activating caspases (caspases-8 and -9) due to the enrichment of residues in the P2 and P3 substrate positions that are preferred by GrB but not tolerated by caspases (Casciola-Rosen et al., 1999); 4) GrB activation of caspases leads to significant amplification of caspase cleavages, and when efficiency of cleavage of a substrate by caspases and GrB is similar, products of caspase cleavage generally predominate. Generation of GrB frag-

ments is thus enhanced by inhibition of the caspase pathway (Andrade et al., 1998; Casciola-Rosen et al., 1999). Also of particular note, GrB and other components of the lytic granule pathway are not expressed in the thymus (Shresta et al., 1995), and cleavage products generated by such proteases are therefore unlikely to have been tolerized.

The striking association between susceptibility of a substrate to cleavage by GrB and autoantigen status strongly suggests that these properties are mechanistically related. As noted for the caspases above, it remains unknown whether it is the properties of the cleavage site or cleavage itself that plays a role in selecting molecules against which autoimmune responses are generated. If cleavage is the important parameter, the reciprocal relationship between caspase activity and generation of granzyme-specific autoantigen fragments suggests that initial immunization occurs in a setting in which caspases are under endogenous (e.g., inhibitors of apoptosis (IAP) proteins) or exogenous inhibition (e.g., viral caspases inhibitors) (Kobzik et al., 1994; Deveraux et al,. 1997; 1998; Roy et al., 1997; Li et al., 1998).

The effect of autoantigen cleavage on recognition by autoantibodies has been addressed in part using an immunoblotting approach; however, there is, as yet, no common feature that unifies all the antigens in terms of antibody recognition. Indeed, it is striking that GrB cleavage can have various effects, described below, on recognition of different molecules by autoantibodies. For example, although infrequently observed, GrB-generated fragments of autoantigens may be recognized better by autoantibodies than the intact molecule. A striking example of this is the scleroderma autoantigen CENP-C (Schachna et al., 2002), for which GrB cleavage greatly enhances autoantibody recognition. Interestingly, such CENP-C fragment-preferential autoantibodies are particularly enriched in patients with scleroderma and ischemic digital loss. Similar findings have also been made for nuclear mitotic apparatus protein (NuMA) (Andrade et al., 1998). Enhanced autoantibody recognition of GrB-cleaved autoantigens may be indicative of several things: 1) exposure of a neoepitope at the site of granzyme cleavage; or 2) a conformational change at a site more distant from the scissile bond, which improves antibody access to the epitope. Either way, these data indicate that the intact cleavage site suppresses or restrains access to the epitope, which becomes dominant in the autoantibody response. How this relates to the driving T-cell response is still unknown, but is of significant importance. There are also clear examples where GrB cleavage of an autoantigen greatly inhibits recognition by autoantibodies. For example, Gershwin and colleagues (Matsumura et al., 2002) demonstrated that autoantibodies recognizing the intact pyruvate dehyrdrogenase E2 subunit (PDC-E2) fail to recognize the GrB-cleaved form of PDC-E2. Since previous studies had demonstrated that the dominant B- and T-cell epitopes in PDC-E2 coincide, and include the GrB cleavage site, these data demonstrate that the intact cleavage site itself forms part of the dominant B-cell epitope. Similar findings have also been made for XRCC4 (Lee et al., 2002). Lastly, for most autoantigens studied, cleavage by GrB has no effect on recognition by autoantibodies.

The fact that cleavage can enhance or destroy recognition of some molecules by autoantibodies demonstrates that the GrB cleavage site can either enhance or suppress accessibility of epitopes, occasionally at the level of the autoantibody, but potentially more generally at the level of the T cell. Although autoantibodies are excellent probes of the targets of the autoimmune response, they are less well suited to defining the particular conformation of the antigen that initiated the T-cell response. Interestingly, studies by Mamula et al. (1999) examining the generation of autoimmune responses to an isoaspartyl-containing Sm-D or cytochrome c peptide have demonstrated that T cells recognize only the isoaspartyl form of the antigen, while autoantibodies bind both modified and unmodified forms. Defining the effects of the intact GrB cleavage site, and its destruction after proteolysis, on the processing and presentation of antigens to T cells therefore remains a major priority.

Cleavage of Tissue-Specific Autoantigens

Structural changes of autoantigens induced by post-translational modification can alter the processing of self-antigens and influence the ability to generate an immune response against self. For example, studies have shown that the neuronal glutamate receptor subunit 3 is an autoantigen in patients with a severe form of pediatric epilepsy, Rasmussen encephalitis (Rogers et al., 1994). Autoantibodies tend to be of low affinity, and many recognize a well-defined extracellular epitope residing in the receptor-activating epitope, which is aligned on the surface of the folded protein (Twyman et al., 1995). Of note, the GrB cleavage site contains an asparagine that is normally N-glycosylated, and is found within a major epitope that is recognized by autoantibodies in Rasmussen encephalitis (Gahring et al., 2001). Interestingly, Gharing et al. (2001) showed that deglycosylated GluR3 is susceptible to cleavage by GrB, whereas the glycosylated form of this receptor is poorly cleaved, possibly because the N-linked sugar sterically hinders the ability of GrB to bind to its substrate. The authors postulate that inflammatory events may inhibit the glycosylation of GluR3, thus rendering it susceptible to cleavage by GrB, and potentially to initiation of GluR3-directed autoimmunity.

Novel Conformation of Disease-Specific Autoantigens

In spite of the fact that many autoantigens in systemic autoimmune diseases are ubiquitously expressed, there is

nevertheless a striking association of specific antibody responses with unique clinical phenotypes. One potential explanation for this observation is that changes in autoantigen structure may be limited to the relevant disease microenvironment and may contribute to initiation of an autoimmune response. As several autoantigens that are targeted in systemic autoimmune diseases can also be targeted in patients with hepatocellular carcinoma (HCC), we have sought to define microenvironment-specific changes in autoantigens in liver tissue of patients with HCC. Interestingly, the nucleolar HCC autoantigen B23 exists in a truncated form in HCC liver lacking six amino acids at the N-terminus. While full-length B23 (expressed in all other tissues) is very resistant to cleavage by GrB, HCC B23 is strikingly sensitive to such cleavage (Ulanet et al., 2003). Whether exposure of the GrB cleavage site or cleavage itself plays a role in selecting B23 as an HCC antigen remains unknown, but the striking restriction of this novel conformation to the likely site of immunization is of great importance.

Additional Post-Translational Modifications that Affect Autoantigen Structure

Although this chapter has focused on apoptosis-specific proteolysis as a primary mechanism of structural change during cell death, other post-translational changes (e.g., phosphorylation/dephosphorylation, isoaspartyl modification, transglutamination, and deimination) occur frequently during various death processes, and may profoundly affect antigen processing and presentation (Utz et al., 2000; Doyle and Mamula, 2002). It should also be noted that autoantigens may undergo novel proteolytic modifications distinct from those observed during apoptosis during necrotic death (Casiano et al., 1998).

MODEL OF ANTIGEN SELECTION DURING CELL DEATH

We propose that apoptotic cells are sources of cleaved antigens that can either tolerize or activate lymphocytes, depending on the type of cell death (homeostatic or proimmune), the species of aspartic acid-specific protease that preferentially process the self-antigen, and the efficiency of clearance of the apoptotic cell. Under normal homeostatic circumstances, apoptotic cells are efficiently cleared and actively induce tolerance (Figure 15.1A, left side). These apoptotic cells are highly enriched in autoantigen fragments generated by caspase cleavage. Such peptide fragments generated by caspases are likely the form of the autoantigen that is tolerized during development and homeostasis. Where apoptotic cells are efficiently cleared and captured by immature dendritic cells, tolerance to caspase-cleaved antigens is fully established, and autoreactive T cells recognizing caspase-cleaved antigens are likely deleted. In contrast, where clearance of, or tolerance induction by, apoptotic cells is abnormal, establishment of tolerance to caspase-cleaved antigens will be incomplete, and may later allow activation of autoreactive T cells recognizing such caspase-generated fragments during a major apoptosis-inducing event

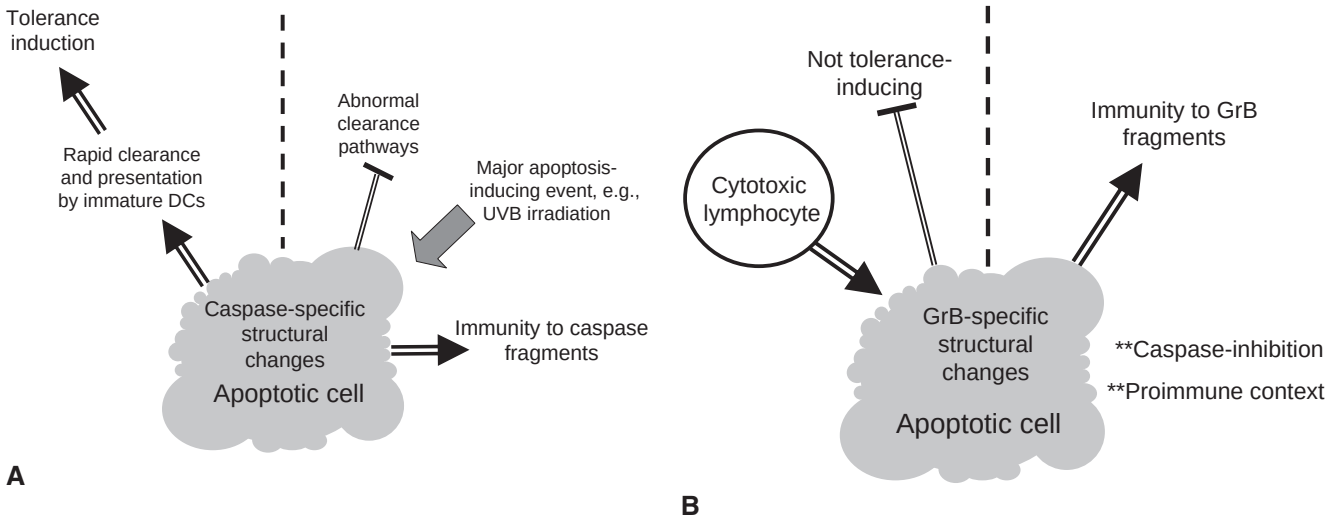

FIGURE 15.1 Model of antigen selection during cell death. *A,* Homeostatic death. The predominant form of the molecule tolerized during development and homeostasis is the caspase-induced form. Tolerance to caspase-cleaved fragments results when apoptotic clearance is normal. *B,* Proimmune death. Certain proimmune circumstances allow preferential activity of the granzyme (GrB) pathway, generating novel autoantigen fragments not previously tolerized by the host. DC, dendritic cell.

(Figure 15.1A, right side). Even where apoptotic cell clearance is normal, and tolerance to the default caspase-induced death pathways fully established, some proinflammatory forms of cell death (e.g., cytotoxic lymphocyte granule pathway-induced death of virus-infected or transformed cells) may generate novel forms of autoantigens not usually generated during tolerance induction (Figure 15.1B). This will most likely occur under circumstances in which caspases are under exogenous or endogenous inhibition, maximizing the generation of granzyme-induced fragments. Such fragments may allow the activation of autoreactive T cells recognizing nontolerized epitopes. Direct demonstration of the differential immunogenicity of different forms of caspase/granzyme-cleaved apoptosis is a major priority.

Effector Mechanisms of Autoimmunity: Antibodies and Immune Complexes

LARS RÖNNBLOM*

**Department of Medical Sciences, Section of Rheumatology, Uppsala University*

GUNNAR V. ALM†

†Department of Molecular Biosciences, Section of Veterinary Immunology and Virology, Swedish University of Agricultural Sciences, Uppsala, Sweden

Immune complex (IC) formation occurs in all immune responses associated with antibody production, as long as antigen is available. Such ICs principally occur in two forms, either as antibodies bound to antigens that are part of intact cells or tissues (including extracellular matrix), or as antibodies bound to antigens that are freely diffusible molecules or subcellular particles. The ICs are involved in many different diseases with very diverse clinical manifestations. This is due both to the many different actions by ICs and the actual constituents of the IC. In immune reactions against various types of microorganisms, formation of ICs is considered important in the pathogenesis of infections (Mims et al., 2001). In many acute infections, ICs contribute to inflammatory reactions, such as skin rashes and conjunctivitis, which subside as production of microbial antigens ceases and ICs are eliminated. In persistent infections, such as hepatitis C virus, with long-term production of antigens, ICs are continuously formed and may result in a chronic inflammatory disease (Trendelenburg and Schifferli, 2003).

In autoimmunity, antibodies to a vast number of autoantigens have been described, and moreover, many of these antigens are continuously available for binding autoantibodies. This sometimes results in a very high load of ICs in autoimmune rheumatic diseases, such as circulating ICs in systemic lupus erythematosus (SLE) (see Chapter 28) and ICs in the joint compartment of patients with rheumatoid arthritis (RA) (see Chapter 32; Jarvis et al., 1995). Such ICs contribute to clinical manifestations that resemble those in some infections, with IC deposits causing inflammatory changes in organs and tissues, e.g., vasculitis in blood vessels and glomerulonephritis in kidneys. It is, however, important to distinguish IC-mediated disease due to infections or to autoimmunity, not least when appropriate treatment for a certain condition is discussed.

The pathogenic effects of antibodies is often regarded in the context of the original Coombs and Gell classification of hypersensitivity reactions, where type II hypersensivity is due to antibodies binding to cells, tissues, and organs, while type III hypersensitivity is due to the effects of soluble ICs. In both cases antibody and ICs can be inflammatory and promote consumption and/or destruction of cells. However, the actual underlying mechanisms behind inflammation and tissue destruction are not always clear. Furthermore, it is less well recognized that the combination of antigens and antibodies, especially as soluble ICs, in addition can have profound immunoregulatory effects and in this way either suppress or promote immune responses.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

EFFECTS OF ANTIBODIES ON LIVING CELLS, TISSUES, AND ORGANS

Autoantibodies binding to cells can occasionally directly affect cell function and viability, for instance, if they are directed to molecules involved in Fas/CD95 activation or in ion transport (see Chapter 17). Because of the fluidity of cell membranes and the fact that many autoantibodies are directed to separate epitopes on cell-surface autoantigens, the latter can be cross-linked in cell membranes, resulting in clustering and capping of ICs (Latif et al., 2001; Kwiatkowska et al., 2003). The antibodies in such cell-associated ICs can in turn efficiently interact with Fc-receptors (FcRs) that are present on many effector cells in the immune system and can also activate the complement system. The principal modes of action of these antibodies are described in Figure 16.1.

The properties and functions of both the FcRs and complement receptors (CRs) have been extensively reviewed (Ravetch and Bolland, 2001; Hogarth, 2002; Takai, 2002; Monteiro and van de Winkel, 2003; Prodinger et al., 2003). Several human FcRs are present (Table 16.1), and of particular relevance here are the FcγR, that is FcγRI (CD64), FcγRIIa, b, and c (CD32), FcγRIIIa and b (CD16), as well as the FcεRI, FcεRII, FcαRI (CD89), and Fcα/μR. Table 16.1 also indicates the affinities of FcRs for immunoglobulin isotypes and subclasses and their expression on different types of cells. Other FcRs include the neonatal FcR (FcRn) that is involved in transport of immunoglobulins across the placenta. The FcRn is also present on endothelial cells and serves to prolong the lifespan of serum IgG (Ober et al., 2004). The poly-IgR transports IgA and IgM across intestinal epithelium (Monteiro and van de Winkel, 2003).

When the extracellular parts of the α chains of FcR bind to the Fc portions of immunoglobulin, cross-linking of FcR can occur and signals are then generated by activation of tyrosine kinases noncovalently interacting with intracellular FcR domains. In all FcRs, except the FcγRII, FcγRIIIb, FcRn, and poly-IgR, this is due to the activation of FcR-γ chains, present as disulfide-linked dimers. The γ chains contain the immunoreceptor tyrosine-based activation motif (ITAM), also present in several other proteins in the immune system that are associated with activation of cells, such as the B-cell receptor (BCR) for antigen (Billadeau and Leibson, 2002; Takai, 2002). The ITAM consists of a conserved amino acid sequence and is also present in the α chain of the single-chain FcγRIIa, an FcR present in man and other primates but not in mice. Upon FcR cross-linking ITAMs are tyrosine-phosphorylated by activation of Src-family kinases, creating docking sites for the SH2 domain

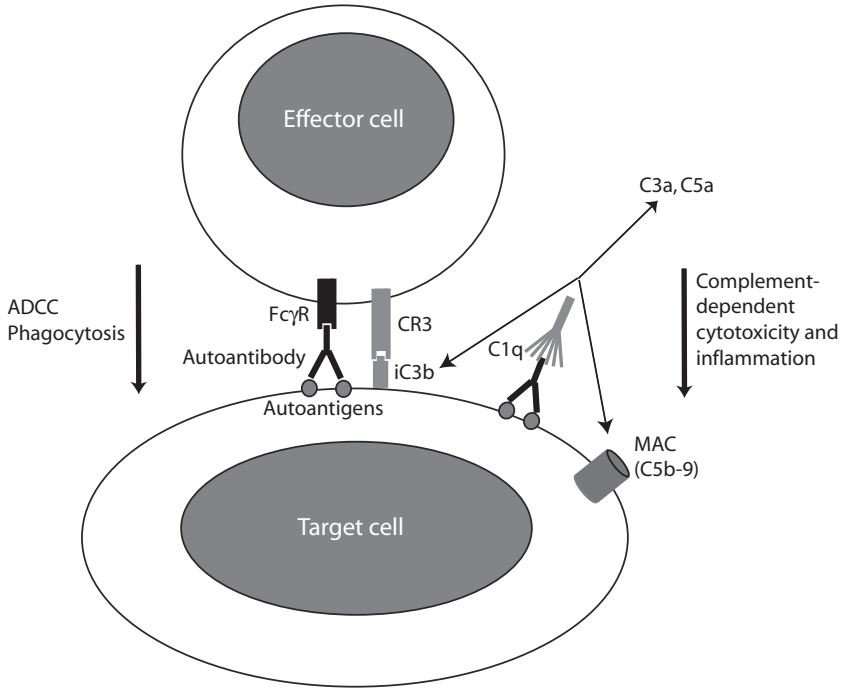

FIGURE 16.1 Basic mechanisms whereby autoantibodies bind to and damage cells or tissues. Autoantibodies bind to cell-surface antigens and activate the complement system, with deposition of iC3b, generation of the inflammatory split products C3a and C5a, and formation of the membrane attack complex (MAC). Effector cells, such as monocytes/macrophages, neutrophils, and natural killer cells use the FcγR to bind to IgG autoantibodies and the complement receptor 3 (CR3) to bind to iC3b on target cell membranes. This activates mechanisms involved in antibody-dependent cellular cytotoxicity (ADCC). Alternatively, target cells can be phagocytosed.

TABLE 16.1 Summary of human Fc receptors involved in inflammation and immunoregulation

Designation (CD number)	General structure	Affinity for immunoglobulin	Expression
FcγRI (CD64)	α,γ2 (ITAM)	Medium (10^7–10^9/M) IgG1, 3 > 4 > 2	Monocytes/macrophages, dendritic cells (DCs), mast cells, neutrophils (inducible)
FcγRIIa (CD32)*	α (ITAM)	Low (<10^7/M) IgG3 > 1 >> 2, 4	Platelets, myeloid cells, DCs, plasmacytoid DCs (PDCs), B cells (?)
FcγRIIb (CD32)*†	α (ITIM)	Low (<10^7/M) IgG3 > 1 > 4 > 2	B cells, mast cells, basophils, eosinophils, neutrophils, DCs, macrophages
FcγRIIc (CD32)	α (ITAM)	Low	Macrophages, natural killer (NK) cells, neutrophils
FcγRIIIa (CD16)*	α,γ2 (ITAM)	Medium (2×10^7/M) IgG1, 3 >> 2, 4	NK cells, macrophages, mast cells
FcγRIIIb (CD16)*	α (GPI)	Low (<10^7/M) IgG1, 3 >> 2, 4	Neutrophils, eosinophils
FcεRI	α,γ2,β (ITAM)	High (10^{10}/M) IgE	Monocytes, DCs, PDCs (no β chain). Mast cells, basophils, eosinophils
FcεRII (CD23)	Lectin-like trimer	Low (≤10^7/M) IgE	Ubiquitous, platelets
FcαRI (CD89)	α,γ2,β (ITAM)	Medium (2×10^7/M) IgA	Macrophages, neutrophils, eosinophils
Fcα/μR	α	Medium (10^8/M) IgA, IgM	Mesangial cells, B cells, macrophages
FcRn	α,β_2m	IgG	Placenta, endothelium, monocytes, intestine
Poly-IgR	α	High, transport of IgA dimers, IgM	Epithelium in intestine and lung, liver

GpI, Glycosylphosphatidylinositol-anchored; ITAM, immunoreceptor tyrosine-based activation motif; ITIM, immunoreceptor tyrosine-based inhibitory motif; β_2m, β_2-microglobulin; α,γ,β refer to the different chains; γ2 dimer of γ-chain.

*Allelic variants of FcγRIIa, FcγRIIb, FcγRIIIa, and FcγRIIIb exist and differ in their expression and/or function (see text).

†Alternative splicing of FcγRIIb results in FcR isoforms that differ with respect to function and expression in different cell types.

of the cytosolic protein kinase Syk. The docking and activation of Syk kinases leads to the phosphorylation and recruitment of several intracellular proteins, which results in stimulation of, for instance, phospholipase Cγ, phosphatidylinositol 3-kinase (PI3K), the Ras pathway with activation of, for example, MAP kinase and GTPases of the Rac and Rho families (Takai, 2002). This results in activated functions in different cells, including phagocytosis, production of cytokines, an oxidative burst, degranulation of mast cells, and antibody-dependent cellular cytotoxicity (ADCC). This FcR-mediated activation can be achieved by antibodies attached to cell surfaces or by soluble ICs.

The activating effects of FcR can be inhibited by the FcγRIIb, which is present on B cells and most myeloid cells, but absent in natural killer (NK) cells, T cells, and plasmacytoid dendritic cells (PDCs) (Ravetch and Bolland, 2001; Båve et al., 2003). This is due to the presence of the immunoreceptor tyrosine-based inhibitory motif (ITIM) in the cytoplasmic domain of this single-chain FcR. Upon activation by coaggregation with, for example, BCR or other FcR, Src-family kinases tyrosine-phosphorylate the ITIM, which results in recruitment of SH2-domain containing phosphatases, primarily protein tyrosine phosphatase (SHP1, SHP2) and the inositol polyphosphate 5′ phosphatase (SHIP). These enzymes, especially SHIP, inhibit the pathways triggered by activating receptors, preventing, for example, intracellular calcium mobilization, activation of MAPK, and antiapoptotic signals. In addition, homoaggregation of FcR produces ITIM-independent apoptotic signals. Thus, the FcγRIIb can downregulate the many effects caused by ITAM-containing FcR and other molecules, such as BCR (Ravetch and Bolland, 2001; Takai, 2002).

A number of functionally important polymorphisms have been described in the genes encoding the low-affinity FcRs in man (van Sorge et al., 2003; Reefman et al., 2003; Magnusson et al., 2004; Takai, 2005). The most investigated FcγRIIa polymorphism is a point mutation affecting the amino acid at position 131, coding for either arginine (R131) or histidine (H131). The FcγRIIa-131R has been shown to bind IgG in ICs less efficiently than the 131H genotype, especially IgG2. The FcγRIIIa polymorphism, which results in either valine (158V) or phenylalanine (158F) in amino acid position 158, alters the ligand affinity. Thus, the 158V genotype has higher affinity for IgG1 and IgG3 than does the 158F genotype. The lower-affinity FcRs allele 131R and 158F have both been associated with an

increased risk to develop systemic lupus erythematosus (SLE). At least three alleles of the FcγRIIIb gene have been identified, designated NA1, NA2, and SH. The NA2 allele appears to have lower capacity to mediate phagocytosis than NA1 and has been reported to be associated with SLE in Japanese and Spanish patients. Finally, polymorphisms occur in both the coding and promotor regions of the FcγRIIb gene, affect the function or expression of this important inhibitory FcR, and have been reported to be associated with SLE (Takai, 2005).

Whenever autoantibodies bind to cell-surface autoantigens, their Fc portions can interact with and activate FcR on effector cells, such as NK cells, neutrophils, eosinophils, and macrophages (Figure 16.1). All three FcγR types can be involved, but in many human *in vitro* experimental systems, FcγRIIIa, and to some extent FγRIIa, are important. The FcγRI, which has the highest binding affinity for IgG, seems to be less important, although it is expressed on monocytes/macrophages. It is poorly expressed on granulocytes, but the expression can be increased by exposure of cells to interferon (IFN)-γ (Pan et al., 1990). The affinities of FcR for IgG subclasses differ, the IgG1 and IgG3 showing higher affinity, while IgG2 and IgG4 have lower affinity. As part of activation via FcRs, the effector cells secrete a variety of mediators that differ depending on the type of cells, e.g., proinflammatory cytokines derived from monocytes/macrophages (see below) and cytotoxic molecules, such as perforin and granzyme B derived from NK cells (Russell and Ley, 2002; Lieberman, 2003; Wagner et al., 2004). At least NK cells also upregulate FasL, which can activate apoptosis in Fas-expressing target cells (Eischen et al., 1996). The killing of antibody-coated target cells by the different effector cells is termed antibody-dependent cellular cytotoxicity (ADCC). Its relative importance in autoimmunity *in vivo* needs to be clarified. Alternatively, cells coated by autoantibodies can be phagocytosed, which should be especially important with free cells, e.g. erythrocytes and leukocytes.

Depending on immunoglobulin isotype and IgG subclass, autoantibodies bound to cells may activate the classical pathway of the complement system (Figure 16.1) (Walport, 2001a; 2001b; Prodinger et al., 2003). Here, IgM, IgG1, and IgG3 are efficient activators, while IgG2 and IgG4 are poor activators. Cross-linking with resulting close proximity of antibody molecules is important both for FcR-mediated activation of, for example, phagocytes, and for initiation of complement activation upon binding of C1q to the antibodies. The ensuing activation of factors C4, C2, and C3 results in the formation of membrane attack complex (MAC) that consists of C5-9, resulting in some damage to target cells. The deposition of C3b and iC3b on cells sets them up for interactions with CR present on a variety of cells, including neutrophils and macrophages (Prodinger et al., 2003; Gelderman et al., 2004). Several membrane-bound complement regulatory proteins (CD46, CD55, and CD59) and soluble proteins inhibit activation and deposition of complement factors on mammalian cells, thus reducing complement-mediated cytotoxicity. However, the interaction between iC3b deposited on target cells and CR3 on effector cells can enhance ADCC, although not causing cytotoxicity alone (van Spriel et al., 2001; Gelderman et al., 2004; Salio et al., 2004). Furthermore, activation of the complement system results in the inflammatory split products C3a and C5a that act via the complement receptors C3aR and C5aR, present on many different types of cells (Drouin et al., 2001; Prodinger et al., 2003).

Many autoantibodies are directed against intracellular antigens, in which case they may be incapable of binding to living cells. There are exceptions to this rule, because antibodies to DNA can penetrate cells and even enter the nuclei, where they might affect cellular functions (Portales-Perez et al., 1998; Ruiz-Arguelles et al., 2003). The situation is different with cells dying by apoptosis, because several important intracellular autoantigens (e.g., RNA- and DNA-binding proteins, calreticulin, heat-shock proteins) are concentrated in apoptotic blebs and/or are exposed on the cell surface (Casciola-Rosen et al., 1994; Rosen and Casciola-Rosen, 1999). To some extent these autoantigens are modified during the apoptotic process and autoantibodies can recognize such modifications (see Chapter 15).

FORMATION AND PROPERTIES OF SOLUBLE IMMUNE COMPLEXES

Many of the effects of soluble ICs in autoimmune diseases are due to mechanisms that are also involved in the direct effects of autoantibodies on cells. However, ICs present many unique features with regard to their immunoregulatory and pathogenic effects. The properties of ICs, including lattice size, depend on the relative concentrations and net charge of antigen and antibodies, the antibody affinity, and immunoglobulin isotype and subclass, as well as on the size and number of epitopes of the antigen (Doekes et al., 1984; Jarvis et al., 1995; 1999; Voice and Lachmann, 1997). Obviously, IgM theoretically has the possibility to bind 10 antigen epitopes, secretory IgA binds four epitopes, while, for instance, IgG only binds two epitopes. However, IgG3 has been reported to self-associate and this might increase the propensity to form ICs (Panka, 1997). Antigen excess in combination with high concentrations of high-affinity antibodies may result in the formation of very large ICs. Such ICs are more easily trapped, or even precipitate, in tissues. Furthermore, ICs that contain anti-DNA antibodies with cationic charge and DNA have much increased propensity to bind to the polyanionic parts of glomerular basal membranes, and are therefore more prone to cause nephritis (Mohan and Datta, 1995). A special form

of IC is the cryoglobulins, which are immunoglobulins precipitating at a temperature below 37°C. Such ICs are classified into types I, II or III, and usually contain IgM. The IgM in cryoglobulinemia type II and III show rheumatoid factor activity and are also in complex with IgG. Their existence is associated with malignant, infectious, and autoimmune diseases (Dammacco et al., 2001; see Chapter 65).

The biologic activity of ICs is, however, a much more complex issue, and to a large extent related to the ability of IC-associated antibodies to interact with FcR and also to activate the complement system. Also important is the intrinsic ability of the antigen in ICs to interact with cellular receptors, such as Toll-like receptors (TLRs) (Takeda and Akira, 2004). The principal functional parts of ICs are shown in Figure 16.2A. The fact that the interaction between TLR and soluble IC containing DNA or RNA actually occurs in an endosomal/phagosomal compartment in B cells (Figure 16.2B) and in PDCs (Figure 16.2C) is discussed below.

The major immunoglobulin isotype in soluble ICs is IgG and the FcγRI (CD64), II (CD32), and III (CD16) are therefore important for the interaction of ICs with different cells, resulting in activation or inhibition of various cell functions. The low affinity of FcγRII and FcγRIII for Fc-portions of IgG requires the multiple Fc portions present in IC for binding. Thus, only IC can interact with these FcRs, which are expressed on many different cell types (Table 16.1), ensuring that only physiologically relevant ICs, and not monomeric immunoglobulin, activate the effector responses. The FcγRI has in contrast a high affinity for the Fc portions of IgG and can therefore bind solitary immunoglobulin molecules, but such FcRs must still be cross-linked in order to become activated. Antibodies in ICs can activate the classical pathway of the complement system, and IgM, IgG1, and IgG3 are efficient at this, as mentioned above. However, IgG2 also can activate the complement system at higher epitope density; both this subclass and IgA can activate the alternative complement pathway, and IgA can activate the lectin pathway (Endo et al., 1998; Roos et al., 2001). Therefore, complement components C1q, C4b, C3b, C3d, and iC3b are usually present in ICs and are functionally relevant in several ways, via interactions with the complement receptors C1qR and CR1-4 (Prodinger

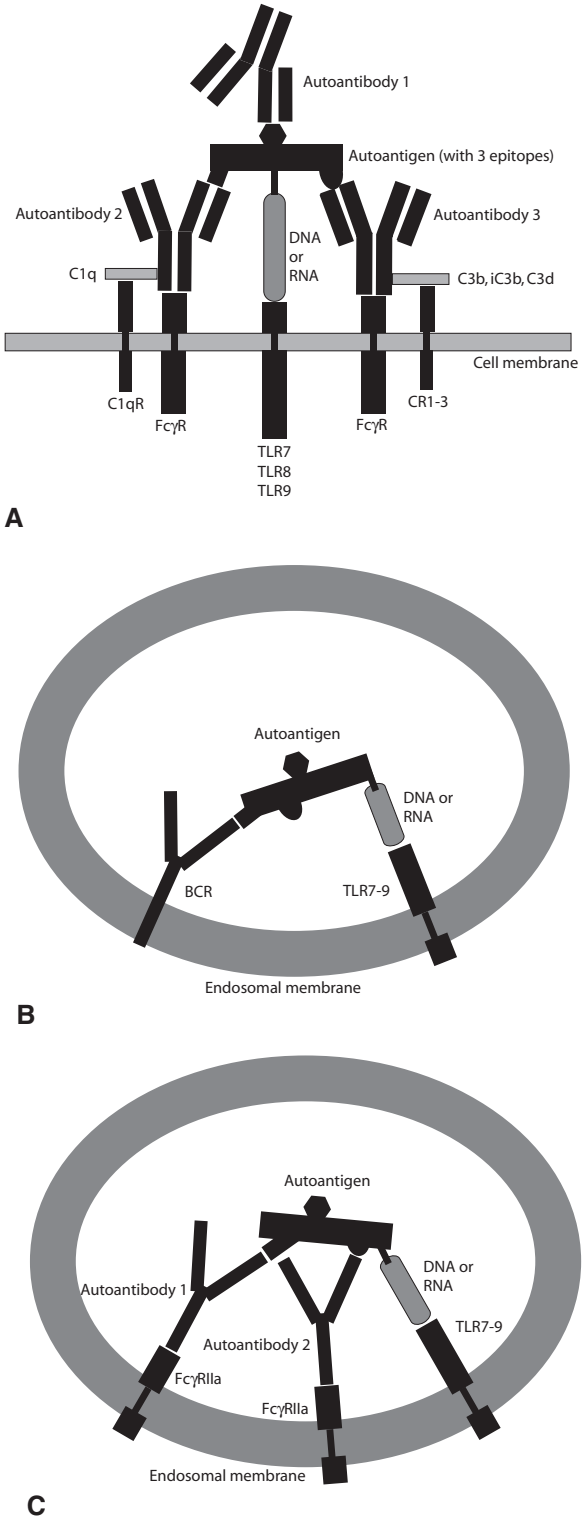

FIGURE 16.2 Composition of immune complexes (ICs) and their interaction with cellular receptors. *A*, Principal components of ICs are autoantigens, autoantibodies (e.g., IgG isotype) that bind to Fc-receptors (e.g., FcγR), as well as complement components (e.g., C1q, C3, iC3b and C3d) that bind to complement receptors (CR). Autoantigens can contain biologically active components, such as DNA or RNA that bind and activate Toll-like receptors (e.g., TLR7-9). *B*, In B cells, autoantigens that contain DNA or possibly RNA can be internalized by binding to the B-cell receptor (BCR) for antigen and then activate TLR7-9. *C*, In immature plasmacytoid dendritic cells (PDCs), also termed natural type I interferon-producing cells (NIPCs), ICs consisting of autoantibodies (IgG isotype) and RNA/DNA-containing autoantigens are internalized by the FcγRIIa and then activate TLR7-9. The DNA/RNA and TLR interact in an intracellular endoplasmatic reticulum–endosomal/phagosomal compartment.

et al., 2003). When ICs activate the complement system via the classical pathway, the split products C3a and C5a form and are highly inflammatory (Baumann et al., 2001).

Antigen can contribute to the biologic activity of ICs in other ways than influencing IC size, charge, and number of available Fc portions and complement factors. Thus, portions of the antigen can directly interact with receptors on cells, including the TLR1-10, scavenger receptors, and macrophage mannose receptors (Gordon, 2002). For instance, when ICs contain DNA and DNA-binding proteins (even nucleosomes) or RNA and RNA-binding proteins, the nucleic acids can interact with TLRs (see below) (Akira and Hemmi, 2003; Takeda and Akira, 2004). Furthermore, proteins that include calreticulins, heat-shock proteins (hsp), and high-mobility group 1 protein (HMGB1) may interact with yet other receptors, e.g., HMGB1 with RAGE (Huttunen and Rauvala, 2004), hsp with CD91 and TLR2/4 (Akira and Hemmi, 2003), and calreticulin with scavenger receptor-A (Berwin et al., 2003). Consequently, an IC can bind and activate different receptors on cells, e.g. FcR, CR, and TLR, resulting in responses that vary depending on the particular cell types and receptors engaged.

ELIMINATION OF IMMUNE COMPLEXES

The inflammatory and immunostimulatory effects of ICs (see below) are in part inhibited by systems that eliminate ICs (Prodinger et al., 2003). Activation of the complement system with deposition of C3b in ICs prevents precipitation and maintains ICs in a soluble form. In primates, such ICs can bind to the CR1 on erythrocytes and lysis of these cells is prevented because of the presence of the complement regulatory protein CD59. The ICs are then transported to the liver and spleen especially where they are released by the degradation of C3b to iC3b and C3dg. The ICs subsequently bind to CR3, CR4, and FcγRI-III on macrophages, are endocytosed, and finally degraded. In the autoimmune disease SLE, this function may be deficient (Manderson et al., 2004). The low levels of CR1 and complement components seen in SLE especially is probably secondary to the great load of circulating ICs in this disease, but may still be of pathogenic significance (Sturfelt et al., 2000). It is interesting that there is a striking increase in the incidence of SLE in individuals with hereditary deficiencies in the early complement components C1, C4, and C2 (Manderson et al., 2004). This may be due to decreased elimination of immunostimulatory ICs (see below), but the early components of the complement system, especially C1q, are also involved in the elimination of apoptotic and perhaps also necrotic cells. A reduced clearance of dead cells therefore increases the amount of autoantigens that are available for autoimmunization and IC formation.

A special situation pertains with regard to IgA-containing ICs, which can be transported across, for example, intestinal epithelia by the poly-IgR. This may be one way of eliminating antigens that otherwise may cause local inflammation in the intestine and immunization of the gut-associated lymphoid tissue especially (Monteiro and van de Winkel, 2003). Also the FcRn has functions that suggest involvement in some autoimmune diseases. This FcR prolongs the lifespan of serum IgG by preventing its uptake and degradation in endothelial and perhaps other cells (Ober et al., 2004). In a murine autoimmune arthritis model, the presence of FcRn afforded partial or complete protection against disease (Akilesh et al., 2004). The relation of the FcRn to ICs of different types remains to be evaluated.

INFLAMMATORY RESPONSES CAUSED BY IMMUNE COMPLEXES

The classical Arthus reaction was described as a dermal inflammatory reaction due to local IC formation after repeated subcutaneous or intradermal injections of foreign antigens. It has served as a model for IC-induced inflammation and the mechanism has been thought to involve activation of the complement system. Recent data indicate that, at least in mice, complement plays no major part. Instead, activation of FcγRIII by ICs is the essential trigger of the Arthus reaction, while activation of FcγRIIb is inhibitory (Ierino et al., 1993; Ravetch and Clynes, 1998; Ravetch, 2002). The complement system may still play an important accessory role, because the inflammatory complement component C5a acts by upregulating FcγRIII (Shushakova et al., 2002). In humans, FcγRIIa is also relevant in IC-induced inflammation (Tan Sardjono et al., 2003; Hart et al., 2004). This activating FcγR is lacking in mice and is expressed on many cells in the human immune system, including monocytes/macrophages, DCs, neutrophils, and thrombocytes, but not clearly on T and B cells. Importantly, mice transgenic for the human FcγRIIa can be made to display an immune thrombocytopenia that resembles that in man (McKenzie et al., 1999) and furthermore develop autoimmune diseases resembling human rheumatoid arthritis and SLE (Tan Sardjono et al., 2003).

ICs in the circulation, or formed in tissues, activate many key cells in inflammatory processes (Figure 16.3). Endothelial cells express FcγRIIa and become activated by ICs to increase expression of cell-adhesion molecules, such as VCAM-1 and E-selectin, and to produce several chemokines (Groger et al., 1996; Norman et al., 2003; Christopherson and Hromas, 2004). Thrombocytes can be directly activated via FcγRIIa, resulting in their aggregation and adherence to the blood vessel wall, blood coagulation, and endothelial cell proliferation. Granulocytes and monocytes/macrophages express all three FcγR and can, via FcγRIIa or

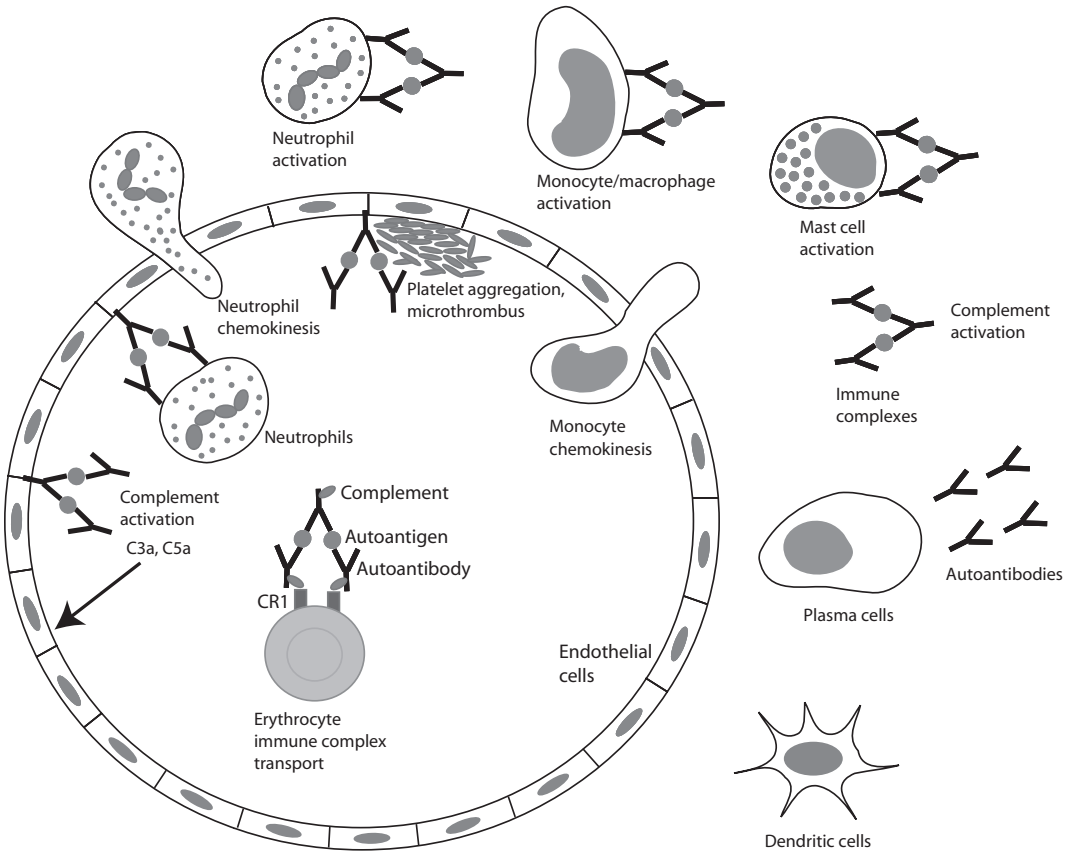

FIGURE 16.3 Inflammation in blood vessels and tissues caused by immune complexes (ICs). The ICs can activate the complement system, resulting in production of inflammatory C3a and C5a. The ICs can cause aggregation of platelets on the endothelium and also trigger release of inflammatory and cytotoxic mediators from indicated effector cells (e.g., neutrophils, monocytes/macrophages and mast cells), as well as endothelial cells. Migration of blood leukocytes to tissues occurs by chemokinesis, governed by induced expression of chemokines and cell-adhesion molecules. Migrating cells include B cells that, as plasma cells, produce autoantibodies, resulting in local IC formation, and dendritic cells that can be loaded with autoantigens and aid in the propagation of the autoimmune response.

FcγRIIIa, be activated by ICs to produce a wide range of proinflammatory cytokines and chemokines (see below). Other cells that are involved in IC-mediated inflammation are mast cells and basophilic granulocytes that, besides being triggered by antigen via cross-linking of the FcεRI-associated IgE, also can become activated by IgG-containing ICs via FcγRI or FcγRIIa (Takai, 2002; Tkaczyk et al., 2004). Inflammatory cytokines and chemokines, and expression of cell adhesion molecules on endothelial cells and leukocytes, result in adhesion of the latter to blood vessel walls and migration into tissues. Besides the cell types mentioned so far, B and T cells, as well as type 1 DCs (e.g., monocyte-derived DCs) and PDCs, express different FcRs and are involved in the inflammatory process. B cells mature into autoantibody-forming plasma cells that can give rise to local formation of ICs that sustain the inflammatory process. Thus, all cells that are considered important in the development of inflammatory changes in blood vessels and tissues can interact with ICs and become activated in various ways.

IMMUNOINHIBITORY EFFECTS OF IMMUNE COMPLEXES

Antibodies can regulate feedback their production, being either suppressive or enhancing. A wealth of experimental data, especially in mice, have revealed suppressions of more than 99% and enhancements of more than 100-fold (Heyman, 2000; 2003). In both cases, IC formation appears to be a prerequisite for these effects. Suppression of immune responses to particulate antigens, often erythrocytes, has primarily been seen with IgG antibodies, although IgM and IgE antibodies can also suppress. Attempts to demonstrate involvement of, for example, FcγR have failed and led to the conclusion that the suppressive effects of antibodies are due

to masking of antigens. The situation appears different with ICs containing soluble antigens. It seems that such ICs normally enhance antibody responses, but there is a simultaneous regulation of negative feedback that tends to restrict the enhancement and which involves the FcγRIIb. Thus, greatly increased antibody titers were seen in FcγRIIb knock-out mice after injection with IgG1-, IgG2a- or IgG2b-complexed antigens (Wernersson et al., 1999). This FcR is inhibitory in nature via its content of ITIM; is expressed on B cells, for example; and inhibits BCR activation when cross-linked with the BCR (Ravetch and Bolland, 2001). The FcγRIIb is also expressed on many other cells, including DCs and mast cells, and can inhibit the functions of such cells in immune responses (Kepley et al., 2003; 2004; Tkaczyk et al., 2004). The observation that FcγRIIb knock-out mice develop autoimmune diseases supports the contention that ICs interacting with this FcR are involved in the inhibition of autoimmune responses *in vivo* (Bolland and Ravetch, 2000).

Another way by which ICs can inhibit immune responses is via induction of interleukin (IL)-10 (see below). This cytokine has potent inhibitory effects on the production of proinflammatory cytokines, such as tumor necrosis factor (TNF)-α, and immunostimulatory cytokines, such as IL-12 and IFN-α (Moore et al., 2001). For instance, experimental IC-induced pulmonary disease in rats is aggravated upon neutralization of endogenous IL-10 (Shanley et al., 1995).

IMMUNOSTIMULATORY EFFECTS OF IMMUNE COMPLEXES

Immunostimulatory ICs can have an important role in the normal immunizing process, because antibodies appear sufficiently early in the local environment of the lymphoid organs to have a major effect on the early immune response to exogenous antigens. In fact, preformed natural antibodies may be important for the initiation of immune responses in mice (Diaz de Stahl et al., 2003; Zinkernagel, 2003). Classical complement pathway activation and FcRs are also important for normal primary immune responses, supporting a crucial role for ICs (Diaz de Stahl et al., 2003). Against this background, it is likely that ICs should also have a major impact on the immunization against autoantigens, and consequently in autoimmune diseases. Regarding possible mechanisms for this, the IC-mediated enhancement of antibody production is dependent on FcγR with respect to murine IgG1 and IgG2, and CR for IgG3 and IgM (Heyman, 2003). On the other hand, the immunostimulatory effect of IgE is due to the low-affinity FcεRII (Getahun and Heyman, 2004).

ICs consisting of aggregated immunoglobulin, or ICs containing antibodies and proteins such as ovalbumin (OVA), have at least two major effects on monocytes and DCs. They can trigger production of cytokines, such as IL-10, IL-6, and TNF-α, by monocytes/macrophages and by monocyte-derived DCs (Rönnelid et al., 2003; Radstake et al., 2004). The IC-activated DCs produce IL-10 but not IL-12, despite findings that ICs induce DC maturation (Kalergis and Ravetch, 2002; Radstake et al., 2004). Consequently, ICs have been suggested to promote type 2 helper T (Th2)-cell responses and even tolerance. A further important property of ICs is their ability to enhance uptake of exogenous antigens for presentation not only by major histocompatibility complex (MHC) class II molecules, but also MHC class I molecules (Villinger et al., 2003; Gil-Torregrosa et al., 2004). Maturation of DCs, together with MHC class I- and II-associated presentation of antigen, sets the stage for activation of Th1 cells and cytotoxic T lymphocytes (CTLs). However, this requires costimulation by appropriate cytokines, such as IL-12 and/or IFN-α, the production of which is not readily triggered by simple ICs.

Another mechanism of action of ICs is their ability to activate B cells via their content of C3b/d and antigen (Carter and Barrington, 2004). This is achieved by cross-linking the BCR and the B-cell coreceptor CD21(=CR2)–CD19 complex, resulting in decrease in the threshold for B-cell activation of more than 1000-fold. This function of ICs is at least in part exerted by follicular DCs (FDCs) that reside in the primary and secondary follicles (germinal centers) in lymphoid organs (Haberman and Shlomchik, 2003; Kosco-Vilbois, 2003). The FDCs trap ICs via FcγRII and CR1/CR2, sequester antigen in the form of ICs for long time periods, and present antigen to B cells that have hypermutated and switched class. Recognition of the antigen has been proposed to prevent apoptosis of B cells and to favor survival and selection of memory B cells and pre-plasma cells that produce antibodies with higher affinity for antigen. This dogma has, however, been questioned, primarily because affinity maturation of B cells and memory development proceeds in the absence of FDCs in certain murine experimental systems.

FUNCTION OF IMMUNE COMPLEXES CONTAINING DNA OR RNA

Nucleic acids, DNA or RNA, as part of autoantigens or ICs may be important in the etiology and pathogenesis of autoimmune diseases, because they can activate key cells in the immune system, in particular B cells (Leadbetter et al., 2002; Viglianti et al., 2003) and immature PDCs, also termed natural IFN-producing cells (NIPC) (Vallin et al., 1999a; 1999b). In order to be activating, the DNA usually needs to contain nonmethylated CpG motifs in a certain base context (Krieg, 2002), while the requirements for RNA are less well studied, but may be dependent on GU-rich single-stranded RNA (Diebold et al., 2004; Heil et al., 2004). The

RNA probably activates cells via binding to TLR7 and TLR8, and the DNA activates via TLR9. However, these TLRs are intracellular in resting cells, and the RNA or DNA must therefore enter cells in order to interact with them (Latz et al., 2004). B cells can internalize nucleic acid complexed with proteins via BCRs that recognize antigenic epitopes on the complex (Figure 16.2B). The NIPCs/PDCs can internalize ICs containing nucleic acids via interaction with FcγRIIa (Figure 16.2C) (Båve et al., 2003). In fact, TLR7-9 appears to react with DNA and RNA in the same endoplasmic reticulum–endosomal/phagosomal compartment that is used to load MHC class I molecules with peptides of an external antigen (i.e., cross-presentation) in DCs (Latz et al., 2004; Gil-Torregrosa et al., 2004).

The findings that proliferation and immunoglobulin secretion in B cells can be activated via dual engagement of BCR and TLR9, either by ICs that contain chromatin or CpG-rich dsDNA, has implications for autoimmunity (Leadbetter et al., 2002; Viglianti et al., 2003). Thus, any autoantigen that associates either with DNA that can activate TLR9, or with RNA that activates TLR7/TLR8, may stimulate production of autoantibodies with specificity for proteins or for associated DNA or RNA. Such autoantibodies are in fact common, especially in systemic autoimmune diseases. This T-cell-independent activation of B cells by means of BCR and TLR9 presents an obvious danger, giving rise to potentially pathogenic autoantibodies, and should be efficiently controlled in order to maintain self-tolerance. One such controlling mechanism may involve prevention of the response to antigen and CpG-DNA in anergic B cells by uncoupling the BCR-activated calcineurin-dependent NFκB pathway, which inhibits their proliferation, as well as by continuous stimulation of the ERK MAP kinase pathway, which inhibits their differentiation to plasma cells (Rui et al., 2003).

With regard to the NIPCs/PDCs, the activation of TLR7-9 triggers the immediate production of cytokines and the further maturation of these immature cells into efficient antigen-presenting cells (APCs) (Coccia et al., 2004; Salio et al., 2004). The NIPCs/PDCs are the principal and extremely efficient producers of type I IFN (IFN-α, -β, -ω, -ε, and -κ), the 12 different IFN-α subtypes being dominant (Fitzgerald-Bocarsly, 2002; Izaguirre et al., 2003). Besides IFN-α, NIPCs/PDCs produce other cytokines under certain conditions, including IL-6, IL-12, IP-10, MIP-1α, and IL-8. During viral infections, the produced IFN-α directly inhibits virus replication as part of the innate immunity, but also promotes development of adaptive antiviral immunity and sometimes also autoimmunity with production of autoantibodies (Hunziker et al., 2003). In recent years, IFN-α has been shown to have a variety of actions on cells in the immune system that can be important in the promotion of autoimmunity, e.g., inducing maturation of potent monocyte-derived DCs; promoting survival, proliferation, and CD40-independent immunoglobulin class switching in B cells; as well as preventing apoptosis and stimulating development of Th1 cells and cytotoxic T cells (Rönnblom et al., 2003). Autoantibodies with specificity for DNA or RNA or associated proteins can form IFN-inducing (interferogenic) ICs when combined with DNA/RNA-containing material released by apoptotic or necrotic cells (Lövgren et al., 2004), and act as endogenous IFN-α inducers that can result in continued triggering of the IFN-α production in NIPCs/PDCs. In fact, small DNA-containing ICs with the capacity to induce IFN-α production in NIPCs/PDCs have been identified in the circulation of SLE patients (Vallin et al., 1999a).

Several findings support the view that ongoing IFN-α production driven by interferogenic ICs may have a pivotal role in the etiology and pathogenesis of some autoimmune diseases (Rönnblom and Alm, 2001; Rönnblom et al., 2003). The latter include SLE, Sjögren syndrome, dermatomyositis, type 1 diabetes, and psoriasis, which all have an activated type I IFN system, and this, at least in SLE, correlates to disease activity and severity. The possible etiopathogenic role for DNA/RNA-containing ICs in such autoimmune diseases, notably SLE, is outlined in Figure 16.4. Initially, autoantibodies to antigens that contain RNA or DNA are produced, perhaps as a result of a viral infection. These autoantibodies then form ICs that serve as endogenous IFN-α inducers, activating NIPCs/PDCs via FcγRIIa and TLR. The IFN-α produced stimulates the immune system as outlined above, so as to promote an autoimmune response. This action of IFN-α is made more efficient by the fact that presentation of antigens and production of type I IFNs occur in DCs that are similar, if not identical, and located primarily in the lymphoid organs. B cells are activated by T cells, but can also be stimulated directly by chromatin–IgG complexes, which will favor production of antibodies that form IFN-α-inducing ICs. A process that has the features of a vicious circle is thus established, which maintains the autoimmune process by continuously exposing the immune system to endogenous IFN-α inducers and to IFN-α produced by the NIPCs/PDCs (Rönnblom and Alm, 2001; Rönnblom et al., 2003). This process is facilitated by increased apoptosis and reduced clearance of apoptotic material in SLE. Antibodies against autoantigens that are not associated with material containing nucleic acids are expected to occur with time.

IMMUNE COMPLEXES AND DISEASES

The prototypic autoimmune IC-mediated disease is SLE (see Chapters 27 and 28), but ICs are also involved in several other rheumatic diseases. Among the most common is RA (see Chapter 32), where IC formation can occur both in

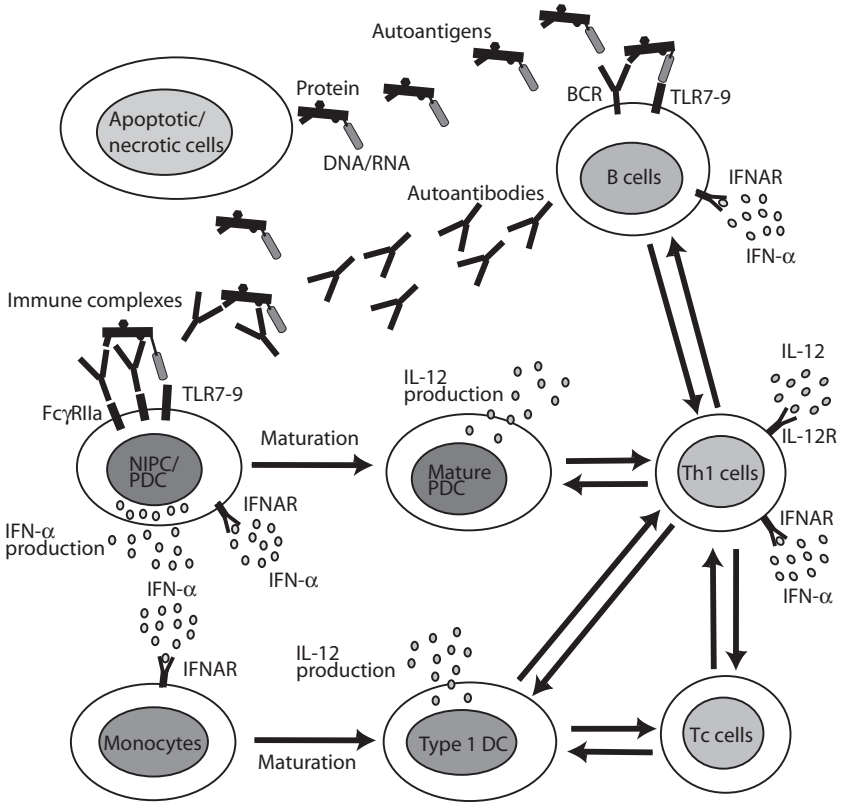

FIGURE 16.4 Role of DNA/RNA-containing immune complexes (ICs) in the induction and maintenance of autoimmune disease. Apoptotic or necrotic cells release DNA- or RNA-containing autoantigens that can activate IgG autoantibody-producing B cells. Such autoantibodies can occur during viral infections, due to stimulatory effects on B cells and induced type I interferon (IFN) production in immature plasmacytoid dendritic cells (NIPCs/PDCs). Autoantibodies and DNA/RNA-containing autoantigens form ICs that act as endogenous inducers of type I IFN production in NIPCs/PDCs. The type I IFN, especially IFN-α, has multiple immunostimulatory actions that include induced maturation of monocyte-derived DCs (type 1 DCs), development of type 1 helper T (Th1) cells and cytotoxic T (Tc) cells, as well as facilitation of B-cell activation. The resulting further autoantibody production causes formation of more IFN-inducing ICs, IFN-α production, and IFN-mediated immunostimulation. The autoimmune process is consequently sustained by a mechanism with the features of a vicious circle. IFNAR, denotes the type I IFN receptor.

tissues (Jarvis et al., 1995) and in the circulation, the latter especially in conjunction with extra-articular disease (Zlabinger et al., 1990). Several of the vasculitides affecting small vessels are IC mediated, and among these are Henöch-Schönlein purpura, cryoglobulinemic vasculitis, and polyarteritis nodosa (see Chapter 65). It is also important to note that circulating ICs may not only cause dramatic diseases such as vasculitis, but may contribute to such a common disease as atherosclerosis (see Chapters 64 and 71). Here, ICs that contain antibodies against low-density lipoprotein (LDL) and oxLDL can trigger cholesterol ester accumulation in macrophages, activation of these cells, inflammation, and plaque formation (Virella et al., 2002; Wick et al., 2004). In several organ-specific autoimmune diseases, ICs can be detected in affected tissues and/or in the circulation. Among these are type 1 diabetes mellitus (Ahmed et al., 1999), Hashimoto's thyroiditis (Nielsen et al., 2004), and pemphigus vulgaris (Wang et al., 2004). The exact role of the ICs in the disease process is unclear, but once formed they may play an important role in the perpetuation of the autoimmune reaction, as discussed above. Consequently, several procedures aimed at reducing the levels of circulating ICs or their biologic effects have been explored. Plasmapheresis or plasma exchange has thus been used for many years with some benefit mainly in severe vasculitis (Braun-Moscovici and Furst, 2003b). To more specifically remove IgG-containing ICs, a staphylococcus protein A column has been developed and used, for example, in severe refractory RA (Kunkel et al., 2002; Braun-Moscovici and Furst, 2003b) and a C1q column in SLE (Hiepe et al., 1999). Furthermore, high-dose intravenous IgG treatment can inhibit FcR-mediated effects by ICs, and has been used in several autoimmune diseases, such as autoimmune thrombocytopenic purpura, vasculitis, and SLE with glomeru-

lonephritis (Braun-Moscovici and Furst, 2003a). In future, more specific inhibitors of IC actions and efficient methods to eliminate detrimental ICs can be anticipated.

Acknowledgments

We thank Professor Birgitta Heyman and Dr Johan Rönnelid for reviewing the manuscript and providing many good suggestions. This work was supported by grants from the Swedish Research Council, the Swedish Rheumatism Foundation, the King Gustav V 80-year Foundation and the Uppsala University Hospital Research and Development Fund.

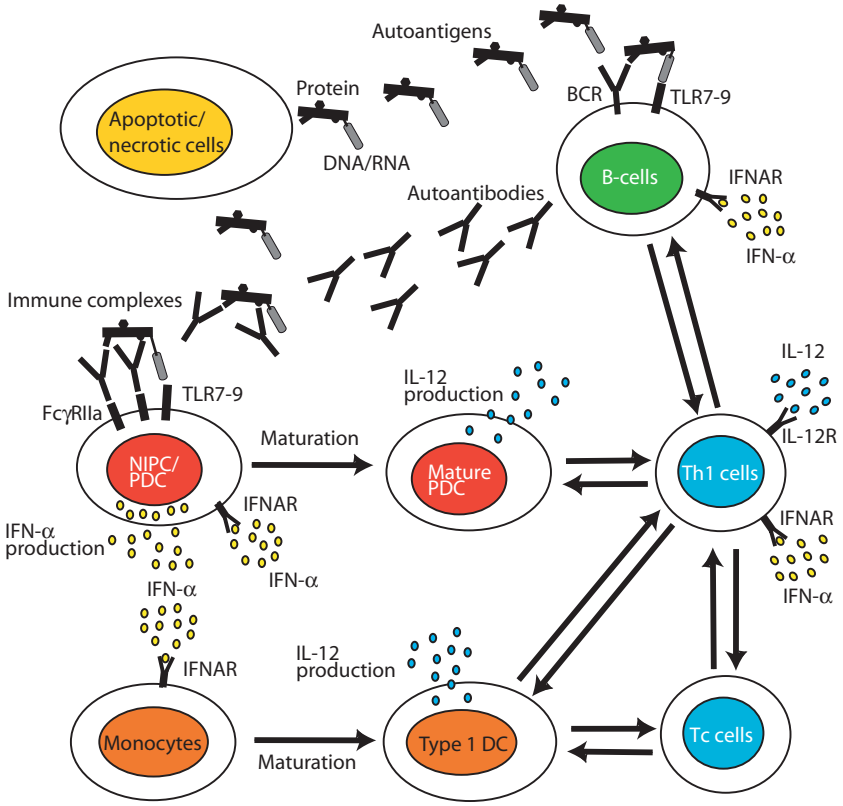

FIGURE 16.4 Role of DNA/RNA-containing immune complexes (ICs) in the induction and maintenance of autoimmune disease. Apoptotic or necrotic cells release DNA- or RNA-containing autoantigens that can activate IgG autoantibody-producing B cells. Such autoantibodies can occur during viral infections, due to stimulatory effects on B cells and induced type I interferon (IFN) production in immature plasmacytoid dendritic cells (NIPCs/PDCs). Autoantibodies and DNA/RNA-containing autoantigens form ICs that act as endogenous inducers of type I IFN production in NIPCs/PDCs. The type I IFN, especially IFN-α, has multiple immunostimulatory actions that include induced maturation of monocyte-derived DCs (type 1 DCs), development of type 1 helper T (Th1) cells and cytotoxic T (Tc) cells, as well as facilitation of B-cell activation. The resulting further autoantibody production causes formation of more IFN-inducing ICs, IFN-α production, and IFN-mediated immunostimulation. The autoimmune process is consequently sustained by a mechanism with the features of a vicious circle. IFNAR, denotes the type I IFN receptor.

Functional Effects of Autoantibodies

SALLY A. WATERMAN, MICHAEL W. JACKSON, AND TOM P. GORDON

Department of Immunology, Allergy and Arthritis, Flinders Medical Centre, Bedford Park, South Australia, Australia

Functional autoantibodies may be defined as antibodies that produce a pharmacologic-type effect on whole organs, tissues or cells *in vivo* and *in vitro*, in the absence of activation of immune mechanisms. These antibodies recognize extracellular epitopes, frequently on neurotransmitter receptors or ion channels, and may contribute to the pathogenesis of the autoimmune disease. They contrast with the majority of classical autoantibodies, such as anticentromere autoantibodies, which are useful as diagnostic markers, recognize intracellular epitopes, and are unlikely to contribute to disease pathogenesis (Table 17.1). The first functional autoantibodies to be characterized were anti-thyroid stimulating hormone (TSH) receptor autoantibodies in the 1950s (see Chapter 35; Adams and Purves, 1956; Lessof et al., 1959), followed by autoantibodies to skeletal muscle nicotinic receptors in myasthenia gravis in the 1970s (see Chapter 48; Almon et al., 1974; Lindstrom et al., 1976) and autoantibodies to neuronal voltage-gated calcium channels (VGCCs) in Lambert–Eaton myasthenic syndrome (LEMS) in the 1980s (see Chapter 48; Prior et al., 1985; Lang et al., 1987; Leys et al., 1989). Since then, new functional autoantibodies have been described in cardiac, endocrine, gastroenterologic, neurologic, and rheumatologic disorders (Table 17.2); a better understanding of these autoantibodies is likely to enhance greatly our ability to diagnose, monitor, and treat the associated autoimmune diseases.

GENERAL FEATURES OF FUNCTIONAL AUTOANTIBODIES

Epitopes

Most functional autoantibodies appear to recognize epitopes on large molecules that are either receptors or ion channels (Figure 17.1) (see Chapter 48). These molecules have complex conformations that alter depending, for example, on ligand binding or changes in membrane potential. Thus, autoantibodies may bind only under highly specific conditions. This necessitates the development of new strategies for studying and identifying functional antibodies.

Neurotransmitter Receptors

The first major class of autoantibody target is the neurotransmitter receptors. These are classified as either metabotropic (usually with a seven-transmembrane domain structure and coupled to intracellular second messenger systems; Figure 17.1B) or ionotropic (containing an intrinsic ion channel and usually comprising multiple subunits; Figure 17.1C). Neurotransmitters such as acetylcholine and glutamate have both metabotropic and ionotropic receptors, and in each case, functional autoantibodies exist to both the metabotropic and ionotropic forms (Table 17.1). Nonpeptide

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

TABLE 17.1 Comparison of the features of functional versus classical autoantibodies

Functional autoantibodies	Classical autoantibodies
Recognize extracellular epitopes such as neurotransmitter receptors and ion channels	Recognize intracellular epitopes
Very useful as diagnostic markers in some diseases, but simple assays remain to be developed for some autoantibodies	Useful diagnostic markers
Have a pharmacologic effect on cell function	No detectable effect on cell function
Activation of immune mechanisms, such as complement is not required for autoantibody-mediated effect, but may occur	May activate immune mechanisms or have no effect on function
Mimic disease symptoms following passive transfer	No effect on passive transfer, e.g. Sutton and Winer (2002)
Can be difficult to detect by standard immunochemical methods	Detectable by standard immunochemical methods, including ELISA, immunoblot, immunofluorescence
Recognize conformational, fixation-sensitive epitopes	Can recognize linear peptides
Detectable by functional assays and effective in passive transfer	No effect on functional assays or by passive transfer
Examples include anticalcium channel antibodies in LEMS and antimuscarinic receptor antibodies in Sjögren syndrome	Examples include anticentromere and anti-Sc170 antibodies in scleroderma, and anti-Hu and anti-Yo antibodies in paraneoplastic syndromes

LEMS, Lambert–Eaton myasthenic syndrome.

neurotransmitters that act at metabotropic receptors bind to a complex binding pocket composed of multiple amino acids from different transmembrane domains, but which includes part of the second extracellular loop (Zeng and Wess, 1999; Hulme et al., 2003). There has been variable success in detecting functional autoantibodies using short peptides corresponding to the second extracellular loop (see below). *In vivo*, this region of the receptor is linked by disulfide bonds to the first extracellular loop, and may be involved in the formation of receptor multimers (Zeng and Wess, 1999; Figure 17.1B). Thus, linear peptides are unlikely to mimic the conformation of the epitope *in vivo*. However, extracting whole receptors in their native conformation for use in detecting autoantibodies may be difficult, if not impossible, due to the importance of associated molecules in retaining the appropriate conformation of the receptor. Extraction of lipid rafts containing the receptor may be a compromise between using purified receptor and obtaining receptors in the correct conformation.

Ion Channels

The second major class of autoantibody target besides receptors is ion channels (Figure 17.1A). To date, autoantibodies against VGCCs and voltage-gated potassium channels (VGKCs) have been well described (Table 17.1). VGCCs are composed of four major subunits: α_1, β, $\alpha_2\delta$, and in some regions, a γ subunit. The α_1 subunit is the pore-forming subunit and spans the cell membrane. Several subtypes of α_1 subunit exist, each with different pharmacologic and electrophysiologic properties, and each present in different cell types (Jones, 1998). Neurotransmitter release depends principally on calcium influx into nerve terminals through α_{1A} or α_{1B} subunit-containing channels, and autoantibodies recognizing these subunits are present in LEMS, where they inhibit transmitter release (Lang et al., 1987; Motomura et al., 1997). Voltage-gated channels change conformation in response to membrane depolarization; thus, different epitopes may be present depending on the membrane potential of the cell. The α_{1C} subunit that forms the pore of L-type VGCCs in smooth muscle has a binding site for the dihydropyridine class of drugs. Dihydropyridine agonists bind preferentially when the cell is depolarized and the calcium channel is open, whereas the dihydropyridine antagonists bind preferentially to the closed channel at resting membrane potential (Hockerman et al., 1997). Similarly, functional autoantibodies in type 1 diabetes that mimic dihydropyridine agonists may recognize only the depolarized state of the α_{1C} calcium channel subunit (Jackson et al., 2004). Such specificity of binding is likely to explain why some autoantibodies are difficult to detect using standard techniques (see below). VGKCs have a similar structure to that of calcium channels except that four pore-forming α subunits form a complex with four intracellular β subunits (Benatar, 2000). Autoantibodies in patients with neuromyotonia recognize one of the subtypes of α subunit: Kv1.1a, Kv1.2 or Kv1.6 (Hart et al., 1997).

A small group of functional autoantibodies recognizes other structures, including gangliosides and membrane-bound enzymes. Gangliosides are sialic acid-containing glycolipids present in the outer leaflet of cell membranes, and are highly enriched in the nervous system. Bacterial

TABLE 17.2 Functional autoantibodies and their targets in autoimmune disease

Autoantibody target	Disease	Reference
N-type voltage-gated calcium channel (α_{1B} subunit)	Lambert–Eaton myasthenic syndrome	Prior et al. (1985), Lang et al. (1987), Motomura et al. (1997), Waterman et al. (1997)
P/Q-type voltage-gated calcium channel (α_{1A} subunit)	Lambert–Eaton myasthenic syndrome	Prior et al. (1985), Lang et al. (1987), Motomura et al. (1997), Waterman et al. (1997)
	Paraneoplastic cerebellar degeneration	Mason et al. (1997), Graus et al. (2002), Fukuda et al. (2003)
	Amyotrophic lateral sclerosis	Llinas et al. (1993)
L-Type voltage-gated calcium channel (α_{1C} subunit, smooth muscle isoform)	Diabetes	Jackson et al. (2004)
L-Type voltage-gated calcium channel (α_{1S} subunit)	Amyotrophic lateral sclerosis	Kimura et al. (1994)
L-type voltage-gated calcium channel (α_{1C} subunit, cardiac isoform)	Neonatal lupus congenital heart block	Xiao et al. (2001a)
Voltage-gated potassium channel	Neuromyotonia and immune-mediated peripheral nerve hyperexcitability	Shillito et al. (1995), Hart et al. (1997; 2002), Vernino and Lennon (2002)

Lysoganglioside GM1	Sydenham chorea	Kirvan et al. (2003)
Muscle-specific serine kinase (MuSK)	Myasthenia gravis	Hoch et al. (2001), Evoli et al. (2003), Sanders et al. (2003)

*AMPA receptor.

NMDA, *N*-methyl-D-aspartate; TSH, thyroid-stimulating hormone.

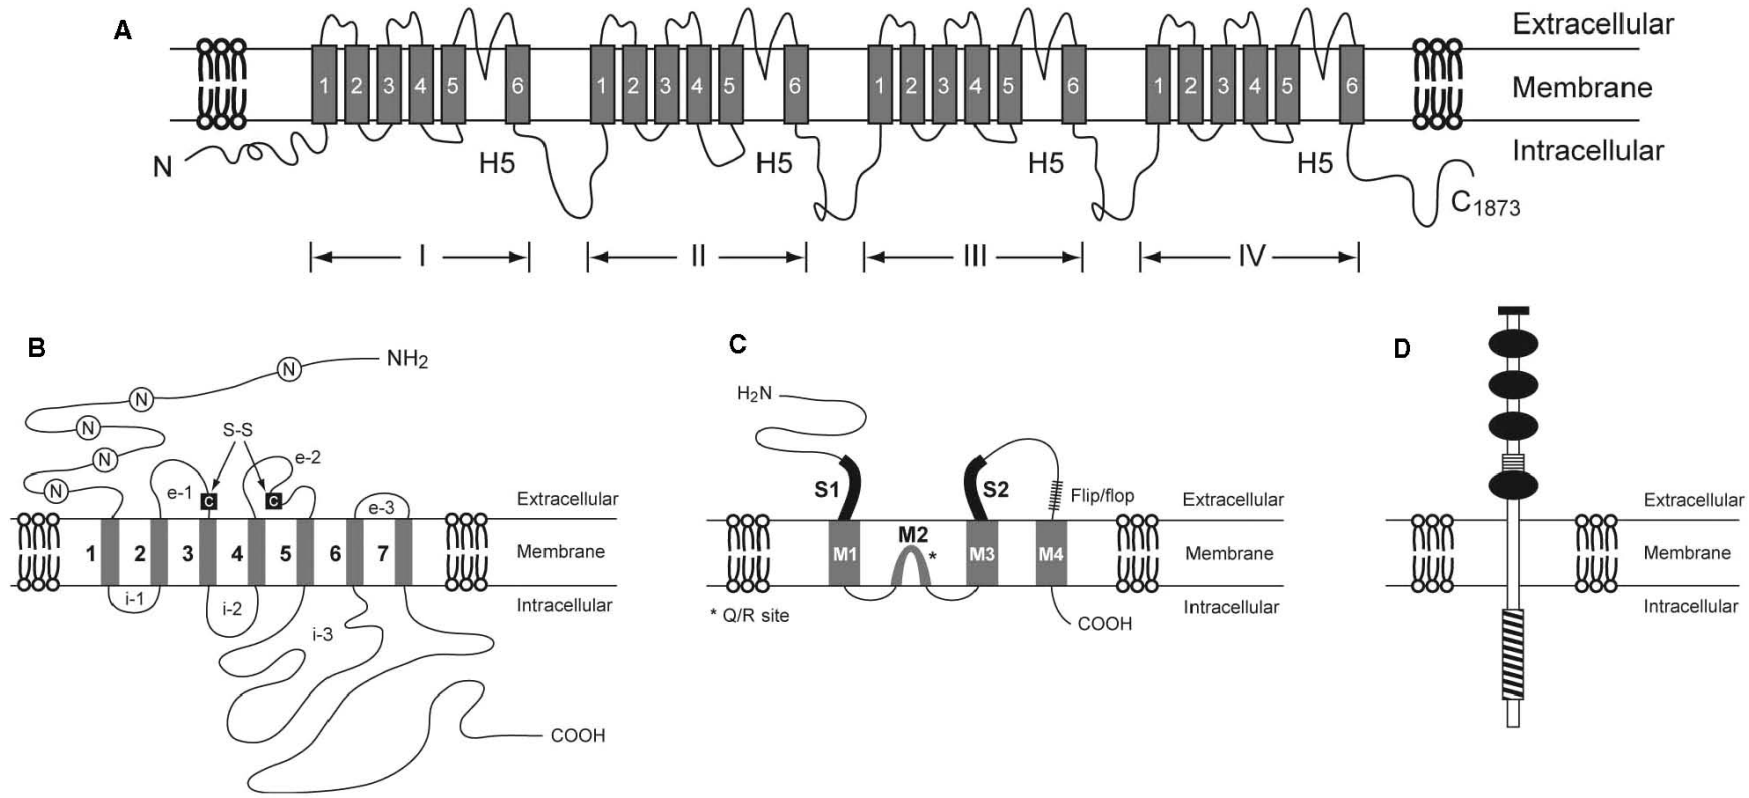

FIGURE 17.1 Structures of some channels and receptors targeted by functional autoantibodies. *A*, α Subunit of a voltage-gated calcium channel, with four repeats (I–IV) each with six hydrophobic transmembrane segments (S1–6). The fourth transmembrane domain in each repeat contains the voltage sensor, and the S5-6 hairpin regions form the lining of the channel pore and confer ion selectivity. *B*, Muscarinic receptor with seven transmembrane domains. The extracellular N-terminal has a number of glycosylation sites (N). A disulfide bond (S–S) occurs between the first and second extracellular loops (e-1 and e-2). i-1–i-3, intracellular loops. *C*, One subunit of an ionotropic glutamate receptor of the AMPA subtype, with its three transmembrane domains (M1, M3, and M4) and a cytoplasm-facing re-entrant membrane loop (M2). Each receptor is composed of four such subunits. S1 and S2 are ligand-binding domains. *D*, Muscle-specific tyrosine kinase (MuSK), with its immunoglobulin-like domains indicated by filled ovals, an N-terminal signal sequence (filled rectangle), extracellular cysteine-rich domain (shaded), and an intracellular kinase domain (hatched).

Adapted from Muth et al. (2001), Smith (1996), Dingledine et al. (1999), and Hoch et al. (2001).

lipopolysaccharides can mimic gangliosides, and most functional autoantibodies in this group of diseases have been proposed to arise as a result of molecular mimicry. Thus, autoantibodies to GM1 and GQ1b in Guillain–Barré syndrome and Miller–Fisher syndrome may arise following infection by *Campylobacter jejuni* (Schwerer, 2002), and antibodies to lysoganglioside GM1 in Sydenham chorea may follow *Streptococcus pyogenes* infection (Kirvan et al., 2003).

Muscle-Specific Tyrosine Kinase

Recently, functional autoantibodies to muscle-specific tyrosine kinase (MuSK) have been described in seronegative myasthenia gravis (Hoch et al., 2001). MuSK is required for agrin-induced clustering of skeletal muscle nicotinic receptors. It has four extracellular immunoglobulin-like domains at its N-terminus, to which autoantibodies bind (Figure 17.1D; Hoch et al., 2001). Anti-MuSK antibodies inhibit receptor clustering, thereby inhibiting skeletal neuromuscular transmission (Hoch et al., 2001).

Tumor Cell Antigens

A significant number of diseases with functional autoantibodies occur as paraneoplastic syndromes. In these diseases, the autoantigen has usually been identified in the tumor cells. It has therefore been proposed that an immune response initially directed against the tumor produces antibodies that cross-react with receptors and ion channels in normal tissues (Vincent, 2002). Myasthenia gravis can occur in association with thymoma, and skeletal muscle nicotinic receptors have been identified in thymoma cells (Newsom-Davis, 1997a). Thymoma can also be present in patients with neuromyotonia (Hart et al., 2002), reversible limbic encephalitis (Buckley et al., 2001) or Morvan syndrome (Lee et al., 1998), all with anti-VGKC autoantibodies. Whether these channels are expressed by thymoma cells is not yet known. Small cell lung carcinoma cells have a neuroectodermal origin and express many neuronal proteins, including N-type and P/Q-type VGCCs, and the α3 subunit of neuronal nicotinic receptors. Small cell lung carcinoma occurs in association with LEMS and paraneoplastic cerebellar degeneration (with anti-P/Q–type VGCC autoantibodies) (Vincent, 2002), and with autoimmune autonomic neuropathy (with antineuronal nicotinic receptor autoantibodies) (Vernino et al., 1998). Some patients with paraneoplastic cerebellar degeneration or paraneoplastic ataxia/opsoclonus produce autoantibodies to ionotropic glutamate receptors (GluR1, GluR4, and GluR6); in these particular cases, the syndromes were associated with transitional cell carcinoma of the bladder and breast cancer (Gahring et al., 1995). It is not yet known whether these tumors express glutamate receptors.

Detection of Functional Autoantibodies

Assay Characteristics

By definition, functional autoantibodies alter the activity of another molecule and must therefore recognize conformational epitopes, sometimes even activity-dependent epitopes, *in vivo*. Consequently, functional autoantibodies can be difficult to detect by standard immunochemical approaches in which molecules may be denatured, reduced or fixed, or short peptides used. This is compounded by the low serum levels of these autoantibodies and the requirement for high serum concentration, leading to an increase in background binding and low signal-to-noise ratios (McLachlan and Rapoport, 1996). Functional autoantibody detection ideally requires the use of sensitive physiologic assays, as described below. Exceptions to this are the three well-studied neurologic disorders in which highly sensitive immunoprecipitation assays with radioiodinated toxins are used diagnostically: myasthenia gravis (α-bungarotoxin-labeled nicotinic receptors), LEMS (ω-conotoxin MVIIC-labeled P/Q-type calcium channels), and neuromyotonia (α-dendrotoxin-labeled VGKCs) [reviewed in Vincent (2002)]. However, it is not certain that autoantibodies detected using these assays are capable of producing a functional effect, since binding to intracellular versus extracellular regions of the antigen is not distinguished. Nevertheless, there is a generally good correlation between disease severity and titer for individual patients with these methods (Newsom-Davis et al., 1978; Shillito et al., 1995; Motomura et al., 1997).

Flow Cytometry

Alternative methods such as flow cytometry are needed to demonstrate binding of autoantibody to extracellular epitopes (Nguyen et al., 2000), but antigens are frequently not expressed at high enough density in native cell lines to enable sufficiently sensitive analysis; transfected cell lines are an alternative (see below; Vincent, 2002), although receptors and channels are not necessarily expressed in their native form in such systems.

Limitations of Conventional Assays

For most other diseases in which functional autoantibodies have been detected, functional assays have proved the most sensitive and specific. Assays used successfully to demonstrate functional effects of autoantibodies can employ isolated cells through to tissues and whole organs undergoing physiologic behaviors (see below). Functional assays are time consuming and not readily automated. A number of investigators have thus attempted to detect functional autoantibodies using simpler techniques, including peptide-based enzyme-linked immunosorbent assays (ELISAs).

However, these may not detect autoantibodies that recognize complex conformational epitopes. The most commonly studied autoantibodies in this regard are to G-protein-coupled (metabotropic) receptors; numerous studies have used linear peptides corresponding to the second extracellular loop of the receptor in ELISAs to detect the autoantibodies. However, in the majority of studies, the methods were not sufficiently stringent to rule out nonspecific binding of antibodies to peptides. Jahns et al. (1999) reported that when significant reactivity with a peptide was defined as a signal above the mean and two standard deviations of healthy subjects, a large number of false-positive anti-β_1-adrenoceptor autoantibodies were detected in patients with dilated cardiomyopathy when the peptide ELISA results were not corrected for nonspecific binding. Correcting for nonspecific binding reduced the apparent prevalence of the autoantibodies from 51% to 34%. However, only a subgroup of these autoantibodies, 26%, also recognized native receptor in cell membranes and had a functional effect on β_1-adrenoceptor activity (Jahns et al., 1999). Similarly, reports of autoantibodies binding to the second extracellular loop peptide from 5-hydroxytryptamine-4 (5-HT_4) receptors in Sjögren syndrome and systemic lupus erythematosus (SLE) (Eftekhari et al., 2000) could not be confirmed (Buyon, 1996; Cavill et al., 2002a). Binding of autoantibodies to second extracellular loop peptides from M3- and M4-muscarinic receptors (Bacman et al., 1996; 1998) could also not be confirmed using ELISA (Cavill et al., 2002b). Furthermore, autoantibodies to M3- or M4-muscarinic receptors could not be detected using immunoblot, immunoprecipitation or immunofluorescence techniques (Gordon et al., 2001; Cavill et al., 2002b) when appropriate controls were included, but were detectable in functional assays on colon or bladder smooth muscle (Waterman et al., 2000; Goldblatt et al., 2002). Studies detecting autoantibodies to second extracellular loop peptides from M2-muscarinic receptors in Chagas disease (Goin et al., 1997) and idiopathic dilated myopathy (Fu et al., 1993) also need to be repeated using more stringent techniques, since the autoantibody prevalence rates of 39% and 53%, respectively, are likely to include false positives.

The limitations of traditional immunochemical approaches have no doubt hampered the discovery of new functional autoantibodies. Future studies are most likely to be successful if patient immunoglobulin is tested in functional assays or by passive transfer techniques. Recently, for example, autoantibodies that activate L-type VGCCs and disrupt intestinal motor activity have been detected in patients with type 1 diabetes (Jackson et al., 2004); these autoantibodies were not detected when immunoblots of neuronal or pancreatic islet tissues were screened with patient sera or when tissue sections were screened immunohistochemically. Antibodies to glutamate receptors similarly could not be detected using Western blot or immunohistochemical approaches but could be detected immunocytochemically using human embryonic kidney (HEK) cells transfected with cDNA for the glutamate receptors, or electrophysiologically using fetal mouse cortical neurons in culture (Gahring et al., 1995).

Effects on Cell, Tissue, and Organ Function *In Vitro*

Cardiomyocytes

Functional autoantibodies have been proposed to contribute to a number of cardiovascular disorders, including dilated cardiomyopathy, Chagas disease, congenital heart block, pre-eclampsia, and hypertension. Isolated cultured neonatal rat myocytes have proved useful to demonstrate functional effects of autoantibodies in these diseases on the spontaneous rate of myocyte beating. Cardiomyocytes express M2-muscarinic receptors, β_1-adrenoceptors, α_1-adrenoceptors, and angiotensin 1 (AT1) receptors, among others. Autoantibodies from patients with dilated cardiomyopathy or Chagas disease have an agonist effect at M2-muscarinic receptors and slow the rate of myocyte beating (Wallukat et al., 1999c, Chiale et al., 2001) in an atropine-sensitive manner. Similarly, affinity-purified rabbit anti-M2-muscarinic receptor antibodies have a negative chronotropic effect (Fu et al., 1995). Anti-M2-muscarinic receptor autoantibodies also increase phosphoinositol production (Chiale et al., 2001). Conversely, antibodies that have an agonist effect at β_1-adrenoceptors, also found in patients with dilated cardiomyopathy and Chagas disease, have a positive chronotropic effect and increase cAMP production in a propranolol-sensitive manner (Chiale et al., 2001). These biochemical findings have been repeated in Chinese hamster fibroblasts transfected with β_1-adrenoceptors (Jahns et al., 1999) and COS-7 cells transfected with β_1-adrenoceptors or with M2-muscarinic receptors (Chiale et al., 2001). A subset of patients with primary hypertension, particularly those who are refractory to standard pharmacotherapy (Liao et al., 2002), produce autoantibodies that act as agonists at the α_1-adrenoceptor (Luther et al., 1997); these autoantibodies have a positive chronotropic effect on cultured neonatal rat cardiomyocytes and the effect is reversed by the α_1-adrenoceptor antagonist, prazosin. Similarly, autoantibodies to the AT1 receptor have an agonist-like effect and increase the rate of spontaneous beating of neonatal rat cardiomyocytes; this effect is reversed by the AT1 receptor antagonist, losartan (Wallukat et al., 1999b).

Autoantibodies that modify ion channel function can be studied using patch clamp electrophysiology on single cells. Immunoglobulin from babies born with congenital heart block, or from their mothers, has been shown to reduce whole cell and single-channel L-type VGCC currents in

isolated ventricular cardiomyocytes from rabbit and human fetal hearts (Garcia et al., 1994; Boutjdir et al., 1997).

Single-cell studies have limitations; epitopes that are not exposed *in vivo* may be accessible to the autoantibody in isolated cells, and receptor and channel expression can be altered by cell culturing. Thus, effects of autoantibodies on single cells do not predict responses in intact, fresh tissue. Some investigators have therefore also studied the effects of autoantibodies on whole, beating heart preparations. Garcia et al. (1994) made electrocardiographic recordings from whole rabbit hearts, perfused using the Langendorff technique. Heart block occurred in one-third of hearts perfused with anti-Ro/La-containing IgG from SLE patients but not with anti-ribonucleoprotein-positive IgG or with healthy control IgG. Similarly, affinity-purified anti-Ro52 IgG from mothers of children with congenital heart block induced complete atrioventricular block in human fetal hearts, perfused using the Langendorff technique (Boutjdir et al., 1997). Serum and IgG from patients with Chagas' disease, cardiac arrhythmias, and anti-M2-muscarinic receptor autoantibodies reduced heart rate and induced atrioventricular conduction block in isolated perfused rabbit hearts in an atropine-sensitive manner (de Oliveira et al., 1997); these effects were prevented by preincubation of the patient's IgG with peptides corresponding to the second extracellular loop of the M2-muscarinic receptor (Masuda et al., 1998).

Smooth Muscle Myocytes

Autonomic dysfunction is common in autoantibody-mediated disorders, and smooth muscle-containing organs are frequently affected. A number of recent studies have thus investigated the effect of functional autoantibodies on neuronally- or agonist-evoked smooth muscle contraction in strips of tissue dissected from mouse intestine, bladder, and vas deferens. Autoantibodies from patients with primary and secondary Sjögren syndrome or with scleroderma specifically inhibit M3-muscarinic receptor-mediated contractions in mouse bladder and colon but do not affect contractions mediated by neurotransmitters at other receptors, including P_{2X}-purinoceptors in the bladder and vas deferens, neurokinin-1 and neurokinin-2 receptors in the colon, and α_1-adrenoceptors in the vas deferens (Waterman et al., 2000; Goldblatt et al., 2002; Ohlsson et al., 2002), thus also ruling out effects of the autoantibodies on common ion channels involved in mediating smooth muscle contraction, such as the L-type VGCC. Smooth muscle preparations have proved to be exquisitely sensitive to antibody-mediated effects (Cavill et al., 2004), and are currently the gold standard method for detecting autoantibodies to M3-muscarinic receptors in systemic rheumatic diseases. As discussed above, traditional immunochemical approaches have so far failed to demonstrate consistently or convincingly these autoantibodies.

While tissue strips have been used to detect some novel autoantibodies, more physiologic approaches have also been employed in which whole organs are studied while undergoing spontaneous activity *in vitro*. Migrating motor complexes (MMCs) are a form of intestinal motility that still occurs in segments of isolated colon maintained in physiologic solutions. This behavior involves the activity of many different classes of neurons in the colon in highly organized spatial and temporal patterns (Brierley et al., 2001), by contrast with the synchronous activation of all neurons, which occurs in response to maximal electrical stimulation of tissue strips (Waterman et al., 2000). Jackson et al. (2004) used this approach to identify autoantibodies in patients with type 1 diabetes and autonomic dysfunction that act as agonists at the dihydropyridine-binding site on smooth muscle L-type VGCCs and cause profound disruption of MMC activity. The disruption was mimicked by the dihydropyridine agonist, BayK 8644 and competitively inhibited by the dihydropyridine antagonist, nicardipine (Figure 17.2) (Jackson et al., 2004).

Skeletal Muscle Myocytes

The best described autoimmune neurologic disorders affect skeletal neuromuscular transmission, and the mouse phrenic nerve/hemidiaphragm preparation has become a standard method for testing the effect of functional autoantibodies at the neuromuscular junction. The preparation is usually set up for intracellular recording of electrical activity in the skeletal muscle fibers of the diaphragm, in which spontaneous and evoked transmitter release are measured, respectively, as miniature end-plate potentials (MEPPs) and end-plate potentials (EPPs). EPP amplitudes are decreased by anti-P/Q-type VGCC autoantibodies in LEMS (Lang et al., 1983; Prior et al., 1985), whereas sera from patients with amyotrophic lateral sclerosis (ALS), possibly containing antibodies that activate P/Q-type calcium channels (Llinas et al., 1993), cause an increase in MEPP frequency and in EPP amplitude (Uchitel et al., 1988; Appel et al., 1991; O'Shaughnessy et al., 1998). Autoantibodies to VGKCs in patients with neuromyotonia also cause an increase in EPP amplitude (Shillito et al., 1995). An initial increase in MEPP frequency, followed by a decrease and then absence of MEPPs, has been reported in response to sera containing anti-GQ1b ganglioside antibodies from patients with the Fisher syndrome (Roberts et al., 1994).

Neurons and Neuron-Like Cell Lines

A growing number of neurologic diseases appear to involve functional autoantibody-mediated effects (Vincent et al., 1999), many of which have been characterized using cultured neurons, neuronal-like cell lines, or brain slices.

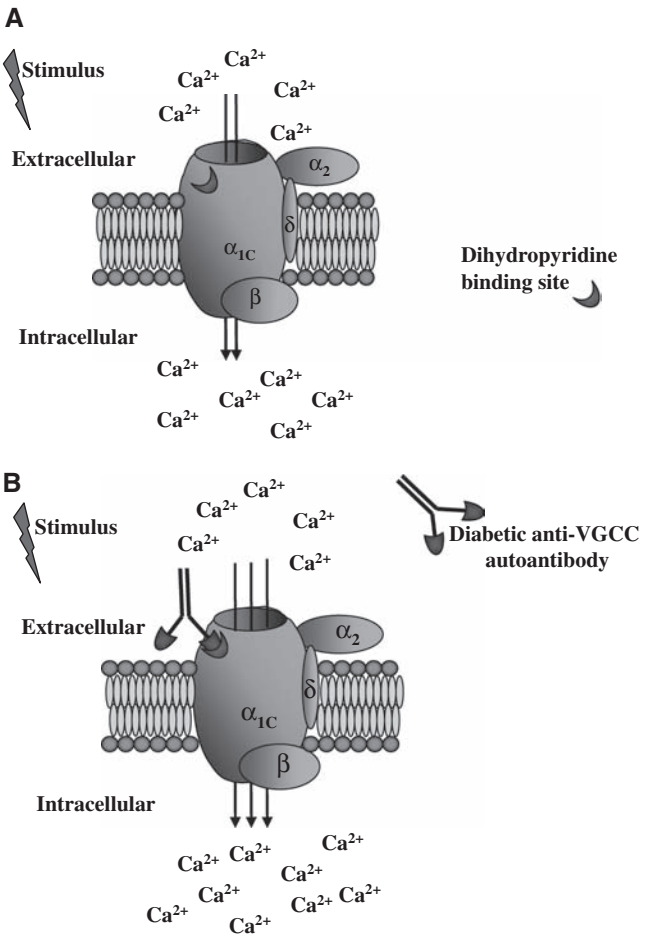

FIGURE 17.2 Schematic representation of the various subunits and their transmembrane organization in a smooth muscle L-type voltage-gated calcium channel (VGCC). In the closed conformation, intracellular entry of ions through the pore formed by the α_{1C} subunit is restricted. *A*, Following membrane depolarization, the channel opens and Ca^{2+} enters the cell. *B*, In type 1 diabetes, binding of autoantibodies to the α_{1C} subunit mimics the action of dihydropridine agonists and increases channel opening, causing enhanced calcium influx and altering calcium-mediated physiologic processes.

Adapted from Striessnig (1999).

Glutamate is the major excitatory neurotransmitter in the central nervous system (CNS), and autoantibodies to both ionotropic and metabotropic subtypes of glutamate receptor have been described in neurologic disorders. Autoantibodies to the ionotropic GluR3 receptor occur in various forms of epilepsy, including Rasmussen encephalitis (RE) (Wiendl et al., 2001; Mantegazza et al., 2002). Antibodies from RE patients activate GluR3 receptors (Twyman et al., 1995). Rabbit and murine antibodies to the GluR3B peptide similarly activate the receptor ion channel and cause death of cultured fetal mouse cortical neurons and of mouse somatosensory cortical neurons in slices, mimicking the excitotoxic effect of excess glutamate (Twyman et al., 1995; Levite et al., 1999). Excitotoxic neuronal cell death is also produced by agonistic anti-NR2 glutamate receptor autoantibodies from patients with neuropsychiatric lupus (DeGiorgio et al., 2001). Antibodies to GluR5 receptors from a subset of patients with paraneoplastic neurologic syndromes increase glutamate-evoked currents in cultured cortical neurons (Gahring et al., 1995). Metabotropic GluR1 receptors are inhibited by autoantibodies from some patients with cerebellar ataxia. Autoantibodies from these patients block induction of long-term depression in cultured cerebellar Purkinje neurons, a form of synaptic plasticity that may be associated with cerebellar motor learning behavior and is dependent on mGluR1 receptors, and also inhibit the basal activity of Purkinje cells in slices of mouse cerebellum (Coesmans et al., 2003).

Anti-VGCC autoantibodies occur in both LEMS and ALS. In LEMS, anti-VGCC autoantibodies cross-link and cause internalization of the channels (Peers et al., 1993), which over a period of hours, inhibits calcium flux and calcium currents in small cell lung carcinoma cells (Roberts et al., 1985; Viglione et al., 1993; 1995; Meriney et al., 1996), the rat neuroblastoma × glioma cell line (Peers et al., 1990), adrenal chromaffin cells (Viglione et al., 1992), and IMR32 neuroblastoma cells (Grassi et al., 1994). These effects are predominantly due to cross-linking of the P/Q-type VGCC (Motomura et al., 1997). The effect of ALS IgG is controversial. In general, the autoantibodies appear to enhance neurotransmitter release, and this has been demonstrated for norepinephrine (noradrenaline) release from rat brain cortical synaptosomes (Grassi et al., 1999), glutamate release from cultured rat hippocampal neurons (Andjus et al., 1997), and acetylcholine release from motor neurons in mouse hemidiaphragm (O'Shaughnessy et al., 1998; Uchitel et al., 1988). Release of each of these transmitters is dependent on calcium influx through P/Q-type VGCCs (Andjus et al., 1996; Grassi et al., 1999; Fratantoni et al., 2000), and increased calcium currents through P/Q-type channels in cerebellar Purkinje cells has been reported (Llinas et al., 1993). Conversely, ALS IgG has also been shown to inhibit dopamine release from rat PC12 cells, a process dependent on L-type VGCCs (Offen et al., 1998), and to inhibit calcium currents through L-type VGCCs in isolated skeletal muscle fibers (Delbono et al., 1993). Others, however, have reported depression of calcium currents in isolated cerebellar granule cells (Zhainazarov et al., 1994), which express P/Q-type VGCCs, or no effect on calcium flux in rat cerebral cortical synaptosomes (Thomas and Dunn, 1997).

Neuroblastoma cells have also been used to demonstrate a functional effect of autoantibodies from patients with Sydenham chorea; these autoantibodies recognize lysoganglioside GM1 and indirectly activate calcium-calmodulin kinase II; preliminary evidence suggests they can also stimulate transmitter release, although the mechanisms are unknown (Kirvan et al., 2003).

Antigen-Transfected Cells

Although effects of functional autoantibodies have been demonstrated on native cell lines, recent studies have capitalized on the specificity of transfected cell lines, and their high expression levels of the putative autoantigen. The majority of studies has measured binding of autoantibodies, rather than their functional effects, however.

Pinto et al. (2002) demonstrated that VGCC autoantibodies from patients with LEMS inhibit calcium flux in HEK cells expressing the α_{1A} calcium channel subunit (present in P/Q-type VGCCs), but not in cells expressing α_{1B} or α_{1E} subunits (present in N- and R-type VGCCs, respectively). In Chinese hamster ovary (CHO) cells transfected with the mGluR1α, but not the related mGluR5 receptor, autoantibodies from patients with cerebellar ataxia blocked glutamate-evoked IP_3 formation (Sillevis Smitt et al., 2000).

Passive Transfer of Human Autoantibodies

Passive immunization of laboratory animals with human functional autoantibodies is a crucial step in proving the pathogenic role of autoantibodies in disease (Drachman, 2003; Vincent, 2004) and can demonstrate the importance of a functional autoantibody, even if the precise target of the autoantibody is unknown. Passive transfer with functional effects has been achieved for relatively few diseases (Table 17.3). Typically, mice or rats are injected with purified IgG or whole serum for a period of 2 or more days, up to several weeks; the animals are then killed and tissues removed for studies *in vitro*, as above, or measurements made *in vivo*. Injection of mice with IgG from patients with LEMS for 8 days, for example, reproduces the characteristic reduction in neurotransmitter release from somatic motor nerve terminals (Lang et al., 1987) and autonomic nerve terminals (Waterman et al., 1997). After injection of IgG for only 2 days, features of Sjögren syndrome, including sicca symptoms, and bladder and gastrointestinal dysfunction, can be reproduced in mice (Robinson et al., 1998; Fang et al., 2004). Daily injection of mice for 3 days to 2 weeks with whole serum or immunoglobulin from patients with ALS causes an increase in neurotransmitter release from the skeletal neuromuscular junction (Uchitel et al., 1992; O'Shaughnessy et al., 1998).

Presumed autoantibody-mediated disorders of the CNS present additional problems for passive transfer studies in that the autoantibodies need to cross the blood–brain barrier. In some CNS disorders, such as cerebellar ataxia, intrathecal synthesis of IgG has been demonstrated; in others, autoantibodies are detectable in the cerebrospinal fluid (CSF), although synthesized peripherally. The presence of intrathecal IgG has been modeled by injecting patient IgG-containing autoantibodies to mGluR1 receptors directly into the cerebellar subarachnoid space of normal mice, producing severe, reversible ataxia (Sillevis Smitt et al., 2000) and reducing compensatory eye movements (Coesmans et al., 2003). An alternative approach has been to inject CSF containing GluR3 autoantibodies into rats via the carotid artery, followed by a pulse of mannitol to open the blood–brain barrier; this protocol produced a movement disorder within 24 h (Solaro et al., 2001). Intracerebral injection into mice of affinity-purified autoantibodies and of CSF from patients with neuropsychiatric lupus and anti-NR2 receptor autoantibodies produced hippocampal cell death; whether or not this altered significantly CNS function is unknown (DeGiorgio et al., 2001). The presence or synthesis of autoantibodies in CSF has also been demonstrated for anti-VGCC autoantibodies in paraneoplastic cerebellar degeneration (Graus et al., 2002), anti-VGKC autoantibodies in limbic encephalitis (Pozo-Rosich et al., 2003; Vincent et al., 2004), in Morvan syndrome (Liguori et al., 2001), and lysoganglioside GM1 antibodies in Sydenham chorea (Kirvan et al., 2003). Passive transfer studies are needed to test whether these autoantibodies have a functional effect in the CNS.

Whereas studies *in vitro* can detect short-term effects of autoantibodies over minutes to hours, passive transfer *in vivo* is valuable because this enables the longer-term effects of autoantibodies to be studied, so reproducing more closely the clinical situation. Furthermore, long-term exposure to functional autoantibodies reveals additional compensatory effects that take longer to develop and are not detectable in short-term studies *in vitro* (see below).

In general, functional autoantibodies appear to be present in human serum at very low concentrations, and the availability of sufficient serum for passive transfer studies has hampered progress. As an alternative, some investigators have raised artificial antibodies that recognize the same antigen as the human functional autoantibodies, and have used these in passive transfer-type studies. Nguyen et al. (2000) demonstrated that salivary secretion was inhibited 72 h after a single injection of monoclonal anti-rat M3-muscarinic receptor antibodies in nonobese diabetic (NOD).scid mice; injection of monoclonal anti-La antibodies had no effect (Nguyen et al., 2000), thus providing evidence for anti-M3-muscarinic receptor autoantibody-mediated secretory dysfunction in Sjögren syndrome. In a different disease, dilated cardiomyopathy, autoantibodies to cardiac troponin I may be pathogenic: administration of monoclonal anticardiac troponin I antibodies to normal BALB/c mice over 11 weeks impaired ventricular function, as assessed by a reduction in left ventricular ejection fraction and decreased systolic pressure development (Okazaki et al., 2003).

TABLE 17.3 Passive and active transfer studies

	Passive transfer studies		Active transfer studies	
Target	**Human autoantibodies**	**Monoclonal antibodies**	**Whole antigen**	**Peptide fragment**
β1-Adrenoceptor				Matsui et al. (1997; 1999), Iwata et al. (2001)
M2-Muscarinic receptor				Fu et al. (1996), Matsui et al. (1997; 1999)
M3-Muscarinic receptor	Fang, et al., 2004	Nguyen et al. (2000)		
TSH receptor			Marion et al. (1994)	Ohmori et al. (1992)
Metabotropic glutamate GluR1 receptor	Sillevis Smitt et al. (2000), Coesmans et al. (2003)			
Glutamate GluR3 receptor				Rogers et al. (1994), Levite and Hermelin (1999)
Neuronal nicotinic receptor			Lennon et al. (2003)	
Skeletal muscle nicotinic receptor	Toyka et al. (1997)		Patrick and Lindstrom (1973), Lennon et al. (1975)	Lindstrom et al. (1978)
P/Q-type VGCCs	LEMS: Fukunaga et al. (1983), Lang et al. (1987), Waterman et al. (1997) ALS: O'Shaughnessy et al. (1998)			
L-type VGCC (α_{1C} smooth muscle isoform)	Jackson et al. (2004)			
L-type VGCC (α_{1C} cardiac isoform)	Boutjdir et al. (1997)		Xiao et al. (2001b) (Ro52)	
VGKC	Sinha et al. (1991), Shillito et al. (1995)			
Cardiac troponin I		Okazaki et al. (2003)		

ALS, Amyotrophic lateral sclerosis, LEMS, Lambert–Eaton myasthenic syndrome; TSH, thyroid-stimulating hormone; VGCC, voltage-gated calcium channel; VGKC, voltage-gated potassium channel.

Active Immunization with Antigen

Where passive immunization with patient IgG has been shown to reproduce pathophysiologic changes in animals, induction of experimental disease by antigen can provide additional evidence for the role of functional autoantibodies. However, the induction of a syndrome following immunization with a putative autoantigen is insufficient to prove a role for functional autoantibodies in the absence of evidence for their presence in patients and for a functional effect following passive transfer. A lupus-like syndrome can be produced in mice following immunization with a peptide fragment corresponding to the second extracellular loop of the 5-HT_4 receptor (Eftekhari et al., 2001). However, autoantibodies to the 5-HT_4 receptor could not be detected in patients with SLE or Sjögren syndrome when more stringent methods were used (Buyon et al., 2002; Cavill et al., 2002a). In the absence of other evidence, antibodies to the 5-HT_4 receptor are, therefore, at present an experimental curiosity and not of clinical relevance.

Glutamate Receptor 3

Active immunization with either whole antigen or a peptide fragment has been performed for a number of diseases in which functional autoantibodies play a role. Immunization of rabbits with GluR3 receptor peptides provided some of the first evidence that RE may be mediated by autoantibodies to these receptors. The rabbits developed seizures and histopathology of the brain reminiscent of that seen in patients with RE (Rogers et al., 1994). While mice immunized with GluR3B peptides also developed anti-GluR antibodies and significant inflammatory brain pathology, they did not show signs of epilepsy, suggesting that addi-

tional factors are required in some species for epilepsy to occur (Levite and Hermelin, 1999).

G-Protein-Coupled Receptors

Several investigators have reported that immunization of rabbits with second extracellular loop peptides from G-protein-coupled receptors results in production of functional autoantibodies to those receptors (Fu, 1995; 1999; Matsui et al., 1997; 1999; Iwata et al., 2001; Cavill et al., 2004). These procedures produce pathologic changes corresponding to those reported in patients (see below). Immunization of rabbits with peptides from β_1-adrenoceptors or M2-muscarinic receptors altered receptor expression and sensitivity, and resulted in dilated cardiomyopathy (Fu et al., 1996; Matsui et al., 1997; Iwata et al., 2001).

Ganglionic Nicotinic Acetylcholine Receptors

Autoantibodies to neuronal nicotinic receptors have been described in autoimmune autonomic neuropathies (Vernino et al., 1998; 2000; Balestra et al., 2000). Lennon et al. (2003) gave rabbits a single injection of a recombinant protein corresponding to the extracellular N-terminal domain of the α3 subunit present on neuronal nicotinic receptors in autonomic ganglia. The majority of rabbits produced antibodies to neuronal nicotinic receptors at serum levels of greater than 3 nM, and developed a dysautonomia syndrome reminiscent of that in patients, affecting sympathetic, parasympathetic, and enteric divisions of the autonomic nervous system. Specifically, the rabbits had gastrointestinal hypomotility, dilated pupils with impaired light response, ptosis, and urinary retention. These changes were evident within 20 days of inoculation, and the severity of the symptoms correlated with antibody titer (Lennon et al., 2003). Passive transfer of autonomic dysfunction to animals by the patient autoantibodies has recently been reported (Vernino et al., 2004).

Voltage-Gated Calcium Channels

VGCCs are targeted in several autoimmune conditions, including LEMS, ALS, type 1 diabetes, and congenital heart block; in each disease the epitopes appear to reside on a specific α_1 subunit. These are very large molecules (see Figure 17.1A), and it has not been possible to inject animals with whole subunits. Since the precise epitopes on the α_1 subunits are not yet known, there have been no obvious peptide sequences to use in active immunization studies. To model LEMS, Komai et al. (1999) chose to inject rats with a peptide corresponding to the S5–S6 linker region from domain III of the α_{1A} subunit. This is an extracellular domain known to be very important for the function of the P/Q-type VGCC, although it had not previously been shown to be antigenic. The rats produced antibodies that bound P/Q-type VGCCs and showed moderate weakness and a reduction in quantal acetylcholine release at the skeletal neuromuscular junction (Komai et al., 1999). Autonomic function in the rats was not assessed.

Antibodies recognizing the α_{1C} subunit of L-type VGCCs alter cardiac function in neonatal lupus congenital heart block (Boutjdir, 2000). The antibodies responsible for this effect have been reported to be the anti-Ro antibodies, and there is some homology between the three-dimensional structures of the L-type VGCC and Ro52 (Qu et al., 2001). To produce an active immunization model of congenital heart block, Xiao et al. (2001b) therefore chose to inject female rabbits with Ro52, rather than with a peptide from the α_{1C} subunit of L-type VGCCs. Offspring born to the immunized mothers had varying degrees of heart block and a reduction in calcium channel density in the heart (Xiao et al., 2001b). Sera and purified IgG from the mothers inhibited calcium currents in oocytes expressing the α_{1C} subunit of L-type VGCCs (Xiao et al., 2001b). Immunization of pregnant mice with recombinant Ro52 also resulted in the production of anti-Ro autoantibodies that crossed the placenta and correlated with atrioventricular conduction block in the pup (Boutjdir et al., 1997). These data are consistent with anti-Ro52 autoantibodies cross-reacting with L-type VGCCs and blocking conduction in the atrioventricular node. This hypothesis remains controversial, however, since sera containing anti-Ro52 antibodies did not alter L-type VGCC-dependent contractile responses of the vas deferens, whose α_{1C} pore-forming subunit shares 96% sequence similarity with the cardiac α_{1C} subunit isoform (Ohlsson et al., 2002).

PATHOPHYSIOLOGIC MECHANISMS OF FUNCTIONAL AUTOANTIBODIES

The effects of functional autoantibodies can be considered to occur in three stages. First, is the primary pharmacologic effect of the autoantibody on its target, which occurs within minutes to hours, and is reversible with time. This may be followed by secondary, plastic changes that compensate for the primary effect of the autoantibody. These changes generally occur over a time course of days to weeks. Lastly, the autoantibody may trigger chronic degenerative changes that are irreversible. Immunotherapies need to be administered prior to this phase of the disease if they are to be effective.

Primary Pharmacologic Effects of Autoantibodies

Primary pharmacologic effects of the autoantibodies are those that have been studied in detail in isolated

cells, tissues, and organs *in vitro* (see above). Functional autoantibodies may act as agonists or antagonists at neurotransmitter receptors, as exemplified by agonistic anti-β_1-adrenoceptor autoantibodies in idiopathic dilated cardiomyopathy and antagonistic anti-M3-muscarinic receptor autoantibodies in Sjögren syndrome. The effects of these autoantibodies are detectable within 30 min (Jahns et al., 1999; Waterman et al., 2000), and mimic the effect of synthetic agonists and antagonists to the receptors by interfering competitively or noncompetitively with ligand binding.

Agonists at G-protein-coupled receptors usually trigger receptor internalization (Edwardson and Szekeres, 1999) via β-arrestin- and clathrin-dependent or -independent mechanisms (Ferguson, 2001). Similarly, autoantibodies with agonist-type effects can cause receptor sequestration. Autoantibodies to M2-muscarinic receptors in Chagas disease cause receptor desensitization and internalization (Leiros et al., 1997) and anti-β_1-adrenoceptor autoantibodies in dilated cardiomyopathy cause receptor sequestration and prevent receptor recycling (Limas et al., 1991). Not all findings are consistent with this pattern, however. Other investigators have reported that autoantibodies to M2-muscarinic receptors (Wallukat et al., 1999a), to β_1-adrenoceptors (Magnusson et al., 1994) in dilated cardiomyopathy, and to α_1-adrenoceptors in hypertension (Luther et al., 1997) act as nondesensitizing agonists and do not cause receptor internalization (Wallukat et al., 1999a). At least some anti-M2-muscarinic receptor and anti-β_1-adrenoceptor antibodies act as only partial agonists, since they cannot evoke a full agonist response (Goin et al., 1994b; Perez Leiros et al., 1994; Staudt et al., 2001). This may account for the apparent lack of receptor internalization since there is a correlation between intrinsic activity of an agonist and its ability to cause receptor internalization (Edwardson and Szekeres, 1999). However, the reasons for the differences between full and partial agonist activity of autoantibodies and between those causing nondesensitizing agonist effects (Wallukat et al., 1999a) versus receptor desensitization and sequestration (Limas et al., 1991) remain to be explained.

Some functional autoantibodies do not produce a direct pharmacologic blockade, but instead inhibit channel or receptor function by causing cross-linking and internalization of the target. Anti-VGCC autoantibodies in LEMS do not have any effect within 6 h, but inhibit transmitter release after a longer period of incubation (Peers et al., 1993; Houzen et al., 1998), corresponding with the time taken to cause internalization of the calcium channels. A reduction in calcium channel number in the brain also occurs in paraneoplastic cerebellar degeneration in association with LEMS (Fukuda et al., 2003).

The acute effects of functional autoantibodies sometimes require bivalent antibodies. This is the case in LEMS, for example, suggesting that the autoantibodies cross-link the VGCCs and trigger their internalization (Peers et al., 1993). Monovalent autoantibodies derived from LEMS IgG do not have a functional effect (Peers et al., 1993). Similarly, a monoclonal antibody to the M2-muscarinic receptor, which mimics autoantibodies from patients with idiopathic dilated cardiomyopathy, only altered the rate of cardiomyocyte beating in its bivalent form (Elies et al., 1998). By contrast, monovalent F(ab) fragments of antibodies to M3-muscarinic receptors in Sjögren syndrome and scleroderma behave similarly to bivalent autoantibodies, and inhibit muscarinic receptor-mediated smooth muscle contraction (Cavill et al., 2003). Functional autoantibodies in myasthenia gravis and the Fisher syndrome also do not require antibody bivalency to exert their pathogenic effects (Sterz et al., 1986; Buchwald et al., 1998). A more complex situation may exist in some disorders involving autoimmunity to G-protein-coupled cardiovascular receptors. A monoclonal antibody to the β_2-adrenoceptor that mimics human autoantibodies has an agonist effect on rat cardiomyocytes; however, monovalent fragments of this antibody have an antagonist effect (Mijares et al., 2000). β_2-Adrenoceptors, like other G-protein-coupled receptors, are thought to exist in an inactive monomeric form and an active dimeric form (Hebert et al., 1996). The bivalent antibody may thus induce the formation of an active dimer, enabling signal transduction and producing an agonist-like effect. The monovalent antibody, however, may cause a conformational change in the ligand-binding site, thereby inhibiting allosterically the binding of agonists (Mijares et al., 2000).

Secondary Effects

Studies of tissues obtained from patients with autoantibody-mediated disorders, and from animals passively immunized with IgG from patients or actively immunized with antigen, provide ample evidence for secondary changes in receptor and channel expression. These compensatory changes can result in the opposite clinical picture from that predicted on the basis only of the acute effect of the autoantibody.

While anti-M3-muscarinic receptors acutely inhibit cholinergic responses and cause a functional denervation (Waterman et al., 2000; Goldblatt et al., 2002), long-term exposure to these antibodies is associated with an increase in muscarinic receptor number. M3-muscarinic receptor expression is increased in salivary gland biopsies of patients with Sjögren syndrome (Beroukas et al., 2002) and in mice passively immunized with IgG from a patient (Fang et al., 2004). These changes are pathophysiologically significant, resulting in cholinergic hyperresponsiveness and a characteristic range of symptoms. Early in Sjögren syndrome, prior to irreversible destruction of the salivary glands, sialorrhea occurs (Mignogna et al., 2003). In the passive transfer model of Sjögren syndrome, bladder smooth muscle shows hyper-

responsiveness to cholinergic stimulation, resulting in bladder detrusor instability (Fang et al., 2004), a feature also reported in patients (Leppilahti et al., 2003; Walker et al., 2003). Bronchial and gastrointestinal smooth muscle hyperresponsiveness also occur in patients with Sjögren syndrome (Tsianos et al., 1985; Gudbjornsson et al., 1991; La Corte et al., 1991; Ludviksdottir et al., 2000; Rosztoczy et al., 2001; Hocevar et al., 2003). The molecular mechanisms causing the upregulation of muscarinic receptors in Sjögren syndrome are unknown, but their manipulation offers potential therapeutic targets for the future.

Changes also occur in cardiovascular receptor expression and function in cardiomyopathy, and β-adrenoceptors have been the most thoroughly studied. Iwata et al. (2001) found a reduction in β_1-adrenoceptor expression and receptor sensitivity in the hearts of rabbits immunized for 6 months with β_1-adrenoceptor peptides [however, see Matsui et al. (1997)]. Incubation of isolated neonatal rat cardiomyocytes with anti-β_1-adrenoceptor autoantibodies for 72 h also caused a decrease in β_1-adrenoceptor expression (Podlowski et al., 1998). These findings correspond with clinical data of decreased adrenoceptor number and receptor sensitivity in patients with dilated cardiomyopathy (Bristow et al., 1982; Denniss et al., 1989). The receptor changes in rabbits and isolated cardiomyocytes could be prevented by treatment with the β_1-selective antagonist bisoprolol, which has inverse agonist activity (Podlowski et al., 1998; Iwata et al., 2001). Similarly, the decreased sensitivity to catecholamines and β-adrenoceptor density in human heart can be reversed using the related drug, metoprolol (Heilbrunn et al., 1989). Ventricular ectopy in patients with ventricular arrhythmias and anti-β_1-adrenoceptor antibodies can be suppressed using the β-adrenoceptor antagonist, nadolol (Chiale et al., 2001). Functional anti-β_1-adrenoceptor autoantibodies are found only in a subpopulation of patients with dilated cardiomyopathy (Jahns et al., 1999), so that other mechanisms such as elevated norepinephrine levels must contribute to altered receptor sensitivity and density in the remainder of patients.

Autoantibodies that stimulate M2-muscarinic receptors also occur in some forms of cardiomyopathy, particularly those associated with sinus node dysfunction (Chiale et al., 2001). Muscarinic receptors are upregulated in the human heart in dilated cardiomyopathy (Le Guludec et al., 1997), but it is not known what proportion of these patients have anti-M2-muscarinic receptor autoantibodies. In a model based on active immunization of rabbits, upregulation of M2-muscarinic receptors occurred after 6–12 months of immunization with peptides corresponding to the second extracellular loops of the receptor (Fu et al., 1996; Matsui et al., 1997). The response to cholinergic stimulation of isolated cardiomyocytes from the actively immunized animals was unfortunately not measured, so it is not clear whether there was any change in receptor sensitivity. Nevertheless, preliminary studies show that the muscarinic receptor antagonist, atropine, totally or partly corrects the cardiac electrophysiologic abnormalities in patients with sinus node dysfunction and anti-M2-muscarinic receptor autoantibodies (Chiale et al., 2001).

Alteration in receptor or channel expression is not always restricted to the specific target of the autoantibody, but may involve related receptors or ion channels. In LEMS, the initial downregulation in P/Q-type VGCCs is followed by an upregulation of N-type calcium channels in autonomic nerve terminals (Waterman et al., 1997) and of L-type calcium channels in motor nerve terminals (Xu et al., 1998; Flink and Atchison, 2002). A similar upregulation of L-type calcium channels at motor nerve terminals has been reported following passive transfer of IgG from patients with ALS (Fratantoni et al., 2000). These changes result in skeletal neuromuscular transmission becoming sensitive to dihydropyridine-type blockers. It is not clear whether similar changes occur *in vivo*; if they do, extra care is warranted in prescribing calcium channel blockers to these patients.

Chronic Degenerative Changes

Long-term studies of actively and passively immunized animals indicate that functional autoantibodies can cause chronic degenerative changes that are irreversible. Such changes are particularly evident in disorders of the CNS, in which neuronal death occurs.

Examination of a postmortem brain from a patient with paraneoplastic cerebellar ataxia and autoantibodies that block mGluR1 receptors showed a two-thirds reduction in the number of cerebellar Purkinje cells in the absence of an inflammatory cell infiltrate, consistent with autoantibody-mediated damage (Coesmans et al., 2003). The mechanism of this damage is unknown, but it is interesting to note that mGluR1 receptor antagonists also cause degeneration of Purkinje cells (Catania et al., 2001).

Autoantibodies that activate ionotropic glutamate receptors have been implicated in causing neuronal death through excitotoxic mechanisms, i.e., by overactivation of the glutamate receptor. Antibodies raised against GluR3 receptor peptides caused apoptosis of cultured rat hippocampal neurons in a complement-independent manner (Levite et al., 1999). Cell death was prevented by coadministration of the glutamate/AMPA receptor antagonist, CNQX, or of the GluR3 receptor peptide (Levite et al., 1999). Antibodies to the NR2 subunit of the *N*-methyl-D-aspartate (NMDA) receptor from patients with SLE are also able to kill neurons within 2 days of intracerebral injection into mice; hippocampal cell death was prevented by coadministration of the NMDA receptor antagonist, MK-801 (DeGiorgio et al., 2001). Serum autoantibodies and CSF from a patient with SLE and progressive cognitive decline also caused apoptosis of cultured human fetal neurons (DeGiorgio et al., 2001).

Apoptotic cell death was complement independent, since it also occurred when $F(ab)'_2$ fragments of the autoantibodies were used (DeGiorgio et al., 2001). In some neurologic disorders, complement-mediated mechanisms may also contribute to neuronal death. Thus, anti-GluR3 autoantibodies can trigger complement-mediated cell death; IgG from rabbits immunized with GluR3 peptides caused complement-dependent death of cultured cortical neurons, and GluR3 antibodies and complement were detected in the neocortex and hippocampus of the immunized rabbits (He et al., 1998). IgG and complement deposition also occur in the cerebral cortex of a subset of patients with RE (He et al., 1998; Whitney et al., 1999).

Functional autoantibodies that activate VGCCs are able to induce neuronal cell death by excitotoxic mechanisms. Immunoglobulin from patients with ALS caused complement-independent death of cultured motor neurons within 2 days, and this was prevented by the addition of toxins that block P/Q-type VGCCs (Smith et al., 1994). Furthermore, injection into mice of IgG from a patient with ALS over 2 weeks caused axonal degeneration and denervation of skeletal muscle fibers, which was evident 2–10 weeks after the treatment (Uchitel et al., 1992).

Whereas cell death is an important degenerative change in autoantibody-mediated neurologic disorders, fibrosis is common in diseases affecting non-neuronal tissues. Idiopathic dilated cardiomyopathy is characterized by dilation of the ventricles and thinning of the walls. These findings have been replicated in active immunization of models of dilated cardiomyopathy, using either M2-muscarinic receptor or β_1-adrenoceptor peptides as antigens over 12 months (Matsui et al., 1997). At the light microscopic level, multifocal degeneration and necrosis of myocardiocytes was evident, together with inflammatory cell infiltrates (Matsui et al., 1997). Another study found myocardial hypertrophy and interstitial fibrosis after 6 months' immunization of rabbits with β_1-adrenoceptor peptides (Iwata et al., 2001). Similarly, Fu et al. (1996) noted ultrastructural changes, such as mitochondrial swelling and disruption of cisternae, in rabbit heart after 6 months' immunization with M2-muscarinic receptor peptides.

CONCLUDING REMARKS

The discovery of functional autoantibodies has provided new insights into potential pathophysiologic mechanisms in numerous autoimmune diseases. Importantly, early detection of these autoantibodies and their removal by immunotherapy (plasma exchange, intravenous immunoglobulin) offers an additional approach to treatment that may halt disease progression and prevent the chronic irreversible changes that are typical of autoimmune disease.

There is likely to be a large family of functional autoantibodies. The earliest functional autoantibodies detected in the neurologic diseases myasthenia gravis, LEMS, and neuromyotonia, have their parallel in naturally occurring genetic disorders affecting the skeletal muscle nicotinic receptor (congenital myasthenia), P/Q-type VGCCs (spinocerebellar ataxia), and VGKCs (episodic ataxia/myokymia). It seems more than reasonable to assume that autoimmune equivalents will also be detected for diseases affecting other ion channels or receptors. Indeed, hundreds of G-protein-coupled receptors have now been discovered and sequenced, and these may represent vulnerable targets for as yet unidentified functional autoantibodies. The physiologic approaches and techniques described in this chapter should facilitate the discovery of these and other autoantibodies that have remained undetected using standard immunochemical approaches.

ULRICH H. VON ANDRIAN†
†CBR Institute for Biomedical Research, Harvard Medical School, Boston, Massachusetts, USA

Cell migration is fundamental to inflammatory processes. The molecules that facilitate cell migration, such as adhesion molecules and chemoattractant receptors, also represent highly attractive targets for therapeutic intervention. Moreover, chemokine receptors and adhesion molecules have proved to be excellent markers for distinguishing functional subsets of T and B cells, since certain subsets need to be placed in the appropriate place to perform their immunologic roles. The discovery of numerous adhesion molecules and chemokine receptors over the past 20 years has enabled a more complete understanding of how specialized leukocyte subsets are channeled to appropriate microenvironments during an immune response. There is also an appreciation that, under resting conditions, lymphocyte migration is highly rationalized, with the existence of lymphoid versus non-lymphoid tissue migration streams, and tissue-specific migration pathways through the skin and gut. Different types of immune response evoke different subsets of leukocytes, which use different adhesion molecules and chemoattractant receptors. Thus type 1 inflammatory responses, which depend on type 1 helper T (Th1) cells and macrophages, differ from type 2 responses, which depend on Th2 cells and eosinophils, in the types of chemokines and chemokine receptors used. This chapter will concentrate on the adhesion, chemoattraction, and migration of leukocytes, particularly T cells, that are associated with autoimmune responses. Adhesion molecules and chemoattractant receptors are particularly promising targets for the development of new therapies to treat autoimmune diseases, so a brief synopsis of the most promising targets and the status of preclinical and clinical trials will be outlined.

MICROVASCULAR DETERMINANTS OF T-CELL RECRUITMENT

Specialized microvessels control T-cell migration from blood into tissues. In most microvascular beds, except the spleen, lung, and liver, postcapillary venules, but not arterioles or capillaries, bind leukocytes. Because intravascular leukocytes are subjected to extreme physical conditions (sheer stress), cells use specialized adhesion receptors, the selectins, which form stable bonds with counter-receptors in the vascular wall (Table 18.1) (Carlos and Harlan, 1994; Springer, 1994). Adhesion receptors on leukocytes and on vascular endothelial cells also function as tissue-specific recognition molecules. For example, the specialized high endothelial venules (HEVs) in lymph nodes and Peyer patches constitutively express *vascular addressins*, which

TABLE 18.1 Selectins, integrins, and their ligands

Adhesion molecule	Distribution	Ligand(s), receptor(s)	Role in T-cell migration
Selectins			
L-selectin (CD62L)	Most leukocytes	PNAd, PSGL-1, MAdCAM-1, E-selectin, others	Homing to lymph nodes and Peyer patches
E-selectin (CD62E)	Endothelial cells	PSGL-1, ESL-1, CLA, sLe^{X+} glycol-proteins and -lipids	Memory/effector cell homing to skin and sites of inflammation
P-selectin (CD62P)	Endothelial cells, platelets	PSGL-1, CD24, PNAd	Memory/effector (Th1) cell homing to sites of inflammation; platelet-mediated interaction with $PNAd^+$ venules
Selectin ligands			
Sialyl-$Lewis^X$ (sCD15)	Myeloid cells; some memory (Th1) cells; HEVs; other cell types	All selectins	Function depends on presentation molecule
PSGL-1	All leukocytes	P-selectin; also binds L-/E-selectin	Effector cell homing to inflamed tissues
Peripheral node addressin (PNAd)	HEVs in LNs and inflamed tissues	L-selectin, P-selectin	Naïve/central memory T-cell homing to LNs
Cutaneous lymphocyte antigen (CLA)	Skin-homing T cells, DCs, granulocytes	E-selectin	Memory/effector T-cell homing to inflamed skin
β2 Integrins*			
αLβ2 (LFA-1, CD11a/CD18)	All leukocytes	ICAM-1, -2, -3, -4 and -5	Homing; inflammation; adhesion to APCs
αMβ2 (Mac-1, CD11b/CD18)	Myeloid cells, some activated T cells	ICAM-1, factor X, fibrinogen, $C3b_i$	Unknown
αXβ2 (p150/95, CD11c/CD18)	Dendritic cells	Fibrinogen, $C3b_i$	Unknown
αDβ2 (CD11d/CD18)	Monocytes, macrophages, eosinophils	VCAM-1, ICAM-1 and -3	Unknown
α4 Integrins*			
α4β1 (VLA-4)	Most leukocytes except neutrophils	VCAM-1, fibronectin, α4 integrin	Memory/effector cell homing to inflamed tissues, esp. lung
α4β7	Lymphocytes, NK, mast cells, basophils, monocytes	MAdCAM-1, fibronectin, weak binding to VCAM-1	Homing to gut and associated lymphoid tissues
Immunoglobulin superfamily			
ICAM-1 (CD54)	Most cell types	LFA-1, Mac-1, fibrinogen	Critical endothelial ligand for β2 integrins
ICAM-2 (CD102)	Endothelial cells, platelets	LFA-1	Unknown
VCAM-1 (CD106)	Endothelial cells, BM stroma, FDC, osteoblasts, mesothelium	α4β1, α4β7, αDβ2	Memory/effector cell homing to inflamed tissues
MAdCAM-1	HEVs in gut-associated lymphoid tissues; lamina propria	α4β7, L-selectin	T-cell homing to gut-associated lymphoid tissues

*The integrins are named according to the composition of their constituent α and β protein chains, which are each identified by a number or letter (e.g., α4β1 or αDβ2), but some integrins are often referred to by alternative names, e.g., LFA-1, shown in parenthesis.

APC, antigen-presenting cell; BM, bone marrow; CD, cluster of differentiation; CLA, cutaneous lymphocyte antigen; ESL-1, E-selectin ligand-1; FucT-VII, fucosyltransferase-VII; GlyCAM-1, glycosylation-dependent cell adhesion molecule-1; HEV, high endothelial venule; ICAM, intercellular cell adhesion molecule; IL-1, interleukin-1; LFA-1, leukocyte function-associated antigen-1; LPS, lipopolysaccharide; Mac-1, macrophage antigen-1; MAdCAM-1, mucosal addressin cell adhesion molecule-1; NK, natural killer cell; p150/95, protein with 150 kDa and 95 kDa subunits; PNAd, peripheral node addressin; PSGL-1, P-selectin glycoprotein ligand-1; sgp200, sialylated glycoprotein of 200 kD; sLe^X, sialyl-$Lewis^X$; Th, T-helper; TNF-α, tumor necrosis factor α; VCAM-1, vascular cell adhesion molecule-1; VLA-4, very late antigen-4.

support a considerable rate of traffic of "resting" lymphocytes, i.e., naïve T and B cells and some memory T cells, whereas endothelial cells elsewhere permit only minimal leukocyte binding unless they are exposed to inflammatory mediators. Thus, two vascular beds can be distinguished, which support fundamentally different types of leukocyte traffic: those in lymphoid organs, which recruit lymphocytes constitutively; and those in normal or inflamed tissues, which typically recruit effector leukocytes whose job is to combat pathogens (Figure 18.1).

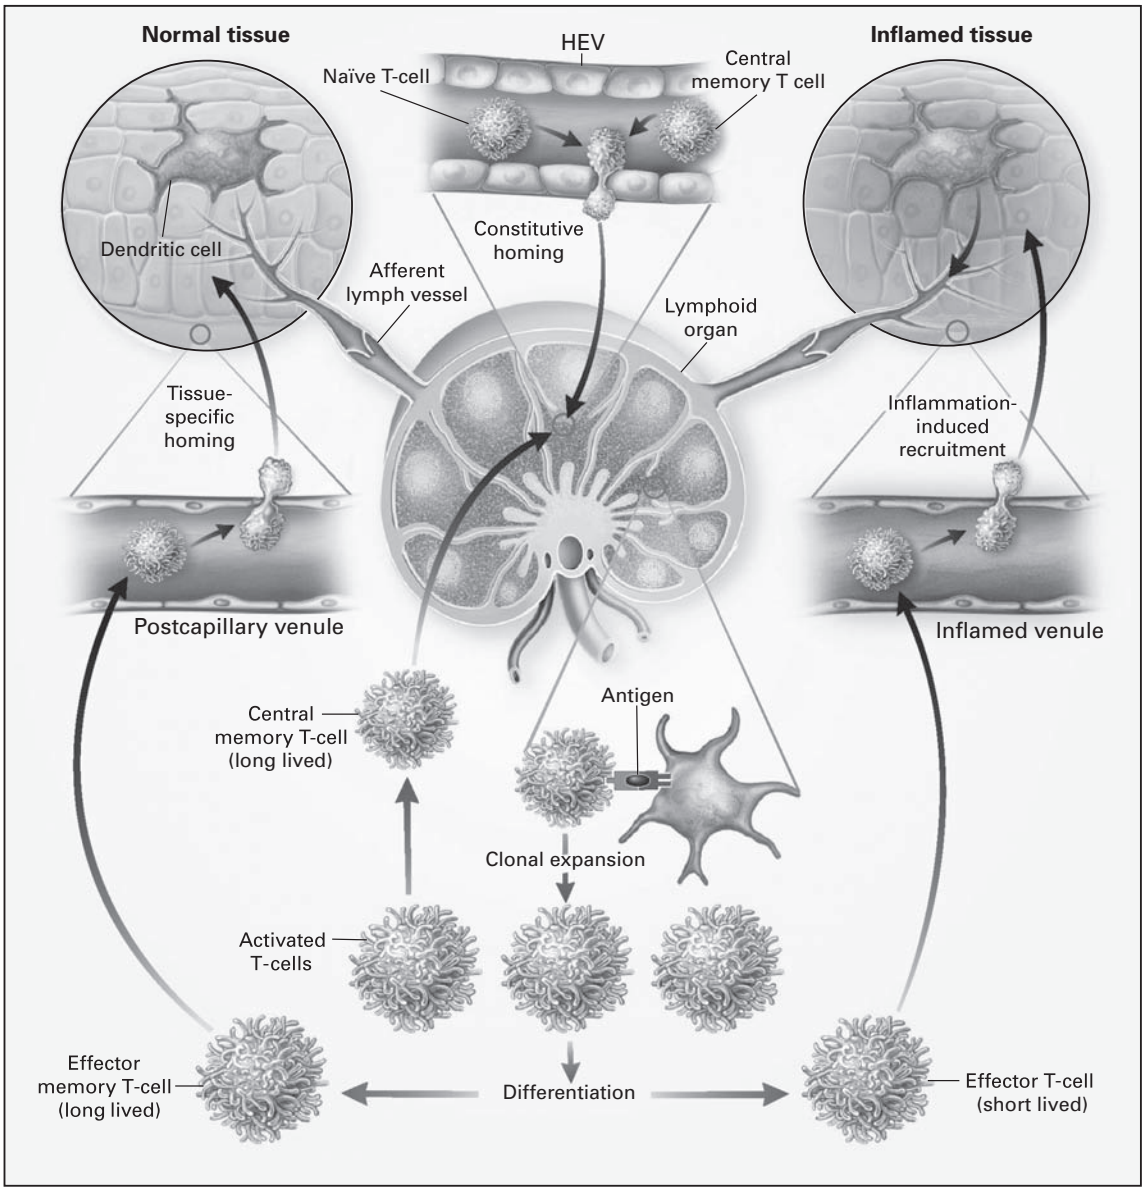

FIGURE 18.1 Migratory routes of T cells. Naïve T cells home continuously from the blood to lymph nodes and other secondary lymphoid tissues. Homing to lymph nodes occurs across high endothelial venules (HEVs), which express traffic molecules for constitutive lymphocyte recruitment. Lymph nodes are percolated by lymph fluid that is channeled to them from peripheral tissues, where dendritic cells (DCs) collect antigenic material. In inflamed tissues, DCs are mobilized to carry antigen to lymph nodes, where they stimulate antigen-specific T cells. Upon stimulation, T cells proliferate and differentiate into effector cells, which express receptors that enable them to migrate to sites of inflammation. While most effector cells are short lived, a few antigen-experienced cells survive for a long time. These memory cells are subdivided into two populations based on their migratory ability (Sallusto et al., 1999): one subset is termed *effector memory* T cells and is localized to peripheral tissues, and the other *central memory* T cells that express a similar repertoire of homing molecules as do naïve T cells migrate preferentially to lymphoid organs. The traffic signals that direct effector and memory cells to peripheral tissues are organ specific; for example, molecules required for migration to the skin are different from those to the gut; they are modulated by inflammatory mediators and are distinct for different T-cell subsets, e.g., Th1 and Th2 cells show differences in their responses to various chemoattractants.

ADHESION MOLECULES

A central paradigm that underpins leukocyte extravasation is the multistep model of leukocyte binding to endothelium (Springer, 1994). Leukocytes must engage several sequential adhesion steps in order to leave the circulation (Figure 18.2). Initially, tethers are formed by adhesion receptors that are specialized to engage rapidly and with high tensile strength. The most important initiators of adhesion are the three selectins, expressed on leukocytes (L-selectin), endothelial cells (P- and E-selectin), and activated platelets (P-selectin) (Kansas, 1996). All selectins bind oligosaccharides related to sialyl-Lewis^X. The most relevant selectin-binding sugars are components of sialomucin-like glycoproteins (Vestweber and Blanks, 1999). Selectin-mediated binding of leukocytes to endothelium results in a characteristic rolling motion. To stop rolling, cells must engage additional (secondary) receptors (Lawrence and Springer, 1991; von Andrian et al., 1991), members of the integrin family, specifically LFA-1 (CD11a/CD18, $\alpha L\beta 2$), and the two $\alpha 4$ integrins, $\alpha 4\beta 1$ (VLA-4) and $\alpha 4\beta 7$. $\alpha 4$ Integrins can also mediate tethering and rolling, albeit less efficiently than selectins (Alon et al., 1995; Berlin et al., 1995).

CHEMOATTRACTANTS AND THEIR RECEPTORS

While selectins are constitutively active, integrins are activated by signals from chemoattractant receptors (Cyster, 1999; Kim and Broxmeyer, 1999). Just like adhesion molecules, chemoattractant receptors can be upregulated or lost as cells differentiate, allowing leukocytes to coordinate their migratory routes with their immunologic function. The most extensive family of chemoattractants, particularly for adaptive immune responses, are the chemokines (Table 18.2). While some chemokines trigger intravascular adhesion (Campbell et al., 1998), others direct leukocyte migration into and within extravascular spaces. Since lymphocytes must be positioned correctly to interact with other cells, the pattern of chemokine receptors and the type and distribution of chemokines in tissues critically influence immune responses (Cyster, 1999; Sallusto et al., 1999; Syrbe et al., 1999). Over 50 chemokines and 18 chemokine receptors have been identified (Kim and Broxmeyer, 1999; Zlotnik and Yoshie, 2000). It has been proposed that this multitude ensures robust recruitment of inflammatory cells, even if individual pathways are disabled by genetic defects or through subversion by pathogens (Mantovani, 1999). Also, the large number of chemokines may reflect the complex nature of the mammalian immune system, the numerous leukocyte cell types, and the distinct microenvironments wherein migration must be regulated. For instance, neutrophils may use different chemoattractant receptors sequentially, to travel from A to B to C, in a process termed *multistep navigation* (Foxman et al., 1997).

Chemokines are divided into four subfamilies based on the position of N-terminal cysteine residues. Chemokines are also classified as *inflammatory* or *lymphoid*. Inflammatory chemokines attract primarily neutrophils, monocytes, and other effector leukocytes. The major sources of these chemokines are activated endothelial cells, epithelial cells, and leukocytes, although virtually any cell has the potential to produce chemokines (and attract leukocytes) when stimulated by lipopolysaccharides (endotoxin) or inflammatory cytokines. Lymphoid chemokines are primarily produced in lymphoid tissues. They maintain constitutive leukocyte traffic and compartmentalization in the lymphoid tissue (Cyster, 1999; Jung and Littman, 1999). In addition to the chemokine receptors, the closely related "classical" chemoattractant receptors, such as C5aR, serve similar roles, particularly during inflammatory responses. The very large number of chemokines, and patterns of chemokine receptor expression on subsets of T cells, suggest that this system of chemoattractants developed to meet the elaborate demands of the adaptive immune system.

MULTISTEP ADHESION CASCADES

One consideration for drug development is how selective or broad-acting an antagonist should be. Chemokine and chemokine-receptor redundancy, and the expression of multiple receptors by cell types such as monocytes, questions whether a single receptor antagonist will always be effective. (Mayadas et al., 1993; Arbones et al., 1994; Bullard et al., 1996; Frenette et al., 1996; Wagner et al., 1996; Andrew et al., 1998; Berlin-Rufenach et al., 1999; Forster et al., 1999; Robinson et al., 1999; Stein et al., 2000; Warnock et al., 2000). Deficiencies in any one of the steps, i.e., selectin binding, chemoattractant signaling or integrin binding, can derail cell migration. The large number of leukocyte adhesion receptors, endothelial counter-receptor(s), chemokines, and chemokine receptors means that there are hundreds of possible three-step combinations, and thus great flexibility in the regulation of leukocyte migration (Butcher, 1991; Springer, 1994). Indeed, several multistep combinations occur uniquely in specialized tissues and serve to attract very distinct subsets of blood-borne leukocytes (Springer, 1994; Butcher and Picker, 1996; Robert and Kupper, 1999; Stein et al., 2000; Warnock et al., 2000). One consideration for drug development is, how selective do inhibitors of cell migration need to be? Apparent chemokine and chemokine receptor redundancy, for instance, multiple receptor expression on monocytes, questions whether a single receptor antagonist will always be effective. Nevertheless, studies *in vivo* using single-receptor antagonists, or with antibodies to individual

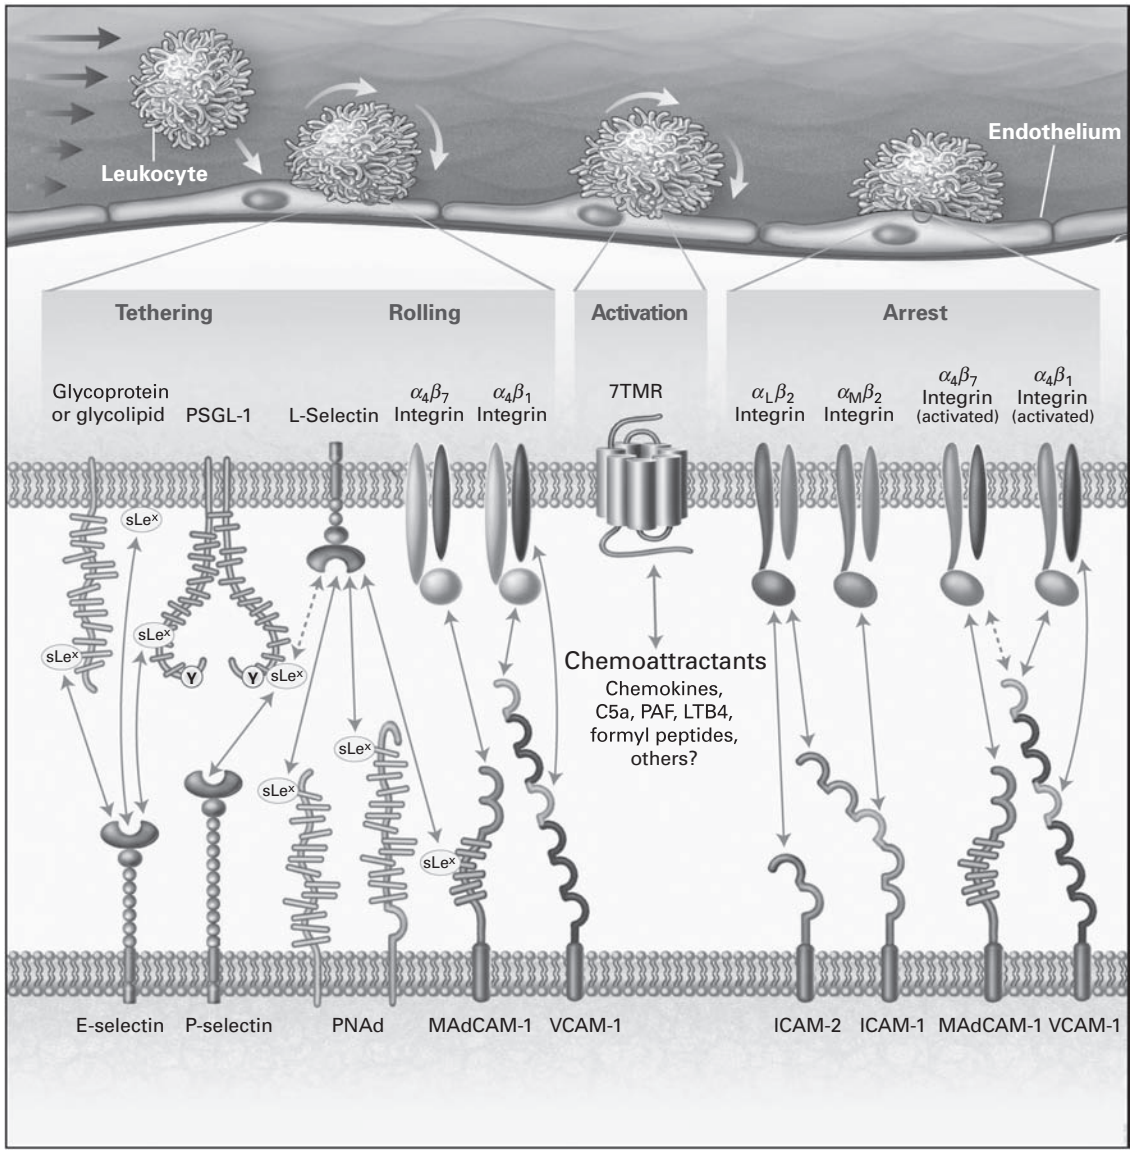

FIGURE 18.2 Essential molecular players in the multistep adhesion cascade. The top of this schematic diagram depicts the four distinct adhesion steps that leukocytes must undergo to accumulate in a blood vessel. Also shown are the predominant molecular determinants of each step with respect to leukocytes (middle of the diagram) and endothelial cells (bottom). A number of molecules can interact with more than one partner, symbolized by arrows. Leukocytes in the bloodstream (arrows at left symbolize the laminar flow profile) tether to endothelial cells and roll slowly downstream. Tethering is greatly facilitated by leukocyte receptors that occur at high density on the tips of microvillous surface protrusions (L-selectin, PSGL-1, and α4 integrins), whereas subsequent rolling is not influenced by the topography of adhesion receptors (Stein et al., 1999). The most efficient tethering molecules are L- and P-selectin. L-selectin recognizes sulfated sialyl-Lewis^X (sLe^X)-like sugars (PNAd) in high endothelial venules. It may also interact with other ligands on inflamed endothelial cells (not shown) and with PSGL-1 on adherent leukocytes (broken arrow). PSGL-1 binding to L- and P-selectin requires decoration with an sLe^X-like sugar in close vicinity to an N-terminal motif containing three tyrosines (Y) that must be sulfated. E-selectin can also interact with PSGL-1, but does not require sulfation and also recognizes other sLe^X-bearing glycoconjugates. E-selectin and the α4 integrins can tether some leukocytes, but their predominant function is to reduce rolling velocities. Rolling leukocytes respond to chemoattractants on endothelial cells because they express specific receptors with seven transmembrane domains (7TMR), which transmit intracellular signals through G proteins. The activating signal induces rapid activation of β2 and/or α4 integrins, which bind to endothelial immunoglobulin superfamily members. Note that α4 integrins can mediate activation-independent rolling interactions as well as firm arrest. However, the latter function requires integrin activation, symbolized by the open conformation of the integrin heterodimer. For a list of abbreviations, see Table 18.1.

TABLE 18.2 Chemoattractant receptors and their ligands in leukocyte migration

Biologic activity	Chemoattractant receptor(s)	Predominant ligands*,†
Naïve T-cell migration		
To LN and Peyer patch	CCR7	CCL21 (SLC); CCL19 (Mip-3β)
Within lymphoid tissues	CXCR4	CXCL12 (SDF-1α)
Memory T-cell migration		
To lymphoid tissues	CCR7	CCL21 (SLC); CCL19 (Mip-3β)
To the skin	CCR4, CCR10	CCL17 (TARC); CCL22 (MDC-1) CCL27 (CTACK)
To the gut	CCR9	CCL25 (TECK)
To sites of inflammation	CCR2 CCR5	CCL2 (MCP-1) CCL5 (RANTES), CCL4 (MIP-1β)
Effector T-cell migration		
Th1 cells	CCR2 CCR5 CXCR3	CCL2 (MCP-1) CCL5, CCL4 (MIP-1β) CXCL9, 10, 11
Th2 cells	CCR3 CCR4 CCR8 CXCR4	CCL11 (Eotaxin) CCL17 (TARC); CCL22 (MDC-1) CCL1 (I-309) CXCL12 (SDF-1α)
B-cell migration	CCR7 CXCR4 CXCR5	CCL21 (SLC); CCL19 (Mip-3β) CXCL12 (SDF-1α) CXCL13 (BLC)
Dendritic cell migration		
To lymphoid tissues	CCR7	CCL21 (SLC); CCL19 (Mip-3β)
To normal skin	CCR6	CCL20 (MIP-3α)
To sites of inflammation	CCR1 CCR2 CCR5 CXCR1	CCL5, CCL3 CCL2 (MCP-1) CCL5, CCL4 (MIP-1β) CXCL8 (IL-8)
Monocyte recruitment	CCR1 CCR2 CCR5 CCR8 CXCR1 CX_3CR1 C5aR	CCL5, CCL3 CCL2 (MCP-1) CCL5, CCL4 (MIP-1β) CCL1 (I-309) CXCL8 (IL-8) C5a
Neutrophil recruitment	CXCR1 CXCR2 C5aR fmlpR	CXCL8 (IL-8) CXCL8 (IL-8); Groα, β, γ C5a fmlp
Eosinophil recruitment	CCR3 C5aR	CCL11 (Eotaxin) C5a

*The physiologic function of several chemokine receptors are multiple, since CCR9 promotes prothymocyte homing to the thymus, and T-cell migration to the gut; CXCR4 is widely expressed and appears to have multiple roles.

†An established nomenclature for chemokines (Zlotnik and Yoshie, 2000) has superseded older and in many cases duplicate names for a single chemokine. Frequently used alternative names are shown in parenthesis.

CCR, receptor for CC chemokine; CXCR, receptor for CXC chemokine; LN, lymph node, Th, helper T cell.

chemokine ligands, have proved very effective in animal models (Gong et al., 1997; Gonzalo et al., 1998; Ulbrich et al., 2003; Szekanecz and Koch, 2004). However, there has been considerable interest in targeting chemoattractant receptor signaling pathways, where numerous receptors would be affected: the phosphoinositide 3-kinases (PI3K) are a good example (Ward, 2004). Mice lacking one of the four isoforms, PI3Kγ, are viable, but their neutrophils and macrophages show impaired activation through chemoattractant receptors (Hirsch et al., 2000; Li et al., 2000), and poor chemotactic responses.

ORGANIZED LYMPHOID TISSUES: VENUES FOR NAÏVE T-CELL HOMING AND DENDRITIC CELL INTERACTIONS

The adhesion cascades that mediate homing of naïve T cells to lymph nodes and Peyer patches are now well understood (Bargatze et al., 1995; Warnock et al., 1998; Stein et al., 2000; Warnock et al., 2000). Circulating lymphocytes gain access to both organs by crossing HEVs (Marchesi and Gowans, 1964; Girard and Springer, 1995). A characteristic feature of HEVs in lymph nodes is expression of the peripheral node addressin (PNAd), whereas HEVs in Peyer patches express mucosal addressin cell adhesion molecule (MAdCAM)-1. L-Selectin binds both of these addressins, but it sustains rolling only on PNAd in lymph nodes, whereas in Peyer patches additional binding of α4β7 integrin to MAdCAM-1 is required (Bargatze et al., 1995; Warnock et al., 1998). Cells expressing high levels of α4β7, such as gut-homing effector T cells, tether directly to MAdCAM-1, whereas naïve T cells first engage L-selectin (Bargatze et al., 1995; Kunkel et al., 1998). The chemokines and chemokine receptors important for lymphocyte entry to lymphoid tissues are CCL19 and CCL21 binding to CCR7. CCR7 is expressed at high levels by naïve T cells and central memory T cells, but not effector memory T cells. CCR7 and another chemokine receptor, CXCR4, are expressed in a reciprocal manner with inflammatory chemokine receptors, such as CCR5 (Bleul et al., 1997), which marks mainly effector memory T cells.

Naïve T cells are normally restricted in their migration to lymphoid tissues. It is here where naïve T cells and other cells necessary for a primary immune response must gather and interact. Dendritic cells (DCs) in lymphoid tissues are usually derived from monocytes, which enter tissues and differentiate to "immature" DCs (see Chapter 4). Both monocytes and immature DCs express receptors for inflammatory chemokines and other chemoattractants that are released during inflammatory responses (Dieu et al., 1998; Sallusto et al., 1998). A subset of DCs in skin, the Langerhans cells, also express CCR6, which may promote their constitutive migration through normal skin. Immature DCs patrol tissues and engulf microorganisms, dead cells, and cellular debris. Upon exposure to inflammatory stimuli, they travel to regional lymph nodes via afferent lymph vessels, lose their receptors for inflammatory chemokines, and upregulate receptors for lymphoid chemokines (Sallusto and Lanzavecchia, 1999). CCR7 expression allows maturing DCs to home to the T-cell area of lymph nodes. While in transit, DCs also alter their functional role to that of antigen presentation, and begin producing chemokines that attract subsets of T cells (Sallusto and Lanzavecchia, 1999).

The rationale for naïve T cells being restricted in their migration to lymphoid tissues is that the large-scale percolation of naïve lymphocytes, all with different antigen receptors, allows the very rare antigen-specific cell to encounter its cognate antigen. Moreover, lymphoid tissues are the venue for T-cell–DC interactions, T–B-cell interactions, including the germinal center (GC) reaction, and are also a place to which antigen drains and is captured and retained. It is also possible that the restriction of naïve T cells to lymphoid tissues facilitates immune tolerance, by restricting exposure of naïve T cells to peripheral self-antigens.

EFFECTOR T-CELL MIGRATION

Naïve T cells differentiate to effector cells in lymphoid organs (see Figure 18.1). However, the principal sites where effector cells are needed are peripheral tissues, where pathogens are encountered. Thus, effector cells upregulate receptors for inflammation-induced endothelial adhesion molecules and inflammatory chemoattractants (Butcher and Picker, 1996). However, different pathogens require different effector responses, e.g., by Th1 or Th2 cells, and Th1 and Th2 cells express distinct receptors and obey different traffic signals (Syrbe et al., 1999). Distinctive chemokine receptors on Th1 cells include CCR5 and CXCR3 (Bonecchi et al., 1998; Sallusto et al., 1998), which bind inflammatory chemokines (see Table 18.1). In rheumatoid arthritis and multiple sclerosis (both often thought of as Th1 related), virtually all infiltrating T cells express CCR5 and CXCR3 (Qin et al., 1998). People with a homozygous mutation that disrupts the CCR5 gene (Paxton and Kang, 1998) may also be less susceptible to some inflammatory disorders, including rheumatoid arthritis (Gomez-Reino et al., 1999). Adhesion molecules also play a role; Th1 cells express abundant selectin ligands. P- and E-selectin, which occur on inflamed endothelium, and their ligand, PSGL-1, are critical for Th1 cell migration to inflamed skin (Austrup et al., 1997; Borges et al., 1997) and peritoneum (Xie et al., 1999). Expression of fucosyltransferase-VII is necessary for cells to synthesize selectin ligands (Maly et al., 1996). This enzyme is induced by interleukin (IL)-12, which drives Th1 differentiation, whereas T-cell exposure to the Th2 cytokine

IL-4 downmodulates selectin ligand expression (Wagers et al., 1998; Lim et al., 1999).

Th2 cells also express distinctive chemoattractant receptors, including CRTh2 and CCR3 (Sallusto et al., 1997). Eotaxin, a ligand of CCR3, has been implicated in eosinophil recruitment into hyperreactive airways and is prominent in mucosal tissues undergoing allergic and antiparasitic responses (Jose et al., 1994). Eotaxin production is stimulated by Th2 cytokines, such as IL-4 or IL-13, and is absent from Th1-mediated lesions (Ponath et al., 1996). CCR3 is also expressed on basophils and mast cells, which presumably allows these allergy-related leukocytes to colocalize and interact at sites of allergic inflammation (Gutierrez-Ramos et al., 1999). Other chemoattractant receptors that are also preferentially, but not exclusively, expressed on Th2 cells include CCR4, CCR8 and CXCR4 (Sallusto et al., 1998).

HOMING TO NON-LYMPHOID TISSUES

Antigen-experienced T cells often display a bias in their tissue migration patterns, which enhances their chances for re-encountering antigen. T cells that respond to cutaneous pathogens in skin-draining lymph nodes migrate preferentially to the skin, whereas effector cells that arise in Peyer patches in response to enteroviral infections migrate preferentially to the gut (Butcher and Picker, 1996). Indeed, lymphocytes express different homing receptors when they respond to orally administered antigen, compared to when the same antigen is given parenterally (Kantele et al., 1999). The best understood tissue-selective homing pathways are in the skin and intestine (Butcher and Picker, 1996; Robert and Kupper, 1999), but other selective migration streams may well exist, such as to the lung, joints, and central nervous system (Salmi et al., 1992). Thus, tissue-selective migration streams offer the prospect of selectively inhibiting cell migration through a diseased tissue, such as the gut, and leaving other tissues unaffected. For instance, inhibitors of $\alpha4\beta7$ integrin have been trialed in patients with inflammatory bowel disease.

CLINICAL APPLICATIONS

Chemoattractant receptors and adhesion molecules are highly promising targets for new anti-inflammatory therapies (Carlos and Harlan, 1994; Strieter et al., 1996; Oppenheimer-Marks and Lipsky, 1998; Homey and Zlotnik, 1999; Mackay, 2001; von Andrian and Engelhardt, 2003; Szekanecz and Koch, 2004), and the development of antagonists has been pursued aggressively by the biotechnology and pharmaceutical industries (Table 18.3). Numerous antibodies, recombinant soluble adhesion molecules, receptor-blocking mutant chemokines, and small molecules are being tested for clinical application in multiple sclerosis, inflammatory bowel disease, arthritis, and psoriasis. In general, studies on experimental animals have validated various receptors or ligands in inflammatory disease models, including asthma, rheumatoid arthritis, multiple sclerosis, sepsis, and transplantation (Grant et al., 2002; Haskell et al., 2002; Miller et al., 2003; von Andrian and Engelhardt, 2003). Subversion of immune responses by pathogens also provides a pointer to the best anti-inflammatory strategies. A telling feature of many pathogens is their subversion of host responses through the chemokine system (Alcami, 2003). Chemoattractant receptors probably offer the most promise, because the seven-transmembrane structure of these receptors lends itself to inhibition with organic small molecules.

Potent small molecule antagonists have been developed for a number of the chemoattractant receptors (see Table 18.3), especially CCR1, CCR3, CCR5, CXCR3, and CXCR4 (Haringman et al., 2003; Szekanecz and Koch, 2004). Chemokine receptor antagonists have proved highly efficacious in animal models, particularly in models of rheumatoid arthritis [reviewed by Szekanecz and Koch (2004)]. A noteworthy example is a small molecule antagonist of both CCR5 and CXCR3, termed TAK-779, which inhibits ligand binding of these two Th1-type chemokine receptors (Gao et al., 2003), and also inhibits the development of arthritis by interfering with T-cell migration to joint lesions (Yang et al., 2002). Effector T cells in the synovium of patients with rheumatoid arthritis express high levels of CCR5 and CXCR3 (Qin et al., 1998). It is highly likely that some of these drugs will succeed in clinical trials and find utility in the treatment of certain autoimmune diseases. Interactions involving integrins or selectins are more difficult to inhibit with small molecules, but there have been promising results with antagonists of $\alpha4\beta1$–VCAM-1 and LFA-1–ICAM-1 interactions (Kelly et al., 1999; Lin et al., 1999). It is likely that cell-migration inhibitors will go far towards alleviating the disabling effects of autoimmune inflammation well before the basic nature of autoimmunity is finally understood.

FUTURE DIRECTIONS

The targeting of cell-migration pathways is an emerging approach to treat inflammatory autoimmune diseases, with promising disease applications being multiple sclerosis, rheumatoid arthritis, and psoriasis, but there are likely many others (see Chapter 76). Eventually, we must translate the wealth of data on trafficking molecules into a clearer understanding of their physiologic and pathologic relevance to human health and disease. This will require new experi-

TABLE 18.3 Adhesion molecules and chemoattractant receptors as targets for the treatment of inflammatory diseases

Target pathway/receptor	Involved in leukocyte or T-cell migration to these sites*	Potential clinical applications†	Comments, examples of drug development†
Adhesion pathways			
α4β1–VCAM-1	Numerous inflamed tissues, Th2 lesions	Asthma, MS, vasculitis	Promising phase II data in MS (Miller et al., 2003; von Andrian and Engelhardt, 2003)
α4β7–MAdCAM-1	Nonpulmonary mucosal tissues	IBD	Promising mouse data, disappointing phase II data using anti-α4β7 mAb
Mac-1–ICAM-1	Inflamed tissues?	Ischemia–reperfusion	Anti-ICAM mAb discontinued in phase III
LFA-1–ICAM-1	Most inflamed tissues, T-cell interactions with APCs	Numerous	Promising phase III data with efazulimab for psoriasis
Selectins–PSGL-1	Acute inflammation, Th1 lesions, esp. in the skin	Numerous	Disappointing phase II data, mixed data with various antagonists (Ulbrich et al., 2003)
Fucosyltransferase-VII	Acutely inflamed tissues, Th1 lesions	Numerous	Requires intracellular inhibitors, none described
Chemokine receptors/ligands			
CXCR1,2–numerous CXC chemokines	Some inflamed tissues, esp. skin	Psoriasis, RA, reperfusion injuries	Efficacy of antagonists not determined in humans
CCR1–CCL3, 5	Numerous inflamed tissues	RA, others	Promising phase Ib data (Haringman et al., 2003)
CCR2–CCL2 (MCP-1)	Numerous inflamed tissues	RA, MS	Promising animal data (Gong et al., 1997)
CCR3–CCL11 (Eotaxin)	Th2 lesions, allergic inflammation	Asthma, allergies	Promising phenotypes in knock-out mice, but possible redundancy issues
CCR4–CCL17, 22	Skin, Th2 lesions	Asthma, psoriasis, atopic dermatitis	Importance not established *in vivo*
CCR5–CCL3, 4, 5	Th1 lesions	RA, HIV infection	Promising small molecule antagonists (Baba et al., 1999; Gao et al., 2003)
CCR9–CCL25	Intestine	IBD	Importance not yet established *in vivo*
CXCR3–CXCL9, 10, 11	Th1 lesions	RA, MS, transplantation	Possible redundancy of Th1 chemokine pathways. Promising data with CXCR3 knock-out mice
SDF-1α–CXCR4	Numerous tissues	HIV infection	Critical for embryogenesis; inhibitors may alter hematopoiesis
Classical and other chemoattractant receptors			
C5aR–C5a	Neutrophil, mast cells	RA, sepsis, reperfusion injuries	Disappointing clinical trial data in RA
BLR–LTB4	Mast-cell initiated inflammatory lesions	RA, asthma	Potent small molecule drugs developed, effectiveness in autoimmune disease unclear
S1P receptors (esp. S1P1)	Lymphocyte egress from tissues	Numerous	S1P receptor agonist drugs, i.e., FTY720, effective in animal models of disease (Goetzl and Graler, 2004; Ward, 2004)

*Most of these molecular pathways have been targeted with either small molecule antagonists or blocking mAbs, and are currently in clinical trials for various indications. In addition, a substantial amount of animal experimentation has validated these pathways for various diseases.

†For reviews of adhesion molecule or chemoattractant receptor antagonists, and their use in preclinical and clinical trials, see Ulbrich et al. (2003) and Szekanecz and Koch (2004).

APC, antigen-presenting cell; CCR, receptor for CC chemokine; CXCR, receptor for CXC chemokine; HIV, human immune deficiency virus; IBD, inflammatory bowel disease; ICAM-1, intercellular cell adhesion molecule-1; IL-8, interleukin-8; LAD, leukocyte adhesion deficiency syndrome; LFA-1, leukocyte function-associated antigen-1; Mac-1, macrophage antigen-1; MAdCAM-1, mucosal addressin cell adhesion molecule-1; MS, multiple sclerosis; PSGL-1, P-selectin glycoprotein ligand-1; RA, rheumatoid arthritis; Th, T-helper; VCAM-1, vascular cell adhesion molecule-1.

mental and therapeutic entities, such as antibodies, recombinant proteins, small molecule inhibitors, screening assays and, not least, meaningful clinical trials. One pivotal question is whether to treat autoimmune diseases with broad inhibitors (the sledge hammer approach, using, for instance, an inhibitor of a common signaling pathway of chemoattractant receptors), or whether such diseases should be treated with much more specific inhibitors, for instance, inflammatory bowel disease with a CCR9 or α4β7 inhibitor? Time will tell.

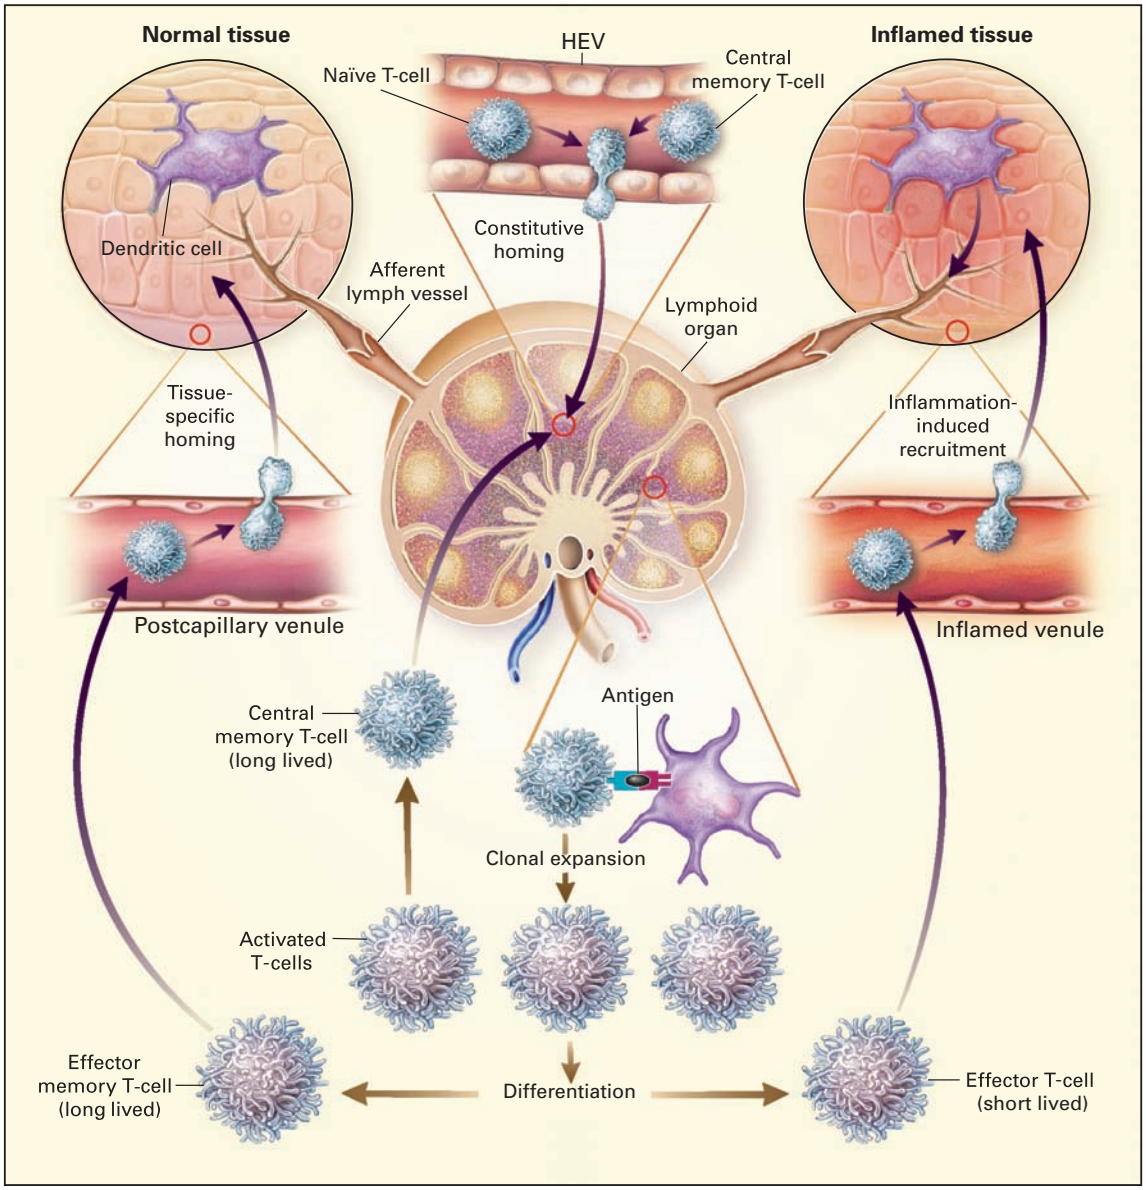

FIGURE 18.1 Migratory routes of T cells. Naïve T cells home continuously from the blood to lymph nodes and other secondary lymphoid tissues. Homing to lymph nodes occurs across high endothelial venules (HEVs), which express traffic molecules for constitutive lymphocyte recruitment. Lymph nodes are percolated by lymph fluid that is channeled to them from peripheral tissues, where dendritic cells (DCs) collect antigenic material. In inflamed tissues, DCs are mobilized to carry antigen to lymph nodes, where they stimulate antigen-specific T cells. Upon stimulation, T cells proliferate and differentiate into effector cells, which express receptors that enable them to migrate to sites of inflammation. While most effector cells are short lived, a few antigen-experienced cells survive for a long time. These memory cells are subdivided into two populations based on their migratory ability (Sallusto et al., 1999): one subset is termed *effector memory* T cells and is localized to peripheral tissues, and the other *central memory* T cells that express a similar repertoire of homing molecules as do naïve T cells migrate preferentially to lymphoid organs. The traffic signals that direct effector and memory cells to peripheral tissues are organ specific; for example, molecules required for migration to the skin are different from those to the gut; they are modulated by inflammatory mediators and are distinct for different T-cell subsets, e.g., Th1 and Th2 cells show differences in their responses to various chemoattractants.

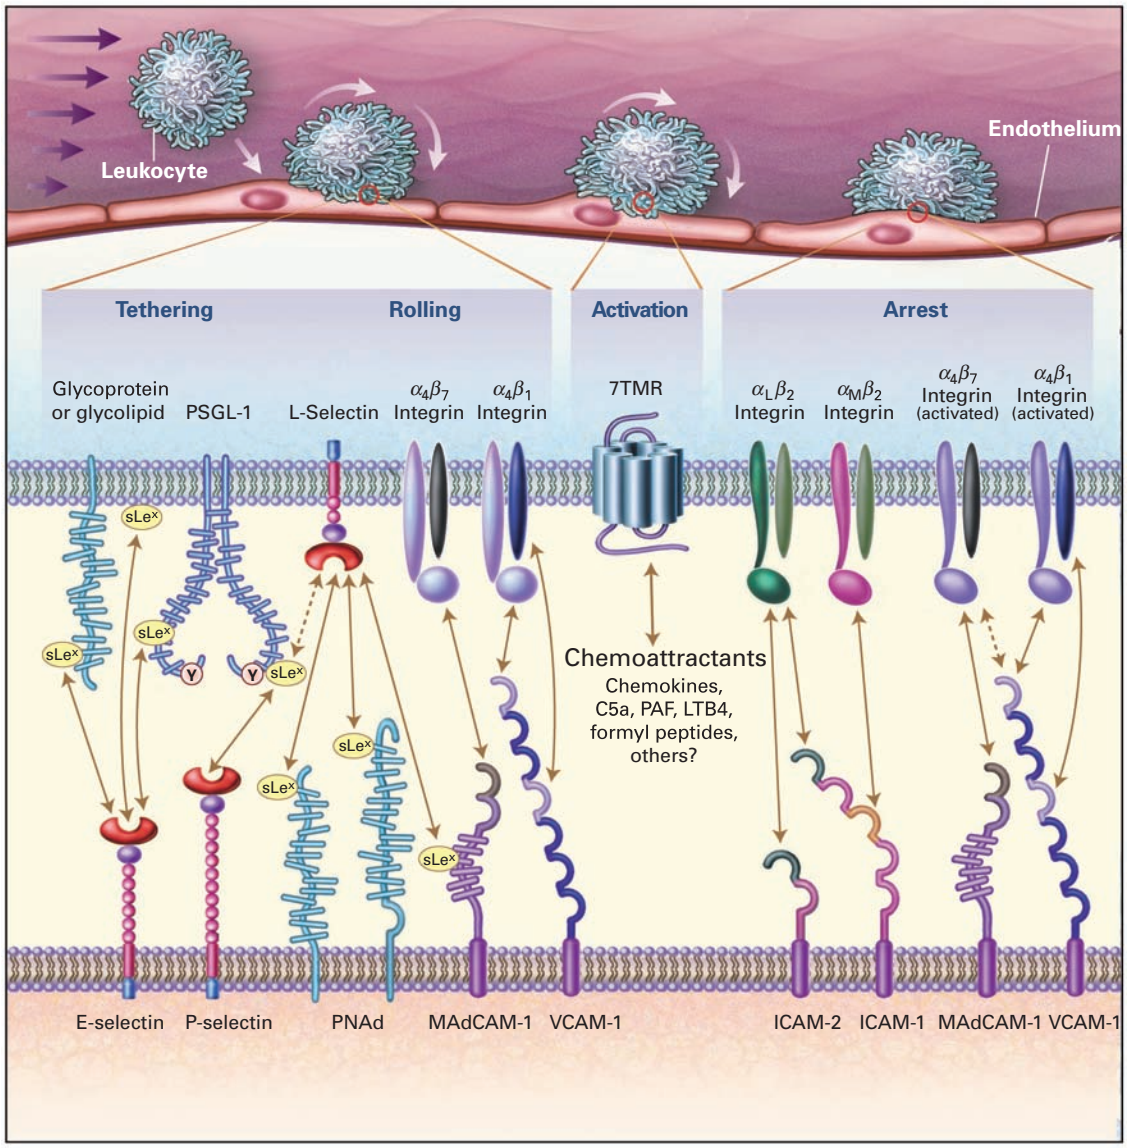

FIGURE 18.2 Essential molecular players in the multistep adhesion cascade. The top of this schematic diagram depicts the four distinct adhesion steps that leukocytes must undergo to accumulate in a blood vessel. Also shown are the predominant molecular determinants of each step with respect to leukocytes (middle of the diagram) and endothelial cells (bottom). A number of molecules can interact with more than one partner, symbolized by arrows. Leukocytes in the bloodstream (arrows at left symbolize the laminar flow profile) tether to endothelial cells and roll slowly downstream. Tethering is greatly facilitated by leukocyte receptors that occur at high density on the tips of microvillous surface protrusions (L-selectin, PSGL-1, and α4 integrins), whereas subsequent rolling is not influenced by the topography of adhesion receptors (Stein et al., 1999). The most efficient tethering molecules are L- and P-selectin. L-selectin recognizes sulfated sialyl-Lewis^X (sLe^X)-like sugars (PNAd) in high endothelial venules. It may also interact with other ligands on inflamed endothelial cells (not shown) and with PSGL-1 on adherent leukocytes (broken arrow). PSGL-1 binding to L- and P-selectin requires decoration with an sLe^X-like sugar in close vicinity to an N-terminal motif containing three tyrosines (Y) that must be sulfated. E-selectin can also interact with PSGL-1, but does not require sulfation and also recognizes other sLe^X-bearing glycoconjugates. E-selectin and the α4 integrins can tether some leukocytes, but their predominant function is to reduce rolling velocities. Rolling leukocytes respond to chemoattractants on endothelial cells because they express specific receptors with seven transmembrane domains (7TMR), which transmit intracellular signals through G proteins. The activating signal induces rapid activation of β2 and/or α4 integrins, which bind to endothelial immunoglobulin superfamily members. Note that α4 integrins can mediate activation-independent rolling interactions as well as firm arrest. However, the latter function requires integrin activation, symbolized by the open conformation of the integrin heterodimer. For a list of abbreviations, see Table 18.1.

Signaling Pathways in T and B Lymphocytes

ELIZABETH G. ARAUJO AND MARCUS R. CLARK

Department of Medicine, Section of Rheumatology, University of Chicago, Chicago, Illinois, USA

Most normal and aberrant immune responses require the coordinated activation of both the innate and adaptive immune responses. The innate immune system responds to patterns and contexts indicative of danger. The lack of specificity of the innate immune system allows it to respond quickly and broadly to infectious organisms. Phylogenically, the innate immune system is ancient. Indeed, the first descriptions of the primary receptors and signaling pathways of the innate immune system were made in invertebrates amenable to genetic dissection.

However, there are limitations to the innate immune system. It does not learn from previous immunologic challenges. The innate immune system is invariant and does not adapt to common pathogens in the environment. For the innate immune system, every war is always the first war. To circumvent these limitations, higher vertebrates have developed adaptive immunity. This system does not respond to broad conserved patterns but to specific non-self-antigenic epitopes restricted to the invading organism. The adaptive and innate immune systems are highly interdependent and rarely does one respond to an infection without the participation of the other. However, it is the adaptive immunity that allows the immune system to develop a memory of previous infections, and to respond quickly and effectively the next time a similar infection occurs. Exploitation of the adaptive immune system, through the use of vaccines, has been used with great success to rid humanity of many forms of pestilence. Unfortunately, aberrant adaptive immune responses are at the root of most autoimmune diseases.

In this chapter we will review the structure and signaling pathways regulated by two important receptors of the adaptive immune system, the T- and B-cell antigen receptors. We will also examine how signaling through important coreceptors determines cellular responses. By comparing and contrasting these two receptor systems, we hope to illustrate both common mechanisms of responding to antigen and important differences. Understanding how the antigen receptors function is of clear and direct importance to those interested in the pathogenesis and treatment of autoimmune diseases. As will be demonstrated, changes in how a lymphocyte responds to antigen can lead to the breaking of tolerance and the development of autoimmune diseases. Conversely, therapeutically targeting the signaling pathways activated by the antigen receptors and their coreceptors holds the promise of reinstating antigen-specific tolerance and inducing drug-free remissions in patients afflicted with autoimmunity.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

COMMON AND DIVERGENT THEMES IN RECEPTOR STRUCTURE

All the antigen recognition receptors of the immune system, including the B-cell receptor (BCR), the T-cell receptor (TCR), and most Fc receptors have a common general structure. Each contains an antigen recognition substructure noncovalently associated with a substructure required for both surface expression and for the activation of signaling pathways. In the case of lymphocytes, the antigen-recognition substructures are clonotypic; specific for one antigenic epitope. As covered in Chapter 2, specificity arises from recombination of the gene segments encoding the variable regions. The TCR antigen recognition substructure is comprised of two transmembrane polypeptide chains, named α and β (or γ and δ in a small subset of T cells), which recognize antigenic peptides presented in the context of either major histocompatibility complex (MHC) class I or class II molecules. The associated signaling substructure is comprised of four different invariant chains, CD3γ, δ, ε, and TCRζ_2. Regarding TCR stoichiometry, recent data have demonstrated that the majority of the complexes contain a single TCRαβ heterodimer associated with one CD3εγ, one CD3εδ, and one homodimer ξ_2 (Figure 19.1). There are three basic (positively charged) residues in the transmembrane region of the TCRαβ heterodimer and a pair of acidic (negatively charged) residues in each of the three signaling dimers. Each acidic residue pair binds a different basic TCRαβ residue to assemble a TCR in which TCRαβ is in the center surrounded by the signaling dimers (Call et al., 2002).

The first evidence that the CD3γ, δ, ε, and TCRζ_2 chains are responsible for signal transduction was demonstrated using a chimeric protein linking the extracellular and transmembrane domains of CD8 to the cytoplasmic domain of the ξ chain (Weiss and Littman, 1994). Similar experiments were used to examine the functional capacity of CD3ε. Subsequent genetic studies have demonstrated that the cytoplasmic tails of the various signaling subunits, especially TCRζ, are required for T-cell development (Shores and Love, 1997). From these data, it is clear that each chain can independently signal and mediate biologic functions. However, it is likely that each signaling chain of the TCR also contributes unique signaling functions to the receptor complex.

The BCR is also comprised of separate antigen recognition and signaling substructures. Antigen is recognized by membrane-bound immunoglobulin (mIg) which is identical in specificity to the secreted immunoglobulin potentially produced by each cell. The IgM and IgD isotypes have short cytosolic tails of only three amino acids, while other isotypes, such as IgG, have larger cytosolic tails that may influence signaling through the BCR (Wakabayashi et al., 2002). The signaling substructure of the BCR is composed of a single disulfide-linked heterodimer of Igα and Igβ noncovalently associated with mIg in a 1:1 stoichiometry (Wolfgang et al., 2000). Like the TCR, the transmembrane domains of mIg and Igα/Igβ have charged amino

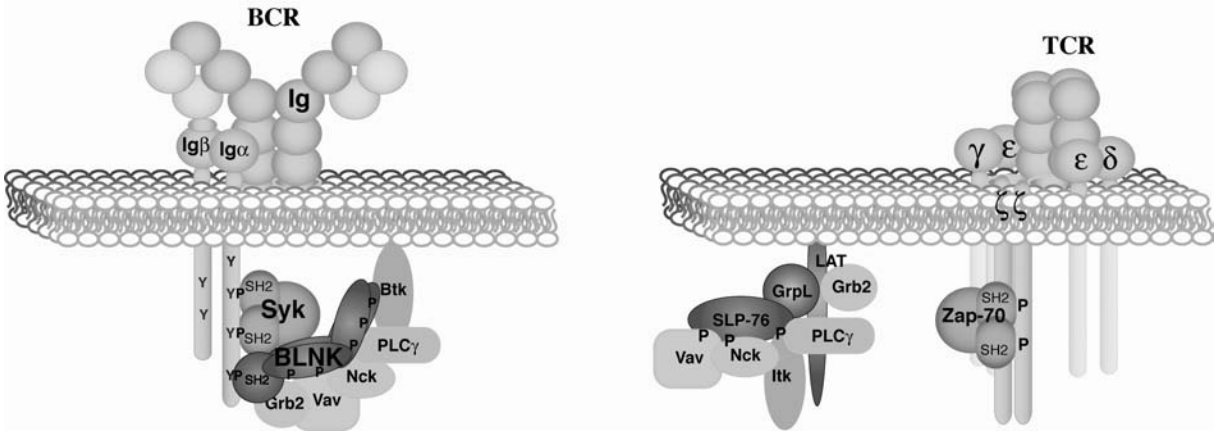

FIGURE 19.1 Schematic comparison of activated antigen receptor complexes. The antigen receptors are multimeric complexes containing separate antigen recognition and signaling substructures. Following engagement by ligand, the immunoreceptor tyrosine-based activation motif (ITAM) tyrosines in the signaling subunits of each receptor are phosphorylated, which serves to recruit either the tyrosine kinase ZAP-70 [T-cell receptor (TCR)] or Syk [B-cell receptor (BCR)]. Scaffolding molecules are then phosphorylated by these kinases. In the case of the TCR, the scaffold consists of LAT–GrpL–SLP-76 and with the BCR, BLNK. Other scaffolding molecules are likely to be involved, including LAB and BAM32. These phosphorylated scaffolds then assemble and coordinate the activation of signaling effectors that initiate downstream signaling pathways.

acids. Those in mIg have been demonstrated to be important for receptor assembly. However, the overall structure of the BCR complex is still unknown. The Igα/Igβ cytosolic tails have also been studied extensively both *in vitro* and *in vivo*. In general, the functions of Igα and Igβ appear to be more specialized than those of each TCR signaling chain. The bulk of evidence indicates that Igα is the major signaling chain of the complex (see below). Expression of both mIg and Igα are required for normal B cell development and for maintaining B cells in the periphery (Lam et al., 1997; Wang and Clark, 2003; Kraus et al., 2004). In contrast, Igβ is required for the maturation of peripheral B cells (Reichlin et al., 2001) and for proper BCR-mediated antigen processing and presentation to T cells (Clark et al., 2004).

RECOGNITION OF ANTIGEN

In contrast to their similarities in overall receptor structure, the TCR and BCR recognize antigen in very different ways. As described in Chapter 6, T cells recognize antigenic peptides processed by antigen-presenting cells (APCs) and presented in the context of either MHC class I or class II. The affinity of a typical TCR for MHC class II/peptide complex is low (Kd = 10^{-5}) and is a compilation of TCR binding to both MHC and peptide. Also, the TCR usually recognizes MHC concurrently with binding of the coreceptors CD4 (MHC class II restricted) or CD8 (MHC class I). Coreceptor engagement enhances binding affinity and, as discussed below, is integral to the initiation of signaling. In spite of such low affinities, productive engagement of a single MHC class II–peptide complex can elicit a detectable signaling response and as few as 10 engaged receptors can initiate full signaling (Irvine et al., 2002). The exquisite sensitivity of the TCR is probably due to several factors, including the ability of engaged TCRs to recruit nonengaged TCRs to the APC interface and the ability of a single MHC–peptide complex to engage multiple TCRs.

In contrast, the BCR usually recognizes native antigens that have not undergone processing. The initial affinities of antigen for receptor are often in the same range as that for the TCR. However, because of the unique ability of the BCR to undergo affinity maturation, affinities at the end of an acute immune response can be 10^{-9} or greater. Although the BCR can recognize monovalent antigens, such antigens are unlikely to be encountered routinely during normal immune responses and they do not lead to productive B-cell activation (see below). Normally, antigens are either presented to B cells directly by infectious agents, which provide repetitive epitope arrays, or by cells of the immune system, including dendritic cells (DCs) which capture antigenic complexes on their cell surface. The normal polyvalency of non-self-antigens induces BCR aggregation and the initiation of signaling pathways that ultimately result in the activation and differentiation of peripheral B cells.

INITIATION OF SIGNALING

Neither the TCR nor the BCR contain intrinsic catalytic activity. Rather, upon receptor engagement, tyrosine kinases are recruited by each complex and these become the primary enzymatic activities that mediate signal initiation. The mechanisms by which this occurs have been studied in great detail (Weiss and Littman, 1994; Campbell, 1999). Within the cytosolic tails of Igα, Igβ, TCRζ, and the CD3 complex are one or more conserved signaling motifs known as the immunoreceptor tyrosine-based activation motifs (ITAMs). Each ITAM contains a pair of YXXL (where X corresponds to a variable residue) spaced by six to eight variable amino acids. In the case of the TCR, the ITAM tyrosines become phosphorylated following coengagement of MHC and CD4/8. The cytosolic tail of the latter is bound to the Src-family tyrosine kinase (SFTK) Lck, which is the primary kinase responsible for phosphorylating the CD3 and TCRζ ITAMs. Another SFTK, Fyn, can phosphorylate the TCR ITAMs under some circumstances. The SFTKs have several important structural features. First, their N-terminal domains can be attached to various lipid moieties (referred to as acetylation) that anchor them to the plasma membrane where they can readily interact with the antigen receptors. Second, besides their enzymatic activity, they can interact with other molecules of the signaling cascade, via interactions through their Src homology-2 (SH2) and -3 (SH3) domains. SH2 domains bind phosphorylated tyrosines in specific peptide contexts while SH3 domains bind to proline-based motifs. Finally, the SFTKs have negative regulatory tyrosines in their C-terminal tails. Phosphorylation of this regulatory tyrosine by Csk (C-terminal Src kinase) provides a binding site for its own SH2 domain, maintaining the SFTKs in a closed and inactive conformation. Dephosphorylation of the C-terminal tyrosine by the transmembrane tyrosine phosphatase CD45 allows the SFTKs to adopt an open and active conformation (Hermiston et al., 2003) As discussed below, a dynamic balance of tyrosine kinases and phosphatases determines SFTK activity.

The regulatory tyrosine kinase Csk contains an N-terminal SH3 domain, an SH2 domain, and a catalytic kinase domain. In contrast to the SFTKs, it is not modified by lipids and therefore always resides in the cytosol. The Csk SH2 domain interacts with a transmembrane protein, known as Cbp/PAG (Csk-binding/phosphoprotein associated with glycosphingolipid-enriched microdomains), which resides in lipid rafts where it is constituitively phosphorylated

by SFTKs. In addition to this SFTK inhibitory loop, the SH3 domain of Csk binds to cytoplasmic protein tyrosine phosphatases (PEP and PTP-PEST), which in turn dephosphorylate the SFTK catalytic domain tyrosine. Hence, the coordinated activities of the tyrosine kinase Csk and the phosphatases PEP and PTP-PEST suppress SFTK activity within lipid rafts (Hermiston et al., 2002).

CD45 is a transmembrane receptor-like phosphatase expressed on all nucleated cells of hematopoietic origin. There are a large number of CD45 isoforms expressed on cells as a consequence of mRNA splicing of three exons that encode portions of its extracellular domain (see below). As with the majority of transmembrane phosphatases, CD45 contains two phosphatase homology domains in its cytosolic region, although it appears that only the catalytic activity of the proximal domain is required for TCR signaling (Desai et al., 1994).

T cells lacking CD45 fail to proliferate or produce cytokines in response to either antigen or TCR cross-linking. Furthermore, patients with mutations in the CD45 gene have severe combined immunodeficiency (Kung et al., 2000). It is thought that CD45 is required for normal lymphocyte development and peripheral function because it is the primary phosphatase that dephosphorylates the C-terminal negative regulatory site of the SKTKs (Mcfarland et al., 1993).

The phosphatase activity of CD45 is inhibited by the formation of homodimers. This occurs when the catalytic domain of one CD45 molecule binds to the highly conserved juxtamembrane region of another. Mutations in this latter inhibitory wedge prevent homodimerization and predispose to autoimmunity (Majeti et al., 2000). Homodimerization is also controlled by extracellular domain O-linked carbohydrates present on specific CD45 isoforms. The smallest isoform of CD45 (CD45RO), which is expressed on activated T cells, homodimerizes with the highest efficiency. In contrast, $CD45RA^+$, which is expressed on naïve T cells, homodimerizes poorly. By regulating homodimerization, the different CD45 isoforms determine basal CD45 phosphatase activity. This, in turn, allows for different TCR-signaling thresholds on different T-cell subsets (Xu and Weiss, 2002).

Once phosphorylated, the TCR ITAMs recruit the tyrosine kinase ZAP-70 (zeta-associated protein of 70 kDa). ZAP-70 has two N-terminal SH2 domains and a C-terminal tyrosine kinase domain. After both autophosphorylation and direct phosphorylation by Lck, ZAP-70 becomes the primary kinase responsible for the activation of downstream pathways. In humans, the absence of ZAP-70 is associated with a severe combined immunodeficiency syndrome in which $CD8^+$ T cells fail to develop and TCR signaling in $CD4^+$ T cells is completely defective (Chan et al., 1994; Elder et al., 1994). In mice, a spontaneous point mutation in ZAP-70 causes defects in thymic selection that lead to chronic autoimmune arthritis that resembles rheumatoid arthritis (Sakaguchi et al., 2003).

The overall organization of BCR signal initiation is similar; however, there are some important differences. Several members of the SFTKs are expressed in B cells, including Fyn, Blk, and Lyn, and they all are capable of phosphorylating the Igα/Igβ ITAM tyrosines. Unlike the TCR, there is no coreceptor that recruits these SFTKs to the receptor. It has been postulated that either the SFTKs are preassembled in the resting receptor (Cambier et al., 1994) or that movement of the BCR into specialized lipid microdomains in the plasma membrane surface (lipid rafts) provides access to the Src-family kinases. This latter possibility will be discussed below.

It is also controversial as to whether the Src-family kinases are even required for BCR ITAM phosphorylation (Saijo et al., 2003). Under some circumstances, this function can be performed by the ZAP-70 homolog in B cells, Syk (Rolli et al., 2002). Furthermore, the Src-family kinases may activate specific signaling pathways independently of Syk (Saijo et al., 2003). Regardless of the specifics, in both the TCR and BCR the coordinated activation of one or more SFTKs and ZAP-70/Syk are required to activate downstream signaling pathways.

PROPAGATION OF SIGNALING: ASSEMBLY OF SIGNALOSOMES

The recruitment of ZAP-70/Syk to the antigen receptors provides an activated kinase at the receptor complex. For these kinases to activate signaling cascades, proximal substrates must be brought into proximity. This is accomplished by a series of linker molecules that have been identified over the past several years. These molecules not only link enzyme to substrate but they assemble divergent signaling molecules together in arrays that ensure the efficient activation of complex and important signaling pathways (see Figure 19.1).

T-Cell Receptor

Once activated, ZAP-70 phosphorylates two important linkers for TCR signaling: LAT (linker for activation of T cells) and SLP-76 (SH2-domain containing leukocyte protein of 76 kDa) (Tomlinson et al., 2000). LAT is a 36–38 kDa protein expressed in T cells, natural killer (NK) cells, and mast cells. The amino acid sequence of this protein reveals 10 tyrosine residues in its cytosolic domain and two cysteine residues in its juxtamembrane region. These cysteine residues are acylated and target LAT to lipid rafts. The phosphorylation of the tyrosine residues creates binding sites for SH2-domain-containing proteins, including phospholipase Cγ1 (PLCγ1), Grb-2 (a regulator of Ras), Gads

(also referred to as GrpL, or Mona), and the p85 subunit of phosphoinositide 3-kinase (PI3K) (Zhang et al., 1998).

SLP-76 contains three tyrosine residues in the N-terminal region, a central proline-rich domain, and a SH2 domain in the C-terminus. Once phosphorylated, the three phosphotyrosines provide docking sites for SH2-domain-containing proteins, including Vav (a guanine-nucleotide-exchange factor for the small GTPase Rac), the adaptor Nck, and Itk, a Tec family tyrosine kinase that activates PLCγ1. The proline-rich region in SLP-76 constitutively binds the SH3-domain Gads, which also contains an SH2 that binds phospho-SLP76 (Law et al., 1999). In this way, Gads acts as a bridge to assemble SLP-76 and LAT into a single activation platform (Jordan et al., 2003).

B-Cell Receptor

The primary linker in B lymphocytes that couples the BCR to most distal signaling pathways is BLNK (B-cell linker protein, also termed SLP-65 or BASH) (Kurosaki and Tsukada, 2000). This 65 kDa protein, which is a direct substrate of Syk, contains a C-terminal SH2-domain, at least five tyrosines that are phosphorylated following BCR ligation, and multiple potential SH3-binding proline-rich motifs (Chiu et al., 2002). Structurally, BLNK is very similar to SLP-76. It binds to many of the same signaling molecules, including Vav, Nck, Btk (the only Tec kinase expressed in B cells), and Grb-2. Additionally, BLNK binds PLCγ2, a function attributed to LAT in T cells. Structurally and functionally, BLNK is a composite of SLP-76 and LAT. A LAT structural homolog has been described in B cells, LAB. However, it is unclear if it is required for normal PLCγ2 activation. Furthermore, it does not detectably interact with BLNK. Therefore, the available evidence indicates that BLNK is the primary linker involved in initial BCR signaling. However, it is not the only linker. In addition to LAB, BAM32 has been implicated in Erk activation and cytoskeletal reorganization (Han et al., 2003). GrpL is also expressed in B cells but apparently does not play a critical role in BCR signaling.

In contrast to the relationship of the TCR with its primary linkers, BLNK is directly recruited to the BCR complex (Kabak et al., 2002). Following BCR engagement, a unique conserved non-ITAM tyrosine in the cytosolic tail of Igα is phosphorylated, and this directly binds the SH2 domain of BLNK. BLNK is then rapidly phosphorylated and the next level of signaling molecules are recruited and activated.

ACTIVATION OF DOWNSTREAM SIGNALING

Following assembly of the signalsomes in T and B cells, there is a multitude of signaling processes that are activated which ultimately regulate transcriptional programs. We will concentrate on the signaling pathways that regulate two of the most important transcriptional factors, nuclear factor of activated T cells (NFAT) and nuclear factor of κ light chain in B cells (NF-κB) (Figure 19.2).

Intracellular Calcium and NFAT

One important molecule that participates in signal propagation is PLCγ (Kurosaki, 1999; Kurosaki et al., 2000). There are at least 10 different isoforms of phospholipase, with PLCγ1 being the predominant isoform in T cells and PLCγ2 being the predominant isoform in B cells. Both PLCγs have a similar structure with an N-terminal pleckstrin homology (PH) domain that binds phosphatidylinositides, followed by a catalytic domain, two tandem SH2-domains, an SH3-domain, and then a second catalytic domain. PLCγ is recruited to either BLNK or SLP76/LAT after phosphorylation by Syk or ZAP-70, respectively. Recruitment brings PLCγ into proximity with the plasma membrane, which contains the phosphatidylinositols that are its substrate. However, this is not sufficient for activation. Concurrent with PLCγ recruitment, a member of the Itk family of tyrosine kinases is also recruited to the linker complex. The Itk [interleukin (IL)-2 tyrosine kinase] family member then phosphorylates PLCγ at several sites, enhancing its intrinsic catalytic activity (Watanabe et al., 2001). In the case of T cells, Itk or Rlk can serve this function, while in B cells, the only Itk family member expressed is Btk (Bruton tyrosine kinase). Illustrating the singular importance of Btk, mutations in the molecule are associated with X-linked agammaglobulinemia (Tsukada et al., 1993).

Once activated, PLCγ cleaves phosphatidylinositol bisphosphate (PIP_2) into inositol trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 binds to specific receptors on specialized endoplasmic reticulum compartments, promoting release of calcium into the cytosol. Increased intracellular calcium activates a variety of signaling molecules, including calcineurin, a serine/threonine phosphatase. This enzyme dephosphorylates a transcription factor known as NFAT (nuclear factor of activated T cells) (Shibasaki et al., 1996), which is expressed in both T and B cells. Once dephosphorylated, NFAT is released from the cytosol and migrates to the nucleus, promoting the initiation of multiple genes either directly or in partnership with other transcriptional factors such as AP-1 (activator protein-1) (Hogan et al., 2003). Independently of calcineurin, intracellular calcium activates other transcriptional factors, including Nur77 and Nor1, which regulate the proapoptotic inhibitor Bim.

The NFAT pathway is important therapeutically because drugs such as cyclosporine A and tacrolimus are selective inhibitors of calcineurin (Shibasaki et al., 1997). They block the translocation of NFAT to the nucleus, preventing the transcription of genes required for lymphocyte survival.

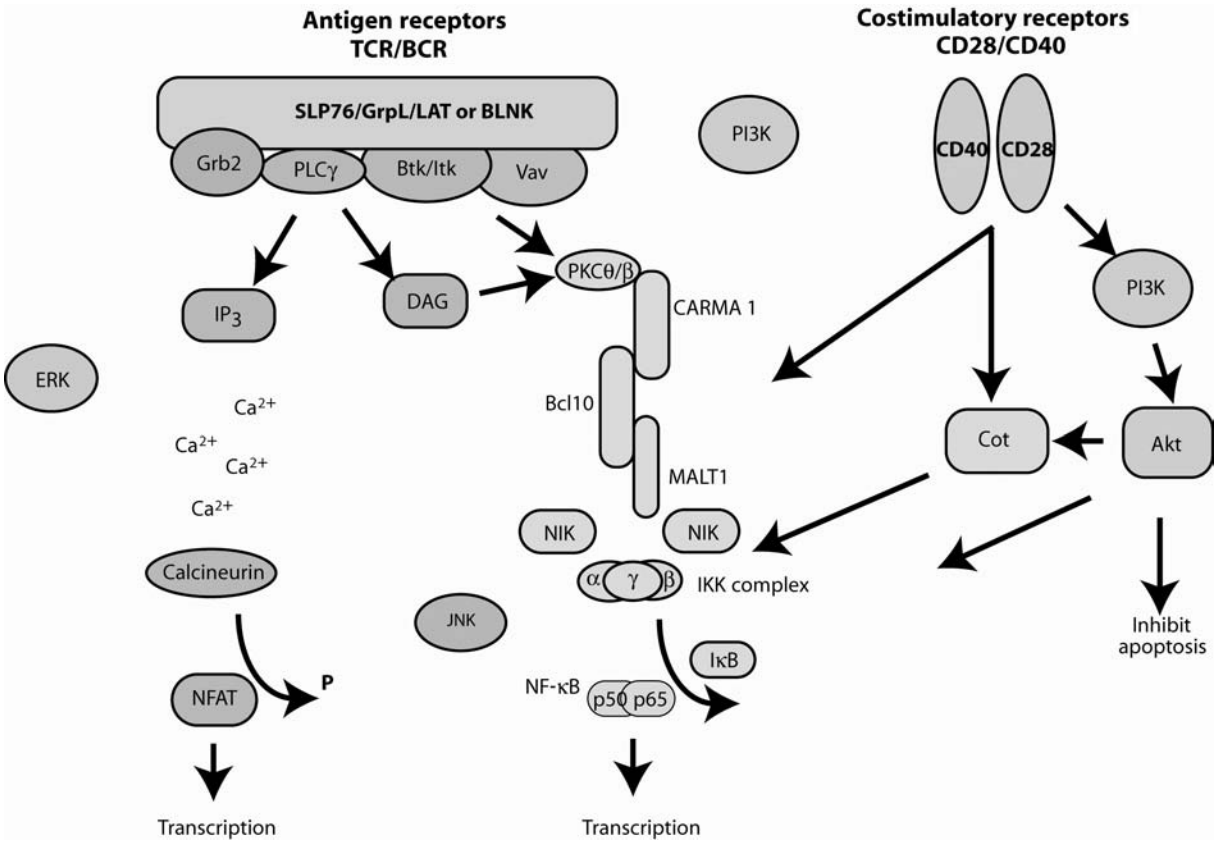

FIGURE 19.2 Signaling pathways activated by the antigen receptors and their primary coreceptors. Following antigen receptor aggregation, multiple molecules are organized on scaffolds that are in close proximity to the activated kinases associated with each receptor. The coordinated recruitment of PLCγ and Btk serves to activate PLCγ and generate free intracellular calcium and diacylglycerol (DAG). Full activation of PLCγ is also dependent upon the activation of phosphoinositide 3-kinase (PI3K) and Vav. Increases in intracellular calcium activate calcineurin, which dephosphorylates nuclear factor of activated T cells (NFAT), allowing it to translocate to the nucleus. ERK is downstream of both Grb2 and PLCγ. Both calcium and DAG contribute to the activation of multiple protein kinase Cs (PKCs), including PKCθ in T cells and PKCβ in B cells. These latter PKCs phosphorylate CARMA1, which leads to IKK activation, IκB degradation, and, finally, the activation of NF-κB. The activation of NF-κB through the T-cell receptor (TCR) is also dependent upon NIK, which can directly phosphorylate IKK. JNK is also downstream of CARMA1. Costimulation provides for the efficient activation of NF-κB through multiple pathways, including CARMA1, NIK (CD40), and, in the case of CD28, indirectly through Akt. Akt also activates multiple downstream pathways, including some which protect against apoptosis. This schematic drawing is a simplified representation of some of the signaling pathways activated by the indicated receptors and has been drawn to emphasize common signaling themes.

These drugs are used in the treatment of several autoimmune diseases and in transplantation. Although quite successful in suppressing the immune system, the use of these inhibitors could theoretically impede the induction of anergy (see below).

The other product that results from cleavage of phosphatidylinositol bisphosphate by PLCγ is DAG. DAG remains in the inner face of the membrane and together with elevated calcium levels activates the classical family of protein kinase Cs (PKC). Of these serine/threonine kinases, PKCθ in T cells and PKCβ in B cells have recently been implicated in the activation of the NF-κB (nuclear factor of kappa light chain in B cells) transcription factor family.

Activation of NF-κB

NF-κB is regulated by a wide variety of receptors of the immune system, including the TCR, BCR, tumor necrosis factor (TNF) receptor family members, and the Toll-like receptors (TLRs). NF-κB activation is central to the proinflammatory effect of these divergent receptors. Not surprisingly, NF-κB is highly activated in a variety of inflammatory diseases and is a major target for drug development in

autoimmune diseases and transplantation. Extensive gene-targeting experiments have demonstrated the importance of the NF-κB pathway in regulating the transcription of genes that control cellular proliferation and cell survival (Li and Verma, 2002).

There are five NF-κB subunits—NF-κB1 (p50), NF-κB2 (p52), RELA (p65), RELB, and c-REL. Active transcriptional complexes contain heterodimers of p50 or p52 paired with a REL transcription factor. NF-κB exists in the cytoplasm in its inactive form, associated with inhibitory proteins that are known as inhibitors of NF-κB (IκB α, β, ε) (Li and Verma, 2002). Upon activation through a variety of receptors, the IκB complex is phosphorylated, ubiquitinated, and degraded, leaving NF-κB free to migrate to the nucleus and initiate transcription. Optimal activation of NF-κB by the antigen receptors usually requires concurrent stimulation through the costimulatory receptors CD28 for T cells or, in the case of B cells, CD40.

Recently, there has been substantial progress in defining the signaling pathways linking the antigen receptors to IκB phosphorylation (Lucas et al., 2004). Following antigen-receptor ligation, PKCθ in T cells and PKCβ in B cells are recruited into proximity of the activated antigen receptors through mechanisms that are still unclear. These kinases recruit the lymphoid-restricted adaptor CARMA1 (CARD 11), which, in turn, leads to the sequential recruitment of the Bcl10 and MALT1 adaptors. This complex then directly regulates the serine-threonine kinase complex that phosphorylates IκB, IKK (IκB kinases). IKK is comprised of two catalytic subunits α and β, and a regulatory subunit, γ(NEMO). Bcl10 targets NEMO for ubiquitination, which is necessary for NF-κB activation (Zhou et al., 2004). In addition to the CARMA1–Bcl10–MALT1 complex, NIK (NF-κB inducing kinase), directly activates IKK and may be required for normal NF-κB activation through the TCR.

The CARMA1 scaffold may provide lymphocytes with a unique integration point for divergent signals that regulate NF-κB (Jun and Goodnow, 2003). For example, in Bcl-$10^{-/-}$ mice, NF-κB activation through the antigen and costimulatory receptors is impaired, but activation through TLR4 is normal. Similarly, point mutations have been introduced into CARMA1 that uncouple BCR and CD28, but not TCR or TLR4, from NF-κB activation. These observations have led to the idea that CARMA1–Bcl10–MALT1 may function to integrate multiple environmental inputs and translate them into a composite signal regulating NF-κB.

LIPID RAFTS AND FORMATION OF THE IMMUNOLOGIC SYNAPSE

The plasma membrane is not homogenous but contains organized subdomains rich in sphingolipid and cholesterol that are rich in acylated signaling molecules, such as the SFTKs, LAT, and Ras. These specialized microdomains are referred to as lipid rafts or glycolipid-enrichedmicrodomains (GEMs) (Dykstra et al., 2003). In resting cells, the antigen receptors are located outside the lipid rafts. However, following receptor ligation there is a rapid translocation of both the TCR and BCR into the lipid rafts. Despite intense investigation, the exact role of lipid rafts in receptor function is still controversial. In immature B cells the BCR does not segregate into lipid rafts and signaling is grossly intact. Therefore, lipid rafts do not appear necessary for signal initiation. However, the concentration of important signaling molecules in the lipid rafts in resting cells, and the recruitment of additional signaling effectors following receptor ligation, suggest that lipid rafts may contribute to signal propagation and amplification.

Concurrent with lipid raft coalescence, productive presentation of antigen to T cells is associated with the organization of the TCR and costimulatory molecules into supramolecular activation clusters (SMACs), which define the immunologic synapse on T cells. Classically, the mature immunologic synapse consists of a central SMAC (c-SMAC) containing engaged TCRs and a peripheral SMAC (p-SMAC) consisting of an encircling ring of adhesion molecules or integrins (Davis and Dustin, 2004). However, variations in this structure have been reported to occur in cytolytic T and NK-cells. As is the case with lipid rafts, there is still controversy as to what the SMACs do. Furthermore, their exact relationship to lipid rafts is not clear. However, formation of the SMAC requires active signaling and a reorganization of the actin cytoskeleton, while simple segregation to lipid rafts does not (Miletic et al., 2003). There is evidence to support a role for SMACs in enhancing signaling and for integrating positive and negative signals (Lee et al., 2003). Formation of the SMAC polarizes the cell, allowing important cytokines or cytotoxic granules to be secreted at the T-cell–APC interface. It has also been postulated that they play a role in the degradation of the receptor and signal termination (Lee et al., 2003). It is likely that SMAC formation helps commit a cell to a particular biologic response.

ROLE OF COSTIMULATION

Lymphocytes require two distinct signals to achieve full activation. The first is antigen specific and involves the TCR and BCR (signal 1). The second signal, also known as signal 2, is antigen independent and requires the participation of costimulatory receptors. In T cells, antigen receptor signaling without concurrent costimulation can result in anergy and clonal deletion. In B cells, a lack of costimulation does not necessarily lead to anergy but can result in developmental arrest and cell death.

Costimulatory receptors cannot activate lymphocytes on their own. Rather, they augment and complement signals provided by the antigen receptor. Below we describe the influence of two main costimulatory molecules in T and B lymphocyte activation and the downstream pathways that they regulate.

CD28

CD28 is a 44-kDa disulfide-linked glycoprotein expressed constitutively in the majority of $CD4^+$ and $CD8^+$ T cells. It binds to CD80 (B7.1) and CD86 (B7.2), expressed on the surface of APCs. The interaction of CD28 with its ligands promotes T-cell proliferation, IL-2 production, and survival of naïve T cells. The latter effect may be related to the fact that CD28 ligation upregulates the antiapoptotic Bcl-2 family member, Bcl-X_L (Alegre et al., 2001). Finally, CD28 costimulation decreases the threshold of T-cell activation, possibly by promoting the formation of the immunologic synapse. Much research has focused on the molecular mechanisms coupling CD28 ligation to its downstream events (Frauwirth and Thompson, 2002).

Like the TCR, CD28 lacks intrinsic kinase activity. The cytoplasmic tail contains four tyrosine residues that are phosphorylated by the SFTKs Lck and Fyn. One effector that is recruited to these phosphotyrosines is PI3K. Once activated, PI3K generates 3′ phosphorylated inositol lipids, which then recruit PH domain-containing proteins to the plasma membrane. One of the best characterized is Akt (previously known as protein kinase B or PKB), which is a serine/threonine kinase that activates NF-κB. The mechanisms that link Akt to NF-κB pathway are not completely understood but possibilities include the direct phosphorylation of IKKα by Akt, or indirect phosphorylation of the IKKs through the activation of intermediate kinases, such as Cot (a member of the mitogen-activated protein kinase family) (Kane and Weiss, 2003). Recruitment of Vav also occurs with CD28 costimulation, contributing to calcium mobilization, cytoskeletal remodeling, and transcriptional activation.

Blockade of the CD28 pathway holds great promise in the treatment of autoimmune diseases. CTLA4Ig is a soluble fusion protein that binds to CD80 (B7.1) and CD86 (B7.2) on APCs, acting as a competitive inhibitor of CD28. CTLA4Ig has been used successfully in animal models of diabetes and systemic lupus erythematosus (SLE). Furthermore, it was efficacious in preliminary clinical trials of psoriasis and rheumatoid arthritis (Dall'Era and Davis, 2004). Larger studies are ongoing in rheumatoid arthritis (See Chapter 76).

CD40

CD40 is a 48-kDa transmembrane glycoprotein expressed in B cells, DCs, macrophages, and epithelial cells. Its ligand is CD154, a membrane protein, expressed mainly on activated T cells. Engagement of CD40 promotes B-cell clonal expansion, germinal center formation, and isotype switching. Engagement of CD40 initiates signaling pathways that activate mitogen-activated protein kinases and the NF-κB pathway. This is accomplished through the recruitment of adapter proteins known as TRAFs (TNF receptor-associated factors) to the cytoplasmic tail of CD40 and the formation of a multimeric signaling complex that includes NIK. In DCs, the activation of the NF-κB pathway via CD40 is associated with upregulation of BCl-x and Bcl-2 (Quezada et al., 2004).

Anti-CD154 has been used to block the CD40/CD154 pathway in many autoimmune disease models with success. These animal models include, but are not limited to, autoimmune encephalomyelitis (EAE), collagen-induced arthritis, diabetes, SLE, and thyroiditis. As with CTLA4Ig, clinical trials will be needed to address the efficacy and safety of CD40 blockade in humans (Quezada et al., 2004) (See Chapter 76).

DETERMINING RECEPTOR THRESHOLD

The signaling threshold through the antigen receptors is dependent upon the presence and activity of coreceptors and regulatory molecules (Pritchard and Smith, 2003). This has been best defined for the BCR in which both positive and negative coreceptors have been defined. However, similar regulatory mechanisms have been recently defined in T cells (Chen, 2004).

A primary negative regulator of the BCR is CD22, which is constitutively associated with the resting BCR. Following BCR stimulation, the cytosolic tail of CD22 is phosphorylated at a tyrosine within a conserved motif known as the immmunoreceptor tyrosine-based inhibitiory motif (ITIM). The ITIMs are found within a wide range of receptors, including NK-cell receptors, PD1, FcγRIIb1, and others involved in the negative regulation of lymphocytes (Ravetch and Lanier, 2000). In the case of CD22, phosphorylation is mediated by the Src-family tyrosine Lyn. In contrast to the general redundancy of most SFTKs, only Lyn can phosphorylate the CD22 ITIM. The CD22 phospho-ITIM then recruits SHP-1, which is an SH2-domain-containing tyrosine phosphatase. SHP-1 has a broad specificity and appears to be able to dephosphorylate several proteins involved in proximal BCR signaling (Cornall et al., 1998; Zhang et al., 2000). The importance of CD22, SHP-1, and Lyn have been defined in genetically targeted and naturally occurring mutant mice (Yu et al., 2003). Deletion of CD22 results in hyperproliferative peripheral B cells and antibodies to dsDNA, while deletion of either Lyn or SHP-1 results in an autoimmune disease similar to SLE. The phenotype of mice

deficient in SHP-1 is the most severe, reflecting the negative regulatory role SHP-1 plays in a wide range of immune receptors, including the TCR.

Another negative regulatory receptor on B cells is FcγRIIb1. Like CD22 it has an ITIM. However, the receptor is not associated with the resting BCR and only becomes phosphorylated if the BCR and FcγRIIb1 are coengaged (Unkeless and Jin, 1997). This occurs when the BCR engages immune complexes or when anti-idiotypic antibodies are generated against the specificity of the BCR. These are negative regulatory loops that inhibit further antibody production. Coengagement of the BCR and FcγRIIb1 leads to the phosphorylation of the FcγRIIb1 ITIM and the recruitment of another negative regulatory molecule SHIP (SH2-containing inositol phosphatase) which dephosphorylates PIP3 (Ono et al., 1997). By counteracting the phosphokinase activity of PI-3 kinase, there is less membrane recruitment of molecules containing PH domains, such as PLCγ and Btk. Through this, and other mechanisms (Tamir et al., 2000), coligation of the BCR and FcγRIIb1 attenuates intracellular calcium responses and inhibits B-cell proliferation.

While CD22 and FcγRIIb1 effectively raise receptor threshold, coengagement of CD19 and the BCR dramatically lowers it (Carter and Barrington, 2004). CD19 is the signaling subunit of a receptor complex for the complement cleavage product C3d [complement receptor 2 (CR2) also containing CD21 and Tapa 81]. Coengagement of CR2 and the BCR by opsonized immune complexes can enhance *in vivo* B-cell–mediated immune responses by up to a 1000-fold (Carter and Fearon, 1992). Enhanced BCR responsiveness is dependent upon SFTK-mediated phosphorylation of the CD19 cytosolic tail, which serves to further amplify SFTK activation and recruit PI-3 kinase (Kurosaki, 2002). Deletion of CD19 results in defects in peripheral maturation and diminished immune responses (Wang and Brooks, 2002). Conversely, transgenic overexpression of CD19 induces SLE-like manifestations (Tuscano et al., 2003).

SIGNALING AND TOLERANCE

Depending upon the nature and context of the ligand, antigen-receptor engagement can result in cellular activation, cell death or tolerance. Each is an active process that arises from the activation of different signaling programs. The signaling pathways induced by activating ligands has been described above. In contrast, anergizing ligands induce only a subset of these signaling pathways and the biologic responses are fundamentally different. In tolerant T cells, the TCR is uncoupled from the ERK, JNK, and NF-κB pathways, while in tolerant B cells the BCR is uncoupled from JNK and NF-κB (Jun and Goodnow, 2003). However, in both cases low-magnitude calcium oscillations are sufficient to activate NFAT. In T cells, costimulation through CD28 can prevent the induction of anergy, while stimulation of B cells through either the lipopolysaccharide (LPS) receptor (TLR4) or CD40 prevents it. It is likely that engaging coreceptors or TLRs prevents anergy by activating NF-κB and JNK.

Recently, it has become apparent that the processes regulating the degradation of antigen receptors and their downstream signaling pathways are important for determining responses to antigen (Davis, 2004). Normal protein homeostasis is regulated by poly-ubiquitination. Ubiquitin is an 8-kDa molecular tag that targets proteins for degradation by the proteosome. Ubiquitination has been demonstrated to regulate TCR internalization and degradation, as well as the steady-state levels of ZAP-70, Syk, PI-3 kinase, the Src-family kinases, and BLNK. Ubiquitin-mediated degradation of IκB is required for normal activation of NF-κB. There are hundreds of ubiquitin ligases but two that have been demonstrated to be important in antigen-receptor function are C-cbl (Casitas B-lineage lymphoma) and Cbl-b (Zhang, 2004). C-cbl is predominantly expressed in developing lymphocytes, while Cbl-b predominates in the periphery. Consistent with their relative expression patterns, thymocytes from C-cbl$^{-/-}$ mice have enhanced ZAP-70 activation and positive selection. In contrast, Cbl-b$^{-/-}$ mice develop a lupus-like disease with hyperproliferative T and B cells. Cbl-b deficiency complements CD28 deficiency, suggesting that Cbl-b might be involved in responses to costimulation. Interestingly, Cbl-b targets PKCθ and is upregulated in anergic T cells. Furthermore, Cbl-b$^{-/-}$-deficient mice are resistant to anergy induction (Heissmeyer et al., 2004). These and other data indicate that targeted degradation of specific signaling molecules may be an important mechanism controlling antigen-receptor responsiveness.

SUMMARY

In this overview, we have provided an outline of what is known about several pathways that regulate lymphocyte activation and tolerance. The discussion is by no means complete. Several important signaling processes were not covered and we have simplified the signaling cascades of others. This was done to provide the reader with an overall concept of how antigen engagement is translated into cellular decisions. Furthermore, we have highlighted the signaling processes that may contribute to autoimmunity and those signaling pathways that hold the most promise for therapeutic intervention.

Acknowledgments

We would like to thank Marisa Alegre and Iannis Aifantis for reading the manuscript and helpful discussions. This work was supported by grants from the NIH (GM 52736) and the Arthritis Foundation.

Genetics and Autoimmunity: HLA and MHC Genes

VEENA TANEJA AND CHELLA S. DAVID

Department of Immunology, Mayo Clinic, Rochester, Minnesota, USA

The human immune system has evolved over the centuries to combat onslaughts of invading microorganisms. The immune system operates via two ways—innate immunity, a nonspecific first line of defense after infection, and adaptive immunity, an acquired immunity against a specific entity. The main feature of the adaptive immunity is its diverse nature of immune response. The major players for adaptive immunity are the genes of the major histocompatibility complex (MHC). The MHC region encodes for polymorphic human leukocyte antigen (HLA) molecules that are critical for differentiating self from nonself. Mature T cells recognize foreign antigen when it is presented in the context of self-MHC. The loss of self-tolerance of the immune system against the body's own tissues/antigens leads to autoimmunity. The development of autoimmune diseases, such as rheumatoid arthritis (RA), type 1 diabetes (T1D), multiple sclerosis (MS) or myasthenia gravis (MG) is determined by both genetic and nongenetic factors. Among the genetics factors, the MHC region is known to be the most important. Within this region, certain HLA class II genes confer the strongest susceptibility to the majority of MHC-associated disorders.

MAJOR HISTOCOMPATIBILITY COMPLEX

Human MHC molecules are called HLAs, which are homologous to the H-2 of mice. The MHC region is located on the short arm of chromosome 6 in humans and is 3500 kb long. It encodes for two types of HLA, designated as class I and class II. HLA class I molecules contain one heavy chain of 44 kDa and one non-MHC-encoded nonpolymorphic β2 microglobulin of 12 kDa. The heavy chain consists of three extracellular domains of 90 residues each. The polymorphic residues in class I molecules are located on the α1 and α2 domains of the heavy chain. The products of class I genes include HLA-A, HLA-B, and HLA-C, and are expressed on all nucleated cells. Class I molecules can bind 8–10 amino acid-long peptides that have been processed endogenously.

HLA class II molecules are present as heterodimers on the cell surface, consisting of an α chain (32–34 kDa) and a β chain (29–32 kDa) each with two extracellular domains of about 90 amino acid residues (α1, α2 and β1, β2). The β chains of three class II genes, HLA-DR, DQ, and DP, are highly polymorphic, while the α chains are generally

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

nonpolymorphic. The class II molecules are expressed on antigen-presenting cells (APCs), like B lymphocytes, macrophages, dendritic cells (DCs), and endothelial and other organ-specific APCs. In general, class II molecules can accommodate peptides of up to 10–25 residues. In humans, DR, DQ, and DP are in linkage disequilibrium and are inherited en bloc. MHC genes are expressed codominantly in each individual. Crystal structures of DR and DQ have shown that the MHC molecule has a single peptide-binding cleft, which can accommodate a variety of peptides according to their charge, stability, and binding affinity.

MAJOR HISTOCOMPATIBILITY COMPLEX AND AUTOIMMUNITY

Susceptibility to many diseases with an autoimmune etiology is associated with HLA-DR and/or -DQ alleles. Table 20.1 gives some of the most significant associations between HLA and diseases. Despite over 25 years of investigation, the exact role of the HLA class II molecules in these disease processes is unknown. However, class I genes have not been associated with any autoimmune disease with the exception of HLA-B27, which is associated with a predisposition to a group of diseases collectively named "spondyloarthropathies" (see Chapter 33).

The major function of MHC genes is to clear infection. The cytotoxic T lymphocytes can lyse virus-infected targets only in the context of MHC class I molecules. During evolution, the HLA genes mutated to cope with the clearance of new pathogens. The migration of populations from Africa and Asia to other parts of the world exposed them to new microenvironments. The survival of such populations depended on clearing infections. This led to mutations of HLA genes and the generation of newer subtypes of a gene. The hypothesis we propose is that these mutations led to selection of subtypes of a gene with flexible antigen-binding sites so as to generate a strong immune response to the pathogens. An inverse quantitative correlation exists between the viral load in blood and T-cell responses to infection by the MHC. The HLA alleles that can generate efficient immune response are selected.

Unfortunately, even though these genes protect from infection, they can present autoantigens in the periphery or influence selection of autoreactive T cells in the thymus that can lead to autoimmunity. In the thymus, T cells are selected on the basis of their weak interaction with self-MHC molecules expressed in the thymus. Thus, T cells reactive with self-peptide that can bind with high affinity to MHC molecules are negatively selected in the thymus, while those with weak interactions with MHC may escape negative selection (Figure 20.1; see Chapters 5, 6 and 8). Such a mechanism may explain the selection of a T-cell repertoire that is protective or susceptible to autoreactivity. Elution of peptides from HLA class II molecules suggests that some of these peptides may indeed be derived from HLA molecules themselves (Chicz et al., 1994; Vogt et al., 1994). Thus HLA molecules not only function in the thymus by presenting peptides but also serve as donors of self-peptides. This intricate relationship between MHC, self-peptides, and the T-cell receptor (TCR) could determine the specificity of T cells in the periphery. Thus, in the periphery T cells can recognize non-self-antigens to clear infection, recognize self-antigens to cause autoimmunity, or can become tolerant/anergic. However, studies to resolve these issues in humans have been hampered by the lack of knowledge of "culprit"

TABLE 20.1 Association of various autoimmune diseases with HLA class II alleles and haplotypes

Disease	Alleles	Haplotypes
Rheumatoid arthritis	DRB1*04, DQB1*0302	DRB1*04\DQB1*0302 DRB1*04\DQB1*0302 DRB1*10\DQB1*0501
Type 1 diabetes	DRB1*03, DRB1*04 DQB1*0302	DRB1*04\DQB1*0302 DRB1*0301\DQB1*02
Multiple sclerosis	DRB1*15	DRB1*15\DQB1*0601
Celiac disease	DRB1*0301, DRB1*0701 DQB1*0302	DRB1*0301\DQB1*02 DRB1*0701\DQB1*02 DRB1*04\DQB1*0302
Graves' disease	DRB1*0301, DQB1*02	DRB1*0301\DQB1*02
Autoimmune thyroiditis	DRB1*0301	DRB1*0301\ DQB1*02
Myasthenia gravis	DRB1*03	DRB1*0301\ DQB1*02
Autoimmune adrenalitis	DRB1*0301	DRB1*0301\DQB1*0201

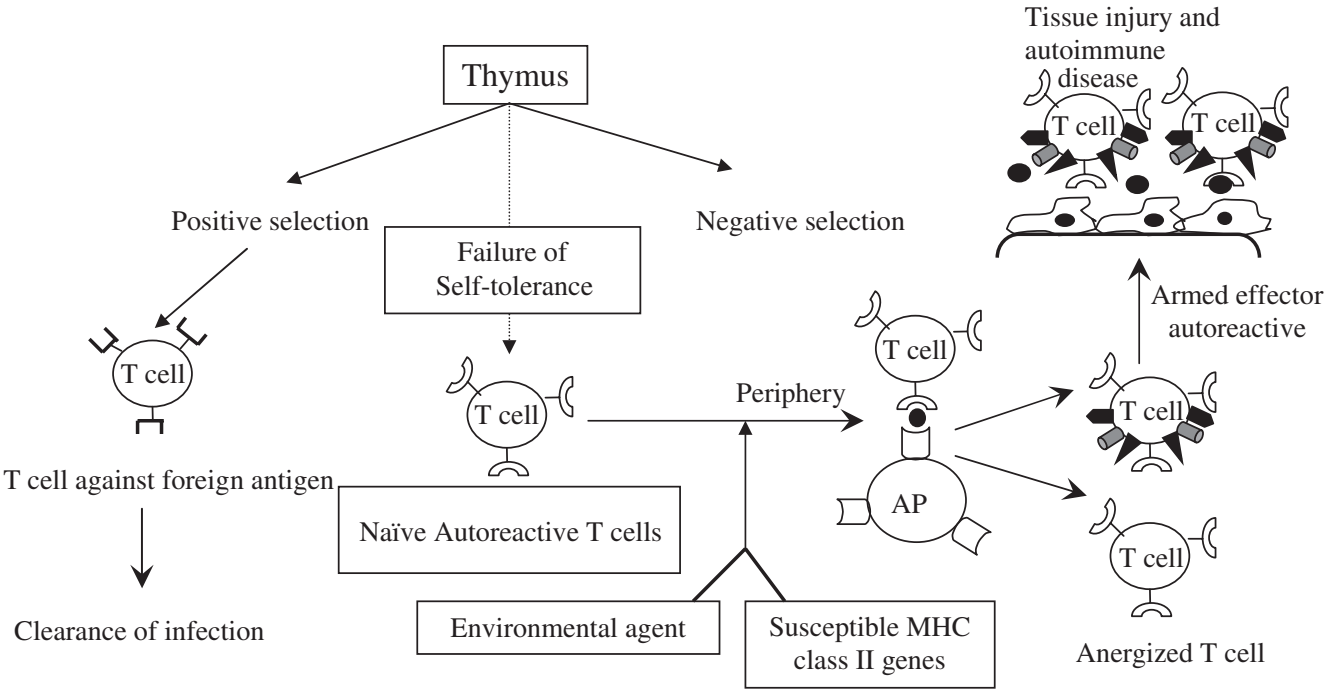

FIGURE 20.1 HLA molecules select the T-cell repertoire in the thymus by presenting peptides and also serving as donors of self-peptides. T cells are selected on the basis of their weak interaction with self-MHC molecules expressed in the thymus. Thus, T cells reactive with self-peptide binding with high affinity to MHC are negatively selected in the thymus, while those with weak interactions may escape negative selection. Such a mechanism may explain the selection of an autoreactive T-cell repertoire. In the periphery, positively selected T cells can recognize nonself antigens and clear infection. The autoreactive T cells that have escaped can recognize viral peptides that mimic self-antigen, or cryptic epitopes that are exposed during infection, causing inflammation and autoimmunity. APC, antigen-presenting cell.

autoantigens and difficulty in obtaining samples from affected organs. The other problem has been the linkage disequilibrium of HLA class II alleles, DR and DQ, which makes it difficult to interpret the association of a disease with a haplotype or specific allele.

HLA-B27

There are 24 HLA-B27 alleles (subtypes), which seem to have evolved from the most commonly observed subtype, B*2705 (Ball and Khan, 2001). Differences in exons 2 and 3, which encode the α1 and α2 domains of the B27 molecule distinguish the various subtypes. However, the natural polymorphism of this molecule influences both peptide specificity and its pathogenic role. Individuals carrying B27 are at lower risk of infection from the human immunodeficiency virus (HIV). B27 recognizes an immunodominant epitope in a conserved part of the capsid protein of HIV (McMichael and Klenerman, 2002). This leads to vigorous cytotoxic T lymphocyte (CTL) responses, resulting in elimination of the virus. Thus HLA-B27 carries out its natural function very effectively. Because of the superiority of the B27 molecule in providing viral immunity, the B27 gene had an advantageous selection during evolution. This could explain why B27 genes are found in almost all geographic regions with such high frequency, and also why so many subtypes of B27 were generated to eliminate new viral antigens that evolve.

HLA-B27 transgenic rats and mice have provided a wealth of information regarding the HLA-B27-linked spondyloarthropathies. Both rat and mouse models proved that the HLA-B27 gene itself is involved in the disease process, although an environmental trigger is required for the onset of the disease (Hammer et al., 1990; Khare et al., 1995). The disease primarily affected the male rodents, similar to the human disease. However, the spontaneous disease in transgenic rats required a high copy number of HLA-B27 and the human β2-microglobulin (β2m) transgenes (Taurog et al., 1993). B27 transgenic mice also developed spontaneous inflammatory arthritis, but only in the absence of mouse β2m or when human β2m was substituted. Replacement of mouse β2m with human β2m led to several conformational changes in HLA-B27, as observed by using several B27-specific monoclonal antibodies. Mice

expressing B27 and the human β_2m transgene showed normal expression of HLA-B27 molecules and β_2m-free heavy chains of HLA-B27 on the cell surface. It was speculated that β_2m-free heavy chain expressed on the cell surface may present extracellular/exogenous peptides, possibly from a bacterial source (Khare et al., 1996). In the transgenic animal model, it was observed that two of the three peptides derived from the third hypervariable region of HLA-B27 can be presented by endogenous mouse class II molecules to $CD4^+$ T cells (Marker-Hermann et al., 1997). However, MHC class II-deficient HLA-B27 transgenic mice were susceptible to nail disease and arthritis, demonstrating that MHC class II molecules are not involved in the disease pathogenesis in the transgenic mouse model (Khare et al., 1998). However, $CD4^{-/-}$ HLA-B27 transgenic mice do not develop arthritis, suggesting that the disease requires $CD4^+$ T cells for the onset of the disease mediated by the antigen-binding pocket of the B27 molecule.

Being an MHC class I molecule, HLA-B27 will be expected to present endogenous antigens such as viral or cytosolic antigens. However, most human spondyloarthropathies have an onset after an infection with enterobacteria (exogenous antigens). Endogenous peptides are transported to the endoplasmic reticulum with the help of molecules involved in the transport of antigenic peptides (Tap1–Tap2 heterodimer). Tap1 knock-out B27 transgenic mice developed spontaneous arthritis and nail disease, indicating that endogenous processing of antigens may not be required in B27-linked diseases (Khare et al., 2001).

Antigen Presentation

B27 presents antigen like class II molecules. Why is HLA-B27, a class I molecule, linked to an autoimmune disease? The B27 molecule turns out to be a unique class I molecule which can form homodimers in the absence of β2m (Allen et al., 1999b). This may be the reason why HLA-B27 is the only class I molecule linked to a human autoimmune disease. Experimental data from transgenic animals are quite suggestive of the notion that the HLA-B27 molecule is an arthritogenic-peptide-presenting molecule. A β2m-free B27 heavy chain homodimer can form an unusual conformation that probably resembles a class II molecule with open ends and can be transported empty to the cell surface. The dimer can be loaded and can present an exogenous peptide longer than nine amino acids, which can go through a class II antigen-processing pathway. The peptide being presented by the heavy chain dimer could be a self-peptide derived from cartilage antigens that could potentially activate some of the autoreactive $CD4^+$ T cells. There are several bacteria with sequence similarities to joint-derived antigens that can bind B27 (Scofield et al., 1995). Data from studies on human cells have confirmed the mouse studies. In humans it has also been shown that B27 dimers can be formed on the cell surface in patients with spondyloarthropathies (Kollnberger et al., 2002).

Molecular Basis for B27 Association

Even though the B27 molecule has a similar conformation to other class I molecules, the mutation in residue 9 (histidine instead of tyrosine) of B27 could have selective advantage during evolution. The crystal structure of class I molecule shows that β2m binds residue 9 of class I (Madden et al., 1992). This mutation could affect the stability of the complex so that β2m can dissociate from heavy chains, resulting in formation of free heavy chain dimers. Alternatively, this mutation probably results in the faster assembly of the B27 molecule and faster transport to the cell surface than other class I molecules, to counter viral infection better. B27-expressing individuals are slow progressors during HIV infection compared with individuals expressing other class I molecules (Goulder et al., 2001). The molecular basis of B27 association can be explained by differences in amino acids of various subtypes of B27 (Allen et al., 1999a; Hulsmeyer et al., 2002). The critical residues involved in the P2 pocket of peptide binding are Glu45 and Cys67. The unpaired cysteine residue could be one potential source of anomalies in the cellular function of B27. During evolution, the HLA molecules would mutate to combat infection. B2705 is the predominant subtype in most populations and B2704 is the predominant subtype in the Asian population (Khan and Ball, 2002). Most of the other alleles have arisen by mutations and differ by two to seven residues in the α1 and α2 domains of B2705. Two B27 alleles that have been reported to lack association with spondyloarthropathies are B*2706 and B*2709. B2706 differs from B2705 at residues 77, 114, and 116, and B2709 differs at position 116 (His for Asp). Residue 116 is involved in the formation of the F pocket of the peptide-binding cleft that accommodates the C-terminal residue of the peptide. The B and F pockets are critical for peptide binding. The differences in residues of the F pocket may account for differences in the peptides that can bind and their association with disease.

Predisposition to Autoimmunity by Class II Molecules

Similar to class I, there is a high polymorphism in class II alleles; there are more than 370 alleles known for the DRB1 locus and 55 for the DQB1 locus. However, autoimmunity is associated with only a few haplotypes. DR2-DQ6, DR3-DQ2, and DR4-DQ8 are the major haplotypes associated with various autoimmune diseases. Since the specificity and affinity of peptide binding and T-cell recognition is determined by polymorphism in the MHC, it is crucial to study the presentation of putative causative agents for various autoimmune diseases by HLA-DR and -DQ alleles.

Genetic analyses of various autoimmune diseases show that such diseases are more often sporadic than familial, suggesting a multifactorial and multigenic basis. For most organ-specific autoimmune disorders, many susceptibility and resistance genes act in concert to modulate the clinical phenotype; however, MHC is the known major factor, which accounts for 50% of the genetic contribution. Most autoimmune diseases are thought to occur as a sequel to an infection or an unknown trigger, as discussed in other chapters in this book.

TRANSGENIC MICE AS MODELS FOR ROLE OF HLA CLASS II IN AUTOIMMUNITY

The advent of transgenic mice lacking endogenous class II molecules ($A\beta^o$) expressing human HLA-DR and HLA-DQ genes has significantly advanced the understanding of the role of individual HLA class II molecules (Taneja and David, 1999). Introduction of an HLA class II transgene in $A\beta^o$ mice led to the expression of a functional HLA class II molecule and a reconstituted CD4 T-cell compartment, thus resulting in CD4-restricted immune response to various peptides. Thus, the HLA transgene in these mice is self. Experimental data from various laboratories have shown that the function of HLA class II molecules in these mice is similar to that in humans.

The first line of evidence came from *in vivo* and *in vitro* studies with superantigens (SAgs) in HLA transgenic mice. Bacterial SAgs have a lower affinity for mouse MHC class II than for human MHC class II molecules. Because of this biologic characteristic, SAg-induced toxicity is much lower in mouse models than it is in humans. When immunized with staphylococcal enterotoxin B (SEB), HLA-DR3-transgenic mice responded to several log lower concentrations of SEB and secreted higher levels of proinflammatory cytokines than did wild-type mice (DaSilva et al., 2002). The response to SAgs in transgenic mice can result in toxic shock and is dependent on the polymorphism of class II alleles.

The second line of evidence comes from peptide presentation by HLA transgenes in mice. HLA-transgenic mice respond to similar epitopes as observed in humans. In a comparison study DR3.Aβo mice recognized only one epitope comprising of a 1–20 amino acid peptide of heat-shock protein (hsp) 65 of *Mycobacterium tuberculosis*, as observed with human DR3-restricted T cells (Geluk et al., 1998). The response was specific in DR3 mice, as DQ8 mice did not respond to this peptide. These studies suggest that processing and presentation of the antigens in the context of class II molecules is similar in transgenic mice and humans.

The third line of evidence that the function of HLA transgenes in mice is similar to that in humans comes from studies with experimental autoimmune myasthenia gravis (EAMG) in DR3-transgenic mice (Infante et al., 2003). The wild-type mice show a highly conserved TCRBV gene usage and CDR3 sequences in response to acetylcholine receptor (AChR), an autoantigen for myasthenia gravis. However, DR3-restricted murine hybridomas generated from DR3 mice immunized with AChR expressed a diverse set of TCR B chains, which is similar to what is observed in humans. The TCRBV sequences from human MG patients were homologous to those of the DR3-restricted murine clones, suggesting that humans and mice can recognize similar epitopes and use similar CDR3 sequences for the recognition of the same peptide–MHC complex. Thus, HLA-transgenic mice can provide an important insight into the peptide presentation by different class II alleles and the ensuing disease pathogenesis.

HLA-DQ Transgenic Mice as a Model for Rheumatoid Arthritis

The first model of autoimmunity to determine the role of human class II molecules was established by using DQA1*0301, DQB1*0302 (DQ8) transgenic mice. DQ8 occurs in linkage disequilibrium with DR4 and has been shown to be associated with RA in certain ethnic groups (Taneja et al., 1992; Yelamos et al., 1993). Collagen-induced arthritis (CIA), an animal model for RA was studied *in vivo* in $A\beta^o$.DQ8 mice. Immunization of $A\beta^o$.DQ8 mice with heterologous type II collagen (CII) led to a pathogenic autoimmune CD4-mediated response and then severe arthritis and antibodies to self-type II collagen (Nabozny et al., 1996). This is the first model with production of rheumatoid factor (RF), one of the major serologic features of patients with RA (Taneja et al., 2002). In none of the previous models of RA using wild-type mice was there production of RF, resulting in uncertainty whether CIA could serve as a model for RA. The scenario for the development of arthritis in transgenic mice can be compared to that of RA in humans. Both require presentation of an arthritogenic epitope by HLA class II molecules to CD4 T cells, leading to a proliferation of autoreactive cells and production of RF by B cells and subsequent joint pathology. Further studies using CD4- and CD8-deficient mice suggested that the disease was mediated by $CD4^+$ T cells while $CD8^+$ T cells may act as regulatory cells, since CD8-deficient mice transgenic for DQ8 developed high amounts of autoantibodies, including RF, antibodies to CII, and antinuclear antibodies (ANA). A similar situation can be envisaged in RA where production of autoantibodies like RF and ANA could be related to the functional status of CD8 T cells. On the other hand, mice expressing DQA1*0103,DQB1*0601 (DQ6) were resistant to the development of CIA (Bradley et al., 1997). The double transgenic mice expressing both DQ6 and DQ8 developed

moderate CIA comparable with the severe arthritis observed in DQ8 transgenic mice (Bradley et al., 1998), much like patients with RA who bear both susceptible and nonsusceptible HLA haplotypes. These observations have contributed to the concept that polymorphism in DQ may be a major contributing factor in human RA.

Role of HLA-DR in rheumatoid arthritis

Predisposition to RA has been associated with the expression of some subtypes of HLA-DR4 in most human studies ever since the first association of Dw4 and RA shown by Stastny (1983). However, most of the studies in different ethnic groups observed that only two alleles, DRB1*0401 and *0404 occur with increased frequency in RA. Further, while DRB1*0401 and *0404 are associated with predisposition, DRB1*0402 is associated with resistance or protection against RA. However, $A\beta^o$.DRB1*0401 mice were not susceptible to CIA. This was puzzling, but could be explained in at least two ways. First, that DR4 may not be able to present many epitopes of CII. Studies in humans have shown that RA-associated DR alleles bind only few epitopes of CII, while DQ8 can present multiple epitopes of CII (Matsushita et al, 1996). Secondly, $A\beta^o$.DR4 mice express both DR4 and mouse Eβ molecules, and polymorphism in E has been shown to be protective in wild-type susceptible mice (Gonzalez-Gay et al., 1994). To determine the role of DR4 molecules in RA, DRB1*0401 mice were generated in complete MHC knock-out mice (AE^o). DRB1*0401.$AE^{-/-}$ mice develop arthritis that mimics human RA. AE^o mice have a deletion of an 80-kb region of class II such that none of the classical murine class II molecules is expressed. Human T cells differ from those of mice in the expression of MHC class II molecules on their cell surface. Interestingly, similar to humans, T cells from AE^o.DR-transgenic mice express HLA-DR molecules on their cell surface, and can present peptide antigen. Thus, presentation of an antigen in the context of HLA by an activated T cell might also contribute to severity.

To simulate human haplotypes, double transgenic mice expressing autoimmune-associated DQ and DR alleles were generated on an AE^o background. DR4\DQ8.AE^o mice developed arthritis similar to DQ8 mice but also showed gender differences. Gender differences in CIA were not observed in DQ8 mice, suggesting modulation of DQ8-restricted disease by the DR4 molecule. To understand modulation by DR polymorphism, DRB1*0402 mice were studied for their influence on the development of CIA. DRB1*0402 mice were not susceptible to CIA, similar to humans. Mice that expressed both susceptible and resistant DR4 subtypes, 0401/0402, developed arthritis with lower incidence than did DRB1*0401 mice (Taneja et al., 2003a).

The experimental and human data led us to hypothesize that DQ polymorphism may be responsible for susceptibility, while DR may be involved in the modulation of disease. Thus, both DQ and DR alleles in a haplotype can influence the development of disease. On the basis of observations in transgenic mice, the following mechanisms can be suggested. First, polymorphism in DRB1 alleles leads to modulation of DQ-mediated disease because of presentation of hypervariable region 3 (HVR3)-derived peptides by RA-associated DQ molecules (Zanelli et al., 1995). Thus, a high-affinity binding DRB1 HVR3 peptide would negatively select autoreactive T cells, while a low-affinity peptide would positively select potential autoreactive T cells. Secondly, presentation of a peptide by a DR molecule might enhance the autoantigenic immune response. From the studies on DQ and DR transgenic mice, it can be extrapolated that gene complementation or interaction between DQ and DR molecules mediates susceptibility to RA in humans. Depending on the haplotypes carried by an individual, they could be susceptible to severe or mild disease. A homozygous haplotype for predisposing DQ and permissive DR will lead to severe disease. Also, heterozygous RA-susceptible haplotypes (DQ and DR) will result in very severe disease since there will be two predisposing DQ molecules. However, one predisposing and one protective haplotype should show less severity and low incidence.

Interaction of Class II in Experimental Autoimmune Disease

Similar to RA, susceptibility to relapsing polychondritis (RP) is significantly associated with the presence of a class II molecule, HLA-DR4 (Zeuner et al, 1997). The presence of anti-CII-specific antibodies and cell-mediated immunity to cartilage antigens observed in patients with RP indicate that the autoimmune response to CII is important in the pathogenesis (Foidart et al., 1978). In addition to type II collagen, there is also evidence suggesting involvement of other collagens, type IX and type XI, in the pathogenesis of RP (Alsalameh et al, 1993).

When DQ8 and DQ6 mice are immunized with CII, DQ8 mice develop CIA without polychondritis, and DQ6 mice are resistant to both. Mice expressing both DQ6 and DQ8 molecules develop experimental polychondritis, exhibiting both polyarthritis and auricular chondritis (Bradley et al., 1998). In this model, the role of hybrid molecules was suggested in the development of chondritis. This would mean that an α chain of one and a β chain of the other HLA molecule would form a heterodimer that can present unique peptides, leading to pathogenesis. The postulated interaction of DQ6 and DQ8 in generating a hybrid molecule and disease association was strengthened by peptide mapping of type II collagen in double transgenic mice. DQ6α/DQ8β mice

responded to two unique peptides of human CII which did not produce T-cell response in either DQ6 or DQ8 mice (Krco et al., 1999). *In vivo* studies using a hybrid class II molecule in transgenic mice provided support for this hypothesis. However, auricular chondritis was seen in only 25% of the immunized animals and no other features associated with RP were observed. This suggested a role of other genes in disease initiation.

Nonobese diabetic (NOD) mice are prone to autoimmunity that involves multiple genes. DQ8.Aβ^o mice were generated on the NOD and B10 background to determine the role of other autoimmune genes. Transgenic mice expressing DQ8 on the NOD background, but lacking endogenous class II molecules, develop auricular chondritis and polyarthritis with high levels of anti-CIX and anti-CII antibodies following immunization with type II collagen (Taneja et al, 2003b). Conversely, CII-immunized B10.DQ8 mice do not develop auricular chondritis and make lower amounts of antibodies. Although CII is a putative autoantigen for both RP and RA, the cross-reactive response to other collagen types expressed in the outer ear, such as type IX, appears to differ in the two strains. NOD.DQ8 mice mounted a strong response to type IX collagen, while in B10.DQ8 mice no response was observed. This suggests that even though DQ8 can select autoreactive cells in the thymus, non-MHC genes or class I may also be important in susceptibility. However, since disease does not occur in MHC-negative littermates, HLA molecules constitute the major predisposing factor for autoimmunity. These studies suggest that interaction between two class II or class II and other genes can lead to presentation of peptides not seen by either allele individually.

PROTECTIVE ALLELE FOR ONE DISEASE CAN PREDISPOSE TO ANOTHER AUTOIMMUNE DISEASE

HLA-DR2 is associated with protection in RA while the strongest association in MS is with HLA-DR2 haplotypes, DRB1*1501, DRB5*0101, DQA1*0102, and DQB1*0602 (Hillert, 1994). Besides DR2, MS has also been associated with HLA-DR3 and DR4 (Marrosu et al., 1998) and the HLA DR3/DQ2 haplotypes have been shown to confer an increased risk for relapsing remitting MS. The lack of a complete association with a particular HLA allele suggests that MS is a heterogeneous disease at the molecular genetic level. MS is hypothesized (Steinman, 1996) to be mediated by autoreactive T cells against a variety of myelin antigens, including myelin basic protein (MBP), proteolipid protein (PLP), and myelin oligodendrocytic glycoprotein (MOG). Immunization of a susceptible strain of mice with autoantigens MBP, PLP or MOG, can lead to development of experimental autoimmune encephalomyelitis (EAE) (Ito et al., 1996; Mangalam et al., 2004; Rich et al., 2004). We and others have shown that HLA transgenic mice can develop EAE using different myelin antigens or by infecting susceptible mice with Theiler virus. DR3 transgenic mice lacking endogenous class II molecules when infected with Theiler virus showed a significantly decreased severity of demyelination, suggesting a DR3 association with benign relapsing MS (Drescher et al., 1998). EAE induction with recombinant MOG (rMOG) in DR2 mice (DRB1*1501, DRB1*1502, and DRB1*1503) showed that all three strains developed EAE; however, the disease incidence and severity was higher in DRB1*1501 transgenic mice. Almost all the T-cell epitopes, identified in HLA transgenic mice using overlapping peptides of MBP, PLP, and MOG, are similar to those identified among MS patients (Kawamura et al., 2000; Khare et al., 2003). Administration of PLP 91–110 peptide induced severe EAE in DR3-transgenic mice (Mangalam et al., 2004). However, disease induced by all the autoantigens in transgenic mice was characterized by paralysis of limbs with mild demyelination, whereas in humans demyelination is the major feature of MS. $CD4^+$ T cells have been shown to infiltrate the central nervous system (CNS) and appear responsible for inflammation and demyelination in MS. It is speculated that class II molecules on T cells may present myelin antigen in the CNS and exacerbate the disease (Authors, unpublished observations). To replicate the human disease, DR3.AE^o transgenic mice were immunized for EAE with PLP peptide. The brain and spinal cord pathology in DR3.AE^o transgenic mice was much more severe than in Aβ^o transgenic mice. The DR3.AE^o mice had severe inflammation and demyelination in the meningial, striatal, and brainstem regions, a hallmark for human MS. Using immunoflourescence staining, MHC class II expression was detected in the CNS, especially on microglial cells. Thus, these experiments suggest that new humanized HLA transgenic mice (AE^o) simulate the human expression of class II molecules and are a better model than Aβ^o mice to study the role of class II molecules in the induction of autoimmune disease.

Data from HLA transgenic mice suggest a role of haplotypes in disease expression. Most DR2/DQ8 double transgenic mice (90%) developed chronic progressive disease with severe inflammatory and demyelinating lesions after immunization with rMOG. DQB1*0601 is stated to be protective in MS (Amirzargar et al., 1998; Marrosu et al., 2001). Disease observed in DR2/DQB1*0601 mice was less frequent (30%) and milder. Neither DQB1*0601 nor DQ8 transgenic mice developed EAE after immunization with rMOG and findings were similar using whole myelin and human PLP peptide 91–110. Also, using whole myelin and PLP peptide 91–110, we have observed that the presence of 1) the HLA-DQ6 or DQ8 molecule alone is not sufficient

for disease induction; 2) disease-susceptible HLA-DR3 transgenic mice bearing HLA-DQ8 had an increased severity and incidence of disease; 3) DQ6 molecules had no effect on disease onset or severity; and 4) transgenic DQ6 or DQ8 molecules on a disease-resistant background had no effect on disease induction, since none of the HLA-DR2/DQ6, DR2/DQ8 or DR4/DQ8 double transgenic mice developed EAE. These data suggest that the presence of more than one susceptibility allele, namely HLA DR2/DQ8 or DR3/DQ8, likely resulted in additional selection and expansion of potential autoreactive T cells, leading to enhanced severity of disease in double transgenic mice. This study also pointed to MS being a heterogeneous disease and to HLA association being specific for various autoantigens that are presumably involved.

REQUIREMENT OF OTHER MOLECULES ALONG WITH MHC FOR AUTOIMMUNE DIABETES

NOD mice develop spontaneous diabetes, which has been linked to IAg7, the class II of the NOD strain. Even though DQ8 is similar in structure to IAg7 of the NOD mice (Wucherpfennig, 2003), DQ8 transgenic mice do not spontaneously develop diabetes as do NOD mice. However, DQ8 transgenic mice lose tolerance to self-GAD65 and potential autoreactive T cells are found in the periphery and pancreas, and cause insulitis but not progression to diabetes (Abraham et al., 1999). As with DQ8 transgenic mice, the presence of a predisposing type I diabetes MHC gene(s) in certain individuals could result in escape of autoreactive T cells against pancreatic antigens. The onset of the disease may require a second injury in the pancreas. This injury could come in the form of a virus/bacterial infection, and/or overproduction of a cytokine or overexpression of an accessory molecule or other genetically-determined variations in immune homeostasis. To simulate such an insult in the pancreas, the HLA-DQ8 (type I-predisposing) and the HLA-DQ6 (diabetes-protective) transgenic mice expressing the costimulatory molecule CD80 (B7.1) in islet β cells under the rat insulin promoter (RIP) were generated. HLA-DQ8/RIP/B7.1 mice developed spontaneous diabetes, while HLA-DQ6/RIP/B7.1 transgenic mice did not (Wen et al, 2000). These studies further confirmed that while HLA is the major predisposing gene in most if not all autoimmune diseases, the presence of the disease-associated HLA allele alone is insufficient for development of autoimmunity in diseased individuals. Further studies using double transgenic mice expressing both DR4 or DR3 and DQ8 suggested that DR4 and DR3 could regulate the diabetogenic effect of DQ8, which in turn suggests interactions between various MHC class II molecules are important in the disease process (Wen et al., 2001; Rajagopalan et al., 2003).

MOLECULAR BASIS FOR DQ ASSOCIATION

Studies using molecular biology and the crystal structure of HLA genes defining the peptide motifs have shown that DQ genes can be important in conferring susceptibility to or protection from diseases, including MG, MS, and T1D. DQ8 is associated with many autoimmune diseases like diabetes, RA, and celiac disease. The crystal structure of the HLA-DQ8 molecule shows that DQ8 differs from DR molecules in the peptide side chain binding pockets for P1, P4 and P9 (Lee et al., 2001). In DQ8, a very polar P1 peptide side chain pocket is observed; the P4 pocket is the largest pocket and differs from that of DR molecules in shape and size. While for DR molecules, P4 is a shallow pocket, the P4 pocket of DQ8 is very deep. The P4 pocket of DQ6, which is associated with protection from diabetes, is similar to DQ8, suggesting no correlation between P4 pocket and diabetes. The major difference in the protecting allele and susceptibility allele lies at residue 57 in the P9 pocket of the DQB1 molecules. The protective DQ7 and DQ6 alleles encode asparagine at position 57 while an alanine, valine or serine at this position characterizes predisposing alleles. Thus, in HLA-DQ8 molecules the presence of alanine at position 57 could interfere with the salt bridge formed between Asp57β and Arg76α, which could potentially make DQ8 a more open molecule and lead to an unstable peptide–MHC complex. This would put fewer constraints on the peptide binding to the DQ8 molecule (Wucherpfennig, 2003). However, a contribution from the P9 pocket of DQ and the P4 pocket of DR have been suggested in disease susceptibility and resistance to T1D (Cucca et al., 2001). Studies in humans and mice have shown that DQ8 is a promiscuous molecule and can bind many more peptides than the DQ6 and DR molecules (Matsushita et al., 1996; Krco et al., 1999; Stratmann et al,, 2000), making it a candidate molecule that can predispose to autoreactivity.

ROLE OF DQ AND DR IN AUTOIMMUNITY

The question arises as to why DQ8 can predispose to so many autoimmune diseases and DR is the regulatory molecule. The association of a particular HLA class II haplotype with disease seems to depend on geographic locations as well as the ethnic composition of the populations. Studies using transgenic mice suggest that DR2-restricted autoimmunity may be directed against MBP, MOG, and PLP, while DR3-restricted autoimmunity may be directed against PLP only. Further, DR2 and DR3 may present different epitopes of MOG and PLP. Evolutionarily, DQ is a stable molecule with less polymorphism than observed in DRB1 locus. The

DQ8 molecule has not undergone many changes evolutionarily and occurs with only three known subtypes. This could be because DQ8 has the advantage of being able to bind and present multiple peptides. On the other hand, DR has many subtypes. For example, DRB1*04 has at least 59 subtypes which differ by one to three amino acids at the peptide-binding groove. However, not all the subtypes are associated with susceptibility to autoimmune diseases. We speculate that DR4 polymorphism has increased to counteract the predisposition to autoimmunity imposed by the DQ8 molecule. Thus, multiple subtypes of DR4 lead to many possible DR4\DQ8 haplotypes. Only those with an advantage of presenting microbial antigens, and clearing infections, and with the capacity to counter the autoimmune responses, may eventually be selected. Thus, the variation in DR subtypes in the peptide-binding region can be important for disease pathogenesis and can be explained by the following proposals.

First, various subtypes of an MHC allele may generate a differential immune response, type 1 helper T cell (Th1) or Th2, after binding similar peptides. For example, some peptides can be bound by both DRB1*0401 and DRB1*0402 even though they differ in the HVR3 region by three peptides and overall charge. The presentation of similar peptides might generate a differential immune response, which would explain the association of DRB1*0401 with predisposition to develop RA and/or the protection provided by DRB1*0402.

Second, the DRB1 HVR3-derived peptides are presented by the DQ molecule that shapes the T-cell repertoire in the thymus; the DR subtypes that are associated with autoimmunity when presented lead to positive selection of an autoreactive TCR that can recognize a self-antigen in the periphery. An infection or any other insult to the immune system could result in exposure of that antigen to the immune system, leading to expansion of T cells.

CONCLUDING REMARKS

From various *in vivo* and *in vitro* studies, it has become clear that MHC and non-MHC genetic components are common elements for various autoimmune diseases and their corresponding animal models. Thus, polymorphism in MHC is an advantage for human survival, but autoimmunity is the price that must be paid for combating infection effectively and for survival. Evolutionarily, only those HLA genes that can generate strong immune responses to infections are selected. The constant mutations observed might be leading to the generation of new subtypes of an allele to circumvent autoimmunity. Haplotypes but not single class II alleles function in the selection of the T-cell repertoire and susceptibility to disease.

CHAPTER

21

Genetics and Autoimmunity: Non-MHC Genes

YARON TOMER

Division of Endocrinology, University of Cincinnati College of Medicine, Cincinnati, USA

Autoimmune diseases are complex diseases in which susceptibility genes and environmental triggers act in concert to initiate the autoimmune response. The paradigm that genetic susceptibility plays a central role in the development of autoimmune diseases is supported by solid epidemiologic data, including family and twin studies. As discussed in Chapters 3, 5 and 20, one of the major genes contributing to the genetic etiology of many autoimmune diseases is the major histocompatiblity complex (MHC) (HLA) gene complex, and in some diseases the HLA genes are believed to contribute most of the genetic susceptibility [e.g., in type 1 diabetes (T1D) (Pociot and McDermott, 2002)]. However, since in most autoimmune diseases the concordance rate for HLA identical siblings is significantly lower than the concordance rate for monozygotic (identical) twins (Stenszky et al., 1985), it is clear that other non-HLA genes must play a major role in the genetic etiology of autoimmune diseases. In this chapter we will focus on the contribution of non-MHC genes to the genetic susceptibility to autoimmune diseases.

FAMILIAL NATURE OF AUTOIMMUNE DISEASES

Family Studies

The first clue that a complex disease has a genetic etiology comes from the observation that the disease clusters in families. Many autoimmune diseases have been reported to show familial clustering. For example, in T1D, siblings and offspring of T1D patients have a much higher frequency of disease than the prevalence in the general population (Melton et al., 1983; Warram et al., 1984). Interestingly, offspring of T1D fathers are at much higher risk for T1D than are offspring of T1D mothers, suggesting that exposure to a diabetic environment in utero may have a protective effect on the offspring, perhaps by inducing immunologic tolerance (Warram et al., 1984; 1991). Similarly, familial clustering has been reported in systemic lupus erythematosus (SLE) (Tsao, 2003), rheumatoid arthritis (RA) (Gregersen,

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

2003), Graves' disease, Hashimoto's thyroiditis (Tomer and Davies, 2003), and multiple sclerosis (MS) (Hochberg, 1987), as well as other autoimmune conditions (Vyse and Todd, 1996). The frequency of autoantibodies is also commonly increased in relatives of patients with autoimmune diseases (Hall and Stanbury, 1967; Chopra et al., 1977; Carey et al., 1980; Tamai et al., 1980; 1986; Burek et al., 1982; Volpe, 1985).

Familial clustering of a disease does not necessarily mean that the disease is genetic. It can be the result of random chance, shared extrinsic (environmental) factors (Tomer and Davies, 1993), shared intrinsic (genetic) factors, or a combination of these. When nongenetic factors are the cause of familial clustering of a disease, the distribution of affected members in families would be random. However, when genetic predisposition is the cause of the familial occurrence of a disease, the distribution of affected members in families would follow a pattern consistent with genetic inheritance (Figure 21.1).

One way to test whether the familial clustering of a disease is consistent with genetic inheritance is by performing a segregation analysis. In this analysis many families in which the disease under study clusters are analyzed to see if the clustering occurs at random or demonstrates Mendelian or a complex pattern of inheritance. Segregation analyses have shown strong genetic influences in several autoimmune diseases, including SLE (Tsao et al., 2002), MS (Rigby et al., 1998; Seldin et al., 1999), RA (Sadovnick et al., 1993), Graves' disease (Villanueva et al., 2000), and thyroid antibody diathesis (Pauls et al., 1993; Phillips et al., 1990; 1991; Jaume et al., 1999).

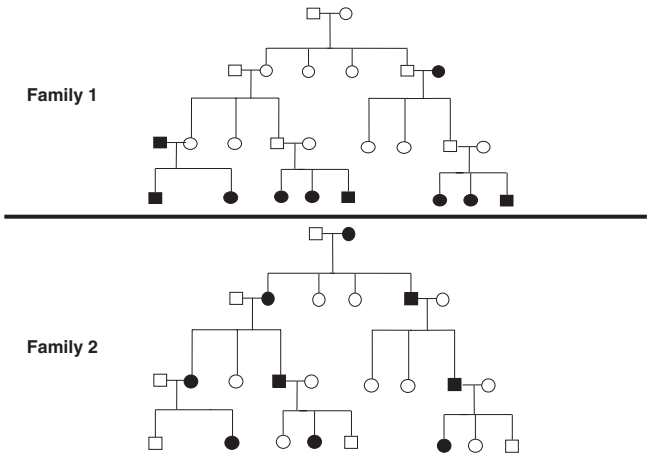

FIGURE 21.1 Clustering of a disease in families does not necessarily mean that the disease has a genetic etiology. Shown are two families in which diseases cluster. In family 1 the clustering is due to an environmental factor (e.g., viral gastroenteritis) and the clustering does not follow Mendelian inheritance. In family 2 the clustering is due to genetic inheritance of the disease and the vertical transmission suggests dominant inheritance (e.g., Huntington disease). In complex diseases, such as type 1 diabetes or systemic lupus erythematosus, the clustering of the disease in families is due to the combined effects of genetic and environmental influences, and therefore, the pedigrees usually do not conform to any of the "interpretable" patterns described above.

The clustering of autoimmune diseases in families is not restricted to a single disease in the same family. Clustering of several autoimmune diseases in the same family has been reported for many autoimmune diseases (Burek et al., 1990; Mumford et al., 1994; Vyse and Todd, 1996; McCanlies et al., 1998; Levin and Tomer, 2003; Tait et al., 2004). These findings are of major importance because they imply that certain genetic variants predispose to autoimmunity in general and are not disease specific. Indeed, an analysis of genetic studies in several autoimmune diseases has revealed overlapping non-MHC susceptibility loci among several autoimmune diseases (Becker et al., 1998).

Sibling Risk Ratio

A very useful method to test the genetic contribution to familial aggregation of a disease is to calculate the sibling risk ratio (λs). The λs is the ratio of the prevalence of the disease in siblings of affected individuals to the prevalence of the disease in the general population (Risch, 1990). The λs expresses the increased risk of developing the disease in an individual who has a sibling with the disease and is a quantitative measure of the genetic contribution to the disease. An λs of $\geqq 5$ usually indicates a significant genetic contribution to the pathogenesis of a disease (Vyse and Todd, 1996). The λs was estimated to be 5–20 in SLE (Hochberg, 1987; Tsao et al., 2002), 20 in MS (Risch, 1987), 17 in autoimmune thyroid disease (AITD) (Villanueva et al., 2003), 15 in T1D (Wagener et al., 1982), and 5 in RA (Rigby et al., 1998). These data support a strong genetic influence on the development of autoimmune diseases.

Twin Studies

Twin studies are the most powerful method for evaluating genetic predisposition to complex diseases. They are based on comparison of the concordance (simultaneous occurrence) of a given disease among monozygotic (MZ; i.e., "identical") twins with the concordance among dizygotic (DZ; i.e., fraternal) twins. MZ twins have nearly identical genetic makeup, whereas DZ twins share 50% of their genes (like siblings). Therefore, if the concordance is higher in the MZ twins when compared to the DZ twins, it suggests that the disease has an inherited component.

Several large twin studies have been reported in autoimmune diseases showing consistently higher concordance in MZ twins compared to DZ twins (Jarvinen and Aho, 1994) (Table 21.1). In RA the concordance rates for MZ and DZ twins have been estimated to be 12–15% and 2–4%, respectively (Seldin et al., 1999). In Graves' disease the concordance rates for MZ twins were higher (17–22%), with much

TABLE 21.1 Twin studies performed in autoimmune diseases

Disease	MZ twin concordance (%)	DZ twin concordance (%)	References
Rheumatoid arthritis	12–15	2–4	Seldin et al. (1999)

DZ, dizygotic; MZ, monozygotic.

lower concordance rates in DZ twins (2%) (Brix et al., 2001; Ringold et al., 2002). Similar concordance rates have been reported in MS: 25–30% in MZ twins compared to 0–5% in DZ twins (Ebers et al., 1986; Heltberg, 1987; Kinnunen et al., 1988; Sadovnick et al., 1993; Mumford et al., 1994). Even higher concordance rates were reported for SLE among MZ twins (25–57%) and among DZ twins were much lower (0–5%) (Block et al., 1975; Jarvinen et al., 1992; Grennan et al., 1997).

One of the difficulties in twins studies is that reports of concordance rates can vary significantly depending on the age of the proband and the follow-up time since proband diagnosis. For example, cross-sectional twin studies in T1D not taking into account proband age and length of follow-up have shown concordance rates of 35%–70% for MZ twins and approximately 10% for DZ twins (Kyvik et al., 1995). Examination of the length of follow-up since proband diagnosis has shown that the concordance rates were 43% within 12 years of proband diagnosis and 50% within 40 years, demonstrating that the concordance increases as the length of follow-up increases (Hawa et al., 1997). Age of proband diagnosis is also crucial. Diabetes risk approaches 65% for the co-twin of an MZ proband diagnosed before 5 years of age (Kyvik et al., 1995; Redondo et al., 2001). These data suggest that early-onset T1D may have a stronger genetic component that late-onset T1D.

Gender Effects

Most autoimmune diseases are more common in females than in males (see Chapters 3 and 25). The increased female preponderance of autoimmune diseases may be secondary to sex steroid effects or X chromosome effects. Some data suggest that estrogens promote induction of autoimmunity. Autoimmunity is most common in fertile women (Tunbridge et al., 1977), and animal studies show induction of susceptibility to autoimmunity in males by estrogens (Grossman et al., 1991; Paavonen, 1994; Van Griensven et al., 1997). Another possibility is that the increased female susceptibility to autoimmunity is related to the X chromosome. One possible mechanism whereby the X chromosome could influence the development of AITD is probabilistic: females are approximately twice as likely as males to inherit an autoimmunity susceptibility gene since they have two X chromosomes while males have one. Another mechanism is related to the phenomenon of X chromosome inactivation. Even though females have two X chromosomes, only one X chromosome gene is expressed in female somatic cells due to X chromosome inactivation. X chromosome inactivation occurs early in embryonic life and, thereafter, in each cell, either the maternal or paternal chromosome is inactivated. This results in a tissue mosaic of paternally and maternally expressed X chromosomal alleles. Therefore, a female who is heterozygous for an X-linked gene encoding for a self-antigen will have two classes of cells that differ in the transcription of this X chromosome-encoded gene. If these two cell classes extend to the thymic cells responsible for tolerizing T cells in embryonic life, some lymphocytes may not be tolerized to one of the two self-antigens encoded by the X-chromosome. Such lymphocytes would be autoreactive to that antigen and could induce an autoimmune response (Stewart, 1998). Several X chromosome loci have been shown to be linked with autoimmune disease (Barbesino et al., 1998; Imrie et al., 2001; Jawaheer et al., 2001; Zhou et al., 2003), but, so far, no X chromosome susceptibility gene for autoimmunity has been identified.

TOOLS USED TO MAP AND IDENTIFY COMPLEX DISEASE GENES

The two basic tools used for mapping complex disease genes are linkage and association studies. Linkage studies look for cosegregation of markers and disease in families. If a tested marker is close to a disease susceptibility gene, the likelihood that a recombination will occur between them during meiosis is low, and therefore, the marker's alleles will cosegregate with the disease in families (Figure 21.2). Association studies compare the frequency of marker disease alleles in patients and controls. In general, linkage studies are best for screening the whole genome for regions (loci) harboring disease susceptibility genes, while association studies are more powerful for fine mapping the genes in these loci. These tools have been successful in mapping new autoimmune disease genes, e.g., in T1D (Davies et al., 1994) and Crohn's disease (Hugot et al., 2001). While different strategies have been employed to identify complex disease genes, one popular approach is outlined below (Glazier et al., 2002). This strategy is based on five steps:

1. *Identifying linked loci*. This is achieved by whole genome screening using microsatellite markers at an average distance of <10 cM.
2. *Confirming linked loci*. A linked locus should be confirmed by finding evidence for linkage in two independent datasets (Lander and Kruglyak, 1995). Confirmed loci most likely harbor susceptibility genes, e.g., HLA in T1D (Davies et al., 1994).
3. *Fine mapping confirmed loci*. Linked loci can be fine mapped by linkage disequilibrium (LD) mapping. LD mapping is based on association studies with markers that saturate the region of interest. The marker that shows the strongest association with the disease is probably closest to the disease gene. This method can narrow down the region of interest to a few hundred kilobases (Ueda et al., 2003).
4. *Testing genes in the linked region*. After the linked region has been fine mapped the genes in this region can be analyzed. Sequencing of the genes in the fine-mapped loci will identify single nucleotide polymorphisms (SNPs) which are then tested for association with the disease. If a certain SNP shows a consistently significant association with the disease, it may be the susceptibility allele in the region, even though LD with another disease-causing polymorphism cannot be ruled out.
5. *Functional studies*. To demonstrate that an associated allele is a true susceptibility allele it is necessary to show that it affects the function of the gene in a way that increases the risk of developing disease. This provides indirect evidence that it may be the actual susceptibility allele for the disease.

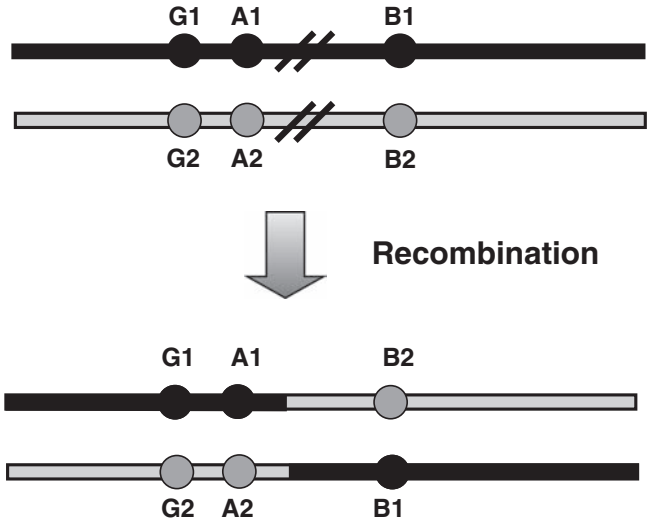

FIGURE 21.2 Principle of linkage. During meiosis, when homologous chromosomes pair, they often break at identical points along their length and switch the distal segments to the breaking point, exchanging identical segments of DNA between two homologous chromosomes (recombination). The principle of linkage analysis is based on the fact that if a marker (A) is close to a mutated gene (G) on a chromosome they will segregate together during recombination, while a marker (B) that is far from the mutated gene will not cosegregate with it. In the example shown, marker allele A1 of marker A is close to the mutated gene (G1) and allele B1 of marker B is far from the mutated gene (G1). Likewise, allele A2 of marker A is close to the normal allele of the gene (G2) and allele B2 of marker B is far from the normal allele of the gene (G2). After recombination, allele A1 cosegregates with the mutated gene (G1), while allele B1 does not. As a result, within a given family a certain allele of marker A (A2) will be seen more frequently than expected by random chance in the affected individuals (i.e., those inheriting the mutated allele of the gene). The closer the marker to the disease gene the stronger the linkage with the disease.

NON-MHC IMMUNE REGULATORY GENES PREDISPOSING TO AUTOIMMUNITY

Several non-MHC immune regulatory genes have been shown to be susceptibility genes for autoimmunity. As expected these genes are not specific for one autoimmune disease but predispose to several autoimmune conditions. However, some variability does exist with certain immune regulatory genes showing a much stronger association with some autoimmune conditions than with others. For example, the CTLA-4 (cytotoxic T-lymphocyte antigen-4) gene shows the strongest association with Graves' disease and a much weaker association with Hashimoto's disease and T1D (Ueda et al., 2003).

CTLA-4 Gene

CTLA-4 is an important costimulatory molecule that plays a key role in the interaction between T cells and antigen-presenting cells (APCs). APCs activate T cells by presenting to the T-cell receptor (TCR) an antigenic peptide bound to an HLA class II protein on the cell surface. However, a second signal is also required for T-cell activation, and these costimulatory signals may be provided by the APCs themselves or other local cells (Reiser and Stadecker, 1996). The costimulatory signals are provided by a variety of proteins that are expressed on the cell surface of APCs (e.g., CD80 (B7-1), CD86 (B7-2), B7h, and CD40) and interact with receptors (CD28, CTLA-4, and CD154 (CD40L)) on the surface of $CD4^+$ T lymphocytes during antigen presentation (Reiser and Stadecker, 1996). The complex interaction between APC proteins and T-cell proteins during antigen presentation is called the "immunologic synapse" (Figure 21.3). Whereas the binding of CD80 (B7) to CD28 on T cells costimulates T cell activation, CTLA-4, which has a higher affinity for CD80 (B7), downregulates T-cell activation by competing for the binding of CD80 (B7) to CD28, and by directly suppressing T-cell activation (Brunner et al., 1999). Indeed, CTLA-4 knock-out mice develop lymphoproliferative disease with multiorgan lymphocytic infiltration and tissue destruction, demonstrating the crucial inhibitory role for CTLA-4 in T-cell activation. The suppressive effects of CTLA-4 on T-cell activation have raised the possibility that mutations/polymorphisms causing reduced CTLA-4 expression and/or function could result in an exaggerated T-cell activation and lead to the development of autoimmunity.

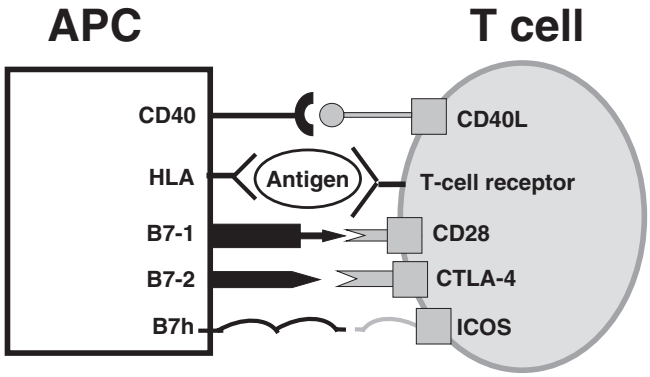

FIGURE 21.3 Immunologic synapse. The antigen-presenting cell (APC) presents a peptide antigen bound to HLA class II molecules, and the peptide is recognized by the T-cell receptor. Engagement of CD80 (B7) molecules with CD28 provides costimulation, while CTLA-4 binding to the CD80 (B7) molecules blocks CD28 activation and also directly suppresses T-cell activation. Engagement of the inducible costimulator (ICOS) with B7h provides additional costimulatory signals. In addition, engagement of CD40 with CD40 ligand activates the APC, and if the APC is a B cell, will result in B-cell proliferation, differentiation, and antibody secretion.

CTLA-4 Association Studies in Autoimmunity

Since the first description of an association between CTLA-4 and Graves' disease in 1995 (Yanagawa et al., 1995) CTLA-4 has been shown to be associated with many autoimmune conditions. This is not unexpected in view of the critical role of CTLA-4 in the immunologic synapse. CTLA-4 has been shown to be associated with both B-cell-mediated autoimmune diseases such as Graves' disease (Donner et al., 1997b) (see below) and T-cell mediated autoimmune diseases such as T1D (Marron et al., 1997) (see below). Additionally, CTLA-4 was shown to be associated with organ-specific autoimmune diseases, e.g., Graves' disease and MS (Donner et al., 1997b), and systemic autoimmune diseases (Ahmed et al., 2001). Thus, it seems that CTLA-4 is a general autoimmunity gene. However, the relative risk conferred by CTLA-4 is low (1.1–1.5) (Ueda et al., 2003), demonstrating that other genes must play a role in the development of autoimmunity, possibly by interactions with CTLA-4 (see below).

Initially, CTLA-4 was reported to be associated with Graves' disease (Yanagawa et al., 1995; Nistico et al., 1996; Donner et al., 1997b; Kotsa et al., 1997; Villanueva et al., 2000; Kouki et al., 2002; Nithiyananthan et al., 2002). The association between Graves' disease and the CTLA-4 3′ untranslated (3′UTR) microsatellite and A/G_{49} SNP has been consistent across populations of different ethnic backgrounds, such as white populations (Yanagawa et al., 1995), Japanese (Yanagawa et al., 1997; Akamizu et al., 2000), and Koreans (Park et al., 2000). Later studies demonstrated associations with Hashimoto thyroiditis, also in populations of diverse ethnic origins, such as white populations (Donner et al., 1997a; Kotsa et al., 1997; Nithiyananthan et al., 2002), and Japanese (Sale et al., 1997; Akamizu et al., 2000). Many other autoimmune diseases have also been shown to be associated with CTLA-4, most notably T1D (Nistico et al., 1996; Marron et al., 1997; Donner et al., 1997b), Addison disease (Vaidya et al., 2000a; Blomhoff et al., 2004), myasthenia gravis (Huang et al., 1998), SLE (Ahmed et al., 2001), MS (Ligers et al., 2001), and primary biliary cirrhosis (Agarwal et al., 2000). Taken together these data strongly support CTLA-4 as a general autoimmunity susceptibility gene (Kristiansen et al., 2000).

CTLA-4 and Antibody Production

Since CTLA-4 does not show disease specificity, it is likely that it is a general autoimmunity gene. To test this hypothesis we tested for linkage of the CTLA-4 locus with the presence of thyroid antibodies (TAbs) without clinical disease. Indeed, we have shown strong evidence for linkage between the CTLA-4 gene region and the production of thyroid antibodies with a maximum LOD score (MLS) of 4.2 (Tomer et al., 2001). Further studies have

confirmed these results (Ban et al., 2003a; Zaletel et al., 2002).

Which CTLA-4 Polymorphism is the Causative One?

The fact that polymorphisms within or near the CTLA-4 gene showed linkage (Vaidya et al., 1999; Tomer et al., 2001) and association (Nistico et al., 1996) with autoimmunity does not necessarily mean that the CTLA-4 is the susceptibility gene in this locus. It is possible that another gene close by in linkage disequilibrium with CTLA-4 is the susceptibility gene in this region. Indeed, the region on chromosome 2q33 containing the CTLA-4 gene is replete with candidate immune regulatory genes for thyroid autoimmunity [e.g., CD28 and inducible costimulator (ICOS)], and it was first unclear whether the CTLA-4 gene itself or another immune regulatory gene in the region was involved in the genetic susceptibility to autoimmunity. Therefore, we (Ban et al., 2003a) and others (Marron et al., 2000; Wood et al., 2002; Ueda et al., 2003) fine mapped the region and have shown that the strongest association was with the CTLA-4 gene, suggesting that it was the susceptibility gene in this locus. That still left the question of which CTLA-4 polymorphism is the causative one. A recent large fine mapping study using over 100 markers in the CTLA-4 region demonstrated that the causative polymorphism is located in the 3′ UTR of the CTLA-4 gene (Ueda et al., 2003). However, several candidate polymorphisms in this 5-kb region still exist, including a microsatellite marker and several SNPs (Ueda et al., 2003), and additional functional studies are needed to identify which of these polymorphism is the causative one (see below).

CD40 Gene

Using a whole genome linkage study we have identified a locus on chromosome 20q11 showing strong evidence for linkage with Graves' disease with a maximum LOD score of 3.5 (Tomer et al., 1998; 1999; 2003). This Graves' disease locus was not linked and associated with Hashimoto's thyroiditis and MS, suggesting that this may be a locus that is specific for Graves' disease. Moreover, in families with individuals with Graves' disease or Hashimoto's thyroiditis, the locus was linked only with Graves' disease, demonstrating its high specificity for Graves' disease (Tomer et al., 1999). This region was also tested by another group from the UK and evidence was reported for linkage with Graves' disease in a subset of their families (Pearce et al., 1999). This further supported the 20q11 locus as an important susceptibility locus for Graves' disease.

The CD40 gene, an important immune modulator, is located within the linked region on chromosome 20q11 and, therefore, it was a likely positional candidate gene for Graves' disease. CD40 is a transmembrane glycoprotein that is expressed predominantly on B cells, monocytes, dendritic cells (DCs), epithelial cells, and other cells (Durie et al., 1994). Binding of CD154 (CD40L) to CD40 induces B cells to proliferate and to undergo immunoglobulin isotype switching (Banchereau et al., 1994). Moreover, *in vivo* blockade of CD40 has been shown to suppress the induction of experimental autoimmune diseases (Carayanniotis et al., 1997; Schaub et al., 1999; Burkly, 2001; Homann et al., 2002). Therefore, we tested whether CD40 could be the Graves' disease susceptibility gene on chromosome 20q11. Sequencing of the CD40 gene revealed a C/T SNP in the 5′UTR region of the gene. The SNP is located within a segment of the 5′UTR that controls the initiation of translation and is designated the Kozak sequence. Analysis of the CD40 Kozak SNP showed an association between the CC genotype and Graves' disease, but with a low relative risk of 1.6 (Tomer et al., 2002a). These results were confirmed by other studies (Kim et al., 2003; Tomer et al., 2005), but not by all studies (Houston et al., 2004). Since the Kozak sequence influences the initiation of translation, we hypothesized that the Kozak SNP might alter CD40 translation, thereby influencing its expression. Expression studies confirmed this hypothesis (see below).

Protein Tyrosine Phosphatase Gene

The protein tyrosine phosphatase (PTPN22) gene is the latest autoimmunity gene to be identified. Several recent studies have shown that PTPN22 is associated with RA (Begovich et al., 2004), SLE (Kyogoku et al., 2004), T1D (Bottini et al., 2004; Smyth et al., 2004), and Graves' disease (Velaga et al., 2004). Thus, like CTLA-4, PTPN22 seems to be a general autoimmunity gene that predisposes to both B- and T-cell-mediated autoimmune diseases. PTPN22 is an important regulator of TCR signaling in memory and effector T cells (Hasegawa et al., 2004). The mouse ortholog (PEP) was shown to be a potent inhibitor of TCR-dependent responses, albeit PEP knock-out mice have a very subtle change in T-cell function. Therefore, additional studies are needed to elucidate the role of PTPN22 in autoimmunity.

Similar to CTLA-4 the relative risk conferred by PTPN22 is relatively low (approximately 2). Therefore, it seems that other autoimmunity genes must play a role in the development of autoimmunity, and it is likely that many genes with small effects (like CTLA-4 and PTPN22) cause predisposition to autoimmunity, and not one or a few major genes.

TISSUE-SPECIFIC GENES IN AUTOIMMUNE DISEASES

While immune regulatory genes may play an important role in the general susceptibility to autoimmunity, it is likely that disease-specific non-immune regulatory genes

contribute to the etiology of specific autoimmune conditions. These disease-specific genes are likely to be expressed in the tissues affected by the autoimmune response in organ-specific autoimmune diseases. Indeed, at least three tissue-specific genes have been identified to date: the insulin variable number of tandem repeats (VNTR) polymorphism in T1D, the NOD2 gene in Crohn's disease, and the thyroglobulin gene in AITD.

Insulin VNTR Polymorphism in Type 1 Diabetes

The first locus, outside the HLA region, which was found to be consistently linked and associated with T1D was the insulin gene region on chromosome 11q, designated insulin-dependent diabetes mellitus (IDDM)-2 (Davies et al., 1994; Hashimoto et al., 1994). This locus conferred a risk that was independent of HLA genotype (Bell et al., 1984; Bain et al., 1992; Lucassen et al., 1993; Van der Auwera et al., 1993; Hashimoto et al., 1994). This locus was estimated to contribute about 10% to disease susceptibility (Davies et al., 1994). It is now known that the polymorphism conferring the susceptibility to IDDM in this locus is the VNTR polymorphism (Undlien et al., 1995). The VNTR is located 365 base pairs upstream from the initiation of transcription of the insulin gene. The polymorphism arises from a variable number of 14 base pair oligonucleotide repeats. Based on the number of repeats, the length of the VNTR can be divided into three classes: class I (approximately 570 bp), class II (approximately 1640 bp), and class III (approximately 2400 bp) (Lucassen et al., 1993; Ahmed et al., 1999). Homozygosity for short class I alleles confers a two- to five-fold increased risk for T1D , while class III alleles are dominantly protective (Nistico et al., 1996; Bennett et al., 1995).

NOD2/CARD15 Gene and Crohn's Disease

The first whole genome scan demonstrating that a locus on chromosome 16q showed strong evidence for linkage with Crohn's disease was reported in 1996 (Hugot et al., 1996). This locus was designated IBD1 and the linkage evidence at IBD1 was replicated by several studies, most notably by an International Genetics Consortium showing a LOD score of 5.8 at IBD1 (Cavanaugh, 2001). Following the mapping of the IBD1 locus, the region was fine mapped and a novel gene, nucleotide-binding oligomerization domain 2 (NOD2), also called caspase activation recruitment domain 15 (CARD15), was identified to within this locus and was shown to be the susceptibility gene at the IBD1 locus (Hugot et al., 2001; Ogura et al., 2001).

NOD2 Polymorphisms Associated with Crohn's Disease

Several polymorphisms were identified within the coding region of the NOD2 gene that showed strong association with Crohn's disease but not with ulcerative colitis (Hugot et al., 2001). The three most important NOD2 polymorphisms that were found to be associated with Crohn's disease are two missense SNPs (i.e., SNPs that change the amino acid sequence of the gene), Arg702Trp and Gly907Arg, and one frameshift mutation (3040insC) causing a premature stop codon (Hugot et al., 2001). The relative risk of developing Crohn's disease in an individual with these polymorphisms ranges from 3 for simple heterozygotes to 38 in homozygotes for the susceptibility allele (Hugot et al., 2001). Therefore, there seems to be a gene dosage effect (McGovern et al., 2001).

Genotype–Phenotype Correlations

The NOD2 SNPs identified to date were found to be associated with Crohn's disease only in white patients but not in Asian (Inoue et al., 2002) or African American patients (Cho, 2004). In addition, the Cly908Arg SNP was found to be more common in Ashkenazi Jewish patients (Sugimura et al., 2003), and a new intronic variant (IVS+158, designated JW1) was reported to be specific for Ashkenazi Jewish Crohn's disease patients (Sugimura et al., 2003). Additional correlations were found with earlier age of onset and ileal disease (Cho, 2004).

NOD2 Function and the Effects of the NOD2 Single Nucleotide Polymorphisms

The NOD2 gene is expressed in peripheral blood monocytes, macrophages, and intestinal epithelial cells (Cho, 2004). NOD2 has three domains: a C-terminal leucine-rich repeat (LRR) domain, a nucleotide oligomerization domain, and an N-terminal region that contains the CARD. The CARD mediates activation of the NF-κB transcription factors, which is a master regulator of inflammatory responses (Watanabe et al., 2004). The C-terminal region of NOD2 contains an LRR that serves as a pattern-recognition receptor for many innate signals such as lipopolysaccharide (Watanabe et al., 2004). Therefore, the LRR domain might be involved in the recognition of microbial products (O'Neill, 2004). Interestingly, the three major SNPs in NOD2 that are associated with Crohn's disease are located in the LRR region of the gene (Cho, 2004). Originally, it was thought that the NOD2 polymorphisms in the LRR domain caused a decreased functional response of NOD2, leading to decreased NF-κB activation (Ogura et al., 2001). However, this model was inconsistent with data pointing to a crucial role for NF-κB activation in the activation of type 1 helper T (Th1) cells and the inflammatory response in Crohn's disease (O'Neill, 2004). Recent data may help

resolve this inconsistency by demonstrating that NOD2 inhibits the activation of the Toll-like receptor 2 (TLR2) by peptidoglycan, and that NOD2 deficiency resulted in increased TLR2-mediated activation of NF-κB (Watanabe et al., 2004). Thus, NOD2 SNPs may predispose to Crohn's disease by decreasing NOD2 activity, which leads to increased TLR2-mediated NF-κB activation and enhanced Th1 inflammatory responses (Watanabe et al., 2004).

Thyroglobulin Gene and Susceptibility to Autoimmune Thyroid Disease

Thyroglobulin (Tg) is the major protein product synthesized in the thyroid gland (Tomer, 1997). There is abundant evidence that Tg plays an important role in the etiology of AITD including: 1) anti-Tg antibodies are detected in most patients with AITD, both Graves' disease and Hashimoto's thyroiditis (Roitt et al., 1958; Ericsson et al., 1985), and there is evidence that Tg antibodies of AITD patients are restricted in their epitope specificity, in contrast to the polyclonal nature of Tg antibodies found in healthy individuals (Kuppers et al., 1992); 2) immunization with Tg induces autoimmune thyroiditis in experimental animals (Vladutiu and Rose, 1971); and 3) spontaneous models of autoimmune thyroiditis in the nonobese diabetic (NOD) mouse and BB/W rat are also characterized by the development of anti-Tg antibodies (Allen et al., 1987; Braley-Mullen et al., 1999). Therefore, Tg is a good candidate gene for thyroid autoimmunity.

Two whole genome screens have shown strong evidence for linkage of AITD with the chromosome 8q24 region which contains the Tg gene (Sakai et al., 2001; Tomer et al., 2002b) (see below). Since the Tg gene was located within the linked region, we proceeded to analyze the Tg gene directly. Analysis of microsatellite markers within intronic regions of the Tg gene gave a significant LOD score of 2.9, confirming that the Tg gene was linked with AITD (Tomer et al., 2002b). Association studies showed an association of Tg microsatellite markers with AITD (Tomer et al., 2002b; Collins et al., 2003; Ban et al., 2004).

The fact that markers within the Tg gene were linked and associated with AITD strongly suggested that the Tg gene was the AITD susceptibility gene on 8q24. Therefore, we sequenced the Tg gene and identified 14 new Tg SNPs. Case–control association studies demonstrated that one SNP cluster in exons 10–12, in strong linkage disequilibrium, and a SNP in exon 33 were significantly associated with AITD (Ban et al., 2003b). Taken together these data suggest that Tg is a major AITD susceptibility gene (Ban et al., 2003b). It can be hypothesized that Tg sequence variants are involved in the susceptibility to AITD; such variants may act by modifying the interaction of Tg peptide profiles, produced by digestion of Tg by cathepsins in endosomes, with HLA class II molecules.

WHOLE GENOME SCREENING IN AUTOIMMUNE DISEASES

As discussed above, whole genome screening is a powerful genetic tool with which to identify loci or genetic regions that might be linked with disease. When a locus which is linked with disease is identified, the region can be fine mapped and the gene identified. This strategy has been used successfully in a number of complex diseases, most notably in the mapping and identification of NOD2 as a susceptibility gene for Crohn's disease (Hugot et al., 2001; Ogura et al., 2001). Numerous genome screens have been performed in autoimmune diseases, resulting in a growing list of loci which might harbor susceptibility genes for autoimmunity.

Genome scans in SLE families identified several loci showing evidence for linkage. Most notable are loci on chromosomes 1q23, 1q41, 2q35, 4p16, and 6p11 (Tsao, 2003). Similarly, loci on chromosomes 1q, 2q, 6p, 9q, 16q, and 18p were identified for MS (Kenealy et al., 2004), loci on chromosomes 1p and 18q were identified for RA (Gregersen, 2003), and loci on chromosomes 2q, 6q, 10q, 12q 14q, and 20q were identified for AITD (Tomer and Davies, 2003; Tomer et al., 2003). Interestingly, significant overlap exists between loci identified for different autoimmune diseases (Becker et al., 1998), suggesting the existence of a significant number of susceptibility genes that predispose to autoimmunity in general and not to any specific autoimmune disease. One locus that was found to be linked with several autoimmune diseases is the 18q locus. The 18q locus was originally identified as a T1D locus but it was later found to be linked with Graves' disease (Vaidya et al., 2000b), as well as MS and RA (Merriman et al., 2001). However, additional studies are necessary to examine whether the 18q locus contains an autoimmunity susceptibility gene. In summary, linkage studies serve as the first step in gene identification. As more linkage studies are being performed it will be possible to examine which loci show the highest level of replication between different centers. These loci represent the best candidates for fine mapping and gene identification.

MECHANISMS BY WHICH GENES CAN INDUCE THYROID AUTOIMMUNITY

General Principles

In classical monogenic diseases the genetic defect changes the action of a gene by decreasing its effectiveness, e.g., the Pendrin gene in Pendred syndrome (Everett et al., 1997), or causing its overactivity, e.g. the RET proto-oncogene in multiple endocrine neoplasia type 2 (Eng, 1996;

Puxeddu and Fagin, 2001). However, in complex diseases, such as the autoimmune diseases, the genetic defect may cause subtle changes in the function of one or more genes that, when combined, increase the risk for disease. Therefore, even when a gene causing a common disease is mapped, proving that the polymorphism is also biologically meaningful can be difficult. Direct and indirect functional studies have been performed for several autoimmunity susceptibility genes, and some of these are summarized below.

CTLA-4 Functional Studies

CTLA-4 gene polymorphisms have been studied extensively for their effects on CTLA-4 function and/or expression. CTLA-4 is an important costimulatory molecule that downregulates T-cell activation and induces tolerance (see Figure 21.3). The suppressive effects of CTLA-4 on T-cell activation have raised the possibility that the CTLA-4 polymorphisms associated with AITD decrease its expression and/or function, thereby promoting the development of autoimmunity.

Several CTLA-4 polymorphisms have been shown to be associated with AITD, including a 3′UTR AT microsatellite (Yanagawa et al., 1995), a 3′UTR SNP (designated CT60) (Ueda et al., 2003), and an A/G polymorphism in the leader sequence of the gene (Donner et al., 1997b). These three polymorphisms have been tested in both direct and indirect functional studies for their effects on the function/expression of CTLA-4. The first functional study examined the effects of the A and G alleles of the CTLA-4 A/G_{49} SNP on the inhibitory function of CTLA-4 (Kouki et al., 2000). The authors showed that blocking of CTLA-4 on T cells isolated from individuals with the G allele had less effect on reducing the inhibitory function of CTLA-4 than blocking CTLA-4 on T cells isolated from individuals with the A allele. Similar results were obtained by our group using a slightly different study design (Ban et al., 2003a). This could imply that the A and G alleles of the CTLA-4 leader sequence influence its function and/or expression. However, since this was an indirect study it cannot rule out that another CTLA-4 polymorphism in linkage disequilibrium with the A/G_{49} SNP is causing this observed effect on CTLA-4 function. We have examined the effects of the CTLA-4 A/G_{49} SNP using an *in vitro* assay by transfecting T-cell lines lacking CTLA-4 with CTLA-4 cDNA having the A or the G allele: no difference was seen in the expression and inhibitory function of CTLA-4 (Xu et al., 2002). Thus, this study demonstrated that the A and G alleles of the CTLA-4 A/G_{49} SNP did not directly influence its function. Other polymorphisms must be responsible for the association of CTLA-4 with AITD. The CT60 3′UTR SNP was also tested by indirect functional studies for its effects on the levels of a splice variant of CTLA-4. The results demonstrated that the G allele of the CT60 SNP allele that predisposes to autoimmunity was associated with reduced production of a splice variant of CTLA-4, resulting in decreased soluble CTLA-4 levels (Ueda et al., 2003). Studies of the 3′UTR AT microsatellite have demonstrated that the long repeats (which predispose to autoimmunity) reduced inhibitory function of CTLA-4 (Takara et al., 2003). Moreover, preliminary data in myasthenia gravis showed that the long repeats of the AT microsatellite at the 3′UTR of the CTLA-4 gene decreased the half life of the CTLA-4 mRNA (Huang et al., 2000; Holopainen and Partanen, 2001). This could provide an attractive explanation for the association between the long repeats of the 3′UTR AT microsatellite and autoimmunity, whereby the long repeats decrease the half life of the CTLA-4 mRNA, causing reduced CTLA-4 expression and hyperactivation of T cells, and leading to autoimmunity (Tomer, 2001).

Insulin VNTR Gene

The insulin VNTR gene is located adjacent to regulatory DNA sequences affecting insulin gene expression. Therefore, it was postulated that the polymorphism influenced disease disposition through influence on insulin gene expression (Docherty, 1992). Indeed, the insulin VNTR was shown to influence gene expression *in vitro* (Kennedy et al., 1995) and *in vivo* (Bennett et al., 1995), with class I alleles being associated with 1.5–3.0-fold increase in insulin gene transcription in the pancreas. However, it was difficult to reconcile lower insulin mRNA levels in the pancreas, associated with class III alleles, with a protective effect on T1D development. Several groups have since reported that class III VNTR alleles are associated with significantly higher insulin mRNA levels in the human fetal thymus (Vafiadis et al., 1997; Puglise et al., 1997). These authors postulated that higher levels of thymic insulin expression in individuals with class III alleles promoted the negative selection of insulin-specific T lymphocytes, thus facilitating immune tolerance induction and protection from T1D. These findings, if confirmed, may represent a general principle in autoimmunity and may apply to other autoimmune conditions.

CONCLUSIONS AND FUTURE DIRECTIONS

The autoimmune diseases are complex diseases believed to be caused by the combined effects of multiple susceptibility genes and environmental triggers. There are sufficient epidemiologic data to support an important genetic contribution to the development of autoimmunity, and in the past few years several loci and genes have shown evidence for linkage and/or association with autoimmune diseases. Thus, the genetic susceptibility to autoimmunity seems to involve

several genes with varying effects. With the completion of the human genome project and the establishment of large SNP databases, the identification of additional non-MHC autoimmunity susceptibility genes will become more feasible.

The autoimmunity loci identified so far show that some putative autoimmune susceptibility genes may be immune-modifying genes that increase the susceptibility to autoimmunity in general (e.g., CTLA-4 and PTPN22), while others may be specific to a certain disease (e.g., insulin VNTR). The next step in investigating the role of these genes in the development of autoimmunity is by functional studies and genotype–phenotype correlations. It is most likely that the susceptibility loci for autoimmune diseases interact and that their interactions may influence disease phenotype and severity (Tomer et al., 1999). The molecular basis for the interactions between susceptibility genes in complex diseases is unknown. These interactions could represent the cumulative effect of increased statistical risk, or alternatively, there may be molecular interactions between the susceptibility genes or their products, which ultimately determine disease phenotype. Another unresolved question is how environmental factors interact with susceptibility genes to modify the risk for disease, as well as the disease phenotype. We are slowly progressing towards identification of the autoimmunity susceptibility genes and once they are identified we will begin to understand the underlying molecular mechanisms by which they induce systemic and organ-specific autoimmunity.

CHAPTER

22

Infections, Immunity, and Autoimmunity

ROLF M. ZINKERNAGEL AND HANS HENGARTNER
Institute of Experimental Immunology, University Hospital, Zurich, Switzerland

In this chapter we review the evidence that some autoimmune diseases are triggered by infections. While infection may not explain the complete pathophysiology of autoimmunity, it could be important in a fair proportion of autoimmune diseases, and therefore, have a great impact on our thinking about prevention and treatment.

Long-term epidemiologic studies are essential to establish the role of infection in autoimmunity. While such studies will take many years to produce results, collections of sera or epidemiologic data, assembled for other reasons, may be usable for such analyses of causes of autoimmunity. We postulate that the encounter between infectious agents and maternal antibodies acquired systematically via the placenta or via milk in the gastrointestinal tract is of major importance in setting the overall host–infection balance for later in life. Therefore, changing hygiene practices, vaccinations, and other epidemiologic parameters may be useful in reversing the increasing predisposition to autoimmune diseases in the developed and developing world.

There is no doubt that the immune system functions to protect the species from infection (Mims, 1987). The specific, adaptive immune system is essentially complemented by a wide range of innate resistance mechanisms, which are probably responsible for greater than 95% of the general resistance against infections. While we usually identify the adaptive immune system with protection against cytopathic acute infections, there is a cost to the system biology of the immune system—as is always the case in biology—in the form of rare immunopathology and even rarer autoimmune disease. The beneficial aspects and strength of the system provide 50–95% protection, but the cost for effective immunity against infectious diseases, such as polio or measles, is that immunity against noncytopathic agents may sometimes produce more immunopathology than immunoprotection (Zinkernagel, 1997). Nevertheless, in the present coevolutionary equilibrium, this cost represents a small price compared to the overall benefit. Similarly, autoimmunity by autoantibodies or autoreactive T cells is part of the cost of the specific reactivity patterns of the immune system to react quickly and efficiently against acute cytopathic agents or toxins. Responses are optimal but not maximal; otherwise coevolutionary selection would not continue, since a genetically fixed system will always be selected against. Thus, immune protection by antibodies or T cells is essential for the survival of the species and immunopathology represents the cost of this. Immunopathology is most easily seen during immune responses of immunocompetent hosts against noncytopathic and persistent infectious agents. If we do not recognize these responses, or do not know about an infection, they eventually (in 1–20 years) cause an immunopathologic disease, often called an "autoimmune" disease (Zinkernagel,

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

1997). Of course, it is impossible to generalize to all autoimmune diseases but, if only a certain percentage of autoimmune diseases could be related to or even clearly associated with infections, then prevention by avoidance or vaccination, or early treatment of infection could at least be envisaged.

While such etiopathophysiology of autoimmunity has been envisaged for many years, concrete examples and results have been slow in coming. But then who would have thought 30 years ago that gastric ulcers are not caused by stress but usually by infection? Or who would have predicted that some neurologic and psychiatric diseases are associated with viral or bacterial infection, such as Borna disease virus or *Borrelia burgdorferi*. While occult infection explains only a few cases of autoimmunity today, many more may be so explained tomorrow.

IMPORTANT PARAMETERS OF THE IMMUNE SYSTEM

Role of Antigen Dose, Time Kinetics, and Distribution

T cells react against antigens that enter and remain in initially few of the secondary lymphoid organs for 3–10 days. T cells ignore antigens that stay strictly outside of secondary lymphatic organs. For example, papilloma virus infections in skin or some peripheral solid tumors are ignored by T cells as long as relevant antigens do not reach draining lymph nodes or spleen. If antigens, infectious or self-antigens, were always expressed in lymphoid organs and if all T cells were then induced either very early in the thymus or later in lymphatic organs, then all T cells would eventually be deleted or exhausted [reviewed by Zinkernagel (1997; 2002b)]. If antigen remains systemically available, new precursor T cells will be deleted immediately and nonreactivity against such antigens will be maintained. T cells engage in specific reactivity that, together with nonspecific resistance mechanisms, including complement, cytokines, and chemokines, will help to rid the host of infections. Antibody responses are called T-independent if the antigen can trigger B cells directly, e.g., by cross-linking surface receptors that are usually repetitive and identical on infectious agents, or alternatively, when antigen is associated with lipopolysacharides (LPS) or other Toll-like receptor (TLR) ligands (reviewed by [Pitha, 2004]).

Immune responses are regulated by various positive and negative regulation mechanisms. These mechanisms are, however, largely unclear and the word ‘regulation’ alone does not solve this problem. On the other hand, there is little argument that antigen itself, including its time of presence and its localization, is a key regulator of the immune response (Zinkernagel, 1997). If antigen is everywhere, including in all lymphatic organs, then no immune response usually ensues. If antigen is strictly extralymphatic, it is ignored. If antigen is temporarily within the lymphatic system, it usually triggers an immune response and will eventually be eliminated. This perhaps oversimplified view can be illustrated with mice that lack the spleen, or all secondary lymphatic organs except the spleen, or have neither spleen nor any secondary lymph nodes or Peyer patches (Zinkernagel, 1997; 2002b). In the absence of draining lymph nodes a subcutaneous infection with a noncytopathic virus renders the host a carrier within a few days. Even though the splenic response may be triggered initially, it will quickly collapse due to the generalized abundance of antigen. The absence of a spleen renders the host more susceptible to generalized infections with encapsulated bacteria. However, because the usual entry point of infections is via skin or mucosa, the initial trigger of the immune response is in the draining lymph nodes or Peyer patches, so that an asplenic host can do well immunologically.

Specificity of Humoral and Cell-Mediated Immunity

Classically T-cell-independent IgM is pentameric and short-lived (1 day), and therefore provides early and immediate protection. Because of its short half-life, IgM is usually nonpathogenic as an autoantibody. In contrast, a switch of T-cell responses to long-lived IgG (half life 7–21 days) usually requires T-cell help, at least initially. As IgG has a considerably longer half life, it provides longer protection against infections, and can be transferred from mother to offspring by Fc receptors in the placenta, or in some species via the gastrointestinal tract. A disadvantage, however, is that the long-lived IgG autoantibodies may cause disease. Therefore, a switch to IgG autoantibodies is efficiently prevented by the usual absence of autoreactive helper T cells.

Specificity of antibodies or T cells is best defined by the discriminatory capacity of the immune response against infections. Neutralizing antibodies that protect against polio virus serotype I will not protect against infections with polio virus II, and vice versa. Similarly cytotoxic T cells (CTLs) specific for hepatitis C virus (HCV) will not protect against hepatitis B virus (HBV) infections and vice versa. It is noteworthy that, in general, antibody or T-cell specificities are imnmunologically defined by either enzyme-linked immunosorbent assays (ELISAs) or T-cell proliferation assays, but not by protection. While these parameters usually correlate well with protection, often they do not.

Antibody specificities defined by ELISAs or coprecipitation assays detect lower avidity antibodies (10^{-5} to perhaps 10^{-7} M). In contrast, protective neutralizing antiviral antibodies require binding affinities of the order of 10^{-8}–10^{-10} M

to be effective. Unfortunately, for most other biologic activities of antibodies, e.g., those involved in autoimmune disease or in immune complex disease or other immunopathologies, these parameters are often unknown.

We have little knowledge about the binding qualities of the T-cell receptor. The peptide specificity of T cells is usually tested at 10^{-6}M, but probably is closer to 10^{-9}–10^{-10}M under physiologic conditions. These parameters have been much less well determined, if at all, for T-cell reactivity with bacterial toxins or parasitic antigens, such as those of the malaria parasite. The various immunoglobulin classes are distinctly regulated. As stated, IgM and IgG are essentially controlling systemically distributed antigens, whereas local mucosal IgA controls commensal flora and local IgE controls ecto-parasitic infections. While the rules of T-cell help for the IgM to IgG switch have been well analyzed, its conditions and parameters are much less clear for IgA or IgE responses.

Immunologic Memory

Immunologic memory has been reviewed repeatedly in the past 10 years (Mackay, 1993; Sprent, 1993; Ahmed and Gray, 1996; Zinkernagel, 2002a) and discussed over the past 100 years. It is defined in textbooks as earlier and higher responses in hosts that have had contact with the same antigen earlier in life. The important question is whether this quality actually corresponds to protection against disease after reinfection? While most immunologists would answer positively, the details of this question are largely unexplored. In fact, all contemporary vaccines that provide excellent protection are vaccines that induce neutralizing antibody responses, whereas all the vaccines that we do not possess yet will need to induce strong and lasting T-cell-mediated immunity. A major and important reason for this discrepancy is that, for coevolutionary reason, only antibodies can be transferred from mother to immunoincompetent newborns, whereas T cells cannot. Because of paternal major histocompatiblity complex (MHC) incompatibilities, a fetus is always a foreign graft within the mother; it is not rejected because of MHC-negative barriers and the immunoincompetence of the offspring. The adoptively acquired maternal antibodies against all relevant infections are therefore essential to help the offspring survive long enough for its own immune system to mature. Experiments with calves deprived of colostral milk, and with mutant mice that lack all antibodies, have clearly shown that without adoptively transferred maternal antibodies the newborn is highly susceptible to many infections (Brambell, 1970). In contrast, under the umbrella of maternal antibodies, any infection encountered by the infant within the first few weeks of life and even up to 1–2 years, will be attenuated by maternal protective antibodies; this process means that these infections simulate a vaccine (Zinkernagel, 2001) by naturally attenuating the infection which can then activate the immune system to produce a protective state.

T-CELL IMMUNOPATHOLOGY: AUTOIMMUNITY

It is remarkable how inert the immune system can be in general, particularly the T-cell component. The following experiments illustrate this convincingly. Transgenic mice that express the lymphocytic choriomeningitis virus glycoprotein (LCMV-GP) under the rat insulin promoter (RIP) express the LCMV-GP only in insulin producing β cells (see Chapter 26). If these mice are left unchallenged, they do not develop diabetes. However, when infected with a low dose of LCMV, these same mice develop diabetes within 10 days and do not recover (Ohashi et al., 1991; Oldstone et al., 1991). Such experiments clearly show that a strictly extralymphatic self-antigen is ignored by the immune system. LCMV-GP-specific T cells are present but are not usually positively induced to become effector cells to cause pathology. However, this experiment also shows that such potentially autoreactive T cells are neither deleted nor negatively selected to establish tolerance. If a hitherto strictly extralymphatic antigen were later to enter secondary lymphatic organs for a few days, as would occur after infection of the transgenic mice with the original "parental" LCMV, CTLs are induced efficiently. These effector T cells will emigrate to the islet β cells and destroy them under the experimental conditions.

If these RIP-GP mice are infected with a recombinant vaccinia virus expressing the same LCMV-GP (VACC-GP_{LCMV}) they do not develop diabetes despite the fact that CTLs have been primed (Ohashi et al., 1993). In this model the difference in the severity of autoimmunity caused by LCMV infection versus VACC-GP_{LCMV} infection indicates that priming of CTL responses of itself does not automatically cause autoimmune disease. Infection with intact LCMV induces about a hundred to a thousand times more effector CTLs over 14 days compared with the VACC-GP_{LCMV} infection. However, if RIP-GP mice also express CD80 (B7.1) in their islet cells (Harlan et al., 1994) or, alternatively, a D^bGP_{33-41}-specific transgenic T-cell receptor (TCR), VAC-GP_{LCMV} does readily induce diabetes (Ehl et al., 1998). Thus, inertia depends on a physiologically low level of precursor T cells and the absence of so-called "second signals" in the extralymphatic periphery. The threshold for autoimmune disease via these induced T-cell responses is therefore very high.

Recently, we have extended these studies with RIP-GP mice to evaluate the conditions under which $CD8^+$ T cells specific for a transgenic β islet antigen can induce disease (Lang et al., 2005). In contrast to infection with a replicating LCMV, immunization with LCMV-GP peptide did not

induce disease despite induction of large numbers of autoreactive CTLs. When this immunization protocol was subsequently supplemented with the administration of TLR ligands, overt diabetes developed. This difference correlated with the interferonally triggered MHC class I upregulation in the target organ. Thus, not only induction of immunopathologic immune responses, but also "target quality" plays a major role in autoimmune disease development (Lang et al., 2005). Within this framework "epitope spreading" needs to be discussed (see Chapter 14). This concept postulates that destruction or decay of cells that are usually strictly extralymphatic may induce autoimmune T- or B-cell responses, leading to autoimmunity involving several of the autoantigens expressed in these cells. For example, virus-infected islet cells may release self-antigen in sufficient amounts and for a sufficient time period to induce T cells not only against viral but also against self-antigen. While such responses have been demonstrated under model situations to be theoretically possible, they have not been shown in human autoimmune disease directly, either for T or B cells. Autoimmune responses either during acute or (more likely) chronic infections may, however, trigger such slowly developing disease. This discussion of "epitope spreading," as later for "mimicry," is rendered so difficult and nonsatisfying because of the following general problems of analytic experimental investigations. Thus, in immunology, it is virtually impossible to definitely exclude postulated mechanisms, but we have to search for pathogenetic principles that are important and frequent. From this point of view, "epitope spreading," which triggers pathology, on the one hand may involve antigens that have been immunologically ignored so far, and on the other hand must be a rare process that usually only occurs after 25–30 years of age. Overall, therefore, epitope spread may represent one of the coevolutionary costs of immunity against acute or chronic infections (Gammon et al., 1991; Vanderlugt and Miller, 2002).

Recombinant vaccinia immunizations are considered usually to be quite strong, and are used successfully to immunize hosts against tumors. However, if the transgenic islet β cells were to be considered as very small tumors, the above example illustrates that, to reject such strictly extralymphatic small tumors, an enormous T-cell immune response would be required. This was formally illustrated by combining the RIP-GP model with a sarcoma expressing the same model tumor antigen LCMV-GP (Ochsenbein et al., 2001). A mouse transgenic for LCMV-GP in islet β cells carrying a tumor expressing the same GP tumor antigen was treated with various vaccines, including recombinant vaccinia virus or dendritic cells expressing the relevant GP-epitope, to assess whether the tumor could be rejected without causing autoimmune diabetes. By means of careful titrations, we found that within a factor of two or three there was no therapeutic window permitting tumor rejection (a wanted result) without induction of autoimmunity causing diabetes (an unwanted result) (Ludewig et al., 1998). From these experiments we can conclude that a high threshold for T-cell induction and activation is an important basis for prevention of autoimmunity or immunopathology against strictly extralymphatic self-antigens, organs or cells. The same threshold also applies to strictly extralymphatic tumors, unfortunately. Overall these examples illustrate why T-cell-mediated autoimmune disease is rare before the age of 25 (a necessity for survival of the human species), and why induction and maintenance of an antiperipheral solid tumor T-cell immune response is apparently very difficult.

B-CELL TOLERANCE AND AUTOANTIBODY (PLUS T-CELL)-DEPENDENT AUTOIMMUNE DISEASES

While T-cell tolerance is relatively clearly defined, at least for deletional forms where specific T cells are simply absent, this is not true to the same extent for B-cell tolerance; there is still a debate as to whether true deletional B-cell tolerance exists and to what level (Goodnow et al., 1989; Nemazee and Buerki, 1989; Bachmann et al., 1993) (see Chapters 11 and 13). This is particularly important because the turnover and regeneration of B cells is more rapid than that of T cells; probably about 10% of B cells are renewed each day (Goldsby et al., 2000). Also, the question of whether B cells are present or absent against intracellular antigens differs according to whether these self-antigens are extracellular and/or membrane expressed, and their densities. While autoantigen-specific B cells probably are present against intracellular antigens, and probably also against rare serum self-antigens, they may be deleted or at least be largely absent against highly expressed membrane antigens. This conclusion is based largely on experiments with antibody in mice carrying a transgene for lysozyme or an alloantigen (Goodnow et al., 1989; Nemazee and Buerki, 1989).

However, studies on mice expressing a virus glycoprotein probably at low density under various promoters have shown that they can promptly respond with a neutralizing antibody response against this particular new self-antigen (Zinkernagel et al., 1990; Bachmann et al., 1993). In the latter case, the IgM response is particularly interesting because it is T-cell independent. In this model, therefore, the question arose whether the B cells themselves were present or absent or whether the absence of T cells was responsible for the absent autoantibody response. Experiments showed that transgenic mice expressing the vesicular stomatis virus

glycoprotein (VSV-G) on host cells promptly responded first with a T-cell-independent IgM response, and then a subsequent T-cell-dependent switched IgG response when immunized with live or ultraviolet (UV)-inactivated VSV virus. In contrast, these same mice did not respond with a neutralizing antibody response if immunized with purified VSV-G in various adjuvants. From these findings we concluded that B cells did not respond to monomeric self-antigens, but did promptly react against repetitive polymeric corpuscular self-antigens, as would be expressed on a virus (Bachmann et al., 1993). The switch to IgG was classically T-cell help dependent. In this VSV-G example, T-cell help was negatively selected against, or deleted, for specific T cells recognizing VSV-G, but of course was still inducible against internal antigens present in replication-competent or UV-inactivated virus. Therefore, it was concluded, as many times previously, that autoantibody responses against self-antigens that usually are available systemically within the host as monomers or oligomers are very rare; this is because T-cell help is deleted, and because T-cell help is obligatory for induction of an IgM and IgG autoantibody response, particularly against monomeric antigen. If, however, self-antigens were somehow to be linked to infectious agents, e.g., on the surface of infected cells or cell fragments, then such autoantibodies could well be induced by appropriate cognate foreign antigen-specific T-cell help.

On the other hand, autoreactive B cells may be readily induced to produce IgM by a highly repetitive antigen. Interestingly, such polymeric highly repetitive self-structures are usually not accessible to B cells in the intact host. For example, acetylcholine receptors expressed in a highly polymeric form in the motor neuronal endplate (Vincent et al., 2003), or DNA or type 2 collagen (Holmdahl et al., 1990), which express repetitive polymeric structures, are not accessible to B cells under normal circumstances. If, however, cells decay or aggregated acetylcholine receptors are expressed without being covered by the endplate, as in thymomas, for example, such structures may become accessible to B cells. They may then induce an IgM response and even get switched to IgG, particularly under circumstances in which hitherto ignored self-antigens have induced helper T cells.

A number of additional experiments support the notion that B cells are probably not as solidly absent or tolerant as T cells. Classical experiments in the 1970s showed that polyclonal B-cell activators, such as lipopolysaccharides, can regularly induce autoantibodies in mice (Moller, 1975). Similarly, highly persistent viral infections in mice and humans have been shown to induce hypergammaglobulinemia, which often includes autoantibody. IgM autoantibodies may be induced, perhaps quite often, but without serious consequences because of the short half life of IgM (1–2 days). In contrast, once the T-cell-help-dependent switch to IgG has occurred, the prolonged half life of IgG may have serious pathologic consequences.

Another important aspect, the binding characteristics of autoantibodies necessary to cause pathology, is largely unknown. As discussed above, for neutralizing antibodies that protect against viral infections, it has been shown that rather high avidities/affinities are necessary, of the order of 10^8-$10^{10}\,M^{-1}$. Since autoantibodies are usually measured by ELISAs or immunohistology, then binding properties are probably, or so we speculate, rather low, of the order of 10^5-$10^{-7}\,M^{-1}$. Direct and well-characterized evidence for autoimmune disease caused by antibodies exists for myasthenia gravis (Vincent et al., 2003), and for a novel antibody-dependent rheumatoid arthritis model (Monach et al., 2004).

ROLE OF ANTIGEN AND INFECTION

As mentioned above, the structure of antigen plays a major role in inducing B-cell responses; thus, highly repetitive structures induce T-cell-help-independent IgM but not IgG responses, whereas monomeric antigens cannot induce a B-cell response independent of T-cell help.

An additional hypothesis, that of mimicry, has been discussed repeatedly during the past 20 years (Oldstone, 1998), and in many chapters in this volume. This concept proposes that a self-antigen resembles antigens expressed or induced by infectious agents. The streptococcal antigen that cross-reacts with heart antigen provides a classical example (see Chapter 62), but many others have been invoked. Of course, such mimicry could be an important cause of autoimmune disease and immunopathologies if the binding qualities and the direct disease-causing correlations were clearly established. However, mimicry is rarely, if ever, demonstrated in the form of pathology. Often only ELISAs, or other antibody-binding assays, including histology, are used as proof. As is often the case in biology, nothing is impossible and mimicry sounds like a good idea, but whether this process is really involved and can explain the role of infectious disease in triggering and causing autoimmune disease, or maintenance of disease, remains to be demonstrated directly. If it does occur, it must be rare or coevolution of host and parasites would not have been successful. What are the alternatives?

It is likely that infections destroy cells that hitherto were ignored immunologically, because self-antigens of those cells did not reach the lymphohemopoeitic system at sufficient levels to either induce an immune response or for the reactive lymphocytes to be completely deleted. Infections of such cells or organs could cause direct destruction of ignored cells to release antigens, or could induce a T-cell-mediated immune response that via immunopathology causes the destruction of these extralymphatic cells. The released

antigen will probably be picked up locally by macrophages and dendritic cells that eventually become trapped in local lymph nodes or the spleen. Antigen that so far had been ignored thus reaches secondary lymphatic organs, usually in association with MHC class II. Above a certain threshold it will induce CD4 T-cell-dependent help and antibody responses. Substantial periods of time and quantities of antigens are required to induce an immune response and to maintain it. The impact of this view on so-called "epitope spreading" is discussed above.

ROLE OF ORGANIZED LYMPHATIC TISSUES

Convincing experiments indicate that antigen must transiently reach secondary lymphatic organs to induce any immune response. If the reverse happens, i.e., secondary lymphatic tissue is exported or newly formed in extralymphatic peripheral organs, an autoimmune response may be maintained (Ludewig et al., 2000). When analyzed by immunohistology, it is striking that many autoantibody-dependent autoimmunities exhibit expression of secondary lymphatic tissues within the diseased target organ. A classical example is Hashimoto's thyroiditis (see Chapter 35), but type 1 diabetes, rheumatoid arthritis, Sjögren syndrome, and various other autoimmune diseases also follow this pattern. To reiterate, there is basically no induction of an immune (or autoimmune) response in the absence of secondary lymphatic organs. However, if secondary lymphatic organs do become organized within a site hitherto immunologically ignored, either islet cells, parotid gland or synovial tissue, the self-antigen expressed there can maintain an autoantibody response for as long as autoantigen remains available and the secondary lymphatic structure is intact. In fact, lymphatic structures may be seen during acute or chronic autoimmune diseases but once all parenchymal cells have been destroyed ("burned out"), these secondary lymphatic structures also disappear.

HORMONAL INFLUENCE

There is roughly a 5 : 1 ratio of females-to-males in most autoantibody-dependent autoimmune diseases. As previously argued, this may correlate with the evolutionary necessity for immune mothers to hand down protective antibodies at optimal levels to their immunoincompetent offspring. Several studies indicate that antibody levels in mice are regulated at least partially by female hormones. Whether this alone is a sufficient explanation of the female bias remains to be seen (see Chapter 25), but in experimental animals, including mice, the preponderance of autoimmune disease in females is striking. The question of hormonal influences on autoimmune diseases remains worthy of further evaluation.

CONCLUSION

Analysis of immunity against infections provides good insights into understanding immunologic tolerance and specificity. While immune protection is the desired result, there is no absolutely safe and entirely beneficial system available in biology: there are always costs. Therefore, there is a balance between protective and immunopathologic aspects of immunity, but this is definitely on the beneficial side for the host. However, the outcome of some ill-balanced situations, which may lead to immunopathology and in some cases to classical autoimmunity, reflects these coevolutionary costs. It is important to note that protection by the immune system guarantees survival of a sufficient number of hosts to assure procreation; for humans this means operationally 20–30 years of age. In fact, both immune reactivities causing autoimmunities and chronic immunopathologies usually appear in patients older than 30, but the inefficiencies of the immune system in dealing with strictly peripheral solid tumors also reflect this similar age barrier. If both the infectious agent and the characteristics of the immune response that is directed against peripheral infections are known, such as cytomegalovirus (CMV), HBV, leprosy, and human immunodeficiency virus (HIV), then an unfavorable balance is called immunopathology and, as a personal viewpoint, if we do not recognize infectious agents associated with a chronic or slowly progressing, often called idiopathic or degenerative, disease then we might tend to call the ensuing immunopathology an autoimmune disease. Even if only a few cases of this category of idiopathic, chronic degenerative autoimmune disease are caused by infections, directly or indirectly, and possibly with very long incubation times, it is worth our greatest efforts to define such relationships, because they are potentially amenable to beneficial actions, be it by avoidance or vaccination, or antibacterial, antiviral or antiparasitic treatments.

CHAPTER

23

Noninfectious Environmental Agents and Autoimmunity

FREDERICK W. MILLER

Environmental Autoimmunity Group, Office of Clinical Research, National Institute of Environmental Health Sciences, National Institutes of Health, Bethesda, Maryland, USA

Although the mechanisms for the development of autoimmune diseases remain obscure, accumulating evidence suggests that these increasingly recognized disorders result from environmental exposures in genetically susceptible individuals (Luppi et al. 1995; Cooper et al., 1999; Miller 1999). Despite the great progress that has been made in understanding a number of major histocompatibility complex (MHC) and non-MHC genetic risk factors for autoimmune diseases (see Chapters 5, 20 and 21), relatively little information is available regarding the role of specific environmental agents in the development of these disorders. This is partly due to the lack of validated exposure biomarkers and environmental assessment tools; difficulties inherent in defining which of the many environmental exposures are related to disease; the little formal training in environmental medicine; the few resources dedicated to this area; and the lack of consensus approaches for the definition of environmentally-associated diseases. As a result, in most autoimmune conditions, the specific environmental triggers remain unknown.

Just as multiple genes are likely to be needed to induce autoimmune disease, multiple environmental exposures may need to occur in a particular sequence, or in tandem, to provoke the chronic immune activation that leads to autoimmunity. It is also possible that epigenetics, referring to modifications in gene expression that are controlled by heritable but potentially reversible changes in DNA methylation and/or chromatin structure, may be influenced by environmental exposures. In this regard, many lessons might be learned from studies and registries of cancers which, like autoimmune diseases, are multifactorial disorders in which multiple genetic and environmental risk factors must interact in a correct sequence, with occasional long latencies, before development of disease (Sarasin, 2003). Thus, in some cases, a change induced by one exposure may be necessary before a subsequent exposure can have its effect. Alternatively, mixtures of exposures, including possible infectious and noninfectious agents, perhaps occurring during critical windows when persons may be more susceptible to them (i.e., in utero, in childhood, during puberty, pregnancy or lactation), may be necessary in order to overcome tolerance. Other general principles from cancer that might be relevant to autoimmunity include the pathogenetic heterogeneity of currently defined disorders, the likely low effect sizes from many environmental exposures, and the possible requirement for inducers, promoters, and sustainers of disease at different points in the pathogenetic process (Cooper et al., 2002). This is particularly borne out by investigations suggesting that autoantibodies precede the development of clinical disease by months to years and are antigen driven (Miller et al., 1990; Leslie et al., 2001; Arbuckle et al., 2003). This suggests that certain

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

environmental exposures may be necessary to overcome tolerance in genetically susceptible individuals and induce autoantibody formation, while other agents may be necessary to promote expression of clinical disease.

If environmental agents are defined as everything outside the genome, then the many exposures that have been suspected of being involved in the pathogenesis of autoimmunity may be divided into two general categories: infectious and noninfectious agents. This chapter will focus on the evidence for the role of noninfectious environmental agents in the pathogenesis of human autoimmune diseases, while infectious agents are reviewed in Chapter 22.

EVIDENCE FOR THE ROLE OF ENVIRONMENTAL AGENTS IN AUTOIMMUNE DISEASE

Evidence for the role of environmental agents in autoimmune disease comes from a variety of investigative approaches (Box 23.1). Although many of these methods are indirect, anecdotal, or may be only applicable to single patients, taken together these diverse findings strongly support the contention that most autoimmune diseases do have an important environmental component (Cooper et al., 1999).

One of the strongest lines of evidence for the role of the environment is that, for autoimmune diseases studied to date, there is generally less than 50% disease concordance in monozygotic twins (Leslie and Hawa, 1994; Cooper et al, 1999). While it has been suggested that this could be due to stochastic or other events, this consistent low level of disease concordance in genetically identical persons among all autoimmune disorders studied, argues against this. These findings also hint that, even if all the genetic risk factors for a given autoimmune disease could be fully identified, this would not allow for disease to be predicted with any greater accuracy than the flip of a coin without the incorporation of environmental or other factors.

Box 23.1
Lines of evidence supporting the role of environmental agents in the development of autoimmune disease

- Less than 50% disease concordance in monozygotic twins
- Strong temporal associations with some environmental exposures and disease onset
- Dechallenge (disease resolution or improvement after removal of the suspect agent)
- Rechallenge (disease recurrence or worsening after re-exposure to the suspect agent)
- Seasonality in birth dates and disease onset
- Geographic clustering in disease incidence or prevalence
- Changes in the prevalence or incidence of disease over time and when genetically similar cohorts move to different geographic locations
- Strong biologic plausibility from animal models
- Epidemiologic associations between particular exposures and certain diseases

For certain agents it can be relatively clear when a given exposure is inducing a disease in an individual patient. The definition of an environmental disease in an individual can be accomplished by identifying a new clinical disorder, which develops soon after a novel exposure, resolves when the exposure is removed (dechallenge), and then recurs after reintroduction of the same exposure (rechallenge). This approach is most easily applied in case of exposures to defined chemical entities, such as drugs, foods, and topical or inhaled toxicants. Unfortunately, many xenobiotics (compounds not naturally found in the body) cannot easily be removed from an organism after exposure, and therefore, for these agents this approach is not usually helpful. Exposures in this category include inhaled silica, vaccines, fat-soluble oils, and collagen or silicone implants.

The nonrandom distribution in time and space of some autoimmune illnesses also implies that nongenetic factors are important in disease development. Studies in these areas are preliminary, and sometimes have not been reproduced, leading critics to posit that referral or other biases might explain some of the findings. Nonetheless, intriguing investigations have suggested that certain autoimmune disorders have a seasonal onset (Samuelsson and Carstensen, 2003) or that there is a seasonal association with subsets of patients based on disease-specific autoantibodies (Leff et al., 1991). Furthermore, studies of type 1 diabetes have found significant associations with birth dates (Ursic-Bratina et al., 2001; Willis et al., 2002), implying that certain exposures at certain times of the year may alter the target tissues or immune systems of fetuses or neonates, resulting in later autoimmunity. While infectious agents are often presumed to be the source of such seasonal or geographic associations, the immune system, like other organ systems, appears to have cyclic or rhythmic patterns (Haus and Smolensky, 1999), possibly related to light exposure and mediated by melatonin or other neurohormones (Nelson and Drazen, 2000). Additionally, many occupational or other exposures are seasonal, including exposures to certain pesticides, chemicals in sunscreens, and some air or water pollutants, so it is possible that noninfectious agents could account for some of these data in ways that have not been accounted for. Geographic clustering or gradients in disease prevalence or

incidence have also been found for some autoimmune diseases. These investigations have primarily shown associations with latitude, suggesting a role of ultraviolet (UV) radiation in inducing disease, as may be the case for dermatomyositis (Okada et al., 2003); altering mortality, as may be the case in systemic lupus erythematosis (SLE) (Grant, 2004); or protecting from disease, as may be the case in multiple sclerosis and type 1 diabetes (Ponsonby et al., 2002).

Measurable increases or decreases in the incidence or prevalence of disease over time imply a nongenetic etiology given the slow rate of genetic change in a population. Although data are limited in this area—and several studies are possibly confounded as a result of improvements in the ability to diagnose some conditions over time—it appears that type 1 diabetes, multiple sclerosis, lupus, and myositis are becoming increasingly prevalent, while rheumatoid arthritis in adults and children may be decreasing in frequency in some populations (Oddis et al., 1990; Onkamo et al., 1999; Uramoto et al., 1999; Cooper and Stroehla, 2003). Studies of genetically similar populations living under different conditions are also illuminating. The incidences of both multiple sclerosis and type 1 diabetes have changed as members of a population move to new regions (Dahlquist, 1998; Noseworthy et al., 2000).

Epidemiologic studies linking specific exposures to autoimmunity are limited and usually consist of relatively small, often underpowered investigations, resulting in low effect sizes and large confidence limits. Much larger, well-designed, multicentered, and sometimes international studies, using appropriate controls and collecting adequate information to minimize confounding, will be needed to more fully define the specific environmental risk factors for disease.

IDENTIFYING AND DEFINING ENVIRONMENTALLY-ASSOCIATED AUTOIMMUNE DISEASES

One of the limitations in making progress toward identifying and defining environmental triggers for autoimmune disorders has been the lack of general consensus on the necessary and sufficient evidence needed to define an environmentally-associated condition. Medicolegal issues that surround many environmental exposures have further complicated this area. A group of experts in the field—who are members of the American College of Rheumatology Environmentally Associated Rheumatic Disease Study Group—have developed consensus on a general approach to overcome this problem (Miller et al., 2000). In their scheme, the overall process, from the identification of the first possible patient who develops a disease after an exposure, to the refinement of classification criteria for the disease, is divided into four stages (Table 23.1).

The first stage begins with the identification of a single case, or a series of cases, which are suspected of resulting from a given exposure. The consensus proposal is that these cases need to meet certain criteria to assure a minimum number of attribution elements are present (Miller et al., 2000). A total of at least four of the eight possible attribution elements need to be present, including at least three of five primary elements. The five primary elements are: temporal plausibility (taking into account the pharmacokinetics/pharmacodynamics of the agent, minimum induction time, and maximum latency); exclusion of other likely causes for the syndrome; dechallenge (if possible); rechallenge (if appropriate); and biologic plausibility. The additional three secondary elements are: identification of prior

TABLE 23.1 Proposed stages for identifying and defining environmentally-associated autoimmune diseases*

Stage	Description	Nomenclature (example)
Stage 1—Proposing the association	Case reports, defined by ascertainment criteria, propose a possible association of a specific clinical syndrome with a given exposure	Syndrome following exposure (rheumatoid arthritis following hepatitis B vaccination)
Stage 2—Testing the association	After a number of such cases are reported, surveillance criteria are proposed and epidemiologic and laboratory studies test that hypothesis	Cardinal signs, symptoms, and laboratory findings, but without the putative exposure (eosinophilia myalgia syndrome)
Stage 3—Defining criteria for the condition	If studies above are positive, then specific preliminary classification and other criteria are defined for that specific environmental disease	Exposure-associated disorder (L-tryptophan-associated eosinophilia myalgia syndrome)
Stage 4—Refining criteria for the condition	Criteria are reassessed and refined as additional data are obtained about the disease	Exposure-induced disorder (hydralazine-induced lupus-like disorder)

Modified from Miller et al. (2000).

reports of similar cases (analogy); identification of prior reports of nearly identical cases (specificity); and evidence for a dose–response effect. In addition to meeting these criteria, it is suggested that complete information regarding the history and examination, laboratory reports, core demographic data, family history, prior infections or physiology-altering exposures, all prior diagnoses, and the type/route/dose/duration of the exposure are detailed in the report.

The second stage involves testing the possible association. This should include epidemiologic studies, using surveillance criteria, to evaluate the relationship between a given exposure and a given syndrome. *In vitro*, *in vivo*, and animal studies should also assess the biologic effects of the agent and plausibility of the development of the syndrome. Other approaches, such as clinical, laboratory or genetic risk factor studies, could determine in case–control settings if cases of environmental disease differ from those with similar diseases without the exposure or from those similarly exposed who do not develop disease.

If data from the second stage result in convincing evidence that the assocation is real, then the third stage will be the development of preliminary criteria for that environmentally-associated disease. Classification criteria will define, with reasonable sensitivity and specificity, groups of patients with one disorder from closely related diseases. Expert committee consensus, mathematical algorithms or other approaches could develop these criteria. Symptom, sign, and laboratory criteria should be expressed in clinically sensible and practical formats with precise definitions of constituent elements. Diagnostic, prognostic, and outcome criteria, and disease activity and damage indexes should be considered when adequate data exist. The fourth stage repeats the same processes used in the third stage if new information is collected to warrant a redefinition of the disease.

Although this proposed staging structure has limitations, in that the decisions as to when to progress to the next stage remain somewhat subjective, it nonetheless provides an overall framework to plan for future studies, and it allows the classification of the current environmental agents into groups with different levels of evidence for their association with specific syndromes. Unfortunately, most environmental agents suspected of being associated with autoimmune diseases today remain in stages 1 or 2.

TABLE 23.2 Selected drugs associated in case reports or case series with autoimmune disorders*

Drug	Associated autoimmune disorder
α-Methyldopa	Lupus-like syndrome, hemolytic anemia, thrombocytopenia
Allopurinol	Lupus-like syndrome, vasculitis
Bleomycin	Scleroderma
Captopril	Lupus-like syndrome, vasculitis, membranous glomerulopathy
Chlorpromazine	Lupus-like syndrome, hemolytic anemia
D-penicillamine	Lupus-like syndrome, myositis, hypothyroidism, Goodpasture syndrome
Erythromycins	Lupus-like syndrome, myositis, hepatitis
Estrogens	Lupus-like syndrome, myositis
Gold salts	Lupus-like syndrome, membranous glomerulopathy
Halothane	Hepatitis
Hydralazines	Lupus-like syndrome, vasculitis, hepatitis
Interferon-α	Lupus-like syndrome, antiphospholipid syndrome, arthritis, hemolytic anemia, thrombocytopenia, hepatitis, hypothyroidism
Interferon-γ	Lupus-like syndrome, myositis, arthritis, hypothyroidism
Interleukin-2	Scleroderma, antiphospholipid syndrome, arthritis, hypothyroidism
Iodine	Hypothyroidism
Isoniazid	Lupus-like syndrome, arthritis, hepatitis, vasculitis, hypothyroidism
L-trytophan	Eosinophilia myalgia syndrome, scleroderma, myositis, neuropathies
Lipid-lowering agents	Lupus-like syndrome, myositis, hepatitis
Penicillins	Anemia, lupus-like syndrome, hepatitis
Phenytoin	Scleroderma, lupus-like syndrome, hepatitis, thrombocytopenia
Procainamide	Lupus-like syndrome
Propylthiouracil	Lupus-like syndrome, ANCA vasculitis, myositis
Quinidine	Lupus-like syndrome, arthritis, thrombocytopenia
Rifampicin	Thrombocytopenia, vasculitis
Sulfonamides	Lupus-like syndrome, vasculitis
Tetracyclines	Lupus-like syndrome, arthritis, vasculitis

ANCA, antineutrophil cytoplasmic antibodies.

SPECIFIC NONINFECTIOUS AGENTS ASSOCIATED WITH AUTOIMMUNE DISEASES

Drugs

Of all the noninfectious environmental exposures associated with autoimmunity, drugs are the best recognized and most often reported (Table 23.2). This is partly due to their widespread use and careful monitoring by clinicians, the strict regulatory oversight and adverse event reporting systems in many countries, and the ease of collection of dechallenge and rechallenge evidence to make associations in individual patients. Despite the fact that several hundred drugs have been associated in case reports or case series with a number of immune-mediated or autoimmune illnesses, few of the publications have met the consensus criteria described

above to allow exclusion of confounding factors, and few have been studied in epidemiologic investigations. Chemical agents have been the most often reported drugs preceding the development of autoimmunity, although in recent years, with their increasing use, there has been more focus on biologic agents.

The most commonly recognized drug-related syndromes are lupus-like disorders (Hess, 1991). These are characterized by autoantibodies to histones and single-stranded DNA, rather than autoantibodies to double-stranded DNA as are found more often in idiopathic lupus. Drug-related SLE also differs from idiopathic SLE in having more frequent arthritis and less frequent neurologic and renal involvement, as well as having possibly different genetic risk factors. Virtually all of the 80 or more autoimmune diseases have been anecdotally reported to be associated with one or more drugs. In some of these cases drug-linked disorders differ from the idiopathic forms in clinical, serologic or genetic features, while in other cases they do not.

It is noteworthy that although some drugs appear to be associated with a number of autoimmune conditions (Table 23.2), they do not consistently share common structures, mechanisms of action, metabolites or other features, which would allow toxicity to be predicted or an understanding to be gained of the pathogenesis of these syndromes. The challenge is to begin to decipher the genetic and other risk factors that interact with exposure to these drugs and result in disease, so that disease can be predicted and prevented.

Occupational Exposures

Limited but growing epidemiologic and experimental data have linked a number of occupational exposures to autoimmune diseases (Table 23.3). The most studied of these include silica, solvents, pesticides, and UV radiation (Cooper et al., 2002). One of the first occupationally-associated rheumatic diseases identified was Caplan syndrome, which is seropositive rheumatoid arthritis associated with a specific form of pneumoconiosis that develops in anthracite coal miners and in persons exposed to silica and asbestos (Williams, 1991). The strongest occupational associations with autoimmune disease (i.e., relative risks of 3.0 and higher) have been documented in investigations of silica dust and rheumatoid arthritis, SLE, scleroderma, and anti-neutrophil cytoplasmic autoantibody (ANCA)-associated glomerulonephritis (Parks et al., 1999; Khuder et al., 2002). Weaker associations are seen, however, for solvent exposures (in systemic sclerosis (SSc), undifferentiated connective tissue disease, and multiple sclerosis) and for farming or pesticide exposures (in rheumatoid arthritis). Vinyl chloride has been linked to the development of a scleroderma-like disease characterized by skin thickening, Raynaud phenomenon, acroosteolysis, and pulmonary involvement. This observation, and the publication of several case reports, stimulated research into associations between SSc and other chlorinated solvents (e.g., trichloroethylene and trichloroethane) with varying results (Cooper et al., 2002).

TABLE 23.3 Occupational exposures associated with autoimmune diseases in epidemiologic studies*

Exposure	Disease	Summary of results
Silica	Systemic sclerosis	3-fold increased risk in four occupational cohort studies; mixed results in five population-based case-control studies
	Rheumatoid arthritis	3-fold (or higher) increased risk in five occupational cohort studies
	SLE	>10-fold increased risk in three occupational cohort studies
	ANCA vasculitis	4-fold increased risk in three case-control studies
Solvents	Systemic sclerosis	Mixed results, but some evidence of 2–3-fold increased risk with specific solvents (e.g., paint thinners and removers, trichloroethylene) and with "any" solvent
	Undifferentiated connective tissue disease	2-fold increased risk with paint thinners and removers, mineral spirits; 3-fold increased risk with specific solvent-related occupations
	Rheumatoid arthritis	Weak or no association with specific solvents, but 2-fold increased risk among spray painters and lacquer workers
	Multiple sclerosis	2–3-fold increased risk with solvent exposures in most studies
Pesticides	Rheumatoid arthritis	Weak associations (relative risks <2.0) seen with pesticide exposure and in farmers and horticultural workers
Ultraviolet radiation	Multiple sclerosis	Reduced risk (OR 0.74) of multiple sclerosis and mortality with increased occupational exposure to sunlight
	Dermatomyositis	Positive correlation of the proportion of dermatomyositis with global surface sunlight intensity at 15 referral centers on four continents

*Modified from Cooper et al. (2002).

ANCA, antineutrophil cytoplasmic antibodies; OR, odds ratio.

There are many difficulties in assessing the role of occupational exposures in disease. First, there are few biomarkers for such exposures and essentially none that allows an estimate of lifetime cumulative exposure. Secondly, there are few validated occupational exposure questionnaires and those that do exist are awkward and costly to apply. Thirdly, most studies in this area have been underpowered given the rarity of the diseases and the occupations of interest, resulting in imprecise risk estimates. Finally, there is possible confounding from multiple exposures that makes it difficult to ascertain whether different effects can be attributed to different chemicals. Thus, it may not be surprising that in some cases discrepancies exist in different investigations, making it difficult to assess the true overall risks of most occupational exposures.

Other Exposures

A wide variety of other exposures with greatly different properties have been proposed to be associated with autoimmune diseases (Table 23.4). The evidence supporting these proposed associations range from case reports to epidemiologic studies and many are speculative at this time. These are listed below under the major categories into which they may be classified.

Foods

Foods represent some of the better examples of environmental agents associated with autoimmune diseases. The best example is celiac disease (see Chapter 51), which is characterized by an immune response to ingested wheat gluten and related proteins of rye and barley, which leads to autoantibodies to transglutaminase and inflammation, villous atrophy, and crypt hyperplasia in the intestine (Alaedini and Green, 2005). These is also good evidence for gene–environment interaction in celiac disease with human leukocyte antigens DQ2 and DQ8 being the major known genetic risk factors. Celiac disease is one of the few medical conditions for which dietary intervention is the main treatment modality and a gluten-free diet markedly decreases symptoms in most individuals. Although there is less support for an autoimmune etiology of other food-associated inflammatory disorders, including the L-tryptophan-

TABLE 23.4 Other exposures proposed as possible risk factors for autoimmune diseases

Exposure	Disease	Comments (reference)
Foods (gluten)	Celiac disease	Celiac disease develops after ingestion of foods containing gluten and related proteins in some genetically susceptible persons (Alaedini and Green, 2005)
Cigarette smoking	Rheumatoid arthritis	Studies suggest relative risks of 1.5–3 with a greater effect in men and seropositive disease (Krishnan, 2003; Stolt et al., 2003)
	Autoimmune thyroid disease	Meta-analyses suggest 2–3 fold increased risks of Graves' and Hashimoto's (Vestergaard, 2002)
	Inflammatory bowel disease	Smoking increases risks for Crohn's disease but decreases risks for ulcerative colitis (Timmer, 2003)
Heavy metals	Multiple syndromes	"Pink disease" (acrodynia) and glomerulopathy from mercury toxicity; related syndromes with elements of autoimmunity from cadmium and gold salt toxicity; granulomatous pneumonitis from beryllium exposure; support for genetic risk factors in animal models (Bigazzi, 1994; Dally, 1997; Fontenot and Kotzin, 2003)
Microchimerism	SSc, SLE, primary biliary cirrhosis, autoimmune thyroid disease	Fetal cells detected in maternal blood or target tissue specimens years after pregnancy—not all findings have been reproduced, possibly due to different methodologies with different sensitivities to detect rare microchimeric cells (Sarkar and Miller, 2004)
	Juvenile myositis	Maternal cells detected in children who developed myositis (Artlett et al., 2000)
Vaccines	Multiple syndromes	Arthritis after rubella virus vaccines; thrombocytopenia after measles vaccines; Guillain–Barré syndrome after swine flu vaccine and tetanus; controversy remains over others (Wraith et al., 2003)
Collagen implants	Myositis	In one study, OR = 5.05; 95% CI = 2.31–9.59 for all forms of myositis (Cukier et al., 1993)
Silicone implants	Multiple syndromes	Most studies do not find associations with common autoimmune diseases (Janowsky et al., 2000; Tugwell et al., 2001); rare or atypical connective tissue disease and fibromyalgia remain inadequately studied (Brown et al., 1998; Brown 2002)
Stress	Graves' disease	Stressful life events in the 12 months preceding the diagnosis were significantly higher than controls (OR = 6.3, CI = 2.7–14.7 (Winsa et al., 1991); other diseases poorly studied

ANCA, antineutrophil cytoplasmic antibodies; CI, 95% confidence interval; OR, odds ratio.

associated eosinophilia myalgia syndrome (Sullivan et al., 1996) and the contaminated rapeseed oil-associated toxic oil syndrome (Gelpi et al., 2002), it is possible that some of these represent cases of food-associated autoimmunity.

Tobacco Smoke

Tobacco smoke has been associated epidemiologically with an increased risk of rheumatoid arthritis, autoimmune thyroid disease, and Crohn's disease in several studies, but inconsistent results were found in studies of smoking and systemic lupus erythematosus (SLE). Smoking may be associated with a reduced risk of ulcerative colitis, an inflammatory bowel disease, implying that the complex mix of chemicals in tobacco smoke may have different effects in different genetic backgrounds.

Heavy Metals

Exposures to heavy metals, including mercury, cadmium, gold salts, and beryllium have been associated with a variety of pathologic syndromes, some of which have features of autoimmunity. A recent study of communities in Amazonian Brazil with well-characterized exposures to mercury was the first to document immunologic changes, indicative of autoimmune dysfunction, in persons exposed to mercury (Silva et al., 2004). Additionally, many animal models have documented inflammatory, and sometimes highly specific, autoimmune responses to heavy metals, even at subtoxic doses, and which appear to differ in different genetic backgrounds (Bagenstose et al., 1999). The mechanisms for these many effects remain unclear, but possibilities include changing the response repertoire by direct and indirect means via changes in cytokine profiles, influencing expression of new antigens, new peptides, and/or antigen presentation by modifying the antigen-presenting complex (Rowley and Monestier, 2005).

Microchimerism

Microchimerism is the persistence of a low level of nonhost stem cells or their progeny in an individual. A possible role of microchimerism in the pathogenesis of some (systemic sclerosis, SLE, primary biliary cirrhosis, autoimmune thyroid diseases, and juvenile myositis), but not all, autoimmune diseases has been suggested by recent studies (Sarkar and Miller, 2004). The initial impetus to explore this exposure was that many of the diseases associated with microchimerism have features that are shared with graft-versus-host disease, suggesting a possible mechanism. Although an appealing hypothesis, controversy in the area continues due to the lack of reproducible studies and the lack of proof of the role of microchimeric cells in the pathogenesis of these disorders. That cells of multiple origins and different genetic backgrounds may combine to result in functional organ systems, both in mothers and their offspring, requires a re-evaluation of many current paradigms. It is possible that such chimeric mixtures play a role in autoimmunity, tissue repair, and other areas. Further research—using standardized, sensitive, and validated methods—is needed to address the many questions that the early findings in this field have raised.

Vaccines

Because vaccines are foreign proteins often injected with adjuvants into muscle to induce immune responses, it may not be surprising that immune-mediated adverse events have been reported after a wide variety of immunizations. Although a number of autoimmune diseases have been found to develop following vaccinations, in the US only a few have been deemed associated with disease by the Advisory Committee on Immunization Practices (1996) and are now compensated by the National Vaccine Injury Compensation Program (http://www.hrsa.gov/osp/vicp/INDEX.HTM). These include cases of arthritis after rubella virus vaccines, thrombocytopenic purpura after measles vaccines, and Guillain–Barré syndrome after swine flu or tetanus vaccines. There remains significant controversy over other illnesses possibly caused by immunizations, but most epidemiologic studies in this area have not shown significant associations (Wraith et al., 2003) (See Chapter 24).

Implants

Bovine collagen implants are biomaterials used for the correction of dermal contour deformities. The use of bovine collagen implants in patients with a personal history of autoimmune diseases is contraindicated by the manufacturer due to concerns that they may induce adverse immune responses, since anticollagen autoantibodies are present in some patients with connective tissue diseases. Few epidemiologic studies have been performed in this area, although one study has evaluated the development of myositis in nine patients following collagen implants (Cukier et al., 1993). Eight of the nine patients had a delayed-type hypersensitivity response at the test or treatment sites, and five of six patients tested were found to have increased serum antibodies to collagen. Compared with the general population, the incidence of dermatomyositis or polymyositis among collagen-treated patients was significantly increased.

Silicone implants remain some of the most controversial environmental agents proposed to be associated with connective tissue disorders. Studies in this area have been hampered by the extensive litigation involved in adverse events following silicone breast implants and the lack of adequate regulatory review prior to their initial use. Most studies have

not found associations with common autoimmune diseases (Janowsky et al., 2000; Tugwell et al., 2001); however, some investigators believe that rare or atypical connective tissue diseases and fibromyalgia remain inadequately studied (Brown et al., 1998; Brown, 2002). Of interest, women who develop myositis after silicone implants appear to be an immunogenetically distinct subgroup with allelic associations different from those seen in women who develop myositis without implants (O'Hanlon et al., 2004).

Stress

Anecdotes have been reported that stressful life events have preceded the development of many autoimmune diseases. A large population-based, case–control study of Graves' disease showed that patients had more negative life events in the 12 months preceding the diagnosis of Graves', and negative life-event scores were also significantly higher (Winsa et al., 1991). Other diseases have not been adequately studied. Although the mechanisms by which stress may play a role remain unclear, it has been hypothesized that, under certain conditions, stress hormones may boost immune responses through induction of tumor necrosis factor (TNF)-α, interleukin (IL)-1, and IL-8, and by inhibiting TGF-β production (Elenkov and Chrousos, 1999). Therefore, conditions that are associated with significant changes in stress system activity may modulate the neuroendocrine–immune axis and perturb systemic cytokine balances, resulting in proinflammatory changes and disease induction.

POSSIBLE MECHANISMS BY WHICH ENVIRONMENTAL AGENTS MAY INDUCE AUTOIMMUNE DISEASES

Although the mechanisms for the development of autoimmune diseases associated with noninfectious agent exposures remain poorly understood, a variety of theories have been postulated to explain how xenobiotics may induce disease (Box 23.2). The wide range of these theories emphasizes the lack of understanding of mechanisms even for the most carefully defined environmentally-associated diseases. This also suggests that different pathogenic mechanisms are likely at work in different syndromes.

Whatever the specific mechanisms for the development of an autoimmune disease, it has been suggested that an overall framework should include the concept of heterogeneity within the currently defined diseases. A working hypothesis that addresses this issue has been termed the "elemental disorder hypothesis," which posits that each autoimmune disease as currently recognized contains many elemental disorders (Shamim and Miller, 2000). In this scenario, an elemental disorder is defined as a unique sign–symptom–laboratory complex (syndrome) that results from a distinct pathogenesis as a result of the interaction of the necessary and sufficient genetic and environmental risk factors (Figure 23.1). If this concept is true, elemental disorders are likely confounding most studies of disease by inducing "comparisons of apples and oranges." If identified, elemental disorders should greatly increase the homogeneity of populations under study and thus decrease the numbers of individuals needed for genetic, environmental, and therapeutic studies. In the future, elemental disorder identification could allow for the prevention of some illnesses by avoidance of environmental risk factors or via gene therapy to correct deleterious genetic risk factors.

Box 23.2
Possible mechanisms by which environmental agents may induce autoimmunity and promote and sustain autoimmune diseases (possible examples in parentheses)*

- Alteration of target tissue autoantigen structure (bystander drugs, heavy metals)
- Upregulation or altered locations of normally sequestered autoantigens (UV radiation)
- Cytotoxic, inhibitory or stimulatory effects on components of the immune system (interferons, interleukins)
- Molecular mimicry—structures shared between environmental agent and self (infectious agents)
- Other effects and combinations of the above

*Initiators of autoimmunity may differ in action from promoters and sustainers of autoimmune disease.

SUMMARY AND FUTURE DIRECTIONS

The multifactorial nature of autoimmune diseases has inhibited understanding of the mechanisms that initiate and sustain them. Autoimmune syndromes are believed to arise, however, from a complex and ill-understood interplay of predisposing genetic and environmental risk factors. While some progress is being made in defining the genetic risk factors, we are in our infancy in the identification of the environmental risk factors for autoimmune illnesses. Understanding the interactions of those elements that are necessary for disease development offers the promise of preventing or treating autoimmune diseases in novel ways. But before that can be accomplished, important questions remain to be answered. Which specific gene–environment interactions lead to which specific clinical syndromes? What are the pathogenic mechanisms involved? Is every autoimmune disease, as currently understood, actually composed

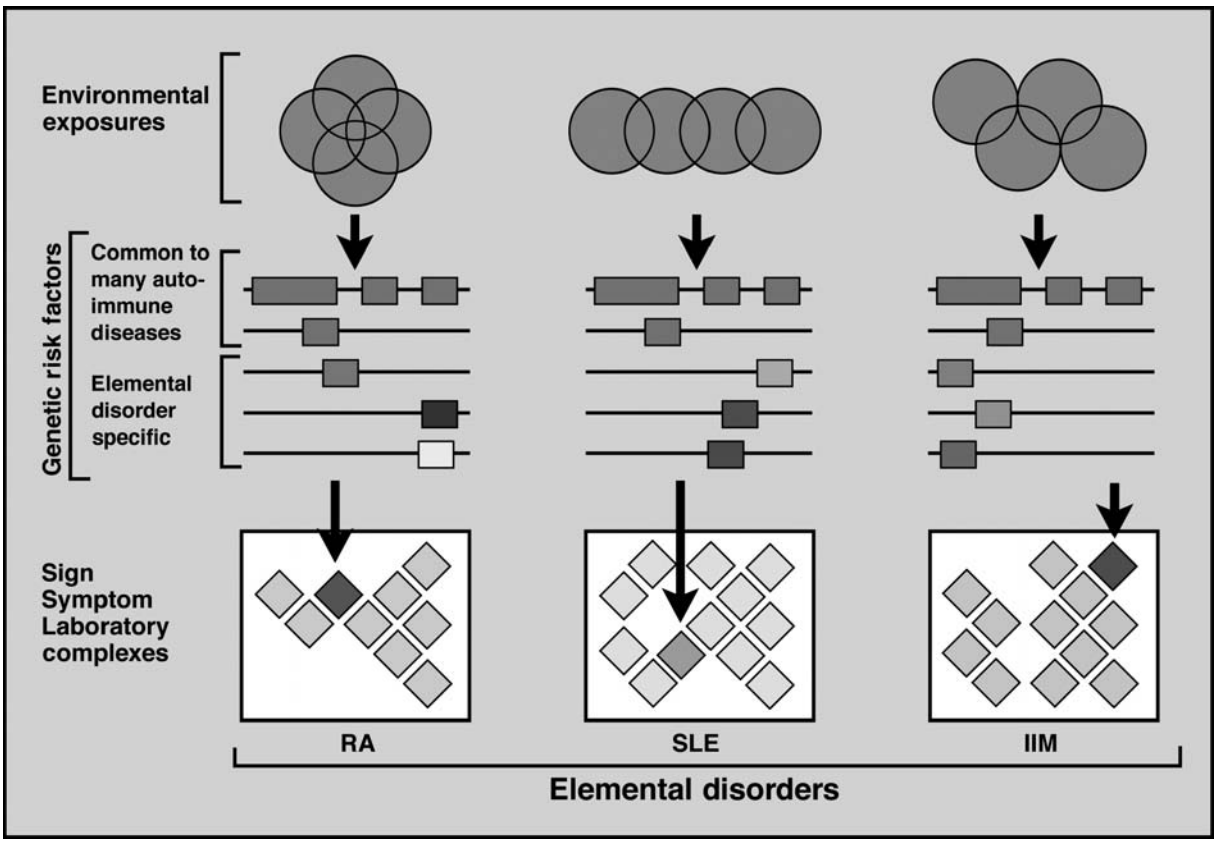

FIGURE 23.1 Possible mechanisms by which autoimmune diseases may arise—the elemental disorder hypothesis. In this view, every autoimmune disease, as currently classified, is a heterogeneous collection of clinical signs, symptoms, and laboratory findings, and is composed of many elemental disorders. Elemental disorders are defined as unique clusters of signs, symptoms, and laboratory features that result from a distinct pathology induced by the interaction of necessary and sufficient environmental and genetic risk factors for that elemental disorder. IIM, idiopathic inflammatory myopathies; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

of many subsets or "elemental disorders," each of which may be defined by a unique pathogenesis resulting from interactions of the necessary and sufficient risk factors? Can selected autoimmune diseases be better treated, cured, or even prevented through answers to some of the above questions?

We live in an increasingly complex sea of xenobiotics, which complicates exposure assessments. More than 80,000 chemicals are registered for use in commerce in the US, and an estimated 2000 new ones are introduced annually to be included in our foods, personal care products, drugs, household cleaners, and a host of industrial processes. The long-term effects of most of these chemicals on human health are unknown, yet we may be exposed to them during the manufacture, distribution, use, and disposal of products or as pollutants in our air, water, or soil. As a result, none of us knows the full range of environmental agents we are exposed to on a daily basis.

Many challenges have prevented further understanding of the environmental risk factors that might trigger autoimmune diseases in genetically susceptible individuals. These include: inadequate validated exposure assessment tools and bioassays; poor training in the evaluation of environmental exposures; the lack of population-based incidence, prevalence, demographic information and databases or repositories for most diseases; inadequate funding; and the lack of accepted and standardized approaches for defining the minimal criteria for an environmental disease. A number of coordinated initiatives may be useful in overcoming these obstacles and making more progress in the future (Box 23.3). Central to all these efforts are greater attention to and funding for understanding the essential environmental exposures that initiate, promote or sustain autoimmune disorders. Such investments are likely very cost-effective since they would have important clinical and financial implications for improving the public health.

Box 23.3
Possible approaches to enhance identification of environmental risk factors for autoimmune diseases

- Foster national and international collaborations and coordination to integrate existing and newly developed clinical databases, registries, specimen repositories, and other resources
- Develop and validate clinically useful standardized environmental exposure assessment tools
- Develop and validate standardized biomarkers for environmental exposures
- Increase support for well-designed, population-based, and case–control hypothesis-testing studies for suspected environmental agents
- Increase support for hypothesis-generating studies to identify new agents and syndromes
- Collect systematic descriptive epidemiologic data for all autoimmune diseases as a baseline for future comparisons
- Increase use of information technology and other novel approaches to enhance communications, coordinate efforts, and facilitate clinical studies
- Improve coordination between animal model and epidemiologic studies
- Develop novel mathematic, statistical, and bioinformatic approaches to enhance epidemiology studies
- Define gene–gene, gene–environment, and environment–environment interactions
- Establish an international coordinating committee to oversee and facilitate the above, encourage multidisciplinary research, and prepare for and respond to epidemics of environmentally-induced immune-mediated diseases

Autoimmune diseases affect approximately 5–10% of the population in Europe and North America. Although the overall prevalence of most autoimmune diseases is quite low, the individual incidence of several such diseases has been steadily increasing in recent years, as documented for type 1 diabetes and multiple sclerosis (Wynn et al., 1990; EURODIAB ACE Study Group, 2000). Some autoimmune disorders occur in age groups for which vaccination programs are required. Therefore, the question of a connection between vaccination and autoimmune occurrences is of importance.

The history of vaccination started with Jenner's inoculation of humans with cow serum as a means of immunization against smallpox. Pasteur further developed the technique and added new vaccines. Vaccination is clearly one of medicine's greatest achievements and a cornerstone of disease prevention, significantly reducing mortality and morbidity. The vaccines contain either a live generally attenuated infectious agent, an inactivated infectious agent, or sometimes products obtained by genetic recombination. Usually vaccines contain not just the specific infectious antigens but also adjuvants such as aluminum salts or carrier proteins. The purpose of vaccination is to induce immunization, a process by which the immune system provides the host with protection against disease.

Nevertheless, since the mid-1990s, reports have accumulated on various side effects of vaccines that had not been observed previously, or perhaps not acknowledged (Cohen and Shoenfeld, 1996; Shoenfeld and Aharon-Maor, 2000; Shoenfeld et al., 2000). These effects include autoimmune expressions as well as actual autoimmune disease. The association between vaccination and autoimmunity has stimulated debate as to whether autoimmune diseases could be triggered by a vaccine. In this chapter the possibility of a link between infection, vaccination and autoimmunity will be discussed.

PATHOGENESIS OF VACCINE-RELATED AUTOIMMUNITY

The autoimmune process in the human being is a result of complex interactions between environmental factors, genetic background, hormones and immunologic defects, thus forming the "mosaic of autoimmunity" (Shoenfeld and

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Isenberg, 1989). Autoimmune responses are not usually followed by any clinical manifestation unless additional factors cause disease expression. A key role in the occurrence of immune responses is played by infectious agents. Today there is solid evidence that infections can either prevent, or more commonly initiate, autoimmune disorders (Bach, 2002; Shoenfeld and Rose, in press).

An infection can initiate autoimmune disease by antigen-specific or non–antigen-specific pathways: these mechanisms can operate in the host either singly or together. The disease itself will be manifested only in an individual who is genetically predisposed. A popular and appealing possibility for the initiation of autoimmunity by an infectious agent is molecular mimicry (Wucherpfennig, 2001). According to this process, antigenic determinants of the microorganisms are recognized by the host's immune system as similar to its own antigenic determinants (Albert and Inman, 1999) and, because of the structural resemblance, antibodies and autoreactive T cells not only destroy the invading pathogen but can react with host tissues as well. Molecular mimicry is exemplified by infections with microorganisms that express sugar structures, thus leading to antibody-mediated neuropathies (Willison and Yuki, 2002). This theory is well represented by the Guillain–Barré syndrome (GBS) in which approximately one third of cases are preceded by *Campylobacter jejuni* infection (Carpo et al., 1999) (see Chapter 47). This bacterium expresses a lipopolysaccharide molecule that mimics various gangliosides presented in high concentration in peripheral nerves. Thus, in sera taken from GBS patients in the acute phase of the disease, antibodies against gangliosides are present. Furthermore, the specificity of these antiganglioside antibodies is closely related to the nature of the infection preceding GBS. There is also a relationship between the specificity of the antibodies and the pattern of clinical features in these patients (Ang et al., 2004).

Molecular mimicry becomes more complex when T cells are involved. In order to serve as a molecular mimic for an autoreactive T cell, a microbial antigen must copy the shape of a self-antigenic epitope bound to an appropriate major histocompatibility complex (MHC) molecule. This type of T-cell mimicry has been documented in an experimental multiple sclerosis (MS) model in which a hepatitis-B virus polymerase peptide caused histologically proven autoimmune encephalitis in rabbits (Theophilopoulos et al., 2001). According to the mimicry hypothesis, it is possible that any microorganism that expresses an epitope which could serve as a molecular mimic for an autoantigen could induce autoimmune disease. In the model of the experimental antiphospholipid syndrome (APS), bacterial peptides homologous with beta-2 glycoprotein I (GPI) induced pathogenic anti beta-2 GPI antibodies along with APS manifestations in mice (Blank et al., 2002). Recent progress in our understanding of the interface between T-cell receptor (TCR) and peptide/MHC (pMHC) complexes has revealed the potential for degenerate recognition of numerous structurally similar pMHC complexes by each T lymphocyte. Experimental findings have shown that each TCR can recognize a broad range of epitopes, including peptides with totally different sequences (Hemmer et al., 2000). Due to this flexibility of the TCR moieties in contacting pMHC and the degeneracy of MHC binding motifs, very limited direct sequence identity between mimetic peptides is sufficient for T-cell cross-recognition. Thus, theoretically, the likelihood of T-cell cross-reactivity is very high, and induction of autoimmune disease by infection should not be an uncommon occurrence (Fourneau et al., 2004).

The second mechanism by which a microorganism might induce autoimmune disease involves bystander activation in a non-antigen-specific mechanism. In this case, microbial infection causes tissue damage, which leads to the release of self-antigens or stimulation of the innate immune response, thus activating the antigen presenting cell that expresses self-antigen (see Chapter 15). The engaging of Toll-like receptors on antigen-presenting cells by microbial molecules results in upregulation of MHC and costimulatory molecule expression, leading to secretion of various cytokines, local inflammation, and recruitment of additional autoreactive lymphocytes (Panoutsakopouilou et al., 2001). The high probability that microbial antigens can cross-react with self antigens together with the innate immune response to microorganisms increases the chance of provoking autoimmune disease following infection. The same mechanisms that act in infectious invasion of the host could apply equally to the host's response to vaccination (i.e., an antigen of a recombinant vaccine or of a live attenuated virus may resemble a host antigen and so trigger autoimmunity). Some of the molecules presumably involved in these processes are a group of proteins called "stress proteins" (Winfield, 1989). These substances, which have been well conserved among species in the course of evolution, are involved in reactions occurring in the body during stress. The stress proteins—one of which is the heat-shock protein 65 kDa of *Mycobacterium tuberculosis*, the organism that causes tuberculosis (TB)—have a remarkable structural similarity among different species: viruses, microbes, and mammals. As infections do not cause overt autoimmune disease in most individuals, the interplay of several factors is needed for the development of autoimmunity. Hence, patients with genetic predisposition for autoimmunity probably also have an increased risk for post-vaccination autoimmune disease. Theoretically, the more complex a vaccine and the more varied the array of its antigens, the more likely it would be to trigger an autoimmune response that may eventually turn into an established autoimmune disease.

AUTOIMMUNE DISEASES AND VACCINATION

Measurable laboratory signs of autoimmunity can appear following infection or vaccination. The medical literature is replete with claims and counter claims with respect to the risk of developing autoimmune disease as a consequence of vaccination (Wraith et al., 2003). The accumulating reports in the literature concerning neurologic manifestations, articular disease, and other autoimmune expressions following various vaccines have troubled both professional and lay communities, leading to the appointment of national investigational committees both in Europe and in the United States (Aharon-Maor and Shoenfeld, 2000). The wide spectrum of disorders claimed to be connected temporally and/or causally with vaccination, many of them autoimmune, are listed in Table 24.1.

GUILLAIN–BARRÉ SYNDROME

Guillain–Barré syndrome is a transient neurologic disorder characterized by a reflex motor paralysis, infrequent involvement of cranial nerves, with only mild sensory disturbances (see Chapter 47). Although its exact etiology is unclear, it is likely to be an immune-mediated disease affecting both the myelin sheath and the axons. Guillain–Barré syndrome is a monophasic disease with an acute course that can involve respiratory muscles, and spontaneous recovery occurs in most cases; the mortality in acute care units ranges between 3% and 7% (Hughes and Rees, 1997). Prior viral infections are often associated with GBS, particularly herpes virus, Epstein–Barr virus (EBV), cytomegalovirus, measles and others (Ropper, 1992). Furthermore, approximately 30% of GBS cases are preceded by *C. jejuni* infection. Autoantibodies to various myelin-associated glycoconjugates (gangliosides), which are a major constituent of the nerve cell membrane, have been detected (Willison and Yuki, 2002). The specificity of these antiganglioside antibodies is closely related to the nature of the preceding infection**.** The presence of microbe-specific antibodies and T cells with cross-reactivity to various nerve sheath components probably initiates a demyelinating process with shedding of peripheral-nerve autoantigens (Terryberry et al., 1995). Vaccines that contain live attenuated or killed microorganisms can presumably induce an autoimmune reaction. Although a temporal association of GBS with several vaccines has been reported, the firmest data are those for influenza vaccine.

The first report on the association of GBS with influenza vaccine was published in 1977 after a mass inoculation program in the United States in which 45 million adults received the "swine-flu" virus vaccine. While the estimated risk of GBS in the adult population was less than one case per 100,000 vaccinations, the occurrence of GBS in the "swine-flu" vaccinated population within 5 weeks after

TABLE 24.1 Status of autoimmune diseases reported after vaccination

Disease	Type of vaccine	References	Comments

vaccination was 7.6 times greater (Shonberger et al., 1979). Subsequent studies in the following years found only a slight increase in GBS incidence (1–2 additional cases per million vaccinated persons) after the 1990–1993 and 1993–1999 vaccination programs (Lasky et al., 1998). Later studies found that the influenza vaccines were safe and concluded that the risk of developing GBS after vaccination is lower than the risk for severe influenza and/or influenza-related complications (Chen et al., 2001). However, a recent study has again raised the issue of influenza vaccination and GBS. In this report, which analyzed the database of the Vaccine Adverse Events Reporting System (VAERS), GBS incidence following influenza vaccination was compared with that of an adult diphtheria-tetanus vaccine (DPT) control group (Geier et al., 2003). The authors found that in the years 1991–1999, a total of 382 cases of GBS were reported to the VAERS. The median onset of GBS following influenza vaccination was 12 days, and the relative risk for acute GBS was 4.3 compared with the adult DPT control group. They found that the maximal incidence of GBS following influenza vaccination occurred in the years 1993, 1996, and 1998, and that there were statistically significant variations in the incidence of GBS among influenza vaccines from different manufacturers. This important issue led the Center for Disease Control and Prevention to assess once again the trends of reports to VAERS of GBS following influenza vaccination in adults. The authors analyzed the reports to VAERS from 1990 to 2003 and conducted also an active follow-up from 1994 to verify the diagnosis of GBS. They concluded that that there is a possible causal association between GBS and influenza vaccine, although the annual reporting rate decreased four-fold from a high of 0.17 per 100,000 vaccinated in 1993–1994 to 0.04 in 2002–2003 (Haber et al. 2004). To date there are no studies that specifically address the question of the risk of relapse in GBS patients after influenza vaccination, although a threat of relapse has been reported following tetanus toxoid vaccination (Hugges et al., 1996).

These data suggest that, although in most cases influenza vaccination is safe, the chance still exists that in the future another serotype of influenza virus that becomes included in a vaccine might induce autoimmune expression as previously observed.

MULTIPLE SCLEROSIS

Multiple sclerosis is a disease characterized by a central nervous system (CNS) demyelinating process associated with clinical progressive paralysis (see Chapter 46). This disease is considered to be an autoimmune disorder, and autoantibodies specific for CNS myelin/oligodendrocyte glycoprotein have been identified (O'Connor et al., 2003). These autoantibodies were specifically bound to the disintegrating myelin around axons in lesions of acute MS. The possibility of an association between MS and hepatitis B virus (HBV) vaccination was first suggested in France following a report of 35 cases of demyelinating disease occurring within 8 weeks of recombinant hepatitis B vaccination (Tourbah et al., 1999). The neurologic manifestations were similar to those of MS. Inflammatory changes in the cerebrospinal fluid and specific lesions detected on magnetic resonance (MR) images were compatible with definite MS in 50% of affected patients. Most patients diagnosed as having MS were in a high-risk group, i.e. a preponderance of women, a higher presentation of HLA-DR2, and a family history for MS. Following this report, more than 600 cases of illness, most of them with MS-like symptoms, were identified in France from 1993 to 1999 after recombinant HBV vaccination. Subsequently, several large-scale studies tried to solve this enigma, but most did not have the statistical power to do so. However, two large-scale studies have shown no significant association between HBV vaccination and the occurrence of MS. The first study looked at patients included in the European Database for Multiple Sclerosis who had a relapse of their disease between 1993 and 1997; no increase in the specific short-term risk of relapse could be found in association with HBV vaccination (Confavreux et al., 2001). The second analyzed the Nurses' Health Study in the USA; which has followed up 121,700 nurses since 1976; in this study, the relative risk of MS associated with exposure to HBV vaccine at any time before the onset of the disease was 0.9 (Ascherio et al., 2001).

Due to the discrepancy in the results, two recent studies tried to solve this complicated issue. The first study was a nested case-control study using the General Practice Data Base in the United Kingdom, which used data of MS diagnosis recorded between 1993 and 2000. The analysis, which included 163 cases of MS and 1604 controls, revealed a 3.1-fold risk of MS following HBV vaccination while no increased risk of MS was recorded following tetanus or influenza vaccination (Hernan et al., 2004). Another study analyzing the VAERS found that HBV vaccination was associated with a number of serious conditions including arthritis, myelitis, systemic lupus erythematosus (SLE), GBS, glomerulonephritis, thrombocytopenia, and MS. In some of these cases a positive re-challenge was reported with an overall median onset of disease of 1 day (Geier and Geier, 2004). Nevertheless, it should be noted that some changes that had been made to the vaccines by the manufacturers in the mid 1990s could have changed their toxic effect. In contrast to several other viruses including Epstein–Barr virus that have been postulated to cause MS, HBV has not been discussed as causing MS, therefore, it is unclear how a vaccine that contains purified HbsAg, a portion of the HBV, could trigger an immunologic process leading to MS.

Although the data are conflicting, the large-scale studies support the safety of the vaccines against HBV used nowadays.

TYPE I DIABETES MELLITUS

The fact that the incidence of type I diabetes (T1D) is increasing rapidly in children in many developed countries throughout the world has raised a serious question about the role of vaccination as a factor contributing to this. A case-control study conducted in the mid-1980s in Sweden did not reveal any effect of vaccination against tuberculosis, pertussis, or rubella on the children's risk of developing diabetes mellitus (DM) (Blom et al., 1991). Another study that followed 100,000 Finnish children who received *Hemophilus influenza* type B (HiB) vaccine for 10 years also supported these findings (Karvonen et al., 1999). Results of this study showed no increased risk of diabetes when children who had received four doses of HiB vaccine at ages 3, 4, 6 and 18 months were compared with those receiving only one dose at the age of 2 years. On the other hand, there are several studies that show opposite results. A group from The Netherlands has shown that the timing of vaccination in childhood is an important factor in the development of T1D. While immunization in the first month of life was associated with a decline in the incidence of T1D, vaccination with HiB vaccine given at age 2 months or older can increase the risk (Classen and Classen, 1999a, 1999b). Another recently published study of a cohort of 4400 babies from southeast Sweden investigated the induction of diabetes-related autoantibodies following HiB vaccination, and found that HiB vaccination stimulated the immune system. Vaccination with HiB appeared to be a risk factor for the production of tyrosine phosphatase antibodies (1A-2A) and glutamic acid decarboxylase antibodies (GADA) which may be of importance under special circumstances when the pancreatic β cell-related immune response is activated by other mechanisms (Wahrberg et al., 2003). Conflicting results were found in a controlled study conducted in Belgrade between 1994 and 1997 wherein children with recent onset diabetes were compared with controls matched by age, sex, and place of residence. The results of this study showed that infections during the 6 months preceding the onset of T1D increased the risk of developing the disease 4.5-fold, while regular vaccination decreased that risk significantly (Sipetic et al., 2003). A recently published study evaluating the development of T1D in a cohort of all children born in Denmark from January 1, 1990, through December 31, 2000, supplies more solid evidence for this issue. The results of this comprehensive study disclosed that the rate ratio for T1D in children who received at least one dose of vaccine compared with unvaccinated children was 0.91. These results were also true for each of the specific vaccines evaluated in this study: HiB, DPT, inactivated polio virus, whole-cell pertussis, and measles, mumps, rubella (MMR) vaccines (Hviid et al., 2004).The advantage of this study is that it was able to evaluate the association of T1D and vaccination in a nationwide cohort with longitudinal information. The conclusion of the authors excludes any relation between childhood vaccination and T1D. Although there are conflicting results, most of the well-conducted studies do not support such a causal relationship.

VACCINATION AND AUTISM

Autism is a behavioral syndrome in children identified by neuropsychiatric manifestations, such as lack of imaginative and language skills; self-injurious behavior; and abnormal responses to people, sensations, or triggering. The etiology of this syndrome is obscure, yet an autoimmune hypothesis has been suggested as a possible pathogenic mechanism (Weizman et al., 1982). The findings of slightly higher titers of measles IgG in autistic children compared with normal controls, which were associated with brain autoantibodies, raised the hypothesis that the measles component of the MMR vaccine can be implicated in the etiology of this syndrome (Lee et al., 1998). In the late 1990s, it was suggested that there was a connection between gastrointestinal findings of lymphoid nodular hyperplasia, MMR vaccine and autism (Wakenfield et al., 1998), but other epidemiologic studies failed to demonstrate such a connection (Taylor et al., 1999). The lack of association between MMR vaccine and autism has lately received support from the authors of the original article connecting these two who retracted their initial interpretation of the data presented in 1998 (Murch et al., 2004).

To date we can be sure that no relationship exists between autism and MMR vaccine, and it can be used safely.

ARTHRITIS

Arthritis and the Measles, Mumps, Rubella Vaccines

Arthritis, a common complication of rubella virus infection in adults, occurs less often in children. In most cases, this type of arthritis resolves completely without any permanent sequelae; only in rare cases does a systemic chronic polyarthritis resembling rheumatoid arthritis (RA) develop. There is only one large study that assessed joint manifestations in children 6 weeks after MMR vaccination. In this study of 5000 children, there was an increased occurrence of joint symptoms—arthralgia and/or arthritis—in the immunized children, although the incidence of frank arthritis was lower than that after natural rubella infection (Benjamin et al., 1992). The risk of developing joint

manifestations was examined in 1998 in 283 women receiving rubella vaccination post partum in relation to HLA-DR (Mitchell et al., 1998). The conclusion of this study based on statistical analysis was that the risk for developing arthritis in this group of women was 1.9 times greater compared with placebo. The risk of arthropathy was also influenced by DR, since individuals with both DR1 and DR4 had an odds ratio of 8:1 of developing post-vaccination arthropathy.

Arthritis and Hepatitus B Virus Vaccine

Only a few cases of arthritis following HBV vaccination have been reported. One study describes three cases of seronegative arthritis showing a pattern resembling reactive arthritis with a slowly remitting course (Gross et al., 1995). An additional series of 11 otherwise healthy patients who developed polyarthritis after HBV inoculation is described (Pope et al., 1998). All of them developed persistent arthritis fulfilling the American College of Rheumatology criteria for RA, and five expressed the HLA-DR4 antigen.

Arthritis and *Bacillus Calmette–Guerin* Vaccine

Arthritis secondary to intravesical *Bacillus Calmette–Guerin* (BCG) administration for bladder cancer is a rare and poorly documented side effect. BCG-induced arthritis has been reported only as case reports, with no more than 30 cases published thus far. It is manifested by oligo- or polyarthritis affecting the large joints of the lower limbs, associated with low back pain. Approximately 50% of the cases are HLA-B27 positive and most cases resolve completely without sequelae with nonsteroidal anti-inflammatory drug (NSAID) treatment only (Tishler, 2004).

Arthritis and Other Vaccines

There are several case series of healthy people who had been immunized against a variety of microorganisms (tetanus, typhoid, paratyphoid, mumps, diphtheria, polio, smallpox) and developed either a transient elevation in rheumatoid factor or some form of arthritis (Grasland and Vinceneux, 1994).

The pattern of arthritis following various types of vaccination is not clear since the numbers involved are too small to reach a firm decision. There is no doubt that major investigations are required before conclusions can be drawn.

OTHER AUTOIMMUNE DISORDERS

A variety of additional autoimmune manifestations have been described in relation to vaccination. Systemic lupus erythematosus following HBV vaccination has been described in some case reports (Tudela et al., 1992; Guiserix, 1996; Finierz et al., 1998). Autoimmune thrombocytopenic purpura has been documented following either MMR vaccination or HBV vaccination (Finierz et al., 1998; Miller et al., 2001).There are also isolated reports linking influenza vaccine with both development and relapse of autoimmune thrombocytopenic purpura (Casoli and Tumiati, 1989). Systemic vasculitis resembling polyarthritis nodosa with gastrointestinal, respiratory and kidney involvement with histologic evidence of glomerulonephritis has been described in some case reports following vaccination against HBV (LeHello et al., 1999, De Keyser et al., 2000), pertussis (Bishop et al., 1966), and influenza (Yanai-Berar et al., 2002). Recently an immune form of perimyocarditis was documented in more than 20 patients following mass smallpox vaccination of USA military personnel before the second war in Iraq (Halsell et al., 2003). A recent report from Switzerland found a strong association between inactivated intranasal influenza vaccine used during the 2000–2001 season and Bell's palsy. In contrast to parenteral vaccine the intranasal vaccine increased the risk of Bell's palsy 19-fold (Mutsch et al., 2004).

VACCINATION OF PATIENTS WITH KNOWN AUTOIMMUNE DISEASE

The question of tolerance to vaccination by patients already suffering from autoimmune diseases was addressed in a number of studies over the years. Studies on influenza vaccination in patients with MS and in patients with SLE did not reveal any worsening of these diseases and the rates of systemic adverse effects were similar to those after vaccination of the general population (Williams et al., 1978; Salvetti et al., 1995). However, the immune response to influenza vaccine in SLE patients was lower than that seen in adults in the general population (Abu-Shaakra et al., 2002). A similar kind of reduced response to vaccination was observed in RA patients in whom influenza vaccination did not cause a flare in their disease (Cimmino et al., 1995). Furthermore, HBV vaccination in patients with RA was not associated with deterioration of any laboratory or clinical indicators of the disease and antibodies were produced by 68% of patients (Elkayam et al., 2002). It seems that vaccination in patients with autoimmune diseases is safe, and the infection against which the vaccine is given itself poses danger to these patients which is greater than that of vaccination.

EXPERIMENTAL MODELS

The first and, to our knowledge, only controlled experimental model to test the effects of vaccination on the

immune system was performed in dogs in 1999 (Hogenesch et al., 1999). The purpose of this study was to investigate the effect of vaccination in young dogs that had not been immunized previously. A marked increase in titers of autoantibodies directed against fibronectin and laminin was observed. Both these antibodies have been found in humans with a variety of autoimmune diseases: SLE, RA, and vasculitis. Although there was an elevation in autoantibody titers, no evidence of autoimmune disease was found in any of the immunized animals.

CONCLUSIONS

1. Vaccination has greatly improved the quality and length of life by reducing morbidity and mortality, especially in children but also in the adult population. The available epidemiologic data are reassuring although we must stay vigilant particularly with some of the newer vaccines to which there are no long-term post-marketing data.
2. There are clear data that vaccination can potentially induce autoimmune effects but, fortunately, most of them do not cause a frank autoimmune disease.
3. The only case in which there is almost a complete agreement that vaccination can cause an autoimmune disease is induction of GBS after influenza vaccination. Nevertheless, even in this case the incidence is low and has been declining in the last few years.
4. We are as yet unable to identify those who are prone to develop these complications. It is apparent that susceptibility to vaccine-induced autoimmunity would be determined by genetic predisposition, which further illustrates the concept of "the mosaic of autoimmunity."
5. Although surveillance systems in many countries watch carefully the data concerning the safety of vaccinations, investigations are required to reach firmer decisions, especially since it is surprising that simple subunit vaccines have been proposed as a cause for such autoimmune effects.

CHAPTER

25

Sex, Pregnancy, and Autoimmunity

ROBERT G. LAHITA

Professor of Medicine Mount Sinai Medical School, New York, N. Y. Chairman of Medicine and Vice President, Liberty Health System, Jersey City Medical Center

Sex hormones have a major role in the manifestation of autoimmune disease. Sex steroids affect the phenotype of the individual and have a major role to play in biological development of the brain and the immune system. In the early part of this chapter, the role of sex steroids on immune function in general will be detailed, and the role such hormones have on the expression of human disease will be discussed. The role of sex steroids in the pregnant patient with autoimmune disease will then be explored.

SEX HORMONES AND AUTOIMMUNITY

Androgen Effects on Immune Function

Androgens have many effects on immune function (Grossman, 1984). They are considered immunosuppressive hormones because of *in vitro* observations of their effects on normal lymphocytes and because of their effects on the disease manifestations of inbred autoimmune mice (Ahmed et al., 1985).

Androgens are more suppressive than estrogens—and this may be one reason why females have an increased incidence of autoimmunity.

Testosterone suppresses DNA antibody production in peripheral blood mononuclear cells from patients with systemic lupus erythematosus (SLE) (Blank et al., 1990) and also inhibits pokeweed mitogen stimulation of B-cell differentiation (Sthoeger et al., 1988). This suppression involves downregulation of interleukin 6 (IL-6) and the inhibition of B-cell activity. Graft rejection in rodents is delayed by the injection of testosterone (Weinstein and Berkovich, 1981). Resistance to certain viral infections can be reduced but in some cases enhanced when androgens are given at certain doses (Yohn 1973; Jungers et al., 1982; Lahita et al., 1987). A consistent effect of androgens in the chicken is immunosuppression through retardation of the function and development of the bursa of fabricius (Meyer et al 1959; Hirota et al., 1976; Hirota, Suzuki and Bito, 1980; Verheul et al., 1986). Androgens accelerate the proliferation and differentiation of pluripotent stem cells from bone marrow into compartments of cells that include lymphoid elements (Dunkel et al., 1985).

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Importantly, receptors for estrogen and dihydrotestosterone, a 5α-reduced metabolite of testosterone, exist in the thymus (Sholitan et al., 1980; Grossman et al., 1982; Grossman et al., 1989) and these receptors are functional and present on thymocytes (Grossman, 1989). Lymphocytes, specifically $CD8^+$ T cells, have androgen receptors as well, but the data are inconsistent (Raveche et al., 1980; Cohen et al., 1983). Androgens inhibit B- and T-cell maturation, reduce B-cell synthesis of immunoglobulins, and suppress the phytohemagglutinin-induced blast transformation of lymphocytes (Weinstein and Isakov, 1983; Dunkel et al., 1985). These male hormones are also implicated as modifiers of regulatory genes that influence the function of structural genes (Lubahn et al., 1988), and this may be their principal mode of action. Inhibition of thymocyte function depends on androgen receptors on thymic stroma, and such receptors need to be expressed for atrophy to occur. Androgens induce apoptosis via the tumor necrosis factor receptor (TNFR). Of interest, guinea pig mammary epithelial major histocompatibility (MHC) antigens are increased in number through the effects of estrogens and prolactin, and these MHC antigens are decreased by testosterone (Klareskog et al., 1980). Yet, despite these findings, male and female mice have equivalent numbers of MHC antigens. The wide range of effects that testosterone has on immune function might be due to variable androgen sensitivity of certain cell groups and the *in vivo* conversion of androgens to estrogens through well-recognized pathways.

In the presence of estrogen, the thymus gland does not atrophy. On the contrary, it enlarges, whereas androgens cause apoptosis of thymic cells (Olsen et al., 2001). Some investigators have described an age-dependent change in thymic maturation in the presence of estrogens (Forsberg, 1996).

Androgen Metabolism and Autoimmune Disease

Studies of the levels and metabolism of androgens in certain autoimmune diseases are of interest (Folomeev et al., 1992; Lahita 1992). The occasional male with autoimmune disease defies explanation when sex hormone levels are examined. For example, SLE in males is not merely the result of too little androgen, although there are recent data that might support this; thus men with hypogonadism and testicular dysfunction have a higher incidence of autoimmune disease (Lahita, unpublished observation). An early reason proposed for SLE in the male was the result of too little androgen and too much estrogen (Inman et al., 1982; Bhardwaj et al., 1989). Actual studies have shown no hormonal differences between men with and men without SLE (Chang et al., 1999). Men with SLE have normal hormone levels and estrogen: androgen ratios are not altered in the majority of patients. None of the hormonal data from the studies of patients with SLE explain the large number of females who predominate with the disease. Females with SLE differ from males in the overall metabolism of androgens, but it is unclear whether these findings are reason enough for the female predilection for SLE. The oxidation of testosterone at C17 in females with SLE is increased in comparison with males, who have both normal oxidations of testosterone and normal plasma androgen levels (Lahita et al., 1983). Females with active SLE had decreased plasma levels of androgen (Folomeev et al., 1992; Lahita, 1992) and these values were from patients who did not take corticosteroid, an independent reason for low levels (Jungers et al., 1980). This observation is also found in Klinefelter patients (XXY) but not in men (Lahita and Bradlow, 1987). Low plasma androgens in women with SLE form the basis for androgen replacement therapy in this disease (Lahita et al., 1983). Clinical studies involving the use of dehydroepiandrosterone (DHEA) as a therapy (Van et al., 1995) for SLE are also a result of this observation (Van and McGuire, 1996).

The end products of androgen metabolism in a normal male or female are the same, but the total amount of testosterone in the male is very high compared with the female. Testosterone from either sex is oxidized to androstenedione, converted to DHEA and then sulfated. Both testosterone and androstenedione can be metabolized to estrone and estradiol. After the male hormones are aromatized to estrogens they can then enter the pathways for estrone hydroxylation. Specific cytokine levels change with levels of the sex steroids (van Vollenhoven et al., 1994; Soffer et al., 1982; McMurray et al., 1997). By this mechanism, certain sex steroid levels affect the T-cell populations and may determine anti-inflammatory versus proinflammatory cytokine profiles.

Estrogens and their Effects on Immune Mechanisms

The early work on the effects of sex hormones on autoimmune diseases involved careful studies with murine strains that were genetically prone to the acquisition of SLE. In some strains females were more likely to die sooner than males, with this effect being linked to estrogen (Roubinian et al., 1977; Roubinian et al., 1979; Siiteri et al., 1980; Talal, 1981; Ahmed et al., 1985). Furthermore, female mice made more antibodies to foreign antigens than males (Terres et al., 1968). In another study, after injection of humans with the antigen flagellin, men produced significantly lower titers of antibody than women. This may be due to the fact that women have higher levels of serum IgM than men, but the men produced less IgG and IgM antibody (Rowley and Mackay, 1969). Paradoxically, however, estrogens, depending on dose and condition, were both immunosuppressors and immunostimulants. The steroid 17β-estradiol prolongs first and second set skin grafts in mice after X-irradiation

and inhibits corneal graft acceptance in preimmunized rabbits (Thompson et al., 1957).

The overall effects of estrogen on various immune parameters begin early in the life of the animal. Skin allograft rejection is naturally more likely in females than in males (Graff et al., 1969; Waltman et al., 1971), and estrogens regulate immunity by causing thymic atrophy in rodents (Golsteyn and Fritzler, 1987) and decreasing the overall thymic population. Castrated male and certain female mice display enlarged thymus and hyperplastic spleens after challenge with thymic-dependent antigens, indicating an effect of the estrogens on T-cell activity (Shirai et al., 1972; Mc Cruden and Stimson, 1980; Smith et al., 1989). Estradiol and diethylstilbestrol (in concentrations of 10–50 mg/mL) are known to reduce the phytohemagglutinin and concanavalin-A response of lymphocytes *in vitro* (Wyle and Kent, 1977), although the mixed lymphocyte reaction (MLR) may be enhanced by estradiol. For example, during normal menses (Bjune, 1979), pregnancy, and during the use of oral contraceptives (Satoh et al., 1977), the immune response may be heightened. Moreover, castration of males leads to accelerated allograft rejection through a mechanism that involves an increase in the levels of T cells. T cells from such mice proliferate more vigorously to T-cell receptor (TCR)- and CD28-mediated costimulation, as well as antigen-specific activation (Roden et al., 2004). Syngeneic grafts of ovaries in males and grafts of testes in females have no significant effect on allograft rejection (Graff et al., 1969; Sasson and Mayer, 1981). Estrogen given prior to bone marrow transplantation results in increased graft failure; however, with regard to renal transplants, there is essentially no difference in graft survival with regard to gender over a long period of time. Females have a higher incidence of acute rejection while chronic allograft failure in the female is decreased (Meier-Kriesche et al., 2001). Sustained levels of estrogens in mice lead to a marked reduction in natural killer cell activity (Seaman et al., 1978; Tuo et al., 1993). In other studies, estrogens depress cell-mediated immunity, natural killer cell function, and cancer cell immune surveillance. Estrogens prevent monocytes from responding to various chemokines and also prevent the secretion of specific chemokines like IP-10, CXCR3 and CCR5 (Aronica et al., 2004). This suppression of the monocytes may be interpreted as a decrease in the overall process of immune surveillance associated with estrogens (Janis et al., 2004). This effect can be specific to $CD8^+$ T cells (Effros, 2004). When given in excessive amounts, estrogens also deplete thymic hormones and are known to produce a relative lymphopenia (Olsen et al., 1991; Olsen et al., 1993).

The effects of estrogens on disease depend on the specific diagnosis. Estrogens increase the severity of SLE but appear to have no effect or a salutary effect on rheumatoid arthritis (RA) by different mechanisms (Lahita, 1985). Tamoxifen and antiestradiol antibody have beneficial effects on experimental SLE, and the mechanism may be via cytokine regulation (Dayan et al., 1997). Men with prostate cancer who are given diethylstilbestrol have markedly depressed cell-mediated immunity. The use of gonadotropin-releasing hormone (GnRH) to suppress prostate cancer is also based in part on immunosuppression (Hurwitz et al., 2003; Roden et al., 2004). Using normal lymphocytes, estradiol treatment of pokeweed mitogen-treated B cells shows an increase in plaque-forming cells (*in vitro*) (Paavonen et al., 1981; Paavonen et al., 1991; Dayan et al., 1997). Estrogen receptors are found on $CD8^+$ and $CD4^+$ T lymphocytes in some studies from both mice and men (Cohen et al., 1983; Danel et al., 1983; Arthreya et al., 1989; Kassi et al., 2001). In that regard, there are studies to show that $CD4^+$ helper T cells increase after estrogen therapy (Stimson, 1988), while other studies show estrogen as an inhibitor of $CD8^+$ suppressor T cells. Consequently, estrogen would increase helper T cells, which would result in enhanced polyclonal B-cell immunoglobulin production. Estradiol inhibits apoptosis *in vitro*, using peripheral blood mononuclear cells from women with normal menses (Evans et al., 1997). Estradiol decreases production of TNF-α by blood mononuclear cells in SLE but not those from unaffected people (Evans et al., 1997). This would suggest that flares of SLE might occur through the inhibition of TNF-α in the SLE patient (Gomez et al., 2004).

Estrogen Metabolism and Autoimmunity

Estradiol is quickly converted to estrone, which can be metabolized in one of two ways. Estrone can enter one pathway, a very feminizing pathway, by being hydroxylated to 16α-hydroxyestrone or estriol. Alternatively, the estrone can be metabolized to one of the catechol estrogens, 2-hydroxy or 2-methoxy estrone, which are less feminizing hormones (Lahita et al., 1981; Lahita, 1986). The change appears to have some importance for the normal physiology of the individual, and the amount of the products depends on the substrate amounts of estradiol. In the female the metabolism is likely to have profound effects, whereas in the male the overall effects of the lesser amounts of estradiol are unknown. An elevation of the 16-hydroxylated estrogens in the male results in adverse effects such as gynecomastia or decreased libido. Any significant change of estrone hydroxylation toward the catechol estrogens in the female will result in oligomenorrhea or osteoporosis. Factors such as smoking, diet, and the normal changes of pregnancy affect the direction of estrone metabolism (Fishman and Martucci, 1980; Michnovicz and Bradlow, 1991). Whereas smoking and dietary change might increase the metabolism of estrone toward the 2-hydroxylated compounds, pregnancy shifts the hydroxylation of estrone toward the very feminizing compounds.

One estrogen, 16α-hydroxyestrone, is feminizing, highly uterotropic, and modestly bound to cytosol receptors and testosterone/estradiol-binding globulin (TEBG) in contradistinction to compounds like 17β-estradiol (Fishman and Martucci, 1980). A radioimmunoassay, however, failed to show uniformly elevated levels of 16α-hydroxyestrone in all active SLE patients (Ikegawa et al., 1983). This suggested either that a conjugated form of this steroid was active or that there are other metabolites of importance to SLE that are not apparent. Enzymatic systems in certain animals might favor the formation of such compounds, although nothing is known about SLE mice with regard to the metabolism of estrone.

Clinical studies on the steroid 16α-hydroxyestrone show interesting properties *in vivo* that might explain its possible role in disease; these include covalent binding of this steroid to erythrocytes and lymphocytes via a Heyn's rearrangement *in vivo*, and the possibility that this covalent binding might occur at the level of the estrogen receptor or the TCR and result in an alteration of immune function (Bucala et al., 1982, 1984a, 1984b, 1987). Studies of family members of SLE patients indicated that elevated hydroxylation of estradiol was commonly observed in non-affected first-degree relatives as well as patients (Lahita et al., 1982) suggesting a genetic basis for this metabolic pathway.

Unaffected women who ingest oral contraceptives have enhanced binding of l6α-hydroxyestrone to various cell proteins (Bucala et al., 1987). Specific antiestrogen–protein adduct immunoglobulins are isolated from unaffected women and SLE patients ingesting oral contraceptives, which means that these adducts are common. This finding suggested a common pathway to adduct formation in all women who ingest large amounts of estradiol or for one reason or another have an endogenous high estrogen level (Bucala et al., 1987). Males with SLE were also reported to have hormone–protein adduct-specific IgG in their sera (Bucala et al., 1982)

Progestogens

Progesterone, like other steroids, has been considered as a therapeutic agent in diseases like SLE because it plays such a prominent role during pregnancy, a time of careful immunosuppression. This is because progesterone is an immunosuppressive agent (Clemens et al., 1979; Holdstock et al., 1982; Ashworth et al., 1990; Keisler et al., 1990), and its levels rise during pregnancy when the placenta assumes an active role in its synthesis and secretion. This steroid at concentrations of 10–15 mg/mL reduces lymphocyte responses to phytohemagglutinin and to concanavalin A *in vitro*. Other analogs such as 20α-hydroxyprogesterone have similar effects (Mori et al., 1977). Progesterone has been known to increase the relative amounts of $CD8^+$ suppressor T cells in humans and to decrease them in mice. In addition, progesterone has been invoked to explain many of the suppressive effects found in the sera of pregnant females (Van Vollenhoven and McGuire, 1994). A logical consequence of all these suppressive effects would be to facilitate acceptance of the fetal "graft."

Gonadotrophins

Prolactin is an immunomodulatory pituitary hormone and could be considered a cytokine itself. In the human, prolactin elevations have been observed in SLE juveniles and correlated with both disease activity and CNS manifestations (El-Garf et al., 1996). This finding is supported by in-vitro work showing IgG- and IgM-induced anti-DNA antibodies by both normal and SLE lymphocytes in the presence of high levels of prolactin. Lectins did not produce this effect (Gutierrez et al., 1996). One study correlates elevated prolactin levels with elevated cortisol levels (Neidhart, 1997; Dostal et al., 2002).

Women who are pregnant have higher serum prolactin levels if they have SLE (Jara-Quezada et al., 1991). Moreover, some investigators have associated the decline in serum testosterone during pregnancy in SLE patients with hyperprolactinemia. Perhaps, however, the most significant descriptions of hyperprolactinemia have been in men with SLE (Lavalle et al., 1987). This is of particular interest since hyperprolactinemia is readily treated with bromocriptine; however, studies using bromocriptine to treat SLE are not routine and data have been inconclusive (McMurray et al., 1995).

Many studies refute the significance of prolactin in human SLE (Buskila et al., 1996; Mok and Lau, 1996; Ostendorf et al., 1996). In a detailed study of a Chinese cohort of patients with SLE, Mok et al. (1997) found no correlation of clinical activity with levels of prolactin in 72 SLE patients. A look at autoantibodies in patients with SLE found no association of prolactin levels with specific SLE autoantibodies (Kozakova et al., 2000). One particular study suggests that prolactin is complexed with IgG but remains biologically active in the SLE patient (Leanos-Miranda et al., 2001a, 2001b). This binding of prolactin (a specific 23-kDa nonglycosylated form) to IgG is not covalent. Delayed clearance of this complex due to its high molecular weight is the proposed reason for the activity of the prolactin in most patients with SLE.

Many investigators associate prolactin with disease activity (Pacilio et al., 2001). In one study, 61.9% of patients with hyperprolactinemia had active disease. However, elevated prolactin levels are found in only 20–30% of patients with SLE in most clinics (Jara et al., 2001). The Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) correlated with the levels of prolactin in these patients as well when

prolactin levels were measured whether by tests of immunoreactivity or biological activity. Another series noted an association of hyperprolactinemia in the serum and urine of patients with severe renal disease (Miranda et al., 1998). The weak statistical power of most of these prolactin studies could explain the lack of consistency between research laboratories. One study suggests that the published results are contradictory due to the weakness of the statistical power of the studies. In fact, the authors reviewed five studies and found that two of the studies did not have the statistical power to conclude an association with SLE activity and prolactin levels, while the other three studies did suggest an association (Blanco-Favela et al., 1999). In addition to the suggestion that prolactin is itself a cytokine that provokes the synthesis of immunoglobulins by lymphocytes (Jacobi et al., 2001b), German investigators found using lymphocytes from SLE patients and measuring clinical activity with the European activity measure (ECLAM), that SLE patients have lymphocytes that are sensitive to normal levels of prolactin and likely to be activated by normal plasma concentrations (Jacobi et al., 2001a). These data are supported by the findings that T lymphocytes from SLE patients secrete more prolactin than controls, suggesting a difference in regulation of genes responsible for control of this cytokine. In fact, single nucleotide polymorphisms in the upstream promoter regions of both pituitary and non-pituitary prolactin secretion exist. Such polymorphisms that are specific could have affected prolactin transcription and possibly disease association in a cohort of SLE patients; this was the case in a study where patients had an increased frequency of the prolactin-1149G allele compared with control subjects (Stevens et al., 2001). Whether prolactin is a cytokine or is itself increased by cytokines common in certain active SLE patients requires major investigation.

Finally, prolactin levels of women who were pregnant or breastfeeding and had SLE were studied as reproductive risk factors for the development of disease (Cooper et al., 2002). Surprisingly, breastfeeding was associated with a decreasing risk of developing SLE. In addition, the numbers of pregnancies or live births with SLE activity showed no relationship to levels of prolactin. These authors found no association of elevated prolactin levels with an increased risk of SLE.

Sex Chromosomal Abnormalities and Autoimmunity

Autoimmunity is not common in patients with Klinefelter syndrome. In fact it is not correct to say that autoimmunity is more common in men who have the extra X chromosome (Fam et al., 1980; Lahita and Bradlow 1987; Gilliland and Stashower, 2000; Oktenli et al., 2002). There is a report of monosomy X in patients with primary biliary cirrhosis, and it is suggested that haploinsufficiency of specific X-linked genes leads to female susceptibility for primary biliary cirrhosis (Invernizzi et al., 2004).

SPECIFIC DISEASES AND THE EFFECTS OF SEX STEROIDS

Systemic Lupus Erythematosus

Sex steroids affect the severity of SLE (but they are also important in fibromyalgia or Hashimoto's thyroiditis), but a direct relationship between both androgen and estrogen metabolites with the severity of the disease, the production of antibodies, or the appearance of certain clinical signs in SLE has never been established. It is widely accepted, however, that estrogen does increase the severity of this disease (Petri et al., 1991). The basic observations found in SLE patients involve the hydroxylation of estrone and the oxidation of testosterone as mentioned above.

Rheumatoid Arthritis

Rheumatoid arthritis is also associated with hormone changes. As is the case with SLE, RA patients have low androgen levels (Cutolo et al., 1988). In many cases of RA, the signs and symptoms of disease coincide with the menstrual cycle (Latman, 1983), an observation that has also been made anecdotally in SLE patients. Exacerbations of RA occur during certain times in the menstrual cycle. This disease, multiple sclerosis, and thyroiditis are illnesses where this observation is made (Kim et al., 2004). Several observations about RA are not clear, namely the remission of RA in the pregnant woman and also the response of many patients and animal models to estrogen (Bijllsma et al., 1987; Spector et al., 1991).

Sjögren Syndrome, Antiphospholipid Syndrome, and Other Conditions

There are data from Sjögren syndrome to show that the levels of androgens in the tears of patients with the disease are low (Sullivan et al., 1990). The significance of this finding is not known.

New data from animals indicates that the withdrawal of estrogen promotes the infiltration of both kidney and salivary glands in mouse models and the development of a Sjögren-like syndrome. Experiments with aromatase-knockout mice show that those exposed to an estrogen-containing diet have no Sjögren-like changes or anti-fodrin antibodies (Shim et al., 2004).

The antiphospholipid syndrome, an autoimmune disease that produces a procoagulant condition, has no apparent

predilection for sex, although the secondary form of the disease affects more women than men.

AUTOIMMUNE DISEASE AND PREGNANCY

In pregnancy a semi-allograft is allowed to flourish for 9 months because of certain events that involve the immune system. Some aspects of pregnancy, fertility, and fetal health are dependent on normal immune function. This section will examine the role of pregnancy and autoimmunity. The immunology of pregnancy will be considered, followed by a review of the effects that the mother's immune system has on the fetus and the effects that the pregnancy has on the mother's autoimmune disease.

Immunology and Pregnancy

Neither spermatozoa nor the embryonic trophoblast express MHC class I or class II molecules (Johnson, 1993). This allows the trophoblast to avoid the immune system in the development of the fetus and also allows spermatozoa to gain easy entry into a charged ovarian milieu of cytokines and protective antibodies. Certain seminal proteins including transforming growth factor-β (TGF-β) act to suppress the immune response locally, while animal studies indicate that this cytokine increases the endometrial inflammatory response (Robertson et al., 1997). This inflammatory response could be responsible for the shift of cytokines from Th1 to Th2 in the pregnant state. This shift has theoretical and practical implications for both the mother and the fetus, since many of the autoimmune diseases like SLE are of Th2 cytokine character and RA or MS are predominantly Th1 illnesses (Raghupathy, 1997; Lim et al., 1998). The trophoblast is not without genetic identity since it expresses a unique MHC marker called HLA-G. This antigen is responsible for the protection of the trophoblast (VanVoorhis and Stovall, 1997). There is a population of natural killer cells within the reproductive tract that would easily destroy the trophoblast, were it not for the HLA-G MHC as well as the new cytokine milieu induced by TGF-β (Kovats et al., 1990; Carosella et al., 1996).

Other relevant immune functions such as apoptosis are essential to the normal pregnancy. The Fas ligand (FAS-L) is a part of the protective network for the fetus. The expression of this ligand allows for apoptosis of the mother's Fas-positive T cells, which in turn protects the fetus from total destruction by the mother's immune system (Makrigiannakis et al., 2001).

The role of complement in the pregnancy process is very important. There are complement regulation proteins that are expressed by the trophoblast that limit the activation of complement (Holmes and Simpson, 1992). In animals that lack these proteins, there is enhanced fetal loss. In animal models of the antiphospholipid syndrome (APS), complement is essential for fetal loss. In recent work, C3 is deposited in the placentas of affected APS animals whereas mice deficient in C3 were resistant to the lethal effects of APS (Xu et al., 2000).

As one might suspect, the Th1 cytokines are lethal to the pregnant female since Th2 cytokine profiles are the natural milieu for a normal pregnancy; for example, TNF-α induces apoptosis of the cells of the trophoblast (Yui et al., 1994). Besides the previously mentioned effects of TGF-β on induction of Th2 cytokines, both progesterone and PGE2 suppress Th1 cytokine production. This may be the reason for remission of disease in patients with RA (Hench, 1938). The role of the adhesins, such as annexin, are also important during pregnancy (Rand et al., 1998; Rand 2000). Specifically, annexin V, thought to be another target antigen for the antiphospholipid antibodies, shields the trophoblast from harm in the normal state. There are doubtless other glycoproteins within this family of adhesins that have importance (Aarli and Matre, 1998).

Infertility and Fetal Loss

Autoimmunity is intimately tied together with fetal loss and infertility (Wilson et al., 1975; Taylor et al., 1989). In fact, there is evidence that infertility is common in patients with autoimmune diseases (Roussex et al., 1996). One disease that is common to patients with infertility and is a harbinger of autoimmune disease is thyroiditis. Studies have shown that the thyroid peroxidase antibodies are commonly found in infertile women, and this may be the way that autoimmunity is defined in this population. Endometriosis and polycystic ovarian disease are two diseases of the gonads that have been associated with autoimmune phenomena (Gleicher et al., 1987; Gleicher and El-Roeiy, 1988; Gleicher et al., 1989; Gleicher, 1992). Endometriosis has been thought to be itself an autoimmune disease (Odukoya et al., 1995). Both of these illnesses are associated with autoimmune disorders. Interestingly, infertility is more common with organ-specific diseases like thyroiditis and less common in patients with diseases like SLE and RA, which are more systemic (Gerhard et al., 1991; Krassas, 2000).

Fetal loss is a common feature of both systemic and organ-specific autoimmune disease. However, RA, one of the most common autoimmune disease, is not associated with fetal loss. Patients with APS and SLE have more fetal loss than any other subgroup. Much of it depends on the activity of the disease in the mother at the time of conception. Growth retardation, pre-eclampsia, and multiple miscarriages are common with these two entities. The presence of antiphospholipid antibody leads to placental infarction, the suppression of annexin V, and has other direct effects on

the placental health; it is largely responsible for the fetal demise syndrome. Much of the latter pathology related to infarction has been obviated with anticoagulation during gestation; however, there are still other reasons for this increased fetal loss that await elucidation.

Disease activity in SLE is the principal cause of fetal demise in this group if they do not have secondary APS (Fraga et al., 1974; Petri et al., 1992; Petri, 1997). Parke suggests 6 months of disease remission prior to attempting conception (Parke, 1992).

Among those who have SLE and Sjogren syndrome, there are patients who have anti-Ro and anti-La antibodies that can be passed transplacentally to the fetus. Such antibodies can result in conditions such as neonatal heart block and transient neonatal lupus syndrome in offspring of mothers with these antibodies (Reed et al., 1983; Alexander et al., 1992; Buyon, 1992; Buyon et al., 1995) (See Chapter 71). In other conditions such as scleroderma, Graves' disease, and polymyositis in the mother, there will be a slight increase of infertility and fetal loss.

Effect of Pregnancy on the Mother's Disease

One of the most interesting aspects of autoimmune disease is the effect of pregnancy on conditions like multiple sclerosis and RA, where patients achieve a complete remission. Some 80% of patients who have RA and are pregnant have remission of their illness (Allebeck et al., 1984; Del Junco et al., 1985; Bijllsma et al., 1987; Berczi et al., 1989; Cutolo and Accardo, 1991). Early explanations for this remission suggested that estrogens like estriol were responsible for this remission. This was especially suggested by the fact that RA seemed to decrease in incidence with the widespread use of estrogen-containing oral contraceptives (Allebeck et al., 1984; Rook et al., 1990). This was not a long-lived hypothesis, however, and most experts note that the remission continues into the postpartum period, when the hormone surges observed during the pregnancy are no longer applicable. The epidemiologic effects of this protective effect are difficult to prove. Exposure to oral contraceptives but not hormone replacement therapy reduces the risk of developing RA. This is particularly true if the exposure to the hormones occurs in a woman's early years (Doran et al., 2004). The Th1 cytokines have been suggested as reasons for this remission; however, no definitive data on this exist (Wingrave and Kay, 1978; Kanik and Wilder, 2000; Weidler et al., 2004).

Another condition that remits during pregnancy is Graves' disease which, as with all other autoimmune diseases, can return with a vengeance after parturition (Kung and Jones, 1998; Badenhoop, 2004). Moreover, thyroiditis is common in women with autoimmune disease and can occur after parturition and cause hypothyroidism. This hypothyroid state can become permanent. Multiple sclerosis might also remit with pregnancy, but like RA can recur after parturition. Interestingly, there are new data to suggest that in mice estradiol might cause remission of the model disease experimental autoimmune encephalomyelitis (Polanczyk et al., 2003). This remission is dependent on a form of the estrogen receptor, estrogen receptor-α, and indicates a real role for sex steroids. The suggested reason for this improvement is the effect of the estriol on the down-regulatory cytokine IL-10.

There is much controversy over the effects of pregnancy on SLE. Petri and Ruiz-Iraslorza (Ruiz-Irastorza et al., 1996) indicate that the flare rates of the disease in patients who are pregnant are significantly higher than control patients with SLE who are not pregnant. This is supported by data from others as well (Khamashta et al., 1997; Cooper et al., 2002). Patients who have SLE require immunosuppression if their disease becomes active during gestation. Patients who have secondary APS associated with SLE must also be considered for anticoagulation to prevent fetal loss, as well as continued immunosuppression.

Microchimerism and Autoimmune Disease

There is a phenomenon called microchimerism, which is associated with the onset of SLE, scleroderma, and thyroid disease (Nelson, 1996). It is included here under pregnancy and autoimmune disease because it has relevance to the mother, and includes the fetus and gestation. This is essentially the presence in the circulation of women who have autoimmune disease of cells that belong to an offspring (Galliard et al., 1997). The interesting aspect of this condition is that the offspring could have been born many years before the onset of the mother's illness, meaning that the fetal cells persist for many years in the mother's circulation. Similar conditions have been proposed for host-versus-graft disease in both animals (Feikje et al., 1982; Kuppers et al., 1988) and recipients of allogeneic bone marrow transplants.

Chimerism is normally linked to host-graft tolerance induction. It can induce autoimmunity, however, as in early mouse models of the disease. There is now evidence that the presence of fetal cells in the mother induces a host-versus-graft, and this in turn induces autoimmune disease (Johnson et al., 2001).

SUMMARY AND CONCLUSION

Both sex hormones and pregnancy greatly affect the immune system in many ways. Androgens, estrogens, and gonadotropins have effects on antigen presentation, the synthesis of cytokines and chemokines, and, consequently, the function of various cell types within the immune system.

The fundamental answers about why women predominate with diseases of the immune system are not known. However, much insight comes from both animal and clinical models of disease.

BACKGROUND

Emerging Knowledge Gaps in Understanding the Pathogenesis of Autoimmunity

Despite intensive research over the past decades, there are some crucial elements in human and animal autoimmunity that we do not comprehend yet. One major one is the nature of the initiating autoantigens and precipitating events (Bach et al., 1998) and for most major autoimmune diseases we cannot precisely define the targets of the initial autoimmune response, exceptions being gluten hypersensitivity (Lundin et al., 1993) and pemphigus vulgaris (Veldman et al., 2004). However, difficulties in defining the primary initiating autoantigen(s) pertain not only to human disease but also to animal models of autoimmunity, such as the nonobese diabetic (NOD) mouse where we can readily access the target organs (Bach et al., 1998, Horwitz et al., 2002). Novel approaches to identify instigating autoantigens and the nature of the early autoimmune response may require novel high-throughput technologies. Identifying autoaggressive T-cell specificities on an individual basis will be crucial. The heterogeneity in individual T- and B-cell repertoires even in inbred mice is likely responsible for the fact that only very rarely do all individuals of a given inbred mouse strain exhibit the same course and severity of disease (Sercarz, 2000). Deciphering of underlying heterogeneity in autoreactive repertoires will be key to understanding and predicting development of autoimmune diseases. Real-time imaging and selective detection technologies, potentially relying on high-throughput proteomic approaches, are being developed to overcome this impasse (Robinson et al., 2003). Thus, heterogeneity in individual repertoires might result in differential recognition patterns of autoantigens, which impede the recognition of autoantigens that are always targeted. However, we have defined a relatively large number of self-antigens for many diseases, which has been possible by analyzing specificities of autoantibodies and, more recently, by using knockout technology (Eisenbarth et al., 2002; Greeley et al., 2002; Moriyama et al., 2003; Robinson et al., 2003; Mantegazza et al., 2004).

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

An additional factor that interferes with the identification of the initiating autoantigens is antigenic spreading that occurs during disease progression. Both human and animal studies indicate that once an autoimmune process has been initiated, there is a rather rapid increase in the number of autoantigenic targets (Katz-Levy et al., 1999; Croxford et al., 2002). It is unclear whether tolerizing "driver" clones would be sufficient to reverse an ongoing autoimmune process and have therapeutic value. Restricted T-cell receptor (TCR) usage in pancreatic-draining lymph nodes of diabetic individuals must be investigated to understand whether a few clonally expanded T cells can cause destruction of the pancreatic islets. Recent investigations suggest a striking oligoclonality, which might make deletional immunotherapy using one or a few autoantigenic determinants feasible (Hafler et al., 2005). This concept is supported by the fact that only a few antigen-specific cytotoxic T cells (2/100 islet-infiltrating $CD8^+$ lymphocytes) are required to initiate diabetes to a defined autoantigen expressed in β cells in a transgenic diabetes model (Christen et al., 2004).

In the immunogenetic arena, animal models have provided useful insights. For diseases that are determined by one or a few genes, and where no major epigenetic factors are involved, we have learnt much from immunodeficient animals as well as humans. However, in some cases the respective human immunodeficiency will yield a different phenotype than the genetic knockout mouse, i.e., ICOS, IRAK (Medzhitov et al., 1998; Dong et al., 2001; Grimbacher et al., 2003; Puel et al., 2004), illustrating differences between men and mice that are likely linked to epigenetic and environmental factors. For example, ICOS deficiency in humans has immunologic consequences that are found in some patients with common variable immunodeficiency. In contrast, the ICOS-deficient mouse has a rather uniform phenotype involving immune deviation of T-cell responses and their cytokine production, as well as effects on B-cell function. Overall, comparison between mouse models and the humans deficient in respective genes greatly contributes to our understanding of autoimmunity (AIRE, fox-P3, CD25) (Sakaguchi et al., 1982; Anderson, 2002; Ramsdell and Ziegler, 2003), even if complete phenotypic homology between knockout mice and the respective human genetic deficiency is lacking. Unfortunately, we can be certain that one single genetic defect or polymorphism will not be the cause for most human autoimmune disorders. We have learnt recently that the far more common scenario is a substantial degree of polygenic complexity involving many protective and predisposing genes that act in concert, leading to disease manifestation in a fraction of their bearers. For example, in addition to major histocompatibility complex (MHC) class II molecules that are found in significant association with several autoimmune diseases in mouse models and humans i.e. multiple sclerosis (MS), type 1 diabetes (T1D), rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), other genetic factors with rather low LOD-scores (McDevitt, 1998; Todd and Wicker, 2001; Weber et al., 2003; Bielekova et al., 2004) contribute to the expression of autoimmune disease. Frequently, these associations are weak enough to allow for the possibility that environmental factors in addition to genetic ones determine penetrance of disease (Bielekova et al., 2004). In addition, frequently the genes or regions that are connected more weakly with a given disease functionally point towards immunologic mediators that are already known and whose effect on pathogenesis has been well studied, i.e. the interleukin 2 (IL-2) locus and polymorphism in cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) genes that are associated with T1D (Lyons and Wicker, 1999; Hill et al., 2000; Ueda et al., 2003; Tabeta et al., 2004). Therefore, immunogenetics in animal models is at an important crossroads: seeking direct relevance to the human disorder becomes very important, and the assumption that there is a necessity to identify genetic defects in animal models in order to obtain the best pathways to cure human disease may not be correct. Indeed, in today's medicine, there is little evidence that the optimal treatment for a given disease is always the elimination of its cause. Immunogenetics in animal models might still help the adoption of novel predictive strategies and subclassifications for autoimmune diseases, which might in the future allow for more individualized treatments. However, genetic studies carried out in humans become of paramount importance. Future promising strategies involve large-scale haplotype mapping initiatives in humans (van Heel et al., 2004). In addition, reverse genetic approaches carried out in animals can define novel genetic causes for diseases, since this approach is a phenotype- rather than a genotype-driven screening approach (Tabeta et al., 2004).

Animal models have helped us understand the complexity of biologic processes and be cautious in predicting the limitations of therapeutic interventions in humans. For example, in T1D, there are many different pathways to kill β cells. If one of them is inactivated (i.e., perforin or interferon-γ knockout), others will take over. The consequence is that it will be very difficult to engineer a "death-defying" β cell that could be used for islet transplantations, since too many death pathways have to be eliminated in order to achieve resistance to immune destruction (Thomas and Kay, 2001).

Animal Models—Advantages and Disadvantages

As illustrated in Box 26.1, there are several areas of investigation, where we have learned much from animal models. The first is investigation of immune responses at different locations. This is particularly important for under-

Box 26.1
What can animal models teach us that we cannot learn otherwise?

- *In vivo* immune kinetics at **sites that are difficult to access** in humans.
- **Proof of concept** using techniques that cannot be used in humans, i.e., adoptive transfers, genetic knockouts, conditional knockouts, etc.
- Large-scale assessment of **dose range, toxicity,** and immunization sites in drug and vaccine development.
- *In vivo* events that would never have been anticipated.

standing autoimmune diseases that frequently affect certain sites, cell types, or organs. Second, it is difficult to establish proof of concept in humans. Lastly, of course, the use of animal experimentation is at this point frequently indispensable to defining dose ranges and regimens for immunotherapies.

How far reaching should the conclusions that we draw from observations in a given animal model be? The prevailing attitude is still that once a discovery has been made in one of the animal models thought to faithfully represent the human disease (i.e., the NOD mouse for diabetes, EAE model for MS or NZB mouse for SLE) there is no urgent need to look at this issue in other model systems. If the same result is found, it is considered "confirmatory", if a different result is discovered, the "secondary" model is frequently labeled as not-as-good or even flawed, for which then various reasons are cited. This, we believe, can be treacherous and may hamper translation of research performed in animal models, because our pathogenetic insight into human diseases is often still rather limited due to ethical constraints. For example, only about 10% of patients with T1D exhibit the same clinical features as the NOD diabetic mouse, which is characterized by a polyglandular autoimmune syndrome affecting thyroid, salivary glands, and testes (Atkinson and Leiter, 1999; Roep et al. Nature Reviews Immunology 2004). However, there are also striking similarities between NOD and human diabetes, for example, the occurrence of autoantibodies that precedes the development of clinical disease in NOD mice and humans (Pietropaolo and Eisenbarth, 2001). Another caveat in directly applying scenarios from animal models to humans is the MRL-lymphoproliferation (lpr) mouse. The lpr mutation in the MRL mouse results in autoimmunity that is perfectly correctable by transfer of the Fas gene. Yet, defects in Fas expression and Fas-mediated signaling leads to autoimmune lymphoproliferative syndrome (ALPS) in humans (Silvestris et al., 1996; see also Chapter 70). Similarly, the generalized lymphoproliferative disease (gld) mutation (defective FasL expression) in mice leads to systemic autoimmunity, yet only very rare patients with SLE have a mutation in the FasL gene (Lin et al., 2004). It follows that we should elevate the importance of validation of crucial findings in other model settings.

ANIMAL MODELS FOR ORGAN-SPECIFIC AUTOIMMUNE DISEASES

Animal Models of Spontaneous Organ-Specific Autoimmunity

The widely utilized NOD mouse expresses multiple autoimmune features in various organs—sialitis, T1D, orchitis, thyroiditis (Atkinson and Leiter, 1999)—and is prone to develop other autoimmune disorders including autoimmune hepatitis in NOD congenics (Ridgway et al., 1999), EAE (Winer et al., 2001; 2003), neuritis in NOD 86 (B7.2) deficient strains (Salomon et al., 2001). It was discovered in Japan and exhibits spontaneous diabetes penetrance of 20–100% depending on the environment (see Chapter 36). In addition, females develop diabetes about four times as frequently as males. In contrast to most patients with diabetes, the NOD mouse develops multiglandular and other organ-specific autoimmunity. The immunologic causes for diabetes development are uncertain, but the genetics of the NOD has been studied extensively and is strikingly similar to the genetics of human T1D (Lyons and Wicker, 1999), particularly in MHC class II molecules linked to disease expression (McDevitt, 2002). In addition, susceptibility loci that contain, among others, the genes for IL-2 and CTLA-4 have been linked to disease or protection. In the case for CTLA-4, polymorphisms have been described in the NOD mouse that might play a similar role in the human disease. However, in both humans and NOD mice, environmental factors strongly influence disease expression. Monozygotic twins exhibit discordance in T1D penetrance, and NOD mice do not develop diabetes unless they are kept under specific pathogen-free (SPF) conditions. Current investigations indicate that viral infections can have both enhancing and protective effects in T1D animal models (Christen et al., 2004) and a large-scale investigation to define potential associations with infectious events or their absence is under way in humans (Graves et al., 2003).

Immunologically, it is still unclear to what degree NOD mice and humans with T1D are similar. The appearance of autoantibodies predicts the risk to develop islet autoimmunity and, in many cases, T1D on an individual basis; the antigens targeted, however, differ that for NOD mice autoantibodies almost exclusively recognize insulin, whereas anti-GAD and anti-IA2 are present in humans (Eisenbarth, 2003). T lymphocytes with a Th1-like profile correlate with destructive insulitis in the NOD and, as reported more recently using a panel of pro-insulin peptides, also in humans (Arif et al., 2004). However, the question of

which features characterize an "optimal" autoaggressive T cell is not resolved. Transfer studies in the NOD model have shown that Th1 as well as Th2 cells can cause disease in immunodeficient NOD/SCID or NOD/RAG hosts, when sufficient cell numbers are transferred (Pakala et al., 1997). There may be a determining factor that will always correlate with autoaggression, or the destructive immune response may be adaptable and able to use multiple pathways to destroy β cells, which seems the more likely answer (Kay et al., 2003). The situation is not that different for the responses of regulatory T cells (Tregs). Regulatory T cells are thought to control most immune responses and can be antigen-induced (adaptive) or spontaneous (likely autoantigen specific and mostly characterized by constitutive CD25 expression). In NOD mice, such cells can protect from diabetes, but until now only when cotransferred into immunodeficient recipients together with diabetogenic T cells. This is not the case in other animal models and their antigen-specific induction and transfer in immune competent hosts has been described (see below). In human T1D, lymphocytes with increased IL-10 production in response to autoantigens have been found in healthy but not prediabetic or diabetic individuals, indicating the possibility of autoreactive regulatory or beneficial responses (Peakman et al., 2001). Indeed, such physiological autoreactivity might be essential to maintain self-tolerance in healthy individuals. Overall, the predisposition to autoimmunity in the NOD mouse could also be linked to defective thymic selection and/or presentation of autoantigens in the thymus (Sprent and Surh, 2003; Stratmann et al., 2003). Here, mechanistically, the predisposing MHC class II allele may also play a role by possibly insufficiently presenting self-peptides, resulting in suboptimal elimination of a variety of autoreactive T-cell specificities. Indeed, autoantigens and their variants that are targeted by the aggressive organ-specific response might be characterized by insufficient expression in the thymus, which has been observed in several animal models as well as humans (Pietropaolo et al., 2002).

Genetic Engineered Animal Models for Organ-Specific Autoimmunity

Genetic engineered defects involving the systemic deficiency or overexpression of a distinct molecule will rarely result in a disease that is limited merely to one or a few target organs. Systemic knockouts that "take the brakes off" the immune system such as foxp3 (defective Tregs), AIRE (defective thymic negative selection), Cbl-b (defective signaling), lpr (defective lymphocyte elimination), TGF-β (defective regulation) usually result in disease affecting multiple organs and are, therefore, discussed under the respective section in systemic autoimmune diseases (Anderson et al., 2002; Gorelik and Flavell, 2002; Walker et al., 2003; Liu, 2004). There are, however, a few exceptions, one being the CD86-(B7.2)-deficient NOD strain (Salomon et al., 2001). The autoimmunity that is usually directed towards the pancreatic islets in the NOD was redirected to attack peripheral nerves, resulting in neuritis. The reason may be altered local regulation of costimulatory molecules as well as defective thymic selection, resulting in higher levels of naïve T cells that can recognize neuronal antigens.

In summary, although systemic immune defects will more likely lead to more severe autoimmunity affecting multiple organs, there are exceptions to the rule. In humans, a combination of genetic factors leads to an overall predisposition state, yet not to actual clinical disease. Then, manifestation of organ-specific autoimmunity may occur after a local inflammatory insult, either a virus infection (Von Herrath et al., 2003) or other events that could lead to expansion of autoaggressive T cells (Von Herrath, 1996).

Animal Models for Induced Organ-Specific Autoimmune Diseases

Among many antigen-specific models for diabetes and other organ-specific autoimmune disorders are those based on transgenic technology to express a defined autoantigen under the control of a tissue-specific promoter—e.g., the rat insulin promoter (RIP) to direct expression to β cells (von Herrath et al., 1994); the keratin promoter to direct expression to the skin (McGargill et al., 2002); myelin basic protein (MBP), neural-specific enolase (NSE), or glial-fibril acidic protein (GFAP) promoters to achieve expression in the brain, liver, or eye (de la Torre et al., 1993; Rall et al., 1995; Evans et al., 1996). For diabetes, examples include the mouse models RIP-Tag (large T-antigen from SV40 virus), RIP-Ova (ovalbumin), RIP-HA (influenza hemagluttinin) and RIP-LCMV (lymphocytic choriomeningitis virus-derived proteins) (Ohashi et al., 1991; von Herrath et al., 1994; Forster et al., 1995; Kurts et al., 1996; Murtaza et al., 2001). Such antigen-specific models have the advantage that the initiation of the autoaggressive response can be defined precisely, and at least the initial autoaggressive "driver" T cell is known. Notably, immunization with the protein antigen does not lead to diabetes in any of the RIP-antigen models. In some models, infection with a virus expressing the self-protein (transgene) or immunization in conjunction with Toll-like receptor (TLR) stimuli leads to T1D reliably (RIP-LCMV mice), whereas in other situations, tolerance cannot even be broken by viral infection (RIP-HA). In these cases, adoptive transfer of activated T cells is necessary to elicit disease (T1D), which works well in RIP-HA and Rat insulin promoter transgenic mice that express membrane-bound Ova under control of the rat insulin promoter (RIP-mOva). Overall, these antigen-induced diabetes models have been very useful to address a variety of defined questions.

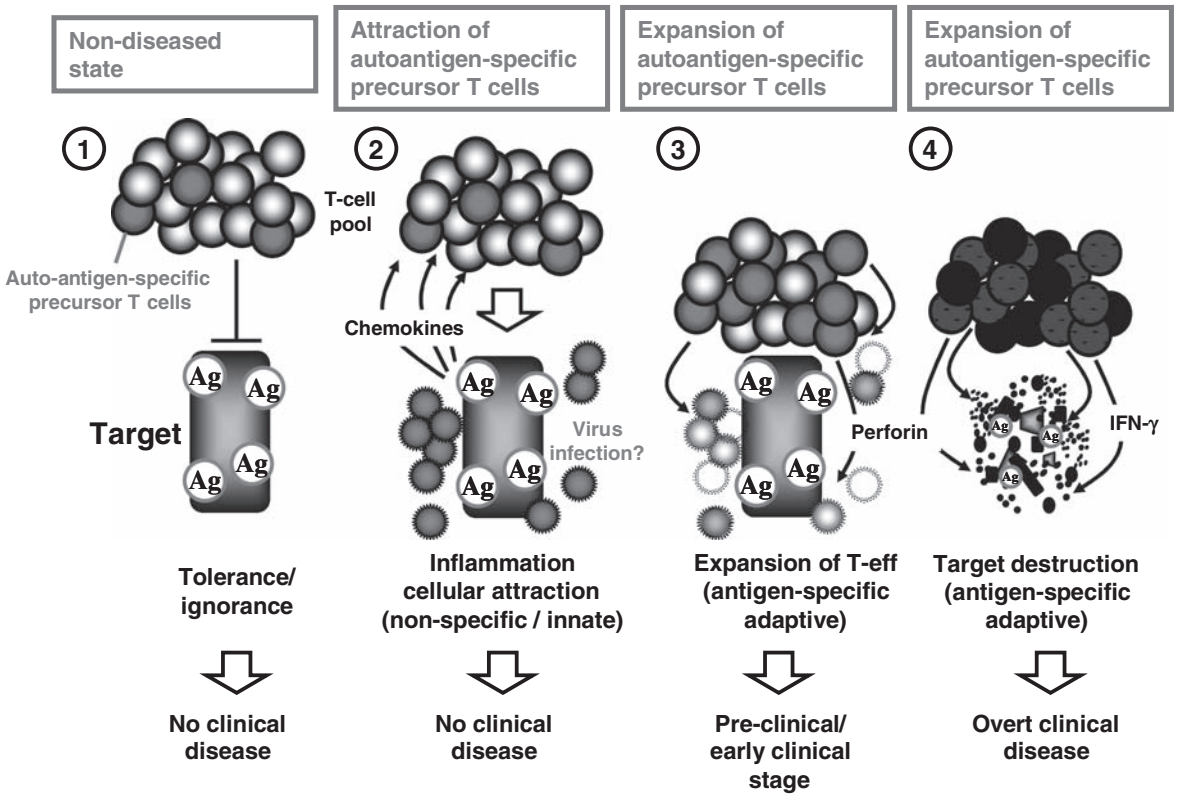

FIGURE 26.1 Pathogenesis of organ specific autoimmunity. For organ-specific autoimmunity one can assume that the initiating events might be antigen non-specific or specific. (1) A combination of genetic and environmental factors might lead to the breaking of self-tolerance and activation of autoreactive T cells. (2) Further inflammation might attract more such cells, for example, if a virus persists or autoantigens are being presented in a chronic manner. Certainly, activation of T-cell receptors and antigen-presenting cells will serve to propagate disease. (3) The ultimate outcome is determined by the magnitude and class of the autoreactive response. Many aggressive T cells, such as cytotoxic T cells and Th1 lymphocytes, will enhance progression, whereas the presence of (autoreactive) regulatory T cells (Tregs) will dampen inflammation. (4) Penetrance of clinical disease is directly correlated with the amount of target cell (organ) destruction and is determined by this balance of Tregs to aggressive T cells. Ag, antigen; IFNγ, interferon γ; Teff, effector T cell. See color plate section.

1. *Breaking tolerance to an autoantigen* is a "numbers game" and $CD8^+$ cytotoxic T lymphocytes (CTLs) can eliminate target cells such as keratinocytes or islet β cells, when activated and able to enter the organ in sufficient numbers (Figure 26.1). Interesting differences emerge here for different target organs that express the same antigen: the pancreas and skin more readily show clinical signs of autoimmunity, but the brain appears to be capable of suppressing activated autoaggressive T cells, even after they cross the blood–brain barrier, as evidenced by mild disease in MBP-LCMV-Ag transgenic mice despite intracerebral infiltration (Evans et al., 1996). $CD4^+$ help and local expression of the costimulatory CD80 (B7.1) can both reduce the requirement of $CD8^+$ cells to elicit disease, as can immunomodulatory approaches that either dampen regulatory components or enhance the lifespan (i.e., decrease apoptosis) of autoaggressive $CD8^+$ lymphocytes (von Herrath et al., 1994; 1995; Christen et al., 2001b; 2004). These rules appear generally applicable to various models. Thus, induction of organ-specific autoimmunity can be expected to follow quantitative rules and reduction of autoaggressive T cells beyond a certain threshold level will abrogate disease development.
2. *Inflammation within any specific target organ* (e.g., the pancreas, brain, eye or skin) induced by means of a local viral infection (von Herrath and Holz, 1997; Horwitz et al., 2002) can activate macrophages and "set the stage" for further development of disease. Thus, breaking of tolerance might require the association with localized specific or non-specific inflammatory processes that could have, in addition to viral infections, a variety of other causes. In some models it was demonstrated that viral recombinants that express autoantigenic mimics can aggravate disease in an antigen-specific direct way (Olson et al., 2001). In other situations, there may be activation of antigen-presenting cells that then increasingly present autoantigens (Horwitz et al., 1998). However,

viral infections can under certain conditions even protect from autoimmunity. Infection of prediabetic RIP-LCMV and NOD mice with Coxsackie virus or LCMV prevents disease in most scenarios. Hence, the autoimmune response can be redirected through an inflammatory insult, which is at least in part due to recruiting aggressive lymphocytes away from the islets (Christen et al., 2004).

3. *Regulatory cells* can prevent autoimmune disease. Using antigen-specific models one can clearly delineate the concept of bystander suppression, namely that a Treg with one antigenic specificity can downmodulate aggressive T cells with other antigenic specificities (Figure 26.2). This concept will, in our opinion, be instrumental in antigen-specific immunotherapy (Homann et al., 1999). The route of self-antigen administration to induce bystander suppressor autoreactive Tregs appears important. Oral or nasal routes induce regulatory cells more readily in various models. In this context, it is important to distinguish between direct elimination of aggressive T cells specific to the antigen used for immunization, and the induction of autoreactive regulators that can then act as bystander suppressors of a variety of antigen specific responses. Strategies that aim at eliminating or tolerizing autoaggressive T cells with specificity for one single antigenic epitope include high-dose tolerance (Vandenbark et al., 2000), the injection of 1-ethyl-3-(3-dimethylaminoproypl)-carbodiimide (ECDI)-coupled splenocytes (currently being investigated in clinical trials), and the coupling of toxic molecules to MHC tetramers or dimers. These strategies will be effective, if autoimmunity in a given individual is caused only by one or a few autoaggressive driver clones (Sercarz, 2000), or antigenic spreading has not progressed far (early in preclinical autoimmunity). In contrast, there will be a need for bystander suppression when T-cell populations with multiple autoaggressive specificities act in concert, and it might be necessary to dampen many to see an effect. At this point, it is not clear yet whether autoimmune processes are driven by a few or many specificities.
4. *Death of the target cells* (see also point 3). A close look at many of the antigen-specific autoimmune models suggests that the destruction of the attacked cell type or organ can occur via a variety of pathways that are not

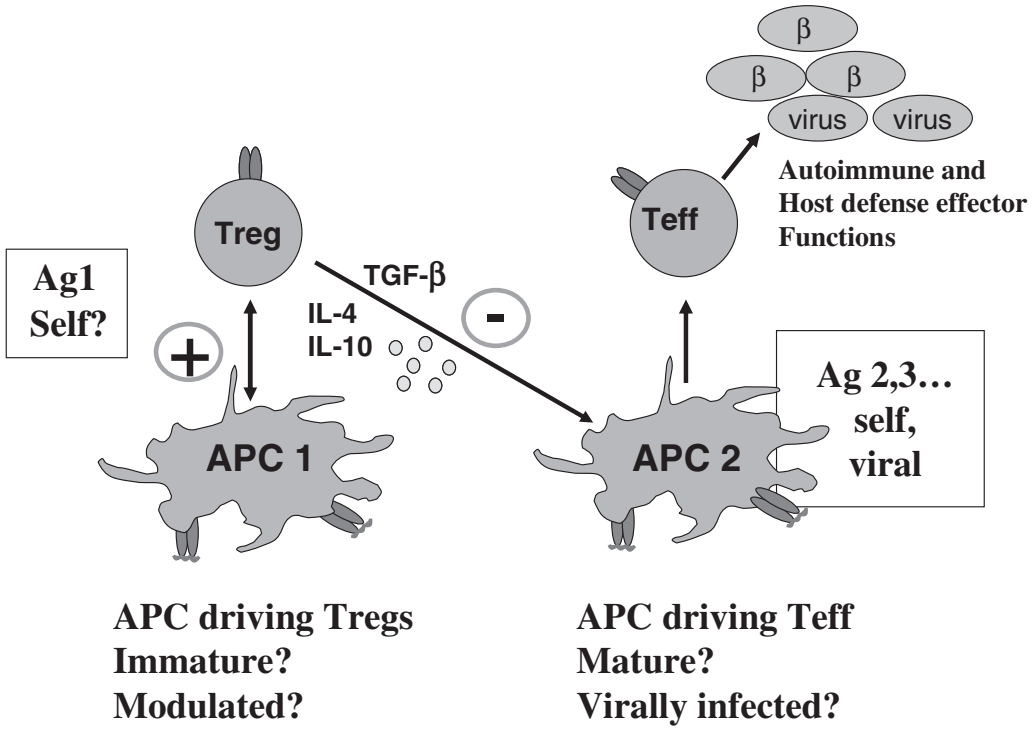

FIGURE 26.2 Regulation in autoimmunity: bystander suppression and the "drivers" of regulatory cells (Treg) and effector cells (Teff). Bystander suppression proposes that an autoreactive Treg with one specificity (Ag 1) can downmodulate autoaggressive Teff with different antigenic specificities (Ag 2, 3 . . . etc). Perhaps immature dendritic cells (DCs) favor Treg activation, whereas fully matured DCs favor Teff activation (see Chapter 4). In addition, Tregs might be set at different numeric levels *in vivo* varying in different disease stages and adaptive regulatory (Treg) function should be viewed in the context of the pathogenesis of the disease. Thus, each organ-specific autoimmune disease might have an optimal antigen-induced Treg, which is defined by the precise profile of effector cytokine or chemokine molecules secreted. Ag, antigen; APC, antigen-presenting cell; IL, interleukin; TGF-β, transforming growth factor-β.

mutually exclusive. In addition, the autoaggressive response exhibits plasticity in the sense that blocking of one specific effector arm, e.g., killing of CTL by Fas or perforin or inflammatory cytokines, will result in the emergence of alternative pathways.

How Do Animal Models Compare to Human Organ-Specific Autoimmune Disorders?

Every model will reflect certain aspects of the human disease and for this reason will be suited for some but not all of the scientific questions. Two examples of this are T1D and MS.

Type 1 Diabetes

One has to acknowledge that there is no conclusive proof that the cause for T1D in humans is (always) autoimmune, because autoantibodies found in almost all patients seem not to be necessary for disease development as evidenced by earlier plasmapheresis experiments, and the disease can occur in the absence of B lymphocytes (Martin et al., 2001). In addition, there is no association between maternal autoantibodies to islet antigens and diabetes incidence in offspring, unlike in the NOD model (Greeley et al., 2002; Ziegler et al., 2002). Therefore, perhaps the initiating events in human T1D and also major parts of the pathogenesis are not autoimmune in nature. Certain MHC class II alleles predispose to T1D, but genetic predisposition cannot alone explain development of disease (although it might fully explain autoimmunity), and other environmental factors have to be present as well (Gale, 2002) including viral infections and other, possibly epigenetic, factors. So, the NOD model resembles human T1D in many but not all aspects. In addition, it probably exhibits insufficient stringency to vigorously test immune-based interventions: some 190 interventions can prevent T1D in the NOD mouse when given early enough, but many have been unsuccessful in humans. Consequently, we should experimentally increase the stringency of the animal model test, and evaluate potential candidate interventions, both in NOD mice with recent-onset diabetes and in other diabetes models (see Chapter 75).

Multiple Sclerosis

In striking similarity to the NOD model for T1D, more than 90% of research on MS utilizes the EAE model. Just as virally-induced models are claimed to not reflect human disease faithfully, since we are not certain that a virus causes MS, we can be certain that immunization with myelin extract or peptides in conjunction with pertussis toxin and Freund's adjuvant does not cause human MS. Thus, we need a more open attitude towards alternative models that might highlight different and potentially important aspects of the human disease.

ANIMAL MODELS FOR SYSTEMIC AUTOIMMUNE DISEASES

Animal models have greatly facilitated the study of systemic autoimmune diseases, notably SLE and RA, and helped to develop rational new treatments (Figure 26.3).

Spontaneous Models of Systemic Autoimmunity

Murine models that develop spontaneously SLE have generated significant information on the role of hormones in the expression of autoimmunity (Fernandes and Talal, 1986; see Chapter 25); the contribution of aberrant immune regulation (Theofilopoulos and Dixon, 1985); the role of cytokines, chemokines, and adhesion molecules (Handwerger et al., 1994) in the expression of the disease; and, lastly, they have been used to identify loci that contribute to the genetic pool required for the development of disease (Drake et al., 1995; Choubey and Kotzin, 2002; Theofilopoulos and Kono, 2002; see Chapters 20 and 21). Gene complementation studies have shed light on the epistatic interactions of genes (Wakeland et al., 1997; Morel and Wakeland, 1998). Candidate genes have been identified including those of the CD2 family, the interferon (IFN)-inducible genes (Rozzo et al., 2001) and the complement receptor gene Cr2 (Boackle et al., 2001). These results have shown that introduction of an IFN-α/β receptor null gene into the NZB mouse results in decreased production of anti-erythrocytic antibodies (Santiago-Raber et al., 2003). Since IFN-α has been found to be increased in patients with SLE and to promote dendritic cell maturation (Blanco et al., 2001), a case can be made for the construction of biologics to limit the action of type 1 IFNs in systemic autoimmunity. Moreover, identification of contributing genes and loci in animal models has guided the search for orthologs in humans with systemic autoimmune diseases (Tsao et al., 1997; 2002; Gaffney et al., 1998; 2000; Harley et al., 1998; Moser et al., 1999).

The NZB (H-2^d) mouse develops anemia due to anti-erythrocytic antibodies. When crossed to the NZW (H-2^z), systemic autoimmunity ensues with anti-DNA antibodies and severe glomerulonephritis. The decreased average lifespan of these mice is 8 months for females and 13 months for males (Vyse et al., 1998; Ibnou-Zekri et al., 1999).

The MRL mouse, which has two doses of the lpr mutation and develops accelerated autoimmune disease, has allowed identification of genes whose products are central to expression of systemic disease. For example, while deletion of the cyclin-dependent kinase inhibitor p21 does not lead to autoimmunity (Lawson et al., 2002), transfer of the p21 null gene into the MRL$^{lpr/lpr}$ mouse results in reduced autoimmune disease by allowing T-cell death and

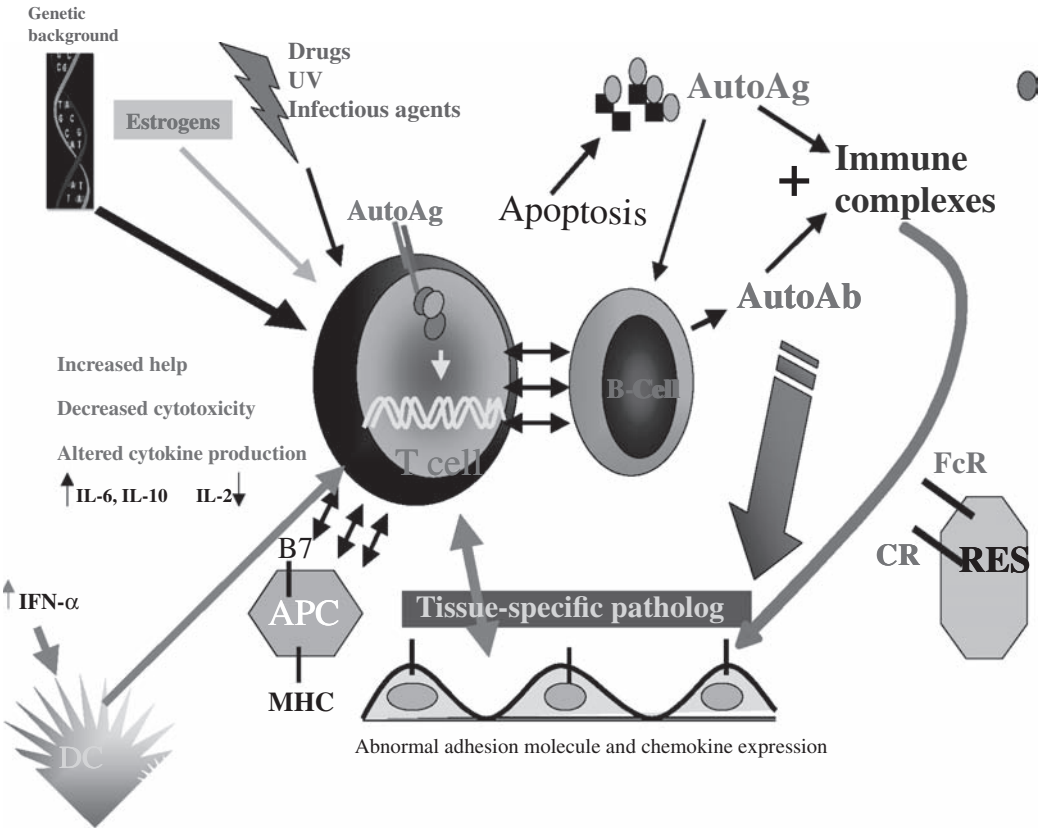

FIGURE 26.3 Pathogenesis of systemic autoimmunity compiled from studies on mice and humans with systemic lupus erythematosus (SLE). Similar to organ-specific autoimmunity, systemic autoimmunity is a function of a deleterious combination of genetic and environmental factors that lead in concert to the loss of self-tolerance. For example, certain genes such as CD40 ligand may be overtranscribed, whereas others, e.g. IL-2, may be undertranscribed. T cells may display numerous aberrations in the form of defective cytotoxic responses, defective immunoregulatory function, and increased ability to provide help to B cells to produce autoantibodies (AutoAbs). In systemic autoimmunity, autoantibodies are frequently directed against nuclear antigens, with which they form immune complexes. Defective clearance of such immune complexes is the result of defective expression and function of Fc and complement receptors, and increased levels of nuclear material may propagate the autoimmune response. Lastly, humans and mice with SLE have defects in the expression and function of costimulatory molecules and interferon-α (IFN-α) appears to be over-expressed, which stimulates dendritic cells and enhances autoantigen presentation. APC, antigen-presenting cell; AutoAg, autoantigen; DC, dendritic cell; IL, interleukin; MHC, major histocompatibility complex; UV, ultraviolet radiation. See color plate section.

decreasing the accumulation of G0/G1 arrested cells (Lawson et al., 2004).

Male only BXSB mice develop severe glomerulonephritis and autoantibodies. The genetic locus responsible for the expression of the disease is located in the Y chromosome and is known as Yaa (Y-chromosome accelerated autoimmunity). The disease is heavily dependent on the presence of the H-2^b allele, because its replacement with the H-2^d allele results in prolonged survival. Of interest, the BXSB × NZW F1 mouse develops thrombocytopenia and coronary artery disease accompanied by the presence of antiphospholipid antibodies (Kono and Theofilopoulos, 2002).

Palmerston North (PN) mice develop spontaneously autoimmunity manifested by the production of multiple autoantibodies, vasculitis and glomerulonephritis. PN × NZB F1 mice develop more severe disease (Luzina et al., 1999, Handwerger et al., 1999).

Mice homozygous for the ank mutation. ank/ank mice develop early-onset joint ankylosis in the spine and peripheral joints resembling spondyloarthropathies (Krug et al., 1989).

K/BxN T-cell receptor mice, a spontaneous mouse model of autoimmune arthritis, generated fortuitously by crossing a TCR transgenic line with the NOD strain (Monach et al., 2004), all spontaneously develop an autoimmune disease with most (although not all) of the clinical, histologic, and immunologic features of RA in humans. The murine disease is critically dependent on both T and B cells and is joint specific, but it is initiated and perpetuated by T- and B-cell autoreactivity to a ubiquitously expressed antigen, glucose

phosphate isomerase (GPI). Transfer of serum (or purified anti-GPI immunoglobulins) from arthritic K/BxN mice into healthy animals regularly provokes arthritis within a few days, even when recipients are devoid of lymphocytes. Complement components, Fc receptors, and mast cells are important for the expression of the disease. The relevance of the K/BxN model to human RA is supported by one report showing that serum from almost two-thirds of patients with RA contain anti-GPI antibodies, which are absent from serum of normal individuals or of patients with Lyme arthritis or Sjögren syndrome (Matsumoto et al., 2003). However, not all investigators agree. The K/BxN model has been particularly useful in illustrating the role of immune-inflammatory components in the development of arthritis and notably the characterization of the role of mast cells (Lee et al., 2002); yet, this model offers little evidence that autoantibodies are involved in the pathogenesis of RA.

There is a new murine model of *spontaneous, T-cell mediated arthritis*, SKG, due to a mutation of the gene encoding an Src homology 2 (SH2) domain of ζ-associated protein of 70 kDa (ZAP-70), a key signal transduction molecule in T cells. The disturbance in the thymic T-cell selection that results from absence of ZAP-70 results in the generation of arthritogenic T cells. Besides synovitis, SKG mice develop extra-articular lesions, including pneumonitis and vasculitis. Serologically, they develop high levels of rheumatoid factor (RF) and autoantibodies specific for type II collagen (Sakaguchi et al., 2003). A molecule termed synoviolin/Hrd1 was found to play a key role in the development of synovitis. This represents an E3 ubiquitin ligase, which, by promoting the growth of synoviocytes, facilitates the development of arthritis. Mice lacking synoviolin are resistant to arthritis (Amano et al., 2003).

Mice that develop spontaneous autoimmunity have helped our understanding of hormonal and immunoregulatory influences in autoimmunity, but obvious restraints limit direct transfer of this information to human disease. As for T1D in the NOD mouse model, some hundreds of measures are curative for SLE in these mice; yet, we are still left with just three (aspirin, prednisone and plaquenil) that are approved by the Food and Drug Administration (FDA) for the treatment of human SLE! Treatment of humans with hormones, cytotoxic drugs, and rational biologics (including anti-CD154 (CD40) ligand, tolerizing small DNA tetramers, and others) has had limited success or elicited serious side effects. However, some monoclonal antibody treatments such as tumor necrosis factor (TNF) blockade and anti-CD20 are promising (See Chapter 76). Perhaps, each of the models may only reflect a proportion of SLE patients, which may account for the failure to develop effective therapeutics so far. Further, human disease develops in individuals with a permissive genetic background in conjunction with environmental and stressful factors, possibly acting over a long period. Clinical researchers can study the disease only in patients in whom significant pathogenetic processes have occurred and tissue injury has begun. We may have to accept that it will be more difficult to alter pathogenic pathways that have already been set into motion and focus our attention on understanding and limiting the tissue injury-mediating processes.

Genetically Manipulated Models of Systemic Autoimmunity

The advent of genetic manipulation has led to development of numerous single-gene modified strains that develop autoantibodies and other features of SLE. These mice have provided great insights into the mechanisms that govern tolerance and autoimmunity and suggested novel rational treatments.

Defects in Signaling Molecules

Human SLE T cells are known to express less TCR-ζ chain (Liossis et al., 1998) and to use alternative signaling though the FcR-γ chain (Enyedy et al., 2001). Mice that lack TCR-ζ chain develop autoimmune manifestations and display disturbed positive and negative thymic selection (Yamazaki et al., 1997), and the phenotype can be rescued successfully by introducing the FcR-γ chain (Shores and Love, 1997). The pathophysiology for the murine and human phenotypes may well differ and, although in mice lack of the ζ chain may lead to autoimmunity by altering early thymic events that limit the export of autoimmune T cells, in humans the rewiring of the TCR with the newly upregulated FcR-γ chain will lead to increased TCR-mediated signaling processes (Tsokos et al., 2003).

The *B7-CD28/CTLA-4 costimulatory pathway* is pivotal for T-cell activation. Signaling through this pathway is complex due to the presence of at least two B7 family members, CD80 (B7-1) and CD86 (B7-2), and two counter-receptors, CD28 and CTLA-4. CTLA-4-deficient mice rapidly develop lymphoproliferative disease with multi-organ lymphocytic infiltration and tissue destruction, with particularly severe myocarditis and pancreatitis, and die by 3–4 weeks of age (Tivol et al., 1995). CTLA4-Ig limits effectively murine lupus (Finck et al., 1994) and the use of CTLA-4-Ig biologics has helped patients with RA (Kremer et al., 2003) and psoriatic arthritis (Abrams et al., 2000).

Program death-1 (*PD1*) is a member of the CD28 family of receptors and its intracytoplasmic domain defines an immunoreceptor tyrosine-based inhibition motif (ITIM), and when engaged it delivers a negative signal. Strains of mice lacking the PD1 gene develop either cardiomyopathy (Okazaki et al., 2003) or lupus glomerulonephritis (Nishimura et al., 1999). PD1 polymorphisms have been identified among SLE patients (Prokunina et al., 2004).

Src homology 2-containing phosphatase 1 (*SHP1)* is one of the best-characterized protein tyrosine phosphatases (PTPase). The homozygous loss in mice leads to the "moth-eaten" phenotype characterized by spotty hair loss and abnormalities in the immune system that lead to systemic autoimmunity and skin inflammation (Kozlowski et al., 1993; Tsui et al., 1993; Bignon and Siminovitch, 1994). T lymphocytes from these mice are hyper-responsive to TCR stimulation (Pani et al., 1996). Since neutrophils from "moth-eaten" mice demonstrate increased oxidant production, surface expression of CD18, and adhesion to protein-coated plastic, the autoimmune phenotype in these mice may not directly reflect lymphocyte aberrations (Kruger et al., 2000).

Other lines of research suggest T cells from *lupus prone mice (MRL/lpr) that are transgenic for a specific receptor* have decreased antigen-initiated T-cell stimulation thresholds (Vratsanos et al., 2001; Bouzahzah et al., 2003). A similar concept of an "over-excitable" antigen-initiated proximal lymphocyte signaling phenotype has been proposed for human SLE (Tsokos et al., 2003). There is no information on the levels and function of phosphatases in spontaneous models of autoimmunity or in human SLE and this appears a promising area of study.

Mice with *N-acetylglucosaminyltransferase deficiency* show decreased glycosylation of T-cell membrane proteins, which prevents galectin binding and thereby disrupts the galectin-glycoprotein lattice leading to increased clustering of TCR (Demetriou et al., 2001). Increased TCR clustering in these autoimmune mice provides a phenotype comparable with human SLE, involving lowered T-cell activation thresholds and increased TCR signaling. In human SLE T cells, increased association of the TCR-ζ chain with lipid-rafts, as well as membrane clustering, are claimed to lead to decreased tolerance and abnormal signaling (Nambiar et al., 2002). Thus, defects in the expression and function of glycosylation processes may predispose to autoimmunity and, along the same lines, glycosylation of the transcription factor Elf-1, which enables the 80-kDa form to transform to the DNA-binding 98-kDa form, is defective in human SLE T cells (Juang et al., 2002).

A state of B lymphocyte hyperactivity resembling SLE is seen in *mice lacking the src-family kinase Lyn* (Chan et al., 1997). Lyn is not required to initiate B-cell antigen receptor (BCR) signaling, but is an essential inhibitory component. $Lyn^{-/-}$ B cells have a delayed but increased calcium flux and exaggerated negative selection responses in the presence of antigen, and spontaneous hyperactivity in the absence of antigen. B cells in human SLE have a similar phenotype by displaying increased calcium responses following BCR stimulation and they appear to have decreased levels of Lyn kinase protein and mRNA (Liossis et al., 2001). On the other hand, Lyn deficiency causes increased tolerance of Ig^{HEL} B cells to soluble hen-egg lysozyme (HEL) (Cornall et al., 1998). Sustained activation of Lyn *in vivo* using a targeted gain-of-function mutation ($Lyn^{up/up}$ mice) led to the development of autoantibodies and lethal autoimmune glomerulonephritis. Interestingly, B cells show a heightened calcium flux in response to BCR stimulation (Hibbs et al., 2002). These data in humans and mice suggest that mechanisms that lead to sustained BCR signaling may override control mechanisms and lead to autoimmunity.

CD22 is a B lineage-specific protein member of the sialoadhesin family with a still unknown ligand. The intracytoplasmic domain defines three immunoreceptor tyrosine-based inhibitory motifs (ITIM), which provide anchors for inhibitory downstream molecules. The BCR-stimulated calcium fluxes are increased in B cells from $CD22^{-/-}$ mice, and one line of such mice develops autoimmune features (O'Keefe et al., 1999).

Toll-like receptors recognize bacterial components and they share MyD88 to process signaling following the engagement of proper ligands. The AM14 transgenic mouse expresses a heavy chain that is a component of a rheumatoid-factor heavy chain that recognizes IgG2a and corresponding immune complexes (Wang and Shlomchik, 1997). The use of MyD88-deficient mice has enabled the molecular characterization of the role of infectious agents in the expression of autoimmunity, since B cells from $AM14/MyD88^{-/-}$ animals fail to respond to IgG2a immune complexes containing chromatin (Leadbetter et al., 2002). Use of the already available TLR (1 through 9) knockout mice in this and other systems should help to delineate the mechanisms whereby infectious agents influence the expression of autoimmunity at the molecular level. It is known that patients with SLE experience a flare after an infection.

Increased levels of DNA/anti-DNA immune complexes can initiate tissue inflammation and also may provide positive feedback to B cells through cognate recognition of nuclear antigens by the BCR, and costimulation through TLR9. Mice defective in DNAse1 develop systemic autoimmunity (Napirei et al., 2000). In addition, there are reports of two patients with SLE with defects at DNAse1 locus (Yasutomo et al., 2001). These findings reinforce the concept that complement proteins clear nuclear material from the circulation, and suggest that it may be useful to focus on novel treatments to lower circulating DNA levels in SLE.

Antigen presented in the context of immune complexes engages not only the BCR but also the FcγRIIb, which results in the phosphorylation of the ITIM defined by its intracytoplasmic domain. Recruitment of the phosphatases SHIP (Src homology 2 domain-containing inositol-5-phosphatase) and SHP1 suppresses signaling. Introduction of the FcγRIIb null phenotype into the C57BL/6 background caused production of autoantibodies and glomerulonephritis (Bolland and Ravetch, 2000). Yet the same null phenotype on the BALB/c background did not result in autoimmunity.

Although SHIP is considered responsible for FcγRIIb-mediated suppression, the SHIP null phenotype does not result in autoimmunity (Helgason et al., 2000). In humans, polymorphisms of the Fc receptors have been associated with systemic autoimmunity and particularly SLE and Wegener's granulomatosis (Kimberly et al., 1995; Gibson et al., 1999). The therapeutic effect of many biologics that contain IgG Fc components could be determined by the FcR polymorphism expressed by the treated subject.

Complement Protein Knockout Mice

The B6/lpr mouse develops minor autoimmune features. Introduction of the *CR1/CR2 deficiency* into this strain permits development of intense autoimmune features (Boackle and Holers, 2003) indicating that complement receptors are important in the elimination of B cells that display reactivity with self antigens. This explanation assumes that self antigens initiate a strong B-cell signal, which leads to B-cell death and the absence of the CR2-mediated enhancement of the signal permits their survival (Tsokos et al., 1990; Dempsey et al., 1996). When the complement receptor deficiency was introduced into the HEL double transgenic mouse model for cell tolerance, the paucity of production of anti-HEL antibodies was not reversed; yet, the numbers of circulating B cells increased, and they responded normally to stimulation (Fischer et al., 1998; Prodeus et al., 1998) indicating that there is some effect on B-cell biology, but not enough to break tolerance. These two sets of experiments suggest a relative role for CR2 in the maintenance of tolerance for self antigens—that is, the absence of CR2 can cause autoimmune disease only when there is genetic predisposition to autoimmunity. Also, evidence for the involvement of Cr2 in systemic autoimmunity comes from the NZM2410 mouse. A major murine SLE susceptibility locus, Sle1, which corresponds to three loci independently affecting loss of tolerance to chromatin, has been identified in this congenic mouse. The congenic interval corresponding to Sle1c contains Cr2, which encodes CR1/CR2 (CD35/CD21). NZM2410/NZW Cr2 exhibits a single nucleotide polymorphism that introduces a novel glycosylation site, resulting in higher molecular weight proteins. This polymorphism, located in the C3d binding domain, reduces ligand binding and receptor-mediated cell signaling. Molecular modeling based on the recently solved CR2 structure in complex with C3d has revealed that this glycosylation interferes with receptor dimerization (Boackle et al., 2001).

In contrast to these experiments, when $Cr2^{-/-}$ mice were immunized with myosin, they failed to develop the expected myocarditis (Kaya et al., 2001). Regardless of the claimed role of CR2 on the surface of T cells as part of an activated T-cell phenotype, the role of complement in this inducible model of autoimmune disease must be different from that in the spontaneous models of autoimmunity. This implies distinct functions for complement as an effector of tissue pathology and regulator of positive and negative selection.

C1q deficiency alone is sufficient to cause autoimmunity in humans, whereas in mice a genetic lack of C1q does not suffice, since there was no evidence of autoimmunity in C1q-deficient C57BL/6 and C57BL/$6^{lpr/lpr}$ mice. However, in C1q-deficient MRL/$Mp^{+/+}$ mice, there was an acceleration of both the onset and the magnitude of antinuclear antibodies (ANA) and of glomerulonephritis, particularly in females, which developed severe crescentic glomerulonephritis. Thus, the expression of autoimmunity in C1q-deficient mice is strongly influenced by other background genes (Botto and Walport, 2002; Moldenhauer et al., 1987).

Since *disruption of the C1q, C4 and CR1/CR2* leads to reduced selection against autoreactive B cells and to impaired humoral responses, C1 and C4 could act through CR1/CR2 to enhance humoral immunity and suppress autoimmunity, but each complement component appears to act independently (Chen et al., 2000). High titers of spontaneous ANA and "SLE-like" autoimmunity developed in all $C4^{-/-}$ females and most male animals but not in $Cr2^{-/-}$ animals. The fact that the clearance of circulating immune complexes was impaired in pre-autoimmune $C4^{-/-}$, but not $Cr2^{-/-}$ mice favors the role of nuclear antigen-ANA immune complexes in the development of autoimmune disease.

Membranoproliferative glomerulonephritis (MPGN) occurs in *factor H-deficient humans* and pigs. Pickering et al. (2002) showed that mice deficient in factor H ($Cfh^{-/-}$ mice) develop MPGN spontaneously and are predisposed to renal injury caused by immune complexes. The contribution of complement activation was confirmed, because, after a second mutation in the gene encoding complement factor B was introduced which prevents C3 turnover *in vivo*, the phenotype of $Cfh^{-/-}$ was not expressed any more. Thus, uncontrolled C3 activation *in vivo* is essential for the development of MPGN due to deficiency of factor H. The mechanism can include a direct effect of C5b-9 on mesangial cell proliferations (Niculescu et al., 1997) or through the production of C5a. Thus, in patients with systemic autoimmunity, tissue injury is not caused not only by circulating immune complexes but also through the action of complement-activation products.

Glomerular deposition of C3 is quite typical for glomerulonephritis in both humans and mice. However, some humans with C3 deficiency have been found to develop glomerulonephritis, whereas C3- and C4-deficient mice were protected from the development of anti-glomerular basement membrane (GBM)-mediated nephritis (Sheerin et al., 1997). In B6/lpr mice that produce low titer anti-DNA antibodies without developing glomerular disease, C4 deficiency enhances autoantibody production and proliferative glomerulitis occurs. C3 deficiency, however, neither

influenced antibody production nor led to renal disease (Prodeus et al., 1998). In MRL/lpr mice, C3 deficiency had minimal to no effect on skin disease, spleen size, B-cell or T-cell numbers, B-cell activation, pathologic renal scores, or production of autoantibodies. C3 deficiency did, however, result in significantly greater albuminuria and glomerular IgG deposition compared with wild-type C3-producing littermates (Sekine et al., 2001). Therefore, C3 may actually not be needed for the development of glomerulonephritis, and its role could be protective: it may serve either in the facilitation of clearance of immune complexes, or indirectly control autoreactive cells during their expansion.

The experiments discussed above point to a dichotomous effect of complement in immunopathology: one effect is on the negative and positive selection of the immune cell repertoire and the other is on effector processes.

Tumor Necrosis Factor/Tumor Necrosis Factor Receptor Family

The TNR/TNFR system acts on the homeostasis of the immune system in different ways. Tumor necrosis factor is produced in response to many stimuli, and after binding to TNFR1 (p55) or TNFR2 (p75) it may result in cell death or cell survival, respectively. The role of TNF in the expression of human and murine autoimmunity is complex and anti-TNF treatment of some autoimmune disease, with the exception of RA, was limited by side effects. HLA-DR3$^+$ patients with SLE, and lpr/lpr and BXSB mice, produce high levels of TNF whereas HLADR2$^+$ SLE patients and NZB $\times$ NZWF1 mice produce less TNF. Transgenic mice expressing wild-type p75TNFR develop a severe inflammatory syndrome (Douni and Kollias, 1998; Kollias and Kontoyiannis, 2002; Kollias et al., 2002). Accordingly, the lpr phenotype is accelerated in p55$^{-/-}$lpr/lpr mice (Zhou et al., 1996), and TNF$^{-/-}$gld/gld mice have less autoimmune disease (Korner et al., 2000). These excerpts from the vast literature indicate the complexity of the effects of cytokines coupled with the major role of the genetic background in the expression of the clinical phenotype. It also points to the complexities and unpredictability of the use of some biologics in the modulation of human disease.

Tumor Necrosis Factor Overexpression and Autoimmunity

The successful clinical introduction of treatment with anti-TNF confirmed the biologic relevance of TNF function in chronic inflammatory diseases, particularly RA and Crohn's disease (see Chapters 32 and 52). The introduction of a modified human TNF-globin hybrid transgene in mice was the first demonstration in animal models that TNF has arthritogenic properties. These mice (tg 197) spontaneously develop (with 100% penetrance and a predictable time of onset) a chronic, erosive, inflammatory polyarthritis with histologic lesions resembling human RA (Kontoyiannis et al., 1999). AU-rich elements (AREs) are important for TNF mRNA destabilization and translational repression in hematopoietic and stromal cells. Development of two specific pathologies in mutant mice—chronic inflammatory arthritis and colitis akin to Crohn's disease—suggests that a defective function of AREs may participate in the pathogenesis of analogous human pathologies. These mice have proven quite informative in dissecting the pleiotropic effects of TNF on the immune response and on the expression of various forms of autoimmune pathology.

Interleukin-2 and its Receptors

Mice that are deficient in IL-2 and IL-2Rα have disrupted immunologic homeostasis that eventually leads to fatal autoimmune manifestations (Nelson, 2002). Specifically, these mice develop autoimmune hemolytic anemia and colitis. IL-2R$\beta^{-/-}$ mice likewise develop anemia, splenomegaly, and lymphadenopathy, but not colitis. In humans, IL-2 deficiency is clinically manifested as severe combined immunodeficiency, whereas a patient lacking IL-2Rα is immunocompromised, and several organs are infiltrated with inflammatory cells (Sharfe et al., 1997). The autoimmune manifestations depend on the presence of both T and B cells and environmental antigens since, if the mice are kept under pathogen-free conditions, they do not develop autoimmunity. Activation-induced cell death (AICD) is central for the elimination of activated autoreactive cells, and this depends on IL-2 signaling. Defective AICD obviously plays a role in the development of autoimmunity. Humans with SLE have defective AICD that appears to be multifactorial: defective TNF-α (Kovacs et al., 1996) and IL-2 production (Tsokos et al., 1996) or increased cyclooxygenase-2 (COX-2) expression (Xu et al., 2004). COX-2$^{-/-}$ mice do not have significantly increased AICD. It could be helpful to know whether correction of IL-2 production alters the severity of autoimmune disease in the MRL-lpr/lpr mouse that produces limited amounts of IL-2 (Theofilopoulos and Dixon, 1985), as this may represent a form of treatment for patients with SLE. It is of interest that when the IL-2$^{-/-}$ locus is crossed into the MRL-lpr/lpr mouse, both autoimmune syndromes are corrected (Xiao et al., 2003), an observation calling for consideration of gene subtraction rather than gene supplementation in the treatment of autoimmune disease.

Ubiquitination-Protein Ligases

Ubiquitination-protein ligases (Casitas B-lineage lymphoma [cbl]-family of proteins) are important in the signal-

ing transduction process and as determinants of energy and activation (Liu, 2004). Cbl-b is considered a negative regulator of T-cell activation, and Cbl-b$^{-/-}$ T cells proliferate and produce more IL-2 following TCR stimulation (Rudd and Schneider, 2000). Cbl-b-deficient mice display massive mononuclear cell infiltration of many organs and peripheral T cells express activation markers (Bachmaier et al., 2000). One intriguing disease model is Cbl-b deficiency in T1D (Yoko et al. Nature Genetics 2000), but a human counterpart for Cbl-b deficiency has not yet been described.

Apoptosis-Related Genes

The lpr mutation represents a CD95(Fas), CD152(FasL) gene mutation and its presence limits apoptosis of T cells. The lpr mutation is recessive and greatly accelerates disease in autoimmune-prone strains such as MRL and BXSB. When present in C57BL/6 mice, it results in the production of autoanti-bodies and limited glomerulonephritis (Kono and Theofilopoulos, 1999). Heterozygous mutations in CD95, CD95 ligand or caspase-10 in humans underlie most cases of autoimmune lymphoproliferative syndrome (ALPS), a human disorder that is characterized by defective lymphocyte apoptosis, lymphadenopathy, splenomegaly, and autoimmunity (Chun and Lenardo, 2001; see Chapter 70). In contrast, mutations in caspase-8 lead to immunodeficiency (Chun et al., 2002).

In a similar fashion the gld mutation accelerates autoimmunity in predisposed mouse strains and leads to milder disease in non-autoimmune prone strains. A patient with SLE has been described with a mutation in the CD178 (FasL) gene (Wu et al., 1996). On the other hand, the expression of CD178 (FasL) is increased in T cells from SLE patients (Tsokos et al., 1996; Kovacs et al., 1997) and this may reflect resistance of autoimmune T cells to killing.

The association of CD95/CD178 (Fas/FasL) defects with "lupus-like disease" susceptibility strongly suggests that mutations of other genes whose products are involved in the apopto-sis signaling cascade should similarly contribute to such expressions. Indeed, overexpression of the apoptosis inhibitor Bcl-2 leads to mild autoimmunity (Strasser et al., 1990; 1991), and patients with SLE have been reported to have higher levels of Bcl-2 protein (Aringer et al., 1994). Similarly, overexpression of Bcl-2 in C57BL/6-lpr mice leads to accelerated autoimmune disease (Reap et al., 1995) as does the overexpression of another apoptosis inhibitor, the cytoplasmic serine/threonine kinase Pim-1 (Moroy et al., 1993).

Mice lacking the membrane tyrosine kinase c-mer have impaired clearance of infused apoptotic cells, and develop progressive lupus-like autoimmunity, with antibodies to chromatin, DNA, and IgG. Since they have minimal polyclonal B-cell activation, the development of autoimmunity in these mice favors the concept that autoantigens present in apoptotic debris can enhance systemic autoimmunity (Scott et al., 2001; see Chapter 15).

Induced Models of Systemic Autoimmunity

Information has been acquired over many years from study of models based on induction of autoimmunity, including immunoregulatory events that lead to the expression of clinical disease and proximal events associated with triggering of autoimmune disease.

The *isoprenoid alkane pristane* induces autoantibodies characteristic of SLE, including anti-Sm, anti-dsDNA, and anti-ribosomal P in BALB/c and SJL/J mice (Richards et al., 1999) and CD1d deficiency exacerbates lupus nephritis induced by pristane (Yang et al., 2003). For unexplained reasons, the lpr and gld mutations protect mice from the production of antibodies routinely induced by pristane (Satoh et al., 2000).

Graft-versus-host induced models of systemic autoimmunity involve the injection of parent cells into F1 offspring and clarified early events in the induction of autoimmunity. Donor CD4$^+$ cells are stimulated by recipient F1 MHC class II cells, which presumably present a chromatin-associated nuclear antigen and produce initially IL-2 and later on IL-4 and IL-10. Anti-DNA antibodies are produced, while the generation of CD8$^+$ CTL cells is silenced (Via and Shearer, 1988).

Intraperitoneal injection of cell walls from varying types of bacteria results in a biphasic inflammatory arthritis. Initially, there is an acute inflammatory arthritis over 1–2 weeks followed by a month-long chronic arthritis (Cromartie et al., 1977). This model of arthritis has led to the characterization of cell, cytokine, and chemokine factors that are responsible for the synovial inflammation and the destruction of diarthrodial joints and, in parallel, to establishing the efficacy of various anticytokine treatments in arthritis.

Injection of *allogeneic collagen type II (CII)* or certain peptides of this protein in complete or incomplete Freund's adjuvant into susceptible strains of rats or mice results in collagen-induced arthritis (CIA) resembling RA. The role of MHC in the expression of CIA is indicated, only in H-2^q mice after injection of chicken CII, whereas H-2^r mice are susceptible to pig CII (Stuart et al., 1983; Watson et al., 1987). CD4$^+$ cells and various cytokines including IL-1 and TNF-α, as well as antibody to CII, have been shown to participate in the expression of CIA.

Immunization of BALB/c mice with *partially deglycosylated human aggrecan* induces chronic progressive polyarthritis and spondylitis (Glant et al., 2003). This proteoglycan (aggrecan)-induced arthritis (PGIA) resembles RA (as judged by clinical assessments, laboratory tests,

radiography, and histopathology of the peripheral joints). Occurrence of PGIA depends on development of cross-reactive T- and B-cell responses between the immunizing human and self (mouse) cartilage aggrecan.

How Do Animal Models of Systemic Autoimmunity Resemble Human Disease?

Animal models of systemic human autoimmune disease have served us well for understanding autoimmunity. Given the facts that human systemic autoimmune disease is highly heterogeneous and its origins and pathogenetic processes are multiple and highly complicated, each model will likely mimic pathogenesis of disease just in a small proportion of patients. Therefore, some therapies that are highly successful in animal models have only limited utility in humans. However, many false hypotheses have been dispelled by proper manipulation of animal models. For example, although B cells are needed for the development of glomerulonephritis, antibody production is not mandatory (Chan et al., 1999). Wakeland and colleagues (Wakeland et al., 1997; Mohan et al., 1999) have solidified the concept that several genetic loci have to act in concert for expression of autoimmunity and even more are needed for expression of disease. This explains the clinical experience that the presence of autoantibodies alone does not necessarily herald an upcoming disease. In addition, mutation of a gene often leads to disparate diseases in humans and mice, e.g., the Fas and FasL mutations that promote autoimmunity in mice and ALPS in humans (discussed above). In other situations, mice and humans can develop very similar autoimmune disease, e.g., when the DNAse1 gene is mutated (discussed above). Therefore, experiments should be designed to address specific questions that arise from the close study of human disease, but for which no answer is available from *in vivo* or *ex vivo* experiments in humans.

CONCLUSIONS

Our message is that a given animal model is only as good as the question it is used to answer, and particular models are well-suited for some but not all questions. Consequently, a careful choice is needed in advance. Inbred mouse strains that are used to limit variability of *in vivo* studies will essentially tell the story of just one or a few human patients—for translating findings in animal models to human therapy, this is a particularly important realization—and a much higher degree of variation can be expected in human populations. In addition, it follows that each model will only reflect certain aspects of a given autoimmune disease accurately and, therefore, immunotherapeutic approaches should be validated in more than one model if possible. Nevertheless, the numerous animal models that are available to us are indispensable tools to study *in vivo* pathogenesis and treatments, and are a crucial step when moving from the bench to the bedside.

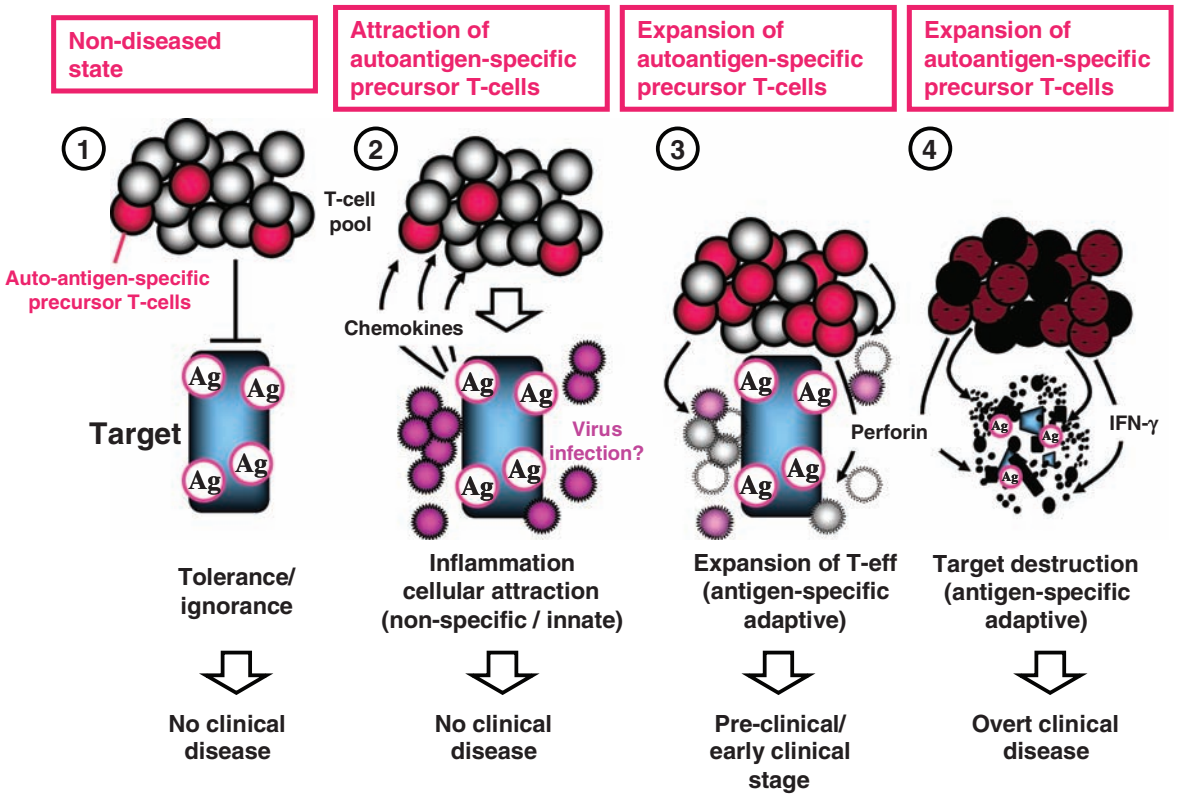

FIGURE 26.1 Pathogenesis of organ specific autoimmunity. For organ-specific autoimmunity one can assume that the initiating events might be antigen non-specific or specific. (1) A combination of genetic and environmental factors might lead to the breaking of self-tolerance and activation of autoreactive T cells. (2) Further inflammation might attract more such cells, for example, if a virus persists or autoantigens are being presented in a chronic manner. Certainly, activation of T-cell receptors and antigen-presenting cells will serve to propagate disease. (3) The ultimate outcome is determined by the magnitude and class of the autoreactive response. Many aggressive T cells, such as cytotoxic T cells and Th1 lymphocytes, will enhance progression, whereas the presence of (autoreactive) regulatory T cells (Tregs) will dampen inflammation. (4) Penetrance of clinical disease is directly correlated with the amount of target cell (organ) destruction and is determined by this balance of Tregs to aggressive T cells. Ag, antigen; IFNγ, interferon γ; Teff, effector T-cell.

27

Systemic Lupus Erythematosus and Related Diseases: Clinical Features

MICHELLE PETRI
Johns Hopkins University School of Medicine
Baltimore, Maryland, USA

SYSTEMIC LUPUS ERYTHEMATOSUS

Epidemiology

Systemic lupus erythematosus (SLE) is the classic multisystem autoimmune disease. It occurs more frequently in women, with a 9 : 1 ratio, and is more common in African-Americans, Asian-Americans, and Hispanic-Americans than in whites. Its incidence may have tripled since the 1960s and 70s (Uramoto et al., 1999). The incidence is approximately 4 in 100,000 in most countries, with an especially high incidence of 8.7 in 100,000 in Brazil (Vilar and Sato, 2002).

There is a genetic predisposition to SLE, but only 2% of children of affected women develop SLE. The genetic predisposition may involve over 100 different genes. Recent work has found that an "interferon signature" characterizes many genes that are activated in SLE (Baechler et al., 2003). Identified predisposing genes include HLA DR and DQ alleles that are associated with the production of specific autoantibodies (Arnett et al., 1991; Olsen et al., 1993). Both complement deficiency states and certain Fc-γ receptor alleles predispose to SLE, and affect clearance of immune complexes (see Chapter 16).

Multiple environmental factors contribute to the pathogenesis of SLE. Ultraviolet radiation is the best understood, leading to the exposure of Ro on the surface of keratinocytes. Other environmental triggers of SLE include certain drugs. For idiopathic lupus, echinacea and sulfonamide antibiotics can trigger SLE or SLE flares. For drug-induced lupus, isoniazid, hydralazine, procainamide, minocycline, and anti-tumor necrosis factor (TNF) biologics have been identified. Infections including Epstein–Barr virus (James et al., 2001) and parvovirus are associated with SLE. A recently identified toxic exposure that increases risk of SLE is silica (Parks et al., 2002). Smoking is a risk factor for SLE (Costenbader et al., 2004) and, in addition, in patients with established SLE, smoking increases the risk of discoid lupus.

The hormonal milieu is important in the gender ratio and timing of SLE. In children, the gender ratio is equal. In women, SLE usually develops after puberty. Women with SLE tend to be "super women," in that they preferentially employ hydroxylation pathways that lead to the production of more feminizing metabolites of estradiol (Lahita et al., 2004) (see Chapter 25). In women with SLE, levels of the adrenal hormone dehydroepiandrosterone (DHEA) are usually low, and drop even lower if the patient is treated with prednisone.

Immunopathogenesis

The hallmark of SLE is the production of autoantibodies by B cells. However, there is also ample evidence for

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

abnormal T-cell function (Tsokos, 2001) and abnormal reticuloendothelial system function. One of the most important discoveries in SLE was the finding that the proteins to which SLE patients make autoantibodies are exposed in nuclear blebs during apoptosis (Casciola-Rosen et al., 1994). This has led to the "waste disposal" theory of SLE, namely that ineffective clearance of apoptotic bodies leads to the initial break in self-tolerance (Manderson et al., 2004) (see Chapter 15).

Clinical Presentation

The most common organ system presentations are cutaneous, musculoskeletal, and renal. Cutaneous involvement includes photosensitivity, malar rash, discoid rash, nasal and/or oral ulcers, and cutaneous vasculitis. Cutaneous lupus often first presents after ultraviolet light exposure, with a maculopapular rash in sun-exposed areas. Musculoskeletal features consist of polyarthralgias or polyarthritis, and, more rarely, myositis. Lupus arthritis affects the small joints of the hand (posterior interphalangeal [PIP] and metacarpophalangeal [MCP] joints) and wrists. It may be initially confused with rheumatoid arthritis. Unlike rheumatoid arthritis, however, it is rarely erosive. Instead, over time, it may lead to reducible deformities, secondary to tendon and ligament laxity, called Jaccoud arthropathy. Renal lupus presents as proteinuria, hematuria, and/or red blood cell casts.

Almost any organ can be involved. Hematologic abnormalities include leukopenia, lymphopenia, thrombocytopenia, and hemolytic anemia. Serositis manifests as pleurisy or pleural effusion, pericarditis with or without effusion, and rarely as abdominal pain or ascites. Neurologic lupus runs the gamut from cognitive impairment (common) to rare features such as seizures, psychosis, transverse myelitis, cranial or peripheral neuropathy, mononeuritis multiplex, encephalopathy, and stroke.

Almost 50% of SLE patients make antiphospholipid antibodies (lupus anticoagulant, anticardiolipin, or anti-β2 glycoprotein 1), which lead to hypercoagulability. The antiphospholipid syndrome is defined as arterial or venous thrombosis or vasculopathy or pregnancy morbidity (early losses, late fetal loss, or severe pre-eclampsia or placental insufficiency) (Wilson et al., 1999) (see Chapter 30). Lupus nephritis is described in Chapter 59.

Diagnosis

The American College of Rheumatology has devised classification criteria that require the presence of four of the following eleven to "classify" SLE: malar rash, discoid rash, photosensitivity, oral ulcers, arthritis, serositis, renal disorder, neurologic disorder (psychosis or seizures), hematologic disorder (hemolytic anemia, leucopenia, lymphopenia or thrombocytopenia), immunologic disorder (anti-DNA, anti-Sm, or antiphospholipid antibodies) and positive antinuclear antibodies (ANA) (Tan et al., 1982).

However, the clinical diagnosis of SLE can be made without four criteria. Alopecia and Raynaud's phenomenon occur frequently in SLE. Several other autoantibodies may be helpful, although not specific for SLE, including antiribonuclear protein (anti-RNP), anti-Ro, or anti-La. Low complement (C3, C4, or CH50) is very common in SLE. Several neurologic manifestations, including encephalopathy, mononeuritis multiplex, and transverse myelitis may lead to the consideration of SLE.

Autoantibodies

Of all the autoantibodies associated with SLE, ANA is one of the least helpful in diagnosis. A negative ANA makes the diagnosis of SLE unlikely. A positive ANA, especially at lower titers, can occur in 20% of normal young women, in localized autoimmune disorders, in other multisystem autoimmune diseases, in vasculitis, in infections, in ageing, with many drugs, and in malignancy.

Anti-dsDNA is specific for SLE, especially if the assay used is immunofluoresence on Crithidia. Low titers of anti-DNA in enzyme-linked immunosorbant assay (ELISA) may not be specific for SLE. Patients with SLE and anti-dsDNA are at greater risk of renal disease. Anti-Sm is also specific for SLE, but is less frequent than anti-dsDNA. Patients with SLE who are positive for anti-Sm are also at greater risk for renal disease.

Anti-Ro and anti-La are classically considered to be Sjögren syndrome antibodies. In SLE, secondary Sjögren syndrome can occur with or without these autoantibodies. Patients with anti-Ro are more likely to be photosensitive. Anti-Ro and anti-La increase the risk of congenital heart block during pregnancy (see Chapter 71).

Anti-RNP can also occur in rheumatoid arthritis and in mixed connective tissue disease. Patients with SLE who are positive for anti-RNP are more likely to have Raynaud's phenomenon or myositis.

Differential Diagnosis

Early symptoms, including low-grade fever, fatigue, malaise, mild hair loss, and arthralgias, are not specific for SLE. Often there is a delay of several years before a diagnosis of SLE is made. Other multisystem autoimmune diseases that share features with SLE include Sjögren syndrome, rheumatoid arthritis, and systemic sclerosis. Vasculitis, especially hypocomplementemic urticarial vasculitis, overlaps with SLE. Other vasculitides, including Wegener's granulomatosis, polyarteritis nodosa, vasculitis secondary to hepatitis B or hepatitis C, and lymphomatoid granulomatosis need to be considered. Sarcoidosis can share

some features with SLE, including fever, lymphadenopathy, and polyarthritis. Several viral infections, including cytolomegalovirus, parvovirus, human imunodeficiency virus (HIV), and hepatitis B can cause polyarthritis, and, sometimes, autoantibodies. Malignancy can lead to polyarthritis, vasculitis, and autoantibodies including ANA.

Disease Course

The classic pattern of SLE is a relapsing-remitting, or "flare" pattern, but some patients have chronic activity. Periods of long quiescence can occur, but are rare (Barr et al., 1999). Lack of flares (Swaak et al., 1989) and lack of organ damage (Rahman et al., 2001) are associated with normal survival. However, more than 50% of SLE patients have one or more organs that are chronically damaged. Some organs are damaged by the disease itself, such as renal insufficiency (or renal failure), but a large component of organ damage in SLE is also due to chronic treatment with corticosteroids. Corticosteroid-induced damage includes osteoporotic fractures, osteonecrosis, cataracts, and diabetes mellitus.

Osteopenia or osteoporosis occurs in the majority of SLE patients on chronic corticosteroids. Bone loss from corticosteroids occurs early. If corticosteroids are stopped, some bone loss may be reversible. However, there is also evidence that SLE itself is a risk factor for osteoporosis, likely due to inflammatory cytokines such as interleukin 6 (IL-6). Other risk factors for osteoporosis include post-menopausal status, being white, smoking, and sedentary lifestyle. All women with SLE should be on calcium and vitamin D supplementation. Those with osteoporosis should start bisphosphonate therapy, unless there is a contraindication such as renal insufficiency/failure or plans for a future pregnancy.

Osteonecrosis (or avascular necrosis of bone) is a complication of high-dose corticosteroid use, usually greater than 30 mg prednisone (or equivalent) daily. The pathogenesis is poorly understood, but it is thought that corticosteroids lead to fat replacement in the marrow, increased intraosseous pressure, and necrosis of bone. Hypercoagulability may further increase the risk (Mont et al., 1997a). If detected early, core decompression of the affected joint may allow growth of new bone (Mont et al., 1997b). Hips are most frequently involved, followed by knees and shoulders. Joint involvement is almost always bilateral. Most patients eventually require total joint replacement. Prevention is avoidance of high-dose corticosteroids. There is interest in calcium-channel blockers, which may reduce the intraosseous pressure (Barbosa et al., 1995).

Both cataracts and glaucoma are increased in SLE patients treated with corticosteroids. Both high-dose daily prednisone and chronic low-dose (<7.5 mg/day) prednisone increase the risk of posterior subcapsular cataracts. Hydroxychloroquine is rarely associated with retinopathy, which is nearly always reversible (Rynes and Bernstein, 1993). The dose of hydroxychloroquine should be reduced in renal insufficiency.

Diabetes mellitus is increased in SLE patients on corticosteroids, especially in those with a positive family history or who have gained weight. Weight gain is one of the most common complications of chronic corticosteroid treatment of SLE.

The major cause of late death in SLE is actually cardiovascular disease (Urowitz et al., 1976). The rate of myocardial infarction in young women with SLE is 50 times higher than Framingham offspring controls (Manzi et al., 1997). The increased risk of cardiovascular disease remains even after adjustment for traditional cardiovascular risk factors (Esdaile et al., 2001).

Surprisingly, the SLE patients at risk for angina pectoris and myocardial infarction are not those who clinically have the most severe disease (Zonana-Nacach et al., 1995). The patients at greatest risk are those chronically on corticosteroids, usually low-dose. Similarly, SLE patients with atherosclerosis detected by noninvasive means are those on less treatment and with less autoantibodies (Roman et al., 2003). Thus, the "lupus factor" associated with atherosclerosis cannot be identified using clinical indices of disease activity or serologic markers such as anti-dsDNA or low complement.

Traditional cardiovascular risk factors predictive of later myocardial infarction in SLE include age, male sex, hypertension, diabetes mellitus, renal insufficiency, homocysteine, and the lupus anticoagulant. Homocysteine is a risk factor for later stroke (or any arterial thrombotic event) (Petri et al., 1996). Reduction in and control of traditional cardiovascular risk factors is an essential part of the management of SLE.

Infection is a major cause of both morbidity and mortality in SLE. The disease itself is associated with infection; the risk increases with the use of corticosteroids and immunosuppressive drugs (Petri, 1998). Patients with SLE are especially susceptible to certain bacterial infections (pneumococcus, meningococcus, salmonella), and viral (cytomegalovirus, herpes zoster, warts) infections.

Malignancy is increased with the use of cytotoxic drugs such as cyclophosphamide. Recent studies suggest SLE itself is associated with malignancy, including lymphoma (Sweeney et al., 1995) (see Chapter 69). Cervical dysplasia and cervical cancer are increased in SLE (Blumenfeld et al., 1994).

Treatment

Treatment is determined by organ involvement. Photosensitive rashes are treated by sun avoidance, sun block, and by hydroxychloroquine, an antimalarial drug with an immunomodulating effect. Arthritis is managed with

nonsteroidal anti-inflammatory drugs (NSAIDs) and with hydroxychloroquine; severe cases may require immunosuppressive drugs, including methotrexate or leflunomide. Anti-TNF biologic agents, approved for rheumatoid arthritis, are generally avoided in SLE arthritis, because they have been associated with rare cases of drug-induced lupus and with the development of anticardiolipin and anti-dsDNA antibodies. Mild serositis may be controlled with NSAIDs, whereas severe cases may require initial high-dose corticosteroid therapy (often given as a 3-day methylprednisolone "pulse") followed by taper of oral prednisone. A severe pericardial effusion that leads to pericardial tamponade may require a pericardial window. Mild hematologic lupus often requires no treatment, but severe hemolytic anemia or thrombocytopenia is treated with corticosteroids and/or intravenous immunoglobulin. Recalcitrant hematologic lupus may require splenectomy. Granulocyte colony-stimulating factor (G-CSF), which is used to treat neutropenia (including neutropenia from cyclophosphamide) is associated with SLE flares (Euler et al., 1997).

Severe internal organ involvement will require immunosuppressive regimens. Lupus nephritis occurs in mild (mesangial, focal) and severe (diffuse proliferative) forms, as well as in the form of membranous nephritis. Mycophenolate mofetil is appropriate initial therapy, along with corticosteroids (Chan et al., 2000; Contreras et al., 2004). Rapidly progressive nephritis may require intravenous cyclophosphamide, usually given monthly for six months as "induction therapy" (Boumpas et al., 1992), followed by a maintenance regimen of mycophenolate mofetil, azathioprine, or quarterly cyclophosphamide. Angiotensin converting enzyme (ACE) inhibitor therapy is given to most nephritis patients to retard renal sclerosis, and may reduce proteinuria in membranous nephritis.

Encephalopathy mononeuritis multiplex and transverse myelitis are treated by high-dose corticosteroids, often with the addition of intravenous "pulse" cyclophosphamide. Seizures due to active lupus are treated with both corticosteroids and anti-epileptics. Psychosis can be caused by both SLE and by high-dose corticosteroids. Cognitive impairment occurs in 80% of SLE patients within 10 years of diagnosis. Early detection is difficult, given lack of access to cognitive function testing. In some studies, antiphospholipid positivity appears to be associated with progression (Hanly et al., 1999; Menon et al., 1999).

New approaches are being developed for life-threatening SLE, recalcitrant to current regimens. Both high-dose cyclophosphamide alone (Petri et al., 2003) and high-dose cyclophosphamide followed by stem-cell rescue (Burt et al., 1998) have shown long-term benefit, but, over time, relapses are frequent. New approaches that target B cells include rituximab (Leandro et al., 2002) and monoclonals directed against the B lymphocyte stimulator protein (Stohl et al., 2003) (see Chapter 76).

CHRONIC CUTANEOUS LUPUS

Lupus also occurs in a form limited to the skin, usually as discoid lupus. Over time, only 5% of patients presenting as chronic cutaneous lupus evolve to the systemic form. Initial clues to the subgroup, which may progress to SLE, include discoid lesions above and below the neck, or the presence of polyarthralgias. Other rare forms of chronic cutaneous lupus include hypertrophic (verrucous) lupus, lupus panniculitis, mucosal lupus, tumid lupus, chilblains lupus, and discoid lupus/lichen planus overlap. Subacute cutaneous lupus is an exception to the rule, in that as many as 50% may have SLE.

Chronic cutaneous lupus is treated with topical corticosteroids, corticosteroid injections, antimalarial drugs including hydroxychloroquine and quinacrine, thalidomide, and mycophenolate mofetil.

MIXED CONNECTIVE TISSUE DISEASE

Mixed connective tissue disease (MCTD) is defined in patients with high-titer RNP and features of SLE, scleroderma, and myositis, including arthritis, Raynaud phenomenon, esophageal dysmotility, decreased carbon monoxide diffusion opacity in the lung (DLCO) and myositis (Sharp et al., 1976). However, this utility of the diagnosis over time has been questioned, because of a high rate of progression to SLE or systemic sclerosis (Isenburg and Black, 1999).

UNDIFFERENTIATED CONNECTIVE TISSUE DISEASES

About 5% of women have symptoms or signs of autoimmune disease without meeting classification criteria for SLE, rheumatoid arthritis, systemic sclerosis, myositis, or vasculitis. Onset is typically in women in their thirties. Arthralgias/arthritis, cutaneous, and Raynaud phenomenon are the most frequent symptoms and signs (Danieli et al, 1999). Ten to thirty-five percent of patients with undifferentiated multisystem autoimmune diseases progress to a classifiable autoimmune disease over five years or longer of follow-up (Danieli et al, 1999; Williams et al., 1999; Mosca et al., 2002; Bodolay et al., 2003). Progression to a defined illness usually occurs within the first 2 years after onset.

Systemic Lupus Erythematosus: Immunologic Features

INSOO KANG* AND JOE CRAFT*†

**Section of Rheumatology, Department of Medicine, and †Section of Immunobiology, Yale University School of Medicine, New Haven, CT 06520-8031*

Systemic lupus erythematosus (SLE) is unique among autoimmune illnesses in its breadth of clinical manifestations, in the variability of disease progression, and in the nature of its underlying immunologic abnormalities (Vratsanos et al., 2001a). The hallmark of lupus is the presence of serum antibodies directed against nuclear antigens (antinuclear antibodies or ANA) (Friou, 1957; Holman and Kunkel, 1957; Deicher et al., 1959) that indicate the breakdown of tolerance to self-antigens. Such an event is secondary to complex genetic and environmental interactions that lead to the activation of autoantibody-producing B cells. We have previously reviewed these interactions (Vratsanos et al., 2001a), and they are recounted and updated below. In this review, we have used the terms SLE and lupus interchangeably, identifying the same systemic disease.

AUTOANTIBODIES

Autoantibodies against chromatin and ribonucleoproteins, in addition to being serologic hallmarks for SLE (Tan, 1989) appear to have a pathogenic role in lupus (Shlomchik et al., 2001). The deposition of immune complexes of these autoantibodies with their respective autoantigens in target organs, such as the kidney, leads to activation of complement and Fc receptor binding with subsequent tissue injury (Lefkowith and Gilkeson, 1996; Clynes et al., 1998). Presumably, similar mechanisms account for tissue inflammation in other organs, such as the skin and joints.

Evidence of the pathogenicity of certain autoantibodies comes from studies of human polyclonal anti-dsDNA and murine monoclonal anti-dsDNA or anti-nucleosome (anti-chromatin) IgG antibodies. The passive transfer of these antibodies into non-autoimmune mice induces glomerular pathology that is similar to that seen in human lupus (Raz et al., 1989; Vlahakos et al., 1992). Mice that transgenically express immunoglobulin genes coding for anti-dsDNA antibodies also develop immune complex-mediated proliferative glomerulonephritis (Roark et al., 1995a; 1995b). In addition, genetic disruption of the ability of B cells to produce (auto)antibodies results in markedly diminished glomerular pathology in lupus-prone mice (Shlomchik et al., 1994; Chan et al., 1999). In humans, increases in serum titer often precede, or are coincident with, worsening of renal disease (Koffler et al., 1967; Hecht et al., 1976). Autoantibodies other than those directed against chromatin may also incite immune complex renal disease, and end-organ injury may also result from non-antibody dependent mechanisms (Chan and Shlomchik, 1998; Chan et al., 1999; Shlomchik et al., 2001).

The precise site of interactions between autoantibody and autoantigen is unclear. Three hypotheses have been proposed to explain the process by which immune complexes containing anti-chromatin antibodies are formed (reviewed in Gilkeson, 1999). The first proposes that the interaction between these autoantibodies and antigen occurs exclusively in the serum, with subsequent deposition in tissues. This explanation now appears unlikely since multiple attempts to detect immune complexes containing DNA in the serum of lupus patients have failed (Izui et al., 1977; Sano and

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Morimoto, 1981). Further, the passive transfer of preformed complexes containing anti-DNA antibodies in mice has not resulted in glomerular inflammation (Emlen and Mannik, 1982). A second postulates that anti-chromatin or anti-DNA antibodies may cross-react with antigens, such as laminin or actin, in the glomerulus to form immune complexes (Jacob et al., 1985; Faaber et al., 1986; Madaio et al., 1987; Raz et al., 1993; Mostoslavsky et al., 2001; Deocharan et al., 2002; Mason et al., 2004; Zhao et al., 2005), and/or that a subset of autoantibodies directly binds glomerular structures (Liang et al., 2004). An alternative possibility is that circulating antigen is trapped *in situ* within the kidney and subsequently binds anti-dsDNA antibodies. Evidence for the latter hypothesis comes from the observation that circulating nucleosomes, normally generated during the process of apoptosis (Bell et al., 1990; Emlen et al., 1994; Tax et al., 1995), can bind to proteins within the glomerular basement membrane, particularly type IV collagen (Izui et al., 1976; Schmiedeke et al., 1989; Bernstein et al., 1995; Di Valerio et al., 1995). Regardless of the precise mechanism(s) involved, immune complexes that are located within the kidney can induce inflammation and tissue destruction by activating phagocytic cells bearing Fc and complement receptors (Clynes et al., 1998).

Properties of autoantibodies influence pathogenicity. These properties include the net charge of the antigen-binding region, isotype, and avidity of the antibody for DNA. Cationic antibodies are more likely to be pathogenic (Lefkowith et al., 1996; Liang et al., 2004), presumably due to increased avidity for negatively charged antigens such as DNA, and preferentially bind in the kidney (Dang and Harbeck, 1984). Isotypes that bind complement well (IgG2a) are more pathogenic in murine models than other isotypes (IgG1). Some studies have found no striking difference in the variable (V) gene segment usage of heavy or light immunoglobulin chains found between lupus-prone and non-autoimmune mice, or in studies of human lupus patients (Gilkeson, 1999), suggesting that germline gene segment rearrangement does not affect the pathogenicity of anti-dsDNA antibodies; however, ANA isolated from lupus-prone mice do have increased utilization of certain gene families, compared with non-ANA binding antibodies (Liang et al., 2004).

Anti-dsDNA antibodies may also induce tissue injury in the brain. Recent studies have demonstrated that a subset of anti-dsDNA antibodies in the mouse can cross-react with *N*-methyl-D-aspartate (NMDA) receptors in the brain, with the functional capacity to induce excitotoxic neuronal cell death, providing a putative mechanism for induction of pathologic responses in central nervous system (CNS) lupus (DeGiorgio et al., 2001). More recent work by these investigators has shed light on this issue, with the demonstration that lipopolysaccharide (LPS), a ligand for Toll-like receptor (TLR) 4, can accentuate autoantibody-mediated brain injury in a peptide-induced lupus model (Kowal et al., 2004). Given the capacity of LPS to induce a breach in the blood–brain barrier (BBB) (Xaio et al., 2001), this work suggests an initiating mechanism whereby autoantibodies produced in the periphery in SLE can enter the brain.

ABNORMALITIES OF B-CELL ACTIVATION

Experimental evidence from murine and human lupus has consistently suggested that there is an intrinsic abnormality in lupus B cells that leads to dysregulated production of autoantibodies. Work done over a decade ago supported this conclusion with the demonstration that pre-B cells isolated from the fetal liver of lupus-prone NZB × NZW F1 mice (NZB/W), transferred into scid mice, led to IgM and IgG hyperglobulinemia, production of antinuclear antibodies, and, in some mice, lupus-like deposition of IgG in the kidney with significant proteinuria (Reininger et al., 1992). The transfer of pre-B cells from non-autoimmune mice did not lead to these characteristic signs of autoimmunity. B cells from lupus-prone mice are also more sensitive to stimulation from T cells (Jongstra-Bilen et al., 1997). These data are consistent with studies in human lupus that demonstrate that B cells are hyperproliferative and produce more antibodies spontaneously, including autoantibodies (Blaese et al., 1980).

The mechanism(s) responsible for this hyper-effector phenotype of lupus B cells remains largely unknown. Such alterations can be secondary to changes in B-cell subsets, cytokine production, expression of effector molecules, and/or cell signaling pathways. An expansion of the early plasma cells ($CD38^+$ $CD19^+$ $CD10^-$ $CD20^-$ $CD21^+$ $CD24^-$ $CD39^+$ $CD5^-$ VLA-4^+ VLA-5^- MPC-1^- and surface membrane IgM^-) has been noticed in peripheral blood of lupus patients (Harada et al., 1996). Others have confirmed these results by showing an increased frequency and absolute number of plasmablasts and plasma cells ($CD19^+$ $CD27^{high}$ B cells) in lupus patients (Odendahl et al., 2000; Arce et al., 2001). Correlation between circulating $CD27^{high}$ plasma cells and disease activity in patients with SLE is also found (Jacobi et al., 2003).

Abnormal cytokine production and expression of effector molecules on the cell surface have been investigated in both human and murine lupus. B cells and monocytes from lupus patients produce more interleukin 10 (IL-10) and are more sensitive to IL-10 stimulation (Llorente et al., 1993; 1994; 1995; Csiszar et al., 2000). Further, B cells from lupus patients with active disease abnormally express CD40 ligand, compared with those isolated from patients in remission or from healthy controls (Desai-Mehta et al., 1995). Expression of CD40L could be induced on B cells from lupus patients in remission but not on control B cells,

supporting the idea of an intrinsic difference in lupus B-cell phenotype. Indeed, a short course of anti-CD40L antibody has improved serologic activity and hematuria in lupus patients with nephritis (Boumpas et al., 2003). Such treatment has reduced the frequency of IgG and IgG anti-DNA antibody-producing B cells (Huang et al., 2002) and eliminated CD38 (bright) Ig-secreting cells that are found in lupus patients, in particular those with active disease (Grammer et al., 2003). Taken together, these findings demonstrate that, in lupus, opportunities for T/B interaction exist that do not exist in unaffected individuals. It seems likely that aberrant production of cytokines (such as IL-10) and expression of surface effector molecules such as CD154 (CD40L) sets up a self-perpetuating cycle of lymphocyte activation that ultimately enhances disease progression.

Evidence suggests that signal transduction in B cells is abnormal in lupus. Abnormalities in both positive and negative regulation of B-cell receptor (BCR) signaling have been described. For example, in human lupus, B cells differ in their biochemical imprint after BCR stimulation, having greater protein tyrosine phosphorylation and free calcium release than control B cells after BCR stimulation (Liossis et al., 1996). The reasons for these differences are unclear, although genetic studies from mice indicate that deficiencies in molecules that down-regulate B-cell activation lead to a lupus phenotype. For example, CD22 is a B-cell specific transmembrane glycoprotein, which is phosphorylated after BCR signaling and assists in the recruitment of SHP-1 phosphatase into the BCR signaling complex. It, therefore, serves as an important downregulator of B-cell activation (O'Keefe et al., 1996). B cells from mice deficient in CD22 (through targeted gene knockout) are also hyper-responsive after BCR stimulation and develop high titers of IgG anti-dsDNA antibodies (O'Keefe et al., 1996; 1999). Similarly, genetic disruption of other negative signaling molecules in mouse B cells, for example the inhibitory receptor FcγRIIB, also lead to a lupus-like phenotype, depending upon the background murine strain (Bolland and Ravetch, 2000; Fukuyama et al., 2005). The role of CD22, inhibitory Fc receptors, and other B-cell receptor-associated proteins, such as CD21, in regulating B-cell activity in human lupus is unknown and is an important area for investigation.

The role of B cells as antigen-presenting cells (APCs) also appears important to the development of lupus. Lupus-prone MRL/Fas^{lpr} mice genetically deficient in B cells had a significantly reduced number of activated and memory T cells with a shift towards a naïve phenotype, when compared with B-cell intact animals (Chan and Shlomchik, 1998). As a consequence, T-cell infiltration of the skin and kidney was markedly reduced.

In summary, lupus B cells appear to be intrinsically abnormal in terms of BCR signaling, with enhanced production of, and sensitivity to, cytokines tropic to B cells as well as aberrant expression of effector molecules. These abnormalities result in dysregulation of antibody production and may also lead to inappropriate activation of T cells and abnormal T/B collaboration.

The conclusions that autoantibodies against chromatin and other nucleoproteins are central to the pathogenesis of lupus, and that B-cell abnormalities exist in disease, assume even greater significance in view of emerging evidence from several laboratories that TLR stimulation by endogenous ligands such as chromatin may play an important role in the pathogenesis of SLE. Toll-like receptors are pattern recognition receptors that recognize various pathogen-associated molecular structures including LPS, dsRNA, ssRNA and hypomethylated cytosine and guanosine sequence (CpG) DNA (Iwasaki and Medzhitov, 2004). Signals from TLR9 upon engagement by chromatin, presumably released from apoptotic cells, may potentiate autoimmune responses in lupus (Leadbetter et al., 2002). TLR9, as well as TLR3, recognize ligands not restricted to pathogens, unmethylated DNA present in mammalian chromatin (Viglianti et al., 2003), and dsRNA, respectively (for review, see Pasare and Medzhitov, 2003). In the former example, DNA upon direct engagement of anti-DNA-specific surface Ig, even in the absence of immune complexes, can initiate TLR9 signaling and sequential autoreactive B-cell activation (Viglianti et al., 2003); i.e., chromatin engaged by surface anti-DNA Ig may be delivered to intracellular TLR9 after endocytosis (Ahmad-Nejad et al., 2002). Such a scenario may be likely in SLE with its apparent abnormalities in the signaling threshold for B cells (Liossis et al., 1996), enabling them to bypass the normal anergic signals induced via surface Ig in contact with continually present self-antigen (Rui et al., 2003), and allowing them to garner help from available self-reactive, chromatin-specific, $CD4^+$ T cells (Mohan et al., 1993) (Figure 28.1).

T CELLS ARE REQUIRED FOR AUTOANTIBODY GENESIS AND DISEASE

The production of antibodies against chromatin and ribonucleoproteins is an antigen-driven process that is dependent on T-cell help (see Figure 28.1). This conclusion is based upon two essential lines of evidence. First, genetic analyses of high affinity, pathogenic murine and human IgG anti-DNA autoantibodies has revealed clonal selection and somatic mutation (Shlomchik et al., 1987; 1990; Davidson et al., 1990; Marion et al., 1990; O'Keefe et al., 1990). Apparent antigen selection and somatic hypermutation of autoantibodies suggests that autoreactive B cells in lupus require autoantigen-specific cognate and contact-dependent αβ T-cell help (reviewed in Craft et al., 1999), given the requirement of αβ T cells for immunoglobulin somatic

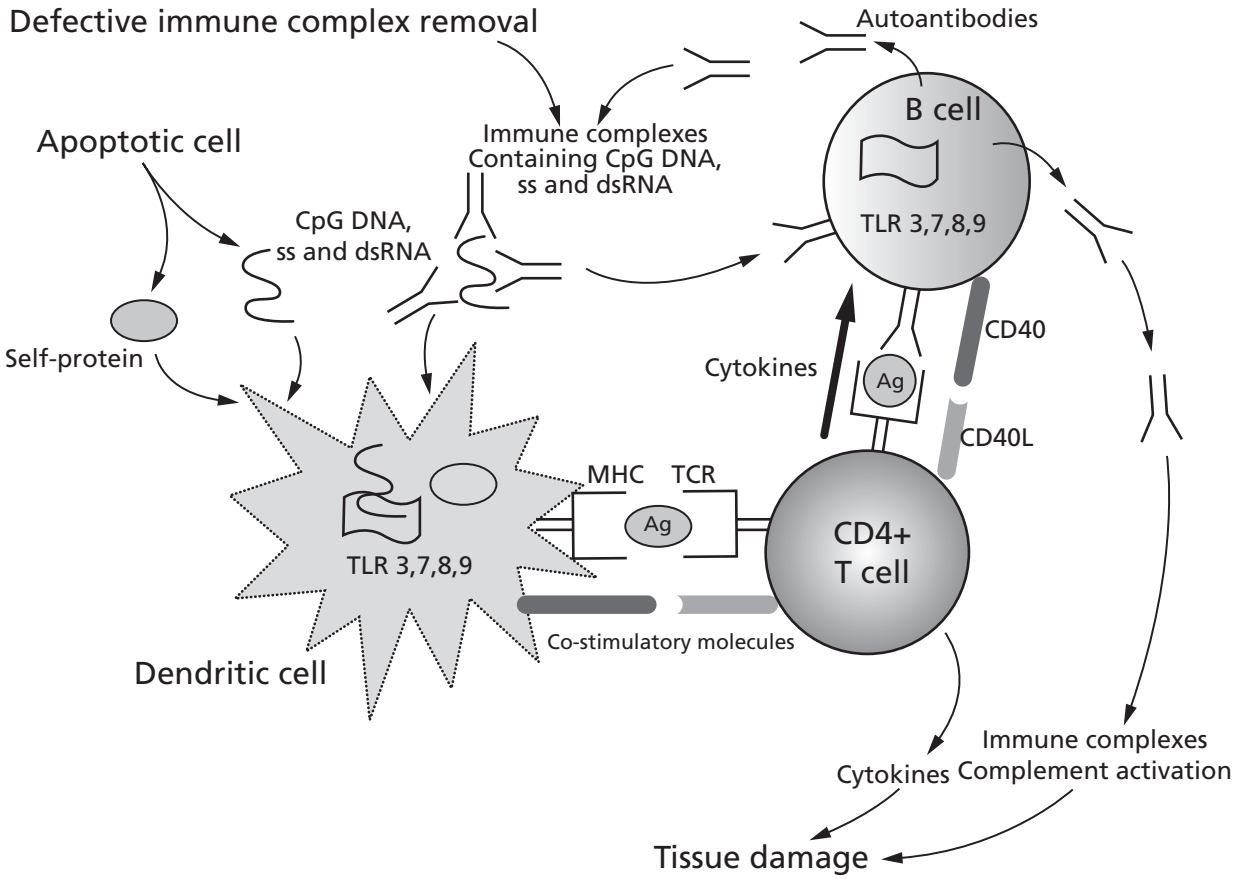

FIGURE 28.1 Immunologic pathogenesis of systemic lupus erythematosus (SLE). The figure depicts potential immunologic mechanisms involved in the development of SLE. These include defects in immune complex removal, apoptosis, and antigen presentations by antigen presenting cells (APCs) such as dendritic cells, as well as altered T- and B-cell interactions and their cytokine and autoantibody production. Nucleic acids (CpG DNA and ssRNA) from self and from microorganisms can also participate in stimulating APCs and B cells through Toll-like receptors (TLRs). Ag, antigen; ds, double stranded; MHC, major histocompatibility complex; ss, single stranded; TCR, T-cell receptor.

hypermutation and isotype switching in secondary lymphoid organs.

Second, early work demonstrating that neonatal thymectomy of lupus-prone mice led to abrogation of IgG anti-dsDNA synthesis and glomerulonephritis, and to improved mortality, indicated the T-cell dependence of autoantibody production (Steinberg et al., 1980). Similar results were obtained after treatment of these animals with antibodies that depleted $Thy1^+$ cells (Wofsy et al., 1985) or $CD4^+$ cells (Santoro et al., 1988). Genetic studies targeting $CD4^+$ T cells (Jevnikar et al., 1994; Koh et al., 1995) or αβ T-cell receptors (Peng et al., 1996b) in lupus-prone mice have provided further evidence for the T-cell dependence of disease in lupus. Furthermore, T cells have been isolated from (NZB × NZW)F1 and from (SWR × NZB)F1 (SNF1) lupus-prone mice that help anti-DNA production *in vitro* and accelerated disease when transferred to pre-nephritic mice *in vivo* (Ando et al., 1987; Mohan et al., 1993; Singh et al., 1995; Kaliyaperumal et al., 1996). Presumably similar pathways exist in SLE that account for the production of pathogenic autoantibodies by chromatin-peptide specific autoreactive T cells (Lu et al., 1999).

T cells that are reactive with lupus nuclear antigens including DNA-histones and small nuclear ribonucleoproteins have been isolated from peripheral blood of lupus patients (Rajagopalan et al., 1990; Crow et al., 1994; Desai-Mehta et al., 1995; Hoffman, 2004). These cells are typically $CD4^+$ and can provide help to B cells in producing anti-DNA and antihistone antibodies, supporting the idea that T cells that promote autoantibody generation are autoreactive. In fact, lupus-prone mice with transgenic T cells recognizing foreign antigens failed to promote the development of lymphadenopathy or pathogenic immune-complex disease, as assayed by cutaneous, renal, and salivary gland lesions (Peng et al., 1996a).

As in a normal immune response, αβ T-cell help in lupus is an MHC-restricted interaction between an αβ T-cell and B-cell recognizing epitopes derived from the same antigen.

This interaction is dependent upon binding of CD154 (CD40L) on the activated T cells to CD40 on the B-cell surface. Interruption of either CD154-CD40 or the CD28 CD80/86 (B7.1/B7.2) ligand pair interactions in lupus-prone mice by antibodies, fusion protein (CTLA-4Ig), or genetic knockout results in diminished autoantibody synthesis and end-organ disease (Finck et al., 1994; Mohan et al., 1995; Early et al., 1996; Ma et al., 1996; Daikh et al., 1997; Peng et al., 1997; Kalled et al., 1998). In addition, soluble CD154, cleaved from the cell membrane by matrix metalloproteinases, may serve as an additional pathway to activation of both cognate and non-cognate APCs (Kato et al., 1999; Vakkalanka et al., 1999). In fact, soluble CD154 levels are elevated in lupus patients, particularly in those with active disease (Kato et al., 1999; Vakkalanka et al., 1999).

ABNORMALITIES OF T CELLS

In human and murine lupus, αβ T cells are necessary for full penetrance of autoantibody production and disease. It appears that activation of such cells in lupus is a consequence of peripheral tolerance abrogation, as central tolerance appears intact to conventional peptide antigens (Singer and Abbas, 1994; Fatenejad et al., 1998), with the subsequent development of autoantigen-reactive T cells (Hoffman et al., 1993; Yan and Mamula, 2002). The events that lead to this are largely unknown. The potential mechanisms for the loss of T-cell tolerance to autoantigens in lupus include exposure to cryptic or self-antigens during apoptosis (Lanzavecchia, 1995; Doyle and Mamula, 2001), an abnormal activation threshold (Tsokos et al., 2003), excess costimulation (Desai-Mehta et al., 1996; Crow and Kirou, 2001), or inappropriate control by regulatory T cells (Shevach, 2000; Powrie and Maloy, 2003).

Regarding these possibilities, evidence suggests that lupus T cells may have intrinsic (genetic) defects that render them more susceptible to activation through their T-cell receptor (TCR)–CD3 complex after contact with self-peptides. This hypothesis stems from several observations. First, T cells from humans with SLE appear to have abnormalities in TCR signaling (Kammer et al., 1996; Vassilopoulos et al., 1995; Wong et al., 1999; Tsokos et al., 2003), anergy avoidance (Yi et al., 2000; Xu et al., 2004) and apoptosis (Elkon, 1994; Kovacs et al., 1996; Budagyan et al., 1998), as well as in expression of effector molecules, including CD40 ligand (CD154) (Desai-Mehta et al., 1996; Koshy et al., 1996; Kato et al., 1999; Vakkalanka et al., 1999). Second, lupus-prone mice have increased numbers of activated T cells (Rozzo et al., 1994; Sabzevari et al., 1997; Ishikawa et al., 1998) as well as enhanced responsiveness to TCR triggering *in vitro* and *in vivo* (Vratsanos et al., 2001b; Bouzahzah et al., 2003; Zielinski et al., 2005). Moreover, initial B-cell help and follicular migration in lupus appears to depend upon polyclonally activated T cells, rather than merely upon monoclonal or oligoclonal populations (Busser et al., 2003), adding credence to the notion that polyclonal activation is critical for disease initiation. Third, a genetic locus on chromosome 7 from lupus-prone New Zealand mice (NZM; New Zealand mixed) contributes to a heightened threshold of T-cell activation and a lower threshold for apoptotic death (Morel et al., 1997; Mohan et al., 1999) although these latter defects may be secondary to APC abnormalities (Sobel et al., 2002).

A series of defects in intracellular signaling have been identified in human lupus T cells (Kammer, 2005). Such T cells appear hyper-responsive after TCR engagement, with exaggerated intracellular calcium concentration and increased cytoplasmic protein tyrosine phosphorylation following anti-CD3 antibody stimulation (Liossis et al., 1998; Tsokos et al., 2003). In addition, lupus T cells have decreased TCR/CD3ζ expression, with upregulated FcRγ chain that replaces the TCR/CD3ζ chain (Enyedy et al., 2001). FcRγ forms a complex with Syk kinase, which is known to signal 100 times more effectively than ζ-ZAP-70 complex. This rewiring of T-cell signaling in lupus could be responsible for abnormally increased T-cell responses (Tsokos et al., 2003), and may be a consequence of abnormal lipid raft formation observed in T cells from patients (Jury et al., 2004; Krishnan et al., 2004). In addition to these proximal defects in TCR-mediated signal transduction, more distal signaling abnormalities also have been identified, with the ultimate activation of the Ca^{2+}-calmodulin kinase IV signaling cascade and downregulation of IL-2 gene transcription (Elliott et al., 2004; Juang et al., 2005) (reviewed in Kammer et al., 2002; Kammer, 2005). Given the role of IL-2 in tolerance maintenance, these signaling events could lead to aberrant T-cell function in SLE (Kammer, 2005).

Coincident with the above explanation are the several studies that have reported abnormalities in T-cell activation-induced cell death in lupus (Kovacs et al., 1996; Budagyan et al., 1998; Xu et al., 2004). For example, a recent study has demonstrated that activated T cells of lupus patients resist anergy and apoptosis by markedly upregulating and sustaining cyclooxygenase-2 (COX-2) expression (Xu et al., 2004). Inhibition of COX-2 induced apoptosis of the anergy-resistant lupus T cells by augmenting Fas signaling and markedly decreasing the survival molecule c-FLIP (cellular homolog of viral FLICE inhibitory protein). Of interest, the gene encoding COX-2 is located in a lupus-susceptibility region on chromosome 1, which supports the notion of genetic (intrinsic) T-cell defects in lupus.

T cells expressing $CD4^+CD25^+$ are regulatory T cells that suppress immune responses and maintain self-tolerance (Shevach, 2000). A decreased frequency of regulatory T cells has been reported in peripheral blood of lupus patients during active disease, when compared with healthy controls

(Liu et al., 2004). However, the result of this study is complicated by the fact that activated T cells also express CD25, the α chain of the IL-2 receptor. It will be useful to employ an additional marker such as forkhead box P3 (FOXP3) for better understanding of the role of regulatory T cells in lupus (Coffer and Burgering, 2004; Mills, 2004).

Abnormalities in T-cell-mediated cytotoxic activity also have been reported in lupus patients. T cells from lupus patients have impaired mitogen-induced cytotoxicity (Stohl, 1995; Warrington and Rutherford, 1990) and decreased cytotoxic response against allogeneic or xenogeneic targets (Charpentier et al., 1979; Tsokos et al., 1985). However, the effect of such abnormalities on controlling of pathogens was not known. Recently, Kang and colleagues demonstrated that lupus patients have increased Epstein–Barr virus (EBV) viral loads in peripheral blood cells that likely stems from inadequate $CD8^+$ T-cell responses against EBV (Kang et al., 2004). However, these patients can mount appropriate EBV-specific $CD4^+$ T-cell responses that account for lack of the development of EBV-associated lymphoproliferative diseases. The results of this study support the notion that lupus patients have abnormal $CD8^+$ T-cell function that can potentially affect the control of pathogens.

T-cell cytokines have been extensively studied in lupus patients. For example, spontaneous production of IL-10, a Th2 cytokine, from peripheral blood cells is significantly higher in lupus patients compared with controls (Llorente et al., 1993; 1994). This result is further validated by the findings of increased IL-10 mRNA expression in peripheral blood cells (Csiszar et al., 2000) and increased serum IL-10 levels in lupus patients (Houssiau et al., 1995). Such increased IL-10 production in lupus may have a pathogenic role since this cytokine is a potent stimulator of B-cell proliferation and differentiation. In fact, serum IL-10 levels correlate with disease activity and anti-dsDNA antibody titers (Houssiau et al., 1995; Park et al., 1998; Tyrrell-Price et al., 2001). Although T cells produce IL-10, the predominant source of IL-10 in lupus appears to be non-T cells such as B cells and monocytes (Llorente et al., 1993; 1994; Csiszar et al., 2000). In fact, a recent study has demonstrated that immune complexes in SLE sera stimulate IL-10 production from peripheral blood mononuclear cells (PBMC) possibly acting through FcγRII expressed by $CD14^+$ monocytes (Ronnelid et al., 2003).

INNATE IMMUNITY AND LUPUS

The potential role of interferon-α (IFN-α) in the pathogenesis of lupus was suggested in the late 1970s by a study reporting increased serum levels of IFN-α in lupus patients (Hooks et al., 1979). This notion has been recently revived by several groups that have demonstrated increased expression of interferon-induced genes in peripheral blood cells from lupus patients, using microarray analyses (Baechler et al., 2003; Bennett et al., 2003). The role of IFN-α in lupus is further supported by the clinical findings that some patients receiving IFN-α for the treatment of viral hepatitis and malignancy develop drug-induced lupus and other autoimmune diseases (Baechler et al., 2004; Crow and Kirou, 2004).

Interferon-α can affect innate and adaptive immune cell function. It has antiproliferative effects on T cells (Petricoin et al., 1997) and enhances immunoglobulin isotype switching by stimulating dendritic cells (Doyle and Mamula, 2001). Interferon-α induces maturation of dendritic cells and drives monocytes to become more effective in stimulating allogeneic T cells (Radvanyi et al., 1999; Blanco et al., 2001; Dalod et al., 2003). In addition, IFN-α can regulate the production of cytokines such as IL-10 and IL-12 by monocytes in response to bacterial stimulation (Hermann et al., 1998). The results of murine lupus studies also provide evidence for the role of IFN-α in the development of lupus. Administration of poly(inosine-cytosine), a synthetic dsRNA and strong IFN-α inducer, accelerated development of disease in (NZB × NZW) F1 mice (Reeves et al., 1981). Lupus-prone mice lacking receptors for type I interferons including IFN-α had reduced anti-dsDNA antibodies and disease activity (Santiago-Raber et al., 2003).

The mechanisms of induction of IFN-α in lupus patients are not clear yet. Obviously, viral infection is a strong inducer of IFN-α. However, there is no convincing data yet showing that lupus patients have chronic active viral infection that causes increased IFN-α production. Of interest, Rönnblom and Alm have demonstrated that immune complexes in lupus serum containing autoantibodies associated with apoptotic fragments, DNA, or RNA can stimulate plasmacytoid dendritic cells (PDCs) to produce IFN-α (Rönnblom and Alm, 2001a; 2001b). Such events can be mediated by TLRs (Baechler et al., 2004; Crow and Kirou, 2004). Plasmacytoid dendritic cells express TLR9, which recognize CpG DNA (Iwasaki and Medzhitov, 2004). Thus, immune complexes in lupus serum containing CpG DNA and anti-DNA antibodies can stimulate PDC to produce IFN-α (see Figure 28.1). This notion is supported, as discussed above, by two studies showing that murine B-cell hybridomas with specificity to rheumatoid factor or DNA activate B cells by engaging both immunoglobulin receptors and TLR9 (Leadbetter et al., 2002; Viglianti et al., 2003). A similar concept has been raised by recent studies demonstrating the role of TLR7 and TLR8 in cellular responses to ssRNA (Diebold et al., 2004; Heil et al., 2004) since antibodies against small nuclear RNA and protein complexes are often found in lupus patients (Baechler et al., 2004; Crow and Kirou, 2004).

SUMMARY AND FUTURE DIRECTIONS

The immunopathogenesis of SLE involves the broad spectrum of the immune system from innate to adaptive immunity. In the latter, both T and B cells are critical for the development of clinical disease, with autoantibodies against chromatin and ribonucleoproteins as serologic hallmarks (Shlomchik et al., 2001). B and T cells in SLE appear to be intrinsically abnormal in terms of antigen–receptor mediated activation, events likely related to genetic abnormalities (Shlomchik et al., 2001; Vratsanos et al., 2001a). Recently, sizeable data supporting a role for aberrant innate immune responses in SLE have accumulated, based on the studies demonstrating upregulation of IFN-α inducible genes in peripheral blood cells of patients, and activation of PDCs with IFN-α production in response to the immune complexes containing DNA and RNA via TLRs (reviewed in Crow and Kirou, 2004). However, there are still a number of missing links in these observations. We do not know the initial event(s) leading to the development of SLE and the characteristic pathogenic autoantibodies, and whether such an event is continuously required for the maintenance of autoantibody production and clinical disease. Although there is a potential link between innate and adaptive immunity as suggested by DC and IFN-α studies, it is unclear how IFN-α affects the function of adaptive immune cells like B- and T cells. Furthermore, fuller identification of the potential genetic alterations responsible for intrinsic B- and T-cell abnormalities and the immunologic consequences of such abnormalities are needed in human lupus. The results of these investigations will provide new diagnostic and therapeutic insights in SLE.

Systemic Sclerosis, Scleroderma

CHRISTOPHER P. DENTON AND CAROL M. BLACK

Centre for Rheumatology, Royal Free and University College Medical School, Rowland Hill Street, London NW3 2PF, U.K.

The first convincing description of systemic sclerosis (SSc) was a report of Carlo Curzio in 1753, although the term scleroderma was not applied until a century later (Gintrac, 1847). These early cases focused upon the diffuse cutaneous subset, recognition of limited cutaneous SSc was much later, with the definition of CREST (Calcinosis, Raynaud phenomenon, Esophageal involvement, Sclerodactyly, Telangiectasis) syndrome by Winterbauer in 1964. As outlined below, the terms CREST and progressive systemic sclerosis (PSS) are generally avoided as they are potentially misleading. Patients with CREST represent a subset of cases of limited cutaneous SSc, and other complications such as lung fibrosis, gut disease, and pulmonary hypertension are not highlighted. Progressive SSc is misleading as not all cases of diffuse cutaneous SSc are progressive. Regression of skin involvement for example is common.

Systemic sclerosis, although uncommon, has the highest case-specific mortality of any of the autoimmune rheumatic diseases. This is largely as a consequence of organ-based vascular and fibrotic complications. In fact SSc can be regarded as a prototypic fibrotic disease and serves as a reminder that much of the morbidity of autoimmune and inflammatory disease occurs due to fibrosis, or scarring. Autoimmunity is nevertheless a hallmark of the condition; evidenced by the near universal occurrence of antinuclear antibodies (ANA) and the association of a number of hallmark ANA reactivities with SSc. In addition, there is evidence of immunologic reactivity to extracellular matrix components and early-stage skin and lung involvement is characterized by a T-lymphocyte-rich mononuclear inflammatory cell infiltrate.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Clinical Features

Systemic sclerosis is a multisystem disease, and the clinical features can be divided into those that are generally present in all cases, to a greater or lesser degree, and the features only present in a minority of affected individuals (Figure 29.1). The former include skin and musculoskeletal involvement leading to sclerodactyly; Raynaud phenomenon, the absence of which in established SSc should lead to the diagnosis being questioned, and esophageal dysmotility and reflux. Changes in the skin usually proceed through three phases: early, established, and late. The early stage can be difficult to diagnose, and a high level of suspicion is needed in the edematous phase when the only feature may be puffiness of the hands and feet, most marked in the morn-

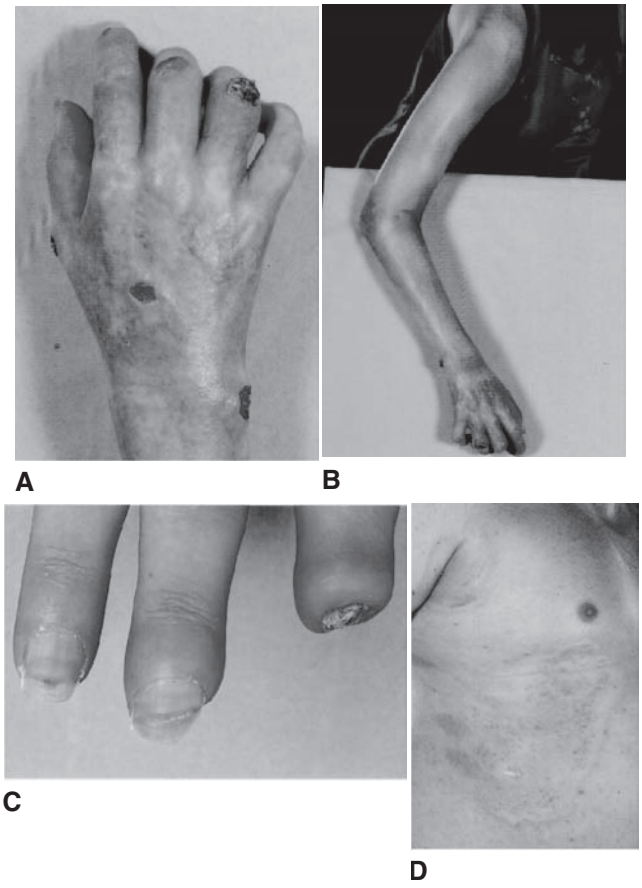

FIGURE 29.1 Clinical features of scleroderma. Skin involvement is widespread in diffuse cutaneous systemic sclerosis *(A,B)* but much more restricted in limited cutaneous systemic sclerosis *(C)*. Digital loss from severe vascular disease is common. *D,* Morphea plaque: although histologically similar to systemic sclerosis, skin involvement in localized scleroderma has a distinctive clinical appearance and distribution. See color plate section.

ings. Edema may be dependent and can lead to symptoms of neural compression including carpal tunnel syndrome. The face may feel slightly taut at this stage and Raynaud phenomenon may be present. On examination there is a nonpitting edema with intact epidermal and dermal appendages. The subsequent, often abrupt, development of firm, taut, hidebound skin proximal to the metacarpophalangeal joints, adherent to deeper structures such as tendons and joints, causing limitation of their movement and subsequent contractures, permits a definitive diagnosis in over 90% of patients. The skin may be coarse, pigmented, and dry at this stage. The epidermis thins, hair growth ceases, sweating is impaired, and skin creases disappear.

A consensus classification for scleroderma spectrum disorders has been developed that separates localized from systemic disease (Table 29.1). Localized scleroderma encompasses the various forms of morphea and linear scleroderma occurring in adults or children. In its classical forms, it is not associated with internal-organ disease. The traditional boundaries between different clinical subgroups of the scleroderma spectrum are being blurred although the basic principles of classification remain (Anonymous, 1980). It is now appreciated that there are some cases of SSc that develop one or more areas of localized scleroderma, generally plaque morphea, and conversely it is reported that some patients with typical localized scleroderma develop serologic features of systemic disease or other autoimmune rheumatic disorders such as systemic lupus erythematosus (SLE). Also, a subset of patients with clinical features of isolated Raynaud phenomenon have evidence of microvasculopathy based upon nailfold capillaroscopy, or have serum autoantibodies against nuclear antigens. Such cases may progress to develop a defined multisystem autoimmune disease, with best estimates suggesting between 10 and 15% of cases evolving in this way within 5 years of presentation. Also, presence of scleroderma-related capillaroscopic findings or ANAs against hallmark scleroderma antigens may identify a subset of patients who will develop features of limited cutaneous SSc. Based upon the absence of skin changes at presentation, the term “limited systemic sclerosis” has been proposed for this group (LeRoy et al., 2001). Further, there is a small number of patients who have

TABLE 29.1 Classification of Scleroderma and Systemic Sclerosis

Classification	Description
Localized scleroderma	
Plaque morphea	Fewer than four patches of localized scleroderma not following a linear distribution. Face generally spared.
Generalized morphea	More than four patches of localized scleroderma. May be very extensive but spares the hands, and Raynaud usually absent.
Linear scleroderma	Localized scleroderma in a linear distribution. Often affects the face and scalp. Usually asymmetrical even when bilateral. Most common form of childhood-onset scleroderma. Can lead to major growth deficit of underlying connective tissues. Variants include *en coup de sabre* and hemifacial atrophy.
Systemic sclerosis	
Diffuse cutaneous systemic sclerosis	Skin involvement proximal to knees, elbows or neck. Approximately 30% of SSc cases. Inflammatory features prominent in first 3 years of disease. Renal and interstitial lung involvement more common. Raynaud phenomenon may not be the first manifestation.
Limited cutaneous systemic sclerosis	Distal skin involvement. Prominent vascular rather than inflammatory features. Raynaud phenomenon invariably the first manifestation. Around 60% of SSc cases. Severe bowel involvement and isolated pulmonary hypertension are common. Lung fibrosis and renal involvement also occur.
Overlap syndromes	Cases of SSc but also manifestations of another rheumatic disease such as SLE, myositis, or polyarthritis. Approximately 15–20% cases of SSc have overlap features.
Systemic sclerosis sine scleroderma	Vascular, serologic, and organ-based manifestations of SSc but without definite skin sclerosis. A rare subset, less than 5% of cases.

SLE, systemic lupus erythematosus; SSc, systemic sclerosis.

vascular and serologic features of diffuse cutaneous SSc (dcSSc) but lack significant skin sclerosis, designated as systemic sclerosis sine scleroderma (Poomoghim et al., 2000).

Pathologic Features

In the early phase, there are collections of mononuclear cells in the dermis, particularly around blood vessels. The soluble products of these monocytes and lymphocytes may have pathogenetic significance in the disease process. Later, fibrosis replaces the cellular infiltrate and may extend deep into the connective tissue to surround tendons, nerves, muscle bundles, and joint capsules. In the final stage, the fibrosis may be less evident, with epidermal thinning and loss of appendages a prominent feature.

The pathology of SSc involves vascular change with endothelial cell activation and microvascular damage. Later, there is an inflammatory phase with mononuclear cell infiltration. Overexpression of a number of key growth factors and cytokines is common to both pathologies including transforming growth factor-β (TGF-β) isoforms and connective tissue growth factor. Later, the sclerotic phase of localized scleroderma resembles the established fibrotic lesion of SSc, and activated fibroblasts and myofibroblasts predominate. There are serologic features in common between the two conditions, including the presence of ANA reactivity or the hallmark scleroderma autoantibodies (Marzano et al., 2003) (and see later). In addition, minor reactivities against extracellular matrix components including fibrillin 1 have been demonstrated in localized as well as systemic forms of scleroderma (Tan et al., 1999). These shared features suggest that there are similar pathogenic mechanisms for these diseases and that genetic or environmental predisposition in common may underlie them.

Epidemiologic Features

Scleroderma is an uncommon disorder and most of the descriptive epidemiology is derived from retrospective or prospective reviews of patients attending hospitals or institutions serving a defined denominator population: there is only one true population-based study (Maricq et al., 1989). Although there are apparently different disease frequencies between populations, some of these may be accounted for by methodologic factors. Interestingly, although the prevalence in the UK was previously estimated in a large West Midlands population as several-fold lower than in the study of Maricq (1989), a smaller but thorough examination has recently been reported (Allcock et al., 2004) that finds higher frequency, in line with that in North America (Mayes et al., 2003) and Australia (Roberts-Thomson et al., 2001). Currently, the best estimate for UK prevalence overall is approximately 12 in 100,000 of the population (Allcock et al., 2004), which is lower than reported for North America, but not the order of magnitude lower that was suggested in earlier work. The demographic conclusions that may be drawn from these data are that the disease is rare in childhood, and that its incidence increases steadily with age among adults. Its rarity suggests that the genetic and/or

environmental exposures necessary for disease susceptibility occur infrequently in the population. Systemic sclerosis is a disorder with a female to male excess (4:1 male to female overall).

A number of geographical clusters of SSc have been reported, including clustering close to international airports in the UK (Silman, 1995). A cluster of patients with a variety of autoimmune rheumatic diseases is reported from The Republic of Georgia (Freni-Titulaer, 1989), and a clearer cluster of SSc in a region of Italy close to Rome (Valesini, 1993). In North America a high prevalence has been observed among Choctaw Native Americans in Oklahoma. There is increasing evidence for a genetic basis for this high prevalence and on-going studies are defining this in detail (Tan and Arnett, 2000). Finally, in common with some other autoimmune rheumatic diseases, various environmental agents have been implicated in SSc, including increased silica exposure.

AUTOIMMUNE FEATURES

Some of the clinical and immunologic features of SSc resemble those of other autoimmune disorders such as SLE, dermatomyositis, and rheumatoid arthritis, and there are also patients who have overlap syndromes or who have sequential development of more than one autoimmune rheumatic disease. Cases of familial SSc and familial associations of SSc with other autoimmune diseases such as rheumatoid arthritis and SLE occur and have already been mentioned. Abnormalities in both humoral and cell-mediated immunity occur in SSc, although the importance of these immunologic events in the pathogenesis remains uncertain. The lack of a generalized immune dysfunction in SSc suggests that the derangement of immune-cell dysfunction may be specific to certain antigens or cell types (Lupoli et al., 1990).

T-Cell Abnormalities

The association of SSc with particular HLA alleles and the close association of certain HLA alleles with SSc-specific antibodies is indirect evidence for T-cell involvement in SSc. Evidence for T-cell activation in SSc includes an increased ratio of circulating $CD4^+$:$CD8^+$ cells, reflecting an increased number of $CD4^+$ and/or a reduced number of $CD8^+$ lymphocytes. A particular role for $\gamma\delta$ T-cells has been suggested (White, 1994; Tiev et al., 2005), including a potential predisposition to microchimerism (Giacomelli et al., 2004), and others have reported increased numbers of lymphokine-activated killer and natural killer cells in blood samples from patients with SSc. Furthermore, several studies have found increased soluble interleukin 2 (IL-2) receptor in serum in SSc, sometimes appearing to correlate with disease activity. Support for the possibility that activated T-cells are important in pathogenesis is provided by the presence of infiltrates in lesions of $\alpha\beta$ T-cells that are $CD3^+$, $CD4^+$, $CD450^+$, interleukin 2-producing, HLA-DR^+, and leukocyte function-associated antigen-1-positive (Prescott et al., 1992). Also, in humans, chronic graft-versus-host disease (GvHD) shows several histologic and clinical similarities with SSc, and is known to be a T-cell-mediated process. Although circulating immune complexes have been reported in SSc, most studies have not found functional complement abnormalities, probably because most SSc-associated autoantibodies do not activate the complement cascade (White, 1994).

B-Cell Abnormalities

Humoral abnormalities in SSc are most clearly reflected by the presence of autoantibodies with well-defined target specificities. Autoantibody production is an early and almost universal feature of SSc, and the number of autoantibody targets identified in SSc continues to increase. The major reactants are topoisomerase 1, centromeric proteins, and RNA polymerases I, II, and III. Virtually all patients have antinuclear antibodies when HEp-2 lines are used in indirect immunofluorescence (IIF) tests. Characteristic staining patterns for ANAs within the nuclear structures are relatively specific and can be confirmed by more refined tests such as counterimmunoelectrophoresis (CIE) and Western immunoblotting. A diffusely grainy pattern of ANA staining is associated with the presence of antibodies to topoisomerase 1 (Topo 1, Scl-70), a nuclear enzyme required for the unwinding of DNA for replication and RNA transcription. Topo 1 to Scl-70 occur in up to 40% of patients with diffuse SSc and 15% of those with limited disease (Bunn and Black, 1999). The frequency of occurrence of this antibody in SSc varies between laboratories; the immunoblot technique is more sensitive than CIE and by this technique the positivity rate is 30–40% in dcSSc.

Anticentromere staining by IIF occurs in some 80% of patients with the limited form of SSc, although it is also sometimes present in other diseases including primary biliary cirrhosis and in otherwise healthy subjects. The antigens recognized by positive sera are CENP-A, CENP-B, and CENP-C, with molecular weights of 19, 80, and 140 kDa, respectively (Earnshaw et al., 1986). Since a correlation has been shown (Jabs et al., 1993) between anticentromere antibodies and aneuploidy in patients with SSc, anticentromere antibodies could disrupt centromere function and allow chromosomes to segregate inappropriately during mitosis, leading to a high rate of chromosomal breakage and sister chromatid exchange. However, this would assume that antibody can penetrate cells and, to date, no correlation has been found between the presence of anticentromere antibody and chromosomal changes.

Antibodies against RNA polymerase (RNAP) occur mainly in patients with diffuse disease, and antibodies

TABLE 29.2 Autoantibodies Associated with Systemic Sclerosis

Antigen	Frequency	Immunofluorescence pattern	Clinical association*
Centromere	60% lcSSc up to 25% in primary biliary cirrhosis, often with features of lcSSc	Centromere	Almost restricted to lcSSc subset. These patients are at risk of isolated pulmonary hypertension and severe gut disease but relatively protected from lung fibrosis
Topoisomerase 1 (Scl 70)	35% dcSSc 10–15% lcSSc	Nuclear (diffuse fine speckles)	Associated with diffuse skin involvement and especially with lung fibrosis in both subsets of SSc
RNA polymerases I and III	20% dcSSc	Nucleolar (punctate)	Associated with diffuse skin involvement and especially with renal involvement in both subsets
Fibrillarin	5%	Nucleolar (clumpy) staining of coilin bodies	Occurs in both major subsets. Associated with poor outcome in dcSSc with cardiac disease, pulmonary hypertension, renal involvement, and myositis
Polymyositis-scleroderma PM-Scl	3%	Nucleolar (homogeneous)	High frequency of myositis. In childhood may associate with milder disease but renal involvement increased in adult SSc
U1 RNP	10% SSc 5% dcSSc 14% lcSSc	Speckled antinuclear	Higher frequency in black patients with SSc. Associated with joint involvement and lung fibrosis in SSc. Also frequent in overlap syndromes

*For further details see Bunn et al., 1998; Bunn and Black 1999; Tormey et al., 2001.
dcSSc, diffuse cutaneous systemic sclerosis; lcSSc, limited cutaneous systemic sclerosis; RNP, ribonuclear protein; SSc, systemic sclerosis.

against RNAPI, II, and III have been described (Bunn et al., 1998). The RNAPs are multiprotein complexes and are components of the transcription complex (Reeves et al., 1994). Each RNAP is composed of collections of smaller proteins shared by other RNAPs and two large distinct proteins: RNAPI synthesizes ribosomal RNA precursors in nucleoli, whereas RNAPs II and III are found in nuclei. Most of the small nuclear RNAs found in ribonucleoprotein particles that mediate pre-mRNA splicing and synthesize precursors of mRNA are synthesized by RNAPII, and RNAPIII synthesizes small RNAs including single-strand ribosomal RNA and transfer RNA. Anti-RNAP antibodies target both the smaller shared subunits and the larger distinct proteins, which explains antibody reactivity against several RNAPs in one serum sample. Radioprecipitation assays are currently the only way of identifying anti-RNAPs, and require the facilities of specialized laboratories. Autoantibodies associated with SSc are detailed in Table 29.2.

Anti-fibrillarin (U3-RNP) antibodies produce a typical clumpy nucleolar staining pattern by IIF with coilin bodies appearing as bright nuclear dots. Several studies have associated this reactivity with a poor outcome, particularly in dcSSc (Tormey et al., 2001). Initial reports suggested a high frequency of isolated pulmonary hypertension, myositis, and cardiac disease in African-American SSc patients (Arnett et al., 1996).

The antinuclear antibody response is not as clear-cut in the juvenile as in the adult form of SSc, although some trends are emerging. Serum ANAs have been reported in 25–55% of juveniles (onset under 16 years of age) with localized scleroderma, the association being most marked in the linear group and in patients with extensive cutaneous lesions. Antibodies to single-stranded DNA also appear to be correlated with the extent of localized disease, whereas antibodies to double-stranded DNA are rarely found. Notably, in the generalized form of childhood scleroderma, anticentromere antibodies have not been reported, even in those children with disease identical to that found in the adult.

A direct pathogenetic role for various autoantibodies in SSc has long been sought. There are defined epitopes for several of the autoantibodies (Bunn and Black, 1999) and recent work has shown homology between target autoantigens in SSc and retroviral proteins (Prokop et al., 2004), suggesting molecular mimicry, which may have significance in disease pathogenesis. There are reports that some of the antibodies present in SSc are also able to enter intracellular compartments (Ma et al., 1991) and, thereby, to mediate intracellular events, such as the reported ability of anticentromeric antibodies to disrupt the centromere, although this remains very controversial. In addition, autoantibodies might be able to activate cells that bear the target autoantigens; for example, patients with SSc produce antibodies that bind FcγRI (CD64), FcγRII (CD32: activating), and FcγRIII (CD16: inhibitory) (Boros et al., 1993). It has been suggested that some of the autoantibodies in serum from SSc may mediate antibody-dependent cytotoxicity, and potential effector cells have been found in the skin of some patients (White et al., 1994). Another speculation is that these antibodies might contribute to the pathology if they mediated complement-dependent cellular lysis or

phagocytosis. However, these ideas must be kept in perspective balanced against the lack of correlation of antibody titer with disease duration or activity.

Other Autoantibodies

Anti-endothelial cell antibodies (AECA) have been recognized in SSc sera for many years, but their significance remains uncertain. Cross-reactivity with viral antigens has been reported, and this may provide a clue concerning the origin of these antibodies and possibly implicate viral infection in endothelial cells as a pathogenic mechanism in SSc (Lunardi et al., 2000). More recently, functional effects of AECA in SSc have been explored in detail and the ability of AECA to induce endothelial cell apoptosis has been demonstrated (Worda et al., 2003). It has been demonstrated that AECA may also react with other cell types, including fibroblasts (Renaudineau et al., 2001) and that some AECA recognize hallmark SSc-associated antigens (Garcia de la Pena-Lefebvre et al., 2004).

Other autoantibodies have also been detected in SSc as well as localized scleroderma, such as those reacting against the microfibrillar protein fibrillin 1 and antibodies against a number of different cytokines (White, 1994). These reactivities appear more likely to be related to abnormal protein expression or processing for these antigens and may provide insight into the biochemical processes that are perturbed in scleroderma spectrum disorders, although it seems unlikely that they are directly involved in disease pathogenesis.

Circulating antibodies to the extracellular matrix proteins, collagens I, III, IV and VI, and laminin and fibrillin have also been found in SSc, but their role is undetermined (Mackel et al., 1982; Tan et al., 1999).

GENETIC FEATURES

Certain of the SSc autoantibodies are closely related to particular HLA alleles. For example, the class II major histocompatibility complex (MHC) haplotype is an important factor determining *in vitro* responsiveness to topoisomerase antigen, both in patients with SSc and in healthy control individuals (Kuwana et al., 1995). Moreover, there may be racial differences in HLA associations for the various autoantibodies. These antibodies not only mark out certain subsets of patients with SSc but are of increasing importance in defining that subgroup of patients with isolated Raynaud phenomenon likely to develop SSc.

It is likely that new approaches to SSc genetics will identify additional susceptibility and severity genes. For example, gene-profiling experiments that have been fruitful in identifying over- or underexpressed genes that are associated with lesional SSc skin or fibroblasts. Interestingly, many of these genes are regulated by TGF-β, providing additional evidence that this is a key cytokine in pathogenesis of SSc (Kissin and Korn, 2002). Association studies have also been performed including a recent genome-wide screen of Choctaw Native American patients (Zhou et al., 2003). There has been recent interest in comparing gene expression in non-involved skin sites with healthy controls to determine potential susceptibility loci (Whitfield et al., 2003). Recent reports have highlighted several genes that may underlie fibroblast dysfunction in SSc through genetic linkage or association studies, and by differential display methodologies including cDNA based transcriptional profiling and polymerase chain reaction (PCR) based subtractive hybridization methods. Candidate genes include protease nexin 1 (Strehlow et al., 1999), connective tissue growth factor (Shi-wen et al., 2000), TGF-β2, -β3, and TIMP1 (Susol et al., 2000). A major challenge arising from such studies is confirmation that overexpression of these genes leads to fibrosis.

ENVIRONMENTAL INFLUENCES

A range of agents can induce a SSc-like disease and certain chemically induced SSc-like disorders tend to be associated with males, partly due to an occupational bias. It is almost certain that sporadic cases can follow certain occupational exposures, but that both the absolute and attributable risks are low (see Chapter 23). There are some MHC associations with the environmentally induced cases, for example, toxic oil syndrome is characterized by a raised incidence of HLA-DR4, while vinyl chloride disease is primarily associated with HLA-DR5 and HLA-DR3 being a marker of severity. Another environmentally induced, SSc-like condition is the eosinophilic-myalgic syndrome associated with the oral ingestion of certain preparations of the essential amino acid L-tryptophan. Although there has been much speculation about a possible association of silicone-containing cosmetic prostheses and the development of multisystem autoimmune disease, several well-conducted studies and reviews have failed to show any statistically significant association between these and SSc. Much of the work in this area has been generated by the need to obtain accurate data because of considerable litigation, particularly in the United States. Hochberg (1994) has carefully reviewed the epidemiologic aspects of the literature and has reasonably concluded that none of the available studies has demonstrated a statistical association between augmentation mammoplasty with silicone gel-filled prostheses and SSc.

ANIMAL MODELS

There are several established animal models for scleroderma, each demonstrating some features of the disease

(Christner and Jimenez, 2004). The early vascular events of scleroderma, including endothelial cell apoptosis, are demonstrated in the UCD2000 tight-skin chicken model. Fibrosis in this condition remains localized although scleroderma-associated hallmark autoantibodies have been reported at later stages. The two tight-skin mouse models for scleroderma, types 1 and 2 designated Tsk1 and Tsk2, respectively, are both genetically determined. Tsk1 is a spontaneous mutant strain demonstrating fibrosis in the skin and some internal organs (though not the lungs) from around 10 days old. It has been mapped to a partial reduplication at the fibrillin 1 gene locus on chromosome 2. This leads to secretion of a larger-than-normal fibrillin 1 protein although the mechanism by which this leads to generalized connective tissue fibrosis is unclear. Recent association of human SSc with microsatellite marker haplotypes near the fibrillin 1 locus, and detection of anti-fibrillin autoantibodies in scleroderma-spectrum disorders have revived interest in the Tsk1 model. In contrast, the precise genetic basis for Tsk2 has not yet been determined, although it has been mapped to a 25 kb region of chromosome 1. There are reports that an inflammatory cell infiltrate may precede the development of skin fibrosis and the induced nature of this strain by an environmental mutagen (ethylnitrosourea) similar to some agents associated with development of human disease, and in these respects it is possible that Tsk2 is a more complete, though less well-characterized animal model.

Chronic murine GvHD occurs after bone marrow engraftment in susceptible strains across certain H-2 differences. This model is clearly immunologically determined and has prominent mononuclear cell infiltrates in the skin and viscera. It has been shown to be treatable using agents that neutralize TGF-β. Other models that have recently been described include induction of skin sclerosis by bleomycin in certain mouse strains that are resistant to lung disease. This process has also been demonstrated to be TGF-β dependent, as it is absent in Smad3-deficient animals. A hybrid mouse strain in which the IFN-γ receptor knockout line is back-crossed with a pro-inflammatory line has also been described. Other genetically modified mice are now being characterized, which may further illuminate pathogenic processes *in vivo* and allow the role of key pathways and gene products in the development of scleroderma to be assessed.

Lineage-specific gene expression can be used to develop novel genetic models for SSc (Denton et al., 2003). For example, transgenic mice expressing a mutant kinase-deficient type II TGF-β receptor provide an exciting and novel genetically determined model for SSc. Paradoxically, although this construct sometimes operates as a dominant negative inhibitor of TGF-β signaling, *in vivo* under the control of a fibroblast-specific expression cassette this construct appears to result in facilitation of basal TGF-β signaling activity. Transgenic mice develop dermal and sporadic pulmonary fibrosis, recapitulating two of the key pathologic features of SSc (Denton and Abraham, 2004).

PATHOGENIC MECHANISMS

There have been intensive efforts over the past two decades to define the key pathogenetic components that drive the scleroderma process. These efforts have been hampered by disease heterogeneity, which implies that some events occur to a different extent in the two major subsets, and also by the necessity to explain different patterns of organ-based disease. As with many complex diseases, it is accepted that there are important host (genetic) and environmental factors involved in pathogenesis, and for many patients it seems likely that a triggering event occurring in the context of a susceptible host is a key process.

Macrophages, mast cells, eosinophils, and basophils are found in increased numbers and in an activated state in tissues of patients with SSc. These cells are capable of producing soluble mediators and can thereby modify endothelial and fibroblast function; for example, mast cells produce histamine, which stimulates both proliferation and matrix synthesis by fibroblasts and causes retraction of endothelial cells.

The initiating stimulus in idiopathic scleroderma is unknown, although the identification of chemical precipitants for environmentally induced SSc as discussed above (e.g., vinyl chloride and epoxy resin) may provide some clues to the processes involved, particularly in view of the similar immunogenetic associations for both idiopathic and chemically induced disease (Black et al., 1983). The most obvious major targets for the immune response in SSc are endothelial cells and fibroblasts. Stimulation of collagen synthesis could involve an increasing number of cytokines known to modulate the properties of fibroblasts. It is possible that cascades of such cytokines or autocrine/paracrine loops stimulate or maintain the disease process. It is now appreciated that the repertoire of mediators and cytokines produced by immune cells, fibroblasts, and endothelial cells is large. It is possible that the aberrant properties of connective tissue cells (e.g., excess synthesis of collagen, fibronectin, and glycosaminoglycans) and the endothelial-cell damage and vasculopathy, are consequences of the immunological events in SSc.

The ultimate effector cell of scleroderma is a matrix synthesizing fibroblastic cell. These cells often express markers and phenotypic properties of myofibroblasts (Kissin and Korn, 2002). There may well be phenotypic fluidity between fibroblasts and myofibroblasts and also between components of the vasculature such as microvascular pericytes. It has also been suggested that circulating progenitor cells may be deposited at sites of fibrosis; in line with this, there are recent reports of circulating endothelial cells in SSc (Del Papa

et al., 2004). Embryonically defined regulatory elements within extracellular matrix genes have recently been identified as potential targets for activation in a mouse model of scleroderma (see earlier), and these elements are also present in human matrix genes. A persistent population of cells in which embryonic regulatory pathways of gene regulation are active and susceptible to upregulation is intriguing.

It suggests that there may be a resident population of progenitor fibroblasts that can be activated in fibrosis (Denton et al., 2001).

There has been recent interest in the potential role of microchimerism in the pathogenesis of SSc (Evans et al., 1999). The observation that fetal cells and even naked fetal DNA may persist in the maternal circulation after pregnancy has fueled the hypothesis that some of these fetal cells may become reactivated, and that scleroderma could represent a graft-versus-host disease. Indeed it has even been suggested that maternal cells passed to the fetus may persist, allowing an alloreactive process to be implicated in male patients with scleroderma. Although the concept is attractive, there is only weak evidence to support it and recent data have suggested that differences between scleroderma and control levels of foreign DNA are at most quantitative (Jimenez and Artlett, 2005).

There is considerable evidence that oxidant stress may play a role in pathogenesis of SSc. It is potentially involved in the fragmentation of autoantigens to expose cryptic epitopes and facilitate the development of autoantibodies (see Chapter 15). This has been shown for RNA polymerases and topoisomerase 1 and may be catalyzed by heavy metal ions. There are some data to support an additional association between heavy metal exposure and the development of autoantibodies. The combination of an appropriate HLA haplotype and exposure to appropriate immunogenic epitopes offers a unifying hypothesis to link different hallmark events in scleroderma. Since tissue hypoxia may occur secondary to Raynaud phenomenon and the vasculopathy of scleroderma, perhaps in concert with the relative tissue hypoxia of the established lesional tissue, it is possible that oxidant stress may promote disease development. Moreover, there is additional evidence that oxidative modification of proteins may also facilitate the development of scleroderma. Antioxidant strategies for therapy offer an exciting possibility for treatment and are being pursued.

IMMUNOLOGIC MARKERS IN DISEASE

Serologic associations are now much better understood. It has been clearly shown that the ability of an individual to respond to immunogenic determinants of hallmark scleroderma autoantigens is associated with certain class II HLA alleles. This is consistent with current understanding of antigen presentation and accessory/costimulatory signals. It is less certain whether such associations are held across different ethnic or geographic boundaries, although an ongoing study in three different North American groups can be expected to specifically address this (Reveille et al., 2001). Intriguingly, the hallmark autoantibodies associated with SSc have proven to be associated with different patterns of disease (Bunn et al., 1998; Tormey et al., 2001). This suggests that the antibodies themselves, or more likely the host factors that determine the development of these antibodies, influence the interplay between other key events in disease progression. Within single center cohorts, associations are now well established and are listed in Table 29.2. It appears that anti-RNA polymerase I or III reactivity is an independent risk factor for scleroderma renal crisis although anti-topoisomerase 1 is not. There is increased frequency of anti-topoisomerase 1 with interstitial pulmonary fibrosis. Pulmonary hypertension occurs commonly in SSc, and is associated with anticentromere antibody reactivity and also with anti-U3-RNP reactivity. In the latter case, it occurs typically in the absence of major lung fibrosis. Ultimately, serologically defined subsets may be helpful in risk stratification, used in conjunction with other clinical features so that protocols for investigation, monitoring, and treating SSc patients can be individualized. Eventually, genetic markers and other soluble serum factors are likely to be used in a similar way.

TREATMENT AND OUTCOME

The principles of effective management of these diseases include establishment of a robust diagnosis, determining the clinical subset and stage of SSc, and confirming the presence or absence of overlap features that might require specific therapy such as arthritis or myositis. In dcSSc it is generally considered appropriate to attempt to treat active skin disease, whereas vascular therapy is the major focus for limited cutaneous SSc (lcSSc). In all SSc it is critical that internal organ involvement is identified early and managed appropriately.

Many treatments for skin involvement have been assessed and, although a number of studies have been encouraging, none of the major controlled trials has been positive. This is important since the extent and severity of skin involvement has been shown in these same trials to associate with outcome and the occurrence of major organ-based complications. It has, therefore, been suggested that if a treatment was developed that modified skin involvement it could be expected, based upon a common pathogenic process, to influence other disease outcome and might be defined a true disease-modifying therapy. At present, many strategies are under evaluation or suggested ranging from oral tolerization to type I collagen to targeted

biological therapies aimed at putative key cytokines driving the disease. Intensive immunosuppression with autologous peripheral stem cell rescue has also been used in a number of centers and is the focus of two major international controlled trials (Binks et al., 2001; Farge et al., 2002).

There are many potential treatments for SSc, and it should no longer be regarded as untreatable even if a cure is certainly not possible. Our approach is to treat the vascular and inflammatory components of dcSSc and enroll patients vigorously into controlled trials or the ongoing observational study of protocolized therapy. In this way, treatments shown to be ineffective can be avoided and much more information obtained about clinical progression and potential response to current best practice treatment. Early dcSSc is treated with immunosuppression generally using cyclophosphamide, mycophenolate mofetil or antithymocyte globulin. Other possible agents include azathioprine or methotrexate. The rationale and experience of these agents is reviewed elsewhere (Denton and Black, 2004). All dcSSc cases should be closely followed and screened for major complications. Vascular treatments including vasodilators for Raynaud phenomenon and drugs such as bosartan with potential remodeling effects are used. There are clinical trials underway to examine whether endothelin receptor blockade with bosentan, an ET-A and ET-B receptor blocking drug, may have beneficial effects on SSc vasculopathy. Initial data suggest a possible beneficial effect for bosentan treatment in preventing new ischemic digital ulceration (Korn et al., 2004). Since there is some evidence implicating endothelin 1 as a mediator of fibrosis in SSc, there is also interest in the potential beneficial effect of bosentan in lung fibrosis in SSc and clinical trials are currently underway. Intermittent prostacyclin may be beneficial and undoubtedly benefits digital ulceration and Raynaud phenomenon. There are studies ongoing to evaluate biological therapies for dcSSc. These include evaluation of anti-TNF-α strategies as well as agents targeting other potential mediators. One of the most exciting approaches has been the development of fully human recombinant antibodies specific for TGF-β isoforms. So far only one study has been reported in dcSSc. Antibodies specific for TGF-β1 were shown to be safe and well tolerated in a study cohort of early stage dcSSc cases (Denton et al., 2004). No data regarding efficacy of such novel treatments are yet available.

CONCLUDING REMARKS—FUTURE PROSPECTS

Systemic sclerosis has an increasingly high profile as a result of advances in the understanding of organ-based disease and an appreciation of the importance of regular follow-up and screening for treatable complications. However, progress is hampered by its relative rarity and the clinical heterogeneity. Strong clinical and research collaborative links are being established internationally and a number of data collection initiatives across centers are underway. These should provide the tools for future clinical trials and epidemiological studies that will shed light upon this challenging autoimmune rheumatic disease.

Antiphospholipid Syndrome

ROBERT A.S. ROUBEY

Division of Rheumatology and Immunology, University of North Carolina, CB 7280 Thurston Building/Rm 3330, Chapel Hill, NC 27599-7280, USA

The antiphospholipid syndrome (APS) is the association of autoantibodies having an apparent specificity for anionic phospholipids with one or more clinical manifestations that include venous and arterial thrombosis and pregnancy loss and morbidity.

HISTORICAL BACKGROUND

The history of antiphospholipid antibodies (aPL) dates to the early twentieth century and the development of serologic tests for syphilis. It was not until 1941, however, that Pangborn identified the essential antigenic component of the tissue extracts used in these tests as cardiolipin, a novel phospholipid isolated from heart tissue (Pangborn, 1941). Widespread screening for syphilis, beginning in the late 1930s, led to the identification of individuals with false-positive serologic tests (Moore and Mohr, 1952; Moore and Lutz, 1955). Transiently false-positive tests were found to be associated with various infections, while chronically false-positive tests were associated with the subsequent development of systemic lupus erythematosus (SLE) and similar conditions. In the early 1950s, acquired inhibitors that blocked phospholipid-dependent coagulation reactions *in vitro* were found in a number of patients with SLE, some of whom had false-positive syphilis serology (Conley and Hartmann, 1952; Frick, 1955; Laurell and Nilsson, 1957). These inhibitors came to be known as *lupus anticoagulants (LA)* (Feinstein and Rapaport, 1972), although they occur in many individuals without SLE and are not typically associated with bleeding (Margolius et al., 1961).

The first case report of APS was probably that of a 35-year-old woman with five spontaneous abortions, an episode of thrombophlebitis, and an anticoagulant acting in the middle stages of coagulation (Alagille et al., 1956). In the English literature, Bowie et al. (1963) were the first to report

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

the association of lupus anticoagulants with thrombosis. Lechner, in a review, described the association of chronic false-positive syphilis serology, LA, thrombosis, and thrombocytopenia in patients with SLE (Lechner, 1974). In addition to Alagille's case, several other early reports associated pregnancy loss with LA (Nilsson et al., 1975; Firkin et al., 1980; Soulier and Boffa, 1980; Carreras et al. 1981). Of note, a number of these cases occurred in patients without SLE. Much of the current awareness of APS derives from the work of Hughes and colleagues in the 1980s (Boey et al., 1983; Hughes, 1983), including the development of immunoassays for anticardiolipin antibodies (Harris et al., 1983; Loizou et al., 1985). The term *primary APS* to refer to APS occurring in the absence of SLE or related autoimmune disease was introduced by Alarcon-Segovia's and Hughes' groups (Alarcon-Segovia and Sanchez-Guerrero, 1989a; Asherson et al., 1989a) In contrast, the term *secondary APS* refers to APS in the setting of SLE or related conditions. More recently, a multicenter study indicates that there is little fundamental difference between the primary and secondary syndromes (Vianna et al., 1994).

Through the 1980s, it was generally thought that aPL were directed against anionic phospholipids, e.g., cardiolipin and phosphatidylserine. In 1990, however, three groups independently discovered that anticardiolipin antibodies in most patients with APS did not bind to cardiolipin, but rather were directed against the phospholipid-binding plasma protein, β2-glycoprotein I (β2GPI) (Galli et al., 1990; Matsuura et al., 1990; McNeil et al., 1990). It was subsequently found that most LAs were directed against either β2GPI or prothrombin (Bevers et al., 1991; Galli et al., 1992; Oosting et al., 1992b; Roubey et al., 1992). In retrospect, a number of early reports suggested that certain plasma proteins played an important role in the expression of LA activity. Loeliger was among the first to describe the LA "cofactor" phenomenon (normal plasma contains a cofactor that potentiates lupus anticoagulant activity), and concluded that the cofactor was most likely prothrombin itself (Loeliger, 1959). In 1965, Yin and Gaston purified a LA antibody and demonstrated that its anticoagulant activity required a protein cofactor distinct from prothrombin (Yin and Gaston, 1965). Although the cofactor was not completely characterized, it may well have been β2GPI.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Thrombosis

Thrombosis is a major clinical manifestation of APS, and has been reported in nearly all sites of the vascular tree. The most common sites of venous thrombosis are the deep and superficial veins of the lower extremities (Alarcon-Segovia et al., 1992; Asherson et al., 1989b; Vianna et al., 1994). Pulmonary embolism may occur in up to half the cases of deep venous thrombosis. The most common form of arterial thrombosis in APS is stroke (Asherson et al., 1989b; Levine et al., 1990). Thrombosis may be the underlying pathophysiological process in a number of other clinical manifestations of APS. Examples include placental thrombosis and infarction leading to pregnancy loss (Magid et al., 1998; Sebire et al., 2003), cutaneous ulcers (thrombosis of dermal blood vessels) (Grattan and Burton, 1991), certain forms of neurological disease (multi-infarct dementia) (Chapman et al., 2003), pulmonary hypertension (recurrent pulmonary emboli) (Asherson et al., 1990), and renal dysfunction (thrombosis of intrarenal blood vessels) (Nochy et al., 1999).

Pregnancy Mortality and Morbidity

Fetal deaths occurring from the late first trimester onward are strongly associated with aPL (Branch and Khamashta, 2003). The association of aPL with losses at less than 10 weeks gestation is somewhat less well established due to the high incidence of such losses in the general population (Branch, 1994). Various types of pregnancy morbidity are also associated with aPL. Most cases of fetal death related to aPL are preceded by fetal growth impairment and oligohydramnios. Other obstetric complications include preeclampsia, fetal distress, fetal growth impairment, premature delivery, and maternal thrombotic events in the postpartum period.

Skin Manifestations

Livedo reticularis, a latticework of blue-to red subcutaneous mottling, is often present in patients with aPL (Englert et al., 1989). Sneddon syndrome, the association of livedo reticularis and stroke, is associated with aPL in many instances (Frances et al., 1999). Cutaneous ulcers, typically involving the legs, have been reported in several series (Johansson et al., 1977; Grattan and Burton, 1991; Naldi et al., 1993). Skin necrosis may also occur (Paira et al., 1999; Sharkey et al., 2002).

Thrombocytopenia

Thrombocytopenia in SLE patients is associated with aPL, occurring in approximately 40% of patients with aPL and only 10% of patients without aPL (McNeil et al., 1991). Between 70 and 80% of lupus patients with thrombocytopenia have aPL (Diz-Kucukkaya et al., 2001), and aPL are also present in nearly one-third of patients with chronic autoimmune thrombocytopenia. Thrombocytopenia in APS is usually moderate and not associated with hemorrhage. Low platelet counts do not appear to protect APS patients

from the risk of thrombosis (Alarcón-Segovia and Sanchez-Guerrero, 1989b).

Heart Valve Disease

Valvular heart disease is associated with aPL in patients with and without SLE (Khamashta et al., 1990; Leung et al., 1990; Galve et al., 1992; Vianna et al., 1994). Non-infective verrucous vegetations (Libman–Sacks endocarditis) are characteristic. These vegetations may embolize, causing stroke and other ischemic events (Bulckaen et al., 2003).

Neurologic Syndromes

The major neurologic manifestations of APS are cerebrovascular thrombosis and embolic stroke. Transient ischemic attacks may also occur (Tietjen et al., 1993). Recurrent strokes may lead to multi-infarct dementia (Coull et al. 1987; Asherson et al., 1989a). A variety of non-stroke neurologic events have been reported in patients with aPL including migraine headache (Brey et al., 1993), transverse myelitis (Lavalle et al., 1990), Guillain–Barré syndrome, chorea (Cervera et al., 1997), and syndromes resembling multiple sclerosis (Tourbah et al., 1998; Ijdo et al., 1999). The strength of these associations is controversial, however (Chapman et al., 2003). There is growing evidence that aPL are associated with cognitive dysfunction (Denburg et al., 1997; Menon et al. 1999; McLaurin et al., 2005).

Catastrophic Antiphospholipid Syndrome

Catastrophic APS is a syndrome of widespread, multiple vascular occlusions associated with aPL (Asherson et al., 2003). It has been reported in over 130 patients (Asherson et al., 1998; 2001). Common features include multiple vascular occlusive events presenting over a short period of time (days to weeks). Thrombosis typically affects small vessels supplying organs (e.g., brain, lungs, kidney, heart, liver). Large vessel occlusions such as deep vein thromboses are less common than in typical APS. Many patients with catastrophic APS have a history of SLE, a lupus-like disease, or primary APS; however, the catastrophic syndrome was the first manifestation of APS in about half of the reported cases. Apparent precipitating events, identifiable in 40–50% of cases, include infections, surgery, trauma, neoplasia, and withdrawal of anticoagulant medications. Catastrophic APS was fatal in nearly 50% of cases. Cardiac involvement (myocardial infarction, heart failure due to myocardial microthrombi, heart block) and pulmonary involvement (acute respiratory distress syndrome, pulmonary embolism) were the major causes of death. A long term outcome study of 58 catastrophic APS survivors found that 66% of patients subsequently did well, without any further manifestations of APS (on anticoagulation) over an average follow-up period of 5–6 years (Erkan et al., 2003). In contrast, 26% of patients experienced additional APS-related events, approximately one-quarter of which were fatal. In the remainder of cases, the patients did not develop further APS manifestations, but died either from late complications of the initial catastrophic illness or from apparently unrelated causes.

Prevalence of Antiphospholipid Antibodies and Antiphospholipid Syndrome

In cross-sectional studies, anticardiolipin antibodies or LA are present in approximately one-third of SLE patients (Petri, 2000). A similar prevalence of anticardiolipin antibodies was observed in a community-based cohort of newly diagnosed SLE patients (Cooper et al., 2002). Roughly 30–50% of patients with antibodies (i.e., 10–20% of all SLE patients) have one or more clinical manifestation of APS. The prevalence of the primary APS is more difficult to ascertain. In retrospective studies, aPL are present in 5–30% of patients with thrombosis in the absence of SLE (Exner and Koutts, 1988; Petri, 2000). In a large prospectively followed cohort, medium-to-high levels of anticardiolipin antibodies were found in approximately 20% of patients who subsequently had deep venous thrombosis and/or pulmonary embolism (Ginsburg et al. 1992). No association with ischemic stroke was observed in this study. In contrast, other studies indicate that aPL may account for about one-third of strokes in relatively young patients (under the age of 50 years) (Kittner and Gorelick, 1992). Among women with recurrent pregnancy losses, it is estimated that 10–20% are attributable to APS (Yetman and Kutteh, 1996; Branch and Khamashta, 2003). Antiphospholipid antibodies are present in approximately 2% (range 1–5%) of healthy controls, and this frequency may increase with age (Petri, 2000).

Classification Criteria

International consensus criteria for the classification of definite APS have been proposed (Box 30.1) (Wilson et al., 1999). It should be noted these criteria include only thrombosis and pregnancy morbidity/mortality as clinical manifestations of APS, and are designed for use in research studies, not for the diagnosis of individual patients.

AUTOIMMUNE FEATURES

Autoantibodies

As mentioned above, most autoantibodies associated with APS and detected in routine anticardiolipin and LA assays are not directed against cardiolipin or other anionic

Box 30.1
Preliminary Classification Criteria for Definite Antiphospholipid Syndrome*

Clinical criteria (at least 1 must be present)

1. Vascular thrombosis

One or more clinical episodes of arterial, venous, or small vessel thrombosis in any tissue or organ, confirmed by imaging or Doppler studies, or histopathology (except for superficial venous thrombosis). For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.

2. Pregnancy Morbidity

- One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or direct examination, or
- One or more premature births of a morphologically normal neonate at or before the 34th week of gestation because of severe pre-eclampsia or eclampsia, or severe placental insufficiency, or
- Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and parental chromosomal causes excluded.

Laboratory criteria (at least 1 must be present)

1. Anticardiolipin antibody

IgG and/or IgM isotype in blood, present in medium or high titer, on two or more occasions, at least 6 weeks apart, measured by a standardized enzyme-linked immunosorbent assay (ELISA) for β2-glycoprotein I-dependent anticardiolipin antibodies.

2. Lupus anticoagulant

Present in plasma, on two or more occasions at least 6 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Haemostasis Scientific Standardization Subcommittee on Lupus Anticoagulants/Phospholipid-Dependent Antibodies.†

*Wilson et al., 1999. †Brandt et al., 1995.

phospholipids. At present the most common and best-characterized antigenic targets are β2GPI and prothrombin.

β2-Glycoprotein I

β2-glycoprotein I is a 50 kDa glycoprotein present in normal plasma. Structurally, it is a member of the complement control protein family of molecules (Reid et al., 1986), although it has no known function in the complement system at this time. It has five of the consensus repeats, or so-called "sushi domains," characteristic of such proteins. The fifth domain, with a concentration of positively charged amino acids, contains a major phospholipid-binding region (Steinkasserer et al., 1992; Hunt et al., 1993). The fifth domain also contains a plasmin cleavage site; when cleaved by plasmin, β2GPI loses its affinity for anionic phospholipids (Matsuura et al., 2000). Although it has no structural similarity to other apolipoproteins, β2GPI has also been termed apolipoprotein H (Lee et al., 1983). The plasma level of β2GPI is under genetic control (Mehdi et al., 2003). Approximately 94% of the population is homozygous for the normal allele, with a mean plasma concentration of approximately 200 μg/mL, whereas about 6% are heterozygous with a concentration of approximately 100 μg/mL. Homozygous deficiency of β2GPI is rare (<1 in 1000). Neither homozygous deficiency nor heterozygosity is clearly associated with a clinical phenotype (Takeuchi et al., 2000; Yasuda et al., 2000).

The physiological role of β2GPI is unknown. It binds to anionic phospholipids under certain conditions (Wurm, 1984), although binding to phospholipid membranes under physiological conditions is relatively weak, compared with coagulation factors (Harper et al., 1998). Some *in vitro* data suggest that β2GPI could function as a physiological anticoagulant (Schousboe, 1985; Nimpf et al., 1986; 1987), however, this is unlikely based on it phospholipid-binding properties. A novel role of β2GPI is suggested by the recent observation that β2GPI binds to factor XI and inhibits activation of factor XI by thrombin (Shi et al., 2004).

The specificity for β2GPI distinguishes the "anticardiolipin" antibodies associated with APS from those that are associated with syphilis and certain other infectious diseases (Matsuura et al., 1990; 1992; Roubey et al., 1992; McNally et al., 1995). Anticardiolipin antibodies associated with syphilis bind to cardiolipin in the absence of β2GPI.

Autoimmune "anticardiolipin" antibodies recognize epitopes expressed on β2GPI and bind to it in the absence of phospholipid under appropriate conditions (Arvieux et al., 1991; Roubey et al., 1995; Tincani et al., 1996; Iverson et al., 1998; Giles et al., 2003). Certain human monoclonal "anticardiolipin" antibodies derived from APS patient B cells similarly bind to β2GPI (Ichikawa et al., 1994).

Most anti-β2GPI autoantibodies in APS patient sera recognize epitopes expressed on native β2GPI (Roubey et al., 1995; Tincani et al., 1996; Giles et al., 2003), with the major autoepitopes residing on domain I (Iverson et al., 1998; 2002). These autoantibodies typically have low intrinsic affinity, with high-avidity binding dependent upon multivalent attachment to immobilized antigen (Giles et al., 1995; Tincani et al., 1996). Other data suggest that certain anti-β2GPI autoantibodies may be specific for conformational epitopes of β2GPI, formed when the protein binds to

anionic phospholipids or other negatively-charged surfaces (Matsuura et al., 1994; Pengo et al., 1995). IgG, IgM, and IgA isotypes of anti-β2GPI are all associated with APS. Among IgG antibodies, the response is skewed toward the IgG2 subclass.

Autoantibodies to β2GPI may have LA activity (Galli et al., 1992; Oosting et al., 1992b; Roubey et al., 1992; Keeling et al., 1993), as do certain anti-β2GPI monoclonal and polyclonal antibodies (Arvieux et al., 1992; Roubey et al., 1992; Arnout et al., 1998a). Lupus anticoagulant activity is due to antibody cross-linking of surface-bound β2GPI (Willems et al., 1996; Arnout et al., 1998b; Lutters et al., 2001). Cross-linked antibody–β2GPI complexes bind to phospholipid membranes with very high avidity, effectively decreasing the amount of phospholipid surface available to participate in the coagulation reaction. Why some anti-β2GPI antibodies have LA activity and others do not is unclear, but may be related to antibody titer, differences in affinity/avidity, and/or epitope specificity.

Prothrombin

Antiprothrombin autoantibodies are the other major specificity of LAs in APS patients (Bevers et al., 1991; Galli et al., 1997; Horbach et al., 1998; Amengual et al., 2003). Similar to anti-β2GPI antibodies, many antiprothrombin antibodies are of relatively low affinity. A small subset of patients with LA has hypoprothrombinemia, probably due to high-affinity antiprothrombin antibodies and the clearance of antibody–antigen complexes (these patients are at risk for bleeding, not APS). Some antiprothrombin antibodies in APS patients may recognize conformational epitopes formed when prothrombin binds to anionic phospholipids, such as phosphatidylserine (Amengual et al., 2003). The mechanism of LA activity appears to be analogous to that of anti-β2GPI antibodies, i.e., by cross-linking of membrane-bound prothrombin. Antibody–prothrombin complexes bind to phospholipid membrane with very high avidity, thereby decreasing the amount of catalytic phospholipid surface available to bind other coagulation factors (Simmelink et al., 2001).

Other Phospholipid-Binding Proteins

Autoantibodies to other phospholipid-binding proteins, although not detectable in standard aPL assays, may also be associated with APS. Antigenic targets include protein C and protein S (Pengo et al., 1996; Song et al., 2000; Nojima et al., 2001), annexin A5 (Matsuda et al., 1994; Lakos et al., 2000; Nojima et al., 2001), and tissue factor pathway inhibitor (TFPI) (Forastiero et al., 2003). Autoantibodies to factor V (Ortel, 1999), factor XI (Sugi and McIntyre, 2001) and factor XII (Åberg and Nilsson, 1972; Jones et al., 2001) have also been reported in small numbers of patients. Rarely, anticardiolipin assays may detect autoantibodies recognizing complement factor H, complement C4b-binding protein, thrombin-modified antithrombin, or lipopolysaccharide binding protein, although it is not clear whether such antibodies are associated with clinical manifestations of APS (Arvieux et al., 1999).

Autoantibodies with an apparent specificity for phosphatidylethanolamine, a zwitterionic phospholipid, have been reported in certain patients with clinical manifestations of APS (Karmochkine et al., 1992; Berard et al., 1996; McIntyre and Wagenknecht, 2000). These antibodies do not recognize phosphatidylethanolamine itself, but are directed against phosphatidylethanolamine-binding plasma proteins, including high- and/or low-molecular-weight kininogens, prekallikrein, and factor XI (Sugi and McIntyre, 1995; Boffa, et al. 1996; Sugi and McIntyre, 2001).

Phospholipids

It is unclear whether antibodies that bind directly to phospholipids are associated with APS. Older studies suggesting these specificities are difficult to interpret due to the fact that serum or plasma was present in most or all of these experiments and the key role of β2GPI and other proteins may have been missed. Data clearly demonstrating antibody specificity for cardiolipin or other phospholipids in the absence of any plasma or serum proteins is scant. In one study, a human monoclonal antibody to cardiolipin has been shown to induce pregnancy loss in an animal model (Ikematsu et al., 1998).
