CHAPTER

56

Pancreatitis

SHIGEYUKI KAWA, HIDEAKI HAMANO, AND KENDO KIYOSAWA

Department of Medicine, Gastroenterology, Shinshu University School of Medicine, Matsumoto, Japan

A unique form of chronic pancreatitis characterized by elderly male preponderance, minimal abdominal pain, irregular narrowing of the pancreatic duct, and swelling of the pancreatic parenchyma has been referred to as autoimmune pancreatitis. Autoimmune pancreatitis, the term used in this chapter, is also characterized by hypergammaglobulinemia, histologic evidence of lymphoplasmacytic inflammation and fibrosis, and a favorable response to glucocorticoid treatment. These findings suggest that autoimmune mechanisms are involved in the pathogenesis of this disease. Another characteristic feature of this disease is high serum IgG4 concentrations, which are closely associated with disease activity. This disease has been frequently misdiagnosed as pancreatic cancer, leading to unnecessary surgery.

HISTORIC BACKGROUND

In 1961, Sarles et al. first reported this disease as "chronic inflammatory sclerosis of the pancreas." They summarized the clinical characteristics as: minimal or no severe abdominal pain, emaciation, jaundice, nonalcoholic background, hyperglobulinemia, diffuse enlargement of the pancreas, no dilatation of the pancreatic duct, and histologically marked lymphocytic infiltration. Waldram et al. (1975) then reported an association in these patients with salivary gland lesions and sclerosing cholangitis. Nakano et al. (1978) reported patients with Sjögren syndrome and pancreatitis who had been successfully treated with corticosteroids. Kawaguchi et al. (1991) then designated this condition as a lymphoplasmacytic sclerosing pancreatitis based on a detailed pathologic study. Toki et al. (1992) focused on the characteristic radioimages of pancreatic duct examination, and reported four patients as having an unusual type of chronic pancreatitis showing diffuse irregular narrowing of the entire main pancreatic duct by endoscopic retrograde cholangiopancreatography (ERCP). They summarized the clinical features and designated this condition as autoimmune pancreatitis based on clinical findings, laboratory evidence of hypergammaglobulinemia, positive autoantibodies and lymphoplasmacytic infiltration in the pancreas, and a favorable response to corticosteroid treatment (Yoshida et al., 1995; Ito et al., 1997). Since then, many patients have been diagnosed based on these characteristic clinical findings. A number of case reports or reports of small series of cases have been published using various other terms such as "nonalcoholic duct-destructive chronic pancreatitis" (Ectors et al., 1997), "chronic sclerosing pancreatitis" (Motoo et al., 1997) and "chronic pancreatitis with diffuse irregular narrowing of the pancreatic duct" (Wakabayashi et al., 1998).

In 2001, a new classification system was proposed for chronic pancreatitis, based on etiologic risk factors, toxic-metabolic causes, idiopathic, genetic, autoimmune, recurrent severe acute pancreatitis-associated chronic pancreatitis, and obstructive chronic pancreatitis (the TIGAR-O risk classification system) (Etemad and Whitcomb, 2001). An autoimmune mechanism was first recognized in this

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

classification system, and isolated autoimmune chronic pancreatitis and syndromic autoimmune pancreatitis were separately identified. "Autoimmune pancreatitis" seems to be equivalent to isolated autoimmune chronic pancreatitis in this system. Hamano et al. (2001) reported that patients with autoimmune pancreatitis frequently and specifically have high serum IgG4 concentrations that correlate well with disease activity, suggesting that this disease is a discrete clinical entity different from ordinary chronic pancreatitis.

In 2002, The Japanese Pancreas Society proposed Japanese diagnostic criteria for autoimmune pancreatitis: 1) diffuse irregular narrowing of the main pancreatic duct and enlargement of the pancreas (essential); 2) serum elevations of γ-globulin and/or IgG, and/or the presence of autoantibodies; and 3) fibrosis with lymphoplasmacytic infiltration in pancreatic tissue. Such diagnostic criteria will allow us to be more stringent in our diagnosis and to differentiate these conditions from pancreatic cancer (Steinberg et al., 2003).

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Clinical Features

We analyzed the clinical findings in over 40 patients with autoimmune pancreatitis who fulfilled the diagnostic criteria proposed by The Japanese Pancreas Society in 2002. These findings are summarized below.

The male-to-female ratio was 34:8 (male 81%), and the mean age of occurrence was 62 ± 9 years (range 38–76), suggesting that this disease shows an elderly male preponderance. Few patients complained of severe attacks of pancreatitis, but many had mild-to-moderate epigastralgia or discomfort (78%). The clinical symptoms were thus different from those of acute or severe pancreatitis. A striking feature was an obstructive jaundice in 68% of patients, which was caused by the stenosis or obstruction of the intrapancreatic common bile duct (Yoshida et al., 1995; Horiuchi et al., 1998; 2001). Diabetes mellitus (DM) was often observed and the majority was thought to have type 2 DM; some patients improved after steroid therapy (Tanaka et al., 2000).

Laboratory Tests

Laboratory tests showed several abnormal findings related to the obstructive jaundice, such as elevated serum levels of bilirubin, biliary enzymes, and transaminase in 70–80% of patients. The tumor-associated antigen, CA19-9, was elevated in 50% of patients, probably due to the cholestasis and not to a malignant process. Serum elevations of pancreatic enzymes were mild or moderate, and were found in 60% of patients. Serum elevations of γ-globulin and IgG were found in 59% and 70%, respectively. Decreased exocrine and endocrine function by the bentiromide test and HbA1c were found in 66% and 51%, respectively (Horiuchi et al., 1998; 2001) (Table 56.1).

Imaging

Abdominal ultrasonography (US) showed characteristic sonolucent swelling—the so-called "sausage-like" appearance (Figure 56.1), and dilatation of the common bile duct. Computed tomography (CT) with contrast material revealed

TABLE 56.1 Normal blood results and abnormal results for patients with autoimmune pancreatitis

	Results for autoimmune pancreatitis patients		
Test (normal values)	**Mean**	**Range**	**Abnormal (%)**
White blood cells (3500–9800/μl)	5929	2130–10.700	2/42 (5)
Eosinophils (%)	5.3	0–20	12/33 (36)
Amylase (44–127 Iμ/L)	231	82–2622	26/42 (62)
Elastase (100–400 ng/dl)	1190	69–5000	16/24 (67)
Total bilirubin (0.3–1.2 mg/dl)	4.0	0.4–20.9	29/42 (69)
Alkaline phosphatase (124–367 μ/L)	1279	132–5562	33/42 (79)
γ-GTP (8–50 IU/L)	645	10–1980	34/42 (81)
AST (12–37 IU/L)	191	13–854	30/42 (71)
ALT (7–45 IU/L)	286	12–1003	32/42 (76)
γ-Globulin (<2 g/dl)	2.23	0.8–4.31	24/41 (59)
IgG (800–1800 mg/dl)	2314	892–4562	28/40 (70)
IgE (0–400 IU/ml)	370	8–1024	10/30 (33)
CA19-9 (<37 IU/ml)	108	0–919	18/34 (53)
HbA1c (4.3–5.8%)	6.3	4.5–11.0	20/39 (51)
Bentiromide test (>70%)	60.6	22–90	19/29 (66)

FIGURE 56.1 Abdominal ultrasonography of autoimmune pancreatitis, showing characteristic sonolucent swelling, the so-called "sausage-like" appearance.

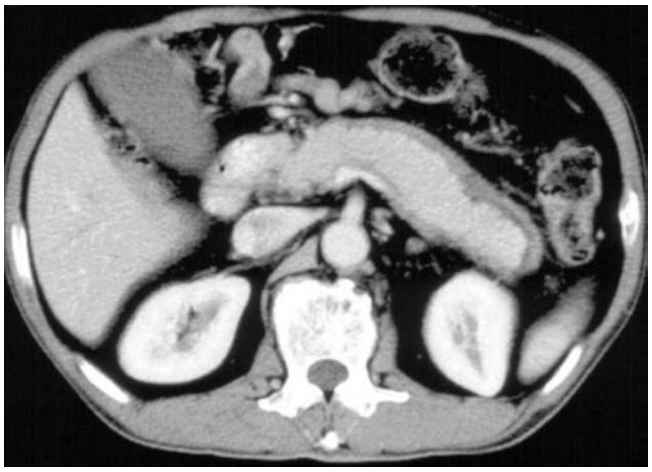

FIGURE 56.2 Computed tomography with contrast material of autoimmune pancreatitis, showing swelling and delayed enhancement of parenchymal tissue, resulting in a peripheral low-density area and a capsule-like rim.

swelling and delayed enhancement of parenchyma, resulting in a peripheral low-density area and a capsule-like rim (Figure 56.2). Absence of pancreatic duct dilatation or pancreatic stones or pseudocysts have been reported to be characteristic features of this disease and are commonly shown by US, CT, and magnetic resonance imaging (MRI) (Yoshida et al., 1995).

ERCP showed a characteristic pancreatogram of diffuse irregular narrowing with the following characteristics: 1) narrow caliber; 2) wall irregularity—both of which can extend for some distance; and (3) the absence of upstream dilatation (Figure 56.3). Approximately 50% of patients showed these changes throughout the main pancreatic duct; however, in other patients, focal changes were restricted to the pancreatic head or tail, which made differentiation from pancreatic cancer difficult in these cases. During follow-up, focal changes often progressed to diffuse disease (Horiuchi et al., 2002a). In patients with severe narrowing of the pancreatic duct, a pancreatogram may show obstruction of the main pancreatic duct (Fernández-del Castillo et al., 2003).

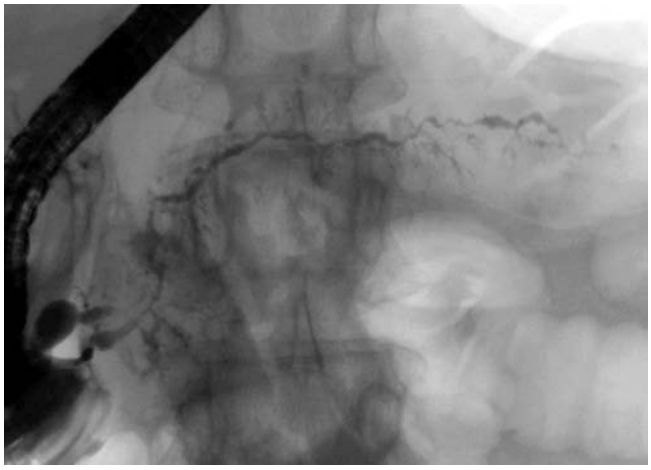

FIGURE 56.3 Endoscopic retrograde cholangiopancreatography in autoimmune pancreatitis showing the characteristic pancreatogram of diffuse irregular narrowing.

Cholangiography showed severe narrowing of the lower bile duct, which was caused by swelling of the head of the pancreas. However, intraductal ultrasonography (IDUS) showed that thickening of the bile duct wall also contributed to narrowing of the bile duct. In some cases, bile duct changes extended to extrapancreatic regions, such as the intrahepatic bile duct system; these cases showed similar findings to primary sclerosing cholangitis (PSC) (Figure 56.4). Gallium-67 scintigraphy showed characteristic hilar and pancreatic accumulation during the active stage of the disease (Saegusa et al., 2003).

Extrapancreatic Lesions

Another characteristic feature of this disease is a variety of complications or extrapancreatic lesions, such as swelling of lacrimal and salivary glands (Kamisawa et al., 2003), sclerosing cholangitis (Erkelens et al., 1999; Horiuchi et al., 2001; Nakazawa et al., 2001), retroperitoneal fibrosis (Hamano 2002), hilar lymphadonopathy (Saegusa, 2003), gastric mucosal disease (Shinji et al., 2004), and hypothyroidism (Komatsu et al., 2005). These extrapancreatic

FIGURE 56.4 Endoscopic retrograde cholangiopancreatography in autoimmune pancreatitis showing the characteristic intrahepatic bile duct changes similar to those of primary sclerosing cholangitis.

lesions have often been misdiagnosed as Sjögren syndrome, PSC, urethral tumor, sarcoidosis, or gastric ulcer. It should be stressed that salivary gland or lacrimal gland lesions and sclerosing cholangitis differ from typical Sjögren syndrome and classical PSC, respectively, because they show a favorable response to corticosteroid therapy and characteristic findings on blood tests or pathology. The diversity of extrapancreatic lesions found in this disease may coincide with those of multifocal fibrosclerosis, which is an uncommon fibroproliferative systemic disorder with multiple manifestations, including retroperitoneal fibrosis, sclerosing cholangitis, Riedel thyroiditis, fibrotic pseudotumor of the orbit, and fibrosis of the salivary glands (Comings et al., 1967). It is possible that autoimmune pancreatitis is a pancreatic manifestation of this systemic fibrosing disease (Kamisawa et al., 2003).

Misdiagnosis of Pancreatic Cancer

Patients with autoimmune pancreatitis sometimes receive a diagnosis of pancreatic cancer because of the preponderance of this disease in the elderly, obstructive jaundice, serum elevations of CA19-9, and irregular narrowing or obstruction of the pancreatic duct. Pathologic analysis after pancreaticoduodenectomy (Whipple resection), performed because of a diagnosis of pancreatic cancer, led to a revised diagnosis of autoimmune pancreatitis (lymphoplasmacytic sclerosing pancreatitis) in 2.2% of patients (Hardacre et al., 2003). Due to similar pathologic findings, this disease has also been diagnosed as pancreatic lymphoma (Horiuchi et al., 1996).

Pathologic Features

On gross examination, the involved pancreas appears glistening white, is firm or hard, and may be enlarged or show mass lesions. The lesion may be limited to one portion of the pancreas, most commonly the head, or may involve the body, tail, or entire organ. Lymphoplasmacytic infiltration and fibrosis are characteristic microscopic features of the pancreatic lesions, and in some cases result in the formation of lymphoid follicles. Immunostaining has demonstrated that T-cells predominate over B-cells among the infiltrating lymphocytes. The infiltrating plasma cells characteristically bear IgG4 (Hamano et al., 2002). The cell infiltration is prominent around the pancreatic duct, resulting in stenosis or obstruction of the duct, stasis of the pancreatic secretions, and damage to the pancreatic lobules. Obliterating phlebitis is another characteristic feature, which shows a marked cellular infiltration of the venous wall and venous thrombosis (Kawaguchi et al., 1991). Conspicuous negative features typically include absence of calculi in ducts, absence of pseudocysts, and absence of more than minimal fatty necrosis. The histologic features observed in the extrapancreatic lesions such as in the salivary glands (Kamisawa et al., 2003) or retroperitoneal fibrosis (Hamano et al., 2002) often resemble those seen in the pancreas.

Epidemiologic Features

The incidence of autoimmune pancreatitis in Japan or in the world at large is not known. However, between September 1994 and September 2002, we identified 42 patients with autoimmune pancreatitis among the 2,215,000 population of the Nagano prefecture in Japan (Takayama et al., 2004). Accordingly, autoimmune pancreatitis is a rare disorder, though its exact prevalence remains unknown.

AUTOIMMUNE FEATURES

The positive rates for various autoantibodies are summarized in Table 56.2. Positive rates for antinuclear antibody were 40%, and those for other antibodies were 10–30%. No patient had a positive test for SS-A or SS-B antibodies, or antimitochondrial antibodies, which are the disease-specific antibodies for the diagnosis of Sjögren syndrome and primary biliary cirrhosis (PBC), respectively. These findings suggest that the autoantibodies found in autoimmune pan-

TABLE 56.2 Positive rates for autoantibodies in patients with autoimmune pancreatitis

Antibody	Cut-off value	Number of positive tests	Positive rate (%)	Method	Substrates
Antinuclear antibody (ANA)	<1:40	24/44	54.5	IFL	Hep-2
	<1:80	17/44	38.6		
Anti-dsDNA antibody	<12 IU/ml	2/44	4.5	ELIAS	dsDNA
Anti-SS-A antibody	<10	0/37	0.0	ELISA	SS-A/Ro protein
Anti-SS-B antibody	<15	0/37	0.0	ELISA	SS-B/La protein
Antimitochondrial antibody	<7	2/44	4.5	ELISA	M2 antigen*

creatitis are not pathogenic, and that patients have a tendency to produce various autoantibodies that are not disease specific. The occasional coexistence of pancreatitis with salivary gland lesions and cholangitis suggests shared target antigens. Carbonic anhydrase II and lactoferrin are distributed in the cells of several exocrine organs, including the pancreas, salivary glands, and biliary duct. In this context, carbonic anhydrase II or lactoferrin have been proposed as candidate target antigens, but the presence of autoantibodies for these antigens is not sufficiently specific or sensitive (Kino-Ohsaki et al., 1996; Okazaki and Chiba, 2002). Autoantibody for α-fodrin, which is a candidate autoantigen for the development of Sjögren syndrome, is useful for discriminating cases with extrapancreatic lesions, such as sclerosing cholangitis or swelling of the salivary and lacrimal glands (Horiuchi et al., 2002b).

In peripheral blood or pancreatic tissue, activated $CD4^+$ or $CD8^+$ T-cells bearing HLA-DR molecules are aggregated mainly around the pancreatic duct, and pancreatic ducts express HLA-DR molecules (Okazaki et al., 2000). $CD4^+$ T-cells are subdivided into type 1 helper T (Th1) and Th2 cells based on profiles of cytokine production (see Chapter 7). In some cases of autoimmune pancreatitis, $CD4^+$ Th1 cells predominate over Th2 cells, suggesting that Th1 cytokines are essential for the induction and maintenance of this disease, whereas Th2 cytokines are involved in disease progression (Okazaki and Chiba, 2002).

Protein electrophoresis of patient's sera showed a polyclonal band in the rapidly migrating fraction of γ-globulins. Immunoelectrophoresis confirmed that this polyclonal band was caused by a high serum concentration of IgG4. We found serum IgG4 elevation in 90% of patients with autoimmune pancreatitis, but in very few patients with other conditions, including pancreatic cancer, chronic pancreatitis, and Sjögren syndrome, suggesting that IgG4 is a sensitive and specific marker for this disease. In addition, IgG4 correlates well with disease activity. Similar to IgG4, IgG4-type immune complexes are also elevated in the serum and correlate well with disease activity (Hamano et al., 2001).

GENETIC FEATURES

HLA-DR4 and -DQ4 are the markers most frequently associated with autoimmune pancreatitis among MHC class I and class II molecules. Among DR4 and DQ4 subtypes, the frequencies of DRB1*0405 and DQB1*0401 are significantly higher in patients with autoimmune pancreatitis than in normal subjects and those with chronic pancreatitis. In the Japanese population, DRB1*0405 is known to be in strong linkage disequilibrium with DQB1*0401, resulting in formation of the DRB1*0405 DQB1*0401 haplotype. The DRB1*0405 DQB1*0401 haplotype in autoimmune pancreatitis shows no significant association with any HLA class I molecules, in contrast to the B54 DRB1*0405 DQB1*0401 haplotype reported in autoimmune hepatitis (Seki et al., 1990; 1992), suggesting that autoimmune pancreatitis has a different immunogenetic background from autoimmune hepatitis. Accordingly, the DRB1*0405 DQB1*0401 haplotype is specifically associated with susceptibility to autoimmune pancreatitis, and may play a functional role in antigen presentation and induction of an autoimmune response (Kawa et al., 2002). The relative linkage disequilibrium value for both risk alleles is 100% in the Japanese population. Thus, it is difficult to determine which allele is actually associated with susceptibility to autoimmune pancreatitis.

ANIMAL MODELS

A putative animal model of autoimmune pancreatitis was created by immunizing neonatally thymectomized mice with carbonic anhydrase II or lactoferrin, and also by transferring immunized spleen cells to nude mice (Uchida et al., 2002). Inflammation was found to be present in the pancreas of immunized neonatally thymectomized mice and of all mice receiving whole spleen cells or $CD4^+$ cells. Carbonic anhydrase II- or lactoferrin-immunized mice developed apoptotic duct cells or acinar cells, respectively. These findings suggest that an immunologic mechanism against carbonic anhydrase II or lactoferrin is involved in the pathogenesis of this pancreatitis model, in which the effector cells appear to be Th1-type $CD4^+$ T-cells, although this requires confirmation.

PATHOLOGIC MECHANISMS

Because serum IgG4 and IgG4-type immune complexes are closely associated with disease activity, they may play a major role in the pathogenesis of autoimmune pancreatitis. To date, the pathologic effects of IgG4 and IgG4-type immune complexes have been reported in limited settings, such as in pemphigus and membranous nephropathy. Pemphigus vulgaris and pemphigus foliaceus are autoimmune skin diseases (see Chapter 57) characterized by the presence of IgG4-type autoantibodies against the cell-adhesion molecules desmoglein-3 and -1; the IgG4-type antidesmoglein antibodies may even cause the characteristic skin lesions of acantholysis. In autoimmune pancreatitis, IgG4-type autoantibody may induce an inflammatory response after interaction with an undefined target antigen. IgG4 is unique among the IgG subclasses in its inability to fix C1q complement and its low affinity for target antigens, resulting in the formation of a unique type of immune complex. In the pathogenesis of membranous nephropathy, these characteristics of IgG4 may account for the slow rate of clearance of IgG4-type immune complexes from the circulation, and for the formation of membrane-attack complexes in tissues by an alternative pathway, or the mannose-binding lectin pathway. As we found high serum concentrations of IgG4-type immune complexes in most patients with autoimmune pancreatitis who had active inflammation, the same mechanism may be operating in the pathogenesis of this disease.

IMMUNOLOGIC MARKERS IN DIAGNOSIS

Positive rates for various immunologic markers are as follows: raised γ-globulin 60%, raised IgG 70%, any of the described autoantibodies 80%, and raised IgG4 90%. Serum IgG4 elevation is observed in very few patients with other conditions, i.e., pancreatic cancer, chronic pancreatitis, Sjögren syndrome, PBC, and PSC, suggesting that IgG4 is the most sensitive and specific immunologic marker for diagnosis (Hamano et al., 2001). IgG4-type immune complexes are another useful marker, but we do not yet have a reliable assay system. Although autoantibodies to carbonic anhydrase II and lactoferrin have been reported to be useful markers, their diagnostic value for autoimmune pancreatitis has not been fully accepted because of their insufficient sensitivity and specificity (Kino-Ohsaki et al., 1996, Okazaki and Chiba, 2002).

TREATMENT AND OUTCOME

For autoimmune pancreatitis, intensive treatment for acute pancreatitis is not required. Most patients with autoimmune pancreatitis respond favorably to corticosteroid treatment, resulting in an improvement in symptoms, laboratory tests, and imaging findings. However, no general agreement has been reached regarding the general usage of corticosteroids for all patients, as we have found spontaneous remission in some patients who needed a biliary drainage procedure for obstructive jaundice. It is possible, however, that early corticosteroid therapy could prevent the residual structural changes of pancreatic parenchyma, such as duct change or fibrosis. Corticosteroid treatment is mandatory for patients who are in a highly active state with systemic manifestations, such as sclerosing cholangitis or retroperitoneal fibrosis. For other cases, corticosteroid therapy remains optional.

As autoimmune pancreatitis is a new disease entity and there are no therapeutic guidelines for this condition, the regimen of steroid therapy was initially based on that for other autoimmune diseases. Patients who showed obstructive jaundice and diffuse pancreatic swelling were treated with 40 mg/day of prednisolone for 4 weeks, after which the dose was reduced by 5 mg/week over 7 weeks until a dose of 5 mg/day was reached. Maintenance therapy was continued, at 2.5–5 mg/day, if the autoimmune process did not resolve.

Surgery is often necessary for differentiation from malignancy.

To clarify the long-term outcome of autoimmune pancreatitis, we performed a follow-up study for periods longer than 12 months (median follow-up: 54.5 months; range: 13–111 months). Twenty-six percent of patients who had been treated with prednisolone had recurrent attacks and 19% developed pancreatic calculi during a median follow-up period of 22 months. Because 55% of patients who suffered relapse showed pancreatic calculi, this appears to be significantly associated with relapsing compared with non-relapsing cases. These findings suggest that autoimmune

pancreatitis has the potential to be a progressive disease with pancreatic lithiasis (Takayama et al., 2004), contrary to a previous report (Yoshida et al., 1995). As few patients suffered from acute attacks, acute inflammation would only play a minor role in pancreatic stone formation. Incomplete obstruction of the pancreatic duct system and stasis of pancreatic secretions provide another possible explanation for the formation of pancreatic calculi.

CONCLUDING REMARKS AND FUTURE PROSPECTS

Autoimmune pancreatitis is clearly distinguishable from ordinary chronic pancreatitis, and shows a distinctive disease profile with characteristic high serum IgG4 concentrations. However, the following issues remain to be clarified: 1) the target antigen recognized by IgG4 autoantibody and the role of IgG4 elevation; 2) details of extrapancreatic lesions with respect to systemic disease, such as multifocal fibrosclerosis; 3) therapeutic strategies, including corticosteroid therapy; and 4) long-term outcome with respect to the pancreatic structure and function, and predisposition to malignancy.

Autoimmune pancreatitis seems to receive particular attention in Japan. Articles on this disease have been mainly published from Japan, with some from Europe and the USA. The major reason for this bias is probably the special interest in this disease in Japan during the past 10 years, and many patients in other countries have been overlooked or given another diagnosis (Kim et al., 2004). Recent increasing awareness of the entity will result in an increase in the diagnosis of autoimmune pancreatitis worldwide.

Bullous Skin Diseases: Pemphigus Pemphigoid

NING LI, ZHI LIU, JULIO HILARIO-VARGAS, AND LUIS A. DIAZ

Department of Dermatology, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA

Autoimmune bullous diseases are rare disorders affecting skin and mucous membranes that are mediated by pathogenic autoantibodies against desmosomal or hemidesmosomal antigens of squamous epithelium (Diaz and Giudice, 2000). In the epidermis, neighboring keratinocytes adhere to each other through organelles known as desmosomes, whereas at the dermoepidermal junction hemidesmosomes anchor the epidermis to the dermis. The majority of these antigens recognized by these autoantibodies is desmosomal and hemidesmosomal transmembrane glycoproteins involved in epidermal cell–cell and epidermal–dermal adherence.

The desmosome contains two parallel intracellular plaques, which are located just underneath the cell membranes of neighboring cells (Figure 57.1A). The narrow extracellular space shared by two cells, at the level of the desmosome, constitutes the desmosomal core. The desmosomal plaques serve as insertion sites for intracellular cytokeratins and are composed of large molecular weight proteins, whereas the core contains a group of transmembrane calcium-dependent cell adhesion molecules known as desmosomal cadherins. They include desmogleins (Dsg1–4) and desmocollins (Dsc1–3) (Getsios et al., 2004). The isoforms of these desmosomal cadherins vary in different cell types. While Dsg1 is expressed throughout the epidermis with predominance in the upper layers of this tissue, Dsg3 is expressed mainly in the suprabasal layers of the epidermis.

The hemidesmosomes, located on the dermal pole of the epidermal basal cells, also contain an intracellular plaque and a core structure (Figure 57.1B). The extracellular space, called the lamina lucida (corresponding to the desmosomal core), separates these cells from the underlying basal lamina (composed of collagen IV) (Diaz and Giudice, 2000). The

sub-basal lamina region contains other matrix molecules and the anchoring fibers (collagen VII). The hemidesmosomal plaque, linked to the cytokeratin network, contains two intracellular proteins, BP230 and plectin. The lamina lucida contains the ectodomains of two transmembrane proteins, BP180 and α6β4 integrin, and laminin 5.

The pemphigus syndromes include diseases that are characterized by loss of epidermal cell–cell cohesion (named acantholysis) (Civatte, 1943) and autoantibodies against desmosomal cadherins (Beutner and Jordon, 1964; Anhalt and Diaz, 2001). This group comprises the two classical forms of pemphigus: pemphigus vulgaris (PV) and pemphigus foliaceus (PF). PV is characterized by suprabasilar acantholysis and anti-Dsg3 IgG autoantibodies, whereas PF is characterized by subcorneal acantholysis and anti-Dsg1 IgG autoantibodies. Other infrequent forms of pemphigus include paraneoplastic pemphigus (PNP), drug-induced pemphigus, and IgA pemphigus (Table 57.1).

The pemphigoid syndromes and other rare subepidermal autoimmune blistering diseases (see Table 57.1) are charac-

TABLE 57.1 Autoimmune blistering diseases of the skin

Disease	Cleavage site	Skin organelle	Autoantigens	Pathogenic autoantibodies
Pemphigus vulgaris	Suprabasilar acantoholysis	Desmosome	Dsg3	Passive transfer
Pemphigus foliaceus	Subcorneal acatoholysis	Desmosome	Dsg1	Passive transfer
Paraneoplastic pemphigus	Suprabasilar acantoholysis	Desmosome, hemidesmosome	Dsg3, Dsg1 and plakin family	Passive transfer (Dsg3)
Drug-induced pemphigus	Suprabasilar acantoholysis (commonly)	Desmosome	Dsg1	?
IgA pemphigus	Subcorneal/intraepidermal pustules	Desmosome	Dsg1	?
Bullous pemphigoid	Subepidermal	Hemidesmosome	BP180 and BP230 antigens	Passive transfer (BP180)
Herpes gestationis	Subepidermal	Hemidesmosome, lamina lucida	BP180 antigen	Passive transfer

terized by separation of the epidermis from the dermis. Bullous pemphigoid (BP), the most common autoimmune bullous disease seen in the elderly (Lever, 1965), is characterized by subepidermal blisters and autoantibodies against the hemidesmosomal BP180 and BP230 antigens (Stanley et al., 1981; Mutasim et al., 1985; Labib et al., 1986). Other subepidermal blistering diseases, such as cicatricial pemphigoid (CP), herpes gestationis (HG), lichen planus pemphigoides (LPP), and linear IgA dermatoses (LAD) exhibit distinctive clinical, histologic, and immunogenetic features, and share a humoral autoimmune response to the BP180 antigen. The remaining acquired subepidermal blistering diseases show autoantibody responses to structural molecules of the dermal extracellular matrix; they include epidermolysis bullosa acquisita (EBA) and dermatitis herpetiformis (DH). The antigen in EBA is collagen VII and in DH is a tissue transglutaminase. The autoantibody response in all these autoimmune skin diseases belongs to the IgG class, except in IgA pemphigus, LAD, and DH, where the immunoglobulin class is IgA.

Passive transfer of IgG from patients with PV, PF, PNP, and CP, or rabbit antiserum against BP and EBA autoantigens, into experimental animals duplicated the main skin features of the human disease in these animals, suggesting that these autoantibodies are indeed pathogenic (Anhalt et al., 1982; Roscoe et al., 1985; Liu et al. 1993; Amagai et al., 1998; Chen et al., 2004). Numerous studies have demonstrated that unique epitopes within the respective antigens are bound by pathogenic autoantibodies in these patients (Guidice et al., 1993; Lapiere et al., 1993; Mahoney et al., 1998; Zillikens et al., 1998; Christophoridis et al., 2000; Sekiguch et al., 2001; Sardy et al., 2002; Li et al., 2003; Zone et al., 2004).

Little is known about the etiology and how the autoimmune response is triggered in these disorders except in the endemic form of PF (also known as fogo selvagem), where an environmental etiology is strongly suggested. In this chapter we shall review the current clinical, histologic, and immunologic features of the most common forms of autoimmune bullous diseases (PV, PF, and BP), and briefly discuss other infrequent forms of pemphigus and other subepidermal autoimmune bullous diseases.

PEMPHIGUS VULGARIS

Clinical and Histopathologic Features

PV is the most severe and common form of pemphigus (Lever, 1965). It affects skin and mucous membranes. Although found in all ethnic and racial groups, the disease is more prevalent in Jewish patients exhibiting the HLA DRB1*0402 allele. Patients affected are usually in their fourth to sixth decade of life. The disease usually begins with painful ulcerations or erosions of the oral mucosa (mucosal PV), which may last for several months. This

process is gradually followed by involvement of the skin (mucocutaneous PV), where the disease produces flaccid blisters and erosions. Other squamous epithelial tissues (e.g., nasal, esophageal, larynx, pharynx, conjunctival, vaginal, and rectal) may also be involved.

Histologically, the epithelial lesions of PV show intraepidermal blisters that are located above the basal cell layer of the epidermis (superbasilar acantholysis) (Figure 57.2, left panel). The basal cells remain attached to the dermis but laterally detached from each other, producing the histologic sign known as "row of tombstones" (Lever, 1965). Inflammatory infiltration is usually negligible, but early lesions may show eosinophilic spongiosis.

Autoimmune Features

Autoantibodies

The serum of PV patients contains IgG autoantibodies that stain the epidermal intercellular spaces (ICSs) by indirect immunofluoresence (IF), producing titers that roughly correlate with disease activity (Beutner and Jordon, 1964). Direct IF of perilesional epidermis reveals IgG bound to keratinocyte cell surfaces. These autoantibodies are predominantly of the IgG4 subclass (Jones et al., 1988).

The target antigen recognized by PV autoantibodies is Dsg3, a 130-kDa desmosomal core glycoprotein (Amagai et al., 1991). While patients with limited mucosal lesions have

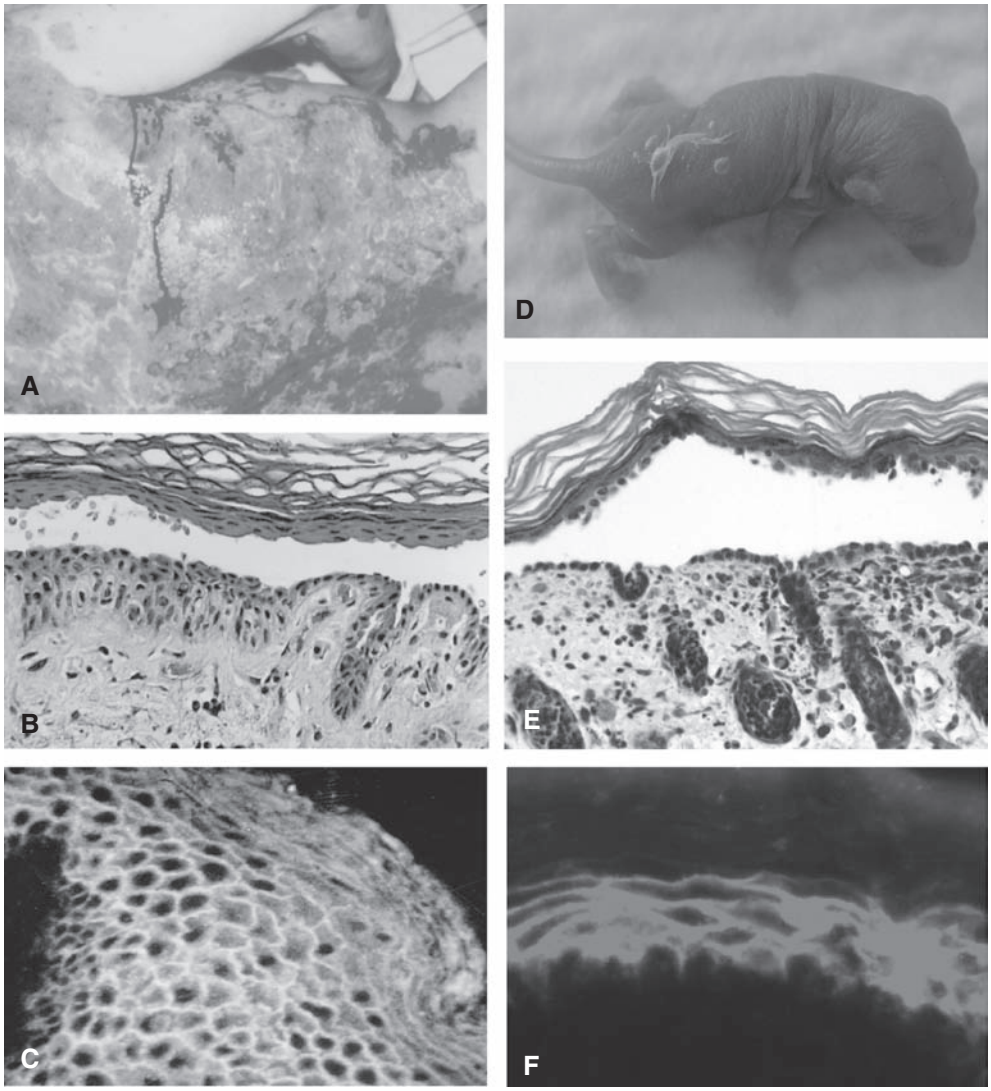

FIGURE 57.2 Left panel, clinical (A), histologic (B), and immunofluorescent (C) features of pemphigus vulgaris (PV). Right panel, mouse model of PV. The key features of the human disease are reproduced in these animals by passive transfer of PV autoantibodies (D–F). See color plate section.

autoantibodies to Dsg3 exclusively, patients who develop skin lesions may possess another population of autoantibodies against Dsg1, the autoantigen of PF (Ding et al., 1997). It is well established that about 50% of PV patients show autoantibodies against Dgs3 and Dsg1. Mucosal epithelium expresses Dsg3 predominantely, whereas the lower epidermis coexpresses both Dsg1 and Dsg3, compensating their function in pathologic states (compensation theory) (Mahoney et al., 1999a). Thus, anti-Dsg3 autoantibodies alone are not sufficient to induce spontaneous blisters in the skin, but they are pathogenic to mucosal epithelium.

Dsg1 and Dsg3 belong to the cadherin superfamily of calcium-dependent cell adhesion molecules and share high sequence homology (Getsios et al., 2004). The ectodomain of these glycoproteins are composed of four cadherin repeats (EC1–4) and a variable extracellular anchor (EC5) (Figure 57.3). The six putative calcium-binding motifs residing on the ectodomain are believed to be involved in maintaining the conformation and adhesive function of Dsg3. A putative adhesion site (RAL) is located on the EC1 domain. The ectodomain of Dsg3 has been expressed in the baculovirus system and employed to adsorb pathogenic autoantibodies from PV serum. The affinity-purified autoantibodies against Dsg3 induced suprabasilar acantholysis in neonatal mice (Amagai et al., 1992; Ding et al., 1999). These pathogenic autoantibodies recognize conformational and calcium-dependent epitopes located on the EC1 domain of Dsg3 (Sekiguch et al., 2001), which is believed to be involved in the adhesive function of the molecule.

Pathogenic Role

Several studies have demonstrated the correlation of PV autoantibody titers and disease extent and activity. Further, it was observed that these autoantibodies are present in the serum of babies born to mothers with active disease. This PV neonatorum was transient, i.e., the skin lesions healed spontaneously and the autoantibodies disappeared from the serum of the babies shortly after birth. *In vitro* studies also showed that PV IgG can induce acantholysis in skin organ cultures and cell detachment in primary epidermal cell cultures. The *in vivo* passive transfer studies, demonstrating that PV IgG is able to faithfully reproduce the disease in neonatal mice, finally attributed a pathogenic role to PV autoantibodies (see Figure 57.2, right panel) (Anhalt et al., 1982). These pioneer studies were extended to demonstrate that PV autoantibodies are able to induce disease by passive transfer in a process that is independent of activation of complement or plaminogen activator (Anhalt et al., 1986; Mascaro et al., 1997; Mahoney et al., 1999b).

Another area of intense research is addressing the molecular mechanisms of acantholysis, i.e., how PV autoantibodies trigger cell detachment. Earlier ultrastructural studies showed that PV autoantibodies bind keratinocyte cell surfaces, forming clusters of immune complexes that are internalized and fused with lysosomes (Patel et al., 1984). Mice passively transferred with PV IgG showed binding of these autoantibodies to the epidermal ICSs and initiation of the process of cell detachment in the spaces between desmosomes. This process was followed by desmosome splitting and completes cell detachment (Takahashi et al., 1985). Similar findings were also reported in an active mouse model for PV (Shimizu et al., 2004).

Two hypotheses on the molecular mechanisms of acantholysis are currently under investigation: impairment of the adhesive function of Dsg3 by steric hindrance (Diaz and Marcelo, 1978) and the activation of intracellular signaling pathways by binding of PV autoantibodies to Dsg3 (Caldelari et al., 2001; Kitajima, 2003; Rubenstein et al., 2004). Results of these studies are promising.

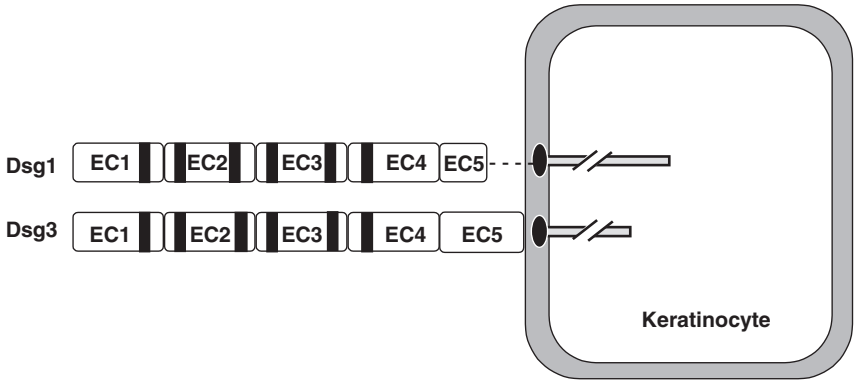

FIGURE 57.3 Molecular structure of desmoglein 1 (Dsg1) and desmoglein 3 (Dsg3). Dsg1 and Dsg3 are structurally similar desmosomal transmembrane glycoproteins. The extracellular domain of the two molecules contains four cadherin-like domains (EC1–EC4) and a membrane-proximal domain (EC5). The black stripes represent six putative Ca^{2+}-binding motifs found in the cadherin repeats.

T-Cell Activation

Like for most other antibodies, induction of anti-Dsg3 autoantibodies is also T-cell dependent. Indeed, *in vitro* anti-Dsg3 antibody production by autoreactive B cells was abolished upon depletion of $CD4^+$ T cells (Nishifuji et al., 2000). Other investigators have successfully derived T-cell clones from PV patients that proliferated when stimulated with various Dsg3 peptides (Wucherpfennig et al., 1995; Lin et al., 1997; Veldman et al., 2004). Most of the T-cell epitopes identified are located in the first three ectodomains of Dsg3. The HLA restrictions and cytokine profiles of the T-cell clones have been characterized. It was shown that the reactivity of one of these T-cell clones with the Dsg3 peptide (residues 190–204) was restricted to the PV-associated DRB1*0402 allele, and secreted high levels of type 2 helper T (Th2)-cell cytokines (Wucherpfennig et al., 1995). Similarly, $CD4^+$ T cells from PV patients responsive to three polypeptides (residues 145–192, 240–303, and 570–614) were also restricted to HLA-DR and exhibited a Th2-like cytokine profile (Lin et al., 1997). These studies suggest that Th2 cells are relevant in the induction of Dsg3-specific autoantibodies. However, a recent study by Veldman et al. (2004) showed that not only autoreactive Th2 cells are present in PV patients, but also Th1 cells. It was suggested that both Th1 and Th2 cells may be involved in the production of PV autoantibodies, since the ratio of Dsg3-specific Th1:Th2 cells in PV patients correlated well with the serum autoantibody titers of these patients.

Interestingly, Dsg3-specific T cells are not only detected in PV patients, but also detected in healthy individuals who carry PV-susceptible HLA alleles (Veldman et al., 2004). However, in contrast to PV patients, Dsg3-responsive T-cell clones from healthy donors exhibit exclusively Th1 [interferon (IFN)-γ] cytokine profiles. Of note, nonpathogenic anti-Dsg3 autoantibodies have been detected in first-degree relatives of PV patients, which are mainly IgG1 subclass (Bhol et al., 1995; Kricheli et al., 2000).

Genetic Features

HLA alleles may play important roles in the development and progression of PV (Sinha et al., 1988; Delgado et al., 1997). Two haplotypes, DR4 (DRB1*0402 or 0406)/DQB1*0302 and DR14 (DRB1*1401, 1404, or 1405)/DQB1*0503) are strongly associated with PV in different ethnic groups. It is suggested that the association of DRB1*0402 and DQB1*0503 is primary, whereas the association of DRB1*1401 and DQB1*0302 is secondary due to linkage disequilibrium. While DRB1*0402 is highly associated with PV in Jewish and white patients, DQB1*0503 is found in non-Jewish patients.

Animal Models

Autoantibody Passive Transfer Model

As described above, neonatal mice have been used as targets for passive transfer experiments of PV IgG (Anhalt et al., 1982). The small size of these animals and their lack of hair allow the use of smaller amounts of IgG and the lesions are easily visible on the hairless skin. PV IgG transferred into neonatal mice reproduces the clinical, histologic, and immunologic features of human disease (see Figure 57.2, right panel). The disease induced in these animals is dose-dependent and also correlates with the titers of PV autoantibodies detected in the sera of the injected mice.

Active Immunization Model

Efforts to induce PV phenotype in adult mice by conventional active immunization with human Dsg3 have been largely unsuccessful. The immunized animals, however, do produce antibodies that were able to induce skin blisters when passively transferred into neonatal mice (Fan et al., 1999). Amagai et al. (2000) have developed an active mouse model of PV using a novel strategy to overcome the barrier of self-tolerance. They immunized Dsg3 knock-out mice (Koch et al., 1997) with human Dsg3, and adoptively transferred the splenocytes from these immunized animals to immunodeficient mice, Rag-$2^{-/-}$, which express Dsg3 in their epidermis. The recipient mice produced anti-Dsg3 antibodies and showed suprabasilar acantholysis histologically. Some of the animals developed spontaneous crusted erosions on the skin around the snout.

PEMPHIGUS FOLIACEUS

Clinical and Histopathologic Features

Unlike PV, PF affects skin only, where the disease manifests as superficial blisters and erosions that may lead to crusting and formation of keratotic plaques (Figure 57.4, left panel). The skin lesions initially involve the central areas of the face, scalp, the mid chest, and the upper back. From these areas the disease may spread to involve the entire body, producing an exfoliative erythroderma. Histologic examination of these lesions reveals subcorneal vesicles and acantholysis, predominantly in the upper layers of the stratum spinosum (Lever, 1965).

The classical form of PF is nonendemic and is seen sporadically in different parts of the world. A second form of PF is endemic and was originally described in certain states of Brazil under the name of fogo selvagem (FS) (Diaz et al., 1989). Endemic forms of PF have also been reported in

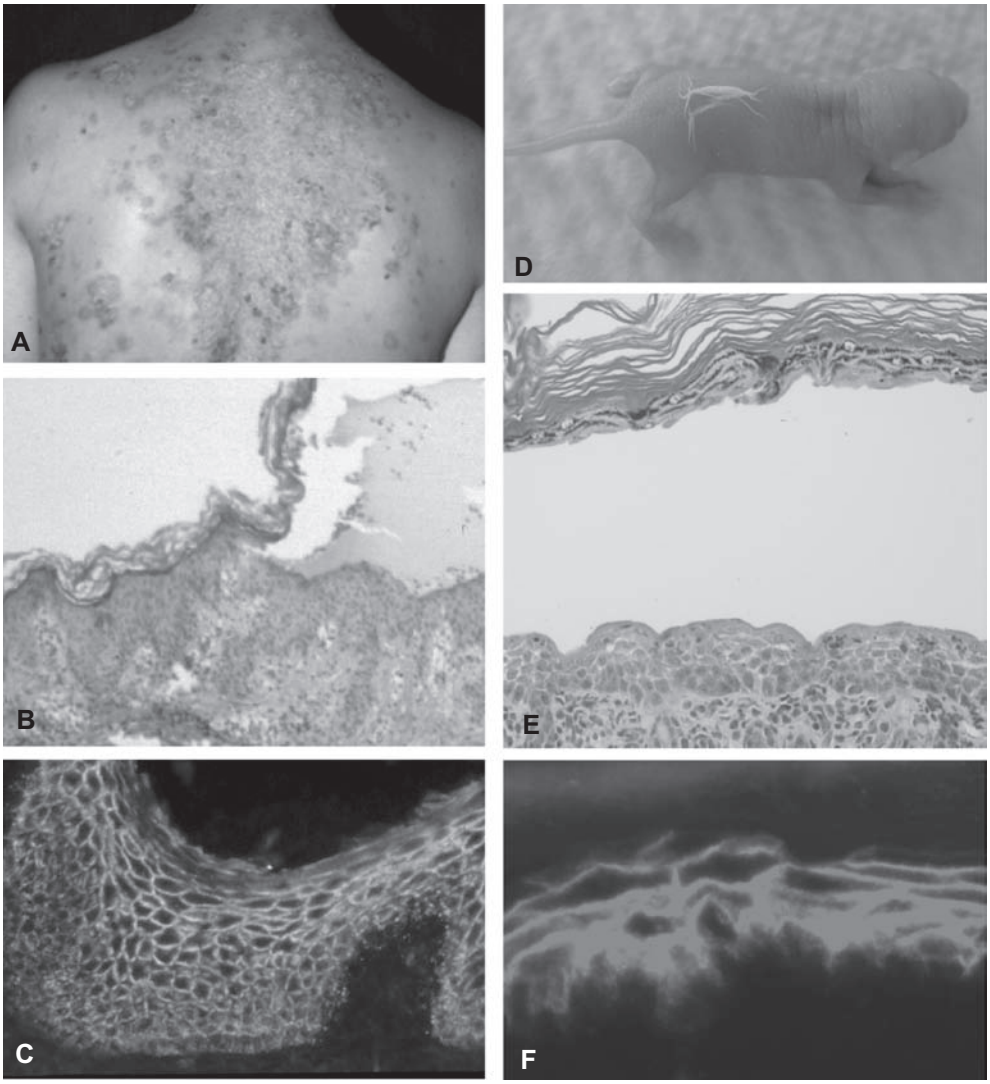

FIGURE 57.4 Left panel, clinical (A), histologic (B), and immunofluorescent (C) features of endemic pemphigus foliaceus (PF) (fogo selvagem). Right panel, mouse model of PF. The animals have been passively transferred with human PF IgG (and IgG4) and develop skin lesions (D), which histologically (E) are similar to the human disease. The human anti-Dsg1 autoantibodies are detected bound to the lesional epidermis (F) and circulating in the mouse serum. See color plate section.

Colombia and Tunisia. Epidemiologic studies suggest environmental triggers for FS development (Aoki et al., 2004).

Autoimmune Features

Autoantibodies

Similar to PV, PF patients are also characterized by anti-epidermal ICS autoantibodies, predominantly of the IgG4 subclass (Rock et al., 1989). These autoantibodies are detected bound to diseased epidermis and circulating in the serum of the patients. These titers roughly correlate with disease extent and activity. The IgG4 autoantibodies are pathogenic as demonstrated by passive transfer studies (Figure 57.4, right panel) (Rock et al., 1989). Activation of the complement cascade or plasminogen activator is not required for the induction of acantholysis by these autoantibodies in the mouse model (España et al., 1997; Mahoney et al., 1999b).

Dsg1, expressed mostly in the superficial layers of the epidermis, is the target antigen of PF autoantibodies. Affinity-purified anti-Dsg1 antibodies from PF serum are able to induce disease in neonatal mice (Amagai et al., 1995). The majority of PF autoantibodies recognize

conformational and calcium-dependent epitopes residing in the N-terminal amino acids 1–161 of Dsg1 (Sekiguch et al., 2001). We have recently shown that the anti-Dsg1 autoantibodies in FS recognize different domains of the ectodomain of the molecule. In the preclinical stage of FS or during disease remission and in normal individuals not exhibiting skin disease, the anti-Dsg1 autoantibodies recognize the EC5 domain only. On the contrary, FS anti-Dsg1 autoantibodies from patients showing active disease or during disease relapses recognize the EC1/EC2 domains (Li et al., 2003). Although the majority of PF/FS autoantibodies are of the IgG4 subclass, it appears that epitope specificity, rather than the subclass of IgG, is the driver of the pathogenicity of the autoantibodies (Li et al., 2002; Hacker-Foegen et al., 2003). Considering these findings, we hypothesized that an environmental agent(s) cross-reacts with the EC5 domain of Dsg1 and triggers an initial nonpathogenic anti-EC5 autoimmune response (Figure 57.5) (Diaz et al., 2004). In genetically predisposed individuals, the autoimmune response may undergo intramolecular epitope spreading toward pathogenic epitopes on the EC1/EC2 domains of Dsg1, which leads to disease onset.

T-Cell Activation

It has been demonstrated that $CD4^+$ T-cell lines and clones derived from peripheral blood of FS patients show a proliferative response when incubated with the Dsg1 ectodomain (Lin et al., 2000a). The stimulation of these $CD4^+$ T cells is HLA-DR restricted. Moreover, these cells secrete Th2-like cytokines. The Dsg1 epitopes recognized by these T cells have not yet been characterized.

Genetic Features

The HLA alleles strongly associated with FS are DRB1*0404, *1406, *1402 (relative risk = 14) and *0102 (relative risk = 7.3) (Moraes et al., 1997). A common epitope of LLEQRRAA, the residues 67–74 of the third hypervariable region of the DRB1 molecule, is shared by these susceptibility alleles. Similarly, a strong association of DRB1*0102 and DRB1*0404 is also found in nonendemic PF patients in France (Loiseau et al., 2000). Interestingly, two susceptible alleles in PV, DRB1*1401 and DQB1*0503, have been reported also with high frequencies in Italian and Japanese PF patients (Lombardi et al., 1999; Miyagawa et al., 1999).

Animal Models

The classic animal model of PF was developed by passively transferring IgG from PF patients into neonatal mice (Roscoe et al., 1985). These animals develop skin blisters, which show the typical histologic features of the human disease, i.e., subcorneal vesicles (Figure 57.4, right panel). The extent of the disease correlates well with the indirect IF titers of human autoantibodies detected in the mouse model. These animals develop classical ultrastructural subcorneal acantholysis (Futamura et al., 1989). The disease was induced as a complement-independent process and by monovalent PF IgG fragments as well (España et al., 1997). Despite the availability of recombinant human and murine Dsg1, studies on inducing disease by active immunization have been unsuccessful.

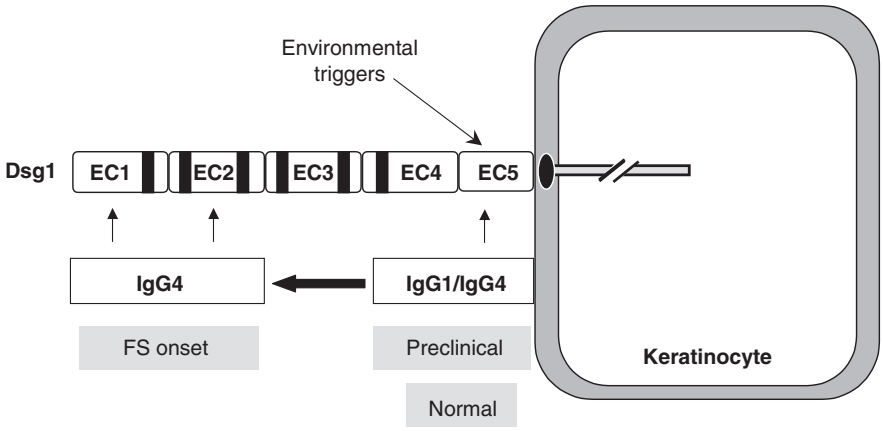

FIGURE 57.5 Proposed intramolecular epitope spreading in fogo selvagem (FS). An environmental factor(s) may initiate the production of nonpathogenic IgG1 and IgG4 antibodies against the EC5 domain of Dsg1. In certain genetically predisposed individuals, intramolecular epitope spreading results in the generation of predominantly IgG4 antibodies against the EC1 and EC2 domains of the molecule, resulting in disease.

Environmental Factors Involved in Fogo Selvagem

A remarkable characteristic of FS is its epidemiology. Several independent lines of evidence indicate that FS is precipitated by exposure to an environmental factor(s) (Aoki et al., 2004). Anti-Dsg1 autoantibodies have been detected in 55% of normal individuals living in an area exhibiting a high prevalence (3.4%) of FS (Warren et al., 2000). Remarkably, anti-Dsg1 autoantibodies are also detected in FS patients before the clinical onset of disease. These antibodies are a mixture of IgG1 and IgG4 subclasses and recognize the EC5 domain of Dsg1 (Warren et al., 2003; Li et al., 2003). A case–control epidemiologic study points to a hematophagous insect as a prime etiologic agent of FS (Diaz et al., 1989). For example, we have recently detected anti-Dsg1 EC5 antibodies in the sera of patients with onchocerciasis, leishmaniasis, and Chagas disease, exhibiting no skin lesions of FS (Diaz et al., 2004). It is known that hematophagous vectors (black flies, sand flies, and kissing bugs, respectively) are involved in the transmission of the respective tropical disease. It is postulated that the saliva of these vectors may contain Dsg1 cross-reactive antigens showing certain degrees of sequence homology with the EC5 domain of the molecule, thus inducing a nonpathogenic anti-EC5 domain autoantibody response. This finding may be an example of molecular mimicry. Identification of environmental triggers for FS would shed some light on the pathogenetic mechanisms involved in a human organ-specific autoimmune disease.

OTHER TYPES OF PEMPHIGUS

Paraneoplastic Pemphigus

PNP is a severe mucocutaneous disease that runs a usually lethal course in patients with underlying lymphoproliferative malignancy, i.e., non-Hodgkin lymphoma, chronic lymphocytic leukemia, and Castleman diseases (Anhalt et al., 1990; Anhalt, 2004). Patients exhibit severe stomatitis and skin lesions that may be vesiculobullous, or show erythema multiforme or lichen planus features. In approximately 30% of patients there is a bronchiolitis obliterans syndrome with severe respiratory insufficiency.

Histologic examination of the skin lesions reveals keratinocyte necrosis, basal cell vacuolization, and suprabasilar acantholysis. Direct IF shows deposition of IgG and C3 in the epidermal intercellular spaces (as in pemphigus) and along the basement membrane zone (BMZ). The unique and characteristic immunologic finding in PNP patients is the polyclonal autoantibody response against structural antigens of the desmosome and hemidesmosome. The antigens that have been characterized, besides Dsg3 and Dsg1, are members of the plakin family of proteins, including desmoplakin I and II, BP230, envoplakin, periplakin, and plectin, which are components of the desmosomal and hemidesmosomal plaques. Removal of anti-Dsg3 autoantibodies from PNP sera abrogates the pathogenicity of the IgG fraction (Amagai et al., 1998). Affinity-purified anti-Dsg3 antibodies are able to induce skin lesions in neonatal mice. Autoantibody-mediated disease may explain only part of the complex epithelial injury found in these patients. Other mechanisms of tissue injury that has been proposed are those of cell-mediated cytotoxicity.

It has been proposed that the autoantibody response in PNP is primarily directed against tumor antigens that cross-react with epithelial structural proteins. Additionally, the tumor may produce cytokines that modulate the autoimmune response. Interestingly, Wang et al. (2004) have demonstrated that tumor B cells are able to produce anti-epidermal antibodies.

The diagnosis of PNP is made clinically, histologically, and immunologically. By indirect IF, the serum of PNP patients typically stains rat bladder epithelium, which produces negative results when stained with the serum of PV or PF. Immunoprecipitation techniques using radiolabeled keratinocyte extracts reveal reactivity with the plakin proteins.

Drug-Induced Pemphigus

Certain drugs, particularly thiol-containing drugs, such as penicillamine and captopril, may induce clinical and histologic features of PF, and less commonly PV. The majority of drug-induced pemphigus patients exhibit circulating autoantibodies to the epidermal ICSs and epidermal-bound IgG. In cases of drug-induced PF, the autoantibodies recognize Dsg1. Some of these drugs have been shown to cause acantholysis directly *in vitro*. Drug-induced pemphigus may be transient and usually resolves upon withdrawal of the medication, although in rare cases the disease may run a chronic course. The mechanisms involved in the induction of the autoimmune response by drugs in pemphigus remain obscure.

IgA Pemphigus

This clinical variant of pemphigus is unique because of its clinical and histologic phenotype. Clinically, patients show superficial clusters of small vesicles and pustules, in some cases producing annular patterns. The Nikolski sign is positive and the great majority of patients show no mucosal lesions. The histologic features show, in addition to the acantholysis, an intense neutrophilic infiltrate in the epidermis. This infiltrate may be subcorneal or located in the mid-epidermis. The immunologic hallmark of this form of pemphigus is the presence of IgA class autoantibodies directed

to the epidermal ICSs (like PV or PF). The antigen recognized by some of these antibodies has been shown to be another desmosomal core cadherin, named desmocollin 1 (Hashimoto, 2001). The pathogenic role of these IgA autoantibodies has not been demonstrated. Further, the intense neutrophilic infiltrate of the epidermis and a rapid response of the disease to dapsone (a neutrophilic targeted drug) might indicate a unique IgA-mediated pathway of tissue damage.

BULLOUS PEMPHIGOID

Clinical and Histopathologic Features

BP is the most common autoimmune bullous disease affecting primarily the skin (Lever, 1965). It is estimated that about 5–10 new cases are seen yearly in a large hospital referral center in the USA. BP occurs most frequently in the elderly (60–80 years of age) and affects men and women equally. The skin lesions usually begin as urticarial plaques or erythematous papules, which evolve into large, tense bullae filled with clear fluid (Figure 57.6, left panel). Histologic examination of these lesions shows detachment of the epidermis from the dermis producing subepidermal blisters. The upper dermis exhibits an inflammatory infiltrate, including eosinophils, neutrophils, lymphocytes, and monocytes/macrophages. The predominant inflammatory cells in early lesions are usually eosinophils. Histologic evidence of mast cell degranulation has also been reported (Wintroub et al., 1978).

Autoimmune Features

Autoantibodies

BP patients have circulating and tissue-bound IgG autoantibodies directed against two hemidesmosomal proteins (Mutasim et al., 1985) known as the BP230 (BPAG1) and the BP180 (BPAG2, type XVII collagen) antigens (Jordon et al., 1967; Stanley et al., 1981; Labib et al., 1986). The autoantibodies to BP180 are predominantly of the IgG1 and IgG4 subclasses (Laffitte et al., 2001). In addition to IgG autoantibodies, IgE autoantibodies to BP180 are found in the majority of untreated BP patients (Dimson et al., 2003). Only antibodies to BP180 have been demonstrated to be pathogenic in neonatal mice (Figure 57.6, right panel) (Liu et al., 1993).

The BP230 antigen is an intracellular hemidesmosmal plaque protein belonging to the plakin family (Tanaka et al., 1991), whereas the BP180 antigen is a hemidesmosomal transmembrane protein belonging to the collagen family (Giudice et al., 1992). The BP180 protein shows a type II orientation, with its N-terminal region toward the intracellular hemidesmosomal plaque and its C-terminal half projecting into the extracellular milieu of the BMZ. The anti-BP180 autoantibodies from BP patients recognize multiple epitopes that cluster within the noncollagen 16A (NC16A) domain of the BP180 ectodomain (Giudice et al., 1993) (see Figure 57.8A). It has been reported that the serum levels of autoantibodies to BP180 NC16A in patients are directly correlated to disease severity (Haase et al., 1998).

T-Cell Activation

It has been reported that BP180-specific autoreactive T cells recognize epitopes located predominantly on the NC16A domain of the molecule (Budinger et al., 1998; Lin et al., 2000b). These T lymphocytes express $CD4^+$ memory T-cell surface markers and exhibit a Th1/Th2 mixed cytokine profile.

Genetic Features

HLA studies involving American, Japanese, and British BP patients showed no significant association between the disease and HLA-A, -B, -C, and -DR loci, while a marked increase in the HLA-DR5 allele was found in BP patients from France (Seignate et al., 1987; Venning et al., 1989). More recently, studies have demonstrated that HLA-DQB1*0301 is associated with BP in white patients (Delgado et al., 1996), whereas DRB1*0403, 0406, or DRB1*1101 have high frequency in Japanese patients (Okazaki et al., 2000).

Animal Models

IgG Passive Transfer Model

Early studies on passive transfer of human BP IgG containing anti-BP180 and anti-BP230 autoantibodies to neonatal mice were unsuccessful. It was found later that the murine BP180 protein did not react with human anti-BP180 antibodies largely due to differences at the amino acid level of the NC16A of the molecule. This problem was overcome by raising rabbit antibodies against a segment of murine BP180 homologous to the human epitope. It was demonstrated that these anti-BP180 antibodies were pathogenic if passively transferred into neonatal mice. The animals recapitulate the key clinical and histologic features of the human disease (see Figure 57.6, right panel) (Liu et al., 1993).

In contrast to the PV and PF mouse models, the subepidermal blistering in mice induced by anti-BP180 antibodies depends on complement activation and a subsequent cascade of inflammatory events, including mast cell degranulation and neutrophil infiltration (Figure 57.7). Proteolytic enzymes (neutrophil elastase and gelatinase B) released from recruited neutrophils are the final effector molecules

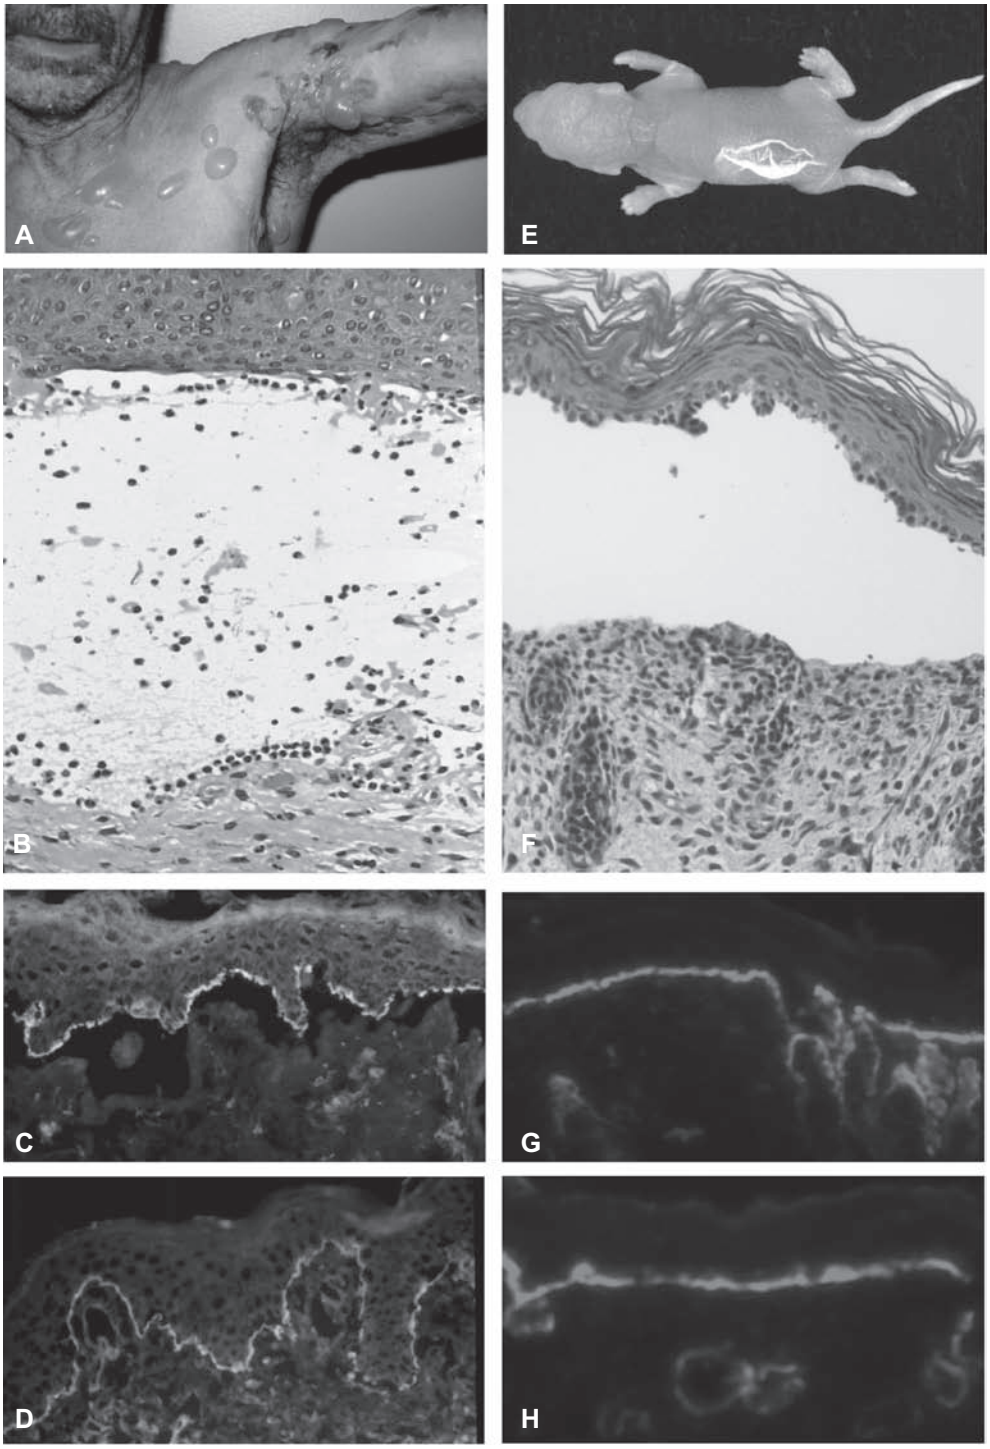

FIGURE 57.6 Bullous pemphigoid (BP). Left panel, key clinical, histologic and immunofluorescent features of BP. Large, tense blisters and erosions are seen in flexural areas (A). The histology reveals subepidermal blisters (B). Direct immunofluorescence (IF) shows *in situ* deposition of IgG (C) and C3 (D) at the cutaneous basement membrane zone (BMZ). Right panel, mouse injected with rabbit antimurine BP180 antibodies. The animals develop skin blisters (E). The histology of these lesions shows dermal–epidermal separation with an inflammatory infiltration (F). Direct IF shows *in situ* deposition of rabbit IgG (G) and mouse C3 (H) at the BMZ. See color plate section.

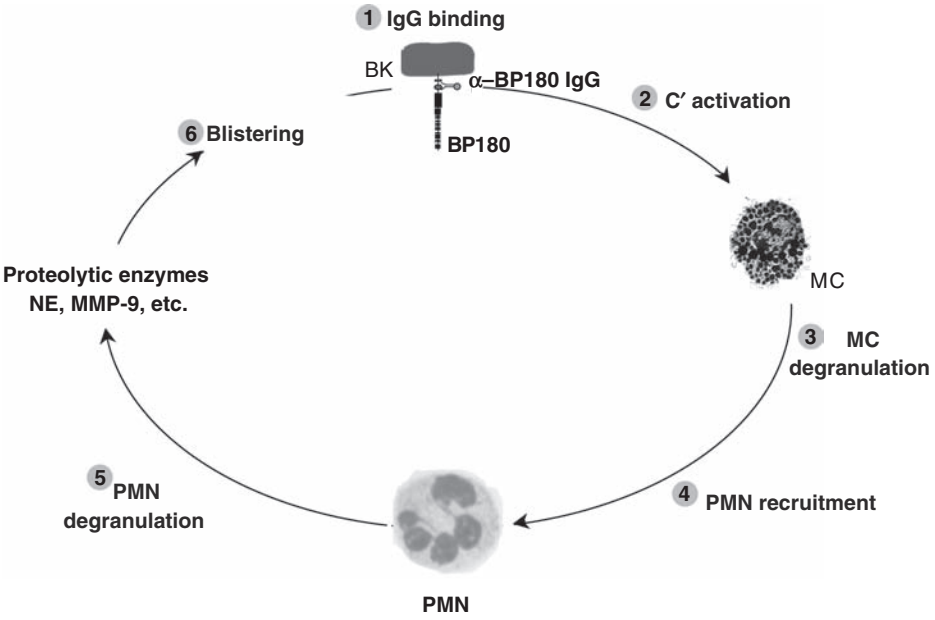

FIGURE 57.7 Proposed mechanism of subepidermal blister formation in experimental bullous pemphigoid. Subepidermal blistering is an inflammatory process that develops in the following steps: 1, anti-BP180 IgG binds to the pathogenic epitope of BP180 antigen in basal keratinocytes (BK); 2, the molecular interaction between BP180 antigen and anti-BP180 IgG activates the complement system (C′); 3, C′ activation products C3a and C5a cause mast cells (MC) to degranulate; 4, proinflammatory mediators released by MC recruit neutrophils (PMN); 5, infiltrating PMNs release proteolytic enzymes, including neutrophil elastase (NE) and gelatinase B (MMP-9); 6, proteolytic enzymes degrade BP180 and other extracellular matrix proteins, leading to subepidermal blistering.

that cause the epidermal–dermal separation seen in skin lesions (Liu, 2004).

Active Immunization Model

Recently, we have developed a new BP animal model by active immunization of adult C57BL/6J mice with a recombinant murine BP180 antigen. Figure 57.8A and B shows the ectodomains of the human and murine BP180 antigen, respectively, and the selected region of the murine protein used to immunize the animals. Three weeks after the boosting immunization, some of the immunized mice developed subepidermal blisters and a dermal inflammatory neutrophilic infiltrate. Perilesional skin of these animals showed *in vivo* deposition of IgG and C3 at the BMZ (Figure 57.8C). The autoimmune response in these animals is an MHC class II-restricted T-cell response (Liu, 2004). Remarkably, BALB/c and SJL mice were unable to mount a pathogenic autoantibody response upon immunization with the murine BP180 antigen.

OTHER SUBEPIDERMAL BULLOUS DISEASES

Herpes Gestationis (Pemphigoid Gestationis)

HG, also known as pemphigoid gestationis (PG), is a variant of BP affecting pregnant women primarily. The incidence is about 1 in 50,000 pregnancies. The disease usually develops during the second or third trimester of pregnancy or in the immediate postpartum period. HG has rarely been associated with underlying trophoblastic tumors. Similar to BP, HG patients develop subepidermal blisters and linear deposition of C3 at the BMZ (Provost and Tomasi, 1973). The sera of these patients is usually negative by conventional indirect IF assays but become positive when complement fixation to the skin is assayed (HG factor) (Provost and Tomasi, 1973). The HG factor was found to be a complement-fixing autoantibody against the BP180 antigen (Jordon et al., 1976; Katz et al., 1976; Morrison et al., 1988; Giudice et al., 1993). This autoantibody is predominantly IgG1 and recognizes the same epitope (within the BP180 NC16A domain) as BP autoantibodies. BP180-specific T cells also recognize the BP180 NC16A and express a $CD4^+$ Th1 memory phenotype (Lin et al., 1999). Like BP, HG is also associated with DQB1*0301. Interestingly, less than 5% of the neonates of mothers with HG develop transient subepidermal vesicles with maternal IgG bound to perilesional skin. The mechanism of autoimmunity in HG and the role of pregnancy are not fully understood.

Cicatricial Pemphigoid

CP, also known as mucous membrane pemphigoid, is a group of heterogeneous diseases characterized by subepithelial blistering involving mucous membranes exclusively

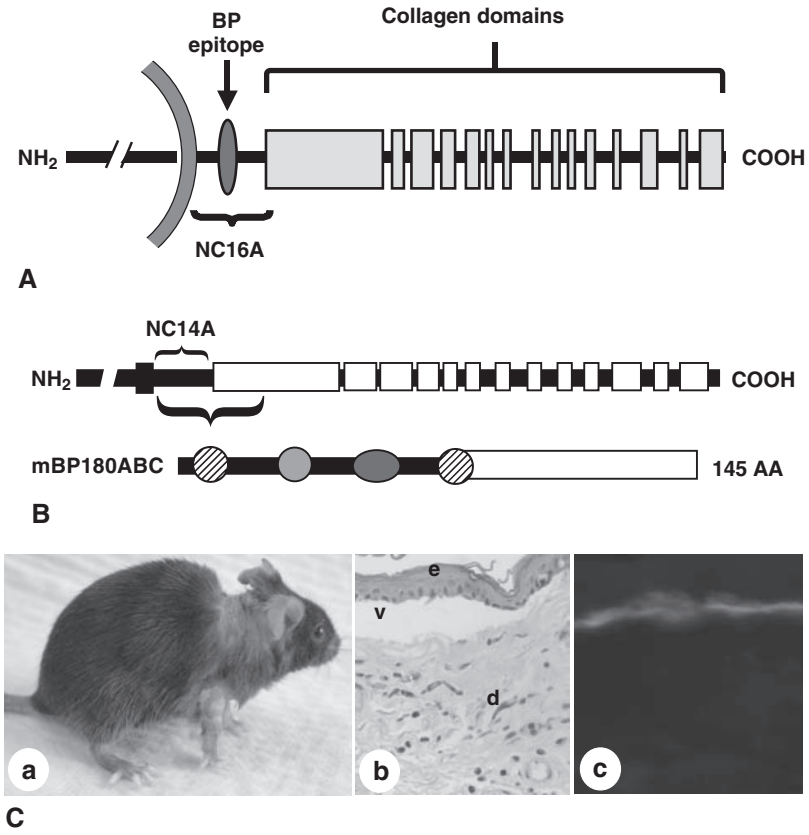

FIGURE 57.8 Active model of bullous pemphigoid (BP). *A*, Schematic diagram of the human BP180 antigen. The C-terminal extracellular region is made up of a series of collagen-like domains (yellow rectangles) interrupted by non-collagen domains (black bars). The major epitope (NC16A) recognized by BP autoantibodies is depicted by the red oval. *B*, Mouse BP180 antigen used to immunize mice. This antigen (referred to as mBP180ABC) contains the largest non-collagen domain (NC14A) and part of the largest collagen-like domain. mBP180ABC harbors four epitopes, one of which (red) is pathogenic. *C*, 8–10-week-old C57BL/6J mouse immunized with mBP180ABC. Some of these mice developed BP-like skin lesions, starting the third week after the boosting immunization (a). Histologic examination shows subepidermal blistering (b). Direct immunofluorescence shows *in vivo* deposition of autoantibodies at the basement membrane zone (c). d, dermis; e, epidermis; v, vesicle. See color plate section.

(Korman and Cooper, 2000). The oral and ocular surfaces are most commonly involved, while skin lesions occur only in one-third of CP patients. A striking clinical feature of CP is that healing of the lesions leads to scarring and dysfunction of the affected organs. For example, ocular involvement may cause blindness due to corneal scarring and fibrosis. Direct IF reveals linear deposition of IgG, IgA or C3 along the epithelial BMZ (Egan et al., 2003). Similarly esophageal involvement may lead to strictures of this organ (Egan et al., 1999). CP is also associated with DQB1*0301 (Delgado et al., 1996).

The heterogeneity of CP is reflected in the sites involved by the autoimmune disease and the syndromes it may produce (ocular only, oral mucosal only, mucocutaneous, and multiple sites). These syndromes may reflect the tissue specificity of targeted autoantigens. The majority of CP patients show circulating IgG autoantibodies against BP180 antigen (Balding et al., 1996). Some of these CP autoantibodies recognize the C-terminal domain of BP180, which is different from BP. A subset of CP patients exhibits circulating autoantibodies against laminin 5, also known as epilagrin (Domloge-Hultsch et al., 1994; Egan et al., 1999). Experimentally, it was shown that antilaminin 5 antibodies are able to induce subepidermal blisters in neonatal mice (Lazarova et al, 1996). Many patients with ocular involvement have autoantibodies against $\alpha 6\beta 4$ integrin (Tyagi et al., 1996). The pathogenic role of the various autoantibodies found in CP and their link to scarring remain to be elucidated. An association of cancer with some CP cases with antilaminin 5 autoantibodies has been reported, but it is not known why these CP patients have an increased relative risk for cancer (Egan et al., 2003).

Lichen Planus Pemphigoides

LPP is characterized by bullae arising on lichen planus papules. Some authors suggest LPP is the concurrence of lichen planus (LP) and BP, while others consider LPP as an

entity in its own right. In contrast to BP, LPP is seen in younger patients and the blisters are often distributed on the distal extremities. Like BP, linear deposition of IgG and C3 is found along the BMZ. LPP IgG autoantibodies recognize an epitope in NC16A of the BP180 antigen that is not reactive with BP autoantibodies (Zillikens et al., 1999).

Linear IgA Disease

LAD is a subepidermal blistering disorder characterized by pruritic lesions and linear deposition of IgA autoantibodies at the BMZ (Nemzer et al., 2000). Mucosal membrane involvement is common (60–80%). LAD can be subdivided into adult-onset, childhood-onset, and drug-induced LAD (Zone et al., 2004). The histology of lesional and perilesional skin reveals subepidermal vesicles with neutrophilic infiltration along the BMZ and in the superficial dermis.

IgA autoantibodies in LAD serum react with multiple antigenic peptides derived from the BP180 ectodomain. The most common antigenic peptides for the major type of LAD (the lamina lucida type), detected by immunoblotting using epidermal extracts, are the 97-kDa protein (LABD97) and the 120-kDa antigen (LAD-1), which are considered to be the proteolytic fragments of the BP180 polypeptide (Zone et al., 2004). These findings suggest that the majority of LAD autoantibodies recognize epitopes on LABD97 and LAD-1, which are different from those bound by BP autoantibodies on the intact BP180 molecule.

Epidermolysis Bullosa Acquisita

EBA is an acquired subepithelial blistering disease of the skin and mucous membranes mediated by IgG autoantibodies against type VII collagen (O'Toole and Woodley, 2000). Lesions occur predominantly on areas of trauma and often heal with scarring, like CP. Subepidermal blister are formed as a result of detachment of the epidermis at the level of the sub-basal lamina densa, as demonstrated by ultrastuctural studies (see Figure 57.1). EBA is associated with HLA-DR2 (Gammon et al., 1988).

The target antigen of EBA is type VII collagen (C-VII), which is confined to anchoring fibers of the sub-basal lamina densa region of the skin. EBA autoantibodies react with four major epitopes within the N-terminal noncollagenous NC1 domain of C-VII. It is hypothesized that binding of these autoantibodies may interfere with dimer formation of the C-VII molecule or may impair the association of C-VII with its ligands, laminin 5 and fibronectin. It has also been suggested that complement activation by the autoantibodies induces inflammation and blistering. EBA IgG autoantibodies, when injected into neonatal mice, induced microscopic subepidermal blisters below the lamina densa similar to the human disease. Furthermore, rabbit antihuman type VII collagen NC1 domain IgG also induced EBA-like lesions in adult hairless mice and nude mice bearing human skin grafts (Chen et al., 2004).

Dermatitis Herpetiformis

DH is an IgA-mediated skin blistering disease characterized by intensive pruritic erythematous papules and vesicles symmetrically distributed over extensor surfaces (Bagheri and Hall, 2000). The skin rash is gluten dependent and responds to a gluten-free diet. Skin biopsies from DH lesions show a characteristic neutrophilic infiltration in the upper dermis involving the dermal papillae. Perilesional and normal skin in DH shows a granular deposition of IgA along the BMZ. It has been shown that DH patients possess in their sera IgA autoantibodies that recognize epidermal transglutaminase (Sardy et al., 2002). It is unknown if these antitransglutaminase autoantibodies are pathogenic or an epiphenomenon, but the autoantibodies can be used as a sensitive serologic marker for DH. A remarkable feature of DH is its high association with celiac disease, another IgA related gluten-sensitive (GSE) disorder involving the small intestine. Patients with DH and GSE share an increased expression of the HLA-A1, HLA-B8, and HLA-DR3, and HLA-DQA1*0505 and DQB1*02 genes (Sollid, 2000) and a humoral response to transglutaminases. Both diseases are exacerbated by the intake of gluten-containing food. The mechanisms of gluten-induced autoimmunity and the relationship of the IgA autoantibody response to transglutaminase in DH remain unclear (see Chapter 51).

TREATMENT

The aim of therapy in all autoimmune blistering diseases of the skin is to abrogate the pathogenic autoantibodies and to decrease the tissue inflammatory response triggered by some of these antibodies. Elimination of pathogenic autoantibodies from the patient is accomplished by immunosuppression or plasmapheresis. The inflammatory response in the skin may be modulated by using topical or systemic steroids or drugs that are known to impair the effector function of neutrophils such as dapsone. It is understood that systemic steroids may modulate the antibody production and also benefit the local inflammatory response in the skin.

Systemic corticosteroids are the first line of therapy for patients with all clinical forms of pemphigus and pemphigoid. Doses of prednisone in the range of 1.0 mg/kg every morning are used initially. If patients continue to develop new lesions, the dose of prednisone can be increased incrementally to 2.0 mg/kg; however, in our practice we rarely exceed a total dose of 100 mg/day. The use of azathioprine, cyclophosphamide, methotrexate or mycophenolate mofetil as adjunctive therapy is beneficial in controlling

the disease and enhancing the chances of inducing a prolonged remission. They are excellent steroid-sparing agents. Patients must be fully evaluated clinically and tested for hematologic, renal and liver function parameters before starting treatment. The doses and side effects for any of these drugs are described in detail in dermatologic textbooks.

The mortality rate for patients with pemphigus has been reduced to less than 10%; however, these patients are prone to develop severe complications of the therapy, i.e., osteoporosis, diabetes, hypertension, and obesity.

It is well documented that some patients are "resistant" to all these therapeutic modalities. These rare patients may benefit from plasmapheresis or parenteral infusions of human immunoglobulin. Recently, it has been reported that therapy with anti-CD20 humanized monoclonal antibodies may induce clinical and serologic remissions in severe cases of pemphigus (Salopek et al., 2002; Dupuy et al., 2004).

Dapsone is the drug of choice in DH. It exerts its anti-inflammatory effects through direct action on the neutrophil by interfering with the myeloperoxidase–hydrogen peroxide–halide-mediated cytotoxic system in neutrophils. Dapsone can cause hemolysis and methemoglobinemia and therefore, it is mandatory to assay the levels of the enzyme glucose 6-phosphate dehydrogenase (G6PD) prior to beginning dapsone therapy as G6PD-deficient patients may experience severe hemolysis. Other side effects of dapsone, such as hepatitis and thrombocytopenia, may need to be monitored. Patients with LAD or IgA pemphigus also show a remarkable clinical response to dapsone. These diseases may be kept in remission with small doses of dapsone. Additionally, CP and certain cases of BP can respond favorably to dapsone.

Therapy for patients with EBA is limited since most of the drugs used to control other autoimmune blistering diseases do not change the course of this disease in most patients. The use of systemic steroids, immunosuppressive drugs or dapsone may be individualized in each patient. Removal of underlying malignancy, steroids, immunosuppressive drugs and supportive therapy has been attempted in PNP patients. The prognosis for these patients, however, is poor.

Non-Bullous Skin Diseases: Alopecia, Vitiligo Psoriasis, and Urticaria

MARGITTA WORM AND WOLFRAM STERRY

Department of Dermatology and Allergy, Charité Campus Mitte, Universitàts Medizin Berlin, Germany

An autoimmune pathomechanism has been discussed or confirmed for several dermatologic diseases within the past decades. The pathogenesis of these diseases is multifactorial and autoimmune mechanisms are often only one component of a complex pathophysiology. Some of these diseases typically affect only the skin and do not involve other organ systems, unlike the systemic autoimmune disorders. However, subsets of patients may be identified who develop either another autoimmune disease, such as Hashimoto's thyroiditis, or in whom another organ system is involved, such as the joints. The autoimmune background of these skin diseases has implications for their treatment, since immune-modulating or -suppressing agents are often effective. The pathophysiologic background of these diseases notably includes an abnormal T-cell response, but also autoantibody production against self-antigens within the skin.

ALOPECIA AREATA

Alopecia areata has a long medical history, first being described in the year 57 AD by Celsus. There is a vast knowledge regarding its pathogenesis and therapy. This disease is quite often associated with certain environmental exposures or particular individual incidents. The high spontaneous remission rate for alopecia areata has led to a wide range of therapies to promote hair growth, including complementary modalities. Strong direct and indirect evidence supports an autoimmune etiology for alopecia areata.

The exact incidence of alopecia areata is not known. A study from the US has revealed a lifetime risk as high as 1.7% (Safavi et al., 1995). The disease occurs most frequently within the second and third decades of life.

Clinical Features

Alopecia areata starts usually with one or several areas of hair loss in the scalp, beard or other hair-bearing sites. The eyebrows or eyelashes are also often affected. The skin area within the area of hair loss appears normal; no signs of atrophy are present (Figure 58.1). Within the areas of active hair shedding, a short fractured hair shaft may be identified, the characteristic "exclamation point" hair. Complete scalp involvement, called alopecia totalis, may occur suddenly or during prolonged progressive disease, and complete or nearly complete loss of the entire body hair, called alopecia universalis, may also occur. In 1–2% of affected

FIGURE 58.1 Typical clinical appearance of alopecia areata.

individuals, alopecia areata is further described as the ophiasis type, in which the hair loss occurs particularly within the retroauricular and occipital area, and alopecia areata diffusa type, which is characterized by a sudden diffuse hair loss without the typical circumscribed areas.

The course of the disease is generally characterized by recurrent hair loss and recovery. However, especially in alopecia areata totalis, universalis, and ophiasis, spontaneous recovery of hair growth often does not occur, resulting in persistent alopecia. Several factors indicative of a poor outcome have been identified, including the early onset of disease, a severe and long-standing course of the disease, and the presence of nail changes or atopic eczema. The nail changes include dimples and transverse furrows. Other organ systems are not affected and the most distressing consequence is the psychosociologic stigmatization of these young patients; social isolation and the development of secondary psychotic diseases are common.

Important differential diagnoses of alopecia areata are trichotillomania, tinea capitis, alopecia syphilitica, cutaneous lupus erythematodes, lichen planopilaris, and idiopathic scarring alopecia.

Pathophysiology

During its cycle the hair turns from an anagen into a catagen and finally into a telogen hair. In the adult scalp the anagen stage (active growth) lasts 3 years, catagen stage (regression) 3 weeks, and telogen stage (resting period) 3 months. At any one time, 84% of the scalp hairs are in the anagen stage, 2% in the catagen stage, and 14% in the telogen stage.

Headington (1991) has suggested that the pathophysiology of alopecia areata can be divided into four distinct stages: 1) acute hair loss; 2) persistent baldness; 3) partial telogen to anagen conversion; and 4) normal recovery. Lymphocytic infiltrates in the peribulbar area of the anagen follicles are observed in all stages. The follicular structures become miniaturized and as a result are identified most superficially in the dermis. In the early active phase of hair loss, diminutive follicles are predominantly observed in the early or late catagen stages and these persist into the chronic active phase of baldness. In long-standing cases, the inflammatory infiltrates in the skin appear to diminish (Messenger et al., 1986). Lymphocytes may invade both the bulbs and the outer root sheaths of early recovering anagen hairs. The lymphocytic infiltrates in the peribulbar area consist of substantial numbers of helper T cells (CD4/CD8 ratio 4 : 1). The ability of the hair follicles to self-recover is retained, and if the hair follicle re-enters the anagen stage, it can be either attacked again by the infiltrating lymphocytes or can undergo spontaneous growth (Messenger et al., 1986). The presence of peri- and intra-follicular $CD4^+$ and $CD8^+$ lymphocytic infiltrates suggests a T-cell-mediated autoimmune pathogenesis of the disease. Recently, a reduction of $CD4^+CD25^+$ regulatory T cells was identified in mice suffering from alopecia areata (Zoller et al., 2002).

Genetic Features

There is a genetic background in 10–25% of alopecia areata patients. Several HLA markers have been associated with alopecia areata, including DR-4, DR-5, DR-6, DR-7, DR-11, and several DQB-1 alleles (McElwee et al., 2001). Studies have identified polymorphisms for proinflammatory genes, including tumor necrosis factor (TNF)-α (Galbraith and Pandey, 1995), interleukin-1 receptor (IL-1R) (Cork et al., 1995), and the IL-1β gene (Galbraith et al., 1999). It is assumed that these polymorphisms within proinflammatory genes are associated with the clinical appearance and severity of alopecia areata.

Animal models have been established to study the pathophysiology of alopecia areata, notably in the C3H/HEJ mouse and the Dundee Experimental Board Rat (DEBR). Initial immunohistochemistry studies from affected patients indicated that the keratinocytes from hair follicles in lesions of alopecia areata are characterized by the expression of major histocompatibility complex (MHC) class I and class II, but also CD54 (Messenger and Bleehen, 1985). Such antigen-presenting molecules are not expressed within the normal hair follicle, because this is an immune-privileged organ that is protected from the immune system (Paus et al., 1994). Several as yet unidentified autoantigens induce a loss of this immune privilege of the hair follicle, resulting in increased expression of MHC- and CD54, and leading to the possibility of antigen presentation by hair follicle cells. The responsible autoantigens in hair follicles have not yet been identified. However, the expression of MHC class I plays a

central role, as $CD8^+$ T cells are located within the center of the peri- and intra-follicular infiltrates close to the MHC class I-expressing keratinocytes. Several studies have demonstrated the central role of $CD8^+$ T cells in the DEBR model by showing hair growth following depletion of $CD8^+$ T cells (McElwee et al., 1996). This was confirmed in a humanized severe combined immune deficiency (SCID) mouse model (Gilhar et al., 1999). $CD8^+$ T cells target the hair follicle keratinocytes and melanocytes by inducing apoptosis through CD95–CD178(CD95L) interaction (Bodemer et al., 2000). It has been shown that animals with a defective CD95–CD178(CD95L) system are resistant to alopecia areata (Freyschmidt-Paul et al., 2003b). The induction of apoptosis within the hair follicle keratinocytes and melanocytes leads to dystrophic changes and the hair shaft is not formed regularly.

Several other cell types may be also involved in alopecia areata, including macrophages, dendritic cells, $CD4^+$ T cells, and B-lymphocytes. The cytokine profile of isolated T cells from mice with alopecia areata reveals both a Th1 and Th2 profile in addition to increased TNF-α and IL-6 production (Zoller et al., 2002). Also, autoantibodies have been described in mouse and man (Tobin et al., 1997), but this is most likely a secondary effect as autoantibodies seem not to be directly involved in the development of hair loss.

Treatment

As mentioned above, the high spontaneous remission rate of alopecia areata means that many treatments have been described. When results of controlled prospective studies are not available, the possibility of spontaneous regrowth of hair needs to be considered.

Corticosteroids are widely used for the treatment of alopecia areata, but only two controlled studies with topical application of steroids have been published (Pascher et al., 1970; Leyden and Kligman, 1972). Another treatment option for alopecia areata is the induction of an allergic contact dermatitis with dinitrochlorobenzol (DNCB) (Happle and Echternacht, 1977). The efficacy of DNCB was confirmed in several controlled studies, therefore excluding the possibility of a spontaneous remission of the disease (Happle and Echternacht, 1977; Freyschmidt-Paul et al., 2003a). However, the success rate ranges from 29 to 78% with a median efficacy rate of 51% (Freyschmidt-Paul et al., 2003a). Future therapeutic approaches could include the application of molecules that are apparently able to penetrate the hair bulbus and inhibit either the CD95–CD178 (CD95L) interaction or MHC class I expression within the hair follicle keratinocytes. Unfortunately, the new topical immune modulators do not reach the hair bulbus in sufficient concentrations to have an effective immunosuppressive effect. Finally, several biologics are being considered, including antibodies to TNF-α/TNF-α receptor antagonists, and molecules, which interfere with costimulatory pathways like CTLA-4, although an efficacy–cost analysis will be necessary for these treatments.

VITILIGO

Clinical Features

Vitiligo is an acquired depigmenting disorder characterized by the loss of melanocytes from the epidermis. It occurs with a frequency of 0.1–2% in various populations. Several types of vitiligo are distinguished according to the distribution of the lesions. Vitiligo that is segmental or focal is called localized vitiligo. Generalized vitiligo, which most commonly affects the face, upper trunk, backs of the hands, genitals, and periocular areas, is characterized by lesions in a symmetrical distribution.

Stable patches of vitiligo often have an irregular border but are sharply demarcated from the surrounding skin (Figure 58.2). In some cases, the surrounding skin is hyperpigmented. A slight rim of erythema at the border may rarely be seen in expanding lesions, together with a thin zone of transitory, partial pigmentation. Hairs and patches of vitiligo usually become wholly white. The scalp and eyelashes are rarely affected.

Pathophysiology

A central process in vitiligo is the destruction of melanocytes at the dermoepidermal junction. The periphery of expanding lesions is hypopigmented rather than completely depigmented, and still shows a few dopa-positive melanocytes and some melanin granules in the basal layer.

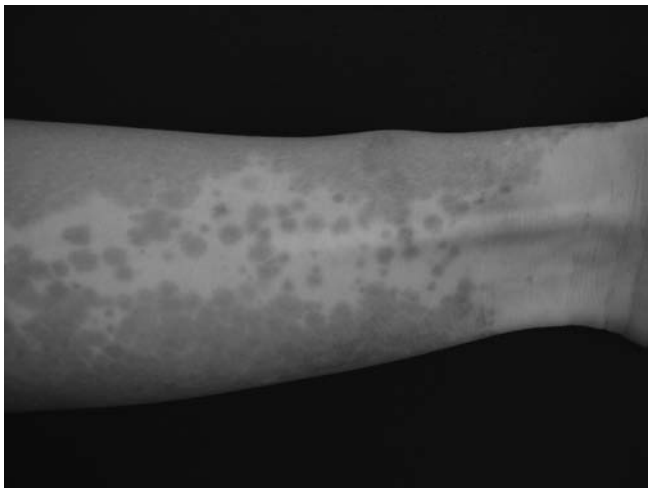

FIGURE 58.2 Vitiligo with typical loss of skin pigment. The border is irregular, but sharply demarcated from the surrounding skin.

In the outer border of patches of vitiligo, melanocytes are often prominent and demonstrate dendritic processes filled with melanin vacuoles. Sometimes, a superficial perivascular mononuclear cell infiltrate is observed at the border of depigmented areas.

Three major hypotheses for the pathogenesis of vitiligo are currently discussed. The first, and longest standing, considers vitiligo to be an autoimmune disease (Ongenae et al., 2003). The second, the neurogenic hypothesis, suggests that an accumulation of neurochemical substances damages the melanocytes, resulting in decreased melanin production (Lazarova et al., 2000). The third, the biochemical hypothesis, implicates cytotoxic metabolites from melanin synthesis as responsible for the destruction of melanocytes (Schallreuter et al., 2004). However, the list of other etiologic factors includes a deficiency of unidentified melanocyte growth factors, genetic defects, and an intrinsic defect in the structure or function of melanocytes (Ongenae et al., 2003).

The association between vitiligo, autoimmune disorders and the presence of organ-specific antibodies, as well as the fact that nonsurgical repigmenting therapies have immune-modulating effects, support the idea of an autoimmune pathogenesis for vitiligo. However, the exact mechanisms remain unclear, including whether autoimmunity is the primary cause or whether an abnormal immune response is simply a secondary effect. Also, different pathogenic pathways may be involved in the various clinical types of vitiligo. The neural hypothesis is thought to be involved in segmental vitiligo, whereas the biochemical or autoimmune hypothesis is thought to relate to generalized or focal non-dermatomal vitiligo.

In addition to the association with other autoimmune disorders and organ-specific antibodies, many other autoimmune features have been described during the course of vitiligo. These include deviations in T-cell and natural killer (NK) cell profiles (al-Fouzan et al., 1995). Immune histochemical studies of the perilesional area in generalized vitiligo reveals $CD4^+$ and $CD8^+$ T cells in the infiltrate (often with an increased CD8:CD4 ratio), which express activation molecules such as IL-2R and MHC class II. The T cells secrete interferon (IFN)-γ, which enhances T-cell trafficking to the skin by increasing CD54 expression (al Badri et al., 1993a; 1993b). An activated phenotype of the T-cell–mediated immune system was confirmed in vitiligo by detecting significantly increased levels of the soluble IL-2R (CD25), especially on T cells in generalized, focal, and non-dermatomal types of vitiligo (Honda et al., 1997). Also, tissue fluids from the margin of hypopigmented macules, especially in active disease, contain higher levels of soluble IL-2R than uninvolved skin of the same patient (Caixia et al., 1999). A substantial number of infiltrating T cells express cutaneous lymphocyte antigen (CLA), which is typical for skin-homing T cells (Le Poole et al., 1996). A recent study localized CLA^+ cytotoxic T cells to disappearing melanocytes in generalized vitiligo. A focal epidermal expression of CD54 and MHC class II at the site of interaction of skin-homing T cells and melanocytes was detected. The primary target of the immune-mediated attack on the keratinocytes–melanocyte unit is unknown. MHC class II-restricted melanocyte killing by T cells has been suggested by some authors (al Badri et al., 1993b). Keratinocytes may contribute to this process by presenting melanocyte antigens in an MHC class II-restricted manner after phagocytosis of melanosomes. However, the changes observed in epidermal keratinocytes with altered expression of antigen-presenting molecules suggest a primary involvement of keratinocytes in vitiligo.

In addition to T-cell infiltrates, macrophages are abundant in the dermis. The role of Langerhans cells, which act as antigen-presenting cells, is unclear. A depletion of epidermal Langerhans cells in active and repigmenting non-segmental vitiligo, and their reappearance in stable nonsegmental vitiligo, have been described (van den Wijngaard et al., 2000). Apoptosis as a primary pathophyiologic event in vitiligo has been suggested recently (Huang et al., 2002). In addition, an imbalance in cytokines in the epidermal microenvironment of lesional vitiligo has been demonstrated (Moretti et al., 2002).

A variety of circulating autoantibodies have been detected in sera from patients with vitiligo (Bystryn, 1989). These autoantibodies are directed to nonpigment cell antigens (common tissue antigens), cytoplasmic pigment cell antigens, and pigment cell surface antigens. Antibodies to surface endocytoplasmatic antigens of melanocytes have been of interest. These autoantibodies belong to the IgG isotypes, and subclasses of IgG1, IgG2, and IgG3 have been described (Harning et al., 1991). The significance of these autoantibodies has so far not been elucidated. It was suggested that antimelanocyte antibodies mediate melanocytotoxicity, whereas coexisting antikeratinocyte antibodies may occur secondary to cellular damage. However, the antibody response may also be secondary to a primary melanocyte destruction mediated by other mechanisms. As yet, only a few autoantigens have been identified. Tyrosinase and tyrosinase-related proteins 1 and 2 (TRP-1 and TRP-2) are key enzymes involved in melanin synthesis and have been implicated as autoantigens (Kemp et al., 1998). Passive immunization with TRP-1 monoclonal antibodies induces melanoma regression and vitiligo-like depigmentation in mice (Hara et al., 1995). However, antibody-mediated destruction requires membrane expression of the target antigens. Recently, the sur-face receptor, melanin-concentrating hormone receptor 1 (MCHR1), was detected as an antibody target in 16% of vitiligo sera. Although the antibodies are highly disease-specific, this neuropeptide receptor is

involved in the regulation of melanogenesis but it is not expressed by melanocytes (Kemp et al., 2002). Sox transcription factors, e.g., Sox9, are involved in the differentiation of tissues derived from the neural crest (Cheung and Briscoe, 2003) and were identified as melanocytic autoantigens in vitiligo associated with other autoimmune diseases (Hedstrand et al., 2001).

All-in-all, the pathogenic role of antimelanocyte antibodies remains unclear. Although the incidence and serum level of antibodies to melanocyte antigens was found to correlate with the disease activity, the extent of depigmentation, presence of other autoimmune diseases, and cellular and biochemical effects must be considered (Naughton et al., 1986). Finally, there is evidence that both cellular and humoral immunity cooperate in the destruction of melanocytes in vitiligo patients.

Genetic Features

Familial clustering of cases is not uncommon. A polygenic basis has been suggested. There is an increased frequency of several autoimmune disorders in vitiligo patients and first-degree relatives. These include autoimmune thyroid disease, pernicious anemia, Addison's disease, systemic lupus erythematosus (SLE), and inflammatory bowel disease. Such associations indicate that vitiligo has common etiologic links with other autoimmune diseases (Alkhateeb et al., 2003) Also, coexistence of vitiligo and psoriasis or lichen planus has been reported (Rubisz-Brzezinska et al., 1996; Dhar and Malakar, 1998; Hwang et al., 1998). In vitiligo patients, there is a strong familial association and relation to atopy. In a study from Asia, a significant percentage (60–70%) of affected patients had an associated personal and family history of atopy (Tan et al., 2002). Other studies have suggested vitiligo susceptibility loci on chromosomes 7, 8, and 17 (Spritz et al., 2004). Although these family clusterings and genetic linkage studies suggest that genetic factors predispose to vitiligo, a clear transmission pattern and cosegregation of vitiligo with specific mutations have not been demonstrated.

Treatment

Treatment of vitiligo is based on immune modulatory and immunosuppressive approaches (Valkova et al., 2004). In general, the efficacy of different types of treatment is variable and in some patients only cosmetic covering gives satisfactory results. Topical corticosteroids are most useful on small patches of recent onset. One percent betamethasone valerate may be used on the face and a superpotent agent, such as 0.05% cobetasol propionate, on the body. If there is no response within 3 months, treatment should be stopped; full response, if it occurs, may take many months. Recently, in uncontrolled studies, topical calcipotriol has shown a possible beneficial effect in patchy areas of vitiligo depigmentation, either alone or in combination with ultraviolet (UV) therapy (Cherif et al., 2003; Vasquez-Lopex et al., 2003). Furthermore, UV-light preventing measures using UV-protection emulsions will help by reducing increased pigmentation of the normal skin, as well as protecting the depigmented skin areas.

Local and systemic PUVA-therapy (psoralen + UVA) is the first-line treatment for adults with a reported skin repigmentation of up to 80–90% (Cherif et al., 2003; Valkova et al., 2004). However, as the long treatment duration with PUVA results in significant UVA exposure, new treatments are being sought. These include PAUVA, the systemic application of phenylalanine followed by UVA radiation, and KUVA, in which systemic khellin and UVA are combined (Valkova et al., 2004).

Punch grafting is recommended as a treatment for localized nonprogressive vitiligo resistant to conventional therapies (Agarwal, 2004). Here autologous keratinocytes may act as a source of growth factors like leukotrienes, endothelin, basic epidermal growth factor, and stem cell factor, which stimulate donor melanocytes to proliferate and migrate into the vitiligo patch, or alternatively to release growth factors that diffuse into the surrounding vitiligo patch and stimulate the viable but dormant melanocytes.

The 308-nm excimer laser has been used in the management of stable plaque psoriasis and has been proposed for the treatment of vitiligo (Asawanonda et al., 2000; Baltas et al., 2001; Spencer et al., 2002). Unlike narrow-band UVB phototherapy and PUVA, the 308-nm excimer laser modality can selectively treat single vitiligous patches, sparing nonaffected areas. However, among the physical methods known to be effective for treating vitiligo, the 308-nm XeCL excimer laser may considerably improve vitiligo and is well-tolerated.

PSORIASIS

The term psoriasis is derived from the Greek psora, meaning scurf, itch, rash. The first clear description was by Willan in 1808 (Willan [re-edited] 1950).

Clinical Features

Psoriasis is divided into different subtypes, including psoriasis vulgaris, generalized pustular psoriasis, and localized pustular psoriasis. The most common form is psoriasis vulgaris, which is a common chronic inflammatory skin disorder that affects approximately 2–5% of the white population (Henseler and Christophers, 1985) and 0.1–0.3% of the population in the Far East (Sagoo et al., 2004). It is

FIGURE 58.3 Sharply demarcated psoriatic plaques.

characterized by pink to red papules and plaques. The lesions are of variable size, sharply demarcated, and covered with scales (Figure 58.3). Both sexes are equally affected and 75% of patients develop the disease before the age of 40 years (Henseler and Christophers, 1985). Two peaks of age onset have been described; one at 20–30 years and a smaller peak at 50–60 years, suggesting that two forms of the disease exist. However, there are exceptions to this since in some families in which there is early onset and severe disease, there appears to be segregation dependent on a highly penetrant autosomal-dominant susceptibility gene distinct from HLA. Psoriasis can also occur with other inflammatory autoimmune diseases, notably psoriatic arthritis (10–30% of cases) (Ruderman and Tambar, 2004).

In the fully developed lesions of psoriasis the histologic picture is characterized by: 1) acanthosis with regular elongation of the rete ridges and thickening in the lower portion; 2) thinning of the suprapapillary epidermis with the occasional presence of small spongioforme pustules; 3) pallor of the upper layers of the epidermis; 4) a diminished to absent granular layer; 5) confluent parakeratosis; 6) the presence of Munro microabscesses (parakeratosis with neutrophils); 7) elongation and edema of the dermal papillae; and 8) tortuous capillaries. Of all these features, Munro microabscesses are characteristic for psoriasis. As a rule Munro microabscesses are found easily in early lesions but are few in number or absent in long-standing lesions. A bleeding point, which may be produced by gentle scraping of the skin (Auspitz sign), corresponds to the tips of the papillae. In ordinary psoriasis, the spongiforme pustule of Kojoi is a very small micropustule that is seen only in early active lesions, whereas it occurs as a macropustule in all variants of generalized pustular psoriasis and represents a characteristic histologic lesion. The epidermis contains an infiltrate of mononuclear cells and neutrophils can often be seen migrating from the capillaries in the papillae into the epidermis.

Pathophyisology

The pathogenesis of psoriasis is due to a combination of a genetic predisposition and particular environmental exposures that include injury, infection, stress or certain medications (Guilhou, 1998). An intriguing characteristic of psoriasis is the Köbner phenomenon, which is the appearance of isomorphic pathologic lesions following skin trauma in patients with preexisting cutaneous disease (Weiss et al., 2002).

Characteristic features of psoriasis suggest an immune-mediated process (Robert and Kupper, 1999). Several lines of direct and indirect evidence suggest that T-cells play a crucial role in pathogenesis (Wrone-Smith and Nickoloff, 1996; Gilhar et al., 1997; Bos and De Rie, 1999). Partially identified antigens, like superantigens but probably also keratinocyte-derived antigens, induce specific $CD4^+$ T cells. The presence of antigen-specific $CD4^+$ T cells secreting type 1 cytokines, IFN-γ, IL-2, and TNF-α was demonstrated in psoriatic skin lesions (Nickoloff, 1991; 1999; Kupper, 2003). In addition, memory T cells present in psoriatic lesions express the CLA molecule on their surface and predominate in the skin, whereas in inflammatory diseases involving tissues other than the skin, predominantly CLA^- T cells are present (Picker et al., 1993). CLA is an adhesion molecule that mediates the initial tethering of T cells to the endothelium in cutaneous postcapillary venules (Picker et al., 1993; Fuhlbrigge et al., 1997). E-selectin is the endothelial ligand for CLA and its expression is upregulated during cutaneous inflammation (Groves et al., 1992). The preferential expression of E-selectin in skin helps select for CLA^+ T cells. Furthermore the activation of T cells through chemokines, other integrins, and cell adhesion molecules is also required (Springer, 1994). The expression of unique chemokine receptors by CLA^+ T cells and the preferential expression of their respective chemokine ligands by skin cells increase the specificity of these T cells for the skin (Campbell et al., 1999). The type 1 cytokine bias has also been observed in circulating blood T cells from psoriatic patients (Lowes et al., 2004). Imbalance between Th1 and Th2 cells in psoriasis was supported by a deficiency of IL-10 in psoriatic lesions. Moreover, with curative antipsoriatic therapy, an increase in IL-10 mRNA expression was observed in peripheral blood mononuclear cells (Asadullah et al., 1998). IL-10 therapy given either intralesionally or subcutaneously resulted in a marked reduction of psoriatic lesions (Asadullah et al., 1998; 1999). These data suggest that psoriasis is an inflammatory $CD4^+$/Th1-mediated autoimmune disorder but the culprit autoantigens have still not been identified.

Further evidence implicating the immune system in psoriasis has come from clinical studies. Drugs that act by suppressing the activity of T cells, such as cyclosporine, FK506, and the recently developed biologics, are effective in treating psoriasis (Krueger, 2002). Further evidence for T-cell-based susceptibility has come from bone marrow transplantations, in which psoriasis of the donor has been transmitted to the recipient (Eedy et al., 1990).

Other evidence has come from animal models. The injection of activated blood-derived T-lymphocytes from a patient with psoriasis into SCID mice bearing autologous human grafted skin resulted in psoriatic plaques and the presence of T-cells with NK cell receptors that accumulate immediately before the onset of acute cutaneous lesions (Nickoloff and Wrone-Smith, 1999). T cells isolated from involved psoriatic skin enhance keratinocyte proliferation. The normal cycle of maturation of keratino-cytes is 28–30 days, whereas in psoriasis this is accelerated to 3–4 days (Guilhou, 1998). During lesion formation, inflammation precedes epidermal hyperproliferation. Also, increased numbers of T cells have been demonstrated in the uninvolved skin of patients with psoriatics (Baadsgaard et al., 1990).

Genetic Features

In 1980 an association of psoriasis with HLA class I alleles was demonstrated, particularly HLA-Cw6 (Tiilikainen et al., 1980). Although not all affected family members are HLA-Cw6$^+$, this locus shows a strong concordance with severity of disease (Gudjonson et al., 2002). As the penetrance of HLA-Cw0602 is only 10%, additional environmental effects or additional genetic susceptibility factors are implicated. Analysis of concurrence of different autoimmune disorders in family members has shown that patients with inflammatory bowel disease and psoriasis share the haplotype HLA-A3, B35, Cw4, and DR-2 (Sels et al., 1997).

The localization of a second psoriasis susceptibility locus to chromosome 17q25 was demonstrated following a genome-wide linkage scan on eight multiply affected families (Tomfohrde et al., 1994). In this study the family contributing the greatest evidence for linkage had 20 affected members and the penetrance of the disease was very high (80–90%). In 1996, linkage of *PSORS3* to chromosome 4q35 was reported in a set of Irish families (Matthews et al., 1996). Additional genome-wide scans have revealed evidence for linkage to chromosome 1q21 (*PSORS4*) in families from the Lazio region of Italy. Others have shown linkage to chromosome 3q21 (*PSORS5*) in Swedish families and 19p13 in German families (Lee et al., 2000). The function of genes at these particular loci has not been determined. However, the identification of multiple susceptibility loci for psoriasis indicates that psoriasis and psoriatic arthritis are genetically heterogeneous (Alarcon-Riquelme, 2003).

Recently, the examination of gene transcripts and peptides with altered expression levels, including a global genome-wide expression study (Zhou et al., 2003), has identified a large number of dysregulated genes and gene clusters, involving particularly epithelial proliferation and the immune system. However, studies have not yet provided sufficient information to identify the molecular defects underlying the disease.

Treatment

Treatment of psoriasis depends on the severity of the disease and the effectiveness of the treatment chosen. It includes local and systemic approaches as well as balneophototherapy. Topical treatment includes the usage of topical vitamin D analogs and retinoids (Takahashi and Iizuka, 2004; Yamauchi, et al., 2004), or combinations of topical treatments (combinations of dithranol, vitamin D3 and retinoids, with a topical corticosteroid can be very effective). The major targets of action of these topical substances are the hyperproliferative keratinocytes. Also, new topical immune modulators like tacrolimus and pimecrolimus are effective in psoriasis (Lebwohl et al., 2004; Wolff, 2004). These substances are approved only for the treatment of atopic dermatitis. Future new developments are most probably the peroxisome proliferation-activating ligands (PPAR-L) (Kuenzli and Saurat, 2004). These have been demonstrated to play an important pathophysiologic role in psoriasis and clinical trials using PPAR-L are underway.

Phototherapy

Phototherapy remains a central treatment option for psoriasis vulgaris. Photochemotherapy and various methods to deliver narrow-band UVB can be used either as monotherapy or in combination with other agents to treat moderate and severe psoriasis. In 1991, a consensus guideline recommended PUVA for patients requiring second-line therapy (Ibbotson et al., 2004). TL-01 UVB has become more widely available and is replacing the less effective broadband sources (Bandow and Koo, 2004). For patients with skin phototypes I–III with chronic plaque psoriasis, TL-01 UVB phototherapy is the treatment of first choice for those requiring photo(chemo)therapy. PUVA should generally be reserved for those patients whose psoriasis does not respond adequately to TL-01 UVB (Dawe et al., 2003).

Current Therapeutic Strategies

Systemic immune therapy includes the suppression of type 1 cytokine-mediated autoimmune reactions and/or immune modulation shifting from a type 1 to type 2 immune response. There is a beneficial effect of the type 2 cytokines

IL-10 and IL-11 (Asadullah et al., 1998). Currently used antipsoriatic drugs include methotrexate, cyclosporine, fumeric acid, azathioprine or mycophenolate mofetil (Geilen et al., 2001; Heydendael et al., 2003; Balasubramaniam et al., 2004; Bigby, 2004). The development of specific immune-modulating or selective suppressive agents includes the large-scale production of humanized, chimeric or purely human antibodies and the development of antisense RNA preparations.

Selective T-cell depletion is achieved with a fusion toxin protein DAB389IL-2 (depletion of activated T-cells expressing IL-2 receptor). It is effective in severe psoriasis, but the side effects are severe and prolonged immunosuppression can occur (Gottlieb et al., 1995; Bagel et al., 1998). Another approach is the blockade of T cells by directly targeting critical surface proteins involved in the process of T-cell activation, or blocking critical type 1 cytokines. Several biologics have already shown considerable clinical efficacy for the treatment of psoriasis in well-designed clinical studies. In a phase II multicenter study on 145 patients, efazilumab (an anti-CD11a antibody that inhibits integrin-binding molecule) induced over 50% improvement in "physicians' global assessment" after 8 weeks of treatment in 48% of patients compared to 15% of patients given placebo (Papp et al., 2001). Anti-TNF-α agents are in clinical trials (Mease et al., 2000; Chaudhari et al., 2001). Etanercept has recently been approved for the treatment of psoriatic arthritis.

Another method of selective depletion of autoreactive lymphocytes is by blocking the T-cell receptor (TCR) assuming that autoreactive T cells in psoriasis are oligoclonal (Chang et al., 1994; Menssen et al., 1995). There is also extensive research on chemokine-blocking drugs. However, the development of selective immune modulatory drugs, which may be considered both anti-inflammatory and immunosuppressive, is complicated by the fact that leukocytes are governed by a complicated network of many and partly redundant chemokines and their receptors (see Chapter 18). Further data are given on various biologics for treatment of psoriasis in Chapter 76.

Psoriasis has a major adverse impact on quality of life and causes much psychological and physical disability. The efficacy of several biologic agents is already proven, and some have been registered for clinical use in psoriasis. Yet, despite these recent advances, the ideal antipsoriatic medication has still to be developed. What is needed is a safe, orally administered compound that provides greater than 80% reduction in disease activity in a significant (>70%) number of patients.

CHRONIC URTICARIA

Hippocrates described urticaria as a distinct entity, but many different subtypes have been recognized during the past century. Approximately 25% of individuals develop an acute urticaria during their lifetime, which is usually a self-limiting disease with the resolution of symptoms in under 6 weeks. If symptoms persist longer, chronic urticaria can be specified, which affects approximately 1% of the population.

Clinical Features

Urticaria is characterized by the rapid appearance of wheals, which may be accompanied by angioedema. Three typical features are characteristics of a wheal: 1) a central swelling of variable size surrounded by a reflex erythema or flare (Figure 58.4); 2) associated itching or sometimes burning; and 3) short duration with normal appearances usually within 24 h. On histologic examination the classical transient wheal shows edema of the epidermis and the upper and mid-dermis, with dilation of postcapillary venules and lymphatics of the upper dermis.

Pathophysiology

Many different factors have been implicated in chronic urticaria, including bacterial infections, adverse reactions to medications or foods, IgE-mediated allergies, and underlying autoimmune diseases, such as SLE.

Depending on the duration of the wheal, a mixed inflammatory perivascular infiltrate of variable intensity consists of neutrophils and/or eosinophils, macrophages, and $CD4^+$ T cells (Haas et al., 1998). In different subtypes of urticaria, alteration of adhesion molecules and cytokine expression is seen in uninvolved skin (Hermes et al., 1999).

Greaves (2002) developed the concept of autoimmune urticaria, postulating that a subgroup of chronic urticaria patients (approximately one-third of patients) has an autoimmune pathophysiology involving activation of cutaneous mast cells. This concept began with the observation that intracutaneous injections of autologous sera caused positive

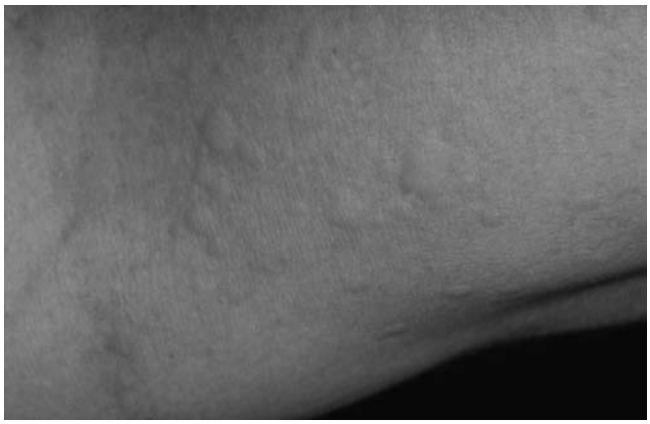

FIGURE 58.4 Urticarial lesions with a central swelling of variable size surrounded by a reflex erythema.

skin reactions (Malmros, 1946). This autologous serum skin test (ASST) procedure has been used to identify autoreactive chronic urticaria patients (Hide et al., 1993), but only skin reactions >1.5 mm should be regarded as positive (Sabroe et al., 1999a). A subgroup of ASST-positive chronic urticaria patients has autoantibodies against FcεRI and/or IgE. Such autologous autoantibodies can degranulate mast cells and basophils and may also induce urticaria-like skin reactions in healthy individuals. These observations were subsequently confirmed by other authors (Fiebiger et al., 1995; 1998; Tong et al., 1997; Sabroe et al., 1999b; Wedi et al., 2000; Zuberbier et al., 2000).

The ASST may be regarded as a useful screening test when used as described by Sabroe et al. (1999b), but its sensitivity and specificity are each only around 80%, and the diagnosis of an autoimmune urticaria cannot be exclusively based on it. Anti-Fcε-RI autoantibodies and the anti-IgE autoantibodies, which may be present in such patients, can be determined either by Western blot or enzyme-linked immunosorbent assay (ELISA). However, these detection systems do not give any explanation of the functional relevance of these antibodies, if present. Only by using cell activation assays can functional data be obtained. This cell activation system is based on enrichment of human basophils, which are stimulated with the patient's sera, with measurements of histamine production. Studies by Kaplan (2002) have suggested that complement also is involved in the activation of mast cells and/or basophils in patients with chronic autoimmune urticaria. The analysis of cell activation assays shows that the presence of anti-FcεRI and IgE autoantibodies does not necessarily lead to mast cell degranulation. This observation has led to the concept that mast cell activating and nonactivating autoantibodies can be distinguished. However, it has also been shown that some patients with a positive ASST have no anti-IgE or anti-IgE receptor antibodies, indicating that there may be other as yet unidentified autoantibodies, e.g., against mast cell membrane components.

Other autoimmune features, particularly antithyroid peroxidase autoantibodies, have been observed in autoimmune urticaria patients (Nettis et al., 2002); thus, among 624 patients with chronic urticaria, there was evidence of thyroid immunity in 14% versus an expected 6% (Nettis et al., 2002).

Treatment

Treatment of chronic urticaria, particularly in patients with an autoimmune background, requires antihistamines and/or leukotrienes in high dosages, and often immune modulatory and/or immunosuppressive treatments are necessary. In some patients even the addition of such treatment is unsatisfactory and they become severely handicapped by the chronic itching course of the disease.

A few reported studies suggest efficacy of removal of autoantibodies by plasmapheresis (Grattan et al., 1992; 2000; Greaves, 2000). Alternatively, immunologic treatment with agents that inhibit antibody formation has been reported, particularly usage of cyclosporine (Fradin et al., 1991; Toubi et al., 1997; Grattan et al., 2000), or high dosages of intravenous immunoglobulin (O'Donnell et al., 1998). However, such treatments are costly and should be reserved for therapy refractory patients.

CONCLUSION

Taken together, several dermatologic diseases with a diverse clinical picture have an autoimmune background. Many other skin diseases, like Behçet's disease, which is characterized by a vasculitis with mucocutaneous, ocular, arthritic, vascular, and other manifestations, have also been discussed as autoimmune diseases. Over the past years more knowledge has been obtained on the mechanisms of many of these diseases. This has had an impact on treatment, which now includes immunosuppressive and immune-modulating agents. As more biologics become available for the treatment of autoimmune diseases, they become an increasing area of interest for dermatology, given the likely application of such substances for the treatment of autoimmune skin diseases. However, in this regard, the severity of the disease has to be considered in relation to the costs of the drug and its potential side effects. As the genetic background plays an important, although as yet undefined, role in autoimmune skin diseases, the possible coexistence of autoimmune diseases of the skin and other tissues must be considered. Every patient presenting with an autoimmune disorder and concomitant skin manifestations should get a dermatologic consultation to unravel associated autoimmune skin disease.

Kidney Disease: Goodpasture's Disease, Lupus Nephritis, ANCA-Associated Glomerulonephritis

BARRAK M. PRESSLER,*† RONALD J. FALK,† AND GLORIA A. PRESTON†

**College of Veterinary Medicine, North Carolina State University, Raleigh, North Carolina, and †Division of Nephrology and Hypertension, Department of Medicine, University of North Carolina at Chapel Hill. Chapel Hill, North Carolina, USA*

Kidney diseases that are caused by autoimmune processes may result from: 1) direct antibody-mediated attack against kidney antigens (anti-glomerular basement membrane disease); 2) immune complex deposition [systemic lupus erythematosus (SLE)]; or 3) antibody-induced leukocyte activation, endothelial cell injury, and glomerulonephritis [antineutrophil cytoplasmic antibody (ANCA) disease]. Although many other kidney diseases are at least partially immune-mediated in nature, we will concentrate on these three diseases as the best examples of autoimmunity in the kidney.

ANTI-GLOMERULAR BASEMENT MEMBRANE DISEASE

Anti-glomerular basement membrane (anti-GBM) disease is the only kidney disease in which it is definitely known that antibodies develop against a native renal antigen—the α3 helix of collagen IV. Ernest Goodpasture first described two patients with renal failure and pulmonary hemorrhage in the early 20th century, although the eponym "Goodpasture's disease" was not suggested until 1958 (Stanton and Tange, 1958). In the 1960s it was discovered that a subset of patients with these clinical signs had circulating antirenal antigen antibodies with deposition of immunoglobulin in the kidney (Salama et al., 2001a). Currently, the pulmonary–renal syndrome can be caused by more than just anti-GBM disease; cryoglobulinemia, SLE, and systemic vasculitides, such as ANCA disease, are also potential culprits. However "Goodpasture's disease" and "Goodpasture syndrome" are terms reserved for those pulmonary–renal syndrome patients with antibodies against the GBM epitope.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Clinical, Pathologic, and Epidemiologic Features

Collagen IV is a normal constituent of basement membranes and thus is distributed widely throughout the body. Six homologous proteins, numbered α1 through α6, assemble into triple-helical protomers that interlock to form the final collagen IV network (Sundaramoorthy et al., 2002). Most collagen IV is composed entirely of α1.α1.α2 protomers, which are basement membrane proteins produced and assembled during fetal development. During *in-utero* maturation these are gradually replaced by α3.α4.α5 protomers in the basement membranes of the glomerulus, renal tubules, lung, cochlea, and eye (Cashman et al., 1988). α5.α5.α6 protomers replace some of the original protomers in Bowman's capsule, skin, and smooth muscle, but these are not affected in anti-GBM disease (Hudson et al., 2003).

All collagen IV protein helices consist of a middle collagenous region bounded by two noncollagenous domains. The proteins initially associate noncovalently via C-terminal noncollagenous domain interactions, which induce winding of the central collagenous regions into a triple helix (Sundaramoorthy et al., 2002). The final collagen IV network is formed by the globular head–globular head interaction of the C-terminal domains of two adjacent protomers and the association of four N-terminal domain regions into a large lattice. The glomerular capillary endothelial cells and podocyte foot processes attach directly to the collagen IV matrix via integrins and dystroglycans (Mundel and Shankland, 2002).

The overwhelming majority (>99%) of patients with anti-GBM disease develop antibodies specific for a single basement membrane epitope in the collagen IV molecule. The "Goodpasture epitope" is made up of nine discontinuous amino acids in the C-terminal noncollagenous domain of the α3 helix [α3(IV)NC1] (Hellmark et al., 1999; Gunnarsson et al., 2000) (Figure 59.1). Although there are sporadic reports of patients with anti-GBM disease who do not have antibodies against this particular epitope or collagen IV (despite the presence of linear immunoglobulin staining on immunohistochemical examination of renal tissue), these cases are rare.

Anti-GBM disease is rare—responsible for less than 5% of all glomerular disease. In white persons, approximately one new case of anti-GBM disease is diagnosed per million people each year, with the incidence in other ethnic populations even lower (Bolton, 1996; Pusey, 2003). Anti-GBM disease has been reported in individuals of all ages and both genders. A bimodal distribution exists, with disease increasing in frequency in young-to-middle aged men and elderly women; however, the first peak may be due to increased exposure to exacerbating environmental factors such as cigarette smoke (Donaghy and Rees, 1983; Hudson et al., 2003; Pusey, 2003).

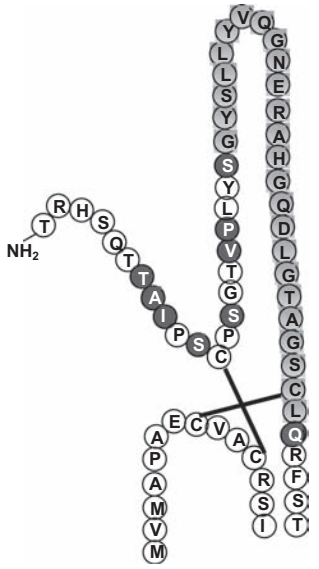

FIGURE 59.1 Schematic of the region of α3(IV)NC1 that contains the anti-glomerular basement membrane antibody epitope. The critical amino acids which make up the discontinuous epitope are colored in blue. Grey amino acids represent a nonantigenic loop that separates a distant antigenic glutamine residue from the other eight antigenic amino acid residues. The thick black lines are disulfide bonds between cysteine residues. Modified from Gunnarsson et al., 2000. See color plate section.

Rapidly progressive glomerulonephritis and pulmonary hemorrhage are the typical clinical manifestations of anti-GBM disease. Patients with pulmonary hemorrhage may be asymptomatic with bleeding only noted upon thoracic radiography or airway endoscopy, or may present with a range of clinical signs from fatigue to cough to fulminant hemoptysis. Many anti-GBM patients with lung involvement have a history of cigarette smoking or other environmental exposure that may exacerbate pulmonary signs (Donaghy and Rees, 1983). Anti-GBM patients with lung involvement usually do not have advanced kidney disease at first diagnosis because pulmonary-related symptoms are more easily observed by the patient, and thus diagnosis may occur earlier (Hudson et al., 2003).

Thirty to 40% of anti-GBM patients have isolated kidney involvement (Pusey, 2003). As with pulmonary disease, glomerulonephritis due to anti-GBM disease may cause a spectrum of clinical signs and clinicopathologic findings at initial presentation. Rarely, patients may present with incidental proteinuria; however, most have clinical signs referable to more severe kidney dysfunction. Patients typically have an active urine sediment, proteinuria, and hematuria. Reduction in renal function may be minimal at the time of diagnosis, although most patients are azotemic and many require dialysis. Younger patients commonly have rapidly progressive pulmonary and kidney disease, whereas older patients have a higher incidence of slowly progressive

kidney disease without precipitous declines in renal and pulmonary function (Hudson et al., 2003). Hypertension is uncommon until endstage kidney disease is imminent.

The most common finding by light microscopy in renal biopsies from patients with anti-GBM disease is diffuse necrotizing crescentic glomerulonephritis. More than 50% of glomeruli are typically affected. GBMs may be disrupted and the mesangium and Bowman's space filled with infiltrating lymphocytes, macrophages, and neutrophils. Chronically affected kidneys may exhibit tubulo-interstitial nephritis and fibrosis of glomeruli. Although the light microscopic appearance of renal biopsies from patients with anti-GBM disease usually reflects the rapidly progressive nature of the disease, examination of kidneys from patients with mild or early disease may reveal normal to mildly affected glomeruli. Similarly, patients with chronic smoldering disease without severe clinicopathologic abnormalities may have global sclerosis and fibrosis without obvious glomerulonephritis and necrosis. ANCA disease or membranous nephropathy is occasionally found in patients with anti-GBM disease; histologic changes typical of these diseases may thus occur as well. Electron microscopy of kidneys from patients with anti-GBM disease reveals nonspecific findings of inflammation, including leukocyte infiltration. As expected the GBM is periodically disrupted, but electron-dense deposits are typically absent.

Regardless of appearance on light or electron microscopy, immunofluorescence microscopic findings are diagnostic for anti-GBM disease. Anti-IgG stains show intense diffuse linear staining of the GBM in all patients (Figure 59.2). Occasional patients have staining of tubular membranes as well, depending on the specificity of the anti-GBM antibodies. Antibodies are predominantly IgG1 and IgG4, although IgM and IgA may also occur. C3 deposition is also typical although not universal in anti-GBM disease; C1q deposition is rare. Diabetic nephropathy and fibrillary glomerulonephritis also are associated with linear staining by immunofluorescence microscopy, but the site of immunoglobulin deposition is not the GBM and the pattern of staining is not identical.

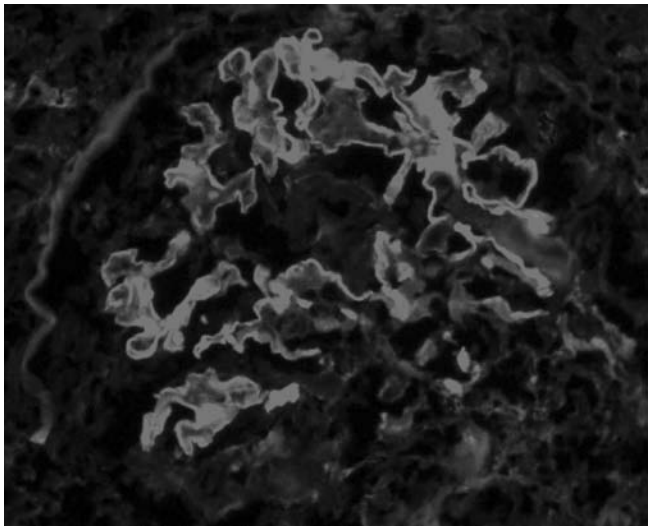

FIGURE 59.2 Glomerulus from a patient with anti-glomerular basement membrane (GBM) disease showing linear staining of the GBM for IgG. There is negative staining in the right lower quadrant of the glomerulus at a site of necrosis in which the GBM has been destroyed. See color plate section.

Autoimmune Features

The role of autoantibodies in disease pathogenesis has been clearly demonstrated. Anti-GBM antibodies bind to the renal and alveolar basement membranes, inducing complement fixation and leukocyte recruitment and activation. Passive transfer of serum from human patients or animal models to naïve animals results in glomerulonephritis. Disease remission and amelioration of renal damage in humans is directly associated with removal of antibodies via plasmapheresis and decrease in anti-GBM antibody titer.

Although anti-α3(IV)NC1 antibodies are the diagnostic hallmark of anti-GBM disease, disease induction and progression is likely dependent on cell-mediated mechanisms as well. The precise role of autoreactive T cells is not understood, although differences in the peripheral blood T-cell repertoire of affected patients have been reported (Cairns et al., 2003). The α3(IV)NC1 Goodpasture epitope is expressed in normal human thymic tissue, and thus autoreactive T lymphocytes should be eliminated during negative selection; however, peripheral blood T cells with anti-α3(IV)NC1 specificity and a type 1 helper T (Th1) cytokine profile are found in patients with acute anti-GBM disease (Derry et al., 1995; Merkel et al., 1996; Salama et al., 2001a; Cairns et al., 2003). One study has provided evidence that patients may have decreased numbers of α3(IV)NC1-specific $CD4^+CD25^+$ regulatory T cells (Tregs), thus allowing autoreactive T lymphocytes to proliferate and induce disease (Salama et al., 2003).

Genetic Features

Susceptibility of humans and mice to anti-GBM disease is highly associated with particular major histocompatibility complex (MHC) II alleles. Approximately 80% of patients with anti-GBM disease carry the HLA-DRB1*1501 or HLA-DRB1*04 alleles, as compared to only 20% of individuals in the general population (Phelps and Rees, 1999). Mouse strains with the MHC $H\text{-}2^s$, $H\text{-}2^b$, or $H\text{-}2^d$ alleles develop experimental anti-GBM disease following immunization with α3(IV)NC1, whereas those with $H\text{-}2^k$ are resistant; similarly, rat strains with MHC Rt1-l alleles have

differing susceptibility to disease as compared to those with Rt1-k alleles (Kalluri et al., 1997; Reynolds et al., 1998). This may reflect an increased ability to present antigenic α3(IV)NC1-derived peptides for recognition by self-reactive T cells in the periphery, or on the contrary an inability to present α3(IV)NC1-derived peptides to T lymphocytes in the thymus during cell maturation, which would normally compromise deletion of autoreactive cells. Regardless, development of disease is polygenic, as two different WKY rat strains with identical MHC haplotypes are not equally susceptible to experimental anti-GBM disease (Reynolds et al., 2002a).

Environmental Influences

Epidemiologic studies and case reports have suggested an association between anti-GBM disease and several environmental agents. The first description of "Goodpasture syndrome" was in two patients with influenza-like clinical signs, and sporadic reports of an association between these two diseases can still be found (Salama et al., 2001b). The facts that clusters of anti-GBM disease do occur, and that 20–60% of patients report a prodromal upper respiratory tract infection, increase the suspicion of involvement of infection or toxin-triggered events (Perez et al., 1974). Hydrocarbon and cigarette smoke exposures have been associated with anti-GBM disease, particularly in patients with significant pulmonary hemorrhage (Stevenson et al., 1995). Similarly, lithotripsy, antimyeloperoxidase ANCAs, and other causes of "renal trauma" have occasionally been reported to be associated with the development of anti-GBM disease (Xenocostas et al., 1999).

Historically it was hypothesized that damage to the pulmonary or renal basement membranes by environmental agents exposed a previously cryptic α3(IV)NC1 antigen, thus allowing anti-GBM disease to develop. However, purified antibodies cause disease in animal models without concurrent tissue damage, and thymic medullary cells in normal children express the anti-GBM epitope, implying that the immune system at one point is tolerant of this region of the protein (Wong et al., 2001). It is more likely that the above-mentioned conditions exacerbate pre-existing disease, and asymptomatic patients thus develop overt clinical signs through increased accessibility of antigen to preexisting antibodies. Patients with asymptomatic or clinically mild anti-GBM disease may thus have faster progression of their disease, and a false temporal association is assumed when fulminant clinical signs develop.

Animal Models

Experimental anti-GBM disease can be induced in chickens and rodents by immunization with sonicated GBM collagen, purified collagen IV NC1 trimers, or recombinant α3(IV)NC1. Less commonly, a prime-boost strategy using allotypic antibodies is used to induce experimental anti-GBM disease in mice and rats (Wakayama et al., 2000). In this technique, initial immunization with polyclonal immunoglobulins from a nonhost species is given so that the recipient animal is sensitized to the Fc antibody fragment of the donor species. A second immunization with purified anti-GBM antibodies from the same foreign species leads to a faster inflammatory response and glomerulonephritis. However, because the resultant glomerulonephritis is likely due to the anti-allotypic antibody response, rather than a true anti-GBM immune response, this model is not favored by most investigators.

Animals with experimental anti-GBM disease develop variable degrees of proteinuria, hematuria, azotemia, and pulmonary hemorrhage. Although analogous to anti-GBM disease, rodents with experimental anti-GBM disease have linear antibody staining of the tubular basement membranes and non-α3(IV)NC1 regions of the GBM in addition to the Goodpasture epitope; this occurs because antibodies develop against multiple components of the collagen immunogen. In rodents, the frequency of disease induction, rate of onset of clinical signs, and severity of experimental anti-GBM disease is highly strain dependent. For example, WKY/CR rats and SJL or DBA mice develop rapidly progressive glomerulonephritis with large numbers of glomeruli affected, whereas WKY/Olac rats and several mouse strains (including NOD and AKR mice) develop less severe to negligible disease (Kalluri et al., 1997; Reynolds et al., 1998; Hopfer et al., 2003). Mice deficient in the FcγIIb antibody receptor are particularly susceptible to experimental anti-GBM disease (Nakamura et al., 2000). When immunized with collagen, greater than 90% of FcγIIb receptor-deficient mice develop anti-GBM disease within 8 weeks; in other mouse models disease typically develops in 25–60% of mice, and may take up to 3 months to manifest (Nakamura et al., 2000; Hopfer et al., 2003).

Induction of experimental anti-GBM disease has been accomplished by transfer or stimulation of T cells specific for anti-GBM epitopes. Disease has been produced in chickens by transfer of mononuclear cells from birds previously immunized with bovine collagen, and in rats by activation or transfer of α3(IV)NC1-specific T cells or immunization with a peptide fragment of α3(IV)NC1 (Wu et al., 2003; 2004). This disease-inducing peptide is presumptively a T-cell epitope that activates α3(IV)NC1-specific T cells (Wu et al., 2003; 2004). The peptide used in these studies significantly overlaps with the known α3(IV)NC1 Goodpasture antigen. However, antibodies induced in this peptide model are of a different specificity from naturally-occurring antibodies from human patients, and glomerulonephritis develops prior to the production of anti-GBM antibodies.

Pathogenic Mechanisms

As discussed above, the initiation and progression of anti-GBM disease likely requires both antibody- and cell-mediated mechanisms. Production of α3(IV)NC1-specific antibodies requires presentation of antigen-derived peptides by cognate T cells. Binding of antibodies to the GBM results in leukocyte recruitment through Fc receptor binding, and complement fixation and activation via the classic pathway.

Studies of animal models have provided additional data on the likely immunogenesis of anti-GBM disease. Glomerulonephritis can be induced following immunization with components of collagen IV both in B-cell-competent (i.e., antibody producing) and -deficient mice and chickens (Dean et al., 2005). Additionally, disease is induced in $RAG^{-/-}$ mice (i.e., B- and T-cell deficient) by transferring serum from affected B-cell-competent mice. Infiltrating T cells in WKY rats with experimental disease are of restricted clonality, suggesting a specific T-lymphocyte response rather than a generalized inflammatory recruitment of all effector T cells (Walters et al., 2004). Depletion of $CD8^+$ T cells, blockade of the CD40 costimulatory pathway, or blockade of the CD28-CD80(B7) "second signal" pathway all prevent induction of experimental anti-GBM disease in rats, providing further evidence of a critical role of T lymphocytes (Reynolds et al., 2000; 2002b; 2004). Blockade of various cytokines in rodent models likewise modulates the severity of experimental anti-GBM disease. Studies on the role of macrophages in animal models demonstrate that antibodies are required for cell recruitment, and that these cells contribute to glomerular damage (Kaneko et al., 2003; Kuroda et al., 2004).

Immunologic Markers in Diagnosis

Demonstration of anti-GBM antibodies within serum or by immunofluorescence antibody staining of renal biopsy specimens is diagnostic for disease. The rare patient will have anti-GBM antibodies that are not specific for the α3(IV)NC1 antigen, although the clinical course and renal biopsy findings are identical to those with classic anti-GBM disease (Salama et al., 2002; Levy et al., 2004). Magnitude of serum antibody titer does not predict patient survival or need for dialysis at diagnosis; however, anti-GBM antibody titer is directly associated with eventual maintenance of renal function in those patients who are not dialysis dependent at initial presentation (Segelmark et al., 2003). Anti-GBM antibody affinity does not correlate with outcome (Segelmark, et al., 2003).

Approximately 30% of patients with anti-GBM disease have ANCAs; 5% of ANCA vasculitis patients have anti-GBM antibodies (Levy et al., 2004). ANCAs are specific for myeloperoxidase in the vast majority of these patients, although antibodies against proteinase-3 and other neutrophil cytoplasmic antigens may occur (Levy, et al., 2004). Differentiation of these two diseases in the presence of both antibodies is based on clinical features, relative magnitude of titers, and renal biopsy findings. The relative concentration and specificity of the anti-GBM antibodies in patients with or without ANCAs are similar (Hellmark et al., 1997; Levy et al., 2004). Patients with both anti-GBM antibodies and ANCAs tend to be significantly older, are more likely to need dialysis at the time of presentation, and have systemic inflammatory disease that is more characteristic of ANCA-associated vasculitis (Levy et al., 2004). Despite these differences patients with both antibodies do not have significantly different mortality or frequency of pulmonary hemorrhage from patients with anti-GBM antibodies only. Because of the relapsing nature of ANCA-associated vasculitis and the potential for systemic clinical signs, patients with anti-GBM disease should have ANCA titers measured routinely.

Treatment and Outcome

The mainstays of treatment of anti-GBM disease are immunosuppression and reduction in circulating anti-GBM antibodies by plasmapheresis. The high association between the presence of anti-GBM antibodies and ongoing glomerulonephritis in affected patients makes decrease in antibody titer a priority. Plasmapheresis effectively removes unbound anti-α3(IV)NC1 antibodies, while cytotoxic agents inhibit continued production of new antibodies by inhibition of B-cell function. Glucocorticoids decrease antibody production and also reduce inflammation within the kidney via inhibition of leukocyte recruitment and function.

A standardized treatment regimen has been proposed based on successful treatment of a large cohort of patients (Levy et al., 2001). Initial treatment is with high-dose oral prednisolone and cyclophosphamide; prednisolone is tapered over several months, while cyclophosphamide is continued for 2–3 months. Plasma exchange is performed daily until the anti-GBM titer returns to normal concentrations or for 1 week; post-exchange transfusion of fresh frozen plasma is recommended if pulmonary hemorrhage is present (Levy et al., 2001). Supportive treatment for renal failure and pulmonary compromise is given as needed. Given this protocol, patients with initial serum creatinine concentration less than 5.7 mg/dl (435 μmol/L) have significantly greater long-term survival; patients who require dialysis at presentation or have global crescentic glomerulonephritis on renal biopsy are more likely to remain dependent on dialysis long-term (Levy et al., 2001). All the patients with initial serum creatinine less than 5.7 mg/dl survived, with 95% renal survival. At the time of last follow-up, 84% of this cohort was still alive, with 74% renal survival (median follow-up time was 10 years) (Levy et al., 2001).

Following resolution of clinical signs and reduction of anti-GBM antibodies to normal levels, immunosuppressive therapy can be tapered and discontinued in most patients. Continued monitoring of urine for increases in protein or blood, and occasional measurement of anti-GBM serum antibody concentration, are recommended during dose reductions. Long-term prognosis for patients who survive the immediate post-diagnosis period is good. The 1-year survival rate is typically greater than 75% (Pusey, 2003). Patients with anti-GBM disease often remain free of clinical signs for life after successful treatment, although relapse occurs rarely (Pusey, 2003).

A rarer type of anti-GBM disease occurs in patients with Alport syndrome following renal transplantation. Alport syndrome is due to a mutation in the α5 chain of collagen IV; patients typically have progressive proteinuria and glomerulopathy, and eventual renal failure (Hudson et al., 2003). Following renal transplantation a subset of Alport syndrome patients develop antibodies against the transplanted normal collagen IV molecule, to which the transplant recipient would not expect to be tolerant due to lack of thymic expression during maturation. However, the immunosuppressive regimen given to renal transplant recipients is usually sufficient to prevent development of anti-GBM disease.

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is a multiorgan disease with diverse manifestations. For a thorough discussion of this disease and its nonrenal clinical and autoimmune features the reader is referred to Chapters 27 and 28. The focus here will be the effects of SLE on the kidney, referred to as lupus nephritis.

The term "lupus erythematosus" was first used in the mid-to-late 1800s to describe patients with cutaneous lesions such as malar or discoid rashes (Lahita, 2004). This disease was recognized as a systemic illness in 1872, when the first list of criteria for diagnosis was published (Lahita, 2004). Lupus nephritis was first reported in the early 20th century in two patients with SLE-associated facial rashes; a second report described the typical pathologic glomerular lesions in lupus nephritis (Osler, 1904; Lahita, 2004). Cases of renal-limited SLE were recognized soon thereafter (Lahita, 2004). Concepts on the nature of SLE were revolutionized by the description by Hargraves (1969) of the lupus erythematosus (LE) cell, which prompted studies in the 1950s on the detection of antinuclear autoantibodies in SLE (see Chapters 28 and 72).

Clinical, Pathologic, and Epidemiologic Features

Four of eleven diagnostic criteria outlined by a 1982 modified American Rheumatism Association standardized protocol are required for diagnosis of SLE (Tan et al., 1982). One of these 11 diagnostic criteria is renal involvement, referred to as lupus nephritis. Although renal biopsy is required for definitive diagnosis of lupus nephritis, persistent proteinuria (>0.5 g/day or greater than 3+ albumin on urine dipstick) or the presence of cellular casts are acceptable for a presumptive diagnosis of nephritis, particularly if a biopsy is contraindicated (Tan et al., 1982). Presence of additional criteria, such as clinicopathologic findings more specific for SLE (i.e., anti-dsDNA antibodies or hypocomplementemia) may also increase the likelihood of correct diagnosis of lupus nephritis in the absence of histopathology (Dooley et al., 2004).

The incidence of lupus nephritis in SLE at the time of first diagnosis is high. Early studies reported clinicopathologic evidence of kidney disease in greater than 50% of patients, and in some reports approached 80% (Dubois and Tuffanelli, 1964; Estes and Christian, 1971). However, likely due to earlier diagnosis of SLE, the incidence of nephritis at diagnosis has decreased to approximately 25–50% depending on the diagnostic criteria used (Alarcon et al., 2002; Cooper et al., 2002).

Lupus nephritis is much more common and severe in black persons at the time of diagnosis, as compared to white persons (Ballou et al., 1982; Cervera et al., 1993; Appel and Valeri, 1994; Dooley et al., 1997; Cooper et al., 2002). In the USA, development of kidney disease in patients without overt lupus nephritis at diagnosis is more likely in Hispanic individuals (Alarcon et al., 2002). Although SLE is significantly more common in females, males may be more likely to have renal involvement, regardless of ethnicity (Cooper et al., 2002). Likewise, although SLE is primarily a disease of adulthood, children are much more likely to have severe kidney disease (Cervera et al., 1993; McCurdy et al., 1992).

The clinical signs and histologic changes seen in lupus nephritis are highly variable. Clinical manifestations range from asymptomatic to acute nephritic disease, nephrotic syndrome, or endstage kidney disease. The severity of disease often correlates with the type of histologic change. Thus, biopsy and characterization of the renal lesions in patients with lupus nephritis are recommended to refine prognosis and to guide therapy. Additionally, serial biopsies have been associated with an improved long-term prognosis (Bajaj et al., 2000; Yoo et al., 2000).

The standardized classification system for lupus nephritis was revised in 2004 under the auspices of the International Society of Nephrology (ISN) and the Renal Pathology Society (RSP) (Table 59.1) (Weening et al., 2004). This updated classification scheme is a revision of the previously used World Health Organization (WHO) system. In this system lupus nephritis is subdivided based on the type and severity of glomerular pathology; however, tubular, interstitial, and vascular lesions often occur in SLE patients as well, and may independently influence clinical presentation and prognosis. For a thorough discussion of the updated classi-

TABLE 59.1 Abbreviated classification of lupus nephritis, revised by the International Society of Nephrology (ISN) and the Renal Pathology Society (RSP), 2004

Class I	Minimal mesangial lupus nephritis	Normal light microscopy; mesangial immune deposits visible only by immunofluorescence microscopy. Formerly known as class IIa
Class II	Mesangioproliferative lupus nephritis	Mesangial proliferation visible by light microscopy. Presence of immune deposits, glomerulonephritis, or fibrosis exclude classification as class II. Formerly known as class IIb
Class III	Focal lupus nephritis	Glomerulonephritis with lesions found in <50% of glomeruli. Lesions are subclassified based on activity (active versus chronic). Lesions are usually segmental
Class IV	Diffuse lupus nephritis	Glomerulonephritis with lesions found in 50% or more of glomeruli. Lesions are subclassified based on activity (active versus chronic) and distribution of glomerular lesions (segmental versus global)
Class V	Membranous lupus nephropathy	May occur in conjunction with class III or class IV lesions
Class VI	Advanced sclerosing lupus nephritis	Most glomeruli (minimum of 90%) are globally sclerosed and "endstage"

fication, interpretation, and differences from the previous system the reader is referred to Weening et al. (2004).

Autoimmune Features

SLE results from hyperactivation of B cells, production of autoantibodies against multiple self-antigens, and activation of cell-mediated immunity secondary to deposition of immune complexes (see Chapters 16 and 28).

Although immune deposits in the kidneys of patients with SLE typically contain IgG, IgM, IgA, and complement, IgG clearly predominates. Antibodies result in lupus nephritis through complement fixation and leukocyte recruitment via Fc receptor ligation (Couser, 1990). Sites of antibody deposition within the kidney may vary, and localization to the subepithelial or subendothelial spaces versus basement membrane, antibody affinity and isotype, and antigen-specificity of the various autoantibodies all may influence the development and severity of lupus nephritis (Vlahakos et al., 1992).

Autoreactive T cells are present in SLE. Lymphocyte infiltration of affected organs is common, particularly the kidneys in lupus nephritis. Persistent or aberrant T-cell activation may be the initiating defect in SLE; abnormal 154(CD40L) expression on lymphocytes and decreased $CD4^+CD25^+$ Treg activity have both been implicated (Desai-Mehta et al., 1996; Powrie and Maloy, 2003).

Genetic Features

Of the genes that have been associated with the development of SLE, Fc receptor polymorphisms have the strongest association with development of nephritis (see Chapter 16). Allelic or single nucleotide polymorphisms of the FcγRIIa, IIb and IIIa genes have been identified with increased risk for development of SLE (Salmon et al., 1996; Wu et al., 1997; Seligman et al., 2001; Edberg et al., 2002; Su et al., 2004). These altered Fc receptors may increase susceptibility to lupus nephritis or affect its rate of progression by altering or inhibiting clearance of immune complexes, or by inappropriately activating leukocytes, which bind deposited complexes (Salmon and Roman, 2001; Tsao, 2004).

Environmental Influences

Studies have not identified any environmental factors that predispose specifically to lupus nephritis. The association of certain autoantibody subsets with kidney disease may argue that unidentified environmental factors dictate the final repertoire of the SLE autoantibodies, and thus expressions of lupus nephritis. Unlike spontaneous SLE, drug-induced SLE syndromes are less likely to cause lupus nephritis (Shapiro et al., 1984; Speirs et al., 1989; Short and Lockwood, 1995).

Animal Models

SLE naturally occurs in dogs, cats, and horses. Although disease in these species is rare and poorly characterized, reports indicate that most cases would satisfy the standardized diagnostic criteria used in humans. Approximately 50% of dogs with SLE develop lupus nephritis based on the presence of proteinuria; progression to renal failure is a common cause of morbidity and mortality (Chabanne et al., 1999). Histopathologic findings in renal biopsies have not been well characterized in this species, but immune complex deposition is a common finding, with variable amounts of proliferative or membranous changes (Center et al., 1987; Chabanne et al., 1999). SLE is much rarer in cats and horses, but nephritis is still a consistent finding (Werner and Gorman, 1984; Pedersen and Barlough, 1991).

Both induced and spontaneously-occurring mouse models of SLE exist (see Chapter 26). Most of these models develop nephritis to varying degrees. The best-characterized spontaneous models of lupus nephritis are the MRL/lpr and NZB/NZW F1 mice (Peutz-Kootstra et al., 2001). MRL/lpr mice are homozygously defective for the Fas^{lpr}

gene, which is essential for normal lymphocyte apoptosis (Theofilopoulos et al., 1985a). These mice invariably develop immune complex glomerulonephritis (Theofilopoulos and Dixon, 1985). NZB/NZW F1 mice spontaneously develop autoantibodies with similar antigenic targets as humans with SLE; lupus nephritis develops due to immune complex deposition (Theofilopoulos et al., 1985b). Although the precise gene or genes responsible for NZB/NZW F1 mouse autoimmunity is unclear, polymorphisms in class II MHC molecules, tumor necrosis factor (TNF)-α, and the Sle gene loci have been implicated (Mocsai et al., 1999; Morel et al., 1999; Rozzo et al., 1999). The finding that these and various other mouse strains can all develop lupus nephritis despite a wide variety of genetic defects supports the hypothesis that naturally-occurring SLE in humans is a syndrome with multiple etiologies.

Pathogenic Mechanisms

Lupus nephritis is predominantly an immune complex disease. Antibody–antigen complexes may form in the peripheral circulation and then be deposited within the kidney, or unbound antigens may first be planted within the renal parenchyma with later *in situ* antibody binding. There is also evidence that lupus nephritis may be due in part to autoantibodies against native renal antigens, particularly components of the GBM and extracellular matrix, such as α-actinin and laminin (Ben-Yehuda et al., 1995; Mostoslavsky et al., 2001).

Regardless of the site of complex formation, not all autoantibodies are equally likely to result in kidney disease in SLE patients. Although serum autoantibody titers do correlate with presence and severity of nephritis, some patients with high titers do not develop kidney disease, whereas others with low titers may have severe nephritis (Chien et al., 2001; Horvath et al., 2001; Reveille, 2004; Linnik et al., 2005). Eluted antibodies from the kidneys of patients with lupus nephritis are not consistently of the same antigen specificity as circulating autoantibodies (Mannik et al., 2003). Autoantigen or immune complex charge and isoelectric point may determine affinity of binding to the GBM or mesangium (Vogt et al., 1990; Suenaga and Abdou, 1993; Woitas and Morioka, 1996). Anti-DNA and antihistone antibodies, in particular, may be more nephritogenic than other autoantibodies due to their overall charge (Xie et al., 2003; Cortes-Hernandez et al., 2004). Anti-dsDNA antibodies may also cross-react with native GBM antigens, and linear staining of renal tissue may be visible by immunofluorescence (Vlahakos et al., 1992; Foster et al., 1993; Lefkowith et al., 1996; Mostoslavsky et al., 2001). Autoantibodies that are frequently found deposited within kidneys of lupus patients include anti-C1q-CLR, anti-SS-A, anti-Sm, anti-SS-B, antihistone, and antichromatin antibodies (Mannik et al., 2003).

The severity of interstitial T-cell infiltration in renal biopsies in lupus nephritis correlates with renal function (Alexopoulos et al., 1990). Infiltrating T cells in the kidney are often oligoclonal and of different specificity from peripheral blood T cells, indicating expansion of a specific subpopulation of cells rather than nonspecific recruitment during inflammation (Massengill et al., 1998; Murata et al., 2002). Recruitment of inflammatory cells is not solely dependent upon binding of immune complex autoantibodies with renal Fc receptors, as experimental Fcγ receptor knockout mice still have localization of immune complexes to the kidney, although nephritis is significantly reduced (Clynes et al., 1998). This finding implies that inflammation is more dependent upon binding of nonrenal Fc receptors, likely those found on circulating leukocytes.

Immunologic Markers in Diagnosis

The sole method for definitive diagnosis of lupus nephritis is renal biopsy; however, if biopsy is contraindicated then the simultaneous presence of proteinuria, anti-dsDNA antibodies, hypocomplementemia, and active urine sediment are accepted by the American College of Rheumatology to be substitutable secondary criteria (Dooley et al., 2004).

Lupus nephritis can occur in any SLE patient with any autoantibody profile; however, specific antibodies or antibody repertoires are associated with a higher incidence of kidney disease (Lefkowith et al., 1996). The strongest association identified thus far is with anti-RNA–protein conjugate antibodies. Anti-Ro/SSA or anti-Sm antibodies, with or without concurrent anti-U_1RNP, predict development of nephritis in approximately 50% of SLE patients. In contrast, anti-U_1RNP alone or concurrent anti-Ro/SSA and anti-La/SSB are protective, with less than 10% of patients developing nephritis (Lefkowith et al., 1996). These associations between specific autoantibodies and lupus nephritis may be modified by other heritable factors, as the predictive value of these repertoires varies with race and gender (McCarty et al., 1993). Other antibodies associated with nephritis include anti-C1q-CLR, antiheparan sulfate, and anti-endothelial cell antibodies (D'Cruz et al., 1991; Coremans et al., 1995; Ravirajan et al., 2001).

SLE and other diseases caused by immune complexes cause hypocomplementemia. Measurement of serum complement concentrations, particularly the C4 and C5 components and total hemolytic complement (CH_{50}), may aid in prediction of lupus nephritis (Appel et al., 1978; Jarrett et al., 1981; Milis et al., 1992; Wada et al., 2004).

Treatment and Outcome

Immunosuppressive therapy is the mainstay of treatment of lupus nephritis. Unfortunately, the optimal drug or drugs and the appropriate treatment regimens are still unclear. It

does appear that treatment should be tailored to the class of lupus nephritis present on renal biopsy. However, study results are often conflicting and the recent modification of the lupus nephritis classification system makes interpretation of historic studies even more difficult. Regardless, it appears that mild forms of lupus nephritis (class I and II) carry a generally good prognosis, and for these, aggressiveness of treatment should instead be based on the severity of any extrarenal disease manifestations. The poorer long-term prognosis of class III and IV lupus nephritis justifies aggressive immunosuppressive therapy. Cyclophosphamide in particular is used for treatment of cases with proliferative lupus nephritis and membranous lupus nephropathy who do not respond to corticosteroid monotherapy. Several studies have shown no benefit from plasmapheresis despite the positive association between decreased antinuclear antibody titers and improved outcome (Lewis, 1992; Wei et al., 1993; Wallace et al., 1998).

Of newer drugs mycophenolate mofetil (MMF) is an attractive alternative in patients with cyclophosphamide toxicity or for rescue therapy in cyclophosphamide-resistant lupus nephritis (Glicklich and Acharya, 1998; Dooley et al., 1999). Patients with newly diagnosed diffuse proliferative lupus nephritis are equally likely to remit with oral MMF and prednisone, oral cyclophosphamide and prednisone, or azathioprine and prednisone; additionally, the incidence of serious infection is reduced with MMF (Chan and Hooi, 2000; Chan et al., 2000). Induction with intravenous (rather than oral) cyclophosphamide at high- or low-dose regimens (either of which is followed by azathioprine) appears to be equally effective at inducing and maintaining remission of proliferative lupus nephritis (Houssiau and Jadoul, 2002). Long-term maintenance with oral azathioprine or MMF appears safer than continued intravenous cyclophosphamide (Contreras et al., 2004). An emerging SLE-specific therapy is LJP 394, a synthetic construct of short dsDNA sequences known to be epitopes for SLE autoantibodies (Alarcon-Segovia et al., 2003).

Several independent factors have been identified as predictors of long-term renal function and patient survival. A prospective cohort study of patients with lupus nephritis has shown that severe renal failure (serum creatinine greater than 2.4 mg/dl), black race, hematocrit less than 20%, and chronic or active histologic lesions, particularly if crescents or interstitial fibrosis are present, are associated with a worse outcome (Austin et al., 1994). Other studies have identified black race, hypertension, and length and number of times out of remission as risk factors for disease progression (Esdaile et al., 1989; Ward and Studenski, 1992; Dooley et al., 1997; Alarcon et al., 2002). Clinicopathologic findings of azotemia, nephritic urine sediment, hypocomplementemia, thrombocytopenia, high anti-DNA antibody titer, and proliferative glomerulonephritis with or without simultaneous membranous nephropathy also predict a worse outcome (Banfi et al., 1985; Esdaile et al., 1989; Nossent et al., 1990; Reveille et al., 1990; Derksen and Meilof, 1992). Histopathologic lesions associated with aggressive, ongoing inflammation (i.e., diffuse proliferative and progressive focal proliferative nephritis) are more serious than mesangial or membranous nephropathy (Baldwin et al., 1970; Gladman et al., 1989).

ANCA GLOMERULONEPHRITIS

Here we focus on the pathogenesis, autoimmune features, and treatment of ANCA-associated glomerulonephritis and renal failure. Nonrenal manifestations of ANCA-associated small vessel vasculitis are discussed in Chapter 65.

Glomerulonephritis and renal failure were associated with small vessel vasculitis prior to the initial description of ANCAs (see Chapter 65). The similar histologic appearance of glomerular lesions noted in Wegener granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome, and renal-limited small vessel vasculitis were only explained once the unifying presence of ANCAs was discovered.

Clinical, Pathologic, and Epidemiologic Features

The clinical presentation of ANCA disease can vary widely, depending on the disease phenotype (i.e., Wegener' granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome, or renal-limited small vessel vasculitis), organ system(s) affected, and chronicity and severity of disease. Regardless of these variables, all ANCA-associated small vessel vasculitis patients have arteriolar and capillary wall inflammation. Fibrinoid necrosis of the vessel walls with karyorrhexis and leukocyte infiltration are classic lesions.

Rapidly progressive glomerulonephritis secondary to vasculitis is one of the most common clinical manifestations of ANCA disease. Renal involvement is found in approximately 90% of patients with microscopic polyangiitis, 80% of patients with Wegener granulomatosis, 45% of patients with the Churg-Strauss syndrome, and by definition 100% of patients with renal-limited small vessel ANCA vasculitis (Jennette and Falk, 1997a; 1997b). The severity of kidney disease at presentation is variable, although proteinuria, hematuria, and renal failure are regularly seen. Kidney disease in patients with Wegener granulomatosis may be more aggressive than in those with microscopic polyangiitis or Churg-Strauss syndrome (Franssen et al., 2000).

The epidemiology of ANCA disease is presented in Chapter 65.

Renal biopsy in patients with ANCA disease glomerulonephritis reveals vascular lesions and necrotizing glomerulonephritis with crescents (filling of Bowman's space with inflammatory cells and cellular debris secondary

to rupture of the visceral epithelium). These lesions are severe, with 50% or more of glomeruli often involved; glomerulonephritis is global, diffuse, and crescents are frequently circumferential. These glomerular lesions are indistinguishable from the rapidly progressive glomerulonephritis seen on light microscopy in patients with anti-GBM disease. Affected glomeruli sclerose over time; a single kidney biopsy specimen may contain glomeruli with both acute and endstage lesions. However, unlike anti-GBM disease, ANCA disease is pauci-immune; immunofluorescent microscopy fails to reveal deposition of significant amounts of immunoglobulin. Electron microscopy reveals generalized inflammation, breaks in the GBM, and a lack of electron-dense immune deposits.

Autoimmune Features

ANCAs occur in greater than 80% of patients with pauci-immune small vessel vasculitis. These antibodies are specific for neutrophil and monocyte granule proteins, with a given patient typically having antibody reactivity to a single antigen. The major neutrophil granule protein targets of ANCA are proteinase-3 (PR3, a serine protease) and myeloperoxidase (MPO, a lysosomal enzyme that produces hypochlorous acid). Indirect immunofluorescence staining of neutrophils using serum from ANCA patients results in cytoplasmic fluorescence. PR3-ANCAs produce a cytoplasmic staining pattern (a C-ANCA pattern), whereas MPO-ANCAs produce a perinuclear cytoplasmic staining pattern (P-ANCA). The majority of Wegener granulomatosis patients have PR3-specific ANCAs, whereas Churg-Strauss syndrome and renal-limited vasculitis patients usually have MPO-ANCAs; microscopic polyangiitis patients are equally likely to have PR3- or MPO-ANCAs. A minority of patients in all disease phenotypes have ANCAs that are specific for neither PR3 nor MPO. ANCAs are IgG, mostly of the IgG1 subclass, with lesser amounts of IgG3 and IgG4. There is no single epitope on either PR3 or MPO that is uniformly recognized by ANCAs from different patients; additionally a single ANCA patient can have antibodies against multiple epitopes of a single protein target.

The role of T cells in the pathogenesis of ANCA disease is unclear. Autoreactive T cells specific for PR3 or MPO are inconsistently present, and may be found in some normal patients (King et al., 1998; van der Geld et al., 2000; Popa et al., 2002; Winek et al., 2004). However, there is evidence that the T-cell repertoire in general in ANCA patients is not normally regulated, as cells may be generally activated above normal levels, or have exaggerated skewing of cytokine profiles in response to antigenic stimulation (Christensson et al., 2000; Masutani et al., 2003). $CD4^+$ T cells from ANCA patients, which proliferate in response to ANCA antigens or nonspecific stimulation, may be either Th1 or Th2; cytokine polarization may be linked to ANCA disease subtype, organ distribution, or whether disease is localized or systemic (Tomer et al., 1999; Masutani et al., 2003; Sanders et al., 2003).

Genetic Features

There have been no genetic associations made as yet between any specific allele or gene and development of glomerulonephritis (as opposed to other organ involvement) in patients with ANCA disease. Genetic features of ANCA disease in general are discussed in Chapter 65.

Environmental Influences

Although statistical associations have been made between environmental exposure to some chemicals and development of ANCA disease (see Chapter 65), no specific links have been made to kidney disease.

Animal Models

The best model of ANCA disease thus far has been induced in $MPO^{-/-}$ mice (see Chapter 65), and there are no naturally-occurring animal models. However, anti-MPO ANCAs and systemic autoimmune disease have been reported in cats treated with propylthiouracil (Aucoin et al., 1985; Waldhauser and Uetrecht, 1996). The frequency of occurrence of these side effects has precluded use of propylthiouracil in treatment of naturally-occurring hyperthyroidism in this species, and unfortunately extensive studies have not been done characterizing the resultant disease. Naturally-occurring ANCAs have recently been described in dogs with inflammatory bowel disease (Allenspach et al., 2004). The presence of ANCA correlates with disease, but the antigen specificity of canine ANCAs is unknown.

Pathogenic Mechanisms

Binding of ANCAs to their specific antigens in combination with Fc region binding to an Fc receptor results in neutrophil and monocyte activation with induction of the respiratory burst, degranulation, and release of cellular inflammatory products into the microenvironment (Falk et al., 1990b; Lai and Lockwood, 1991; Keogan et al., 1992; Savage et al., 1992; Mulder et al., 1994; Porges et al., 1994; Johnson et al., 1997b; Kettritz et al., 1997). Interaction of these leukocytes and their products with the endothelium results in inflammatory damage and vasculitis (Falk et al., 1990b; Dolman et al., 1993; Gross et al., 1993; De'Oliviera et al., 1995).

The extent to which the $F(ab')_2$ region contributes to ANCA-mediated effects is debated. However antibody–antigen interactions are clearly fundamental for the neu-

trophilic perturbations required for vascular injury (Lai and Lockwood, 1991; Keogan et al., 1992; Kettritz et al., 1997; Alcorta et al., 2002; Yang et al., 2002). ANCA-mediated effects on neutrophils and monocytes depend on both the $F(ab')_2$ region binding to its antigen and the engagement of the Fc region with the Fc receptor (Porges et al., 1994; Mulder et al., 1995; Reumaux et al., 1995; Johnson et al., 1997b; Kocher et al., 1998; Kobold et al., 1999; Locke et al., 1999; Yang et al., 2002).

Binding of ANCA is known to affect gene expression in leukocytes, and thus presumptively alter intra- and intercellular signaling. *In vitro* treatment of leukocytes from healthy donors with ANCA IgG or $F(ab')_2$ results in activation of a number of genes, including differentiation-dependent gene 2 (DIF-2), interleukin-8 (IL-8), cyclooxygenase-2 (COX-2), IL-1β, and p21(ras) (Brooks et al., 1996; Yang et al., 2002; Williams and Savage, 2005). It is unknown how exactly ANCAs mediate their effects on signaling pathways. ANCAs may cross-link surface antigens, resulting in clusters of associated molecules in lipid raft-like structures, particularly if the antigens are bound to other cell-surface proteins such as Mac-1 (CD11b/CD18) or other β_2 integrins (Kurosawa et al., 2000; Calderwood et al., 2005).

Alterations in intracellular signaling pathways have been shown to occur following ANCA binding. ANCA induce significant GTPase activity through activation of G_i proteins and diminish FMLP-induced PKC activation and IP_3 generation, thus possibly modulating calcium-dependent pathways (Lai and Lockwood, 1991; Williams et al., 2003; Williams and Savage, 2005). ANCA-induced signals are synergistic with TNF-α effects, indicating that autoantibodies could affect Src-family kinase pathways (Reumaux et al., 1995; Kettritz et al., 1997). Similarly ANCA-activated transcription of the IL-1β gene may imply activation of p38 MAPK (Brooks et al., 1996; Hashimoto et al., 1999). Importantly, gene expression profiling of patients with ANCA disease should become a noninvasive approach to determining disease activity, as demonstrated for IgA nephropathy (Preston et al., 2004).

The lack of ANCAs or ANCA–antigen deposits within the renal vasculature has made it particularly challenging to demonstrate a causal role for these autoantibodies in glomerulonephritis. The endothelium was originally considered a direct target of ANCA-mediated effects because of the hallmark histologic pattern of necrotizing vascular injury, but how ANCAs interact with endothelial cells is unclear as PR3 and MPO are restricted to myeloid lineage cells (Chen et al., 1995; Sturrock, 1996). It was speculated that cytokines induced PR3 and MPO expression on the endothelial cell surface, but PR3 or MPO mRNA transcripts could not be demonstrated in endothelial cells using TaqMan PCR (Mayet et al., 1993a; 1993b; 1997; Johnson et al., 1997a; King et al., 1995; Sibelius et al., 1998; Pendergraft et al., 2000).

A mechanistic link between ANCA binding to neutrophils and glomerular lesions was deduced from studies of neutrophil PR3. Extracellular PR3 can traverse the endothelial plasma membrane and induce apoptosis (Yang et al., 2001). Cell death is linked with sustained activation of c-Jun N-terminal kinase 1 (JNK 1), a primary apoptosis signaling pathway in endothelial cells (Preston et al., 2002). PR3 also functions as a caspase-like protease, cleaving proteins that are normal caspase substrates during the apoptotic program (Jiang et al., 1994; Levkau et al., 1998; Kang et al., 2001; Preston et al., 2002; Witko-Sarsat et al., 2002; Pendergraft et al., 2004b). Cleavage of NF-κB, $p21^{Waf1/Cip1/Sdi1}$, and IL-1β (caspase-1-like activity) and the Sp1 transcription factor (caspase-2- and -3-like activity) has been reported (Coeshott et al., 1999; Pendergraft et al., 2004b; Piedrafita and Pfahl, 1997). Inflamed bowel tissue shows detectible levels of PR3 protein coincident with proteolytically-cleaved $p21^{Waf1/Cip1/Sdi1}$ (Pendergraft et al., 2004b). Thus, PR3 is not merely a protease that degrades matrix proteins but also specifically processes angiotensinogen, TGF-β1, and TNF-α (Csernok et al., 1996; Coeshott et al., 1999; Bank and Ansorge, 2001; Ramaha and Patston, 2002). Less is known about MPO-induced endothelial cell injury. Endothelial cells also internalize MPO by an energy-dependent process (Baldus et al., 2001; Yang et al., 2001). However, unlike PR3, MPO does not cause apoptosis but rather increases intracellular oxidant radical concentration.

The epitope targets of PR3 and MPO ANCA are unknown. The data point to a limited number of epitopes, all of which require an intact tertiary structure (van der Geld et al., 2004). Because both MPO and PR3 have distinct functional domains, ANCA-binding sites could be responsible for the differences in disease presentation.

Dogma is that neutrophil granule protein genes are irreversibly silenced before the cells leave the bone marrow. However, mature leukocytes from the majority of ANCA patients with active disease have high levels of PR3 and MPO mRNA (Yang et al., 2004). Increased transcripts correlate with disease activity and absolute neutrophil values, but not with "left shift" (i.e., neutrophil immaturity), drug treatment regimen, serum inflammatory cytokine concentration, hematuria, proteinuria, ANCA titer, serum creatinine, sex, or age (Yang et al., 2004). This anomaly appears to be ANCA disease specific, as upregulation of these genes was not observed in patients with endstage kidney disease, rheumatoid arthritis or SLE, or in healthy volunteers. Thus, increased transcription of PR3 and MPO may lead to increased protein on the cell surface, conferring risk for the development of ANCA disease (Halbwachs-Mecarelli et al., 1995; van Rossum et al., 2004). In addition to the presence of anti-MPO or -PR3 autoantibodies, a second critical component in the etiology of this disease may be the reactivation of once-silenced genes, leading to increased antigen availability.

Immunogenesis of ANCA: Theory of Autoantigen Complementarity

A recent report offers a new theory of how PR3-ANCA disease, and perhaps other autoimmune diseases, could develop (Pendergraft et al., 2004a). This theory proposes that the initiator of the autoimmune response is not an autoantigen or an exogenous mimic, but rather a peptide or protein that is "antisense" or "complementary" to the autoantigen. The first immune response is production of an antibody specific for this complementary protein. This is followed by an antiantibody (i.e., anti-idiotypic antibody) response, whereby a second immunoglobulin is produced that reacts not only with the first antibody, but also with the corresponding "sense" or self-protein because of surface contour complementarity.

The initiating event in autoantigen complementarity is an immune response against a protein complementary in structure to the autoantigen (Figure 59.3A and B). Complementary proteins could be of exogenous microbial origin; for example, complementary PR3 has homologies with proteins from many different microbes and viruses. Among these microbes are Ross River virus, *Staphylococcus aureus*, and *Entamoeba histolytica*, all of which have been previously linked with ANCA disease (Davies, 1982; Pudifin et al., 1994; Stegeman et al., 1994). Pertinent to this finding, the onset of ANCA disease is commonly associated with a flu-like illness (Falk et al., 1990a). Alternatively, patients may be producing complementary PR3 protein themselves. Recent reports of naturally-occurring antisense transcripts in humans indicate that individuals do in fact transcribe antisense RNA (Lehner et al., 2002). However, PR3 antisense RNA has not been reported in the antisense transcriptome database, indicating that antisense PR3 has not yet been identified in healthy individuals. Leukocytes from PR3-ANCA subjects reveal the presence of PR3 antisense RNA in approximately 50% of cases (Pendergraft et al., 2004a). Whether these antisense transcripts are or can be translated into a protein product to produce the complementary protein is unknown, but translation of an antisense transcript has been reported (Van Den Eynde et al., 1999). It may be that aberrantly expressed antisense transcripts are a component of many human diseases (Lavorgna et al., 2004).

Among patients with PR3-ANCA disease, 21% have antibodies specific for a recombinant protein complementary to PR3, whereas only 1% of normal patients or patients with non-PR3 glomerular diseases are seroreactive to this protein (Pendergraft et al., 2004a). These antibodies may themselves induce an immune response, which is the second proposed event in autoantigen complementarity. Antibodies are known occasionally to act as antigens themselves, and elicit antiantibody antibodies (known as anti-idiotypes), according to the idiotypic network theory (Jerne, 1974). The antigen-binding region (paratope) of an antibody elicits an immune response that results in an anti-idiotype directed against the antigen-binding region. Production of anti-idiotypic antibodies following immunization with antigens or antibodies has been extensively reported (Erlanger et al., 1986; Hill and Erlanger, 1988; Erlanger, 1989; Shoenfeld, 1994; 2004; Shoenfeld et al., 2002). Therefore, anticomplementary PR3 antibodies produced following exposure to complementary PR3 could themselves induce an immune response, resulting in the generation of anti-anticomplementary PR3 antibodies. In fact, affinity-purified anti-PR3-ANCAs bind specifically to anticomplementary-PR3 antibodies, proving that these antibodies are an idiotypic pair (Pendergraft et al., 2004a).

Antigen–antibody complementarity states that the variable region of an antibody molecule is structurally and chemically complementary to the epitope region of the bound antigen (Smith et al., 1987; Blalock and Bost, 1988; Bost and Blalock, 1989; Blalock, 1990; Root-Bernstein and Rallo, 2004). Therefore, because anticomplementary PR3 antibodies bind both complementary PR3 and their anti-idiotypic antibody, both these molecules would be expected to be structurally identical at the epitope regions. It follows then that just as complementary PR3 is expected to bind PR3, the anti-idiotypic antibodies would bind PR3 as well; these anti-idiotypic antibodies are PR3-ANCA and represent the third and final event proposed by autoantigen complementarity (Figure 59.3C).

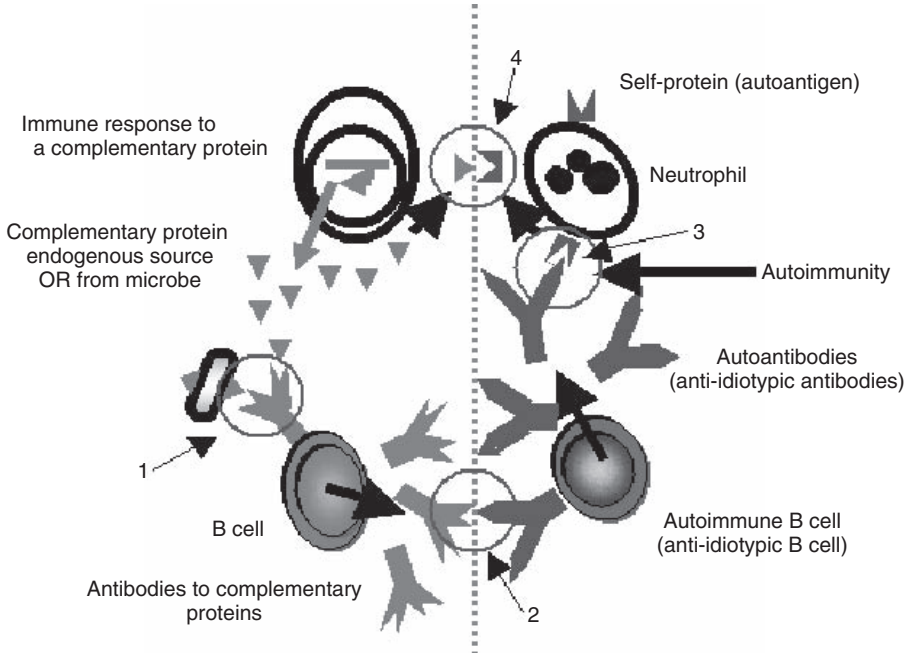
To test the feasibility of these three events, mice were immunized with recombinant complementary human PR3 protein and then evaluated for production of antihuman PR3 antibodies. As predicted, the mice produced not only anticomplementary PR3 antibodies, but antihuman PR3 antibodies as well; PR3-reactive antibodies produced a cytoplasmic (C-ANCA) pattern when examined by immunofluorescence (Pendergraft et al., 2004a).

Immunologic Markers in Diagnosis

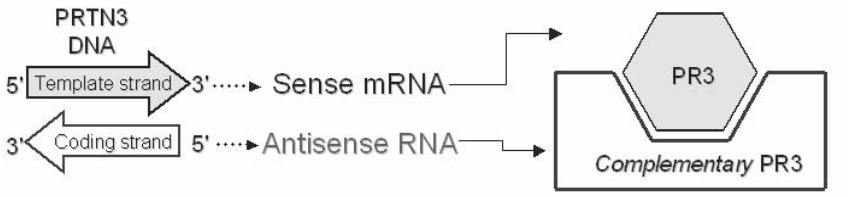
Concurrent presence of kidney disease and ANCA has a relatively high sensitivity and specificity for diagnosis of ANCA glomerulonephritis. Available serum markers, including determination of the precise ANCA target antigen, have little use in predicting presence or later development of kidney disease if clinicopathologic evidence of renal insufficiency or failure is absent. Use of immunologic markers for diagnosis of ANCA disease in general is reviewed in Chapter 65.

Treatment and Outcome

Immunosuppressive treatment of patients with ANCA disease is described in Chapter 65. The short-term renal outcome of patients with ANCA-associated glomerulonephritis is relatively good, with an average patient and renal

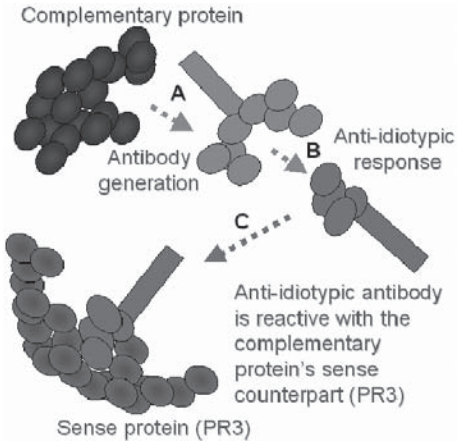


A



- "Antisense RNA" is a general term used to describe a sequence of RNA that is complementary to messenger RNA (mRNA). Antisense RNA is transcribed from the opposite strand of DNA than the one normally used for the RNA transciption.
- A "complementary protein" is one that is translated from antisense RNA (Blalock, 1990). The hydropathy of the complementary protein is exactly opposite to that of the mRNA-coded protein from that same gene. Thus the individual folding patterns result in mirror image structures that can interact in a lock and key manner.

B



C

FIGURE 59.3 *A*, Schematic of the theory of autoantigen complementarity. The theory proposes that the immunogen that begins the sequence of events leading to the production of autoantibodies is not the autoantigen or its mimic, but rather its complementary peptide or its mimic. Step 1: The complementary proteins may be introduced by invading microbes or they may be produced by the individual through translation of antisense RNA. An antibody is produced in response to the complementary protein. Step 2: A second antibody is elicited against the first antibody, referred to as an anti-idiotypic response. Step 3: The resultant anti-idiotypic antibodies react with the autoantigen, whose amino acid sequence is complementary to the sequence of the initiating antigen. Step 4: Complementary proteins have a natural affinity because the hydropathy of one is the opposite of the other. *B*, Definition of terms used in the theory of autoantigen complementarity. *C*, Schematic of anti-PR3 antibody (ANCA) production as a result of an anti-idiotypic response.

survival at 1-year of approximately 75%. Outcome is worse in older patients, patients with endstage kidney disease, or those with severe azotemia at first diagnosis (Booth et al., 2003). Higher creatinine or lower glomerular filtration rate at the time of presentation, persistent proteinuria, and chronic renal lesions, including interstitial fibrosis, tubular atrophy, and glomerulosclerosis, are negative prognostic indicators (Hauer et al., 2002; Neumann et al., 2005). Long-term remission without disease relapse occurs in 60–75% of patients.

CONCLUDING REMARKS AND FUTURE PROSPECTS

Anti-GBM disease, SLE, and ANCA-associated glomerulonephritis are among several kidney diseases that are immune mediated in nature. Other diseases may be consequences of infectious agents, resulting in immune complex deposition, notably membranoproliferative glomerulonephritis or cryoglobulinemic glomerulonephritis, or due to breaks in mucosal immunity, such as IgA nephropathy, or may be secondary to *in situ* formation of immune complexes, such as membranous nephropathy (Table 59.2). There is also an array of tubulo-interstitial nephritides that may be immune mediated in origin, particularly those associated with drug hypersensitivity or autoantibodies to the tubular basement membrane. Each of these entities presents the opportunity for substantial review, although each shares common effector pathways of inflammation with the three diseases described in detail. Membranous glomerulopathy and IgA glomerulonephritis bear names derived from their immunohistologic patterns of kidney injury without regard to their primary pathogenesis, which remains unclear—most target antigens involved in the genesis or maintenance of aberrant immune responses affecting the kidneys remain elusive. Studies using complementary proteins, as described herein, may afford clues as to these, as yet, unknown agents. Certainly, if these inciting antigens and precise epitopes were to be established, more specific and less toxic drugs could be used to supplement or even replace the nonspecific immunomodulating drugs that have hardly changed over the past 30 years.

TABLE 59.2 Infectious agents commonly associated with glomerulonephritides

Bacteria	*Streptococcus* spp.; *Staphylococcus* spp.; chronic bacterial infections of multiple species (atrioventricular shunt infections, endocarditis, osteomyelitis, deep abscesses); *Treponema pallidum* (syphilis); *Salmonella typhi* (typhoid fever)
Viruses	Hepatitis A, B, and C; human immunodeficiency virus; Epstein–Barr virus
Protozoa	*Plasmodium* spp. (malaria)
Parasites	*Schistosoma* spp.

HISTORIC BACKGROUND

The demonstration that the sera of animals sensitized with testicular homogenate or semen were able to immobilize spermatozoa was first reported over 100 years ago. Pioneered by Voisin (Voisin et al., 1951) and Freund (Freund et al., 1953), the first experimental model of autoimmune orchitis, induced by active immunization with homologous testicular antigens and adjuvant, was developed. Between 1970 and 1980, most research focused on the study of antibodies to sperm antigens as a cause of male or female infertility, independent of orchitis, and a major effort was made to standardize the methods of detecting sperm antibodies. Later, research interest shifted to defining the nature of testis-specific autoantigens. As yet, no well-characterized sperm antigen has been identified as a target in sperm autoimmunity or as a suitable candidate antigen in male gamete contraceptive vaccine development.

In this chapter, we review current knowledge on clinical male infertility, with emphasis on autoimmune orchitis and its pathogenetic mechanism.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Male infertility associated with immunologic mechanisms may result from the presence of sperm antibodies or autoimmune disease of the testis and its excurrent ducts. In the first case, antibodies, once generated, may result in infertility by a variety of mechanisms, mainly disturbances in sperm transport or disruptions in gamete interaction. In the second case, immunopathologic damage of the testis (and its excurrent ducts) occurs through T-cell-mediated mechanisms triggered by antigens or pathogens that disrupt testicular immunoprivilege.

Male Infertility Associated with Sperm Antibodies

Male infertility may result from the binding of antisperm antibodies (ASAs) to ejaculated sperm. Clinically, ASAs are found in 3–12% of men with infertility, compared to 0–2% of the general male population [reviewed by Turek and Lipshultz (1994)]. The ASAs present in local secretions of the genital tract rather than serum are associated with infertility [reviewed by Marshburn and Kutteh (1994)].

Importantly, data from *in vitro* fertilization programs indicate that a reduced fertilization rate is associated with IgA and IgG antibody binding to the head region of sperm.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Many potentially important human and animal sperm molecules [reviewed by Frayne and Hall (1999) and Bohring and Krause (2003)] have been identified by means of serum antibodies from infertile patients or monoclonal antibodies that affect different fertilization events—motility, cervical mucus penetration, acrosome reaction, zona binding, zona penetration, oolema binding, and pronucleous formation.

Analysis of the cognate antigens of the ASAs involved in the process of fertilization improves the identification of immunogenic proteins that are candidates for immune contraception.

Obstruction or injury of the male reproductive tract is associated with ASA formation, since leakage of large quantities of sperm antigens can induce antibody production. Sperm antibodies attendant to vasectomy may be responsible for infertility in some patients following vasovasostomy. Indeed, ASAs are common in patients with congenital absence of the vas deferens associated with cystic fibrosis (Box 60.1).

Male Infertility Associated with Autoimmune Orchitis

Autoimmune orchitis is well documented in spontaneously infertile animals and in experimental models of autoimmune orchitis. Human autoimmune orchitis is represented by the granulomatous orchitis of noninfectious origin, aspermatogenesis associated with testicular immune complex deposits, and orchitis associated with systemic viral infections.

Clinically, granulomatous orchitis causes mild testicular pain or swelling. The main challenge is to distinguish it from a tumor; sonographic studies and biopsy may help the diagnosis. The histopathology of the testis shows granuloma formation as an accumulation of histiocytes, macrophages, and epithelioid and multinucleated giant cells, associated with loss of germ cells.

Box 60.1
Human pathologies or conditions associated with antisperm antibodies

Testis
- Granulomatous orchitis
- Orchitis associated with viral infections (mainly mumps virus and HIV) and other infectious agents
- Orchitis associated with cryptorchidism or tumor
- Orchitis associated with trauma, torsion, or biopsy

Vas deferens
- Vasectomy
- Vasectomy reversal
- Agenesia of vas deferens

Autoimmune orchitis can be accompanied by epididymitis and vasitis, although genetic evidence suggests that each can occur as an independent entity (Roper et al., 1998). As in orchitis, spermatic granulomas of noninfectious origin can occur in the epididymis and the vas deferens as an autoimmune response to the host's own extravasated spermatozoa, inducing local immunoglobulin production and accumulation of T lymphocytes (Saravanamuthu et al., 1991). Sperm granuloma are commonly seen in men who have had a vasectomy. However, most cases of orchiepididymitis are due to infection [reviewed by Chan and Schlegel (2002) and Delavierre (2003)] and the main route is retrograde propagation from the vas deferens. Epididymitis can also be iatrogenic, a complication of treatment with amiodarone a drug used for cardiac arrhythmias, and although the exact mechanism of this disease is unknown, the lymphocyte infiltration present in a sterile microenvironment suggests an autoimmune phenomenon.

Two studies in the 1980s (Salomon et al., 1982; Lehman et al., 1987) on testis biopsies from infertile men described deposits of IgG and/or complement (C3) or immunocomplexes in the basement membranes (BM) of seminiferous tubules and damage of the germinal epithelium. Although the evidence for immune complex-induced orchitis is not yet confirmed, the alterations are consistent with the observation in the infertile mink (Tung et al., 1981) and in rats and guinea pigs passively immunized with antibodies to BM antigens (Denduchis and Lustig, 1981; Lustig et al., 2000).

Focal orchitis, presumably due to an autoimmune mechanism, is also observed following testicular damage induced by trauma, physical agents, torsion, biopsy or tumor. Histologic evidence of interstitial and/or intratubular inflammatory cells accompanied by loss of germ cells has been described: 4.8% of testicular biopsies from 166 men with azoospermia or oligozoospermia had focal or general leukocyte infiltration (Suominen and Söderström, 1982).

Nistal et al. (2002) evaluated the focal orchitis present in cryptorchidic testes of men not previously treated for cryptorchidism or antecedents of infectious diseases, and detected focal lymphoid infiltrates in the interstitium and/or seminiferous tubules associated with lesion of the germinal epithelium in 44% of 50 patients. The authors suggest that an alteration in the blood–testis barrier (BTB) allows antigens to enter the testicular interstitium and stimulate an autoimmune process.

Most reported cases of spontaneous autoimmune orchitis are associated with an infectious disease, usually following a viral infection. The pathogens are thought to induce orchitis by disrupting the mechanisms of testicular immuno-

privilege rather than through a direct cytopathologic effect. The best-known orchitogenic viruses in humans are the mumps virus and human immunodeficiency virus (HIV). The symptoms of mumps in most prepubertal boys are limited to infectious parotitis; however, 5–37% of adults with mumps infection also develop orchitis. Lymphocytic infiltration followed by oligozoospermia with tubular atrophy and fibrosis contribute to transient or permanent subfertility or infertility. The mumps virus does not appear to induce germ cell transformation and may not be directly spermatogenotoxic. However, mumps virus replicates in Leydig cells *in vitro*, inhibits testosterone secretion, and induces production of the interferon (IFN)-γ-induced protein 10, a chemokine that recruits leukocytes (Le Goffic et al., 2002; Mouchel et al., 2002).

Acquired immune deficiency syndrome (AIDS) patients often suffer from orchitis, hypogonadism, oligozoospermia or azoospermia. It has been suggested that reduction in testosterone levels in AIDS patients may result from a reduction in Leydig cell number or of their function. For example, alteration of the hypothalamic–pituitary–gonadal axis can be caused by proinflammatory cytokines [reviewed by Dejucq and Jégou, (2001)]. Kierszenbaum (1995) speculates that the uncommon perivascular accumulation of $CD4^+/HIV^+$ cells and cytokine production could affect the integrity of the BTB and favor the development of autoimmune orchitis. For example, antibodies against sperm antigens have been reported in AIDS patients.

The autoimmune component of orchitis associated with infections was investigated in several experimental models, including infection with myxoma virus (Fountain et al., 1997) and Sendai virus, which is closely related to mumps virus (Melaine et al., 2003). In mice unilaterally infected with *Listeria monocytogenes*, the contralateral testis developed orchitis without detectable microorganisms, providing evidence for an autoimmune component in infectious orchitis (Mukasa et al., 1995). This was supported by disease transfer to uninfected recipients by $CD4^+$ T cells from infected donors. It was further shown that the γδ T cells reduced αβ pathogenic T-cell function through cytokines, mainly IL-10 and TGF-β (Mukasa et al., 1998).

TESTICULAR IMMUNOREGULATION

Testicular antigens expressed in haploid germ cells appear after puberty when immunocompetence is already established. The ability of the testis to tolerate these autoantigens as well as to survive in the testicular interstitium of transplanted foreign tissue has led to the consideration that the testis is an immunoprivileged organ. The mechanisms of testis autoimmune disease prevention are described in Box 60.2 (Tung et al., 2000).

Box 60.2
Mechanisms of gonadal autoimmune disease prevention

Systemic immunoregulation (systemic tolerance mechanism)

- Regulation of pathogenic self-reactive T cells by regulatory T cells (Takahashi et al., 1998; Thornton and Shevach, 1998)

Regional immunoregulation (testis immunoprivilege)

- Blood–testis barrier (incomplete immunologic barrier that limits the access of germ cell antigens to the immune cells and antibodies) (Yule et al., 1988; Pelletier, 2001)
- Presence of regulatory T-cells in the testicular interstitium (Mukasa et al., 1995; 1998)
- Secretion of multiple immunosuppressor factors by macrophages, Sertoli and Leydig cells (De Cesaris et al., 1992; Tung et al., 2000; Hedger, 2002)

ANIMAL MODELS AND PATHOGENIC MECHANISMS

Studies on experimental autoimmune orchitis (EAO) have helped elucidate disease mechanisms as well as the systemic regulation that normally prevents disease.

Animal Models

EAO can be elicited by three approaches: 1) immunization with testis antigens with or without adjuvants; 2) passive transfer of testis-sensitized lymphocytes; and 3) manipulation of the normal immune system, such as by thymectomy at day 3 after birth (d3TX) or the transfer of defined T-cell populations from normal inbred mice to syngeneic athymic nu/nu mice recipients. In addition, autoimmune orchitis occurs spontaneously in the dark mink, beagle dog, and aging rat.

EAO is elicited by immunization with testis antigen in complete Freund adjuvant (CFA) in guinea pigs (Voisin et al., 1951) or with testis antigen in CFA and *Bordetella pertussis* toxin in mice (Kohno et al., 1983) or rats (Doncel et al., 1989), or by repeated subcutaneous injections of viable testicular cells, without adjuvants in mice (Sakamoto et al., 1985; Itoh et al., 1991a). Tung et al. (1994) have given a detailed description of the protocols for testicular autoimmune disease.

Pathogenic autoimmune responses to antigens in the male gonad are directed to haploid germ cells in the testis,

including spermatozoa. Although numerous EAO-inducing testis proteins have been isolated, their identity and function are only partially known [reviewed by Tung et al. (2000)].

d3TX or other manipulations that deplete regulatory T cells (Tregs; $CD4^+CD25^+$) also induce EAO, and the fact the disease is suppressed by normal T cells indicates that, although potentially orchitogenic $CD4^+$ T cells exist in normal mice, their action is prevented by natural Tregs. The activation of these cells by endogenous antigens or their molecular mimic, or defective immunoregulation can elicit autoimmune response and tissue injury (Tung et al., 2000).

Pathogenetic Mechanisms

Cellular Mechanisms

EAO is characterized by an interstitial lymphomononuclear cell infiltrate and damage of the seminiferous tubules. The histopathologic distribution of the initiation of inflammation differs between active versus passive EAO: in subcapsular seminiferous tubules far from the rete testis and in straight tubules adjacent to the rete testis (a region more permeable to circulating IgG), respectively (Figure 60.1). Passive EAO experiments in which testis or sperm antigen-specific T-cells that have been activated *in vitro* transfer

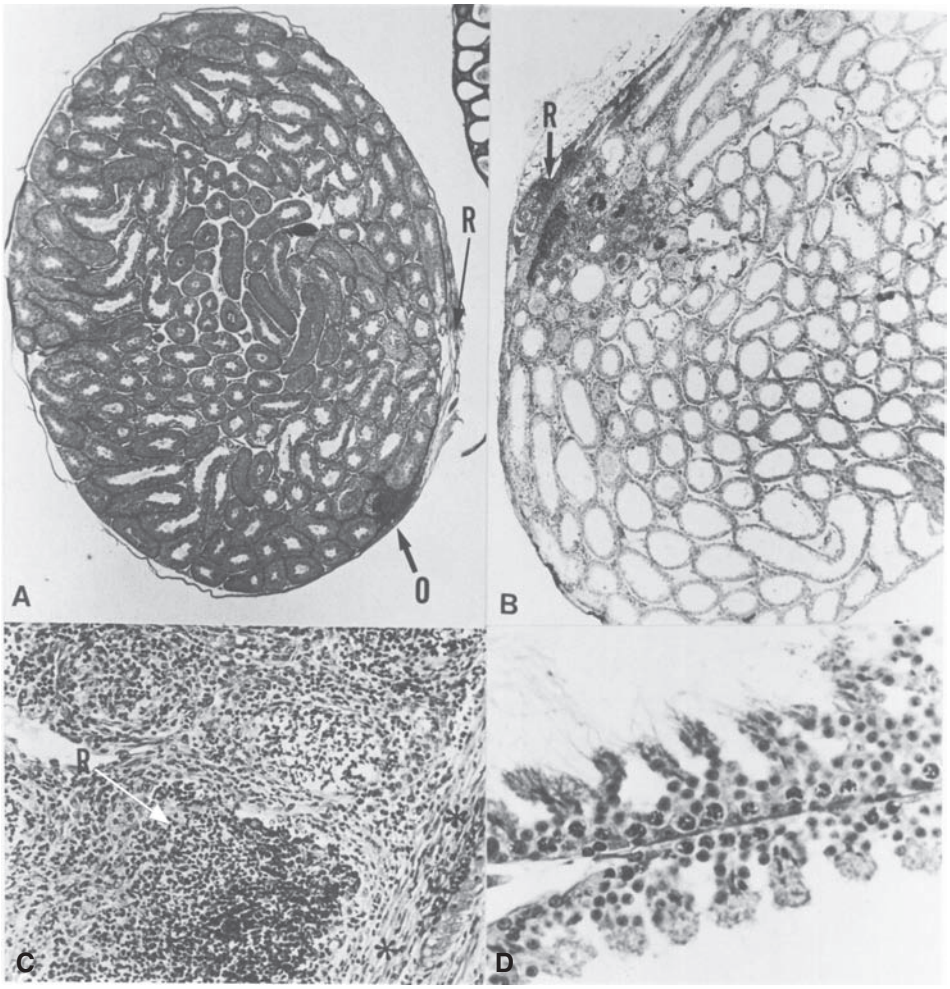

FIGURE 60.1 Predominant histopathologic lesions from mice with *A*, actively induced experimental autoimmune orchitis (active EAO) and *B–D*, from recipients of testis-sensitized lymphocytes (passive EAO). *A*, A common histopathologic finding in active EAO is found under the testicular capsule (arrow), away from the rete testis (R). O, orchitis. Original magnification ×50. *B*, In passive EAO, inflammation in the regions of the straight tubules, adjacent to the rete testis (R), is common, and this leads to severe dilation of seminiferous tubules. Original magnification ×50. *C*, In passive EAO, inflammation in the rete testis (R) is severe and obstructs the lumen. Original magnification ×200. The asterisk shows the capsule adjacent to the rete testis. *D*, In passive EAO, dilated seminiferous tubules have attenuated but intact germinal epithelium, without evidence of orchitis. Original magnification ×400.

Reproduced from Tung et al. (1987), with permission.

severe orchitis and vasitis to syngeneic euthymic mice (Tung et al., 2000) indicate that pathogenic autoreactive T cells against highly specific testis peptides are responsible for the disease. All orchitogenic T-cell clones express CD4, which recognizes peptides in association with MHC class II molecules present in testicular macrophages and dendritic cells, mainly around straight tubules (Tung et al., 1987). Then, orchitis spreads to peripheral seminiferous tubules. T cells produce interleukin (IL)-2 and interferon (IFN)-γ, but not IL-4, which is typical of type 1 helper (Th1) $CD4^+$ T cells. The germ cells undergo apoptosis, and the CD95-CD178 (Fas–Fas L) and tumor necrosis factor (TNF)-α–TNF receptor (TNFR)1 systems are involved in this process (Suescun et al., 2003; Theas et al., 2003). Moreover, the *in vivo* injection of antibodies to TNF-α markedly reduced the severity of EAO in mice transferred with pathogenic T-cell clones (Yule and Tung, 1993).

Humoral Mechanisms

Although autoantibodies to sperm antigens or immune complexes can be detected in EAO, antibody response alone is not sufficient to cause tissue injury. However, the autoantibody binding to a tissue antigen can cause a redistribution of T-cell-mediated inflammation.

GENETICS

Genetic analysis of inbred mouse strains indicates that susceptibility or resistance to autoimmune orchitis is polygenic and strongly influenced by both H2-linked and non-H2-linked genes (Person et al., 1992). The histamine H1 receptor (Hrh1) was definitively identified as the first "shared" non-MHC-linked gene controlling susceptibility to autoimmune orchitis and encephalomyelitis (Ma et al., 2002). These results provided a mechanistic basis for the genetic role of *Bordetella pertussis*-induced histamine sensitization (Bphs)/Hrh1 in eliciting pathogenic T cells during the induction phase of autoimmune disease. Nine chromosomal regions have been linked to EAO and many of these loci are found in regions that govern susceptibility to other autoimmune disease, such as experimental autoimmune encephalitis and type 1 diabetes of nonobese diabetic mice. Microsatellite analysis has mapped distinct chromosomal regions that encode susceptibility to orchitis, epididymitis, and vasitis in EAO, demonstrating the independent regulation of susceptibility to these pathologies (Roper et al., 1998).

Autoimmune orchitis is a component of the autoimmune polyglandular syndromes (APS) that exist as two major clinical entities, APS I and APS II, which differ in age of presentation, characteristic patterns of disease combinations, and modes of inheritance (see Chapter 38). Gonadal failure is more frequently associated with APS I than with APS II.

Recently, two novel immune mechanisms have been identified in patients with APS. APS I patients have a point mutation in the *AIRE* gene (21q23.3), which encodes a transcription factor of unknown function (The Finnish–German APECED Consortium, 1997; Pitkanen and Peterson, 2003). Mice with the knock-out *AIRE* gene spontaneously develop APS (Anderson et al., 2002). Because the *AIRE* protein, expressed in a thymic medullary epithelial cell, influences ectopic expression of peripheral tissue antigens in this thymic cell lineage, a dysfunctional *AIRE* can result in defective central T-cell tolerance (Liston et al., 2003). A second group of APS II patients has an intact *AIRE* gene, but a defective $CD4^+CD25^+$ Treg function (Kriegel et al., 2004).

TREATMENT AND OUTCOME

In patients with high levels of ASAs, corticosteroid treatment has been used to reduce antibody titers, but a direct correlation between ASA titers and fertility has not been observed (Marshburn and Kutteh, 1994).

In recent years new drugs have been used to prevent testicular autoimmunity in mice. Ablake et al. (2002) demonstrated that deoxyspergualin is capable of suppressing alloimmune and autoimmune reactions in experimental models. The authors suggested that the drug may interfere with the function of $CD4^+$ Th1 cells by altering autoantigen presentation and/or by inhibiting T-cell production of IFN-γ. Itoh et al. (1998) demonstrated that a single injection of anti-IFN-γ monoclonal antibody may successfully downregulate testicular autoimmunity in mice with EAO.

More recently, Ito et al. (2004) suggested agents such as α-melanocyte-stimulating hormone (MSH), insulin growth factor (IGF)-1, TGF-β1 or FK506 as promising candidates for immunoprivilege restoration and for suppressing MHC I expression in different autoimmune entities, like mumps autoimmune orchitis.

In assisted reproduction, intracytoplasmic sperm injection (ICSI) is the primary choice of treatment for immunologic infertility, especially when ASAs are located in/on the sperm head [reviewed by Lombardo et al. (2001)].

CONCLUDING REMARKS

Human testicular autoimmune diseases remain incompletely defined and should be a major focus of future research. Nevertheless, research based on models of autoimmune orchitis has contributed significantly to our understanding of the interactions between immune cells and somatic and germ cells of the testis, as well as the overall

concepts of autoimmune disease pathogenesis. The $CD4^+CD25^+$ Tregs play a central role in the control of immune reactivity. New targets for specific therapies may be developed by identifying the mechanisms by which regulatory cells function and the intracellular signaling cascades activated during autoimmune pathology. In addition, the recent finding of a single gene (*AIRE*) defect causing a systemic human autoimmune polyglandular syndrome provides an exciting tool for exploring molecular therapy for these autoimmune diseases.

HISTORIC FEATURES

The concept of autoimmune ovarian disease (AOD), or oophoritis, was suggested over 35 years ago. Irvine observed that Addison's disease was associated with a higher than expected occurrence of premature ovarian failure (POF, or premature menopause before age 40), and steroid cell autoantibodies to adrenal and ovary (Irvine et al., 1968). Independently, antibodies to oocyte cytoplasm were detected in women with infertility (Vallotton and Forbes, 1966). Until recently, studies of the autoimmune basis of POF were more common than studies of AOD in infertility. Interestingly, an animal model of autoimmune ovarian failure, based on mice thymectomized on neonatal day 3, was reported at about the same time (Nishizuka and Sakakura, 1969).

AOD has been identified primarily by indirect and circumstantial evidence according to the criteria summarized by Rose and Bona (1993). Circumstantial evidence for AOD includes lymphocytic infiltration of ovarian follicles in women with POF, frequent association of POF and infertility with other autoimmune diseases, and a tendency of POF to be familial. Indirect evidence for an autoimmune disease of the ovary includes the association of ovarian autoantibodies with POF and some types of infertility [reviewed in Luborsky (2002b)].

CLINICAL, PATHOLOGIC AND EPIDEMIOLOGIC FACTORS

Clinical Features

AOD usually presents as POF or infertility (Figure 61.1; Table 61.1), although these phenotypes represent heterogeneous etiologies.

Etiologies of POF include induction by radiation or chemotherapy (Chiarelli et al., 1999), environmental factors (Vermeulen, 1993; Cooper et al., 1999; Silbergeld and Flaws, 1999), genetic defects and chromosomal deletions (Davis, 1996; Hoek et al., 1997), and unexplained POF. POF is empirically defined as ovarian failure before the age of 40 (Cramer and Xu, 1996; WHO, 1996; Hoek et al., 1997). Like natural menopause around the age of 50, premature menopause is identified by cessation of menstrual cycles for 1 year, accompanied by elevated follicle-stimulating hormone (FSH) and reduced estradiol levels in blood (WHO, 1996). AOD is associated with POF of unknown or iatrogenic etiology (Luborsky, 2002b).

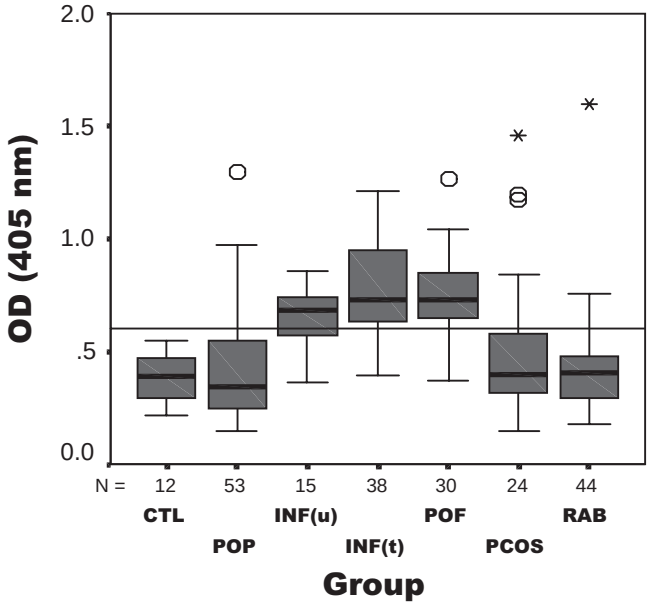

FIGURE 61.1 Association of ovarian autoantibodies with premature menopause and unexplained infertility. The optical density (OD) values obtained by ovarian antibody assay and the corresponding number of positive values are shown. Immunoassay results for ovarian antibodies in different groups of women are shown as a box and whiskers plot of OD values. The horizontal line represents the control mean plus two standard deviations. Values above the line are positive. CTL, control women with normal menstrual cycles or natural menopause and no diagnosed autoimmune disease; INF(u), unexplained infertility and no prior hormone stimulation; INF(t), unexplained infertility and at least two cycles of in-vitro fertilization; PCOS, polycystic ovary syndrome; POF, premature ovarian failure; POP, women aged 18–45 years from a blood bank (anonymous); RAB, recurrent fetal loss.

TABLE 61.1 Association of ovarian antibodies with premature menopause and unexplained infertility. Prevalence of ovarian antibodies in same groups as in Figure 61.1, and the corresponding significance compared with controls

Group	Prevalence of ovarian antibodies (%) (*P*)
Control (CTL)	Reference
Blood bank (POP)	17 (NS)
Unexplained infertility [INF(u)]	33 (<0.001)
Unexplained infertility [INF(t)]	61 (<0.001)
Premature ovarian failure (POF)	53 (<0.001)
Polycystic ovary syndrome (POS)	25 (NS)
Recurrent fetal loss (RAB)	18 (NS)

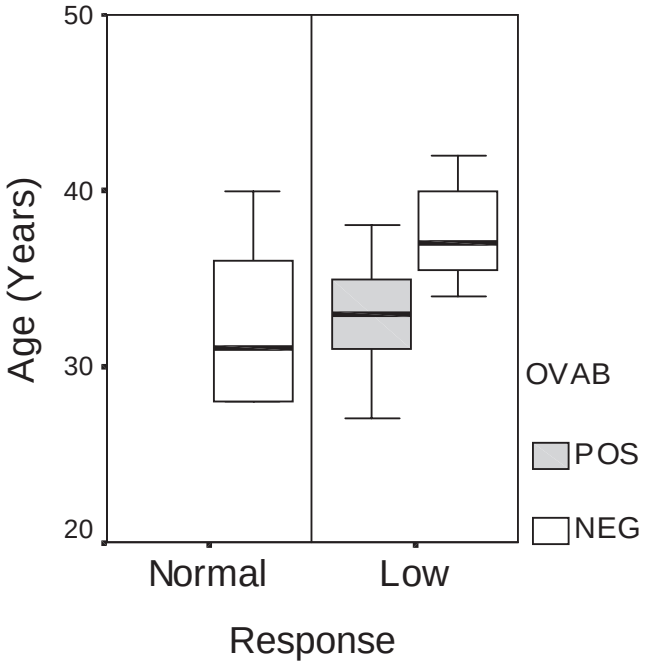

FIGURE 61.2 Ovarian autoantibodies discriminate between low estrogen responses associated with autoimmunity and those associated with aging. Age and estradiol responses are compared in patients with infertility, undergoing hormone stimulation during in-vitro fertilization treatment. Ovarian antibodies (OVAB) were associated with lower than expected estradiol responses to follicle-stimulating hormone (FSH). Data are displayed as a box and whiskers plot of the response to FSH, defined as a ratio of the peak estradiol/dose of FSH. The median, range (whiskers), 25th–75th percentile (box), and outliers (circles) are shown. Normal responders were 32.5 ± 4.6 years old, low responders without ovarian antibodies (NEG) were 37.1 ± 3.8 years old ($P = 0.013$ compared to normal responders), and low responders with ovarian antibodies (POS) were 33.4 ± 4.2 years old ($P = 0.6$ compared to normal responders). This observation suggests that although some poor responses are associated with ovarian failure associated with early stages of natural menopause, other poor responses are associated with an autoimmune process that occurs at a younger age.

Reproduced from Luborsky et al. (2002b), with permission.

Infertility is the inability of a couple to conceive for at least 1 year during unprotected intercourse (WHO, 1992). Of the diagnostic categories of infertility, ovarian autoimmunity is primarily associated with unexplained infertility (Luborsky, 2002b). Unexplained infertility is identified by exclusion, after normal results for semen analysis, postcoital test, ovulation (luteal-phase progesterone), and tubal patency are obtained in a standard clinical evaluation (Forti and Krausz, 1998).

Women with infertility and ovarian autoantibodies tend to have lower than expected estradiol responses to gonadotropin hormone stimulation (i.e., "poor responders") (Meyer et al., 1990) and lower pregnancy rates following infertility treatment (Luborsky and Pong, 2000). Poor responders with ovarian antibodies are younger than poor responders without ovarian antibodies (Luborsky et al., 2002b) (Figure 61.2). This suggests that although some poor responses are associated with early stages of the menopause progression and reduced number of functional follicles, others are associated with an autoimmune process.

In addition to the risk of other autoimmune diseases (Hoek et al., 1997), such as polyglandular syndrome (Baker, 1997), POF is associated with a risk of osteoporosis (Anasti et al., 1998; Luborsky et al., 2002b) and cancer-related mortality (Cooper and Sandler, 1998) that is higher than for menopause. However, there is no information on the relative risk of osteoporosis or other health factors specifically in women with autoimmune POF.

Pathology

Evidence of ovarian pathology is derived from ovarian biopsy. The ovary contains a pool of follicles, which are the functional units of the ovary. A group of primordial follicles are recruited each cycle, and under the influence of hormones, grow and differentiate. In women with POF, histologic features of ovarian inflammation range from extreme cellular destruction with no evidence of primordial follicles, to follicles with lymphocyte invasion, often seen as "cysts" in existing follicles, to normal follicles with no obvious inflammation (Russell et al., 1982; Fox, 1992). Lymphocytic infiltrates tend to be associated with growing and maturing follicles rather than primordial follicles in humans (Rebar and Connolly, 1990). Similar variations in ovarian structure have been confirmed by ultrasound of women with POF (Conway et al., 1996; Kalantaridou and Nelson, 2000). Because there is no rationale for biopsies in women with infertility, there is little information on the pathology of ovarian autoimmunity associated with infertility.

Epidemiology

There are no epidemiologic studies of AOD. The prevalence of POF in population studies is about 1% based on elevated FSH (Coulam et al., 1986) or cessation of menstrual cycles before the age of 40 (Cramer and Xu, 1996). In a multiethnic population study, POF occurred at a general prevalence of 1.1% and varied by ethnic group, with a lower prevalence among Japanese women (Luborsky et al., 2002a).

Using autoantibodies as an indicator, about 40–70% of women with POF have AOD, or about one to two million women in the US (Luborsky, 2002a). This suggests that AOD is not as rare as Addison's disease, myasthenia gravis or systemic lupus erythematosus (SLE), and may rank with moderately prevalent autoimmune diseases such as type 1 diabetes (insulin-independent diabetes mellitus), pernicious anemia, and multiple sclerosis (Jacobson et al., 1997).

It is difficult to determine the prevalence of AOD in infertility since study group definitions may differ, and different antibody tests are often used. In general, about 10% of women experience infertility and about 20% are classified as unexplained (WHO, 1992; Collins, 1995). Ovarian antibodies are detected in 30–60% of cases of unexplained infertility (Luborsky et al., 1999; 2000a).

AUTOIMMUNE FEATURES

Autoantibodies

Several types of ovary-specific autoantibodies have been reported, including those to microsomal antigens, granulosa cells, thecal cells, zona pellucida (ZP), and oocytes [reviewed in Luborsky (2002b)]. Ovarian antibodies are detected in serum of both POF and infertility patients by immunohistochemistry (Cameron et al., 1988; Muechler et al., 1991; Belvisi et al., 1993; Betterle et al., 1993; Horejsi et al., 2000), enzyme immunoassay (Sontag et al., 1982; Luborsky et al., 1990; Meyer et al., 1990; Barbarino-Monnier et al., 1991; Wheatcroft et al., 1994; 1997a; Fenichel et al., 1997; Wheatcroft and Weetman, 1997), immunoprecipitation (Coulam and Ryan, 1979) and Western blot (Wheatcroft et al., 1997a). The prevalence of ovarian autoantibodies reported in different studies varies depending on the test and study group.

ZP antibodies are detected in serum of women with POF and infertility by immunohistochemistry (Shivers and Dunbar, 1977; Buckshee and Mhaskar, 1985; Damewood et al., 1986; Mikulikova et al., 1989; Mantzavinos et al., 1993; Smith and Hosid, 1994), enzyme immunoassay (EIA) (Singh and Mhaskar, 1985; Hovav et al., 1994; Ulcova-Gallova and Mardesic, 1996; Ivanova et al., 1999), and passive hemagglutination (Kamada et al., 1992; Mantzavinos et al., 1993; Ulcova-Gallova and Mardesic, 1996). Antibodies to oocyte cytoplasm detected by immunohistochemistry and EIA were also reported (Damewood et al., 1986; Luborsky et al., 1990; Meyer et al., 1990; Horejsi et al., 2000). The typical prevalence of ZP or oocyte antibodies ranges from 30% to 60%, depending on the test format and study group definition.

Autoantibodies to ovarian antigens, ZP, and oocytes also are detected in follicular fluid obtained at oocyte retrieval during controlled ovarian hyperstimulation of infertility patients undergoing in-vitro fertilization (IVF) (Mantzavinos et al., 1993; Papale et al., 1994; Horejsi et al., 2000; Luborsky et al., 2000a). Interestingly, the content of ZP antibodies among follicles is heterogeneous, with some follicles showing no detectable antibody (Papale et al., 1994).

Cellular Immunity

In women with POF, profiles of total T-cell subtypes also appear to be shifted in favor of CD4 subtypes, along with an overall increase in total $CD8^+$ and $CD4^+$ lymphocytes (Miyake et al., 1987; Huang et al., 1996; Lin et al., 1998). The ratio of $CD4^+/CD8^+$ cells is increased in both infertility

and POF compared to normal control women (van Kasteren et al., 2000). Other markers of immune activation are also altered, e.g., B cells (Hoek et al., 1993), interleukin-2 receptor (IL2-R) expression (Nelson et al., 1991), major histocompatibility complex (MHC) class II expression on granulosa cells (Hill et al., 1990; Giglio et al., 1994), and complement activity (Wheatcroft et al., 1997a) are increased, and tumor necrosis factor (TNF)-α (Naz et al., 1995), natural killer (NK) cells (Hoek et al., 1993), and antigen presentation and surveillance are decreased (Arif et al., 1999; Yan et al., 2000). Interestingly, some immune parameters are reversed by estrogen therapy (Ho et al., 1988; 1993; Hoek et al., 1993).

Faustman and colleagues showed that diabetes, SLE, Sjögren syndrome, rheumatoid arthritis, myasthenia gravis, as well as POF, are associated with a reduced density of conformationally correct HLA class I proteins (Faustman et al., 1991; Fu et al., 1993; Li et al., 1995; Yan et al., 2000). This suggests that autoimmunity is associated with a reduced ability to present peptide fragments of antigens and to maintain peripheral tolerance. About 70% of POF cases are associated with abnormal antigen processing (Yan et al., 2000), which is similar to our estimate that 69% of POF is autoimmune, based on autoantibody detection (Luborsky et al., 1990).

GENETIC FEATURES

In general, the genetics and risk factors for all autoimmune disease expression remain to be fully elucidated. Autoimmune diseases tend to run in families and thus there is a genetic component. However, autoimmunity is not expressed clinically in all twin pairs (Faustman et al., 1991; Li et al., 1995; Fu et al., 1998), suggesting that secondary factors have a role in inducing autoimmune disease in susceptible individuals.

There is little information on the genetic component of AOD. Genetic studies of POF have not differentiated autoimmune from nonautoimmune POF (Bione et al., 1998; Bondy et al., 1998; Christin-Maitre et al., 1998; Laml et al., 2002). In general, POF has a genetic component since it is familial as well as sporadic (Cramer et al., 1995). A preliminary report of an association between POF, antibodies to 3-β hydroxy steroid dehydrogenase and a distinctive HLA-DQ molecule suggested that presentation of antigenic peptides to T lymphocytes by HLA-DQ molecules with Asp57-β chains is important in the pathogenesis of autoimmune POF (Arif et al., 1999). The autoimmune regulator gene (AIRE) in polyglandular syndrome type I has been identified but it is unclear if this is related to ovarian failure (Ruan et al., 1999).

POF is also associated with GALT (galactose-1-phosphate uridyl transferase) polymorphism (Cramer et al., 1989; 1994; Cooper et al., 1994), fragile X syndrome (Partington et al., 1996; Kenneson et al., 1997; Uzielli et al., 1999; Marozzi et al., 2000) and inhibin gene defects (Laml et al., 2002). Inhibin is a product of ovarian granulosa cells and regulates (inhibits) pituitary FSH. A Finnish study reported that defects in the FSH receptor were associated with POF (Aittomaki et al., 1995; 1996), although subsequent studies in other countries have not confirmed this finding (Whitney et al., 1995; da Fonte Kohek et al., 1998; Layman et al., 1998; Conway et al., 1999; Layman, 1999; Takakura et al., 2001), suggesting a founder effect in Finland. The relationship of these genetic defects to AOD was not investigated.

ENVIRONMENTAL INFLUENCES

There is little information on environmental influences that might trigger AOD, but based on twin studies it is likely that there are environmental triggers. Smoking and some toxins reduce the age at menopause (Silbergeld and Flaws, 1999) and contribute to infertility (Hruska et al., 2000), but a relationship to autoimmunity has not been shown. Galactose consumption and altered galactose metabolism have been associated with POF (Santoro, 2001).

ANIMAL MODELS

The pathogenesis of AOD has been investigated in several murine models. Three of these are particularly informative: 1) AOD induced by immunization with a murine ZP3 peptide (pZP3) that contains both T-cell epitopes and a native B-cell epitope (Rhim et al., 1992) (Figure 61.3); 2) AOD that develops spontaneously in mice thymectomized on day 3 after birth (d3TX) (Nishizuka and Sakakura, 1969); and 3) AOD in neonatal mice triggered by maternal antibody to murine ZP3 (Setiady et al., 2003).

An autoimmune disorder of the ovaries is induced when regulatory $CD25^+$ T cells are depleted by d3TX. In these mice, endogenous ovarian antigens spontaneously stimulate pathogenic T-cell responses within 2–3 weeks, and this leads to ovarian inflammation, followed rapidly by ovarian atrophy and development of oocyte antibodies. An important cytoplasmic oocyte autoantigen was identified by Tong and Nelson (Tong and Nelson, 1999; Tong et al., 2000; 2002) by screening an ovarian cDNA library with antiserum from the thymectomized mouse model. The antigen is an oocyte-specific molecule that functions in the two-cell embryo post-fertilization. Although the mouse protein, identified as MATER (maternal antigen that embryos require) and its human homolog are highly conserved, it is not clear if the MATER antigen is relevant to human ovarian autoimmune disease. One of the *aod* genetic loci (*aod* 5),

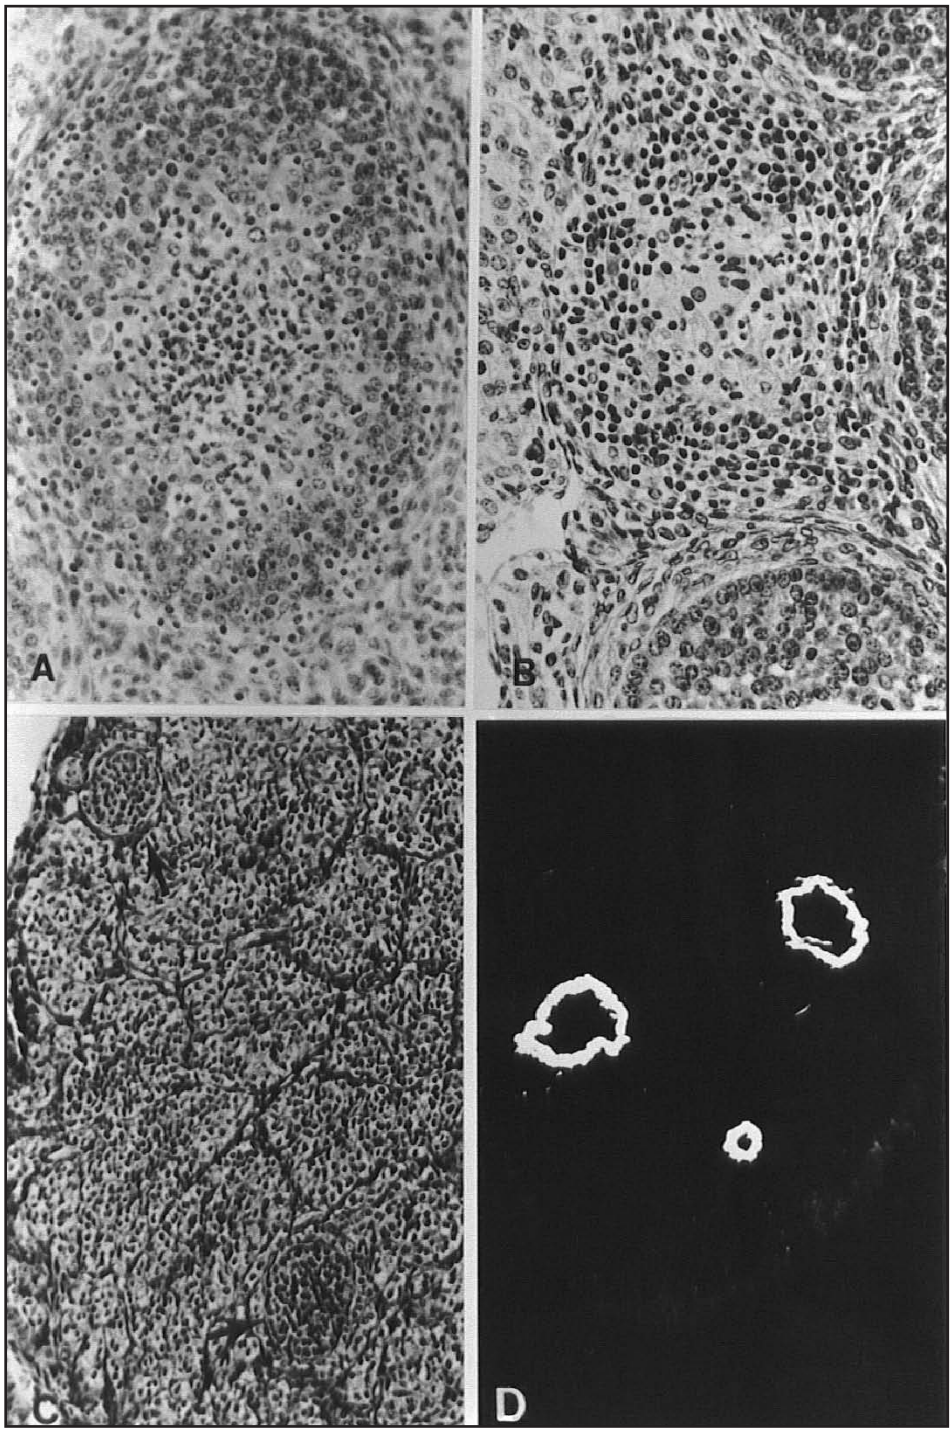

FIGURE 61.3 Histopathology of experimental autoimmune oophoritis induced by immunization with the ZP3 (330–342) peptide in complete Freund adjuvant. *A*, Inflammatory cells have replaced the oocytes in the center of a Graffian follicle; many lymphoid cells can be seen amid granulosa cells. Original magnification, ×100. *B*, A granuloma is found in the interstitial region. Original magnification, ×200. *C*, In severe oophoritis, all oocytes disappear; inflammation is not present, and the ovary is atrophic. Original magnification, ×100. *D*, Ovaries with autoimmune oophoritis show in-vivo binding of IgG antibody to the zona pellucida, as demonstrated by direct immunofluorescence. Original magnification, ×100.

Reproduced from Rhim et al. (1992), with permission.

mentioned below, has been mapped to the region that encodes MATER (Roper et al., 2003).

AOD also can be induced by stimulation by exogenous antigens through the mechanism of T-cell epitope molecular mimicry. Thus, immunization with foreign or unrelated self-peptides with partial sharing of amino acid residues appears critical for T-cell induction (Luo et al., 1993; Garza and Tung, 1995). At least one infectious agent has been implicated in the pathogenesis of AOD. The enteric nematode (the rodent pinworm) operates as a cofactor and, together with a nonimmunogenic stimulus from ovarian pZP3, elicits AOD in neonatal mice. Infected mice are imprinted with long-term memory for the autoantigen and mount a rapid and intense autoimmune response when challenged at a later date (Agersborg et al., 2001). The $CD4^+$ type 1 helper T cell (Th1) is the major pathogenic T cell, requiring both CD28 and CD40 ligand costimulatory pathways for T- and B-cell activation (Griggs et al., 1996). In addition, there is evidence that $CD4^+$ Th2 cells also elicit AOD that result in eosinophilic oophoritis, with autoreactive T cells producing IL-4 and IL-5, but no interferon (IFN)-γ (Agersborg et al., 2001). In human ovarian autoimmune disease, mononuclear cells are the dominant infiltrating cells, although some patients had dominant eosinophilic inflammation (Lewis, 1993).

An unexpected mechanism of autoantibody induction and an unexpected action of autoantibody in tissue inflammation were uncovered during the study of AOD induced by pZP3 in adult mice. Ovarian antibodies are stimulated spontaneously and rapidly by endogenous ovarian antigens in mice in which T cells for ovarian antigen have been activated (Lou et al., 1996; Bagavant et al., 1999). Thus, mice immunized with a pZP3 that lacks native B-cell epitopes develop IgG ZP3 antibodies that recognize distant B-cell epitopes of ZP3, and the antibodies do not cross-react with the pZP3 immunogen. The antibody response is abrogated in mice with ovarian ablation. Thus, autoreactive B cells to ovarian antigens are not tolerized but are primed by endogenous antigens. This discovery, made in parallel with studies on diversification of autoantibody responses to lupus autoantigens, provides the critical evidence that endogenous antigens can drive a diversified antibody response. Secondly, although ZP antibodies do not cause AOD, they influence the distribution of AOD induced by $CD4^+$ T cells. Atretic follicles in the ovarian interstitial space are the prime targets for pathogenic T cells, and T-cell-mediated interstitial oophoritis is compatible with normal ovarian function (Bagavant et al., 1999). In the presence of ZP antibody, the T-cell–mediated inflammation is "retargeted" or shifted to the ovarian follicles, leading to ovarian atrophy (Lou et al., 2000).

A recent model of neonatal AOD was induced by maternal antibody to ZP3 in the progeny. The antibody forms immune complexes in neonatal ovaries, which activate innate cells, including NK cells. Interestingly, immune complexes are also processed by antigen-presenting cells (APCs) and stimulate a *de novo* pathogenic T-cell response that causes severe oophoritis and atrophy (Setiady et al., 2003; 2004). Importantly, the same antibody does not cause ovarian disease in adult mice, and this is due to the presence of competent $CD4^+CD25^+$ regulatory T cells (Tregs) in the adults.

Finally, the pathogenesis of AOD has been investigated by mapping disease-associated genetic loci. Studies on genetic loci that influence AOD induced by d3TX have uncovered six non-H2 chromosomal loci associated with ovarian inflammation, autoantibody induction, and ovarian atrophy (Wardell et al., 1995; Teuscher et al., 1996; Roper et al., 2003).

PATHOGENIC MECHANISMS

Pathogenic mechanisms associated with AOD in humans are not well studied. There is some evidence for cytotoxic mechanisms. Cytotoxic T-cell subsets (CD8 and NK cells) are elevated in the peripheral circulation in POF (Giglio et al., 1994) and complement breakdown product C3a is elevated in women with unexplained infertility and elevated FSH (Wheatcroft et al., 1997b).

Direct actions of autoantibodies on ovarian function were sought but not found. Antibodies from women with POF did not alter gonadotropin action in vitro (van Weissenbruch et al., 1991; Anasti et al., 1995; Lambert et al., 1996), although FSH-induced granulosa cell division and growth were blocked by immunoglobulin from POF sera in one study (van Weissenbruch et al., 1991). Antibodies to partially purified luteinizing hormone (LH) receptor in POF and infertility were reported (Austin et al., 1979; Moncayo et al., 1989). However, stimulating or inhibiting antibodies to gonadotropin receptors were not detected in serum from POF patients tested in functional assays with primary cultures (Wheatcroft et al., 1994; Lambert et al., 1996) or cell lines transfected with recombinant receptor (Anasti et al., 1995).

The majority of reports suggest antibodies to ZP are associated with altered fertilization [reviewed in Luborsky (2002b)]. Antibodies from POF sera were reported to block oocyte maturation and alter Ca^{2+} channel flux (Hotsuliak and Ianchii, 1999). There is relatively little information on the identity of specific oocyte or ZP autoantigens.

IMMUNOLOGIC MARKERS IN DIAGNOSIS

Ovarian autoantibodies are the main diagnostic indicator of AOD. Antibodies are detected by immunoassay or immunohistochemistry, and results may vary slightly

depending on the antigen preparation and assay conditions. There are currently few commercial assays or routine services for detecting ovarian antibodies. Current research is directed at identifying the specific target antigens that will lead to routine commercial tests.

Potential specific antigens have been investigated. The enzymes involved in steroid hormone biosynthesis in ovary and adrenal were likely candidates. The major adrenal enzyme involved in cortisol biosynthesis, 21-hydroxylase (CYP21), was identified in isolated Addison's disease and with polyglandular syndrome (Peterson and Krohn, 1994; Song et al., 1994; Arif et al., 1996; 1999; 2001; Chen et al., 1996; Peterson et al., 1997; Seissler et al., 1999; de Carmo Silva et al., 2000). It was suggested that 17-α hydroxylase (CYP17), the comparable enzyme in the ovary responsible for conversion of progesterone to androgens as precursors to estrogen, is a major antigen in POF. However, consistent with the rare occurrence of steroid cell antibodies that cross-react with steroidogenic tissues (adrenal, placenta, Leydig cells, and granulosa cells) in isolated POF, antibodies to recombinant CYP21 and CYP17, and side-chain cleavage (CYP11A1) enzymes were not major antigens in isolated POF (Chen et al., 1996; Tanaka et al., 1997; Reimand et al., 2000). Similarly, we found that about 20% of infertility sera react with CYP17 (Luborsky, 2002a), suggesting it is a possible antigen, but it does not account for the majority of anti-ovarian antibodies.

Gonadotropin receptors were also investigated as a potential antibody target. There is no clear evidence for anti-FSH or anti-LH receptor antibodies. Other receptors involved in regulation of ovarian cell growth and function, such as those for various growth factors, have not been investigated.

TREATMENT AND OUTCOME

There is no standardized treatment specifically for AOD. Women with infertility may seek assisted reproductive methods. These methods are sometimes successful. However, reduced fertilization (Mantzavinos et al., 1993; Papale et al., 1994; Ivanova et al., 1999), poor response to gonadotropin stimulation (Hovav et al., 1994), and decreased pregnancy rates (Unlu et al., 1990; Kamada et al., 1992) were associated with ZP antibodies in all but one study (Curtis et al., 1991). Likewise, ovarian antibodies were associated with poor response to gonadotropin (Meyer et al., 1990; Luborsky et al., 2002b), and reduced pregnancy rates (Barbarino-Monnier et al., 1991; Horejsi et al., 2000; Luborsky and Pong, 2000).

The heterogeneity of follicles with respect to ZP antibodies (Papale et al., 1994) may explain the partial success of infertility treatment, since there appear to be some "normal" follicles despite the presence of autoimmunity. Fertilization was reduced or absent in follicles with ZP antibodies, and was normal in follicles without autoantibodies within the same ovary.

Spontaneous reversal of POF, or reversal of POF during or after estrogen therapy, or "intermittent" POF have been reported (Alper and Garner, 1985; Alper et al., 1986; Boyers et al., 1988; Letterie et al., 1990; Blumenfeld et al., 1993; Fenichel et al., 1997). Conway et al. (1996) showed by ultrasound that 60% of women had follicular structure. Some women with POF exhibit intermittent estradiol increases (Boyers et al., 1988), mature follicles (Nelson et al., 1994), and evidence of follicular activity by ultrasound (Conway et al., 1996). Interestingly, Fenichel et al (1997) reported that four of 46 women with POF spontaneously conceived during estrogen therapy and of the four, three had ovarian antibodies.

Low-dose corticosteroid treatment has been used to suppress the autoimmune reaction in POF or infertility. Most reports of successful treatment are anecdotal. Success with low-dose corticosteroid treatment of POF with autoimmunity confirmed by ovarian biopsy (Sedmak et al., 1987; Kalantaridou et al., 1999) or ovarian antibody (Rabinowe, 1986; Luborsky et al., 1990) has been reported. Because follicles are recruited at least 1–2 months before the growth and activation cycle, it may require several months for re-expression of normal follicle function after treatment. Two of our POF patients with ovarian antibodies spontaneously resumed menstrual cycles and became pregnant 2 months after corticosteroid immunosuppression with no exogenous hormone stimulation (Luborsky et al., 1990). Similarly, hormone stimulation of patients with AOD and infertility 1–2 months after immunosuppression was successful (Rabinowe, 1986; Barbarino-Monnier et al., 1995; Geva et al., 1999). Controlled clinical trials have not been reported and there are concerns about the side effects of immunosuppressants (Kalantaridou et al., 1999).

FUTURE PROSPECTS

The next significant advance in characterizing AOD will be definitive identification of the specific antigens and development of standardized tests based on use of specific antigens. This will improve clinical diagnosis and permit more precise studies of disease pathogenesis, health risks associated with ovarian autoimmunity, and genetic and environmental factors associated with disease susceptibility.

Rheumatic Heart Disease

LUIZA GUILHERME*† AND JORGE E. KALIL*†‡

*Heart Institute (InCor), School of Medicine, University of São Paulo; †Institute for Immunology Investigation, Millenium Institute; and ‡Clinical Immunology and Allergy, Department of Clinical Medicine, University of São Paulo, School of Medicine, São Paulo, Brazil

HISTORIC BACKGROUND

The relationship between rheumatism and heart disease was first observed by Pitcairn in 1788. It was subsequently described in a textbook approximately 10 years later by Baillie. Since then, several major contributions to the association between acute rheumatism and heart disease have indicated that rheumatic fever (RF) is primarily a disease of children (Baggenstone and Titus, 1968). Bouillaud (1840) made an important remark, "rheumatic fever licks the joint but bites the heart." Cheadle's observation in 1889 that the disease was more frequent in families suggested a genetic pattern of susceptibility. An etiologic agent responsible for RF and thus for rheumatic heart disease (RHD) was sought by several investigators in the period between 1900 and 1940. Many viruses and bacteria were suspected to be the cause of RF. In 1930, Coburn focused on the β-hemolytic *Streptococcus pyogenes* as the possible causative agent of RF (Baggenstone and Titus, 1968).

CLINICAL, PATHOLOGIC AND EPIDEMIOLOGIC FEATURES

The clinical signs and symptoms of RF are the same throughout the world. In the 1950s Jones established the major criteria for diagnosing initial attacks of RF—polyarthritis, carditis, and chorea (Special Writing Group of the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young of the American Heart Association, 1992). These criteria remain useful today, despite small periodic changes. Arthritis is one of the earliest and most common features of the disease, present in 60–80% of patients. It usually affects the peripheral large joints; small joints and the axial skeleton are rarely involved. Knees, ankles, elbows, and wrists are most frequently affected. The arthritis is usually migratory and very painful. Carditis, the most serious manifestation of the disease, occurs a few weeks after group A streptococcal infection, and usually presents as a pancarditis. Endocarditis is the most serious sequel and frequently leads to chronic RHD. Mitral and aortic regurgitation are the most common events caused by valvulitis. Sydenham chorea is characterized by involuntary movements, especially of the face and limbs, muscular weakness, and disturbances of speech, gait, and voluntary movements. It is usually a delayed manifestation, and is often the

ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

sole manifestation of acute RF. Other manifestations, such as subcutaneous nodules and erythema marginatum, can also occur during episodes of RF and are characterized by nodules on the surface of the joints and skin lesions, respectively.

RF is a sequel of throat infection by *S. pyogenes*, affecting 3–4% of untreated children. RHD develops 4–8 weeks (or later) after group A streptococci infection in 30–45% of individuals with RF.

Studies by Rebecca Lancefield (1941) classified streptococci groups by serology based on their cell wall polysaccharides (groups A, B, C, F and G). The *S. pyogenes*, or group A streptococci, cell wall is composed of carbohydrates, such as N-acetyl β-D-glucosamine linked to a polymeric rhamnose backbone. Group A streptococci contain M, T, and R surface proteins and lipoteichoic acid (LTA), which is involved in bacterial adherence to throat epithelial cells. The M protein, which extends from the cell wall, is composed of two polypeptide chains of approximately 450 amino acid residues, in an α-helical coiled-coil configuration. The N-terminal portion presents antigenic variations but has high homology except for the first 11 amino acid residues that define the different serotypes, of which 120 have been identified to date. The C-terminal half is conserved and contains multiple repeat regions (Fischeti, 1991).

Some of the 120 different serotypes of group A streptococci have been consistently found to be more frequently associated with RF, whereas others are more often associated with acute glomerulonephritis. These serotypes or strains are called rheumatogenic and nephritogenic, respectively (Stollerman, 1997).

The M protein is the most important bacterial antigenic structure and shares structural homology with α-helical coiled-coil human proteins like cardiac myosin, tropomyosin, keratin, laminin, vimentin, and several valvular proteins. The pathogenic mechanisms involved in the development of RF and RHD are not fully understood. It is considered that the molecular mimicry mechanism is responsible for the cross-reaction between streptococcal antigens and human tissue proteins, mainly heart tissue proteins in susceptible individuals. It is now clear that the disease is mediated by both humoral and cellular immune responses and that the cellular arm of the immune response is more closely involved in the development of RHD.

The incidence of RF in developed countries has declined over the past decades. However, the prevalence in developing areas is still high, having been estimated as up to 24 in 1000 individuals (Stollerman, 1998). Data from the World Health Organization (WHO) have shown that 25–40% of cardiovascular diseases in developing countries are due to RF. RF occurs most frequently among children and adolescents between the ages of 5 and 18 years, coinciding with the age distribution of the highest prevalence of streptococcal infections. It occurs equally in males and females and it is more prevalent among groups of low socioeconomic status.

AUTOIMMUNE FEATURES

The pathogenesis of RHD depends on several host factors that mediate a pathologic autoimmune response triggered by a defensive immune response against *S. pyogenes*. Genetic predisposition is one of the leading factors contributing to the development of autoimmunity. Several HLA class II alleles have been associated with the development of humoral or cellular-mediated diseases and are considered as genetic markers. One explanation for the association of autoimmune diseases, such as RHD, with some HLA class II alleles could be the fact that these molecules expressed on the surface of antigen-presenting cells (APCs), e.g., macrophages, dendritic cells, and B lymphocytes, trigger activation of some T-cell populations upon specific self-antigen stimulation, leading to autoimmune reactions.

In both acute and chronic RHD, mononuclear cells (macrophages, T and B lymphocytes) infiltrate the heart (Raizada et al, 1983; Kemeny et al, 1989). T and B lymphocytes are able to react against self-antigens through molecular mimicry (Guilherme et al, 1995; Cunningham, 2000, respectively). It has recently been shown that the presence of cross-reactive antibodies in the heart leads to initial tissue inflammation through the action of complement, and to the destruction of myocardial muscle fibers and the valvular endothelial surface. T-cell infiltration takes place through the activated valvular endothelium and the upregulation of certain adhesion molecules, such as VCAM-1, promotes lymphocyte adhesion to the endothelium (Cunningham, 2003).

Furthermore, in acute rheumatic carditis, Aschoff bodies, the pathognomonic sign of the disease, develop in the myocardium and/or endocardium. The Aschoff body is a granulomatous lesion containing both T and B lymphocytes, macrophages, Anitschkow cells, multinucleated cells, and polymorphonuclear leukocytes (Virmani et al, 1999). It is interesting to note that different inflammatory cytokines, such as interleukin (IL)-1, tumor necrosis factor (TNF)-α, and IL-2 have been found, depending on the developmental phase of the Aschoff body (Fraser et al., 1997). These cytokines and others such as interferon (IFN)-γ play a role in the amplification and maintenance of rheumatic heart lesions.

T-cell recognition is mediated by the T-cell receptor (TCR). Combinations of genes for the TCR generate around 10^{18} possible receptors. Both receptor chains have three regions, designated the complementarity-determining regions CDR1, CDR2, CDR3; CDR1 and CDR2 of the TCR interact with major histocompatibility complex (MHC) molecules. The peptide side chains of the MHC–peptide

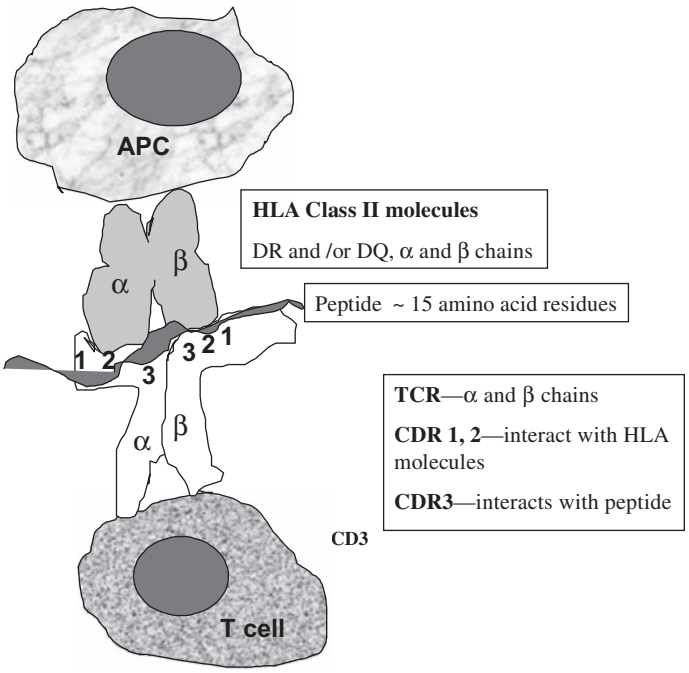

FIGURE 62.1 Trimolecular complex: T-cell receptor (TCR), MHC class II molecules, and immunogenic peptide interactions. Antigen-presenting cells (APCs), such as monocytes in the blood, macrophages in the tissue, dendritic cells, and B lymphocytes take up microbial antigens or self-antigens from damaged tissue, intracellular proteins, generating different peptides by enzymatic degradation. Peptides combined with MHC molecules are presented to $CD4^+$ or $CD8^+$ T lymphocytes, depending on the nature of the protein (extra- or intra-cellular, respectively). Interactions between amino acid residues take place. Complementarity-determining regions (CDRs) 1 and 2, in the α and β chains of the TCR, interact with MHC molecules. CDR3 interacts with the peptide. The peptide interacts only with certain predefined residues of the MHC molecules. In the case of rheumatic heart disease, streptococcal and self-antigens are presented mainly to $CD4^+$ T cells by HLA class II molecules (DR and DQ).

complex on the surface of APCs interact most closely with the hypervariable region of the TCR (CDR3) encoded by the V–D–J region on the TCR β chain. The interactions of HLA class II molecules (mainly DR and DQ) and antigen (microbial or self-antigens) drive the T-cell response (Figure 62.1) and can lead to pathologic or physiologic autoimmunity, as defined by Cohen (2001).

GENETIC FEATURES

RF/RHD occurs only in a select group of individuals, and certain genes appear to be responsible for the disease. Several genetic markers and some molecules involved in the control of immune responses have been studied. Thus, Patarroyo et al. (1979) described an alloantigen on the surface of B cells, designated 883, which was present in high frequency in RF patients. The alloantigen 883 is probably related to the HLA class II molecules. A monoclonal antibody, named D8/17, was produced against B cells from RF patients bearing the 883 alloantigen; however, this monoclonal antibody recognizes another antigen with variable levels of expression on the surface of B cells of RF patients (10–20%). The D8/17 antigen was present in increased frequency in RF patients (90–95%) (Zabriskie et al.,1985).

Association between different HLA class II antigens and RF/RHD has been found in several populations (Table 62.1). HLA-DR7 was the allele most consistently associated with RF (Guilherme et al., 1991; Ozkan et al., 1993; Weidebach et al., 1994, Guédez et al., 1999; Visanteiner et al., 2000; Stanevicha et al., 2003). The association of DR7 with different DQ-B or DQ-A alleles seems to be associated with the development of multiple valvular lesions (MVLs) or mitral valve regurgitation (MVR) in RHD patients (Guédez et al., 1999; Stanevicha et al., 2003). HLA-DR53, another HLA class II molecule, is in linkage disequilibrium with HLA-DR4, -DR7, and -DR9. This allele strongly associated with RF/RHD in two studies with mulatto Brazilian patients (Guilherme et al., 1991; Weidebach et al., 1994), but not in Brazilian white patients (Visanteiner et al., 2000). Although

[†]Defined by RFLP study, 13.81 kb fragment corresponds to the HLA DR53 antigen.
[‡]Studies from Egypt, Japan, Latvia and Mexico employed molecular methods (PCR).
MVL, multivalvular lesions; MVR, mitral valve regurgitation.

DR53 had not been described in previous studies, DR4 and DR9 were associated with RF in American white patients and Arabian patients (Ayoub et al., 1986; Rajapkase et al., 1987), whereas in Egyptian and Latvian patients, DR7 was associated with the disease (Guédez et al., 1999; Stanevicha et al, 2003) (see Table 62.1). In Japanese RHD patients susceptibility to mitral stenosis seems to be in part controlled by the HLA-DQA gene or by genes in close disequilibrium linkage with HLA-DQA*0104 and DQB1*05031 (Koyanagi et al., 1996). HLA-DQA*0501 DQB*0301 with DRB1*1601 (DR2) was associated with RHD in a Mexican Mestizo population (Hernandez-Pacheco et al., 2003) (see Table 62.1). The differences in HLA class II alleles associated with the RF/RHD in different populations are probably due to the ability of these HLA molecules to present various streptococcal epitopes.

ENVIRONMENTAL INFLUENCES

Low socioeconomic status is a marker of regions where RF and RHD are still prevalent. Overcrowding, poor living conditions, and reduced access to healthcare facilitate the spread of streptococcal infections and the development of the disease in individuals with a genetic predisposition. Cold and/or humid climates and high altitude may also increase the prevalence of the disease (Jarvis, 2003).

PATHOGENIC MECHANISMS

The pathogenic mechanisms involved in the development of RF/RHD are not fully understood. However, RF/RHD is the most convincing example of molecular mimicry in

human pathologic autoimmunity, given the cross-reactions between streptococcal antigens and human tissue proteins, mainly heart tissue proteins, which follow throat infection by *S. pyogenes* in susceptible individuals.

RHD is mediated by both humoral and cellular immune responses, but data described in the past 20 years by us and others define RHD as an essentially T-cell-mediated disease. The presence of human and animal antibodies against streptococcal antigens and human heart tissue proteins were described more than 50 years ago, but their role in the development of heart lesions was unknown. Several studies conducted by the Cunningham group showed that cross-reactive antibodies could bind to the endothelial surface, leading to inflammation, cellular infiltration, and valve scarring (Galvin et al., 2000). The upregulation of the adhesion molecule VCAM-1 after binding of cross-reactive antibodies to the valvular endothelium facilitates cellular infiltration (Roberts et al., 2001). These data definitively established the role of the heart tissue cross-reactive antibodies in the early stages of inflammation and T-cell infiltration in RHD lesions.

We shall first describe the major humoral features, followed by the cellular data that have contributed to the current knowledge of autoimmune reactions in RHD, considered to be the human model *par excellence* for post-infection autoimmune diseases.

Humoral Immune Response

Heart-reactive antibodies were first described by Calveti (1945). Kaplan and Suchy (1964) demonstrated the presence of streptococcal and anti-heart cross-reactive antibodies in sera of animals immunized with streptococcal cell wall products, and in sera from RF and RHD patients. They coined the term "biology mimicry" to explain the mechanism for the observed cross-reactivity between human and streptococcal antigens. Kaplan (Kaplan and Svec, 1964) also found immunoglobulins and complement bound to the myocardium of patients with acute RF. After this initial work, several studies were conducted using sera from immunized animals and humans, or monoclonal antibodies, demonstrating the presence of cross-reactive antibodies to streptococcal antigens and human proteins. Among human proteins, cardiac myosin is one of the most studied and seems to be a major cross-reactive antigen [reviewed by Cunningham (2000)].

We have recently analyzed the humoral response against overlapping peptides of the N-terminal portion of the M5 protein and we have identified 11 immunodominant epitopes that are recognized by patients with mild RHD, most with associated Sydenham chorea (Faé et al., 2004). Antibodies from patients with severe RHD recognized five N-terminal epitopes. Only two epitopes, M5(83–103) and M5(181–200), were recognized by antibodies from mild and severe RHD patients (Figure 62.2).

Group A streptococcal antigens, such as hyaluronic acid, M protein N-terminal epitopes, cell wall components (rhamonose, N-acetyl-glucosamine, and peptidoglycan–polysaccharide complexes), and pyrogenic toxins cross-reacted with human proteins, such as laminin, keratin, actin, vimentin, myosin, and tropomyosin [reviewed by Cunnimgham (2000)].

Cellular Immune Response

Studies of the cellular arm of the immune response began in the early 1970s. In light of the important role played by T cells in RF, studies have shown increased numbers of $CD4^+$ T cells in human peripheral blood when compared with normal individuals (Bathia et al, 1989). Also, peripheral T cells are able to recognize streptococcal cell wall and tissue antigens when assessed by proliferation assay of tritiated thymidine incorporation (Read et al., 1974; Gray et al., 1981). The cytotoxic activity of $CD8^+$ T cells from normal peripheral blood towards immortalized human heart cells was also described (Dale et al., 1981). A predominance of $CD4^+$ T cells in rheumatic heart lesions was the first evidence for $CD4^+$ T-cell involvement in RHD (Raizada et al, 1983). The isolation of T cells from heart valves of patients with RF led Yoshinaga et al. (1995) to compare the reactivity of phytohemagglutinin (PHA)-stimulated T-cell lines from heart valve specimens and peripheral blood lymphocytes; such T cells recognized cell wall and membrane streptococcal antigens, but failed to react with the M protein, myosin or other mammalian cytoskeletal proteins.

We have shown the significance of molecular mimicry between β-hemolytic streptococci and heart tissue by analysis of the T-cell repertoire leading to local tissue damage in RHD. Thus, infiltrating T-cell clones from heart lesions of RHD patients with severe RHD do recognize M protein peptides and heart tissue-derived proteins, and there are three M5 immunodominant regions (residues 1–25, 81–103, and 163–177) that cross-react with several heart protein fractions, mainly those derived from valvular tissue, with molecular masses of 95–150, 43–63, and 30–43 kDa (Guilherme et al., 1995). Employing a proteomics approach, we characterized a number of mitral valve proteins identified by molecular weight and isoelectric point. Four valve-derived proteins with molecular masses ranging between 52 and 79 kDa and different isoelectric points cross-reacted with the M5 immunodominant peptides and were recognized by proliferation assay with intralesional T-cell clones from patients with severe RHD (Faé et al., 2005). Figure 62.3 illustrates rheumatic heart lesions and shows the predominance of $CD4^+$ T cells in lesion sites, as well as streptococcal and heart tissue-derived protein reactivity with intralesional $CD4^+$ T-cell clones.

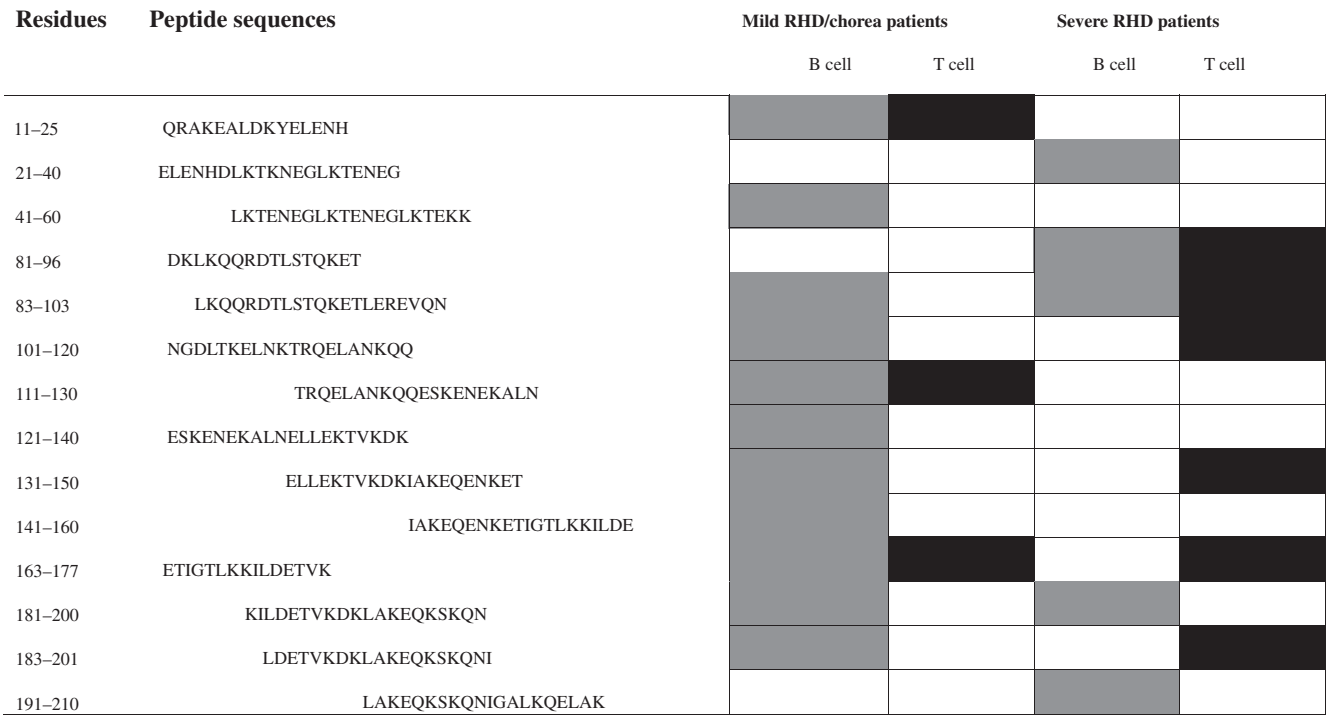

FIGURE 62.2 Immunodominant epitopes of the streptococcal N-terminal region of the M5 protein recognized by peripheral T and B lymphocytes in rheumatic heart disease (RHD) and Sydenham chorea patients. Peptide sequences M5(1–25), M5(81–96), M5(83–103), and M5(163–177) were based on the sequence of the M5 protein published by Manjula et al. (1984). For other peptides the sequences were taken from Miller et al. (1988). Gray boxes, B lymphocyte reactivity; black boxes, T lymphocyte reactivity.

Peripheral blood T lymphocytes from RF/RHD patients also recognize M5 peptides and valve proteins. The M5 epitopes that were preferentially recognized by T lymphocytes from patients with RF presenting mild carditis and/or Sydenham chorea (M5 epitopes 11–25 and 111–130) differed from those recognized by patients with severe RHD (M5 epitopes 81–96, 83–103, 101–120, 131-150, and 183-201). Both groups of patients recognized the M5(163–177) epitope (see Figure 62.2).

The M5(81–96) epitope is included in the M5(81–103) epitope, which is an immunodominant region recognized by intralesional T cells, and was preferentially recognized in patients with severe RHD and expressing HLA-DR7^{+}DR53^{+} (Guilherme et al, 2001). These data suggest a role for the HLA class II molecules DR7 DR53 in presenting the streptococcal immunodominant peptide to the TCR, and show the significance of the propensity of DR7 to cause severe RHD in Brazilian patients, and probably in other populations in which this class II allele is also associated with RHD and the development of valvular lesions (see Table 62.1). Several other valve-derived proteins were also recognized by peripheral blood T lymphocytes, including vimentin and other cytoskeleton proteins.

Myosin/M5 protein cross-reactive T-cell epitopes were investigated in mice immunized with intact cardiac myosin (Cunningham et al., 1997). Lymph-node T cells were tested by proliferation assays against overlapping M5 peptides, and seven regions, termed NT4/5/6, B1B2, B2, B2B3A, and B3A, were predominantly recognized. The NT5/6 and B1B2/B2 regions aligned with the M5 regions previously identified by our group, namely M5(81–103) and M5(163–177), respectively (Table 62.2). Robinson et al. (1991) obtained lymph node T-cell clones from mice immunized with recombinant M5 protein that recognized M5 epitopes; however, of the M5 epitopes recognized by the mouse T-cell clones, only one region, M5 (1–35), could be aligned with the M5 (1–25) region recognized by human heart-infiltrating T-cell clones (see Table 62.2).

Superantigens are proteins that polyclonally activate T cells through an MHC class II-dependent, but haplotype-unrestricted, mechanism. Proliferative responses to superantigens are limited to T cells expressing a particular TCR-BV gene, but are independent of the antigen specificity of the TCR. The M protein plays an important role in host antistreptococcal immune response and for this reason a putative superantigenic property was investigated in the 1990s. A superantigenic effect of streptococcal M5 protein preparations (pepsin-cleaved fragment, pepM5) for normal human T cells expressing TCR-BV2, BV4, and BV8 was found (Kotb et al., 1990; Tomai et al., 1990; Watanabe-

*M5(1–35) were recognized by lymph node cells and T-cell clones from BALB/c mice, and aligned with M5(1–25) recognized by human peripheral T cells and heart-infiltrating T-cell clones from rheumatic heart disease patients. NT5/6 and B1B2/B2 shared sequences with the M5(81–103) and M5(163–177) immunodominant regions recognized by human T cells.

Onishi et al., 1994). However, the superantigenic effect was later discounted by other studies that showed that the superantigenicity of pepM1 and pepM5 was due to contamination with pyrogenic exotoxins, which themselves had a potent superantigen effect on BV2-bearing human T cells (Fleischeir et al., 1992; Li et al., 1997).

We analyzed TCR-BV usage in peripheral blood and heart-infiltrating T-cell lines from patients with severe RHD, looking for oligoclonal β chain expansions in line with antigen-driven immune responses. Our results showed the expansion of several BV families with oligoclonal profiles among heart-infiltrating T cells, favoring the absence of superantigenicity of M proteins in RHD patients (Guilherme et al., 2000).

Cytokines

The cytokine pattern produced by helper T (Th) cells in response to a given antigen is crucial in driving the humoral or cellular immune response.

RF exhibits different clinical features, such as arthritis, chorea, carditis, erythema marginatum, and subcutaneous nodules. Each may involve particular autoantigens as targets of pathologic autoimmunity. Arthritis and mild RHD, frequently associated with chorea, are partly due to a pathologic autoimmune reaction, probably mediated by Th2-type cytokines and leading to an exaggerated humoral response, as reported by several authors [reviewed by Cunningham (2000)]. On the other hand, severe RHD is mediated mainly by T lymphocytes by a delayed-hypersensitivity type reaction, leading to local inflammation, as mentioned above.

The evaluation of proinflammatory cytokine levels produced by peripheral blood and tonsillar mononuclear cells after streptococcal antigen and pokeweed mitogen stimulation from RF/RHD patients without congestive heart failure showed different patterns with peripheral blood mononuclear cells (PBMCs) or tonsillar cells. TNF-α, IL-1, and IL-2 were overproduced by PBMCs but underproduced by tonsillar mononuclear cells (Miller et al., 1989). Increased production of IL-2 in patients with acute RF or active RHD has been reported, with these patients also showing high numbers of $CD4^+CD25^+$ T cells, suggesting expansion of activated $CD4^+$ T cells in peripheral blood during the active phase of the disease (Morris et al., 1993).

In heart lesions, during the acute phase of RHD, the production of IL-1, TNF-α, and IL-2 correlated with the progression of the Aschoff nodule (Fraser et al., 1997). Recently, we showed that intralesional mononuclear cells from heart lesions predominantly secrete IFN-γ and TNF-α in both acute RF and chronic RHD, with low IL-4 production (Guilherme et al, 2004). The predominant Th1-type cytokine produced mainly by $CD4^+$ T cells infiltrating valvular tissue could mediate the severe RHD valve lesions, and an ability of myocardial infiltrating cells to produce regulatory cytokines could contribute to a milder degree of myocardial damage in RHD.

ANIMAL MODELS

In the 1980s it was demonstrated that macrophages of mice infected with group A streptococcus extracts could induce heart lesions when transferred to syngeneic recipients, as well as a specific response to syngeneic heart extracts *in vitro*; this model suggested a key role for macrophages, involving the selection of antigens for presentation to the TCR (Dos Reis et al., 1982). It has been shown, by using M protein synthetic peptides, that immunization with certain peptides could induce inflammatory heart disease in mice (Huber and Cunningham, 1996).

Recently, injection of M6 recombinant protein in Lewis rats was shown to induce myocarditis and inflammatory valvular heart lesions similar to those seen in RHD. A lymph

node $CD4^+$ T-cell line obtained from a rat immunized with M6 recombinant protein responded to the M6 recombinant protein and cardiac myosin by a proliferation assay (Quinn et al., 2001). Following their experiments in animal models, the same group characterized different segments of cardiac myosin capable of inducing myocarditis or valvulitis (Galvin et al., 2002); they described cardiac myosin S2 region epitopes which induced autoimmune myocarditis associated with an upregulation of inflammatory cytokine production in Lewis rats, but without induction of valvulitis (Li et al, 2004).

IMMUNOLOGIC MARKERS IN DIAGNOSIS

Acute-phase reactants and particularly C-reactive protein are useful for diagnosis of acute RF, for exclusion of other diseases, and for monitoring inflammatory activity (Binotto et al., 2002). Elevated or rising levels of antistreptolysin O (ASO) are used to document a previous infection with group A streptococcus, there being a remarkable response during the acute phase of RF. The specificity of this test is 93% when ASO levels are above 960 IU/ml. The detection of autoantibodies and T-cell reactivity of patients with RF and RHD in the sera and peripheral blood, respectively, against streptococcal M protein could help to evaluate the autoimmune responses, but are not currently used for diagnosis.

TREATMENT AND OUTCOME

Prevention of initial attacks of RF requires the eradication of group A streptococcus from the pharynx. Antibiotic therapy is recommended. Benzathine penicillin G is the antibiotic of choice for primary and secondary prevention of RF. In cases of penicillin allergy, other antibiotics should be used as recommended (Dajani et al, 1995). During episodes of arthritis, salicylates continue to be the first-line treatment, but other nonsteroidal anti-inflammatory drugs can also be used. Moderate-to-severe carditis is usually an indication for cortiscoteroids, although efficacy in reducing sequelae has not been proven.

CONCLUDING REMARKS AND FUTURE PROSPECTS

RF/RHD is the most convincing example of molecular mimicry in which the response against *S. pyogenes* triggers autoimmune reactions with human tissues. The development of RHD involves a complex interplay of autoimmune reactions in which several major factors are implicated. $CD4^+$ T lymphocytes are the prime effectors of heart lesions, and display a degenerate pattern of antigen recognition. Several self-antigens, such as vimentin, myosin, and other mitral valve-derived proteins, are recognized by reason of molecular mimicry of streptococcal-immunodominant peptides, particularly in individuals with a genetic predisposition. Some HLA class II alleles have been shown to be genetic markers of susceptibility to RF, particularly HLA-DR7 which is associated with RHD in several countries with populations of different genetic backgrounds. Furthermore, DR7 when combined with certain HLA-DQ alleles seems to be associated with the development of multiple valvular lesions in RHD patients. Autoimmune reactions are mediated mainly by heart-infiltrating $CD4^+$ T lymphocytes; however, a few $CD8^+$ T cells also infiltrate the heart lesions. Th1-type cytokines seem to predominate in heart lesions, especially in valvar lesions. In addition, the deficiencies in IL-4-producing cells in valvular tissue may contribute to the progression of the lesions.

All this information creates a new picture of the development of RHD, opening new possibilities for immunotherapy. Molecular knowledge of the autoimmune reactions mediated by intralesional T cells will certainly aid in the choice of streptococcal-protective epitopes for the construction of an effective and safe vaccine.

HISTORIC BACKGROUND

The role of autoimmunity in cardiovascular disease has long been a topic of investigation in the clinic and the laboratory. Years of research effort were devoted to establishing a link between streptococcal infection and rheumatic heart disease on the basis of an autoimmune response (see Chapter 62). Chagas' disease is believed to be based on a cross-reaction of antibodies to *Trypanosoma cruzi* with myocardial or cardiac conductive tissue (Cunha-Neto et al., 2004). Finally, post-pericardiotomy syndrome and postmyocardial infarction syndrome are sometimes cited as instances of an autoimmune response instigated by damaged or necrotic tissue (Maisch et al., 1979). This chapter reviews the evidence linking autoimmunity with two important forms of heart disease, myocarditis and dilated cardiomyopathy. It must be stated, *ab initio*, that immunologic testing has so far not been effective in allowing a clear distinction between autoimmune and other etiologies of these diseases.

The classic description of myocarditis was given by Corvisart in 1812 [reference in Gravanis and Sternby (1991)], but for many years progress in studying the disease was impeded by the uncertainties of clinical diagnosis. Definitive diagnosis was dependent upon autopsy examination. Interest in the disease increased in recent years because of the availability of better, antemortem diagnostic tools, especially the endomyocardial biopsy, greater understanding of the role of cardiotropic viruses, and the potential of new modalities of therapy.

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Myocarditis

While myocarditis may be asymptomatic, the major features include arrhythmias (palpitations, dizziness, syncope, or sudden cardiac death), embolic events, congestive heart failure, or cardiogenic shock. These clinical findings can be supported by electrocardiographic changes, such as nonspecific ST-T wave abnormalities and atrial or ventricular arrhythmias. Two-dimensional echocardiography, a noninvasive way of evaluating heart size and function, may show normal ventricular size with thick walls and decreased contractility early in the illness or progressive heart enlargement with thinning of the muscle in chronic cases. Biventricular enlargement is seen in chronic cases. A pericardial rub may be detected, indicating pericardial irritation with or

without a pericardial effusion. As the disease progresses, gallop rhythms and signs of congestive heart failure appear. The patient may recall a recent viral illness with symptoms of malaise, chills and fever, upper respiratory or gastrointestinal symptoms, myalgia and chest pain. The majority of cases, however, cannot be traced back to an obvious preceding illness. Most patients with myocarditis present with either left ventricular failure or arrhythmias as their only clinical signs.

None of the clinical features described here is diagnostic of myocarditis. Before the widespread use of the endomyocardial biotome, the diagnosis could only be established with certainty by postmortem examination (Mason and O'Connell, 1989). Even now, most patients who are diagnosed clinically with myocarditis do not meet the strict pathologic standards of the disease, referred to as the Dallas criteria.

Studies of the occurrence of myocarditis in North America, Europe, and Japan have suggested that the incidence varies widely in different areas (Jacobson et al., 1997). Prevalence figures of 1.06, 3.5, 5.4, and as high as 10 have been reported in different series (Gravanis and Sternby, 1991). The reasons for these wide differences are not known, but may be related to the differing diagnostic criteria used or may reflect exposures to different types and strains of cardiotropic viruses, as well as genetic differences in the host populations. The 5-year survival of biopsy-proven myocarditis in adults is only 56% (Grogan et al., 1995). In pediatric populations, the prevalence and mortality are even higher. Noren et al. (1976) described histologic evidence of latent myocarditis in 4.2% of accidental deaths of children and 16.7% of unexplained, unexpected deaths, suggesting that unsuspected myocarditis may be a significant cause of unexpected death in children (Liberthson, 1996).

Felker et al. (2000) and McCarthy et al. (2000) have demonstrated that the prognosis of cardiomyopathy in patients with myocarditis is dependent on the clinical pathologic classification of their initial disorder. Patients with fulminant myocarditis, who do not die within the first 2 weeks, have a survival rate which is virtually identical to that of age-matched controls. Patients with subacute myocarditis who develop persistent left ventricular dysfunction have an outcome that is virtually identical to that of patients with idiopathic dilated cardiomyopathy. Patients with chronic persistent myocarditis, while they continue to have myocardial inflammation, have no deterioration in ventricular function and usually have a normal survival. Patients with chronic active myocarditis and who have ongoing inflammation and fibrosis develop a restrictive cardiomyopathy severe enough to require transplantation within 2–3 years (Lieberman et al., 1991). Patients with giant cell myocarditis (Cooper et al., 1997) develop rapidly progressive mildly dilated but severely hypofunctional cardiomyopathy and have a life-expectancy, without vigorous treatment, that is measured in months.

The so-called Dallas criteria, the consensus of a group of cardiovascular pathologists, led to better standardization of the histopathologic examination (Aretz et al., 1986). Active myocarditis requires the presence of mononuclear inflammation associated with adjacent myocyte damage (Figure 63.1). Myocyte damage can take the form of necrosis or myocyte vacuolization. The term borderline myocarditis is applied when an unequivocal diagnosis of myocarditis cannot be made either because the inflammatory infiltrate is too sparse or because the damage to the myocyte is not clearly demonstrable (Figure 63.2). The terminology used for subsequent biopsies is ongoing, resolving or resolved myocarditis. Ongoing myocarditis indicates persistent myocardial inflammation associated with myocyte damage. Resolving myocarditis resembles borderline myocarditis, but reparative fibrosis is evident. Resolved or healed myocarditis is diagnosed if no inflammatory infiltrate is seen.

The Dallas criteria also require that myocarditis must be distinguished from the histologic pattern of myocardial injury evident in ischemic heart disease. The inflammatory infiltrate in myocarditis is composed primarily of mononuclear cells, although in the more acute phases polymorphonuclear cell infiltration is common. A prominent eosinophilia is seen in hypersensitivity myocarditis.

The Dallas criteria, which have been used extensively for clinical trials, may be too insensitive to diagnose many patients with inflammatory heart disease. Utilizing the Dallas criteria even in patients who have died of myocarditis, and with five tissue samples, it is only possible to establish a histologic diagnosis of myocarditis in approximately

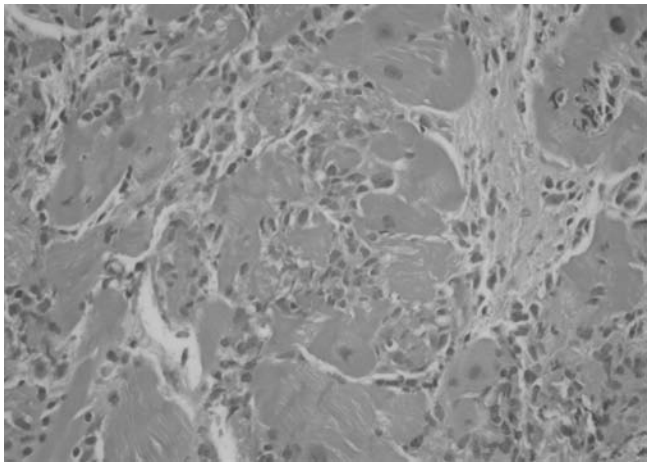

FIGURE 63.1 Lymphocytic myocarditis. There is a heavy infiltrate of large activated lymphocytes throughout the myocardium. Myocyte necrosis is noted in the middle of this image. Fibrosis is present on the right side of the image. (H&E 400×). See color plate section.

FIGURE 63.2 Borderline myocarditis. *A*, A single cluster of perivascular lymphocytes is present. No myocardial damage is identified. (H&E 400×). *B*, A CD8 immunohistochemical stain highlights the infiltrating T lymphocytes. (H&E 400×). See color plate section.

54% of patients (Chow et al., 1989; Hauck et al., 1989). Additionally, in Towbin et al.'s (1994) study of children with suspected clinical myocarditis (67% of these patients had adenoviral infection), 13 of the 26 patients positive for viral nucleic acid by the polymerase chain reaction (PCR) did not display the histopathologic features that would allow the diagnosis of myocarditis to be established. Finally, Wojnicz et al. (2001) and Frustaci et al. (2003), utilizing upregulation of HLA by endomyocardial biopsy or the presence of antiheart antibodies as markers of an autoimmune response, identified patients with suspected myocarditis who appeared to respond to immunosuppressive therapy. It is anticipated that by utilizing other markers of immune activation it will be possible to identify a subpopulation of myocarditis patients who are likely to respond to immunosuppressive therapy.

There are several distinct histologic forms of myocarditis. Drug- or allergy-mediated myocarditis is characterized by an eosinophilic infiltrate. Fulminant myocarditis demonstrates intense infiltration in virtually all sections with marked myocyte necrosis (Figure 63.3). Chronic active myocarditis reveals ongoing myocardial inflammation associated with fibrosis and occasional giant cells (Lieberman et al., 1993). Giant-cell myocarditis is a rare but frequently fatal form of myocarditis (Figure 63.4) (Cooper et al., 1997). The victims are primarily young, healthy adults who die suddenly of heart failure or ventricular arrhythmia. Although cardiac transplantation may be curative, several instances of recurrent disease in the transplanted heart have been reported. Histologic findings in giant-cell myocarditis are diffuse myocardial necrosis with numerous multinucleated giant cells and a mixed inflammatory infiltrate of lymphocytes and macrophages. Collections of eosinophils are seen in some patients.

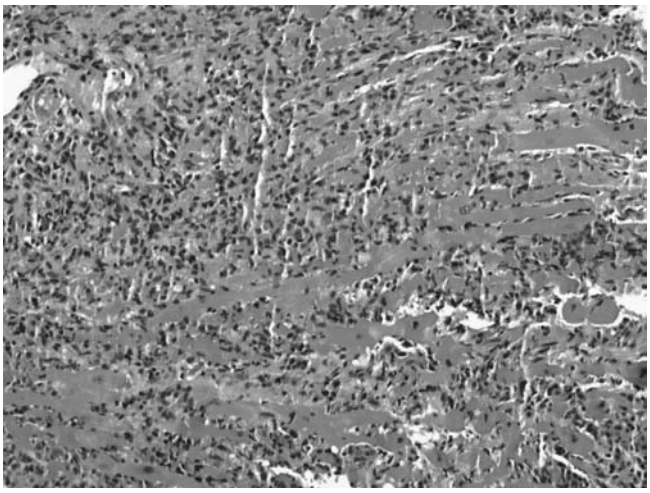

FIGURE 63.3 Fulminant myocarditis. The myocardium is replaced by a marked polymorphous inflammatory infiltrate composed predominantly of lymphocytes and macrophages with rarer eosinophils and neutrophils. Global myocyte injury and loss is noted. No giant cells are present. (H&E 100×). See color plate section.

Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is a chronic form of heart disease characterized by left and right ventricular dilatation and impaired contraction (Gravanis and Ansari, 1987). The clinical spectrum is broad, ranging from individuals with asymptomatic cardiomegaly to patients who present with severe congestive heart failure. Patients may also display symptoms or signs of arrhythmia or systemic embolization with or without congestive heart failure. Other signs include systemic or pulmonary venous congestion,

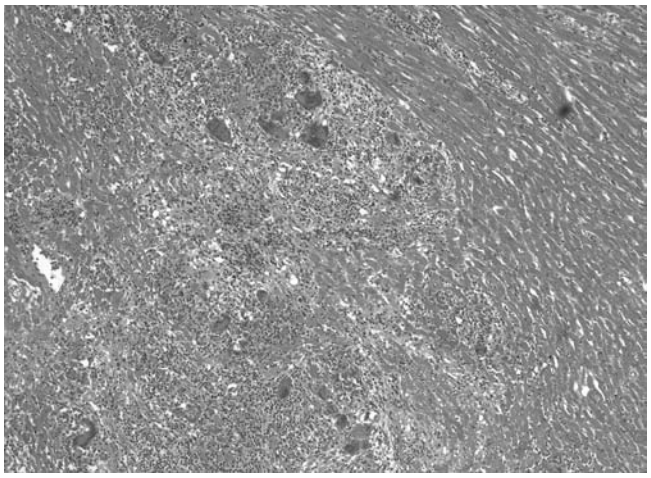

FIGURE 63.4 Giant cell myocarditis. The myocardium is infiltrated by a patchy and diffuse inflammatory infiltrate composed primarily of lymphocytes and macrophages. Multiple collections of giant cells are seen within the infiltrate along with eosinophils. There is significant injury and loss of myocytes in areas of inflammation, while adjacent myocardium is relatively uninvolved. (H&E 50×). See color plate section.

cardiomegaly, gallop rhythms, and mitral or tricuspid regurgitation. The diagnosis requires exclusion of heart failure due to other causes, such as coronary artery disease, toxic exposure, drug allergy, medication (adriamycin) effect or physical agent injury. Once heart failure is established in a patient with DCM, the expected outcome is poor, with a 5-year mortality of 46% (Grogan et al., 1995).

A large number of etiologic agents have been associated with DCM (Felker et al., 2000), including coronary artery disease, infections and metabolic, endocrinologic, and nutritional disturbances, as well as toxins and drugs. However, in approximately 50% of patients, no specific etiology can be identified. The same pathologic process probably results from a number of different etiologies.

In 1985, the prevalence of DCM in Olmsted County, Minnesota, was 36.5 in 100,000. African-American race and male gender were associated with increased risk (Cetta and Michels, 1995). The incidence of DCM in Malmö, Sweden, was reported to be 10 in 100,000 per year (Torp, 1981), and estimated in Great Britain at 0.7–7.5 in 100,000 per year, with a prevalence in 1985 of 8.3 cases in 100,000 (Williams and Olsen, 1985). In a nationwide study in Finland, the incidence of DCM among children and adolescents was 0.34 in 100,000 per year, with a prevalence in 1991 of 2.6 in 100,000. The number of new cases increased each year over the 10-year study period (Arola et al., 1997). Since a number of these patients utilize significant medical resources in their care or eventually require cardiac transplantation, there is a great need for early and definitive diagnosis.

It is still uncertain how many cases represent progression from myocarditis to DCM (Dec et al., 1985). In practice, endomyocardial biopsy is not routinely performed in patients with DCM, so that a possible link between these diseases is based mostly on relatively small case series and anecdotal case reports. For example, Kline and Saphir (1960) documented progressive myocardial failure and death in a series of patients within months to years after acute myocarditis. Miklozek et al. (1986) found that 12 of 16 patients diagnosed as having viral myocarditis had continued cardiac functional abnormalities. Abelmann (1984) reported that half of 16 patients had cardiac symptoms or physical evidence of persistent cardiac dysfunction after recovery from acute myocarditis. Most symptomatic relatives of DCM patients with left ventricular dysfunction have evidence of myocardial inflammation consistent with early or mild myocarditis (Mahon et al., 2002).

Like myocarditis, DCM may be associated with Coxsackievirus infection. In 50 infants and children with DCM, Ayuthya et al. (1974) found significantly increased titers of neutralizing antibody to Coxsackieviruses. Initially, Bowles et al. (1986) and Kandolf et al. (1987) demonstrated Coxsackievirus B-specific nucleic acid sequences in heart tissue of a small number of patients with DCM. Since then molecular testing has become increasingly sophisticated. Towbin et al. (1994) demonstrated that children with suspected myocarditis were PCR positive for viral etiologies on endomyocardial biopsy (26 of 38 samples from 34 patients). Additionally, the viral sequences demonstrated were more frequently adenoviral (15) than enteroviral (8).

In cases of DCM, the heart assumes a globular shape due to enlargement of all of the chambers, especially the left ventricle (Gravanis and Ansari, 1987). The histologic findings are generally nonspecific, and include myocardial cell hypertrophy and an increase in interstitial fibrous connective tissue. In areas of degeneration of the myocardial fibers, small clusters of lymphocytes may be seen. This finding may blur the distinction of DCM from myocarditis.

AUTOIMMUNE FEATURES AND IMMUNOLOGIC MARKERS

Circulating Antibodies

The ambiguities in diagnosing inflammatory disease of the heart muscle are evident. Although the availability of endomyocardial biopsy has helped to clarify the situation, many cases are still inconclusive. There is, at present, a need for noninvasive, inexpensive diagnostic procedures to distinguish autoimmune from other forms of inflammatory heart disease. Much evidence points to a significant role of autoimmunity in some animal models of heart muscle disease. It is logical, therefore, to propose that serologic tests, based on the demonstration of circulating autoantibodies to cardiac antigens, might be useful in the identifica-

tion of autoimmune forms of myocarditis and DCM in humans. The literature was recently reviewed by Caforio et al. (2002) and Rose and Cihakova (2004).

Immunofluorescence

Immunofluorescence tests utilize cardiac tissue of rat or human origin. Both frozen sections and isolated myocytes have been employed. Antibody generally localizes at the surface of the myocyte, giving a sarcolemmal or myolemmal pattern, or on the striations, producing a fibrillar pattern. Whether these two immunofluorescent patterns represent antibodies of different specificities is unclear, because both patterns can be seen in sera from mice immunized with purified cardiac myosin. A major problem in the interpretation of indirect immunofluorescence is the high prevalence of reactions obtained with sera from healthy control subjects. Maisch (1987) found that 91% of patients with myocarditis gave positive reactions with human or rat cardiocytes, but 31–35% of healthy controls showed similar reactions, although generally at lower levels. Neumann et al. (1990) used more conservative criteria, so that 59% of patients with biopsy-proven myocarditis were positive, as were 20% of patients with DCM. In contrast, none of the healthy controls and only 4% of patients with ischemic heart disease were positive in this test under the conditions used.

Western Immunoblot

The Western immunoblot is potentially more sensitive than immunofluorescence and is capable of identifying particular antigens recognized by heart-reactive antibodies. Neumann et al. (1990) detected heart-reactive antibodies in 48 of 103 samples from biopsy-proven myocarditis or DCM patients by immunofluorescence, whereas 97 of the 103 samples exhibited reactivity by Western immunoblotting. No single pattern of antigen reactivity was unique to patients with myocarditis or DCM, but myocarditis sera showed an elevated prevalence of antibody against myosin heavy chain, whereas cardiomyopathy sera exhibited a greater prevalence of reactivity against cardiac muscle actin. Many normal sera reacted with the same antigen, but generally in lower titers. A quantitative immunoassay, such as an enzyme-linked immunosorbent assay (ELISA) using purified human cardiac myosin heavy chain, therefore, is needed for clinical evaluation of these antibodies.

Immunoassay with Defined Antigens

Among the well-characterized antigens used for the study by immunoassay of antibodies in sera of patients with myocarditis and DCM are myosin (Neumann et al., 1990; Caforio et al., 1992), laminin (Wolff et al., 1989) and β1-adrenergic receptors (Limas et al., 1989), and the mitochondrial components, adenine nucleotide translocator (ANT) protein (Schultheiss et al., 1986) and branched-chain ketodehydrogenase (BCKD) (Ansari et al., 1988).

ANT facilitates the transport of ATP into the cytosol and the return of ADP to the inner mitochondrial space. Therefore, it plays a significant role in the energy metabolism of the myocardiocyte. Using a sensitive ELISA, Schultheiss et al. (1986) found that autoantibodies directed to ANT were significantly elevated in 24 of 32 patients with DCM. Control sera from patients with coronary heart disease, alcoholic cardiomyopathy, and hypertrophic obstructive cardiomyopathy were all within normal limits. Since there was less binding of the autoantibodies to the analogous ANT protein from the liver, there was a suggestion of specificity for the cardiac-specific isoform of ANT. Cloning and sequencing of the three isoforms of ANT confirmed the identity of the antigen and identified two protein sequences that react with sera from cardiomyopathy patients (Neckelmann et al., 1987).

IgG fractions of serum were found to inhibit nucleotide exchange in myocytes. Preabsorption of the antisera by isolated heart mitochondria reduced the inhibition of the ADP–ATP catalytic activity. In addition to showing that these antibodies are functionally effective, these experiments suggest that some determinants of the ANT protein are accessible on the surface of the myocardiocyte, possibly as epitopes shared with connexon or calcium channel molecules embedded in the sarcolemma (Morad et al., 1988; Schultheiss et al., 1988).

These results show that many patients with myocarditis and DCM develop autoantibodies to a number of cardiac constituents. Large-scale evaluation is necessary before it can be concluded that detection of any single antibody, or group of antibodies, is sufficiently sensitive and specific to replace the endomyocardial biopsy as a primary diagnostic tool. It does seem, even at this early stage of investigation, that a decline in some antibody titers during treatment may predict a favorable therapeutic response (Müller et al., 2000).

None of these antibodies to cardiac antigens is known to play a direct pathogenetic role in the disease. However, the presence of antibodies to β1-adrenergic receptors in DCM and Chagas' disease is highly suggestive of a direct pathogenetic effect, since the antigen is accessible on the surface of the myocardiocyte. β1-Adrenergic receptor antibodies can induce apoptosis in isolated adult cardiomyocytes (Staudt et al., 2003) and antibodies activating the receptors are associated with reduced cardiac function in chronic heart failure (Jahns et al., 1999). Antibodies to the mitochondrial antigens, ANT and BCKD, may also have adverse consequences on cardiac function. It is not clear, however, whether these antibodies have access to their target antigens *in vivo*. Morad et al. (1988) have provided evidence that ANT antibodies interfere with calcium flux in the isolated

myocardial cell, perhaps because a related antigen is expressed at the cell surface.

While the pathogenetic importance of antibodies is still controversial, the finding that reduction of immunoglobulins in plasma by an immunoadsorption column benefits cardiomyopathy patients provides strong evidence of their involvement (Wallukat et al., 1996; Dorffel et al., 2000; Müller et al., 2000). Although immunoadsorption does not establish the specificity of the autoantibodies that are depleted, reduction of certain immunoglobulin subclasses (IgG3) may be especially beneficial (Staudt et al., 2002).

There is little information about circulating T cells in human disease, although findings from studies in experimental animals indicate that they play a key role in inducing myocarditis (Smith and Allen, 1991).

Immunologic Assessment of Biopsies

In addition to studies of circulating antibody, immunologic methods can contribute to the diagnosis of heart disease by the identification of immunoglobulin and complement in biopsy specimens. Hammond et al. (1988) found that 55% of patients with active myocarditis had deposits of IgG and complement component C3 in their biopsies. Thirty-nine percent of borderline myocarditis (inflammation without myocyte necrosis) cases and 6% of DCM cases were also positive. Patients with other autoimmune diseases, such as systemic lupus erythematosus and scleroderma, sometimes showed deposits of IgG and C3 in their heart tissue, but these usually were coarse, granular deposits in the interstitial spaces of the myocardium or endocardium, probably representing immune complexes.

Immunofluorescence with defined antisera has been used to identify infiltrating cells in cardiac biopsies. Luppi et al. (2003) found that the myocardium of myocarditis and DCM patients was infiltrated by macrophages and $CD4^+$ and $CD8^+$ T lymphocytes. In the majority of patients, the T-cell receptor (TCR) repertoire was restricted with a polyclonal expansion of the Vβ7 gene family. Evidence of Coxsackievirus infection was also found.

The expression of MHC class I and class II antigens in biopsy specimens was evaluated by Herskowitz et al. (1990). In control samples, only low levels of MHC class I molecules were expressed on interstitial cells and vascular epithelium, while MHC class II could not be demonstrated immunohistologically. Increased myocardial expression of MHC class I and *de novo* expression of class II antigens were found in 85% of the myocarditis patients and 33% of the DCM patients.

GENETIC FEATURES

Because of the possible autoimmune origin of myocarditis and DCM in humans, and the well-documented association of experimental myocarditis with the major histocompatibility complex (MHC) in mice (Rose et al., 1988), a number of studies to determine the relationship with the human MHC (HLA) have been carried out. Anderson et al. (1984) reported that DCM patients had an increased frequency of HLA-DR4 and a decreased frequency of HLA-DR6. These findings were corroborated by Limas et al. (1990), who also demonstrated an increased frequency of HLA-DR4 in DCM patients. A genetic predisposition toward cardiac autoimmunity was demonstrated, in that 72% of $HLA\text{-}DR4^+$ patients had anti-β1-adrenergic receptor antibodies compared with 21% of $HLA\text{-}DR4^-$ patients. In the largest study to date, Carlquist et al. (1991) reconfirmed these findings and also found that the DR4-DQw4 haplotype conferred heightened risk of disease. In a meta-analysis of five studies, they confirmed that the DR4 association with myocarditis was sustained among different patient populations. No differences in disease phenotypes have been reported.

A predominance of myocarditis in males has been reported in a number of studies. The proportion of male patients is about 60% (Lieberman et al., 1991; Mason et al., 1995). In this respect, myocarditis differs from most autoimmune diseases, which predominantly affect females.

ENVIRONMENTAL FEATURES

Myocarditis has both infectious and noninfectious causes. As noninfectious agents of myocarditis, a number of drugs have been implicated, acting either directly as toxic agents or as triggers of an allergic response. This section deals with infectious myocarditis; there is little information on cardiac autoimmunity in other forms.

Acute myocarditis is associated with infections of many types, including bacterial, rickettsial, viral, mycotic, protozoan, and helminthic. Several viruses have been implicated in this disease and, in some cases, multiple viruses may be detected in the heart. In Europe and North America, among the most common agents are the enteroviruses and the adenoviruses. Grist and Bell (1974) reported that Coxsackievirus group B infections were associated with at least half of the acute cases of myocarditis. By immunofluorescence, Burch et al. (1968) found Coxsackievirus B antigen in the myocardium of 30.9% of routine autopsy specimens of myocarditis. Serotype B3 is identified most frequently. More recent studies have suggested that adenoviruses are more prevalent in pediatric patients (Bowles et al., 2003).

By using molecular genetic methods, enteroviral and adenoviral genomes were detected in 10–35% of endomyocardial biopsies from patients with myocarditis or DCM (Baboonian and McKenna, 2003; Pauschinger et al., 2004). Among the other viruses found were parvovirus, cytomegalovirus (CMV), influenza A virus, Epstein–Barr virus, and respiratory syncytial virus (Bowles et al., 2003).

Like other enteroviruses, Coxsackieviruses enter the alimentary tract and are acid stable. They multiply in the small intestine. Following replication, viremia develops, seeding the infectious agents in selected tissues. As an obligatory intracellular parasite, the virus must enter a cell through receptor-mediated endocytosis. The virus receptor determines the tropism of the virus. Cardiotropic CB3 employs myocyte surface molecules as receptors, whereas hepatotropic or diabetogenic virus strains utilize receptors on hepatocytes or pancreatic islet cells, respectively. The infection may cause cell death directly, or act indirectly to stimulate an immunopathic host response (Huber, 1997). Coxsackievirus B3 RNA can persist in the myocardium for many days after infectious virus is no longer demonstrable (Klingel et al., 1992) and may, even without the ability to multiply, cause ventricular compromise in the face of a stimulated immune system (Wessely et al., 1998).

The CB3 genome is a single molecule of positive-sense RNA of approximately 7400 nucleotides in length. The genome codes for four capsid proteins as well as for the nonstructural proteins necessary for viral replication. A comparison of cloned cDNA from cardiovirulent and noncardiovirulent strains showed that sites within a nontranslated region and in the capsid protein affect virulence (Tracy et al., 1996).

Nutrition also plays a role in determining susceptibility to viral myocarditis. Beck et al. (1995) demonstrated that mice fed a diet deficient in selenium and infected with a noncardiovirulent strain of CB3 developed severe myocardial damage. Virus isolated from the hearts was fully virulent; six point mutations distinguished the virulent strains. The accumulation of these multiple mutations may be the result of greater viral replication in the hearts of selenium-deficient mice and may be attributable to decreased immune responses compared to selenium-adequate mice (Levander and Beck, 1997). These results may shed light on the etiology of an endemic form of cardiomyopathy known as Keshan disease, seen primarily in selenium-deficient regions of China (Abelmann, 1984).

Chagas' disease is a major cause of heart muscle disease in Latin America, responsible for 50,000 deaths annually (Tanowitz et al., 1992). It is caused by the hemoflagellate, *Trypanosoma cruzi*, which is transmitted to humans via the bite of the reduviid bug, triatomina. Most patients initially have only mild, influenza-like symptoms, but 10–30% of infected individuals develop fulminant myocarditis. Chronic Chagas' disease may present with arrhythmias, thromboembolic events, and congestive heart failure. It represents a particularly lethal form of cardiomyopathy, as survival after presentation is two- to four-fold shorter than that of patients with other forms of DCM (Cunha-Neto et al., 2004).

Antibodies to a number of cardiac antigens, including fibronectin, laminin, and myosin are found in many patients with chronic Chagas' disease, as well as with other forms of DCM (Ballinas-Vedugo et al., 2003). Molecular mimicry between *T. cruzi* and heart disease has been cited as a mechanism to explain the production of autoantibodies during infection (Kalil and Cunha-Neto, 1996). A number of candidate antigens have been described, including a heart-specific epitope of cardiac myosin heavy chain and a 12-amino acid peptide of Fl160, a 160-kDa protein on the surface of *T. cruzi* that mimics a similar protein found on mammalian axonal and myenteric plexus cells (Van Voorhis et al., 1991). The latter antibody is of special interest because of the occurrence of megacolon, megaesophagus, and other neuropathies during chronic Chagas' disease. Among the other antigens described as possible initiators of cross-reactive responses are a peptide of the second extracellular loop of the β1-adrenergic receptor (Ferrari et al., 1995), a *T. cruzi* ribosomal protein R13 (Motran et al., 2000), a ribosomal P protein (Kaplan et al., 1997), and cha. The latter antigen is recognized by T-cells of patients as well as antibodies (Girones et al., 2001).

Kawasaki syndrome is an acute febrile disease of infants and young children that is often associated with myocarditis. Although the etiology is uncertain, available evidence implicates bacterial infection. Cunningham et al. (1999) showed that sera from 5 of 13 patients with Kawasaki syndrome recognized peptides from the light meromysin region of human cardiac myosin and had a different pattern of reactivity from acute rheumatic fever sera.

ANIMAL MODELS AND PATHOGENIC MECHANISMS

Since enteroviruses are most often implicated in human myocarditis and DCM, these agents have been widely used to investigate the pathogenetic mechanisms of these diseases. Although infections by CB3 are relatively common, the development of clinically significant myocardial disease in humans is quite uncommon, suggesting that differences in host response play a critical role in disease susceptibility. These differences are likely to be genetically determined and may relate to the expression of virus-specific receptor on heart tissue or to the immune response of the host. Because it is difficult to examine the role that genetic polymorphisms play in humans, investigators have developed models of Coxsackievirus-induced myocarditis in mice, for which a large number of genetically different, inbred strains are available.

All strains of mice tested developed acute myocarditis, starting 2 or 3 days after CB3 infection. The disease reached its peak on day 7 and gradually resolved, so that by day 21 the heart was histologically normal. In a few strains of mice, however, the myocarditis persisted (Rose et al., 1987). Further studies resolved CB3-induced myocarditis into two distinct phases (Rose et al., 1986). The first phase occurred during the first week after infection and was characterized by focal necrosis of myocytes and an accompanying focal

acute inflammatory response with a mixed-cell infiltrate consisting of polymorphonuclear and mononuclear cells. The second phase became evident about 9 days after infection and was fully manifest 15–21 days after infection. Histologically, the inflammatory process was diffuse rather than focal and consisted mainly of a mononuclear interstitial infiltrate. Little or no myocyte necrosis was evident at that time. Infectious virus could be cultured only during the first phase of disease; no virus was isolated after day 9. Heart-reactive autoantibodies were present in all strains that developed the second phase of myocarditis. Only certain inbred strains of mice developed this secondary autoimmune myocarditis. Susceptibility was determined primarily by non-H2 background genes, although H2-encoded differences influenced the severity of the autoimmune disease (Rose et al., 1988). This finding suggested that the second phase represented an autoimmune response initiated by molecular mimicry between the virus and heart antigens (Cunningham, 2004). Available evidence suggests that the autoimmune response depends upon virus-induced damage to the heart, since Horwitz et al. (2000) found that transgenic mice expressing interferon (IFN)-γ in their pancreatic β cells failed to develop CB3-induced myocarditis, even though the virus proliferated in other sites. This work challenges the concept of molecular mimicry as the mechanism initiating the autoimmune response and suggests that it is due to a "bystander effect" (Rose, 2000). The virus infections may serve as an adjuvant for the cardiac antigens liberated during the viral infection of the heart (Rose, 2000).

The demonstration of autoantibodies in the late phase of CB3-induced myocarditis provided the opportunity to evaluate the pathogenic significance of the autoimmune response. The first step was characterization and isolation of the target antigen. Alvarez et al. (1987) and Neu et al. (1987a) showed that cardiac myosin heavy chain was the major antigen. Using purified mouse cardiac myosin incorporated in complete Freund's adjuvant (CFA), Neu et al. (1987b) were able to produce cardiac lesions that resembled the late phase of CB3-induced myocarditis. Moreover, the inbred strains of mice that were genetically susceptible to the late-phase disease were also susceptible to myosin-induced myocarditis, whereas the strains resistant to the autoimmune phase following viral myocarditis were also resistant to myosin-induced myocarditis. The disease is also induced by short peptides derived from cardiac myosin heavy chain, and by injecting dendritic cells loaded with peptide (Pummerer et al., 1996; Kohno et al., 2000; Eriksson et al., 2003). Taken together, these investigations show that the late phase of CB3-induced myocarditis, which occurs in a few genetically susceptible strains of mice, results from an autoimmune response to cardiac-specific determinants on the myosin heavy chain molecule.

Coincident with the humoral autoimmune response to myosin among both CB3-infected and cardiac myosin-immunized mice, autoreactive T cells are evident. Huber and Job (1983) demonstrated that CB3 infection of BALB/c mice results in the induction of two populations of cytotoxic T cells, one of which is specific for CB3-infected myocytes and one specific for uninfected myocytes. Although the antigen specificity of the latter population has not been determined, Huber et al. (1988) suggested that the reactivity was directed against novel determinants that were expressed on the myocyte surface as a consequence of altered myocyte metabolism. Neumann et al. (1991) reported that spleen cells from CB3-infected mice respond to stimulation *in vitro* with myosin. Also, Smith and Allen (1991) were able to demonstrate, in mice immunized with cardiac myosin, the presence of myosin-specific spleen cells by stimulation *in vitro* of cellular proliferation. Mice depleted of either $CD4^+$ or $CD8^+$ T cells failed to develop myocarditis when immunized with cardiac myosin (Pummerer et al., 1993). Several groups have reported successful transfer of disease from immunized to susceptible mice with T cells (Pummerer et al., 1996; Afanasyeva et al., 2001a).

The pathogenetic role of antibody has also been investigated (see Chapter 7). Neumann et al. (1992) eluted antibody from the hearts of myosin-immunized or CB3-infected mice and showed that it reacted with cardiac myosin. These findings strengthened earlier reports of IgG and complement deposition in the hearts of mice with myocarditis and suggested that antibody as well as T cells participate in the pathologic process. They further suggested that myosin, an intracellular protein, is expressed on the cell surface wholly or in part during the disease. Liao et al. (1995) showed that myosin-specific monoclonal antibody can transfer disease in DBA/2 mice, which express myosin or a myosin-like molecule in the myocardial extracellular matrix. It is possible, therefore, that both humoral and cellular immune processes contribute in differing degrees to the continuing pathology in accordance with the mouse strain investigated. In A/J mice, the disease shows the classic signs of both type 1 helper T-cell (Th1) and Th2 responses (Afanasyeva et al., 2001a; 2001b). Both interleukin (IL)-12 and IL-4 are required for full expression of the typical lesions. Unexpectedly, IFN-γ downregulates the pathogenic immune response to cardiac myosin and reduces the post-viral phase of myocarditis (Afanasyeva et al., 2004; Fairweather et al., 2004a). IFN-γ-deficient mice develop a severe form of heart muscle disease, resembling DCM and often leading to functional evidence of heart failure (Afanasyeva et al., 2005).

Recent investigations direct attention to the critical role of the initial, innate immune response in switching from harmless autoimmunity to a pathogenic autoimmune response (Lane et al., 1991; 1992; 1993; Fairweather et al., 2004a; 2004b). Administration of pro-inflammatory cytokines, IL-1 or TNF-α, to genetically resistant B10.A mice confers susceptibility to myocarditis after challenge

with CB3 or murine myosin in CFA. On the other hand, antibody to TNF-α or IL-1 receptor antagonist prevents or delays the onset of myocarditis in genetically susceptible A/J mice, leading to the conclusion that these early inflammatory mediators are required for autoimmune myocarditis, possibly by inducing nitric oxide and reactive oxygen intermediates (Rose and Hill, 1996).

Myocarditis can be induced in mice by other viruses, including mouse CMV, a herpes virus. Sublethal mouse CMV infection of BALB/c mice induces inflammation of the heart similar to that seen in the CB3-induced disease of mice (Lawson et al., 1992; Lenzo et al., 2003). Infectious virus was not detected in the heart after 10 days, but antibodies to cardiac myosin were evident. As described above, Chagas' disease in humans is caused by *T. cruzi*, and is also associated with autoimmunity to cardiac myosin heavy chain (Cunha-Neto et al., 2004). Thus, immunity to cardiac myosin is a feature common to autoimmune myocarditis induced by diverse infectious agents, making it more likely that endogenous antigen of the host is responsible for the induction of disease.

Myocarditis and autoantibodies to cardiac myosin heavy chain occur spontaneously in mice expressing the human MHC molecule HLA-BQ8 (Taylor et al., 2004), showing that autoimmune disease can occur in the absence of infections.

Okazaki et al. (2003) reported that mice deficient in the programmed cell death-1 (PD-1) immunoinhibitory coreceptor develop DCM accompanied by production of antibodies to cardiac troponin I. Administration of monoclonal antibody to troponin induced cardiac dilatation and dysfunction, indicating that different cardiac-specific antigens may induce a similar autoimmune disease in mice.

TREATMENT AND OUTCOME

Until recently, the only treatment for myocarditis and DCM has been supportive therapies, such as bedrest and treatment of heart failure, arrhythmias, and embolic events if present. In many centers, cardiac transplantation has become the eventual treatment of choice in patients with refractory heart failure. The role of immunosuppressive therapy in myocarditis remains controversial. Numerous reported studies on relatively small numbers of patients have generally found that, while some individuals respond well to immunosuppression (prednisone and cyclosporine), others fail to respond or even have serious adverse reactions that preclude continued treatment. The major problem at present is surely the difficulty in distinguishing immune-mediated cardiac disease from infectious, genetic or toxic forms of the disease. Obviously, until there are reliable biomarkers to distinguish autoimmune myocarditis/DCM, treatment cannot be rational or capable of evaluation.

A placebo-controlled study of the treatment of idiopathic DCM was performed by Parrillo et al. (1989). The study demonstrated that unselected patients with DCM overall did not benefit substantially from immunosuppressive therapy, but a small, if transient, benefit was demonstrated in patients who had histologic evidence of active inflammation by biopsy.

Mason et al. (1995) assigned a series of patients with a histopathologic diagnosis of myocarditis (based on the Dallas criteria) and a low left ventricular ejection fraction to receive conventional therapy, with or without a 24-week course of prednisone plus cyclosporine or azathioprine. The outcome assessed was improvement in the left ventricular ejection fraction at 28 weeks compared with a placebo control group. No significant functional improvement was seen with immunosuppressive therapy. It should be noted, however, that during the establishment of the trial as many as 2233 patients with a clinical and pathologic diagnosis of myocarditis were presented for entry by their cardiologists, but only 111 met the strict Dallas criteria; i.e., some 95% of patients with a preliminary diagnosis of myocarditis failed to fulfill the Dallas criteria. The patients who would be expected to benefit most from immunosuppressive treatment are those with primarily autoimmune rather than viral myocarditis.

This interpretation is favored by the report of Kühl and Schultheiss (1995), who selected 48 patients presenting with mild-to-severe heart failure and immunohistologic evidence of an active immunologic process on biopsy. After a 6-month treatment with 6-methylprednisolone, 23 experienced objective improvement in cardiac function. The suggestion of this study is that in a subgroup of patients with an active immunopathologic process immunosuppressive treatment will confer clinical benefit.

Wojnicz (2001) evaluated 202 patients with idiopathic DCM by endomyocardial biopsy. Eighty-four of these 202 had HLA class II^+ biopsies. Those patients were randomized to immunosuppressive therapy or placebo. While the major outcome of the trial (death, transplantation or hospitalization) was unchanged by treatment, the ejection fraction in the treated population rose from 24% to 36%, while it was virtually unchanged in the placebo group (25% to 27%). In addition, subjective parameters of improvement were noted at 3 months in 72% of the immunosuppressive therapy patients compared with only 21% of the control group. Frustaci et al. (2003) identified 112 of 652 patients with new-onset left ventricular compromise who had a presentation compatible with myocarditis. Forty-one of the 112 had progressive heart failure despite standard heart failure management. This patient population was treated with prednisone and azathiaprine. Twenty of the 41 patients responded while 21 did not. The investigators determined retrospectively that those who responded had antiheart antibodies by immunofluorescence, and those who failed to

respond had persistent virus demonstrated by PCR analysis of the endomyocardial biopsy. Additionally, Jones et al. (1991) demonstrated that in 20 patients with Dallas criteria-positive myocarditis, those with borderline myocarditis had a greater improvement in their ejection fraction by echocardiography and stroke work index from right heart catheterization than those with frank myocarditis. These studies suggest that there soon may be more sensitive and specific biomarkers for immune-mediated heart disease than are currently available by the Dallas criteria.

Different myocarditis populations may respond differently. Patients with fulminant myocarditis usually resolve spontaneously and there is suggestive evidence that immunosuppressive therapy may worsen the outcome. In contrast, the treatment of giant-cell myocarditis with immunosuppression may improve the prognosis by slowing progression of the disease (Cooper, 2002), suggesting that this form of the disease is an autoimmune variant.

Other therapeutic approaches have been based on the possible pathogenic role of humoral antibodies. As described above, several investigators reduced the level of circulating immunoglobulin by means of an immunoabsorption column, and showed improvement in cardiac function. McNamara et al. (2001) demonstrated in a trial of 72 patients with new onset cardiomyopathy that 2 g/kg of intravenous immunoglobulin failed to improve ejection fraction or survival when compared with placebo-treated patients. Importantly, both groups increased their ejection fraction by 14–16% at 6 and 12 months and had transplant-free survivals of 92% at 1 year.

On the premise that many patients with myocarditis or idiopathic DCM have an undisclosed persistent viral infection, Miric et al. (1994) treated a series of 180 patients with IFN-α or thymomodulin. Left ventricular function, exercise tolerance, and survival rate were significantly improved in patients given the immunomodulatory therapy. Kühl et al. (2003) treated 22 patients with proven viral myocarditis with IFN-β. The treatment was well tolerated. All patients cleared the viral genome and showed improved left ventricular function.

The above studies make it obvious that treatment of myocarditis and DCM is still problematic. As more is learned about the pathogenetic mechanisms in these diseases, treatments can be individualized.

PERSONAL THOUGHTS

The diseases described in this chapter exemplify the broad range of cardiovascular disorders with which autoimmune responses have been implicated. Until very recently the role of autoimmunity in cardiovascular diseases had been rather neglected. Yet, before the early 1960s, rheumatic fever was a major topic of investigation. Although the decline of rheumatic fever in the 1960s accounted for a loss of interest in this topic, it must be recognized that the studies of rheumatic fever were the stimulus for many current concepts of autoimmunity and autoimmune disease. The renaissance in cardiovascular immunology followed efforts to define the role of autoimmunity in myocarditis and DCM. There is now a substantial challenge in developing reliable and robust *in vitro* assays that define autoimmune heart disorders with the same sensitivity and specificity now available in autoimmune disorders affecting other major organs. These studies have also served as the impetus to delineate the contribution of autoimmunity to other enigmatic cardiovascular diseases such as atherosclerosis (see Chapter 64). Further, they have served as a general model for studies relating infection to the onset of autoimmune disease.

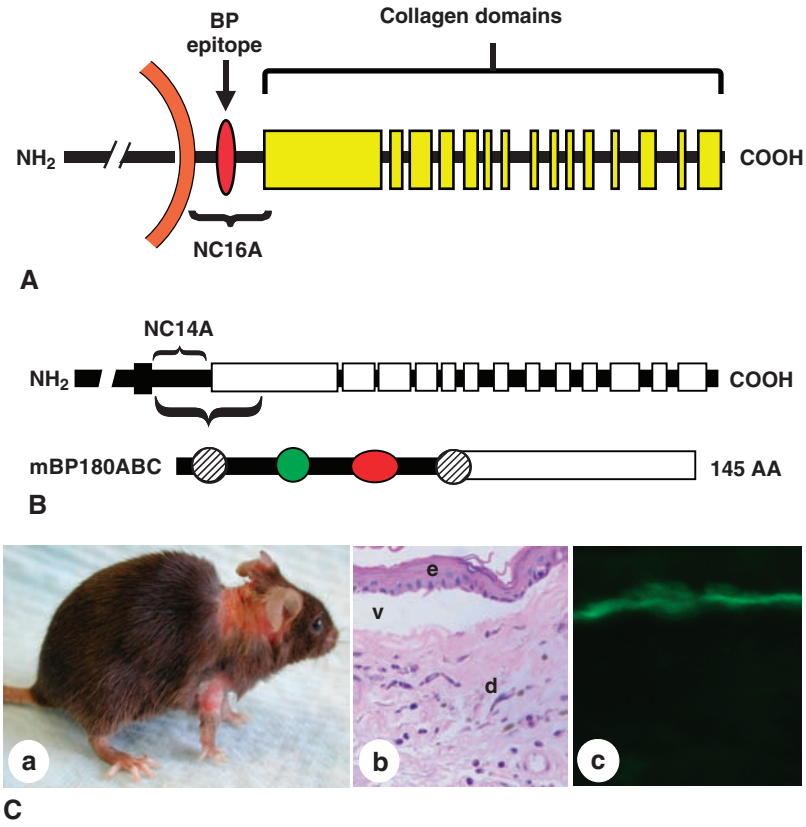

FIGURE 57.8 Active model of bullous pemphigoid (BP). *A*, Schematic diagram of the human BP180 antigen. The C-terminal extracellular region is made up of a series of collagen-like domains (yellow rectangles) interrupted by non-collagen domains (black bars). The major epitope (NC16A) recognized by BP autoantibodies is depicted by the red oval. *B*, Mouse BP180 antigen used to immunize mice. This antigen (referred to as mBP180ABC) contains the largest non-collagen domain (NC14A) and part of the largest collagen-like domain. mBP180ABC harbors four epitopes, one of which (red) is pathogenic. *C*, 8–10-week-old C57BL/6J mice immunized with mBP180ABC. Some of the mice developed BP-like skin lesions, starting the third week after the boosting immunization (a). Histologic examination shows subepidermal blistering (b). Direct immunofluorescence shows in-vivo deposition of autoantibodies at the basement membrane zone (c). d, dermis; e, epidermis; v, vesicle.

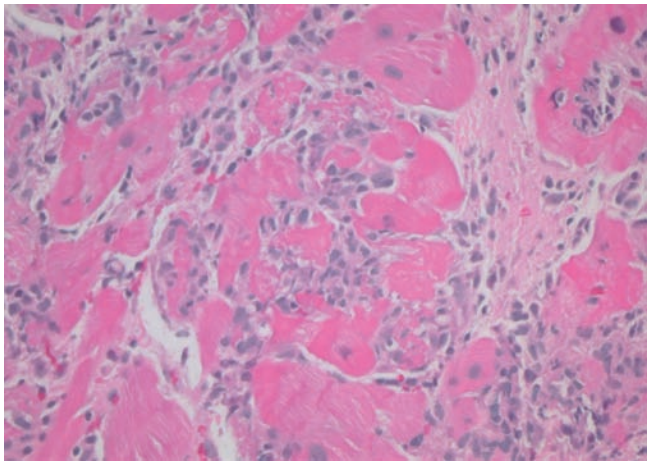

FIGURE 63.1 Lymphocytic myocarditis. There is a heavy infiltrate of large activated lymphocytes throughout the myocardium. Myocyte necrosis is noted in the middle of this image. Fibrosis is present on the right side of the image. (H&E 400×).

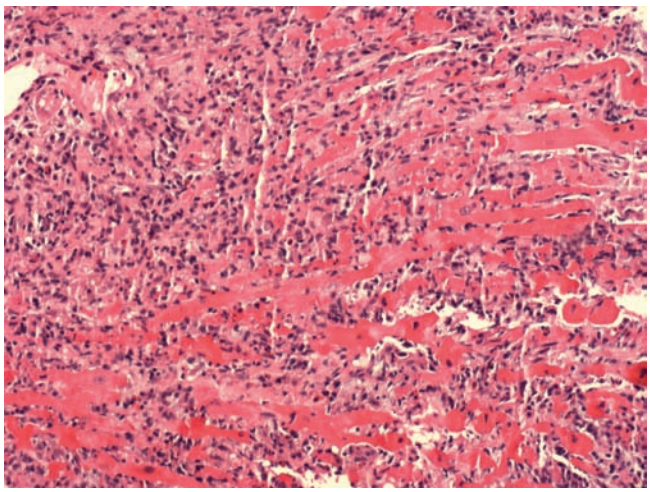

FIGURE 63.3 Fulminant myocarditis. The myocardium is replaced by a marked polymorphous inflammatory infiltrate composed predominantly of lymphocytes and macrophages with rarer eosinophils and neutrophils. Global myocyte injury and loss is noted. No giant cells are present. (H&E 100×).

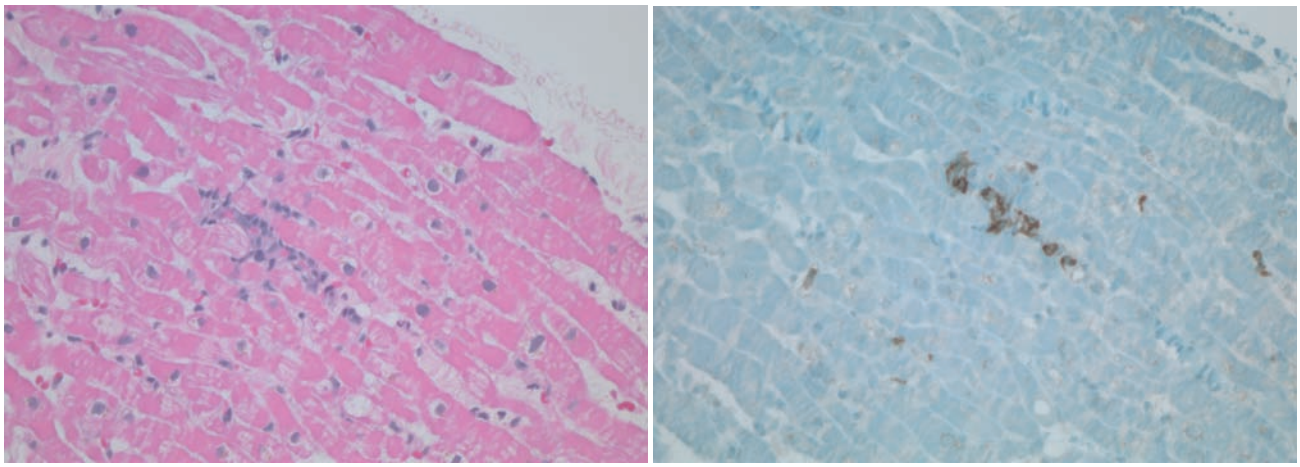

FIGURE 63.2 Borderline myocarditis. *A*, A single cluster of perivascular lymphocytes is present. No myocardial damage is identified. (H&E 400×). *B*, A CD8 immunohistochemical stain highlights the infiltrating T lymphocytes. (H&E 400×). See color plate section.

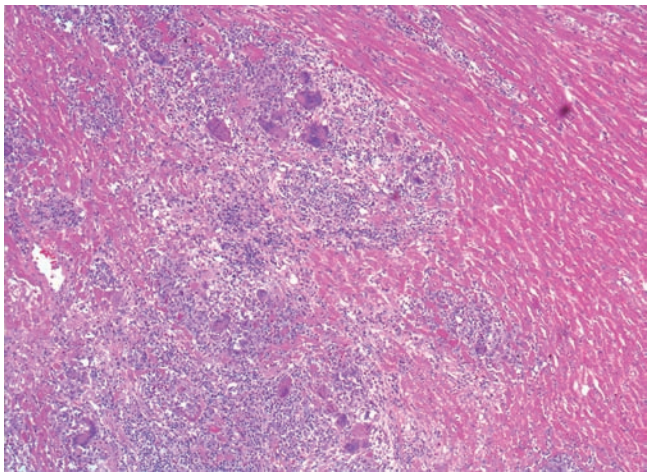

FIGURE 63.4 Giant cell myocarditis. The myocardium is infiltrated by a patchy and diffuse inflammatory infiltrate composed primarily of lymphocytes and macrophages. Multiple collections of giant cells are seen within the infiltrate along with eosinophils. There is significant injury and loss of myocytes in areas of inflammation, while adjacent myocardium is relatively uninvolved. (H&E 50×). See color plate section.

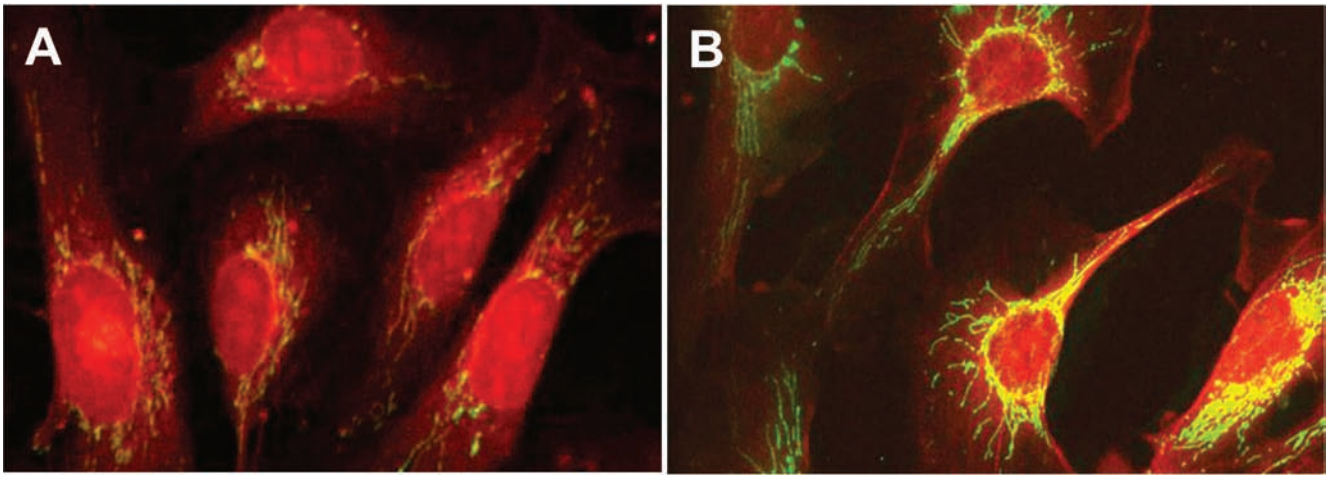

FIGURE 64.1 Acetone-fixed human umbilical vein endothelial cells stained in indirect immunofluorescence for the presence of HSP60 (FITC, green) and counterstained with TRITC-labelled phalloidin (red). A, unstressed cells, and B, heat stressed cells (42 °C for 30 min). Note the weak mitochondrial staining in A, most probably reflecting mild stress from the culture conditions, and the significant upregulation of HSP60 expression in the mitochondria and cytoplasm in B. Laser confocal scanning microscope, original magnification ×1000.

CHAPTER

64

Atherosclerosis: Autoimmunity to Heat-Shock Proteins

GEORGE WICK,* BLAIR HENDERSON,* MICHAEL KNOFLACH,† AGNES MAYR,‡ AND DAVID BERNHARD*

*Division of Experimental Pathophysiology and Immunology, Biocenter, Innsbruck Medical University, †University Hospital for Neurology, Innsbruck, Austria, and ‡Hospital Bruneck, Bruneck, Italy

The pathogenesis of autoimmune diseases is multifactorial. A literature search shows that most groups worldwide working on autoimmune disease continue to concentrate their efforts on the elucidation of an abnormally functioning immune system as the primary cause of clinically overt manifestations of autoimmunity. Our concept for the pathogenesis of autoimmune diseases, including early atherosclerosis, differs markedly from the general dogma, since it assigns a major importance to the *susceptibility of the target structure* to attack by preexisting humoral and cellular autoreactive immune effector mechanisms (Wick et al., 1987). This concept has been developed from studies in the obese strain (OS) of chickens, an animal model with an hereditary, spontaneously occurring, autoimmune disease that resembles human Hashimoto's thyroiditis (Wick et al., 1989). Soon after hatching, OS chicks present with symptoms of hypothyroidism that are due to a severe mononuclear cell (MNC) infiltration of the thyroid glands, leading to their complete destruction within 3–4 weeks. In the periphery, this event is accompanied by humoral and cellular autoimmunity against thyroglobulin. When OS chickens are crossed with birds from a normal healthy inbred strain, the F1 chicks still display the hallmarks of severe peripheral autoimmune reactivity, albeit without thyroid infiltration (Neu et al., 1985) (Table 64.1). Further analyses of F2 and back-cross generations have provided a rather unique picture, since in this model only a relatively small number of genes seem to be involved (Kroemer et al., 1989).

The development of spontaneous autoimmune thyroiditis in OS chickens is based on the presence of two sets of essential genes, one responsible for the autoreactivity of the immune system and the other for target organ susceptibility. The former comprises three to five dominant genes, while organ susceptibility is encoded by a single recessive gene (Hala, 1988). One of the dominant autoimmunity-associated genes is responsible for interleukin (IL)-2 hyperproduction, another for increased expression of the IL-2 receptor (IL-2R) (Kroemer and Wick, 1989). The role of the other two genes has not been identified, but they include neither a certain major histocompatibility complex (MHC) haplotype (*B* locus in chickens) nor a restricted, albeit preferential, use of a given T-cell receptor (TCR) V gene (Cihak et al., 1995). The recessive gene responsible for target organ susceptibility has not been identified, but preliminary evidence points to the possibility that it may be associated with a susceptibility of thyroid epithelial cells to viral infection (Kuhr et al., 1994; Hofmann et al., 2003).

This concept, which attaches a major importance to the role of the target structure in the development of organ-specific as well as systemic autoimmune diseases, has formed the basis of all subsequent work by our group in this field and has gained special momentum in the context of the development of our "autoimmune" hypothesis of atherogenesis (Wick et al., 2004). As described below, the original version of this hypothesis was based on the observation of a preexisting immunity in nearly all humans against a phylogenetically highly conserved group of antigens belonging to the stress proteins, also called heat-shock

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

proteins (HSPs) (Young and Elliott, 1989). Specifically, we have shown humoral and cellular immunity against HSPs belonging to the 60-kDa family (HSP60), which show high bacterial–human homology (Karlin and Brocchieri, 2000). This anti-HSP60 immunity can be induced by infection or vaccination, as well as *bona-fide* autoimmunity against altered autologous HSP60. This protective, beneficial anti-HSP60 immunity only becomes detrimental, leading to the development of the first inflammatory stages of atherosclerosis, when the target cells, in this case arterial endothelial cells (ECs), express the stress protein HSP60 as a response to their confrontation with classical risk factors for atherosclerosis, such as hypertension, diabetes, biochemically altered, e.g., oxidized, low-density lipoproteins (oxLDLs), and toxins, e.g., cigarette smoke. In other words, risk factors for atherosclerosis make the target cells susceptible to attack by a pre-existing immune reaction, and atherosclerosis is therefore the price we pay for maltreating our vascular system (Wick et al., 1995). The fact that atherosclerosis can afflict nearly everybody is based on two prerequisites: 1) the presence of adaptive as well as innate immunity against HSP60 in all healthy humans, as mentioned above; and 2) the subjection of mechanically (by arterial blood pressure) pre-stressed arterial ECs to unnatural additional stress conditions in the form of modern risk factors for atherosclerosis not "foreseen" by natural selection during phylogeny and human development. Clinically manifest atherosclerosis is classified as an age-associated disease, since early, still symptomless, lesions do not impair the reproductive capacity that in the past has driven the shaping of the human genome.

It should be emphasized, however, that our interest, as well as the validity of this concept, concerns only the initial stages of atherogenesis rather than the complicated late lesions. Furthermore, we exclusively focus on "conventional" atherosclerosis, which can afflict nearly everyone, rather than special forms, such as the genetically-determined familial hypercholesterolemia in LDL-receptor-deficient patients. This is also the reason why we only rarely resort to animal models of latter forms of atherosclerosis, e.g., LDL-receptor or ApoE knock-out mice.

DEFINITIONS AND EXPERIMENTAL BACKGROUND

The arterial wall is composed of four layers: 1) the innermost monolayer lining of ECs is separated by a basement membrane from 2) the so-called *intima*, which consists of connective tissue and a few smooth muscle cells (SMCs); 3) the *media* consists of SMCs, and the outer layer, 4) the *adventitia*, which connects the artery with its surrounding tissue, also harbors nerves and small vessels (*vasa vasorum*) that penetrate the wall of larger arteries, providing blood supply to areas that are too distant from the lumen to be maintained by simple diffusion. Atherosclerosis starts in the intima and until the early 1990s it was general dogma that so-called fatty streaks, cushion-like cholesterol-rich microscopically visible lesions, represented the first stage of the disease, later followed by more severe changes, so-called atherosclerotic plaques (Stary et al., 1994; 1995). The latter have a tendency to exulcerate and even calcify, leading to the formation of thromboses and hence sequelae such as myocardial infarction, stroke, and occlusion of peripheral arteries, e.g., in the legs.

Pathologists originally distinguished *arteriosclerosis* from *atherosclerosis*. The former, as the name implies, is characterized by thickening and hardening (sclerosis) of the arterial wall due to infiltration by MNCs, proliferation of pre-existing fibroblasts with increased formation of extracellular matrix (ECM) proteins, notably various types of collagen, and the immigration and subsequent proliferation of SMCs from the media into the intima. Atherosclerosis was considered a special form of arteriosclerosis, the hallmark of which is foam cells, i.e., macrophages and SMCs that have taken up biochemically modified LDL, e.g., oxLDL, via scavenger receptors. In recent years, this distinction has been abandoned by most authors and atherosclerosis frequently serves as a common term for the different forms of the disease, and is so used in this chapter.

In the past 20 years, reports pointing to inflammatory processes that take place within atherosclerotic lesions have appeared in the scientific literature with increasing frequency (Ridker, 1999; Ross, 1999, Hansson, 2001; Libby et al., 2002). However, these papers mainly concentrate on the histologic, electron microscopic, and immunohistologic analyses of advanced lesions where, in addition to the above-mentioned macrophages derived from blood-borne monocytes, T cells can also be demonstrated in high frequency (Hansson et al., 1989). Thus, histologic investigations of specimens from young adults secured within the framework of the PDAY (Pathobiological Determinants of Atherosclerosis in Youth) study originally did not mention

pathologic inflammatory processes in general, or identify the phenotype of lesion-infiltrating MNCs in particular (McGill et al., 2000).

Early in our work, we conducted an elaborate immunohistologic study of arterial specimens with early and mild lesions derived from young donors (younger than 35 years) and more severe lesions from old (older than 65 years) donors, and found clear evidence that the first cells to arise in the intima were not macrophages and SMCs but rather $CD3^+$ T-cells (Xu et al., 1990). The majority of these T cells infiltrating the intima were $CD4^+$ and carried the TCR$\alpha\beta$. They showed the characteristics of activation, i.e., expression of CD25 and HLA-DR. Interestingly, an unexpectedly high percentage of T cells in these early lesions were TCR$\gamma\delta^+$ (10–15% as compared to 1–2% in the peripheral blood). These cells mainly expressed the TCR V δ^1 chain, similar to $\gamma\delta^+$ T cells in the mucosa-associated lymphoid tissue (MALT), while the TCR V γ^9/δ^{2+} was present in the same frequency as in peripheral blood (Kleindienst et al., 1993). Here it is important to mention that $\gamma\delta^+$ T cells at different sites of the MALT show a preferential, non-MHC-restricted reactivity with HSP60, i.e., a bacterial antigen that apparently assumed an important antigenic role during evolution (Born, 1991).

In the course of our original immunohistologic studies, we also had the opportunity to analyze the carotid artery of a 1-year-old baby. Unexpectedly, we found considerable accumulations of MNCs in the intima at the arterial branching points, which are subjected to increased (turbulent) hemodynamic stress and are known to be predilection sites for the possible later development of atherosclerosis. As described below, we then performed an extensive series of experiments that led to the concept of the existence of a vascular-associated lymphoid tissue (VALT) as a so far unknown site of an (inner) surface line of defense (Wick et al., 1997; Waltner-Romen et al., 1998; Millonig et al., 2001). In a similar investigation on specimens from the PDAY study, we confirmed the presence of early inflammatory T-cell-dominated intimal infiltrations, a finding supplemented by the demonstration of dendritic cells (DCs) and mast cells. B cells were scarce and $CD56^+$ K/NK cells were not detected (Millonig et al., 2002).

In our attempts to elucidate the antigenic specificity of the intralesional lymphocytes, we resorted to the classical technique of inducing autoimmune diseases in normal animals. We immunized normocholesterolemic rabbits with human plaque proteins as well as plaque proteins derived from Watanabe rabbits, which develop hypercholesterolemia due to the genetically determined absence of the LDL receptor. Delipidated total plaque proteins were emulsified in complete Freund adjuvant (CFA) and used for the immunization. Ovalbumin (OVA) served as a negative control. Our original intention was to identify the culprit protein moiety among the plaque proteins in case atherosclerotic lesions could be induced by this approach (Xu et al., 1992). To our surprise, all three groups, including the OVA-immunized animals, developed atherosclerotic lesions that were histologically characterized by abundant intimal infiltration with MNCs, mainly lymphocytes. Since CFA was the only common denominator in these experiments, we then immunized rabbits with CFA alone, which again resulted in the development of atherosclerotic lesions. Since heat-killed mycobacteria are the main active component in CFA, we then focused on this constituent. It is known from other experiments that HSP60 of mycobacteria (mHSP65, a 65-kDa protein) is a qualitatively and quantitatively important component of these microorganisms (van der Zee, 1998). Immunization with recombinant mHSP65 had the same atherosclerosis-inducing effect as CFA alone. Immunization with mHSP65 plus feeding a cholesterol-rich diet significantly aggravated the development of these lesions. Furthermore, while the early inflammatory lesions in normocholesterolemic rabbits were still reversible, this was not the case for the severe lesions in immunized plus cholesterol-fed rabbits (Xu et al., 1996). We also included controls that were not immunized but only received a cholesterol-rich diet. While it was not unexpected that *in vitro* cultured T-cell lines derived from lesions of mHSP65-immunized rabbits showed a significant reactivity against this antigen, it was surprising that T cells derived from lesions of unimmunized hypercholesterolemic animals also displayed significantly higher stimulation indices in response to mHSP65, as compared to peripheral blood T-cells of the same animals (Xu et al., 1993a).

Similar experiments were then conducted in apoprotein E knock-out and wild-type C57/BL6 mice. In addition, immunization with oxLDL and a non-HSP60-containing adjuvant was performed in these animals. The results showed that the atherosclerosis that develops spontaneously in hypercholesterolemic mice is aggravated by immunization with mHSP65 (George et al., 1999), while induction of immunity to oxLDL had a protective effect (George et al., 1998). So, in addition to confirming the pro-atherogenic effect of HSP60, these studies also solved another controversy, i.e., they disproved a similar effect of immunity to oxLDL. Also, in the murine system, passive transfer of atherosclerosis was achieved by T cells from mHSP65 C57/BL6 immunized donors to histocompatible recipients (George et al., 2001). Furthermore, peroral induction of immune tolerance against mHSP60 made such animals resistant to the subsequent induction of atherosclerosis by appropriate immunization (Harats et al., 2002). As expected, mHSP65 immunized rabbits and mice also developed humoral antibodies against this antigen, but passive transfer via this mechanism has not yet been attempted.

Reactivity of human T-cells derived from advanced lesions against HSP60 has been described (Mosorin et al., 2000), but so far it has not been possible to perform similar

experiments with T cells harvested from early lesions that are clinically not yet apparent.

HEAT-SHOCK PROTEINS

HSPs are proteins that are expressed by prokaryotic and eukaryotic cells as a response to various stress factors, e.g., heat (hence the name), mechanical stress, toxins, and oxygen radicals (Young, 1992). HSPs are classified according to their molecular weights, which range from very large (90–100 kDa) to small (<10 kDa) (Craig et al., 1993). HSP60 is a special case since, as mentioned above, it is not only an important and highly antigenic component of bacteria and parasites, eliciting immune responses in all animals and humans, but also plays a major role in several autoimmune diseases. HSP60 is phylogenetically highly conserved. Thus, it shows over 95% homology between different bacterial species, and an overall 55% homology with eukaryotic, e.g., human, HSP60 (Jones et al., 1993). HSP60 executes an important physiologic task during the assembly and transport of intracellular proteins. In addition, it acts as a chaperone, i.e., it associates with cellular proteins under mildly stressful conditions, protecting them from denaturation (Benjamin and McMillan, 1998; Craig et al., 1993).

HSP60 is a mitochondrial protein (Figure 64.1). However, it is transported from that site into the cytoplasm and even to the cellular surface (Soltys and Gupta, 1997; Xu et al., 1994) where it seems to act as a danger signal for the innate and adaptive immune system. HSP60 is, of course, expressed by many cells of the body, but ECs are a special case because they are the first to be encountered by circulating antibodies and cells of the adaptive and innate immune system, respectively.

It has recently been shown that extracellular HSP60 can also bind passively to highly conserved pattern-recognition receptors (PRRs), i.e., Toll-like receptors (TLRs) and CD14 (Bulut et al., 2002; Habich et al., 2002). HSP60 belongs to the pathogen-associated molecular patterns (PAMPs), which are present on the surface of pathogens and also in solution. Binding of such ligands to TLRs leads to internalization of the ligand–receptor complex and initiation of signal transduction via the mitogen-activated protein kinase (MAPK) pathway (Akira et al., 2001). This activation is effected via various transcription factors, but mainly NF-κB. HSP60 acts as a ligand for TLR-4 and TLR-6, the former in association with CD14. The potential role of the TLR in the development of atherosclerosis has been reviewed recently by Michelsen et al. (2004); the focus is the triggering of signaling via TLR-4 by foreign pathogens and endogenously generated ligands. A recent report based on data from the BRUNECK study (Kiechl and Willeit, 1999) involving a very large number of volunteers suggests a significant role for TLR-4 polymorphism in atherogenesis (Kiechl et al., 2002). It remains, however, to be clarified if HSP60 binding to different TLR isotypes also involves alteration of signal transduction.

With respect to the adaptive immune response against antigenic determinants that are accessible on the surface of target cells, various scenarios are conceivable. Thus, peptides derived from autochronous HSP60 will be presented in the context of MHC class I molecules on the surface of ECs, where they can be recognized by HSP60-reactive $CD8^+$ cells. In addition, conformational HSP60

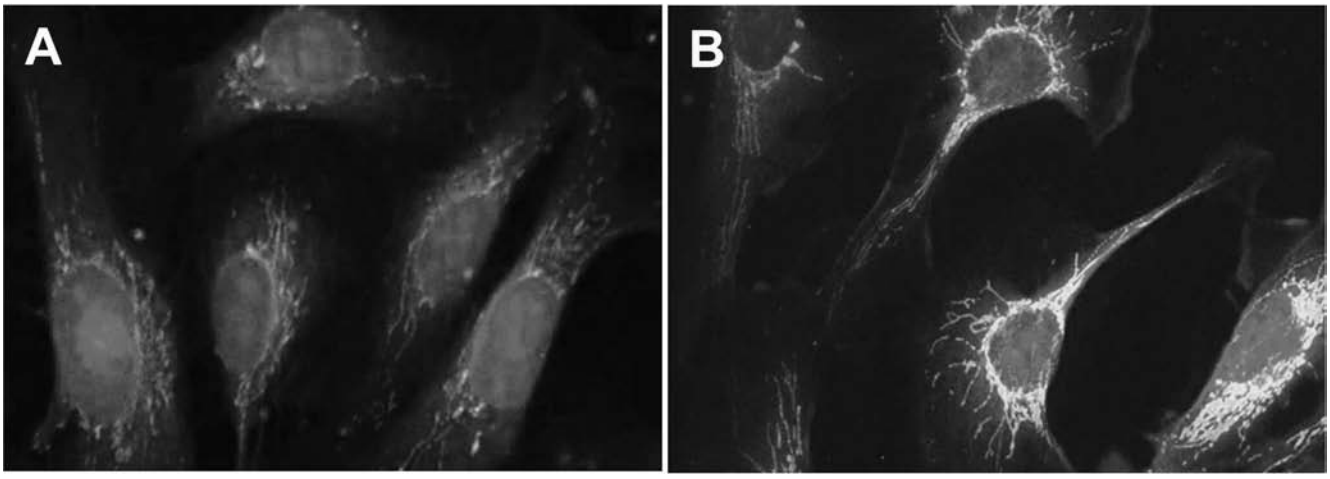

FIGURE 64.1 Acetone-fixed human umbilical vein endothelial cells stained in indirect immunofluorescence for the presence of HSP60 (FITC, green) and counterstained with TRITC-labelled phalloidin (red). *A*, unstressed cells, and *B*, heat stressed cells (42 °C for 30 min). Note the weak mitochondrial staining in *A*, most probably reflecting mild stress from the culture conditions, and the significant upregulation of HSP60 expression in the mitochondria and cytoplasm in *B*. Laser confocal scanning microscope, original magnification ×1000. See color plate section.

epitopes are also exposed on the surface of stressed target cells, where they can be recognized by specific antibodies that will lyse stressed, but not unstressed, cells via complement-mediated cytotoxicity or antibody-dependent cellular cytotoxicity (ADCC) (Schett et al., 1995). Furthermore, soluble HSP60 (sHSP60) that is released by stressed endothelial target cells themselves (Xu et al., 2000) or, to a greater extent, by necrotic cells into the circulation, can bind to the surface of ECs via TLRs and CD14, as described above, or be processed via the MHC class II antigen presentation pathway. In the latter case, they will be recognized by $CD4^+$ T cells or again by specific humoral antibodies. Finally, as mentioned above, γ/δ^+ T cells recognize HSP60 epitopes in a non-MHC-restricted fashion. sHSP60 has proven to be an inflammatory marker that is independent of other classical markers, such as C-reative protein (CRP) (Xu et al., 2000).

CLINICAL STUDIES

Having completed the studies in experimental animals that led to the formulation of our autoimmune hypothesis for atherogenesis (see below), we embarked on studies in a clinical setting within the framework of the BRUNECK study. This is a large population-based atherosclerosis prevention program that has been ongoing since 1990 and originally involved a cohort of nearly 1000 people of both sexes, aged 40–80 years (Willeit and Kiechl, 1993). This cohort is extensively assessed every 5 years with a great number of personal, physical, clinical and laboratory values recorded (Kiechl and Willeit, 1999). Among these, parameters reflecting inflammation in general and immune reactivity in particular are of special interest. The outcome of the three observation points to date, i.e., 1990, 1995 and 2000, have been published and extensively reviewed. In brief, it was shown that although the sera of all volunteers contain antibodies to mHSP65, antibody titers are significantly increased in those who display sonographically demonstrable atherosclerotic lesions (Xu et al., 1993b). Furthermore, such antibodies not only showed the expected high degree of cross-reactivity with HSP60 of other bacterial species (chlamydial HSP60–cHSP60 and GroEL, the HSP60 of *Escherichia coli*), but also with human HSP60 (hHSP60) (Metzler et al., 1997; Mayr et al, 1999). They are cytotoxic for stressed but not unstressed ECs and other target cells, e.g., macrophages (Schett, 1997b). We consider the proatherogenic role of chlamydial infections as compared to other infections a quantitative rather than qualitative phenomenon: chlamydiae are very rich in HSP60, which is highly immunogenic; and chlamydiae have a tropism for ECs and represent an excessive stress factor for these cells, leading to massive eukaryotic HSP60 expression (unpublished observation).

If our concept of the pathogenetic relevance of microbial–human HSP60 cross-reactivity is also of clinical relevance, then the lifelong infectious load should also be associated with an increased odds ratio to develop atherosclerosis. Again, this has been proven within the framework of the BRUNECK study (Mayr et al., 2000; Kiechl et al., 2001). With respect to *Helicobacter pylori* infections, we have shown that an increased odds ratio for the development of atherosclerosis only surfaces when pathogenicity factors are taken into account (Mayr et al., 2003).

The association of anti-HSP60 antibodies with atherosclerosis has subsequently been confirmed by many laboratories [reviewed by Wick et al. (2004)].

We have also identified linear (Perschinka, 2003) and conformational bacterial (H. Perschinka, personal communication) human cross-reactive epitopes that are recognized by human antibodies purified by affinity chromatography over hHSP60 columns.

Numerous reports in the literature concern an association between periodontal disease and atherosclerosis (Kinane and Lowe, 2000). We have, therefore, studied the question whether salivary IgA antibodies to mHSP65 may reflect such an association, and have shown that this is indeed the case. We were also successful in identifying some of the epitopes of HSP60 expressed by the oral bacterial flora (Schett et al., 1997a).

With respect to a possible pathogenetic role of HSP60-reactive T-cells, our data from humans are less clear. We investigated this issue in the peripheral blood of volunteers from the BRUNECK study in 2000, i.e., when the youngest participants were 50 years old. No difference in stimulation indices of peripheral blood T cells derived from volunteers with and without sonographically demonstrable atherosclerotic lesions at various sites of the arterial tree could be demonstrated (B. Mayrl, unpublished observation), although there was still a statistically significant correlation with anti-HSP60 antibodies. Since, as stated above, our concept postulates a pathogenetic role of anti-HSP60 immunity mainly in the early stages of atherosclerosis, we concluded that the first BRUNECK cohort may have been too old for this type of investigation. Therefore, we performed similar studies in a smaller cohort of 17–18-year-old healthy male volunteers within the framework of the ARMY (Atherosclerosis Risk Factors in Male Youth) study (Knoflach et al., 2003). To our surprise, 28% of these young men already showed an increased intima media thickness (IMT) in at least one of eight measured sites. An increased IMT was associated with an increased rate of proliferation of peripheral blood T cells upon incubation with hHSP60 and, less pronounced, with mHSP65, as well as with anti-HSP60/65 antibodies. The association of anti-hHSP60 T-cell reactivity with an increased IMT was only surpassed by an increased odds ratio for atherosclerosis in smokers, but unexpectedly not by an elevated diastolic blood pressure.

This effect of cigarette smoking recently received even greater interest in view of the above-mentioned evidence for binding of HSP60 to cell-surface receptors and the statistically significant association of the concentration of sHSP60 with sonographically diagnosed atherosclerosis. Furthermore, since we have also obtained evidence for biochemical alterations of circulating sHSP60, we consider this fact to be possible basis for the development of *bona-fide* autoimmunity in addition to the already described mechanism of microbial–human HSP60 cross-reactivity. From these data we tentatively conclude that T cells exert a major role in the earliest stages of the disease and humoral antibodies play an initiating and accelerating pathogenetic role. In this context it is of interest that preliminary data show that the injection of a monoclonal anti-HSP60 antibody into mice leads to the development of atherosclerosis (Foteinos et al., 2005).

RISK FACTORS FOR THE SUSCEPTIBILITY OF ENDOTHELIAL TARGET CELLS TO ANTI-HSP60 IMMUNITY

The classical theories for atherogenesis are the "response to injury" hypothesis (Ross and Glomset, 1976a; 1976b) and the "oxLDL" hypothesis (Steinberg et al., 1989). In the former, damage to arterial endothelium is considered the initiating event in the disease, followed by thrombus formation, and eventual occlusion of the afflicted vessel. In the latter, a transgression of oxLDL via the endothelium into the intima has been postulated as the first event leading to foam-cell formation and extracellular cholesterol deposition at that site. More recently, however, evidence has been provided that the LDL oxidation process occurs in the intima itself rather than in the peripheral blood, and that this biochemically altered LDL acts as a chemoattractant for blood-borne monocytes and SMCs from the media, as well as leading to the formation of foam cells. This variant of the oxLDL hypothesis was called the "oxLDL retention" hypothesis (Nishi et al., 2002). We are convinced that the autoimmune hypothesis of atherogenesis comprises and expands these former concepts by explaining the development of the earliest stages of this disease. This view is based on the fact that we do not, of course, deny the well-proven role of atherosclerosis risk factors, but that we assign a different primary importance to them, i.e., as stress factors for ECs. The data that support this notion with respect to *endothelial target susceptibility* to both innate and adaptive defense mechanisms are briefly reviewed below.

In rats, we have shown that injection of bacterial endotoxin [lipopolysaccharide (LPS)] *in vivo* leads to the simultaneous expression by aortic ECs of HSP60 and the adhesion molecule ICAM-1 (Seitz et al., 1996). The latter is reflected by the increased adhesion of leukocytes with a predilection for arterial branching points.

In the rat system we also have demonstrated that increasing the blood flow in one common carotid artery by occlusion of the contralateral vessel leads to an increased expression of HSP60, both at the RNA and protein level (Hochleitner et al., 2000).

Similarly, other stress factors, such as proinflammatory cytokines (TNF-α) and oxygen radicals (H_2O_2), have a HSP60-inducing effect on human ECs *in vitro*. Perhaps most importantly, oxLDL has been shown to be a potent EC stressor (Amberger et al., 1997). All these *in vitro* effects were more pronounced in arterial than venous ECs. We have interpreted these results as showing that arterial ECs have a lower threshold for the effects of various stressors because they are subjected to a lifelong mechanical pre-stress from the higher arterial blood pressure compared with venous blood pressure.

A special case that supports the role of mechanical stress in atherogenesis is arteriovenous bypass restenosis. Since the early stages of atherosclerotic changes in bypass conduits are obviously not available to examination, except in cases of postoperative surgical complications, we addressed this issue in a unique murine arteriovenous bypass model (Zou et al., 1998). In this experimental situation, HSP60 expression by ECs also proved to be the first histochemically sizeable event, followed by mononuclear, i.e., T cell and macrophage, infiltration of the intima, which later even extended into the media and adventitia, and was finally followed by the thickening of the intima and media with complete occlusion as the final result.

Two interesting sidelines of our research are worth mentioning. First, the addition of cyclosporine A to *in vitro* cultures of human ECs in concentrations equal to those found in patients results in a massive expression of both HSP60 and adhesion molecules (Amberger et al., 1999). In contrast, pharmacologic doses of aspirin have no influence on HSP60 expression but downregulate the expression of adhesion molecules. The former observation may in part explain the increased frequency of atherosclerosis in patients treated with cyclosporine A; the latter adds an additional facet to the atherosclerosis preventive properties of aspirin.

Second, we have used our experimental repertoire to answer the often-raised question, do electromagnetic inductions (so-called "electrosmog") represent an atherosclerosis risk factor? We subjected human umbilical vein ECs (HUVECs) *in vitro* (Henderson et al., 2003a) or murine arteriovenous bypass graft-carrying mice *in vivo* (Henderson et al., 2003b) to electrosmog conditions (50 Hz, 700 μT), which can be reached in certain workplace settings. In neither case were we able to demonstrate induction of HSP60 or HSP70, thus making an atherosclerosis-inducing effect of such low-frequency electromagnetic inductions very improbable.

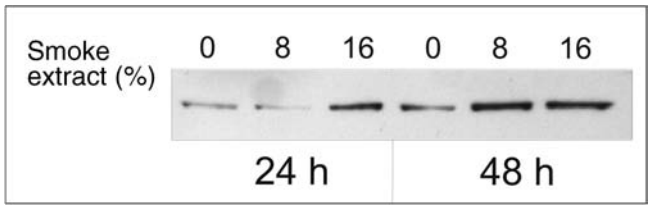

FIGURE 64.2 HSP60 release into supernatant of smoke-extract treated endothelial cells (ECs). Human umbilical vein ECs incubated with cigarette smoke extract, adjusted to *in vivo* compound concentrations, for the times indicated. Supernatants were transferred into 50-ml tubes and centrifuged to remove suspended cells and cell fragments. Supernatants were then concentrated with centrifugal filter devices. Electrophoresis buffer was added to the concentrated supernatants and the samples were subsequently subjected to SDS–polyacrylamide gel electrophoresis. Finally, supernatant proteins were transferred onto nitrocellulose membranes and HSP60 was detected via an antibody-mediated detection system.

In the ARMY study, smoking was identified, as expected, as the most important atherosclerosis risk factor in young male subjects, with an odds ratio of 3.5. Although the many health-deteriorating effects of cigarette smoke have been known for a long time and are highlighted on cigarette packs, we were surprised to learn that very little is known, or published, on the specific effects of smoke components on endothelial function. We have, therefore, approached this issue by devising an experimental method that allows the treatment of HUVECs with water-soluble components of cigarette smoke, again in concentrations that are seen in real life (Bernhard et al., 2004). With respect to this discussion, it is of interest that such treatment leads to EC necrosis rather than apoptosis (Bernhard et al., 2003). Before succumbing to necrosis, the cells undergo a stage of HSP60 expression, which shows that constituents of cigarette smoke act as potent cellular stressors. Subsequently, necrotic cells release abundant amounts of HSP60, which may contribute significantly to the serum concentrations of sHSP60 under *in vivo* conditions (Figure 64.2).

In summary, all risk factors for atherosclerosis that we have analyzed showed HSP60 and simultaneous adhesion molecule induction on endothelial target cells as their first effect. If corroborated by investigations in other laboratories, this crucial observation will further support our autoimmune hypothesis of atherogenesis.

CONCLUSION: THE AUTOIMMUNE HYPOTHESIS OF ATHEROGENESIS

The autoimmune hypothesis of atherogenesis postulates that pre-existing adaptive and innate immunity to HSP60 exposed on the surface of arterial ECs leads to the development of an initial inflammatory stage of this disease. Immunity against HSP60 seems to be an important facet of the defense system, e.g., as reflected by the fact that a considerable proportion of lymphocytes within the VALT show reactivity against HSP60. Also, every healthy animal and human possesses humoral antibodies against HSP60. Cells of the innate immune system recognize HSP60 as a danger signal, be it of microbial or autologous origin. The development of atherosclerosis therefore depends on the expression and accessibility of atherogenic HSP60 epitopes on the surface of ECs. This disease is obviously a price that we pay for maltreating our arterial vascular system with classical risk factors that have as their common denominator the ability to induce the expression of HSP60. Since everybody apparently has either microbial–human cross-reactive immunity or bona-fide autoimmunity, as well as innate immunity against HSP60, whether or not atherosclerosis develops depends exclusively on the state of the endothelial target cell.

Acknowlegments

We would like to thank all present and past members of our group whose work has contributed to our understanding of the immunology of atherosclerosis. We especially thank Dr Gerald Pfister for preparation of *Figure 64.1*, Michaela Kind and Christina Mayerl for expert technical help, Barbara Gschirr for preparation of the manuscript, and Ilona Atzinger for artwork. This work has been supported by the Austrian Research Fund (FWF, Project P14741), the Austrian Ministry of Defense (BMLV) and the Austrian Association of Electricity Companies (VEÖ).

Necrotizing Arteritis and Small Vessel Vasculitis

J. CHARLES JENNETTE*
*Department of Pathology and Laboratory Medicine

RONALD J. FALK†
†Department of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, USA

The three major categories of systemic vasculitis are large vessel vasculitis (chronic granulomatous arteritis), medium-sized vessel vasculitis (necrotizing arteritis), and small vessel vasculitis (necrotizing polyangiitis) (Figure 65.1; Table 65.1). This chapter will focus on medium-sized

vessel vasculitis (necrotizing arteritis) and small vessel vasculitis. Chapter 66 deals with large vessel vasculitis.

HISTORIC BACKGROUND

Necrotizing arteritis was first recognized because of the grossly discernible segmental inflammatory nodular lesions that occur along major arteries (Kussmaul and Maier, 1866). Small vessel vasculitis (SVV) was first recognized because of the palpable purpura that is caused by inflammation of dermal venules (Willan, 1808).

Necrotizing Arteritis

Kussmaul and Maier (1866) gave the first detailed pathologic and clinical description of systemic necrotizing arteritis. They reported a patient with fever, anorexia, muscle weakness, paresthesias, myalgias, abdominal pain, and oliguria, who was found to have inflammatory nodules scattered over medium-sized and small arteries in many organs. They coined the term "periarteritis nodosa" for this process, which, over the following decades, evolved into "polyarteritis nodosa" as it became clear that the inflammation arose in the walls of arteries rather than in the perivascular tissue.

Soon after the recognition of polyarteritis nodosa (PAN), a number of investigators noted that some patients with necrotizing arteritis also had vasculitis affecting arteries that could be seen only by microscopy, and that some patients also had vasculitis affecting glomerular capillaries (glomerulonephritis) and pulmonary capillaries (alveolar capillaritis) (Arkin, 1930; Davson et al., 1948; Zeek et al., 1948; Zeek, 1952; Godman and Churg, 1954). Davson, and Godman and Churg called this the "microscopic form of periarteritis", and Zeek called it "hypersensitivity angiitis." Today, this form of vasculitis usually is designated microscopic polyangiitis (Jennette et al., 1994).

By the 1950s, Wegener's granulomatosis and Churg–Strauss syndrome had been recognized as variants of vasculitis that could have necrotizing arteritis combined with granulomatous inflammation and vasculitis in small vessels (Klinger, 1931; Wegener, 1939; Churg and Strauss, 1951; Godman and Churg, 1954). In their landmark publication in 1954, Godman and Churg concluded that the "microscopic form or periarteritis," Wegener granulomatosis, and Churg–Strauss syndrome are pathologically and clinically distinct from PAN, and probably have a related etiology and

TABLE 65.1 Names and definitions of vasculitis adopted by the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis [Modified from Jennette et al. (1994)]

Systemic vasculitis	Definition
Large vessel vasculitis*	
Giant cell (temporal) arteritis	Granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery. *Often involves the temporal artery. Usually occurs in patients older than 40 years and often is associated with polymyalgia rheumatica*
Takayasu arteritis	Granulomatous inflammation of the aorta and its major branches. *Usually occurs in patients younger than 40 years*
Medium-sized vessel vasculitis*	
Polyarteritis nodosa (classic polyarteritis nodosa)	Necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries or venules
Kawasaki's disease	Arteritis involving large, medium-sized and small arteries, and associated with mucocutaneous lymph node syndrome. *Coronary arteries are often involved. Aorta and veins may be involved. Usually occurs in children*
Small vessel vasculitis*	
Wegener granulomatosis	Granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium-sized vessels, e.g., capillaries, venules, arterioles, and arteries. *Necrotizing glomerulonephritis is common*
Churg–Strauss syndrome	Eosinophil-rich and granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels, and associated with asthma and blood eosinophilia
Microscopic polyangiitis (microscopic polyarteritis)	Necrotizing vasculitis with few or no immune deposits affecting small vessels, i.e., capillaries, venules, or arterioles. *Necrotizing arteritis involving small and medium-sized arteries may be present. Necrotizing glomerulonephritis is very common. Pulmonary capillaritis often occurs*
Henoch–Schönlein purpura	Vasculitis with IgA-dominant immune deposits affecting small vessels, i.e., capillaries, venules, or arterioles. *Typically involves skin, gut, and glomeruli, and is associated with arthralgias or arthritis*
Essential cryoglobulinemic vasculitis	Vasculitis with cryoglobulin immune deposits affecting small vessels, i.e., capillaries, venules, or arterioles, and associated with cryoglobulins in serum. *Skin and glomeruli are often involved*
Cutaneous leukocytoclastic angiitis	Isolated cutaneous leukocytoclastic angiitis without systemic vasculitis or glomerulonephritis

*Large artery refers to the aorta and the largest branches directed toward major body regions (e.g., to the extremities, and the head and neck); medium-sized artery refers to the main visceral arteries (e.g., renal, hepatic, coronary, and mesenteric arteries), and small artery refers to the distal arterial radicals that connect with arterioles. Note that some small and large vessel vasculitides may involve medium-sized arteries, but large and medium-sized vessel vasculitides do not involve vessels smaller than arteries.

pathogenesis. This concept has been born out by the discovery that microscopic polyangiitis, Wegener granulomatosis, and Churg–Strauss syndrome are associated with, and are probably caused by, antineutrophil cytoplasmic autoantibodies (ANCAs), whereas PAN is not (Jennette and Falk, 1997).

An additional form of necrotizing arteritis was discovered that is associated with the mucocutaneous lymph node syndrome (Kawasaki, 1967; Tanaka et al., 1971). This disease has been called "infantile polyarteritis nodosa" because it almost always occurs in young children (Magilavy et al., 1977); however, the clinical, pathologic, and pathogenetic features of Kawasaki's disease are clearly distinct from those of PAN (Jennette et al., 1994).

Purpura and Small Vessel Vasculitis

The evaluation of patients with cutaneous palpable purpura revealed vasculitis involving predominantly small vessels. Although purpura had been described in medical writings at least since the time of Hippocates, Willan (1808) was one of the first to separate purpura caused by febrile infectious disease from noninfectious purpura. The occurrence of purpura in children with arthralgias and arthritis was reported by Schönlein in 1837. Later, Henoch (1868, 1882) described the association of purpura with abdominal pain, nephritis, small visceral hemorrhages, and pathologic changes in small vessels in the skin and internal organs. These pediatric patients probably had what today would be called Henoch–Schönlein purpura.

At the turn of the century, William Osler (1895; 1914) reported numerous adult patients with a more aggressive from of SVV most consistent with what today would be called microscopic polyangiitis. These patients had a broad spectrum of SVV manifestations, including purpura, arthritis, peripheral neuropathy, abdominal pain, pulmonary hemorrhage, epistaxis, iritis, and nephritis, including rapidly progressive renal disease with death from uremia in several months and the autopsy finding of glomeruli with "every tuft compressed by a crescentic mass."

The pathologic findings in SVV of extensive acute inflammation with numerous neutrophils and conspicuous

leukocytoclasia that resembled the Arthus reaction suggested a possible "hypersensitivity" pathogenesis (Winkleman, 1958). A hypersensitivity or allergic cause also was supported by the association of SVV with exposure to certain drugs and with serum sickness (Winkleman, 1958; Clark and Kaplan, 1937; Alarcon Segovia and Brown, 1964; Zeek et al., 1948). In the 1960s, the widespread application of immunofluorescence microscopy revealed that certain forms of SVV had substantial vascular localization of immunoglobulins and complement, suggesting an immune complex pathogenesis. Some patients with pulmonary–renal syndrome had linear deposits of immunoglobulin along glomerular and pulmonary capillary basement membranes (Sturgill and Westervelt, 1965), which were shown to be pathogenic autoantibodies directed against basement membrane collagen (Lerner et al., 1967). Patients with circulating cryoglobulins associated with signs and symptoms of SVV, such as purpura and glomerulonephritis, were found to have granular deposits of IgM, IgG, and complement in vessels walls (Meltzer et al., 1966), indicating an immune complex pathogenesis. This concept of immune complex-mediated SVV was further supported by the detection of hepatitis B antigens and antibodies in the walls of vessels in patients with SVV associated with hepatitis B virus (HBV) infection (Gower et al., 1978). Children with Henoch–Schönlein purpura were found to have deposits of IgA and C3 in dermal venules and glomerular capillaries supporting a distinct type of immune complex pathogenesis (Baart de la Faille-Kuyber et al., 1973). Neutrophilic SVV with extensive leukocytoclastic angiitis also was identified in the acute phase of Behçet's disease (Jorizzo et al., 1985).

By the end of the 1970s, there was a widespread belief that most if not all SVV was mediated by immune complexes (Fauci et al., 1978). However, not all immunohistologic studies of vasculitis showed evidence for substantial vessel wall deposition of immunoglobulins or complement. This was especially true in some of the most common forms of SVV in adults, including Wegener's granulomatosis (Ronco et al., 1983; Weiss and Crissman, 1984). In 1982, Davies et al. reported a new type of autoantibody that reacted with neutrophil cytoplasm in patients with SVV who did not have deposits of immunoglobulin or complement in inflamed glomeruli. Three years later, van der Woude et al. (1985) identified these autoantibodies in patients with Wegener' granulomatosis. Numerous subsequent studies have documented the association of these ANCAs with several clinicopathologic expressions of SVV (Wegener' granulomatosis, microscopic polyangiitis, Churg–Strauss syndrome) that are characterized by the absence or paucity of immunoglobulin and complement deposits in the vessel walls, which suggests a pathogenesis that does not involve extensive vascular deposition of immune complexes (Jennette and Falk, 1997). In fact, there is strong evidence that ANCA-associated pauci-immune SVV is caused by direct activation of neutrophils by autoantibodies directed against granule proteins (Xiao et al., 2002).

POLYARTERITIS NODOSA

Clinical, Pathologic, and Epidemiologic Features

The hallmark of PAN is necrotizing inflammation of medium-sized or small arteries. The prevalence is somewhere between 10 and 30 cases per million population (Watts and Scott, 2004; Mahr et al., 2004). The vascular inflammation initially contains predominantly neutrophils, but within a few days the infiltrates contain predominantly mononuclear leukocytes. Segmental inflammation and necrosis may produce pseudoaneurysms by eroding through the vessel wall into the surrounding tissue. Thrombosis can cause acute ischemia, including infarction. Rupture of pseudoaneurysms results in hemorrhage, which may be severe and life-threatening.

PAN is an acute disease that typically has one major episode with only rare recurrences if remission is attained (Guillevin, 1999). Clinical manifestations include cutaneous erythematous nodules and ulcers caused by dermal and subcutaneous arteritis; peripheral neuropathy (e.g., mononeuritis multiplex) caused by arteritis in epineural arteries; myalgias and elevated circulating muscle enzymes caused by arteritis in skeletal muscle; and pain and dysfunction in virtually any viscera caused by arteritis in the parenchyma. Involvement of the skin and gut is common, whereas involvement of the lungs is rare (Agard et al., 2003). Imaging studies may reveal arterial aneurysms (pseudoaneurysms), visceral infarcts or gut perforation. Diagnosis of PAN in a patient with necrotizing arteritis requires the exclusion of other diseases that also cause arteritis, including Kawasaki's disease, microscopic polyangiitis, Wegener's granulomatosis, and Churg–Strauss syndrome (Jennette et al., 1994; Agard et al., 2003; Mahr et al., 2004). Glomerulonephritis or alveolar capillaritis rule out a diagnosis of PAN and indicate some form of SVV, such as microscopic polyangiitis (Jennette et al., 1994; Agard et al., 2003). Renal involvement can result in renal insufficiency, hematuria, and low-level proteinuria, but this is the result of infarction and hemorrhage rather than glomerulonephritis. Myocardial infarction caused by coronary artery involvement is a rare complication.

Autoimmune Features

Most patients with PAN do not have recognized evidence for an autoimmune pathogenesis. Exceptions are the few patients with systemic lupus erythematosus who have

a vasculitis that is pathologically similar to idiopathic PAN (Korbet et al., 1984). PAN is not associated with ANCAs. As noted later, the serologic detection of ANCAs in a patient who is suspected of having PAN should raise the possibility of pauci-immune SVV instead (Guillevin et al., 1995).

Genetic Features

There is no evidence that genetic factors play a substantial role in the development of PAN. Familial occurrences of PAN are rare and may be related to hepatitis B virus (HBV) infection (Reveille et al., 1989; Mason et al., 1994). No genetic features of HBV have been identified that correlate with the induction of PAN (Janssen et al., 2004).

Environmental Influences

The most commonly recognized environmental factor is infection by HBV (Guillevin, 1999; Janssen et al., 2004). There are anecdotal reports of PAN associated with other infections, such as hepatitis C virus (HCV), human immunodeficiency virus (HIV), and parvovirus B19, but a statistically significant relationship has been established only for HBV infection.

Animal Models

Rich (1942) proposed that PAN was mediated by immunologic mechanisms because he observed arteritis in patients who had serum sickness or had been treated with antibiotics. He acquired support for this hypothesis by inducing necrotizing arteritis in rabbits after injection of horse serum (Rich and Gregory, 1943). However, serum sickness in animals actually is a better model for SVV than for PAN because glomerulonephritis is a very frequent component (Germuth, 1953; Dixon et al., 1958). Interestingly, Pearl Zeek, who was one of the pioneers in delineating the clinical and pathologic features of PAN, studied an animal model of systemic arteritis that resembled PAN and was induced by implanting pieces of silk in the perirenal tissue of rats (Zeek et al., 1948).

Pathogenic Mechanisms

As noted above, at least some examples of PAN are thought to be mediated by immune complex deposition in vessel walls (Figure 65.2). HBV infection may be the source of pathogenic antigens in patients with PAN (Han, 2004; Janssen et al., 2004); however, the vasculitis that is associated with HBV infection often has more features of SVV than necrotizing arteritis alone.

When arterial wall immune complexes are present, they cause inflammation by activating the many interconnected humoral and cellular inflammatory mediator systems; e.g., the complement, kinin, plasmin, and coagulation humoral systems, and the neutrophil, mononuclear phagocyte, lymphocyte, and platelet cellular systems. Endothelial cells and mural smooth muscle cells are capable of modulating vascular inflammation, e.g., by producing lipid metabolites with cytokine activity, and, in the case of endothelial cells, by secreting cytokines, upregulating leukocyte adhesion molecules, and altering surface thrombogenicity (Pober, 1988). This complex interplay of humoral and cellular events results in the influx of inflammatory cells (especially neutrophils), necrosis, and sometimes thrombosis.

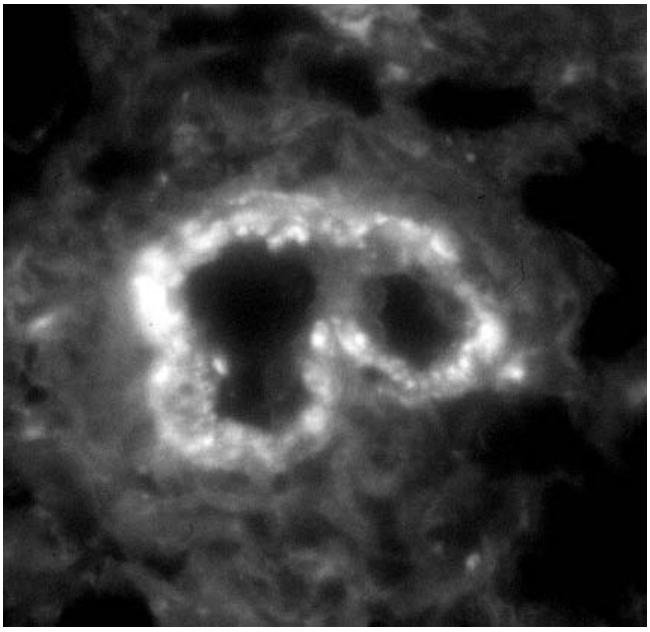

FIGURE 65.2 Direct immunofluorescence photomicrograph demonstrating granular IgG deposits in an artery from the subcutaneous tissue of a patient with hepatitis B-associated polyarteritis nodosa, showing granular vessel wall staining for C3.

Immunologic Markers in Diagnosis

Serologic testing for ANCA helps distinguish between PAN and pauci-immune SVV in a patient with arteritis because <5% of patients with PAN have a positive ANCA (Agard et al., 2003) compared to >80% of patients with pauci-immune SVV. For example, if a patient with mononeuritis multiplex and a peripheral nerve biopsy showing arteritis is ANCA-positive, pauci-immune SVV (e.g., microscopic polyangiitis) is a more likely possibility than PAN. Serologic identification of HBV infection by detection of antigens or antibodies supports a diagnosis of PAN because of the strong association between PAN and hepatitis B (Agard et al., 2003; Janssen et al., 2004) and the

rare occurrence of hepatitis B in other forms of vasculitis (Guillevin, 1999).

Treatment and Outcome

Corticosteroids and cytotoxic drugs have been the most frequently used therapy for PAN and many other form of noninfectious vasculitis. Guillevin (1999) advocates the use of corticosteroids alone for patients with PAN who lack all of the following five factors that indicate a worse prognosis: renal insufficiency, proteinuria >1 g/day, cardiac involvement, central nervous system (CNS) involvement, or gastrointestinal involvement. If 1 or more of these five factors are present, treatment should include combined steroids and cyclophosphamide. If one of these five factors is identified, the 5-year mortality is 25%, if two are identified it is 46%, and if none is identified it is 12%.

The optimal treatment of HBV-associated PAN includes a combination of antiviral and immunosuppressive therapies (Guillevin, 1999; Han, 2004; Janssen et al., 2004). In fact, control of HBV replication may be the most important factor in the resolution of HBV-associated PAN (Janssen et al., 2004). Guillevin (1999) advocates an initial short regimen of corticosteroids to subdue the arteritis, which is most intense during the first weeks of disease. Steroids are then stopped. Continued treatment of the putative immune complex mechanism can be pursued with plasmapheresis if manifestations of arteritis persist. Antiviral therapy also should be instituted, e.g., with interferon (IFN)-α or lamivudine.

KAWASAKI'S DISEASE

Clinical, Pathologic, and Epidemiologic Features

Kawasaki's disease is a self-limited febrile illness with systemic necrotizing arteritis that affects predominantly children, usually under 2 years of age. It was first described in Japan (Kawasaki, 1967), but occurs worldwide. The incidence of Kawasaki's disease in children under 5 years of age ranges from roughly 100 in 100,000 in Japan to 15 in 100,000 in the US to 10 in 100,000 in Europe (Watts and Scott, 2004).

The clinical hallmark of Kawasaki's disease is the mucocutaneous lymph node syndrome, which is characterized by oral mucosal changes, e.g., erythema of the oropharynx; "strawberry tongue," and dryness, redness or fissuring of the lips; skin lesions, e.g., erythema, indurative edema, or desquamation of the distal extremities, or polymorphous macular exanthema on the trunk; bilateral conjunctivitis, and lymphadenopathy (Kawasaki, 1967; Rauch and Hurwitz, 1985; Newburger and Fulton, 2004). The vasculitis of Kawasaki's disease involves medium-sized and small arteries, most notably the coronary arteries. The lesions are characterized histologically by segmental mural necrosis with infiltration by predominantly mononuclear leukocytes with less conspicuous neutrophils (Jennette, 2002). Necrosis occurs but typically has less fibrinoid material, more edema, and more macrophages than seen with PAN. Mural thickening, especially form intimal inflammation, may result in narrowing of the lumen and ischemia. Pseudoaneurysms are most common in the proximal coronary arteries and may be occluded by thrombus, resulting in myocardial infarction. Kawasaki's disease is the major cause of myocardial infarction in young children. Kawasaki's disease has surpassed acute rheumatic fever as the leading cause of acquired heart disease in children in the USA (Newburger and Fulton, 2004).

Autoimmune Features

Patients with Kawasaki's disease have circulating autoantibodies that react with activated endothelial cells (Leung et al., 1986a; 1986b; 1989; Grunebaum et al., 2002; Kaneko et al., 2004). Kaneko et al. (2004) identified a number of candidate target antigens using a cDNA expression library derived from tumor necrosis factor (TNF)-α-stimulated human umbilical vein endothelial cells. Tropomyosin was the most likely autoantigen recognized by anti-endothelial cell autoantibodies. Mor et al. (2002) have identified autoantibodies to tropomyosin in another form of vasculitis, Behçet's disease.

Cunningham et al. (1999) have reported IgM autoantibodies to cardiac myosin in Kawasaki's disease. These autoantibodies differ from the antimyosin antibodies of patients with acute rheumatic fever.

Genetic Features

A role for genetic factors in the pathogenesis of Kawasaki's disease is supported by the observation that children of parents who had Kawasaki's disease in childhood are at greater risk for developing the disease (Uehara et al., 2003). In addition, a child is at 10-fold greater risk of developing the disease within 1 year of onset of the disease in a sibling (Fujita et al., 1989). However, the genetic basis for this familial susceptibility has not been defined. No definite HLA genotype associations have been detected.

Environmental Influences

The clinical and epidemiologic features of Kawasaki's disease, especially the temporal clustering and seasonality, suggest an infectious or environmental etiology. However, in spite of extensive efforts over many decades, no specific infectious agent or environmental factor has been identified (Newburger and Fulton, 2004; Burns et al., 2005).

Animal Models

Takahashi et al. (2004) have developed an animal model of vasculitis that has a remarkable pathologic similarity to the arteritis of Kawasaki's disease. They injected a *Candida albicans* extract intraperitoneally for 5 consecutive days into a variety of mouse strains. Arteritis developed in 66% of CD-1 mice and most often affected the coronary arteries and aortic root close to the orifice of coronary arteries. The gross distribution and histologic pattern of injury closely mimics coronary arteritis in patients with Kawasaki's disease. Not all strains of mice developed disease, indicating a genetic susceptibility in certain strains.

Duong et al. (2003) have described a similar model of coronary arteritis induced by injection of *Lactobacillus casei* cell wall extract into mice. They hypothesized that the pathogenicity of *L. casei* cell wall extract may derive from its ability to function as a superantigen.

Pathogenic Mechanisms

Anti-endothelial cell antibodies (AECAs) have been incriminated in the pathogenesis of vascular injury in patients with Kawasaki's disease by Leung et al. (1986; 1980). They observed that patients with Kawasaki's disease have IgG and IgM AECAs that cause complement-mediated lysis of human umbilical and saphenous vein endothelial cells that had been pretreated with IFN-γ, interleukin (IL)-1, or TNF. From these observations, they hypothesized that the pathogenesis of vasculitis in Kawasaki's disease entails two events: production of AECAs (possibly related to the polyclonal B-cell activation that occurs in Kawasaki's disease) and increased cytokine production (possibly related to the increased activity of CD4 T-lymphocytes and monocytes that also occurs in Kawasaki's disease). The AECAs would bind to upregulated endothelial antigens, and cause endothelial death and vascular inflammation.

A role for bacterial superantigen has been postulated because of selective expansion of T-cell receptor (TCR) V β families in some patients with Kawasaki's disease (Newburger and Fulton, 2004). As noted earlier, observations in animal models also support this possibility.

Immunologic Markers in Diagnosis

No immunologic markers are used in the routine diagnosis of Kawasaki's disease (Newburger and Fulton, 2004). Erythrocyte sedimentation rate and C-reactive protein are consistently elevated but are completely nonspecific.

Treatment and Outcome

The conventional therapy for Kawasaki's disease is aspirin and intravenous gamma-globulin (Furusho et al., 1984; Nagashima, et al., 1987; Rowley, et al., 1988; Newburger and Fulton, 2004). If the interaction of AECAs with cytokine-activated endothelial cells is the major pathogenic mechanism in Kawasaki's disease, intravenous gamma-globulin could be acting by reducing, e.g., through negative feedback control, or neutralizing, e.g., by anti-idiotypic binding, AECAs, or preventing cytokine stimulation of endothelial cells. Leung et al. (1989) have studied these possibilities, and have concluded that the beneficial effects of intravenous gamma-globulin result from reduced circulating cytokines and reduced endothelial cell activation, and not from reduced AECA activity. Interestingly, intravenous gamma-globulin therapy but not aspirin is effective in reducing the severity and complications of the coronary arteritis (Newburger and Fulton, 2004), which indirectly supports the role of antibodies in the pathogenesis of the arteritis.

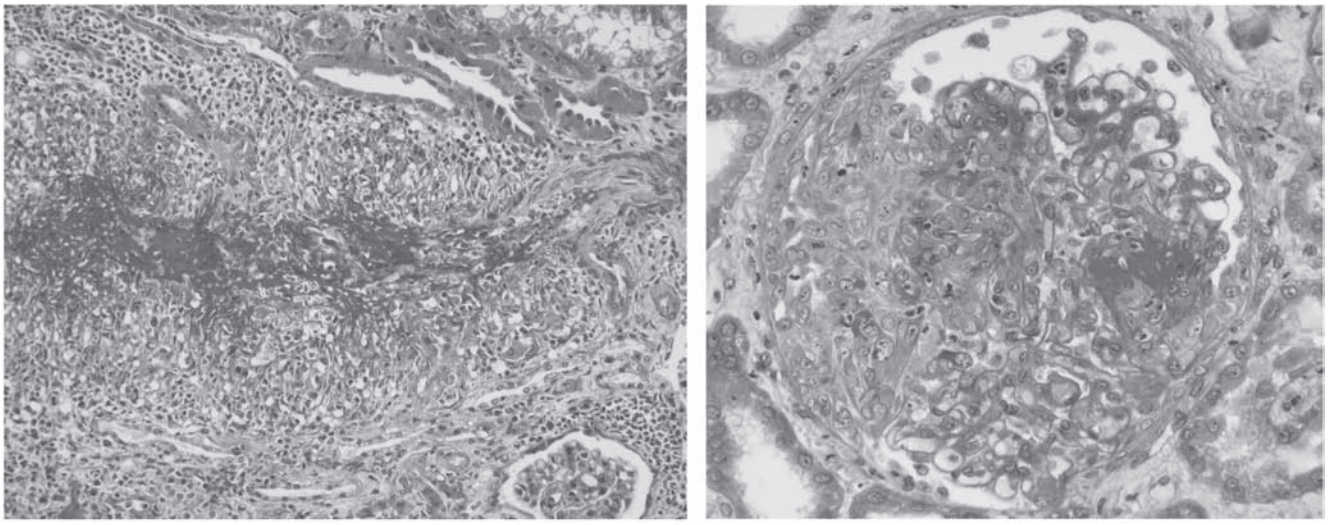
PAUCI-IMMUNE SMALL VESSEL VASCULITIS: WEGENER'S GRANULOMATOSIS, MICROSCOPIC POLYANGIITIS, AND CHURG–STRAUSS SYNDROME

Clinical, Pathologic, and Epidemiologic Features

Pauci-immune SVV has three major clinicopathologic expressions: Wegener's granulomatosis, Churg–Strauss syndrome, and microscopic polyangiitis (Jennette et al., 1994; Jennette and Falk, 1997) (see Table 65.1). All three are characterized by a pauci-immune SVV. Wegener's granulomatosis has necrotizing granulomatous inflammation superimposed on the vasculitis. Churg–Strauss syndrome has asthma, eosinophilia, and granulomatous inflammation in addition to the vasculitis. Microscopic polyangiitis has only the vasculitis, without granulomatous inflammation, asthma, or eosinophilia. Pauci-immune SVV is associated with circulating ANCAs in 80–90% of patients and thus also is called ANCA-associated SVV.

Patients with all clinicopathologic expressions of pauci-immune SVV share a common pathologic manifestation of small vessel inflammation (Jennette, 1991; Jennette and Falk, 1995; Jennette, 2002). This lesion is characterized by mural fibrinoid necrosis with karyorrhexis and infiltrating leukocytes (Figure 65.3). Neutrophils predominate in early lesions but are replaced by mononuclear leukocytes as soon as 48 h after the onset of acute lesions.

The clinical manifestations are protean and can affect many different organs individually or in combination. For example, vasculitis affecting dermal venules causes palpable purpura in skin; inflammation of glomerular capillaries causes glomerulonephritis (see Figure 65.3); pulmonary capillaritis causes pulmonary hemorrhage; vasculitis of



A B

FIGURE 65.3 *A*, Necrotizing arteritis in a small artery and *B*, necrotizing glomerulonephritis in a patient with microscopic polyangiitis. The artery and glomerulus have bright red staining for fibrinoid necrosis in this Masson trichrome stain. The artery and adjacent tissue are infiltrated by neutrophils and mononuclear leukocytes. The glomerulus has a cellular crescent. See color plate section.

TABLE 65.2 Approximate frequency of organ system manifestations in several forms of small vessel vasculitis (Jennette and Falk, 1997)

Organ system	Microscopic polyangiitis (%)	Wegener granulomatosis (%)	Churg–Strauss syndrome (%)	Henoch–Schönlein purpura (%)	Cryoglobulinemic vasculitis (%)
Renal	90	80	45	50	55
Cutaneous	40	40	60	90	90
Pulmonary	50	90	70	<5	<5
Ear, nose, and throat	35	90	50	<5	<5
Musculoskeletal	60	60	50	75	70
Neurologic	30	50	70	10	40
Gastrointestinal	50	50	50	60	30

small vessels in the upper respiratory tract mucosa causes sinusitis and otitis; vasculitis of the small vessels in the uvea (vascular tunic) of the eye causes uveitis; vasculitis affecting small epineural arteries and arterioles causes peripheral neuropathy (usually mononeuritis multiplex); vasculitis in small vessels in the gastrointestinal mucosa and submucosa causes abdominal pain and blood in the stool; and vasculitis affecting small visceral arteries, e.g., in the liver and pancreas, causes pain, dysfunction, and release of intracellular enzymes into the blood. The different clinicopathologic categories of pauci-immune SVV have overlapping clinical features with each other and with other forms of SVV (Table 65.2). Patients with Wegener's granulomatosis may have clinical manifestations of the necrotizing granulomatous inflammation, such as pulmonary nodules and cavities, perforation of the nasal septum, or collapse of the nasal septum causing saddle nose deformity.

In a review of multiple studies, Watts and Scott (2004) reported that the prevalence of Wegener's granulomatosis ranged from 24 to 157 in 1,000,000, of microscopic polyangiitis from 9 to 66, and of Churg–Strauss syndrome from 2 to 38. In accord with this, Mahr et al. (2004) determined that the prevalence of pauci-immune SVV in 1,000,000 adults in France was 25 for microscopic polyangiitis, 24 for Wegener's granulomatosis, and 11 for Churg–Strauss syndrome. The incidence in 1,000,000 adults ranged from 5 to 11 for Wegener's granulomatosis, from 3 to 12 for microscopic polyangiitis, and from 1 to 3 for Churg–Strauss syndrome (Watts and Scott, 2004).

Autoimmune Features

Over 80% of patient with acute untreated pauci-immune SVV have circulating ANCAs (Jennette and Falk, 1995;

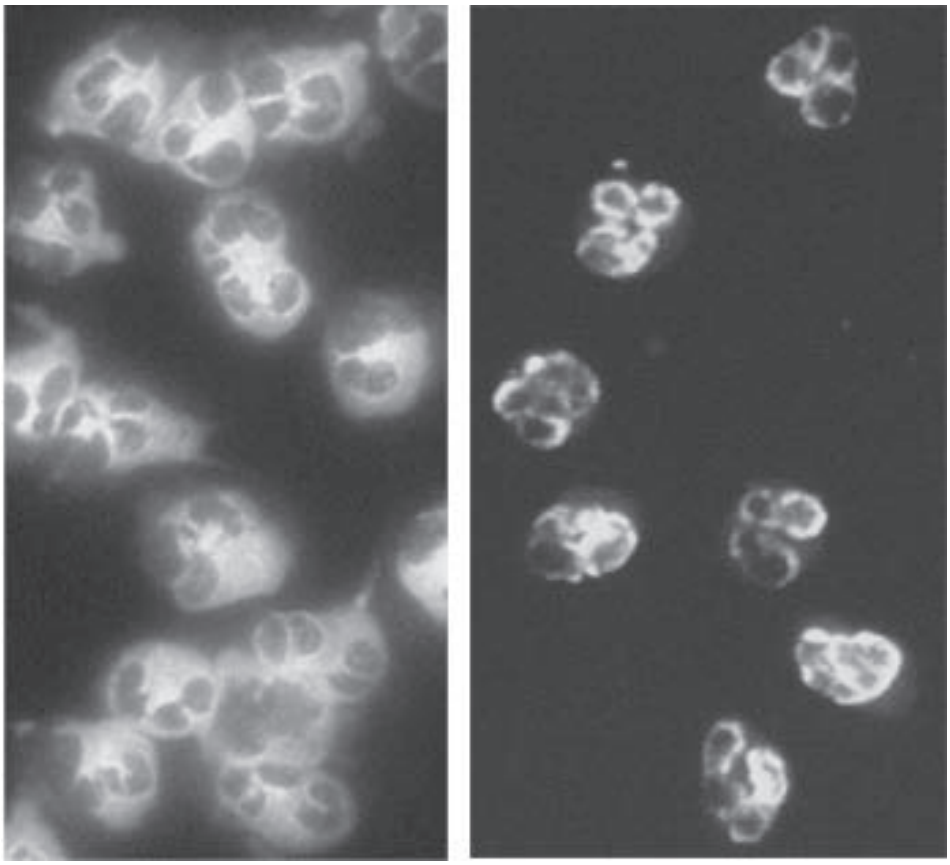


FIGURE 65.4 Indirect immunofluorescence microscopy photomicrograph of *A*, C-ANCA- and *B*, P-ANCA-staining patterns on alcohol-fixed human neutrophils.

1997). ANCAs are specific for proteins in the cytoplasm of neutrophils and monocytes. When detected by indirect immunofluorescence microscopy using alcohol-fixed neutrophils as substrate, the two major antigen specificities cause two different staining patterns: cytoplasmic (C-ANCA) and perinuclear (P-ANCA) (Figure 65.4). The perinuclear pattern is an artifact of substrate preparation caused by diffusion of antigens from the cytoplasm to the nucleus (Charles et al., 1989). When analyzed by specific immunoassays, the most frequent C-ANCA antigen specificity is for proteinase 3 (PR3-ANCA) (Goldschmeding et al., 1989; Niles et al., 1989; Jennette et al., 1990; Ludemann et al., 1990) and the most frequent P-ANCA specificity is for myeloperoxidase (MPO-ANCA) (Falk and Jennette, 1988).

T-cells with specificity for ANCA antigens are present in patients with ANCA vasculitis (Griffith et al., 1996; Clayton and Savage, 2000). T-cells are probably involved in the immunogenesis of the autoimmune response, but their role in the pathogenesis of injury is unknown.

Some patients with Wegener granulomatosis and microscopic polyangiitis have circulating AECAs, often concurrent with ANCA (Chan et al., 1993; Del Papa et al., 1996; Holmen et al., 2004). There is controversy over the diagnostic utility and pathogenic significance of AECAs in pauci-immune SVV.

Genetic Features

The predilection for the disease in white persons and the low prevalence in African-Americans suggests that a genetic background contributes to disease induction. An analysis of 94 patients with Wegener granulomatosis, microscopic polyangiitis or renal-limited vasculitis found no significant association between these vasculitides and any MHC class II allele (Zhang et al., 1995). However, there are several reports of relatively weak associations with a number of HLA-DR alleles (Jagiello et al., 2004; Williams et al., 2005).

Esnault et al. (1993) and Elzouki et al. (1994) reported the association of α-1 antitrypsin-deficiency phenotypes with PR3-ANCA–positive SVV. The fact that α-1 antitrypsin is the major inhibitor in the blood of PR3 is intriguing, but the relevance of this to the relationship between α-1 antitrypsin deficiency and PR3-ANCA is unknown.

Gencik et al. (2000) identified an association between Wegener granulomatosis and a polymorphism in the PR3 promotor affecting a possible transcription factor-binding site. In addition, Borgmann and Haubitz (2004) concluded that the neutrophil expression of PR3 is genetically regulated and correlates with onset and relapse of PR3-ANCA-associated SVV.

Environmental Influences

Drug exposure can induce ANCA formation and SVV. For example, a minority of patients who receive propylthiouracil develop ANCAs concurrent with the onset of pauci-immune SVV and glomerulonephritis (Dolman et al., 1993; Vogt et al., 1994; Tanemoto et al., 1995). Minocycline and hydralazine also have been associated with the development of ANCA disease (Elkayam et al., 1996; Choi et al., 2000).

Silica exposure and farming are risk factors for the development of ANCA SVV (Gregorini et al., 1993; Hogan et al., 2001; Lane et al., 2003). For example, Hogan et al. noted that silica dust exposure was reported by 46% of patients with ANCA SVV, compared with 20% of control subjects ($P = 0.001$). The odds ratio of exposure to silica dust was 4.4 times greater for patients with ANCA SVV compared with control subjects ($P = 0.013$).

Approximately two-thirds of patients with Wegener granulomatosis are chronic nasal carriers of *Staphylococcus aureus*. This is a risk factor for relapse, and prophylactic treatment with antibiotics that eliminate staphylococcal nasal carriage reduces relapse frequency (Stegman et al., 1996). The mechanistic relationship between staphylococcal infection and ANCA disease onset or exacerbation is not clear. However, recent observations by Pendergraft et al. (2004; 2005) raise the possibility that exposure to certain pathogens can result in the induction of the autoimmune ANCA response (see Chapter 59). They propose that pathogens can initiate an autoantibody response through induction of an appropriate antibody response to microbial proteins that have an amino acid sequence that mimics the antisense sequence (complementary sequence) of the autoantigen. These antibodies to the complementary peptide in turn induce anti-idiotypic antibodies that cross-react with the autoantigen (i.e., are autoantibodies). In support of this theory, patients with PR3-ANCA disease have circulating antibodies that react with peptides that have an amino acid sequence that is complementary to PR3, and these antibodies react with anti-PR3 antibodies as an anti-idiotypic pair. Further, immunization of mice with a complementary PR3 peptide induces not only an antibody response to the complementary PR3 peptide but also to native PR3. Interestingly, *Staph. aureus*, which is associated with PR3-ANCA disease, contains a protein that has a sequence that mimics the antisense sequence of PR3. According to the theory of autoantigen complementarity, an antibody response to the *Staph. aureus* peptide that mimics a complementary PR3 peptide results in an anti-idiotypic immune response that targets PR3, resulting in PR3-ANCA production. Also in support of this concept is the association between PR3-ANCA and infection with Ross River virus and *Entamoeba histolytica*, both of which contain proteins with amino acid sequences that mimic complementary peptides of PR3 (Pendergraft et al., 2004).

Animal Models

The most convincing model of ANCA-induced SVV has been described by Xiao et al. (2002). MPO knock-out mice were immunized with murine MPO and produced anti-MPO antibodies. Splenocytes (including T and B cells) or isolated antibodies were then transferred from $MPO^{-/-}$ mice that had been immunized with MPO to $Rag2^{-/-}$mice (lacking functional T- and B-cells), resulting in the development of necrotizing and crescentic glomerulonephritis in all mice and varying degrees of extrarenal SVV in many mice, including pulmonary capillaritis or necrotizing granulomatous inflammation, leukocytoclastic angiitis in the skin, and necrotizing arteritis in multiple viscera (Figure 65.5). The disease in the mice that received splenocytes is complicated by a background of immune complex localization in glomeruli; however, the $Rag2^{-/-}$ mice or wild-type mice that receive anti-MPO IgG alone develop a pauci-immune glomerulonephritis and vasculitis that is pathologically identical to human ANCA-associated pauci-immune disease. Because

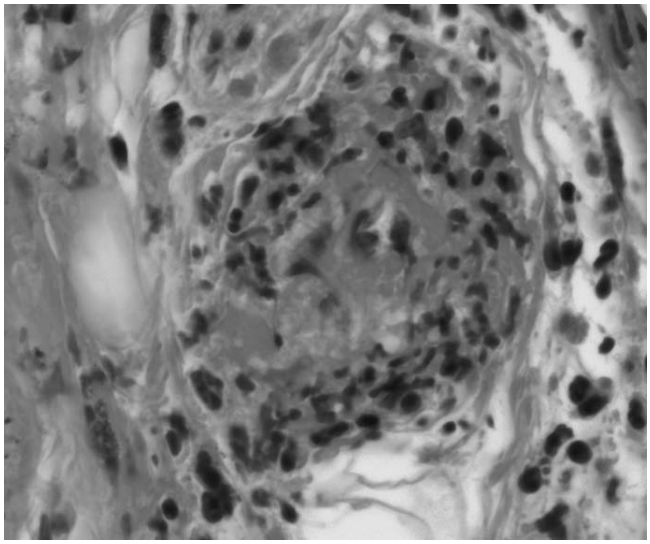

FIGURE 65.5 Necrotizing arteritis in a small artery in the dermis of a mouse 6 days after intravenous injection of mouse antimyeloperoxidase IgG. There is a central area of deeply eosinophilic fibrinoid necrosis surrounded by leukocytes with leukocytoclasia (H&E stain).

this disease can be induced in mice with no functional T cells, T cells are not required for pathogenesis. However, neutrophils are required because elimination of circulating neutrophils with a cytotoxic rat antibody completely abrogates disease induction by anti-MPO IgG (Xiao et al., 2005).

Pathogenic Mechanisms

By definition, pauci-immune SVV has little or no localization of immunoglobulin in vessel walls and thus appears to have a pathogenic mechanism that differs from classical immune complex-mediated vasculitis. The presence of ANCA in the circulation and the correlation of ANCA titers with disease activity raise the possibility that ANCAs have a pathogenic role (Jennette and Falk, 1994; Kallenberg et al., 1994; Han et al., 2003). The induction of ANCA and pauci-immune SVV by drug exposure, discussed above, is strong clinical evidence for the pathogenetic importance of ANCA. The most compelling clinical evidence for the pathogenicity of ANCA is the report of a neonate who developed pulmonary hemorrhage and nephritis following transplacental transfer of maternal MPO-ANCA IgG (Bansal and Tobin, 2004).

In addition to the animal models described earlier, there are numerous *in vitro* observations that support the pathogenic potential of ANCA IgG (Jennette and Falk, 1994; Rarok et al., 2003; Williams et al., 2005). Incubation of ANCA IgG with primed neutrophils induces the release of toxic reactive oxygen species and lytic granule enzymes (Falk et al., 1990a). Neutrophil priming, as occurs with exposure to certain cytokines, results in the expression of small amounts of ANCA antigens at the surface of neutrophils where they can interact with ANCA. The resultant activation of neutrophils is mediated by a combination of Fc receptor-dependent events (Porges et al., 1994; Mulder et al., 1994), as well as Fab′2-mediated events (Kettritz et al., 1997; Williams and Savage, 2005).

In vitro, ANCA-activated neutrophils kill primed endothelial cells (Ewert et al., 1992a; Savage et al., 1992). This process requires adhesion of the neutrophils to endothelial cells via β2 integrins (Ewert et al., 1992b). Further, Radford et al. (2000) have shown that exposure to ANCA IgG causes rolling neutrophils to adhere to endothelial cells in culture through integrin-mediated adhesion.

Instead of, or in addition to, reacting with antigens expressed on the surface of neutrophils and monocytes, ANCAs might react with antigens (e.g., MPO and PR3) that have become planted in vessel walls. Vargunam et al. (1992) have shown that MPO binds to cultured endothelial cells by a charge-dependent mechanism and can subsequently react with ANCA to form immune complexes *in situ*. If this occurs *in vivo*, the magnitude of vessel wall immune complex formation must be substantially less than in conventional immune complex disease because of the absence or paucity of staining for immunoglobulin in vessel walls in ANCA SVV.

Inflammatory process, such as a viral respiratory tract infection, may cause increased levels of circulating cytokines, which in turn prime neutrophils to interact with circulating ANCAs to induce vasculitis (Jennette and Falk, 1994). With respect to this hypothesis, it is interesting to note that approximately 90% of patients report a "flu-like illness" shortly before the onset of the signs and symptoms of ANCA vasculitis (Falk et al., 1990b). Experimental support for this hypothesis is provided by the observation that injection of bacterial lipopolysaccharide into mice prior to induction of glomerulonephritis with anti-MPO IgG causes more severe injury (Huugen et al., 2005).

In summary, the *in vitro* observations support the hypothesis that antigens (PR3 and MPO) that are expressed at the surface of cytokine-primed neutrophils react with ANCA, causing neutrophil activation through both Fc receptor engagement and Fab′2 attachment to antigens, resulting in the attachment to and injury of vascular endothelial cells (Figure 65.6).

AECAs have been detected in some patients with pauci-immune SVV. Del Papa et al. (1996) observed that AECA from patients with Wegener granulomatosis are not toxic to endothelial cells but cause these cells to upregulate adhesion molecules and to release pro-inflammatory cytokines. Holmen et al. (2004) reported that patients with Wegener granulomatosis have noncytotoxic AECAs that selectively bind surface antigens on unstimulated nasal, kidney, and lung endothelial cells, and that serum from patients with Wegener granulomatosis caused agglutination of cytokine-stimulated nasal endothelial cells. AECA could synergize with ANCA to cause disease; however, the pathogenic importance of AECA in pauci-immune SVV has not been clearly delineated.

Immunologic Markers in Diagnosis

In a patient with signs and symptoms of SVV, serology and/or immunohistology may demonstrate diagnostic immunologic markers that distinguish between vasculitides that have very different prognoses and treatments (Table 65.3). For example, in a patient with purpura, arthralgias, hematuria, and proteinuria, IgA-dominant immune deposits in dermal vessels support a diagnosis of Henoch–Schönlein purpura; serum cryoglobulins and antihepatitis C antibodies support cryoglobulinemic vasculitis; serum anti-DNA and hypocomplementemia support lupus vasculitis; and serum ANCAs support one of the categories of pauci-immune SVV. Similarly, in a patient with hemoptysis and rapidly progressive glomerulonephritis (i.e., pulmonary–renal vasculitic syndrome), serum antiglomerular basement membrane (GBM) antibodies indicate Good-

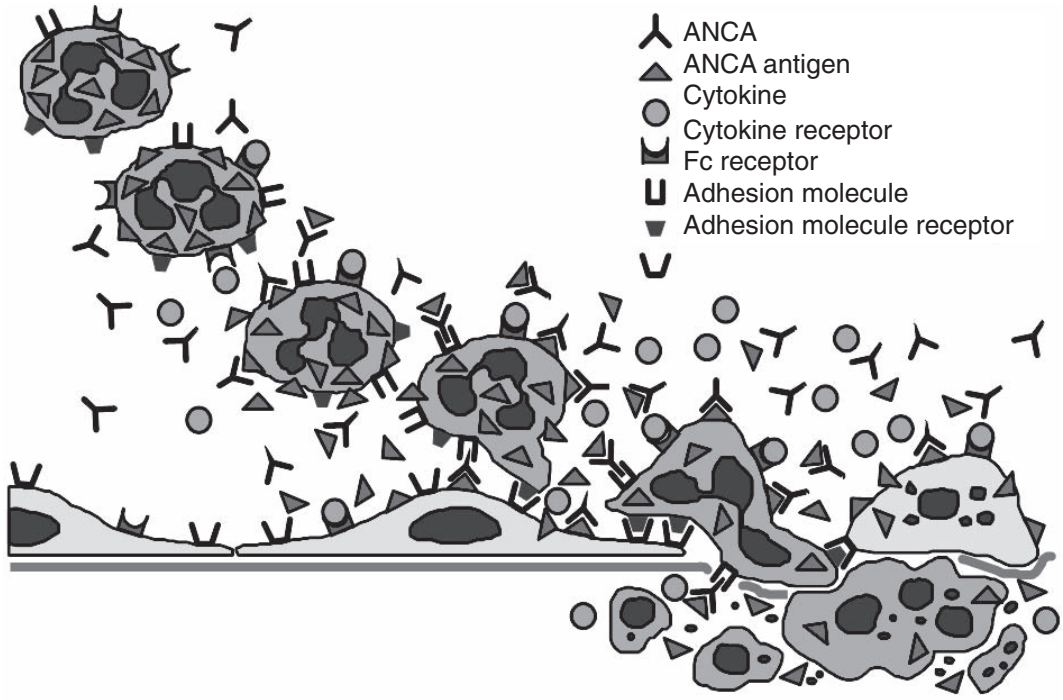

FIGURE 65.6 Putative pathogenic mechanism for antineutrophil cytoplasmic autoantibody (ANCA)-induced vasculitis. ANCA antigens (granule proteins) that are normally within the cytoplasm of neutrophils are transferred to the surface by cytokine priming, where they can interact with ANCAs. Some antigens also are released and can bind to endothelial cells. These free and bound antigens can also react with ANCAs. The interaction of neutrophils with ANCAs induces full activation with respiratory burst and degranulation, which causes vascular injury (vasculitis). See color plate section.

TABLE 65.3 Differential diagnostic features of several forms of small vessel vasculitis (SVV) (Jennette and Falk, 1997)

Diagnostic feature	Microscopic polyangiitis	Wegener granulomatosis	Churg–Strauss syndrome	Henoch–Schönlein purpura	Cryoglobulinemic vasculitis
SVV signs and symptoms*	+	+	+	+	+
IgA-dominant immune deposits	–	–	–	+	–
Cryoglobulins in blood and vessels	–	–	–	–	+
ANCAs in blood	+	+	+	–	–
Necrotizing granulomas	–	+	+	–	–
Asthma and eosinophilia	–	–	+	–	–

ANCAs, antineutrophil cytoplasmic autoantibodies.

*All of these SVVs can manifest any or all of the shared features of SVV, such as purpura, nephritis, abdominal pain, peripheral neuropathy, myalgias, and arthralgias. Each is distinguished by the presence and just as importantly the absence of certain specific features.

pasture syndrome, whereas ANCAs indicate one of the ANCA vasculitides.

ANCA testing should include a specific immunochemical method [e.g., enzyme-linked immunosorbent assay (ELISA)] that will detect MPO-ANCA and PR3-ANCA, not merely an indirect immunofluorescence assay for C-ANCA and P-ANCA (Lim et al., 1999; Savige et al., 1999). This improves diagnostic specificity without a significant drop in sensitivity.

An added complexity of serologic testing for ANCA disease and anti-GBM disease is the increased frequency of anti-GBM antibodies in patients with ANCA and *vice versa* (Saxena et al., 1991; Jennette, 2003; Levy et al., 2004). Patients with both autoantibodies have a worse prognosis than patients with ANCA alone. When both autoantibodies are present, a patient is at risk for manifesting vasculitic features of ANCA-associated disease that do not occur with anti-GBM disease alone, such as cutaneous, skeletal muscle

TABLE 65.4 Approximate frequency of PR3-ANCA and MPO-ANCA in patients with pauci-immune small vessel vasculitis.

	Wegener granulomatosis	Microscopic polyangiitis	Churg–Strauss syndrome	Renal-limited glomerulonephritis
PR3-ANCA	75	40	10	20
MPO-ANCA	20	50	60	70
Negative	5	10	30	10

or gut vasculitis. In some patients, the anti-GBM component of their autoimmune disease resolves, leaving more persistent ANCA disease.

Serology alone can not make the distinction between microscopic polyangiitis, Wegener granulomatosis, Churg–Strauss syndrome or isolated pauci-immune crescentic glomerulonephritis because each syndrome can be associated with either C-ANCA (PR3-ANCA) or P-ANCA (MPO-ANCA). However, the relative frequencies of ANCA specificities vary among the disease variants. For example, most patients with Wegener granulomatosis have C-ANCA (PR3-ANCA) and most patients with renal-limited disease have P-ANCA (MPO-ANCA) (Jennette et al., 1994) (Table 65.4).

Diseases other than pauci-immune SVV can be associated with ANCAs, especially with ANCAs that are not specific for MPO or PR3. P-ANCAs that do not have specificity for MPO are associated with a number of nonvasculitic inflammatory diseases, such as ulcerative colitis, sclerosing cholangiitis, autoimmune hepatitis, and Felty syndrome (Jennette and Falk, 1993; Bartunkova et al., 2002). C-ANCAs that are not associated with SVV occur in patients with cystic fibrosis (Bartunkova et al., 2002).

Detection of circulating endothelial cells may be of value in diagnosing or monitoring ANCA SVV (Haubitz and Woywodt, 2004), but this has not yet been adequately validated for clinical use.

Treatment and Outcome

ANCA vasculitis is usually a very aggressive disease that often will be complicated by endstage renal disease or life-threatening pulmonary hemorrhage if not treated with high-dose corticosteroids and cytotoxic drugs, especially cyclophosphamide (Nachman et al., 1996; Jayne, 2003; Little and Pusey, 2004). Although there is general agreement about the use of corticosteroid and cytotoxic therapy for the induction of remission in patients with pauci-immune SVV, there is controversy over the dose, method of administration, and duration of treatment. Approximately 80% of ANCA SVV patients will enter remission with aggressive immunosuppressive therapy. However, up to 40% will have a relapse within 2 years. There is controversy over how best to treat relapses. A repeat course of corticosteroids and cyclophosphamide often is used for relapses, but less toxic alternatives are azathioprine or mycophenolate mofetil (Little and Pusey, 2004).

Intravenous gamma-globulin and plasma exchange may have a beneficial effect on ANCA SVV, especially in patients with aggressive or persistent disease that does not respond well to conventional therapy (Jordan, 1995; Jayne et al., 2000; Little and Pusey, 2004). Anti-idiotypic antibodies that inhibit ANCA *in vitro* are present in pooled human gamma-globulin preparations, but whether or not an anti-idiotypic effect is the basis for the therapeutic benefits has not been determined. Plasma exchange reduces circulating ANCA levels, which is potentially beneficial if these autoantibodies are in fact pathogenic.

CRYOGLOBULINEMIC VASCULITIS

Clinical, Pathologic, and Epidemiologic Features

Cryoglobulinemic vasculitis is characterized pathologically by inflammation in small vessels (Figure 65.7A) that is associated with deposits of cryoglobulins and complement in vessel lumens and walls. Skin, joints, gut, and glomeruli often are involved (see Table 65.2). Cryoglobulinemic vasculitis affects vessels of many types, including postcapillary venules (e.g., in the dermis), capillaries (e.g., glomerular and rarely pulmonary alveolar capillaries), arterioles, and rarely small arteries (Gorevic et al., 1980; Ferri et al., 2004). Immunofluorescence microscopy reveals granular deposits of immunoglobulins and complement in vessel walls, and sometimes lumenal aggregates of cryoglobulins and complement. The clinical and pathologic manifestations of cryoglobulinemic vasculitis overlap with those of other systemic vasculitides, including purpura with leukocytoclastic angiitis, proliferative and membranoproliferative glomerulonephritis, and, in rare severe cases, pulmonary hemorrhage with alveolar capillaritis. As with many systemic vasculitides, arthralgias and arthritis caused by synovitis are a common feature.

The prevalence of cryoglobulinemic vasculitis is not well defined, but it is more common in southern Europe than in northern Europe or North America (Ferri et al., 2004).

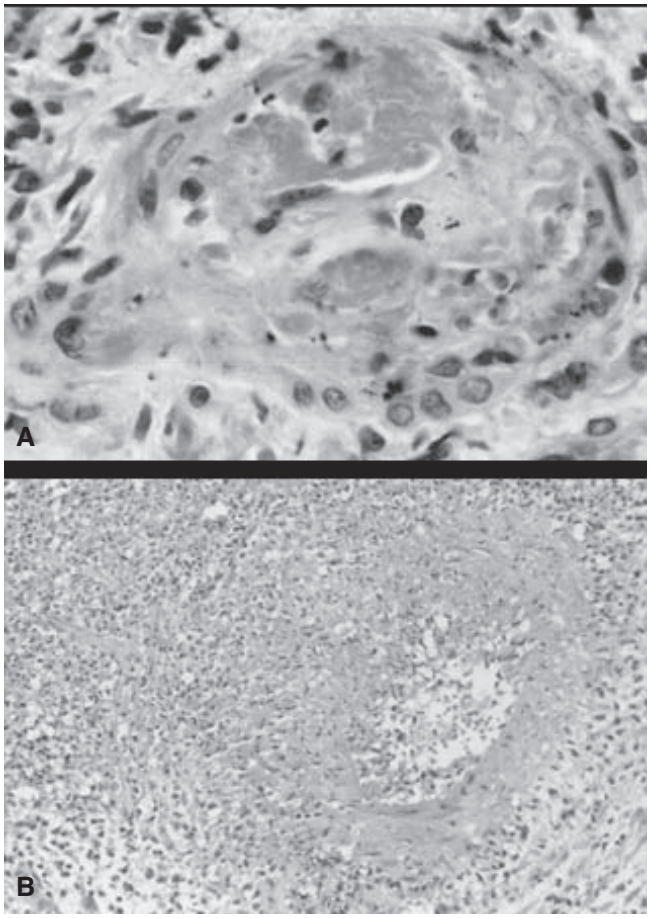

FIGURE 65.7 *A*, Cryoglobulinemic vasculitis affecting a small artery in the kidney. The deeply acidophilic material in the vessel probably is a mixture of thrombus, fibrinoid necrosis, and aggregated cryoglobulins. The vessel wall and adjacent tissue are infiltrated by leukocytes with leukocytoclasia. *B*, Intense neutrophilic inflammation and necrosis in a small dermal artery from a patient with Behçet's disease. The neutrophilic infiltrate also extends into the adjacent dermis, especially on the left.

There is a close association between HCV infection and cryoglobulinemia (D'Amico and Fornasieri, 1995; Ferri et al., 2004).

Autoimmune Features

Most cryoglobulins that cause vasculitis contain autoantibodies directed against immunoglobulins, i.e., rheumatoid factors (Grey and Kohler, 1973; Ferri et al., 2004). Cryoglobulins are divided into three major types: monoclonal (type I), mixed monoclonal–polyclonal (type II), and polyclonal (type III). Mixed cryoglobulins are more pathogenic than monoclonal or polyclonal cryoglobulins. Monoclonal cryoglobulins usually occur in patients with plasma cell dyscrasias or B-cell lymphomas, and cause morbidity primarily by precipitating within vessels and producing occlusion. Monoclonal cryoglobulins are not effective activators of inflammatory mediator systems, and therefore rarely cause overt vasculitis. Mixed cryoglobulins, however, are immune complexes that are capable of activating inflammatory mediators, including the complement system, and therefore characteristically cause systemic vasculitis.

Genetic Features

Not all patients with HCV infection develop cryoglobulinemia. The likelihood of developing cryoglobulinemia is not determined by serum HCV RNA titer or HCV genotype; thus, host factors, including genetic susceptibility, are incriminated as risk factors for this complication. In studies of relatively small numbers of patients, Amoroso et al. (1998) reported an increased frequency of the DRB1*11 (DR5) (36% vs 20%, $P = 0.0035$), Congia et al. (1996) an increased frequency of DRB1*1101–4 (DR5), DQB1*0301, DRB1*0301 (DR3), and DQB1*0201, and Lenzi et al. (1998) an increased frequency of HLA-B8 and HLA-DR3 in patients with cryoglobulinemia compared to healthy controls or patients with hepatitis C but no cryoglobulinemia.

Environmental Influences

There is a strong association between cryoglobulinemic vasculitis and HCV infection (D'Amico et al., 1995; Ferri et al., 2004). HCV antibodies and RNA are detected in the serum of 75–95% of patients with vasculitis and glomerulonephritis caused by mixed cryoglobulins. The HCV is both hepatotropic and lymphotropic. One hypothesis proposes that infection of B cells by HCV triggers the production of polyclonal and monoclonal rheumatoid factors that participate in cryoglobulin formation (D'Amico et al., 1995). Another proposes that HCV lipoprotein induces an IgM response that is initially reactive with a virus–self complex but subsequently mutates to have rheumatoid factor activity (Agnello, 1995).

Animal Models

Gyotoku et al. (1987) have described an experimental model of cryoglobulinemic vasculitis. They established monoclonal IgG rheumatoid factor-secreting hybridomas from MRL/lpr mice. These monoclonal rheumatoid factor antibodies were capable of forming cryoglobulins, and, when injected into normal mice, caused peripheral vasculitis and glomerulonephritis resembling that seen in patients with mixed cryoglobulinemia. Kikuchi et al. (2002) implanted mice with a hybridoma that secreted an IgG3 anti-IgG2a rheumatoid factor. The mice developed circulating cryoglobulins, acute glomerulonephritis, and cutaneous leukocytoclastic vasculitis.

Pathogenic Mechanisms

Cryoglobulinemic vasculitis is mediated by the deposition of mixed cryoglobulins in small vessels. These immune complexes composed of mixed cryoglobulins activate complement and initiate acute inflammation through mechanisms that were discussed above in the section on PAN.

Immunologic Markers in Diagnosis

The laboratory hallmark of cryoglobulinemic vasculitis is the detection of cryoglobulins in the circulation (see Table 65.3). Testing for cryoglobulins requires that the blood be kept warm prior to testing. In a proper clinical setting, hypocomplementemia, positive rheumatoid factor assay, and positive serology for HCV infection support a diagnosis of cryoglobulinemia. The hypocomplementemia characteristically has low C4 but normal or near normal C3.

Treatment and Outcome

If there are circulating pathogenic autoantibodies or immune complexes in patients with vasculitis, theoretically, plasmapheresis combined with immunosuppression would be beneficial. Plasmapheresis has been used in severe cryoglobulinemia (D'Amico et al., 1995). Plasmapheresis is combined with corticosteroid and cytotoxic therapy, which makes it difficult to determine what effect plasmapheresis alone is having on the disease. Therapy with IFN-α, in addition to the immunosuppressive drugs, has also been advocated in patients with cryoglobulinemic vasculitis secondary to HCV infection (D'Amico et al., 1995).

HENOCH–SCHÖNLEIN PURPURA

Clinical, Pathologic, and Epidemiologic Features

Henoch–Schönlein purpura is the most common form of vasculitis in children with an incidence of approximately 20 in 100,000 children, with the highest frequency between 4 and 6 years old (Gardner-Medwin et al., 2002), although it can occur at any age. Henoch–Schönlein purpura is SVV with IgA-dominant immune deposits affecting small vessels, i.e., capillaries, venules, or arterioles (Jennette et al., 1994). It typically involves skin, gut, and glomeruli, and is associated with arthralgias or arthritis (Ting and Hashkes, 2004). The purpura typically affects the buttocks and lower extremities. Table 65.2 provides estimates of involvement of different organs, although this differs among cohorts. Immunofluorescence microscopy of dermal venules and renal glomeruli reveals granular vessel wall deposits of predominantly IgA and C3, supporting a pathogenic mechanism that involves IgA-dominant immune complexes (Baart de la Fille-Kuyber et al., 1973; Namba et al., 1977).

Autoimmune Features

The role of autoimmunity in Henoch–Schönlein purpura is unclear. There have been conflicting reports about the presence of IgA-ANCA in patients with Henoch–Schönlein purpura and IgA nephropathy that is usually detected only by ELISA. This most likely is not an antigen–antibody reaction but rather binding of IgA mediated by the abnormal composition of IgA carbohydrate side chains in patients with Henoch–Schönlein purpura and IgA nephropathy (Coppo et al., 1997).

Davin et al. (1987) detected IgA anti-α-galactosyl antibodies in the serum of children with active Henoch–Schönlein purpura nephritis and IgA nephropathy. This finding is intriguing because of the known association between Henoch–Schönlein purpura and infection with pathogens that have α-galactosyl residues on their surfaces, but the relevance of these antibodies to the pathogenesis of Henoch–Schönlein purpura is uncertain.

Genetic Features

No HLA-A, HLA-B or HLA-C associations were observed in 26 patients with Henoch–Schönlein purpura (Ostergaard et al., 1990). Amoli et al. (2002a; 2002b) reported an increased prevalence of HLA-DRB101 and a decreased prevalence of HLA-DRB107 among Henoch–Schönlein purpura patients. They also observed an increased prevalence of HLA-B35 and IL-1 allele polymorphism in Henoch–Schönlein purpura patients with glomerulonephritis (Amoli et al., 2004). The severity of nephritis and renal outcome were influenced by the IL-1 gene polymorphism.

Environmental Influences

Approximately 40% of children have an upper respiratory tract infection near the time of onset of Henoch–Schönlein purpura, most commonly with group A Streptococcus (Masuda et al., 2003; Gonzalez-Gay et al., 2004; Ting and Hashkes, 2004). The pathogenic relationship between the infection and the onset of disease is unclear. Theoretically, this association could be because of a specific acquired immune response that is initiated by the infection, or because of a nonspecific amplification of immune activation that augments an underlying pathogenic mechanism, such as production of aberrantly glycosylated IgA (Allen et al., 1998).

Animal Models

There is no good animal model for Henoch–Schönlein purpura. There are a few animal models of IgA nephropathy, which is the glomerular lesion of Henoch–Schönlein purpura. Many of these involve oral or nasal immunization with dietary or infectious antigens (Amore et al., 2004). Uteroglobin gene knock-out and uteroglobin antisense transgenic mice develop pathologic features of human IgA nephropathy (Zheng et al., 1999), but the relevance of this to human disease is unclear because reduced uteroglobin has not been observed in patients with IgA nephropathy (Coppo et al., 2002).

Pathogenic Mechanisms

A leading hypothesis is that Henoch–Schönlein purpura is an immune complex vasculitis resulting from a dysregulated mucosal immune response to environmental or infectious antigens in a genetically predisposed individual. IgA-dominant immune complex deposits in vessel walls are the putative mediators of the inflammation. The predominant subclass is IgA1. The major antigen in the complexes is unknown. Because of the association with infections, an antigen derived from a pathogen has been sought. Masuda et al. (2003) reported the discovery of streptococcal antigens in the glomeruli of patients with Henoch–Schönlein purpura glomerulonephritis, but this has not been independently confirmed.

Human IgA1 has an O-glycosylated hinge region that is not found in other immunoglobulin classes. There is a reduction of galactosyl residues in this hinge region in IgA1 from patients with IgA nephropathy and Henoch–Schönlein purpura (Allen et al., 1998). This reduced galactosylation may be due to a functional defect in plasma cell β-1,3-galactosyltransferase. The abnormal hinge region glycosylation alters IgA1 structure, resulting in IgA1 homo aggregation, greater affinity for matrix proteins in vessel walls (including glomerular mesangium), and greater complement activation, which could result in localization of IgA-dominant deposits in vessel walls with resultant complement activation and vasculitis.

Immunologic Markers in Diagnosis

There are no specific immunologic markers for Henoch–Schönlein purpura other than the immunohistologic identification of IgA-dominant immune deposits in vessels. Increased levels of serum IgA–fibronectin aggregates have been observed in patients with IgA nephropathy and Henoch–Schönlein purpura (Jennette et al., 1991), but this finding is not specific or sensitive enough for diagnostic use.

Treatment and Outcome

Henoch–Schönlein purpura usually is a mild, self-limited, vasculitis that does not warrant corticosteroid or cytotoxic therapy (Robson and Leung, 1994). Less than 5% of patients have serious complications, usually progressive renal failure. Patients with rapidly progressive glomerulonephritis or severe CNS disease benefit from immunosuppressive therapy, e.g., with high-dose corticosteroids, cytotoxic drugs or plasmapheresis (Gedalia, 2004; Ting and Hashkes, 2004). The overall prognosis is excellent even though one-third to one-half of patients will have one or more recurrences of symptoms, usually within 6 weeks, but rarely years later (Gedalia, 2004).

BEHÇET'S DISEASE

Clinical, Pathologic, and Epidemiologic Features

Behçet's disease is a multisystem, recurrent inflammatory disease that was described by Behçet (1937; 1940) on the basis of a triad of symptoms—oral ulcers, genital ulcers, and uveitis. However, virtually any organ system can be involved. SVV is the underlying lesion in many tissues (Figure 65.7B). In addition to small vessels, medium-sized and large arteries and veins may be involved, resulting in arterial aneurysms and thrombophlebitis (Ehrlich, 1997). Even here, the initial lesions appear to be in small vessels within the adventitia or muscularis of the larger vessels (Kurokawa et al., 2004). Patients with Behçet's disease are predisposed to venous and arterial thrombosis. Criteria for the diagnosis of Behçet's disease have been established by the International Study Group for Behçet's Disease (1990).

Behçet's disease ("Silk Road disease") has a unique geographic distribution, with highest prevalence centering on the ancient Silk Road from the Mediterranean to Far-East Asia. The prevalence ranges from approximately 400 in 100,000 in Turkey to 100 in 100,000 in Japan to 1 in 100,000 in Western Europe and the US (Watts and Scott, 2004).

The onset of Behçet's disease is usually in the fourth decade of life and rarely before puberty or after the age of 50 years. Male sex, HLA-B51 positivity, and a younger age of onset are associated with more severe disease and more vasculitis (Alpsoy et al., 2005).

Autoimmune Features

Patients with Behçet's disease have T and B cells that are specific for self-peptides derived from heat-shock protein 60 (HSP60) that are highly homologous to bacterial HSP65 (Stanford et al., 1994; Hu et al., 1998). These autoreactive

lymphocytes may play a role in pathogenesis, as described below. AECAs have been reported in Behçet's disease (Direskeneli et al., 1995), but their pathogenic significance is unknown.

Mor et al. (2002) have identified autoantibodies to tropomyosin in some patients with Behçet's disease, but this has not been confirmed.

Genetic Features

Behçet's disease is strongly associated with HLA-B51 in many different ethnic groups between the Middle East and Japan (Mizuki et al., 1997). Interestingly, the distribution of populations with a high frequency of HLA B51 parallels the distribution of Behçet's disease. The association between HLA-B51 and Behçet's disease does not hold true outside the Silk Road area (Sakane et al., 1999).

Environmental Influences

Infections have been implicated in the induction of Behçet's disease; however, a causal relationship has not been elucidated (Sakane et al., 1999). One possible link is through an immune response to microbial HSPs that stimulates an autoimmune response to homologous self-HSPs (Direskeneli, 2001)

Animal Models

Stanford et al. (1994) injected eight HSP peptides into the footpads of Lewis rats. Anterior uveitis, which is a major manifestation of Behçet's disease, was induced with six of the eight peptides. The most pathogenic peptides were derived from the sequence of human 60-kDa HSP and induced uveitis in 64–75% of rats.

Hu et al. (1998) injected a human 60-kDa HSP-derived peptide subcutaneously into rats and induced uveitis in 80%. Uveitis also was induced in 75% of rats given the peptide orally, 75% given the peptide nasally, and 92% given the peptide by both routes. Treatment with monoclonal antibody to CD4 T-lymphocytes or with IL-4 caused a decrease in uveitis. Conversely, treatment of the rats with monoclonal antibody to CD8 lymphocytes greatly enhanced the speed of onset of uveitis.

Mor et al. (2002), who have identified autoantibodies to tropomyosin in the sera of patients with Behçet's disease, immunized Lewis rats with bovine α-tropomyosin. The immunized rats developed uveitis and skin lesions with neutrophil-rich inflammation. Tropomyosin is found in many cell types, including endothelial cells, which raises the possibility that antibodies to tropomyosin can function as AECAs (Kaneko et al., 2004).

Pathogenic Mechanisms

The cause of Behçet's disease has not been completely elucidated. Acute inflammation lesions, including the vasculitis lesions, show intense infiltration of neutrophils. Circulating neutrophils from patients with Behçet's disease have evidence for increased priming (activation), such as increased production of oxygen radicals and enhanced chemotaxis (Sakane et al., 1999). There are increased circulating cytokines that activate neutrophils and endothelial cells, such as TNF-α, IL-1β, and IL-8 (Sakane et al., 1999). This enhanced activation of neutrophils and endothelium could be acting in concert with other acquired or innate immunologic mechanisms to cause vasculitis. Jorizzo et al. (1985) examined the earliest acute lesions in small vessels and suggested an immune complex pathogenesis, but there is no definitive confirmation for participation of vessel wall immune complexes in disease induction. An autoimmune response to HSPs could be playing a primary or secondary role in the inflammation. Direskeneli (2001) has proposed that streptococcal and human HSP60 expression may be upregulated in oral and genital mucosa and skin after nonspecific minor injuries stimulate self-HSP60 reactive clones. These T-cells might then traffic to other organs to cause systemic inflammation, e.g., in the ocular compartment where they could interact with retinal HSP60.

Immunologic Markers in Diagnosis

There is no specific immunologic marker for Behçet's disease. Lehner (1997) has proposed that the specific proliferative response of T-lymphocytes to four peptides derived from HSP65 can be used as a laboratory test for the diagnosis of Behçet's disease, but this approach has not been validated.

The skin pathergy test is a classical marker for Behçet's disease. A positive result is an area of erythematous induration 2 mm or larger in diameter at the site of a sterile needle stick. Typically, a positive reaction peaks at 48 h and resolves in 4–5 days.

Treatment and Outcome

The treatment and outcome of Behçet's disease is dependent on the nature and severity of the clinical manifestations, which vary from very mild and limited to the classical triad locations to very severe with life-threatening involvement of the CNS, gastrointestinal tract or large vessels (Sakane et al., 1999). Anti-TNF-α therapy has been used successfully for refractory or sight-threatening ocular disease, especially uveitis (Murray and Sivaraj, 2005). Topical treatment with corticosteroids usually is sufficient for mucocutaneous lesions unless eye or vital organs are affected. High-dose

corticosteroids sometimes combined with immunosuppresive drugs are required to manage CNS disease or arteritis. Surgical intervention may be required for large vessel disease with aneurysms or occlusion.

CONCLUDING REMARKS

A variety of pathogenic immunologic mechanisms, including autoimmune processes, mediate necrotizing arteritis and SVV. Clinically, and even pathologically, identical disease can be produced by distinctly different mechanisms; and a given pathogenic mechanism can produce more than one clinical and pathologic pattern of vasculitis. Because different organs can be affected in different patients, the clinical manifestations of even relatively specific types of vasculitis are extremely variable among patients. Therefore, the diagnosis of systemic vasculitis, including autoimmune vasculitis, is difficult, and requires skillful integration of clinical, pathologic, and laboratory data. Although difficult, precise diagnosis is essential for proper management, because the prognosis and appropriate treatment vary substantially among different categories of vasculitis. As knowledge of pathogenic immunologic mechanisms and inflammatory mediator systems increases, more effective treatments for immune-mediated vasculitis will emerge, which will make precise diagnosis even more important.

The glomerulus has a cellular crescent.

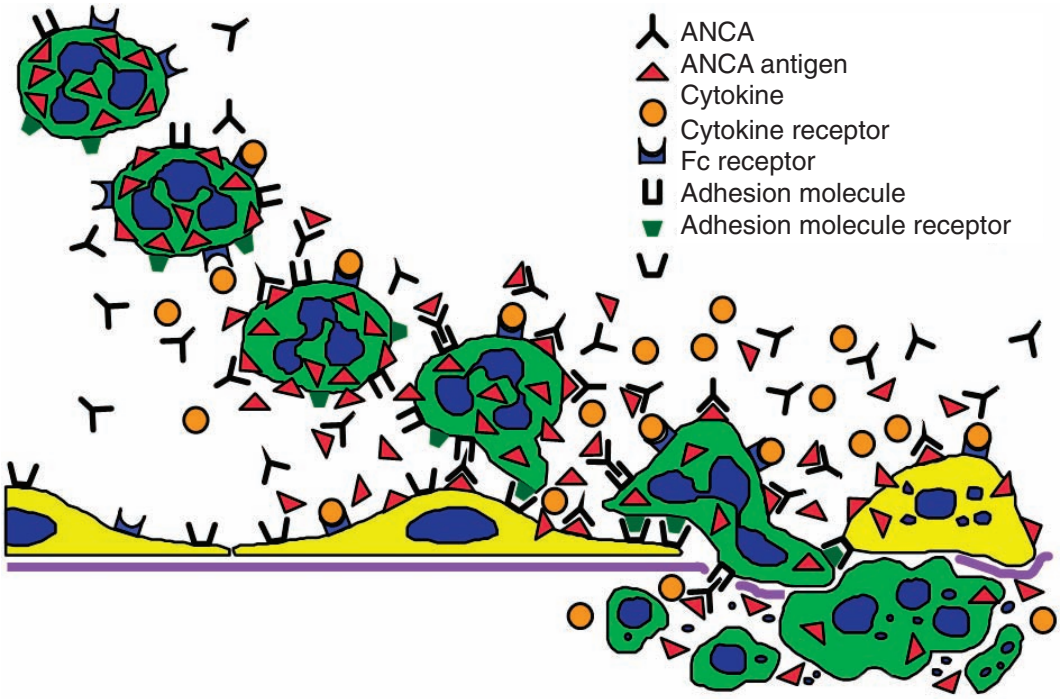

FIGURE 65.6 Putative pathogenic mechanism for antineutrophil cytoplasmic autoantibody (ANCA)-induced vasculitis. ANCA antigens (granule proteins) that are normally within the cytoplasm of neutrophils are transferred to the surface by cytokine priming, where they can interact with ANCAs. Some antigens also are released and can bind to endothelial cells. These free and bound antigens can also react with ANCAs. The interaction of neutrophils with ANCAs induces full activation with respiratory burst and degranulation, which causes vascular injury (vasculitis).

Large and Medium Vessel Vasculitides

CORNELIA M. WEYAND AND JÖRG J. GORONZY

Department of Medicine, Kathleen B. and Mason I. Lowance Center for Human Immunology, Emory University School of Medicine, Room 1003 Woodruff Memorial Research Building, 101 Woodruff Circle, Atlanta, GA

VASCULITIDES OF LARGE AND MEDIUM-SIZED BLOOD VESSELS

Vasculitides stand out among the immune-mediated diseases for their potential to rapidly progress to life-threatening complications. Inflammation in the wall of medium-sized and large blood vessels is considered a medical emergency that requires prompt diagnosis and therapeutic management. Arteritides threaten the host through two different mechanisms (Weyand and Goronzy, 2003a). Destruction of the vessel wall leads to aneurysm formation, rupture, and hemorrhage. Alternatively, arteritis initiates luminal stenosis with subsequent occlusion, tissue ischemia, and infarct.

Inflammation in venous vessels is rare, whereas the layered wall structure of large arteries appears to be a preferred site for granulomatous vasculitis, including giant cell arteritis (GCA) and Takayasu's arteritis (TA) (Table 66.1). Both target the aorta and its major branches. However, the overlap in affected vascular territories is only partial, and each entity also manifests in unique arterial beds. Aortitides can be associated with other syndromes, such as relapsing polyarthritis, sarcoidosis, inflammatory bowel disease, and infections; however, GCA and TA are the most frequent causes of aortic wall inflammation (Rojo-Leyva et al., 2000). Notably, age is a strong risk factor for each for these vasculitides with the old susceptible to GCA and the young susceptible to TA. The pathologic and radiographic features can be indistinguishable, and clinical information is necessary to allow for proper diagnosis and classification (Gravanis, 2000).

GIANT CELL ARTERITIS

Giant cell arteritis is also known as temporal arteritis, cranial arteritis, granulomatous arteritis, polymyalgia arteritis, and Horton's disease. Typically, granulomatous lesions are formed in the wall of medium-sized arteries, particularly in the upper extremity and cranial branches of the aorta. $CD4^+$ T cells are recruited to the adventitia of affected blood vessels where they interact with tissue-residing dendritic cells (DC) and undergo *in situ* activation. Activated T cells regulate the differentiation of macrophages into tissue-injurious effector cells and orchestrate the production of growth factors intimately involved in the process of intimal hyperplasia. Vessel stenosis/occlusion leads to ischemia, and blindness-inducing ischemic optic neuropathy is one of the most feared clinical manifestations. Variations exist in the vascular inflammation, which translate into differences of the clinical disease profile. The diagnosis can be made by biopsy of the temporal artery. Almost all patients are older than 50 years of age, and the highest incidence has been reported in persons of Northern European ancestry. If

TABLE 66.1 Principal features of giant cell arteritis and Takayasu's arteritis

	Giant cell arteritis	Takayasu's arteritis
Clinical	Subacute disease onset Restricted to individuals older than 50 years Highest incidence in individuals with Northern European ancestry Often combined with polymyalgia rheumatica	Subacute disease onset 90% of patients are female Highest risk in Asian and South American populations Systemic inflammatory syndrome with malaise, fever, arthralgias, and chest pain
Preferred vascular territories	Extracranial branches of the carotid artery Subclavian–axillary junction Aorta	Aorta Innominate, carotid, subclavian, mesenteric, renal arteries
Severe complications	Blindness Stroke Aortic aneurysm Wasting	Stroke Pulselessness Visual impairment Aortic regurgitation Hypertension
Pathogenesis	Key cellular elements in vasculitic lesions: arterial wall dendritic cells, interferon-γ-producing $CD4^+$ T cells, tissue injurious macrophages Trigger of immune-mediated vascular inflammation unknown Intense systemic inflammation with highly elevated interleukin-6 and hepatic acute phase reactants	Key cellular elements in the vascular lesions: perforin-producing T cells and natural killer cells Instigator of vessel wall inflammation unknown Systemic inflammatory syndrome

diagnosed early and treated appropriately, the clinical outcome is excellent (Weyand and Goronzy, 2003a; 2003b).

Historic Background

In 1932, Bayard Horton and colleagues (Horton et al., 1932) reported on two patients admitted to the Mayo Clinic with "fever, weakness, anorexia, weight loss, anemia and painful, tender areas over the scalp and along the temporal vessels." Histomorphology of the removed temporal artery described periarteritis and arteritis with granulation tissue in the adventitia. Horton recognized that this type of arteritis was distinct from all other vasculitic syndromes and named it "temporal arteritis." Prior descriptions of temporal artery disease suggest that GCA may be a very old disease. In 1890, the English surgeon Jonathan Hutchinson described a patient with a red and swollen temporal artery who had difficulties wearing his hat (Hutchinson, 1890). In the grave of Pa-Aton-Ern-Hebs, built during the Amarna period (around 1350 AD), a blind harpist was shown with nodularity and swelling of the temporal artery. And Ali Ibn Isa (940–1010 BC), an ophthalmologist in Baghdad, recommended removal of the temporal artery not only to treat headaches, but also inflammation of the scalp muscles associated with blindness (Henriet et al., 1989).

Horton deserves credit for recognizing the connection between the constitutional symptoms and the arteritis of the temporal vessels and for introducing temporal artery biopsy as a diagnostic test.

Clinical, Pathologic, and Epidemiologic Features

The clinical manifestations of GCA are characterized by two major dimensions: 1) arterial stenosis and occlusion of arteries causing impaired blood flow, ischemia, and tissue infarction; and 2) systemic inflammation leading to a massive increase in acute phase proteins, liver abnormalities, anemia, weight loss, malaise, and fever (Table 66.2) (Evans et al., 2000; Weyand and Goronzy, 2003). Evidence suggests that the systemic inflammatory syndrome precedes rather than follows vascular inflammation. Clinical symptoms vary depending on the nature of the vascular lesions and the vascular bed preferentially affected. For clinical purposes it is helpful to subdivide the GCA syndrome into different subtypes, including cranial GCA, non-stenosing GCA, large vessel GCA, and polymyalgia rheumatica (PMR).

In cranial GCA, the major focus of the vasculopathy lies in the branches of the aorta that supply the head and the neck. Most often affected are the superficial temporal artery, the vertebral artery, the ophthalmic and posterior ciliary arteries, and, less frequently, the internal and external carotid

TABLE 66.2 The clinical profile for giant cell arteritis

Sign/Symptom	Frequency (%)	Pathology
Headaches	80	
Scalp tenderness	70	
Jaw claudication	30	Vascular stenosis
Ocular symptoms (blindness, amaurosis fugax, motor deficit)	<20	Vascular stenosis
Painful dysphagia	<10	Vascular stenosis
Cough	<10	Vascular stenosis
Limb claudication	10	Vascular stenosis
Absent pulses	<10	Vascular stenosis
Asymmetric blood pressure readings	<10	Vascular stenosis
CNS ischemia	<5	Vascular stenosis
Peripheral neuropathy	<5	Vascular stenosis
Aortic regurgitation	<5	Vascular dilatation
Intense acute phase response (elevated ESR, CRP, IL-6)	90	Systemic inflammation
Anemia	70	Systemic inflammation
Polymyalgia rheumatica	40	Systemic inflammation
Wasting syndrome	30	Systemic inflammation
Synovitis	<5	Systemic inflammation

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; IL-6, interleukin 6.

arteries. Clinical consequences of vascular insufficiency include headaches, scalp tenderness, claudication of the masseter muscles, and vision loss due to ischemia in the visual pathway. The headaches are often intense, throbbing, and sharp in character, and are combined with temporal tenderness. On physical examination, the temporal vessels are thickened, with nodules and absence of pulses. Other arteries of the scalp can be involved. Vision loss is one of the reasons that GCA is considered a prime ophthalmic emergency. Occlusion in branches of the ophthalmic artery results in ischemic optic neuropathy that causes sudden and pain-free blindness. Amaurosis fugax can precede complete vision loss. Patients with blindness in one eye are at high risk to suffer additional visual loss in the other eye. Vascular insufficiency of arteries supplying the orbita can cause a wide spectrum of ophthalmic complications, but ischemic optic neuropathy remains the most frequent ophthalmic manifestation (Glutz von Blotzheim and Borruat, 1997). Intermittent claudication of the masseter and temporal muscles are relatively disease-specific symptoms but only affect a fraction of patients (Smetana and Shmerling, 2002). Usually, jaw claudication is induced by chewing or prolonged talking. Claudication of the tongue and painful dysphagia can occur. Impaired blood flow in the vertebrobasilar and carotid arteries causes ischemia of the central nervous system, e.g., transient ischemic attacks or stroke. Chronic nonproductive cough has been attributed to vasculitis of pulmonary artery branches.

In a subset of patients, the primary targets of vasculitis are the subclavian, axillary, and carotid arteries, and the aorta itself (Brack et al., 1999; Salvarani, 2003). Presenting symptoms of upper extremity vasculitis are claudication of the arms, loss of pulses, paresthesisas, and, only rarely, frank gangrene. Temporal artery biopsies are often negative, and, in the majority of patients, symptoms indicative of cranial ischemia are lacking (Brack et al., 1999). Aortitis can coexist with cranial arteritis or large vessel involvement and predominantly manifests in the thoracic aorta. Silent aneurysm, aortic dissection, or rupture is a consequence of destruction of the elastic membranes (Evans et al., 1984; Lie, 1995). Not unusually, histomorphologic evidence of vasculitis is found during surgical repair of aortic aneurysm. Aortic involvement is typically seen in patients many years after the initial diagnosis of GCA, suggesting a smoldering disease process.

Inflammation of medium-sized arteries in GCA does not necessarily lead to vascular stenosis but may manifest as non-stenosing vasculitis. Only in recent years has it become clear that patients with non-stenosing GCA present with a different clinical profile than those who have lumenal occlusion (Weyand et al., 1997). In non-stenosing GCA, the dominant features are those of intense systemic inflammation, often manifesting as fever and wasting. Frequently such patients seek medical attention because of nonspecific symptoms such as malaise, depression, anorexia, and weight loss and are subjected to a work-up for underlying malignancy. Lack of cranial symptoms, such as headaches, scalp tenderness, and abnormal temporal artery, can generate a challenging clinical scenario in which only the experienced clinician will search actively for vasculitis. Temporal artery biopsy is the diagnostic procedure of choice.

The vasculitic component of GCA may remain subclinical with the systemic inflammatory syndrome appearing in isolation (Weyand and Goronzy, 2003b). Signs and symptoms of impaired blood flow are missing, and clinical findings are dominated by myalgias, stiffness, and laboratory signs of heightened acute phase response. This subtype of GCA is best known as PMR, a clinical syndrome that is about two- to threefold more frequent in incidence than GCA (Doran et al., 2002; Salvarani et al., 2002). Polymyalgia rheumatica and GCA are closely related entities, affecting the same patient population. They can occur together, and PMR can precede or follow GCA. Histologic examination of arterial biopsies is unrevealing, but molecular analysis of arterial tissues demonstrates the activation of immune responses in the vessel wall (Weyand et al., 1994a). Lead symptoms are those of shoulder girdle and pelvic girdle pain and stiffness. Synovitis of hip and shoulder joints has been described in some patients with PMR (Salvarani et al., 1999; Cantini et al., 2001). It has been suggested that arteritic and synovitic forms of PMR exist. However, the diagnosis of PMR is founded on nonspecific findings, such as pain and

Figure 66.1 Giant cell arteritis. elevated acute phase proteins, making it currently impossible to arrive at an objective case definition.

The Vascular Lesion

In its typical form, GCA is a panarteritis with T lymphocytes and macrophages infiltrating into all layers of the vessel wall (Figure 66.1) (Gravanis, 2000). In about half of the cases, granulomatous formations are seen. Giant cells, which give the name to the syndrome, are not necessarily present. They have a tendency to accumulate at the media–intima border, often closely related to the fragmented internal elastic lamina. Inflammatory infiltrates are usually segmental but can be circumferential. Most typical is the focal placement of lesions producing the so-called "skip" pattern of vasculitis. In some patients, the infiltrates are predominately composed of lymphocytes without granuloma formation. The intima is hyperplastic, obstructing the lumen. Frequently, the adventitia is infiltrated by T cells and macrophages. Clusters of lymphocytes and macrophages in the adventitia, at times arranged as cuffs around vasa vasorum, should be considered sufficient to establish the diagnosis of GCA (Björnsson, 2002).

Epidemiology

Among the vasculitic syndromes, GCA is the most frequent in the Western world. Age is the most significant risk factor; the disease almost exclusively occurs in individuals older than 50 years of age, and susceptibility increases as individuals get older (Machado et al., 1988; Salvarani et al., 2004). The female-to-male ratio of patients is 3 : 1. A characteristic feature of GCA is pronounced geographical variations in prevalence. The range of incidence rates spans between 1 and 25 cases in 100,000 persons aged 50 years and older. Highest incidence rates have been reported in Northern Europe, including Iceland, Denmark, and Sweden (Baldursson et al., 1994; Nordborg et al., 2003), as well as in areas of North America settled by populations of Scandinavian origin (Machado et al., 1988), such as Minnesota. Conversely, blacks and Hispanics are infrequently affected (Smith et al., 1983; Gonzalez et al., 1989).

Genetic Features

Giant cell arteritis is an HLA class II-associated disease (Weyand et al., 1992; 1994b). HLA-DR4 confers the highest risk to develop arteritis. Several allelic variants of HLA DR B1*04 are overrepresented among affected individuals. Sharing of sequence polymorphisms in the antigen-binding groove of HLA-DR molecules have been cited as evidence for a role of antigenic peptides in disease initiation. HLA class II polymorphisms seem not to influence the patterning or severity of the disease. Minor effects of polymorphisms in multiple non-HLA genes, such as corticotrophin-releasing hormone, CCL5 (RANTES), intracellular adhesion molecule 1 (ICAM-1), and interleukin 6 (IL-6), have been suggested, some with controversial results (Gonzalez-Gay et al., 2003). It is possible that the marked geographical variations in disease susceptibility are related to differences in population genetics, for example, the representation of HLA class II haplotypes.

Pathogenic Mechanisms

Progress has been made in deciphering the pathogenic mechanisms relevant for the inflammatory injury of the vessel wall (Weyand, 2000; Weyand and Goronzy, 2003a). Data on the systemic component with the massive upregulation of acute phase responses are more limited. A comprehensive pathogenic model would have to explain why individuals of Scandinavian origin develop granulomatous lesions in the walls of selected medium-sized arteries when they reach the seventh to eighth decades of their lives; how panarteritis translates into occlusive vasculopathy; and how vascular insufficiency is related to the clinical profile of the syndrome. Over the last decade, much progress has been made in understanding the pathways of immunostimulation in the artery and how the immune system regulates vessel stenosis/occlusion. A concept explaining the target tissue susceptibility of selected arterial territories is emerging.

Principally, GCA is a chronic inflammatory disease in which $CD4^+$ T lymphocytes establish stable lymphoid microstructures in the arterial wall and orchestrate the differentiation of tissue-injurious macrophages (Figure 66.2). The response-to-injury program of the vessel is maladaptive and leads to overshooting proliferation of the intimal layer resulting in luminal occlusion, ischemia, and infarct of dependent organ structures.

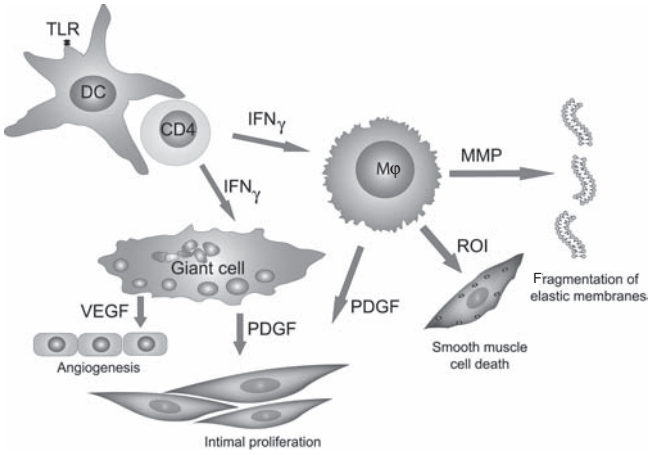

Figure 66.2 Pathogenic pathways in giant cell arteritis. Medium-sized and large arteries possess a population of indigenous dendritic cells (DC) that are located in the inner adventitia and respond to triggering of Toll-like receptors (TLR). Once activated, these DCs recruit and stimulate $CD4^+$ T cells. By producing interferon-γ (IFN-γ), activated $CD4^+$ T-cells orchestrate the effector functions of tissue-injurious macrophages (Mφ) and of multinucleated giant cells. Vessel wall damage is mediated through reactive oxygen intermediates (ROI) and matrix metalloproteinases (MMP). $CD4^+$ T cells also regulate the production of growth and angiogenesis factors (PDGF, VEGF), which facilitate capillary growth and intimal hyperplasia.

T cells and Antigen-presenting Cells in Giant Cell Arteritis

The vast majority of T cells in the lesions are $CD4^+$ T cells of the memory phenotype (Andersson et al., 1987). All evidence suggests that $CD4^+$ T cells enter the vessel wall through the vasa vasorum and not from the main lumen. They infiltrate into the adventitia recruited by chemokines that derive from DCs positioned at the adventitia–media border (Krupa et al., 2002). Adventitial DCs are an indigenous cell population that was only recently described (Ma-Krupa et al., 2004). They form a circumferential ring along the lamina elastica externa. They express typical DC markers, such as CD11c, fascin, and S-100 but lack CD1a and thus are distinct from Langerhans cells in the skin. Functional profiling has demonstrated that they possess Toll-like receptors (TLR) and respond to pathogen-associated molecular patterns.

TLRs are characteristically found on cells of the innate immune system; they are specific for molecular patterns that are generated by pathogens or by tissue injury related to infection (Banchereau and Steinman, 1998; Kaisho and Akira, 2003). Dendritic cells expressing TLRs are placed in strategically important sites, e.g., in the skin and below mucosal surfaces, where they constantly probe their microenvironment for TLR ligands. Classical examples of such ligands are lipopolysaccharides, flagellin, viral RNA, bacterial DNA, and also heat-shock proteins (see Chapter 9). The triggering of TLRs, together with additional signals, initiates the maturation of immature DCs. Upon maturation, such DCs switch their chemokine receptor profile, become migratory, and travel via lymphatic vessels to secondary lymphoid tissues, such as lymph nodes. There they home to the T-cell zones, become stationary, start producing T-cell-attracting chemokines, and upregulate the expression of antigen-presenting HLA molecules and co-stimulatory molecules.

It is not known what the physiological role of adventitial DCs is and what they are checking for. Experiments that utilized the implantation of human temporal arteries into immunodeficient mice have revealed that such adventitial DCs respond to LPS and undergo rapid activation when triggered by blood-borne mediators (Ma-Krupa et al., 2004). In GCA, almost all DCs in the wall are highly activated and have adapted a functional profile reminiscent of that in lymphnode-positioned DCs (Krupa et al., 2002). They produce high amounts of chemokines, are no longer migratory, and can present antigens to T cells. It has been proposed that one of the pathomechanisms in GCA is the trapping of arterial wall DCs in the tissue instead of allowing them to migrate to lymph nodes, which leads to a misplaced immune response.

Experiments in patients with PMR who lack T-cell infiltrates in the temporal artery have supported the concept that DC activation is a very early step in the disease process (Ma-Krupa et al., 2004). In fact, DCs in PMR arteries have already acquired the capability to produce T-cell-attracting chemokines. If appropriate T cells are made available, they will initiate T-cell recruitment and *in situ* activation. How patients with PMR are protected from accumulating T cells in the artery, although tissue-residing DCs have already matured, is not understood.

Once $CD4^+$ T-cells have made their entrance into the adventitial layer of medium-sized arteries, they undergo local activation (Weyand et al., 1994c; Brack et al., 1997). The major consequence is production of interferon-γ (IFN-γ), a key cytokine in the disease (Wagner et al., 1996). Interferon-γ production remains localized in the adventitia, even when the disease progresses and panarteritic infiltrates form. $CD4^+$ T cells undergo clonal expansion and regulate the attraction of macrophages into the lesions. Studies in right-sided and left-sided temporal artery specimens from the same patient have shown that identical T-cell clonotypes emerge in physically separated lesions (Weyand et al., 1994c), providing strong support for antigen-driven selection (Weyand and Goronzy, 1995).

The intensity of IFN-γ production, which could be viewed as a measure of T-cell activation in the vasculitic lesions, has been correlated with the clinical manifestations of this disease. Patients with high production of IFN-γ in the artery have more intense intimal hyperplasia, more visual symptoms, and cranial ischemia. Patients with distinctly low production of IFN-γ in the temporal artery sample often lack

vessel occlusion and tend to present with fever of unknown origin or other constitutional symptoms (Weyand et al., 1997).

Depletion experiments have indicated that $CD83^+$ DCs are the critical antigen-presenting cells and thus have gatekeeper function in the disease (Ma-Krupa et al., 2004). Since DCs sit in a unique position in the artery (outside of the lamina elastica externa), their absence or presence may dictate whether a particular artery is susceptible to be targeted by GCA. This concept pulls together structural characteristics of blood vessels with susceptibility for immune-mediated attack and, for the first time, provides a molecular basis for the unusual patterning of temporal arteritis.

Macrophages in Giant Cell Arteritis

There are no data to suggest that T lymphocytes accumulating in the vasculitic infiltrates have direct involvement in wall injury (Weyand and Goronzy, 1999). Rather, multiple pathways have been identified through which macrophages mediate tissue damage. Macrophage function is closely related to the positioning in the wall, suggesting a tight interaction between infiltrating macrophages and the cellular and matrix components of the particular microenvironment (Weyand et al., 1996).

Macrophages placed in the adventitia usually focus on the production of pro-inflammatory cytokines. IL-1β and IL-6 have been demonstrated in this macrophage population. Tumor necrosis factor-α (TNF-α) has been reported to be present in inflamed arteries, but the cellular source has not been determined. The staining pattern suggests that most of the TNF-α is produced in the media (Hernandez-Rodriguez et al., 2004). Macrophages in the media specialize in generating reactive oxygen intermediates (Rittner et al., 1999a). Numerous lines of evidence have demonstrated the contribution of oxidative stress to the disease process. Gene-expression profiling has guided interest towards oxidative damage. Toxic aldehydes, products of lipid peroxidation, have been detected in the medial smooth muscle cell layer (Rittner et al., 1999a). The formation of nitrotyrosine, a marker of nitrosative stress, has also been localized to the media (Borkowski et al., 2002). Interestingly, only endothelial cells of medial neovessels are affected by nitrotyrosine formation. These studies have pinpointed tissue injury pathways, identified the cellular players, and at least partially described target structures incurring damage.

A noteworthy aspect of the presence of oxidative stress in the media is the induction of protective mechanisms, such as the induction of aldose reductase, a ketoreductase with a role in metabolizing toxic aldehydes (Rittner et al., 1999b). Blocking aldose reductase in GCA lesions increased apoptosis rates of smooth muscle cells, demonstrating a protective role of the enzyme. There is no information about whether patients actually vary in the induction of such protective mechanisms, making them more or less susceptible to oxidative damage.

Other functional properties of media-located macrophages include the secretion of matrix metalloproteinases (MMPs) (Sorbi et al., 1996; Tomita and Imakawa, 1998). CD68-expressing macrophages in the vicinity of the lamina elastica interna are prone to produce MMP-2 as well as MMP-9. Such metalloproteinases almost certainly are the mechanisms underlying the typical fragmentation of the elastic membranes.

So far, macrophages captured in the intima have not been assigned to particular injury pathways (Weyand et al., 1996). They have been described to stain positive for NOS-2, but downstream effects of nitrosative stress have not been detected in the intima itself in GCA.

Intimal Hyperplasia

Blockage of the vascular lumen by hyperplastic intima is the mechanism through which GCA causes vascular insufficiency and tissue ischemia. Myofibroblasts in the intima proliferate and deposit matrix. Whether they originate from undifferentiated precursors or de-differentiate from myocytes is not known. They have migrated to the intima from deeper wall layers, either the media or the adventitia. Factors regulating myofibroblasts migration and differentiation thus have gatekeeper function in the disease process.

Inflamed temporal artery walls produce platelet-derived growth factor (PDGF), which derives from at least two cells types, $CD68^+$ macrophages and resident wall cells (Kaiser et al., 1999). Numerically, the most important sources are macrophages in the media, often close to the lamina elastica interna. Multinucleated giant cells can also produce this growth factor. Fibroblast growth factor has been described to be present in vasculitic lesions; its function is unexplored.

The outgrowth of the expanding intimal layer needs to be supported by the formation of new blood vessels (Kaiser et al., 1998; Cid, 2002). Neoangiogenesis typically affects the media and the hyperplastic intima. Newly formed blood vessels are highly organized. Multinucleated giant cells have been found to secrete vascular endothelial growth factor (VEGF) (Kaiser et al., 1998). In essence, tissue-infiltrating macrophages appear to have a critical role in regulating the process of intimal proliferation and neoangiogenesis. Interestingly, VEGF production is correlated with IFN-γ production, thereby connecting the wall remodeling in the intima and media with the adaptive immune responses in the adventitia.

The Systemic Inflammatory Syndrome

Mechanisms driving the systemic inflammatory component of GCA are less well understood. Patients with PMR

in whom vascular inflammatory infiltrates are undetectable by standard histology are equally affected by systemic inflammation as GCA patients with full-fledged vasculitis (Wagner et al., 1994; Weyand et al., 1999). This clinical constellation has supported the concept that systemic inflammation is not a "spillover" from the vasculitis; instead, it precedes vascular inflammation and has pathogenic roots that do not necessarily lead to arteritis.

Typical findings include a massive acute phase response with manifestations in multiple organ systems (Weyand and Goronzy, 2003b). Patients show signs of abnormalities in hematopoiesis, such as anemia and thrombocytosis. Liver function is often abnormal and shows elevation of alkaline phosphatase levels. By affecting the central nervous system, the acute-phase response causes fever, malaise, and depression. Profound elevation of the erythrocyte sedimentation rate (ESR), a typical laboratory marker of GCA, is also a consequence of excessive production of acute phase proteins.

The only known pathomechanism related to the systemic inflammatory syndrome is the production of high amounts of IL-6 (Roche et al., 1993; Wagner et al., 1994; Weyand et al., 2000), a cytokine that has been implicated in inducing acute phase proteins in hepatocytes. In patients with GCA, as well as those with PMR, circulating monocytes are found to be spontaneously activated and produce IL-6 (Wagner et al., 1994). These data suggest initiator function of an activated innate immune system in the syndrome.

Treatment, Monitoring, and Outcome

The golden standard for treatment of GCA is corticosteroids. Patients respond explicitly well, with prompt and substantial improvement of symptoms within 24–48 hours. Initial doses of 60 mg of prednisone (or approx. 1 mg per kg body weight) have been found to be effective in almost all patients. Indeed, current discussions center on the question of whether at least some patients could be successfully treated with lower doses (Chevalet et al., 2000).

Once patients are stabilized on high doses of corticosteroids, daily prednisone doses should be tapered. A reduction of 10–20% every 2 weeks has proven to be a clinically useful guidance. Both clinical symptoms and laboratory markers of inflammation are monitored to guide the tapering process. There is preliminary evidence that IL-6 is a more sensitive marker of disease activity than ESR, but properly designed clinical trials have not been performed (Weyand et al., 2000). A frequent clinical dilemma is a discrepancy between clinical and laboratory findings. To avoid overutilization of corticosteroids, it has been recommended that treatment decisions should not be solely based on laboratory results.

Many patients develop signs of flaring disease when corticosteroids are reduced. Fortunately, severe manifestations, such as sight-threatening ischemic complications, appear to be rare (Aiello et al., 1993; Weyand et al., 2000). Instead, most disease flares present as PMR or constitutional symptoms. Dose adjustments of corticosteroids can effectively recapture disease control.

Corticosteroids can be discontinued in most patients after approximately 2 years of therapy. There is evidence that the disease process does not enter remission but continues with smoldering activity (Uddhammar, 2000; Weyand et al., 2000). Whether that chronic state of inflammation requires continued immunosuppression or can be managed by watchful monitoring is a matter of discussion.

One of the serious long-term consequences of GCA is the development of aortic aneurysm (Evans et al., 1994; Lie, 1995). Patients need to be informed about this complication, and monitoring for aortic wall thickness and aortic dimension has been recommended. It is unknown whether continuous immunosuppression can prevent aortic wall damage.

With an average age of almost 75 years at disease onset and the duration of therapy for several years, patients are prone to show steroid side effects (Proven et al., 2003). Monitoring of blood glucose and blood pressure is obvious. Also, bone-sparing therapy with calcium and vitamin substitutions (and other agents if necessary) should be a fixed component of management.

Given the high rate of steroid side effects, efforts have been made to identify steroid-sparing therapies. In an experimental model of GCA with human temporal arteries implanted into immunodeficient mice, aspirin effectively suppressed IFN-γ production and augmented the anti-inflammatory effects of corticosteroids (Weyand et al., 2002). In contrast to other chronic inflammatory diseases, patients with GCA seem not to benefit from methotrexate as an immunosuppressant. Although results of clinical trials have been controversial, a well-designed clinical study with a large cohort of patients could not demonstrate any advantage for methotrexate/corticosteroid combination therapy compared with corticosteroids alone (Jover et al., 2001; Spiera et al., 2001; Hoffman et al., 2002). New biologic agents, such as cytokine inhibitors, are in the process of being tested for their steroid-sparing activity in GCA.

Overall, the outcome of GCA is good. No shortening of life expectancy has been reported, emphasizing that highly aggressive therapies may have to be used with caution (Matteson et al., 1996; Gran et al., 2001).

TAKAYASU'S ARTERITIS

Takayasu's arteritis is a systemic arteritis that predominantly manifests in the aorta and its major branches. It is also known as pulseless disease or occlusive thromboaortopathy. The typical patient is a female of Asian or South American origin presenting with vascular insufficiency and

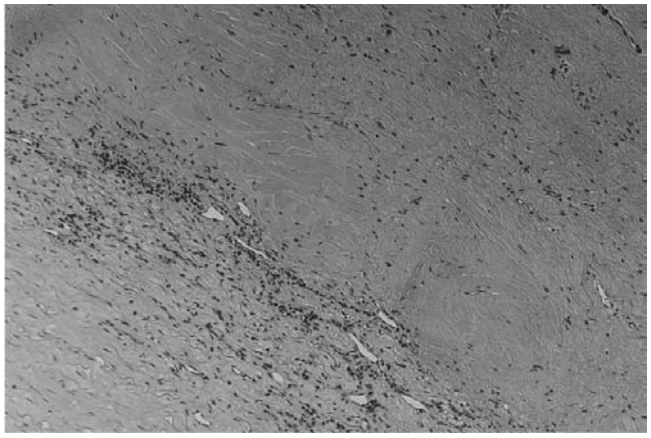

Figure 66.3 Takayasu's arteritis. Cross-section of an innominate artery. Note transmural round cell infiltration with dominance of inflammation along the media–adventitia border. Extensive neovascularization has occurred in the media. The adventitia shows fibrotic expansion.

generalized inflammation in the second or third decades of life. But care has to be taken not to miss the diagnosis in males and middle-aged individuals. Inflammatory infiltrates in the wall of large elastic arteries induce thickening of the adventitia, destruction of the media, and hyperplasia of the intima (Figure 66.3) (Gravanis, 2000). Recently, diagnosis and management of TA have benefited from advances in non-invasive imaging methods and more aggressive use of surgical procedures.

Historic Background

In 1830, Yamamoto reported the first case of TA. In 1908, M. Takayasu was the first to describe peculiar optic fundus abnormalities with coronal anastomosis (Takayasu, 1908), which 40 years later were interpreted as neovascularization and anastomosis secondary to ischemia caused by the occlusion of cervical vessels. In 1951, Shimizu and Sano described a cohort of 31 cases and made the connection between pulselessness, coronal anastomosis of retinal vessels, and carotid abnormalities and called it pulseless disease (Shimizu and Sano, 1951).

Clinical, Pathologic, and Epidemiologic Features

Takayasu's arteritis is a rare disease with incidence rates of 1–2 cases in 1 million individuals per year (Watts and Scott, 1997). The most significant risk factors are female sex, age less than 40 years, and selected ethnic origin. The highest prevalence rates have been reported for Asian countries, including Japan, Korea, China, India, Thailand, and Turkey (Koide, 1992). South American countries, such as Mexico, Brazil, Columbia, and Peru, are now also considered higher incidence areas (Dabague and Reyes, 1996). The disease does occur in whites, can affect males, and needs to be kept in mind as a differential diagnosis in older individuals with aortitis or large vessel vasculitis.

Prominent histomorphologic findings include the thickening of the aortic wall which may involve all three layers (see Figure 66.3) but often is most significant in the adventitia (Gravanis, 2000; Björnsson, 2002). Extensions of inflammatory infiltrates and fibrosis into the periaortic tissues are not unusual. Most often, the aortic lumen is compromised, but stenotic lesions can alternate with aneurysmal dilatation giving rise to fusiform or saccular aneurysms. Also characteristic are "skipped" areas with normal vessel wall next to densely inflamed regions. Besides the aorta and its primary branches, coronary and pulmonary arteries can be involved.

Microscopic examination shows inflammatory infiltrates composed of lymphocytes and plasma cells primarily around the vasa vasorum, causing vasa vasoritis with lumenal stenosis. Lymphocytes, plasma cells, and occasional giant cells accumulate in the media, sometimes complicating the distinction between GCA and TA (Gravanis, 2000). Patches of medial necrosis can occur, and destruction of elastic membranes is typical. Growth of fibroblasts and smooth muscle cells and deposition of acid mucopolysaccharides result in widening of the intimal layer, similar to that in fibromuscular hyperplasia. Vascular insufficiency in the aortic branches is related to ostial stenosis or direct involvement.

Available data suggest that the clinical spectrum of TA is different in distinct geographic areas (Numano, 1997). Japanese, Korean, and North American patients are more likely to present with impairment of cervical, cerebral, and upper extremity blood flow and aortic regurgitation, due to involvement of the ascending aorta and the primary aortic arch branches. Conversely, in Indian patients, the abdominal aorta, including the renal arteries, appears to be the preferred target, resulting in renovascular hypertension. Overall, blindness and severe retinal ischemia are less common now than they used to be (Numano, 2002).

Initial presentation may be dominated by a generalized inflammatory syndrome with fever, night sweats, weakness, arthralgias, and chest pain (Kerr et al., 1994). Direct complications of vessel wall inflammation include headaches, syncope, visual disturbances, and face and neck pain from insufficient blood flow in the cervical vessels (see Table 66.3). Stenotic lesions in the brachiocephalic and subclavian arteries lead to arm claudication, pulselessness, and discrepant blood pressure measurements (Figure 66.4). Ischemic heart disease is a result of reduction in coronary blood flow. A feared complication of TA is aortic regurgitation caused by dilatation of the ascending aorta. Congestive heart failure is not unusual (Endo et al., 2003).

TABLE 66.3 The clinical spectrum for Takayasu's arteritis

Organ system	Sign/symptom	Frequency (%)
Vascular	Bruit	70
	Claudication	70
	Reduced/absent pulses	60
	Asymmetrical blood pressure	50
CNS	Dizziness	40
	Visual abnormalities	30
	Stroke/TIA	10
Constitutional	Malaise	70
	Fever	30
Cardiac	Weight loss	20
	Aortic regurgitation	20
	Angina	10
	Congestive heart failure	<5

Figure 66.4 Takayasu's arteritis. Angiography of the aortic arch and the cervical vessels. The native brachiocephalic artery *(black arrow)* is occluded just distal to its origin. A graft has been placed *(white arrows)* from the ascending aorta to the right common carotid artery with a separate limb connecting to the right subclavian artery. The left carotid artery and both vertebral arteries are normal.

Marked progress has been made in imaging modalities, compensating at least partially for the difficulties in accessing tissue to establish the diagnosis of TA and follow its course for patients receiving therapy. Besides conventional angiography, which has been the standard imaging tool for diagnosing and evaluating patients with TA (see Figure 66.4), a number of alternatives have emerged, including magnetic resonance (MR) imaging and MR angiography, computed tomography (CT), Doppler ultrasound, and metabolic imaging with positron emission tomography (PET) (Kissin and Merkel, 2004). Ultrasound is particularly useful in evaluating the carotid arteries, with high sensitivity for submillimeter changes in wall thickness. Both CT and MR imaging provide excellent visualization of vessels and their relationship to neighboring structures and demonstrate both lumenal and mural abnormalities. Contrast enhancement is necessary for CT to depict the vessel lumen, but it can provide fast information about the aorta and its wall; MR imaging has inherent multiplanar imaging capabilities, can be used with or without contrast enhancement, and lends itself for the evaluation of the aorta ands its major branches (Matsunaga et al., 2003; Nastri et al., 2004). With the potential to assess mural edema and vascularity, it has been hoped that it would be an ideal instrument to monitor disease activity and progress in patients on immunosuppression. However, a recent study has cast doubt on the utility of edema-weighted MR as a sole means to estimate disease activity (Tso et al., 2002). A role for PET, which detects areas of active glucose metabolism in the vascular wall in identifying early disease, has been suggested (Webb et al., 2004), but no large-scale controlled studies are available.

Genetic Features

Like GCA, TA is an HLA-associated disease (Kerr et al., 1994; Salazar et al., 2000). More than half of the Japanese patients carry the HLA A24-B52-DR2 haplotype (Kimura et al., 1996). Non-polymorphic HLA molecules, specifically MICA, have also been reported to be enriched among patients (Kimura et al., 1998).

Pathogenic Mechanisms

Despite considerable overlap in the histomorphology and clinical presentation of GCA and TA, evidence suggests that pathogenic mechanisms are distinct (Seko, 2002). Whereas $CD4^+$ T cells producing IFN-γ have been identified as key regulators in the vascular lesions of GCA, they appear to be less important in TA. In the vascular infiltrates of TA, γδ T cells account for 31% of the cells, natural killer cells for 20% and $CD8^+$ cytotoxic T cells for 15% (Seko, 2000). $CD4^+$ T cells, macrophages, and B cells were less frequent. In support for the concept that cytotoxic cells directly damage resident cells in the aorta, Seko et al. (Seko et al., 1994) have shown cellular expression of perforin and deposition of perforin directly onto wall resident cells (Figure 66.5). Heat-shock proteins, in particular HSP65, have been proposed as the antigen stimulating cytotoxic lymphocytes (Seko et al., 2000). Restricted usage of T-cell receptor AV and BV genes in tissue infiltrating T cells also support the concept of selective expansion of antigen-reactive T cells in the vessel wall infiltrates (Seko et al., 1996). Dense expression of co-stimulatory molecules is in line with a role for adaptive immune responses driving the disease process. Recent data suggesting a possible role of metalloproteinases as

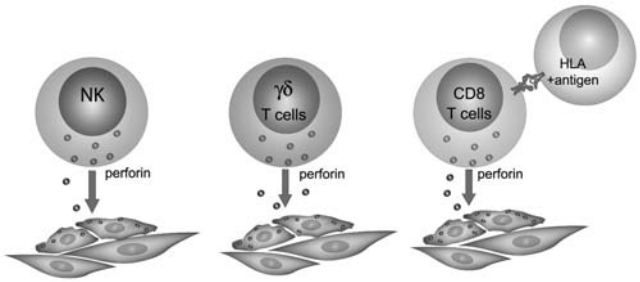

Figure 66.5 Schematic model of pathogenic pathways in Takayasu's arteritis. Vascular infiltrates are predominantly cytotoxic $CD8^+$ T cells, γδ T cells, and natural killer (NK) cells, all of which produce the pore-forming enzyme perforin and, upon activation, release perforin to kill vessel wall cells, such as vascular smooth muscle cells. HLA molecules, which serve as the ligand for $CD8^+$ T cells, and co-stimulatory molecules, which amplify T-cell activation, are both highly expressed in the vascular lesions of Takayasu's arteritis.

biomarkers of disease activities refocus interest on macrophage-dependent disease mechanisms (Matsuyama et al., 2003). Destruction of elastic membranes points towards release of elastolytic enzymes, likely derived from tissue-infiltrating macrophages.

Much less is known about the pathomechanism of the systemic inflammatory syndrome. Cytokine levels of IL-6 and RANTES have been reported to be elevated and to correlate with clinical activity (Noris et al., 1999).

Treatment and Outcome

Immunosuppressive therapy remains the mainstay of treatment for this arteritis, but, in contrast to GCA, surgical procedures are gaining in importance for managing patients with TA (Tada, 1994).

As with most rare disease, randomized controlled treatment trials are explicitly difficult to perform, are missing, or are based on small patient numbers. The immunosuppressants of choice are corticosteroids, which are started at a dose of 40–60 mg/day prednisone. Clinicians in Japan have advocated doses of only 20–30 mg/day (Numano, 2002). Once acute disease activity is controlled, an effort needs to be made to reduce corticosteroids. Tapering by 5 mg/day every 2–3 weeks has been adopted as a useful guideline. However, there has been agreement that a target maintenance dose of 5–10 mg/day should be kept stable over a prolonged period to avoid exacerbation of vascular and generalized inflammation. Although not formally tested, most patients receive aspirin or an alternative agent to reduce platelet aggregation and thrombus formation.

About 50% of patients may be considered to be insufficiently treated with corticosteroid monotherapy (Kerr et al., 1994). Some of these patients may benefit from methotrexate as a steroid-sparing agent (Hoffman et al., 1994). Mycophenolate mofetil has been reported to show clinical efficiency in a small patient cohort (Daina et al., 1999). A recent report suggests that blocking TNF-α may be helpful in treating patients with persistent disease activity (Hoffman et al., 2004).

Monitoring for and managing hypertension is prudent in patients with TA. There is an ongoing discussion about whether vascular inflammation predisposes for the accelerated development and progression of atherosclerosis, although it may be difficult to separate these disease processes (Numano et al., 2000). Accelerated atherosclerosis demands appropriate monitoring for risk factors and treatment of dyslipidemia.

Critical renal artery stenosis, limiting claudication of extremities, cerebrovascular ischemia, coronary ischemia, and aortic regurgitation may represent indications for surgical intervention. If clinically possible, quiescence of vascular inflammation should be aimed for prior to surgery. Prevention of stroke may be possible if critical stenosis of cervical vessels is bypassed with grafts originating from the ascending aorta. Percutaneous transluminal angioplasty has emerged as an alternative to bypass surgery, specifically for renal artery stenosis (Weaver et al., 2004), and may be useful for preserving the competence of vessels in other territories.

The best outcome data for TA are available from Japan where all patients with TA are registered by the government. Analysis of 897 patients through 1998 showed that more than 70% of patients had well-controlled disease, enjoying almost normal lives. Twenty-five percent of patients had severe complications. Cardiac manifestations have become the most common cause of death among TA patients (Numano, 2002).

CONCLUDING REMARKS— FUTURE PERSPECTIVES

Vasculitides are infrequent yet clinically challenging diseases because they threaten blood supply to vital organs. Damage to large and medium-sized arteries immediately puts the host at risk for severe clinical consequences, as compensatory mechanisms for losing the function of the aorta and its major branches are very limited. In contrast to non-inflammatory vasculopathies, arteritides are characterized by a combination of ischemic tissue damage and a syndrome of generalized inflammation. Pathogenic mechanisms relevant for these two dimensions of disease may be distinct and respond differentially to therapy. Systemic inflammation is caused by the excessive production of cytokines. In the cases of GCA and TA, induction of an abrupt and massive acute phase response is typical. As part of the acute phase response, patients produce hepatic acute phase proteins that give rise to diagnostically important laboratory abnormalities, such as increases in ESR and C-reactive protein (CRP).

In both GCA and TA, T lymphocytes are the key regulators of tissue injury in the blood vessel wall. They either mediate direct cellular damage, as in the case of TA, or orchestrate the functional activity of tissue-injurious macrophages, as in GCA. Arterial wall injury causes hyperproliferation of myofibroblasts and results in thickening of the intima, the underlying mechanism of vessel stenosis/occlusion. In GCA, tissue-resident dendritic cells have been implicated in initiating T-cell activation, possibly after being triggered by blood-borne stimuli. There is no evidence that autoantibodies or other B-cell-dependent functions contribute to large vessel vasculitis (Martinez-Taboada et al., 1996).

Giant cell arteritis and TA are unusual among the chronic inflammatory diseases in that they respond very well to corticosteroids. However, even prolonged therapy can usually not induce complete remission, and side effects are common. So far, alternative immunosuppressive agents have been amazingly ineffective in treating GCA but may have a role in TA. Major progress could be made by targeting disease pathways, such as the oxidative damage of vessel wall resident cells, and the process of intimal hyperplasia (Weyand and Goronzy, 2003a).

Despite advances in non-invasive imaging methods, it has proven difficult to monitor patients for disease activity. Cytokines may be useful biomarkers in assessing the "burden of disease," at least as far as the systemic inflammatory syndrome is concerned. Well-designed clinical trials are necessary to validate the use of cytokine levels, particularly for IL-6, as a marker of disease in patients.

The ultimate challenge in understanding GCA and TA remains the identification of the initial triggers of the disease processes. Although infections have been suspected, scientific evidence for their role in starting arteritis is lacking (Regan et al., 2002; Nordborg and Nordborg, 2003). Local factors intrinsic to the artery itself, such as dendritic cells positioned in the adventitia of medium-sized and large arteries, may be instrumental in breaking tolerance and giving rise to misplaced immune responses (Ma-Krupa et al., 2004). Also, age is a major risk factor in GCA and TA, suggesting that age-related changes in T-cell function may be critical determinants of disease susceptibility (Goronzy and Weyand, 2003).

CHAPTER

67

Idiopathic Bronchiolitis Obliterans, Idiopathic Pulmonary Fibrosis, and Autoimmune Disorders of the Lung

BRIAN D. GELBMAN* AND RONALD G. CRYSTAL*†

**Division of Pulmonary and Critical Care Medicine and †Department of Genetic Medicine, Weill Medical College of Cornell University, New York, New York, USA*

Idiopathic bronchiolitis obliterans (IBO), a disorder of the small airways, and idiopathic pulmonary fibrosis (IPF), a disorder that affects primarily the alveoli, are chronic inflammatory/fibrotic disorders that are typically progressive and often fatal. Although both are classified as "lung disorders of unknown etiology," there are multiple clues suggesting that autoimmune mechanisms play a role in the pathogenesis of both disorders. The focus of this chapter is to explore the link between autoimmune mechanisms underlying IBO and IPF as models for autoimmune disorders of the lung. To do so, we will first discuss the history and the clinical features of IBO and IPF, followed by a summary of the autoimmune, genetic, environmental features, current concepts of pathogenesis, and the therapies currently available and under investigation for both disorders.

HISTORY

Although both IBO and IPF are inflammatory/fibrotic disorders, because they are centered on the bronchioles and alveoli, respectively, and have different clinical, radiologic, and pathologic features, they have always been considered to be different disorders.

Idiopathic Bronchiolitis Obliterans

The term "bronchiolitis obliterans" was first used by Lange in 1901 when he described two patients in whom the bronchioles were blocked by plugs of granulation tissue (Lange, 1901), though those patients likely had what is now known as "cryptogenic organizing pneumonia" (COP). In 1966, Baar and Galindo used the term "bronchiolitis fibrosa obliterans" to describe concentric rings of fibrotic tissue in the wall of the airways (Baar and Galindo, 1966). In 1973, Gosink et al. employed "bronchiolitis obliterans" to describe a group of patients that had submucosal and peribronchiolar infiltrate of granulation tissue resulting in extrinsic narrowing of the bronchiolar lumen (Gosink et al., 1973). In 1981, Turton et al. added the term "cryptogenic obliterative bronchiolitis" to patients that had progressive airflow obstruction

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

with no identifiable cause, such as asthma, chronic bronchitis, or emphysema (Turton et al., 1981).

During the 1970s, several rheumatologic conditions, particularly rheumatoid arthritis (RA), were recognized to be associated with bronchiolitis obliterans, as were adverse reactions to therapies used for RA such as gold and penicillamine (Geddes et al., 1977). In 1982, Roca et al. described the first case of bronchiolitis obliterans as a complication of bone marrow transplantation in a patient who developed graft-versus-host disease following an allogeneic bone marrow transplant for aplastic anemia (Roca et al., 1982). In 1984, Burke et al. characterized the first case of bronchiolitis obliterans associated with a heart-lung transplant (Burke et al., 1984).

In this chapter, we will focus on "idiopathic bronchiolitis obliterans," the form of bronchiolitis obliterans that is not associated with any known condition or cause, although we will use information regarding other forms of bronchiolitis obliterans to develop the general concepts of the autoimmune features of these disorders.

Idiopathic Pulmonary Fibrosis

The first recognition of the broad category of idiopathic interstitial lung diseases, which includes IPF, is credited to Osler in 1892, when he described a chronic fibrinoid change occurring between the alveolus and the blood vessels (Osler, 1892). Osler demonstrated great foresight by also noting that there were diverse patterns of the disease that made classification difficult.

Idiopathic pulmonary fibrosis, also referred to as "cryptogenic fibrosing alveolitis," "idiopathic interstitial pneumonitis," "usual interstitial pneumonitis," and "idiopathic interstitial pneumonia," was first described by the Czech pathologist Sandoz in 1907, but went largely unnoticed (Sandoz, 1907). Hamman and Rich are frequently credited with the first description of IPF in 1935 (Hamman and Rich, 1935), despite the fact that their initial cases were more acute in presentation, unlike classic IPF, and may have been descriptions of acute respiratory distress syndrome. In 1964, Scadding coined the term "cryptogenic fibrosing alveolitis" to describe IPF as a diffuse inflammatory and fibrotic lung disease affecting primarily the alveoli (Scadding, 1964). Scadding advanced the concept that IPF was a slow, progressive disease that was distinctly different from the relatively acute process described by Hamman and Rich.

Idiopathic pulmonary fibrosis was further defined by Liebow and Carrington in the 1960s using histologic criteria. These investigators separated IPF into two morphologic patterns, which they referred to as "usual interstitial pneumonia" (UIP; now often referred to as "usual interstitial pneumonitis") and "desquamative interstitial pneumonia" (DIP; (Liebow and Carrington, 1969). The inflammatory component of IPF was characterized by our group using bronchoalveolar lavage to distinguish IPF from other interstitial lung disorders (Crystal et al., 1976; Reynolds et al., 1977). The pathologic pattern of UIP was further refined over the next several decades, including the description of nonspecific interstitial pneumonia (NSIP) by Katzenstein and Fiorelli in 1994 as a distinct entity (Katzenstein and Fiorelli, 1994). The classification system developed by the American Thoracic Society and European Respiratory Society in 2001, separates IPF from NSIP and DIP based primarily on pathologic findings (ATS, 2002).

CLINICAL, PATHOLOGIC, AND EPIDEMIOLOGIC FEATURES

Idiopathic Bronchiolitis Obliterans

Bronchiolitis refers to nonspecific small airway inflammation and consequent damage to the airway epithelium. The current classification of the bronchiolar diseases separates constrictive bronchiolitis, characterized by concentric narrowing of the walls of the bronchioles with luminal obliteration, and proliferative bronchiolitis, characterized by an organizing intraluminal exudate fills and obstructs the bronchioles (Figure 67.1). When proliferative bronchiolitis is associated with diffuse alveolar disease, it is considered a distinct disease entity and is referred to as "cryptogenic organizing pneumonia" or "cryptogenic organizing pneumonitis" (ATS 2002; King, 2003a). The category of constrictive bronchiolitis is subcategorized depending on whether the dominant pathology is "inflammatory" or "fibrotic." The "inflammatory" group of constructive bron-

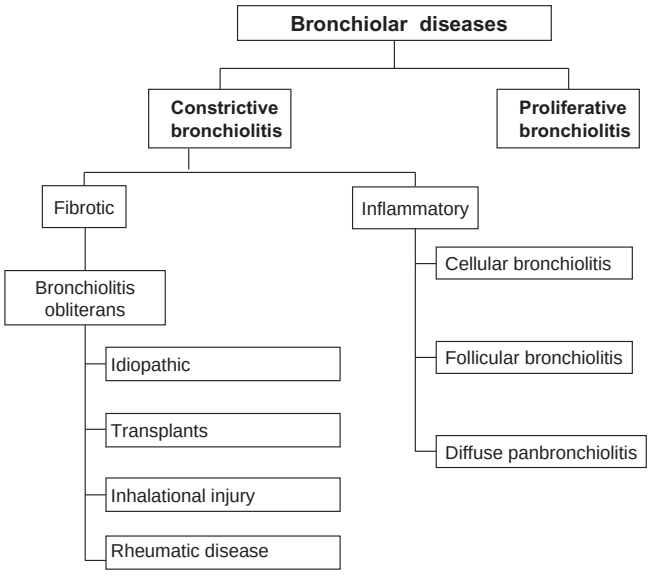

Figure 67.1 Relationship of idiopathic bronchiolitis obliterans to other bronchiolar diseases.

chiolitis disorders includes cellular bronchiolitis, follicular bronchiolitis, and diffuse pan-bronchiolitis. The "fibrotic" group of constrictive bronchiolitis disorders are referred to as "bronchiolitis obliterans," a generic term that describes a bronchiolar disorder with airflow obstruction, in which the primary pathologic features are bronchiolar fibrosis with limited associated bronchiolar inflammation. Bronchiolitis obliterans is associated with several clinical settings, including IBO (the focus of our discussion) as well as bronchiolitis obliterans associated with transplants, inhalational injury, and multisystem autoimmune diseases.

The lack of an accepted classification scheme has led to the continued use of the generic term "bronchiolitis obliterans" to encompass all of these clinicopathologic conditions, independent of whether it is "idiopathic" or associated with another disorder or known cause. For the purpose of this review, we will use the term "idiopathic bronchiolitis obliterans" or IBO to distinguish the idiopathic form from bronchiolitis obliterans associated with transplantation, inhalational injury, and the multisystem autoimmune diseases.

Idiopathic bronchiolitis obliterans is uncommon. It is more prevalent in women (King, 2003a; Kraft et al., 1993). The clinical and pathologic features of bronchiolitis obliterans commonly seen in association with the multisystem autoimmune diseases are identical to the idiopathic form of the disease (King, 2003a; Ryu et al., 2003). A form of bronchiolitis obliterans clinically indistinguishable from the idiopathic form is believed to occur following viral infection; for the purpose of this review, the post-viral form of bronchiolitis obliterans will be considered the same disease entity as IBO.

Individuals with IBO usually present with persistent cough and worsening dyspnea. Physical exam is notable for an end-expiratory wheeze or high pitched end-inspiratory "squeak." Most patients will have an obstructive pattern on pulmonary function testing, although the disease can present with normal, restrictive, or mixed pattern (Markopoulo et al., 2002).

Routine chest radiographs may reveal hyperinflation or reticulonodular opacities, but routine chest X-rays are frequently normal in IBO and are, therefore, limited in utility. High-resolution computed tomography (HRCT), with inspiratory and expiratory views, provides direct and indirect signs suggestive of bronchiolitis (Franquet and Stern, 1999; Markopoulo et al., 2002; Ryu et al., 2003). The only direct sign, bronchiole thickening, is uncommon. The indirect signs include bronchiolar dilatation (bronchiolectasis), and the "mosaic pattern," a heterogeneous display of different densities of the lung parenchyma observed in expiratory views (Figure 67.2). The HRCT mosaic pattern is believed to result from relatively lucent regions that develop from a combination of air-trapping in the alveoli that are unable to collapse during exhalation (because the bronchiole lumens

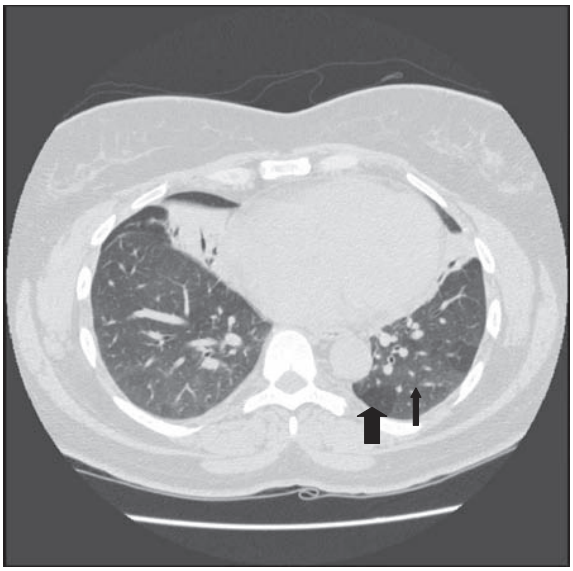

Figure 67.2 Mosaic pattern on high resolution chest tomography taken after expiration typical of idiopathic bronchiolitis obliterans. The thick arrow points to an area of low density, reflecting air-trapping. The thin arrow points to a high density area of lung, which represents normal alveolar collapse during exhalation.

are obstructed) and a decrease in blood flow to the alveoli that remain inflated (Franquet and Stern, 1999; Hansell, 2001). High-resolution computed tomography also is useful for differentiating IBO from disease of the lung parenchyma, such as the interstitial lung diseases of unknown etiology like IPF.

The classic pathologic findings of IBO include extrinsic compression of the bronchiolar lumen caused by surrounding inflammation and fibrosis in the bronchiolar wall (Figure 67.3) (Colby, 1998). In contrast to the "inflammatory" category of constrictive bronchiolitis, in IBO, the fibrosis dominates over the inflammation. As the compression worsens, the airway lumen may become obliterated and scarred. Inflammation and fibrosis can occur in the subepithelial, mural, or adventitial layer of the bronchiole, and usually varies depending on the underlying cause. Other morphologic findings of IBO include smooth muscle hypertrophy, bronchiolectasis, mucostasis, and bronchiolarization of adjacent alveolar spaces (Colby, 1998; Myers and Colby, 1993). The areas affected are scattered and patchy in distribution. For this reason, transbronchial lung biopsy is insensitive as a diagnostic tool for IBO, as it often misses the involved area, and, therefore, a surgical lung biopsy is often necessary to make the diagnosis.

There have been no epidemiologic studies performed to quantify the overall prevalence of IBO. Although it is generally considered a rare disease, it is likely that IBO is underdiagnosed and may account for a small percentage of cases misdiagnosed as asthma or chronic obstructive pulmonary disease (COPD). The prevalence of bronchiolitis obliterans

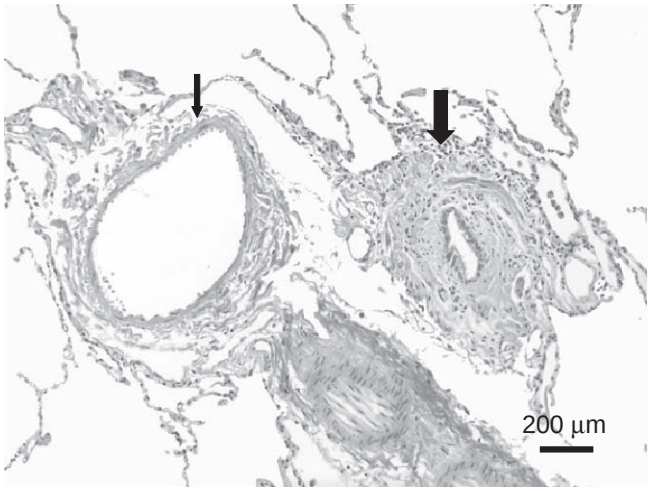

Figure 67.3 Idiopathic bronchiolitis obliterans. The thick arrow points to a narrowed bronchiole, which should have a similar sized lumen as the accompanying blood vessel *(thin arrow)*. The concentric narrowing of the bronchiole is due to fibrosis and scarring in the bronchiole wall. Bronchial smooth muscle hyperplasia is also apparent, while the surrounding alveoli are relatively normal (hematoxylin and eosin, bar = 200 μm).

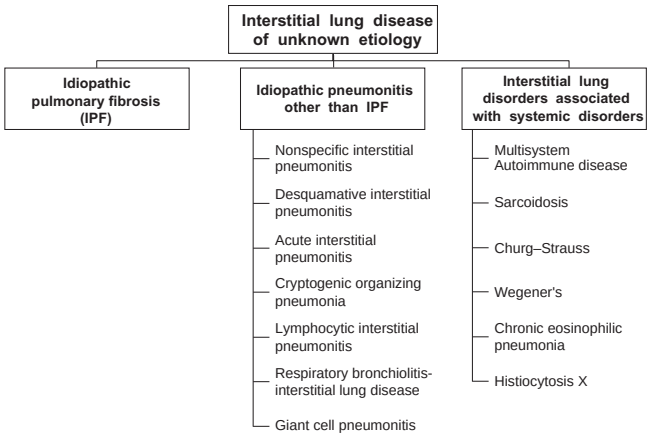

Figure 67.4 Relationship of idiopathic pulmonary fibrosis to other idiopathic interstitial disorders. Some of the rare disorders have been left off the lists (see Schoenberger and Crystal, 1983; Crystal, 1985; ATS 2002 for further details).

in association with RA is less than 1% (King, 2003a). The reported incidence of bronchiolitis obliterans following allogeneic bone marrow transplant is 2–10% of patients who develop graft-versus-host disease (Paz et al., 1993). The incidence in lung transplant recipients is significantly higher, 28, 49, 56, and 71% for individuals at 1, 2, 3, and 5 years post-transplant (Reichenspurner et al., 1996).

Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis (often referred to as "cryptogenic fibrosing alveolitis" in Europe) refers to a distinctive type of chronic inflammatory/fibrotic interstitial lung disorder of unknown cause that is limited to the lungs and associated with a histologic pattern of UIP (Figure 67.4) (ATS, 2002). The pattern of UIP on surgical lung biopsy is also seen in patients with multisystem autoimmune disease who present with similar pulmonary-related clinical features to IPF (Harrison et al., 1991).

Individuals with IPF typically present with the gradual onset of symptoms, most commonly dyspnea on exertion and non-productive cough. Most will have had at least 6 months of symptoms before presentation, with an average duration of 24 months (ATS, 2002). The clinical course typically involves gradual deterioration, occasionally punctuated by periods of rapid decline, although some of the disease stabilizes in some individuals. The best estimates for life expectancy from time of diagnosis to death are derived from case–control cohort studies, because they are not biased like prevalence studies, which tend to be over-represented by survivors. According to two such studies, the average survival from the time of diagnosis to death is 3–4 years (Hubbard et al., 1998; Mapel et al., 1998).

On physical exam, patients with IPF may have digital clubbing (25–50%) and fine, inspiratory, velcro-like crackles confined to the bases of the lungs. As there is progressive loss of alveoli, and the diffusing capacity drops below 50% predicted, pulmonary hypertension develops, first with exercise, and later at rest (Crystal et al., 1976; McLees et al., 1979). Once established at rest, the pulmonary hypertension is associated with an increased pulmonary component of the second sound on cardiac exam, and eventual fixed split of the second sound. In the late stages of the disease, there can be signs of right heart failure such as peripheral edema.

Pulmonary function testing usually shows a restrictive pattern of ventilatory defects and a decrease in diffusing capacity, although in early stages of the disease, these tests can be normal (Fulmer et al., 1979; Keogh and Crystal, 1980; Cherniack et al., 1995). Individuals with IPF typically have mild-to-moderate hypoxemia with concomitant low resting oxygen saturation that falls with exercise (Keogh and Crystal, 1980).

Chest radiographs of individuals with IPF are routinely abnormal with a reticular pattern seen at the periphery and in the bases. Later in the disease, there is honeycombing and volume loss in the lower lobes (Staples et al., 1987). In early stages of the disease, chest radiographs may be normal. The preferred imaging modality is HRCT as it is more sensitive than chest radiograph. The typical HRCT findings are reticular-nodular opacities (Figure 67.5). Later in the disease, traction bronchiectasis is commonly seen in the peripheral and basal segments of the lower lobes. Volume loss, and ground glass opacities are frequently present. As the disease progresses, honeycomb cysts develop and enlarge over time

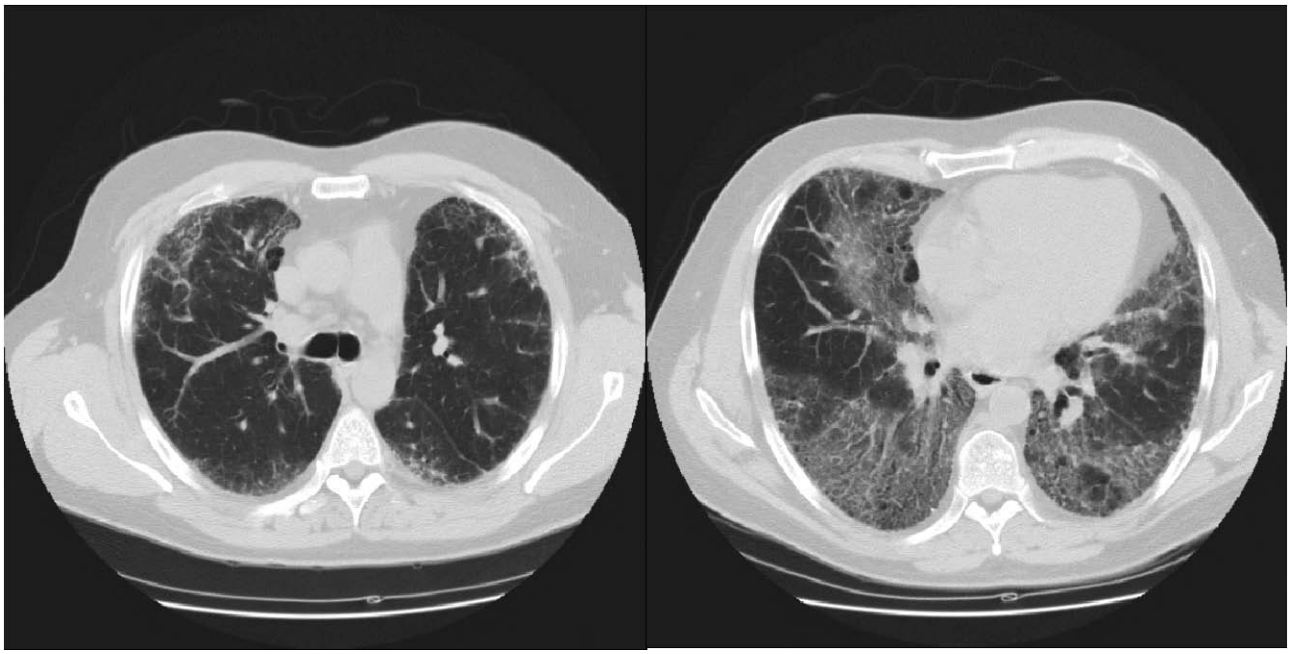

Figure 67.5 Diffuse reticular-nodular pattern on high resolution chest tomography commonly observed in idiopathic pulmonary fibrosis. Note areas of honeycombing in some areas.

(Staples et al., 1987). The chest X-ray and HRCT appearance of IPF is nearly identical to that seen in pulmonary fibrosis associated with the rheumatic disorders, with the lone exception of possibly more basal involvement seen on HRCT in IPF (Chan et al., 1997).

Transbronchial biopsies are insufficient to diagnose IPF because the biopsy specimen is too small and does not preserve the architecture of the lung. However, transbronchial biopsies may be useful to rule out other conditions, such as sarcoidosis, that can mimic IPF. A surgical lung biopsy has been required in the past to firmly establish the diagnosis. However, the recent consensus statement by the American Thoracic Society (ATS) and European Respiratory Society (ERS) permits the diagnosis of IPF when there are typical clinical and HRCT findings of IPF (Hunninghake et al., 2001; ATS, 2002). Surgical lung biopsies are still recommended whenever there are atypical clinical or HRCT features.

The histologic pattern characteristic for IPF is referred to as UIP (Figure 67.6). This pattern is distinct from the other forms of idiopathic interstitial lung disorders such as desquamative interstitial pneumonia, lymphocytic interstitial pneumonia, cryptogenic organizing pneumonia, nonspecific interstitial pneumonia and acute interstitial pneumonia (Liebow and Carrington, 1969; Katzenstein and Fiorelli, 1994; ATS, 2002). There is typically a heterogeneous distribution of interstitial fibrosis interspersed within areas of normal lung, suggesting different temporal stages of involvement. There is patchy inflammation, dominated by alveolar macrophages, and to a lesser extent, lymphocytes, neutrophils, and sometimes eosinophils. The alveolar epithelium undergoes marked changes, referred to as "cuboidalization," with a loss of type I epithelial cells, and their replacement with cuboidal cells, both alveolar type II epithelial cells and bronchiolar epithelium. One hallmark finding in IPF is the subepithelial "fibroblastic focus," which is a nodule of spindle-shaped, mesenchymal cells that produce an abundant deposition of extracellular matrix. These foci are believed to be the "leading edge" of the fibrotic process. Occasionally, the interstitial fibrosis extends through breaks in the epithelium into the alveolar space to form intra-alveolar fibrosis (Basset et al., 1986). Later in the disease there is architectural destruction and fibrosis with honeycombing. Frequently, the subpleural parenchyma is the most severely involved region. When a biopsy shows areas of both UIP and nonspecific interstitial pneumonitis, the default pathologic diagnosis becomes the clinical diagnosis IPF, as these patients have been shown to behave similarly to IPF with UIP-only pattern (Flaherty et al., 2001).

The histologic features of pulmonary fibrosis associated with multisystem autoimmune disease can be classified into the same pathologic descriptions of idiopathic interstitial pneumonias put forth by the ATS and ERS, including UIP, NSIP, DIP, and COP (see Figure 67.4). The UIP pattern that is seen with multisystem autoimmune diseases is essentially identical to the pattern seen in the IPF. In polymyositis, dermatomyositis, and scleroderma, NSIP is the most frequently

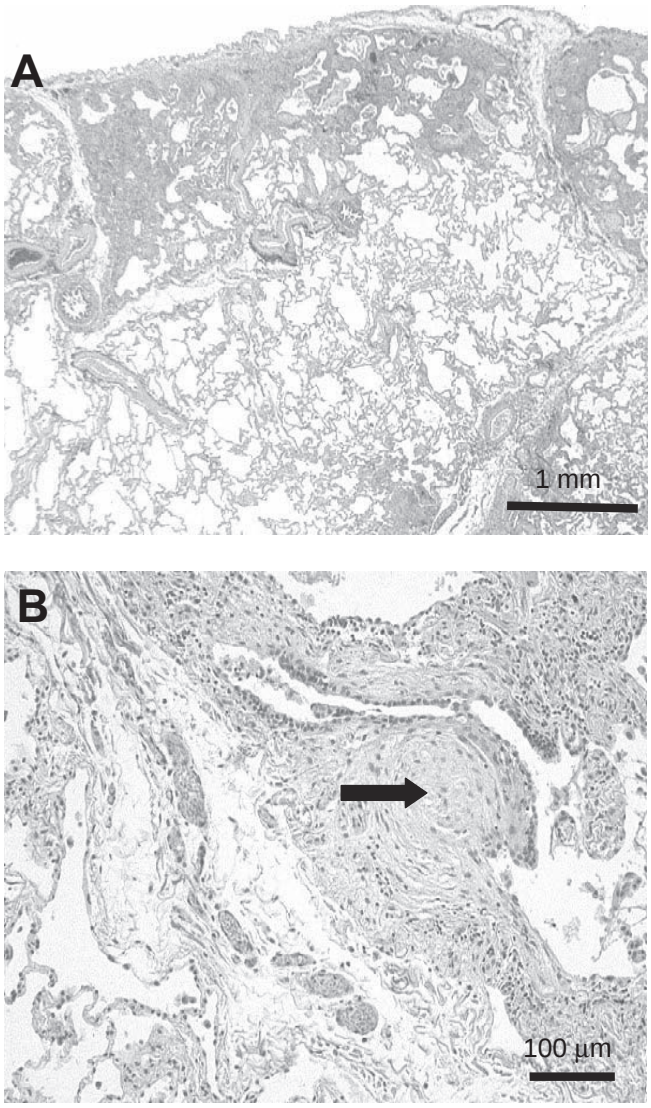

Figure 67.6 Histologic pattern of idiopathic pulmonary fibrosis. The patterns are often referred to as "usual interstitial pneumonitis." *A,* Subpleural, paraseptal and interstitial collagen deposition together with areas of mildly abnormal alveolar parenchyma (hematoxylin and eosin, bar = 1 mm). *B,* Thickened interstitium with collagen deposition, mild to moderate alveolar septal mononuclear cell infiltrates, mainly lymphocytes, cuboidalization of the epithelium and large fibroblastic foci *(thick arrow).* The fibroblastic foci are composed of spindled mesenchymal cells and are thought to represent the "leading edge" of the progressive fibroinflammatory process (hematoxylin and eosin; bar = 100 μm).

seen histologic pattern, followed by UIP (Douglas et al., 2001; Bouros et al., 2002). The prevalence of the different histologic subtypes of idiopathic interstitial pneumonias has not been well characterized in the other multisystem autoimmune diseases.

The estimated annual incidence of idiopathic pulmonary fibrosis is 7 in 100,000 for women and 10 in 100,000 for men. Most patients present between 50 and 70 years of age, however, the incidence, prevalence, and death rate rise with age (Coultas et al., 1994).

Several studies have tried to establish the prevalence of pulmonary fibrosis in patients with the multisystem autoimmune diseases, but the results have varied depending on the method by which patients are screened for pulmonary involvement. Studies that utilize autopsy or lung biopsy data are subject to over-diagnosis since they have been shown to detect subclinical disease that can fail to progress (Cervantes-Perez et al., 1980). Likewise, HRCT screening studies may also overestimate the prevalence of disease by detecting parenchymal changes that may not be clinically significant. In RA, cross-sectional studies using chest radiographs estimate the prevalence to be less than 5% of patients (Hyland et al., 1983). When HRCT is used to screen patients, the prevalence appears to be between 20% and 50%, although these studies are limited by selection bias (Remy-Jardin et al., 1994; Gabbay et al., 1997). Pulmonary fibrosis is most prevalent in scleroderma, where autopsy series have shown it to be present in 70% of cases and chest radiograph series estimate the prevalence between 25% and 65% (Minai et al., 1998; Wiedemann and Matthay, 1989). The prevalence of clinically overt pulmonary fibrosis is 30% in polymyositis and dermatomyositis, 5% in systemic lupus erythematosus, and 10% in Sjögren syndrome (Eisenberg et al., 1973; Gardiner, 1993; Schwarz, 1998).

AUTOIMMUNE FEATURES

Idiopathic Bronchiolitis Obliterans

There are no data regarding autoimmune phenomena in IBO, although bronchiolitis obliterans has been reported in association with many different types of autoimmune disorders, including RA, lupus erythematosus, ankylosing spondylitis, Sjögren syndrome, and systemic sclerosis (Colby, 1998; Ryu et al., 2003). In RA, bronchiolar involvement typically presents in the fifth and sixth decades of life and is more frequently seen in women (Geddes et al., 1977; Epler et al., 1979; Herzog et al., 1981). Most patients with IBO in association with RA have long-standing symptoms of arthritis, though occasionally the pulmonary involvement predates the rheumatologic disease. Immunofluorescence stains in affected lung areas of RA patients have shown IgM and IgG depositions in the alveolar septum (Begin et al., 1982; Yousem et al., 1985).

Further evidence for autoimmune reactivity in bronchiolitis obliterans was demonstrated in bronchiolitis obliterans association with paraneoplastic pemphigus, in which the deposition of IgG antibodies was observed on the surface of bronchial epithelial cells (Nousari et al., 1999). The autoantibodies are reactive against plakins, the cytoskeletal

adhesion molecules (Nousari et al., 1999). These patients also have an inflammatory infiltrate in the bronchiole submucosa consisting of lymphocytes, neutrophils, and plasma cells. Nousari et al. (1999) report that 30% of patients with paraneoplastic pemphigus develop respiratory failure with features of bronchiolitis obliterans.

Indirect evidence for autoimmune mechanisms in IBO comes from the bronchiolitis obliterans syndrome associated with both lung and allogeneic stem cell transplants. These cases, which can be viewed as in-vivo human models of bronchiolar disease, have been more extensively studied than IBO or rheumatic disease-associated form bronchiolitis obliterans. The bronchiolitis obliterans syndrome in association with lung transplantation is the main cause of morbidity and mortality (Arcasoy and Kotloff, 1999). It is a form of chronic lung rejection that is mediated by B-cell and T-cell activation against mismatched HLA class I and II antigens (Kelly and Hertz, 1997). Bronchiolitis obliterans associated with allogeneic bone marrow transplants is also thought to represent graft-versus-host disease. The disease progresses from inflammatory changes around the bronchioles to fibrosis and scarring (Ratanatharathorn et al., 2001). It is interesting to note that in bronchiolitis obliterans syndrome associated with lung transplant or with bone marrow transplant, the bronchioles are the more frequent site for chronic rejection, not the lung parenchyma.

Idiopathic Pulmonary Fibrosis

Although the etiology of IPF remains unknown, it has been hypothesized for 30 years that autoimmune mechanisms to external stimuli are the driving force for repeated injury and inflammation that ultimately leads to fibrosis (Crystal et al., 1976; 1981; 1984). Although no clear infectious or environmental agent has been found as the etiology of IPF (Gross and Hunninghake, 2001), there are extensive data regarding autoimmune cellular and humoral processes ongoing in this disorder.

Initial studies on IPF relevant to autoimmunity focused on identifying autoantibodies that target the pulmonary parenchyma. Turner-Warwick demonstrated that 40% of patients with IPF had circulating, nonspecific autoantibodies such as antinuclear antibodies (ANA) and rheumatoid factor (Turner-Warwick and Doniach, 1965). Increases in circulating ANA and rheumatoid factor were observed in 30% of our patients (Crystal et al., 1976). Similar studies that evaluated the presence of autoantibodies to nuclear antigens, DNA topoisomerase, and cytokeratin detected the antibodies in some patients (Table 67.1). More recent studies have focused on antibodies that are specific to lung proteins, although these studies have also shown variable expression of autoantibodies (Robinson et al., 2001; Wallace et al., 1994). These results raise the possibility that autoantibodies are a secondary consequence of the ongoing immune activation in the setting of inflammation and tissue damage, rather than the causative mechanism.

Similarly, investigations have evaluated the role that immune complex deposition plays in the pathogenesis of inflammation and fibrosis in IPF. Early studies observed elevated levels of circulating immune complexes in certain subsets of patients with IPF, however, these were performed prior to the current classification system and included patients with other forms of interstitial lung disease (Dreisin et al., 1978; Haslam et al., 1979). Hunninghake et al. (1981) demonstrated a correlation between the level of immune complexes in bronchoalveolar lavage fluid and the levels of neutrophil chemotactic factor released by alveolar macrophages in patients with IPF. Other studies have also seen elevated levels of immune complex in lavage fluid, but the levels are variable and do not correlate with disease activity.

The lack of clear evidence for a humoral mechanism as the primary cause for IPF shifted the focus towards cellular immunity. One popular theory is that an unknown stimulus triggers a dysregulated activation of cell-mediated immune response that results in the fibrotic process analogous to that observed in abnormal wound healing. This theory rests on the belief that a normal cell-mediated defense to a pulmonary insult would be a Th1 response, as seen in most infections and in hypersensitivity pneumonitis (Wallace et al., 1995; Lukacs et al., 2001; Kunkel, 2004). The Th1 response is characterized by the release of interferon-γ and the activation of neutrophils and macrophages for efficient clearing of the antigen, as well as suppressing fibroblast activation and collagen deposition. Cytokine profiles in IPF are closer to the Th2 response, which is typified by elevated levels of the interleukins IL-4, IL-5, and IL-13, resulting in fibroblast activation (Hancock et al., 1998; Wallace and Howie, 1999). Early evidence for this T-cell-mediated mechanism in IPF was demonstrated by Kravis et al. (1976), who discovered that circulating lymphocytes from patients with IPF would release migration inhibitor factor after exposure to collagen and would lyse collagen-coated sheep red blood cells.

One experimental model used to demonstrate a cell-mediated autoimmune mechanism is the adoptive transfer, hapten immune pulmonary interstitial fibrosis model (Stein-Streilein et al., 1987). In this model, donor mice are sensitized by a hapten, and then lymph nodes and spleen are transferred to recipient mice. When the recipient mice are then challenged with intratracheal administration of the hapten, they develop pulmonary fibrosis in 7–14 days. Interestingly, when the adoptive transfer with Th1 cells was used, an alveolitis developed, but not fibrosis, thus supporting the Th2 theory regarding the pathogenesis of the fibrotic component of IPF (Irifune et al., 2003).

In pulmonary fibrosis associated with the multisystem autoimmune disease, several serologic and genetic markers

TABLE 67.1 Autoantibodies associated with idiopathic pulmonary fibrosis*

Antigens	Number of patients	Result	Reference
Fresh unfixed lung tissue, rheumatoid factor, nuclear, thyroglobulin, gastric parietal cells	48 IPF	Sensitivity: Positive titers for: RF 49%, ANA 28%, rat liver homogenate 19%, gastric cells 0%; no autoantibodies specific to lung were detected by immunofluorescence	Turner-Warwick and Doniach, 1965
Nuclear: ANA, dsDNA, ssDNA, RF	53 IPF 33 SLE 50 controls	Sensitivity: IPF patients had 42% ANA (titer > 1:10), 25% anti-dsDNA and 100% anti-ssDNA titers that were two standard deviations above the normal range, levels did not correlate with disease activity	Holgate et al., 1983
Nuclear: ANA, nRNP, dsDNA, Sm, SS-A and SS-B	68 IPF 54 PF-AID 47 controls	Sensitivity: ANA present in 21% of IPF and 46% of PF-AID. Anti-nRNP present in 15% of IPF and PF-AID. Other antibodies were not significantly different from control group Specificity: ANA 94%, anti-nRNP 98%	Chapman et al., 1984
Histidyl-tRNA synthetase (Jo-1 antigen)	62 IPF 19 PF-AID (myositis) 53 myositis alone	Sensitivity: Antibody present in 68% of PF-AID (myositis) patients compared to 3% IPF alone and 7.5% myositis alone Specificity: >99% normal and 98% autoimmune controls	Bernstein et al., 1984
Topoisomerase II	41 IPF	Sensitivity: 44% positive. Remained elevated in 17 of 19 follow-up patients. Did not correlate with disease activity	Meliconi et al., 1993
Collagen type I, II, III, IV	16 IPF 29 controls	Sensitivity: 75% of IPF patients had antibody titers to at least one type of collagen > 1:16. Specificity: 83% using cut-off titer 1:16. Negative correlation between antibody level and duration of disease.	Nakos et al., 1993
Lung proteins derived from IPF, sarcoid, and normal lung	17 IPF 17 controls	Sensitivity: 71% of IPF patients had IgG that reacted to lung proteins in the 70–90 kDa range by Western blot; IgG reacted to alveolar lining cells Specificity: 82%	Wallace et al., 1994
Cytokeratin 19	26 IPF 11 PF-AID 52 controls	Significantly higher mean serum levels in IPF compared with control. No cut-off value determined by ELISA because of overlap between groups	Fujita et al., 1999
Expressed cDNA library from lung cancer cell line	11 IPF	Serum from index patient used to probe expressed cDNA library. Antigens recognized were unique to index patient (including anti-alanyl tRNA synthetase), but not shared with sera from other 10 patients	Robinson et al., 2001
Endothelial cell protein extract	45 PF-AID (scleroderma) 16 controls	Sensitivity: 93% PF-AID had positive staining using an indirect immunofluorescent assay against rodent lung tissue Specificity: 88%	Wusirika et al., 2003

*Summary of autoantibody studies in patients with idiopathic pulmonary fibrosis.

ANA, anti-nuclear antibodies; ELISA, enzyme-linked immunosorbent assay; IPF, idiopathic pulmonary fibrosis; nRNP, nuclear ribonucleoprotein; PF-AID, pulmonary fibrosis associated with autoimmune disease; RF, rheumatoid factor; SS-A and SS-B, Sjögren syndrome A and B antigens; SLE, systemic lupus erythematosus; Sm, Smith antigen.

are linked to the development of lung disease. For instance, patients with RA who have high levels of rheumatoid factor and prominent rheumatoid nodules are at increased risk for developing pulmonary fibrosis (Hyland et al., 1983). In systemic sclerosis, the presence of anti-topoisomerase antibodies and diffuse cutaneous involvement is associated with pulmonary fibrosis (Fanning et al., 1998).

Perhaps the best evidence for associating autoantibodies to pulmonary fibrosis is found in patients with polymyositis and dermatomyositis, in which antibodies against the aminoacyl-tRNA synthetases have been shown to be highly correlated with pulmonary fibrosis (Bernstein et al., 1984; Targoff, 1993). At least five known forms of the autoantibodies have been identified, which include anti-alanyl-tRNA synthetase (PL), anti-histidyl-tRNA synthetase (Jo-1), anti-isoleucyl-tRNA synthetase (OJ), anti-glycyl-tRNA synthetase, and anti-threonyl-tRNA synthetase. The strongest correlation appears to be with anti-Jo-1 antibodies, which have been reported to have a frequency in interstitial lung disease of between 50% (Hochberg et al., 1984) and 100% (Yoshida et al., 1983). Patients with polymyositis or dermatomyositis can frequently present with the "antisynthetase syndrome" characterized by pulmonary fibrosis in 50–75% of patients, arthritis, Raynaud phenomenon, and fevers. Occasionally, the antisynthetase syndrome can occur in the absence of clinical myositis (Marguerie et al., 1990). There are also several case series of patients with isolated pulmonary fibrosis occurring in association with aminoacyl-tRNA synthetase antibodies (Friedman et al., 1996; Sauty et al., 1997). These patients have been shown to have a $CD8^+$-lymphocyte predominant bronchoalveolar lavage and nonspecific interstitial pneumonitis pattern on lung biopsy. Most of the patients described in these case series have been more responsive to therapy with cyclosporine and azathioprine than patients with IPF.

GENETIC FEATURES

Idiopathic Bronchiolitis Obliterans

Given the rarity of IBO, there are no studies that demonstrate a genetic predisposition to this condition. The same is true for the autoimmune-associated forms of bronchiolitis obliterans. There is some preliminary work to investigate genetic susceptibility to developing bronchiolitis obliterans after lung transplant, with identification of polymorphisms for genes encoding key cytokines, including tumor necrosis factor-α, transforming growth factor-β, interferon-γ and IL-6 and IL-10, in association with this disorder (Estenne et al., 2002).

Idiopathic Pulmonary Fibrosis

Up to 3% of cases of IPF occur in clusters of families, suggesting that a genetic predisposition may be responsible for susceptibility to disease (Hodgson et al., 2002). A simple pattern of Mendelian inheritance has not been observed. Familial cases appear to be inherited in an autosomal dominant pattern, although the penetrance is variable. In familial cases of IPF, children of individuals with fibrotic lung disease can have evidence of inflammatory alveolitis in bronchial lavage fluid, without having clinical evidence of disease (Bitterman et al., 1986). There have been several reports of pulmonary fibrosis occurring in separately raised monozygotic twins, underscoring the role of genetic factors (Peabody et al., 1950; Javaheri et al., 1980). Using a candidate gene approach in one large family kindred with IPF, Thomas et al. (2002) identified a mutation in the highly conserved coding region of surfactant protein C, resulting in its aberrant cellular distribution in the lung tissue of affected individuals.

In addition to the familial form of the disease, there is evidence for a genetic basis for the more common, sporadic form of the disease. A study from Finland demonstrated a clustering of sporadic cases of IPF in areas where familial cases were found, suggesting a founder's effect (Hodgson et al., 2002). One prevailing hypothesis is that susceptibility does not lie in one gene locus, but rather within multiple genes that interact through inflammatory and fibrotic mechanisms, creating a background genotype of fibrotic potential, yet still requiring an insult to create the profibrotic phenotype. This theory would explain why the familial form of the disease has an earlier age of onset (55 vs. 67 years), yet still present relatively later in life, implying that a reduced threshold for the development of fibrosis exists in familial types (Marshall et al., 2000). This theory is also supported by the fact that only a small proportion of individuals who receive drugs known to cause pulmonary fibrosis (such as bleomycin or amiodarone) actually develop the disease (Tisdale et al., 1995).

One major limitation in the search for genetic sources for susceptibility is that the sizes of the association studies are limited because of the rarity of the disease. Polymorphisms in several genes have been explored as potential causes for the inherited susceptibility to IPF, however, they utilize a traditional candidate gene approach, which is limited by our current understanding of the disease and may lead to false positive associations. These studies are typically focused on genes involved in the inflammatory pathways, such as IL-1α and tumor necrosis factor-β, but they have shown conflicting results (Pantelidis et al., 2001; Whyte et al., 2000). Xaubet et al. (2003), recently demonstrated that transforming growth factor-β polymorphisms were related to disease progression, but they found no association to susceptibility to IPF.

Given recent advances in genomics, microarray analysis, and proteomics, there is an excellent opportunity to perform genome-wide searches for linkage in patients with IPF to identify novel genes that are involved in pathogenesis and may represent therapeutic targets. Many of these genetic

approaches are simply hypothesis generators; however, this may be a necessary first step to decipher the complex interactions of multiple loci. Additionally, microarray technology can be used for "molecular fingerprinting" to identify subclassifications within the general category of IPF.

ENVIRONMENTAL INFLUENCES

Idiopathic Bronchiolitis Obliterans

Environmental factors are clearly linked to the development of bronchiolitis obliterans in general, although specific causative environmental factors for IBO are unknown. Most notably, inhalational injuries can progress into constrictive bronchiolitis. The mechanism is believed to be due to inflammation caused by the irritant in the bronchioles that progresses into irreversible fibrosis and airway obstruction. Frequently, this occurs after exposure to water-insoluble gases (such as oxides of nitrogen in the case of silo-fillers lung) and organic dusts or fumes, which are not rapidly absorbed in the mucus membranes of the upper airways (Ramirez and Dowell, 1971; Fleming et al., 1979). Nitrous fumes are a significant industrial hazard and can be found in agriculture, fire fighting, and chemical industries. The timing of the injury can be delayed from the exposure because the gases are slowly hydrolyzed into acids that act as powerful oxidants, which eventually penetrate the small airways and cause severe tissue injury. Clinical symptoms may present as acute, subacute, or chronic. The chronic form usually presents as a new clinical illness, weeks to months after recovery from the initial acute illness (King, 2003a).

There have been many case reports of industrial exposures followed by the development of bronchiolitis obliterans in people working in unrelated industries, such as battery workers, food flavoring workers, and nylon flock workers (Konichezky et al., 1993; Eschenbacher et al., 1999; Kreiss et al., 2002). It is difficult to prove causation when only a few workers are affected. Kreiss et al. (2002) reported a high incidence of bronchiolitis obliterans in 7% of workers (8 out of 117) at a microwave popcorn plant, which was attributed to inhalation of the volatile agent, diacetyl in the butter flavoring. This observation was supported by toxicity studies of diacetyl inhalation in rats (Hubbs et al., 2002). Bronchiolitis obliterans has also been described in a truck driver who inhaled fly ash as well as in a young man with smoke inhalation from a fire (Boswell and McCunney, 1995; Tasaka et al., 1995). Both cases recovered from the acute illness only to have their symptoms recur and progress weeks to months later.

Bronchiolitis obliterans can also occur as a sequela from prior pulmonary infections, most commonly seen with adenovirus, but also associated with other viruses (RSV, influenza) and mycoplasma (Penn and Liu, 1993; Wright et al., 1992; Chan et al., 1997). Swyer–James syndrome is one variation of bronchiolitis obliterans that occurs in response to infection in children (Swyer and James, 1953). The affected lung fails to develop properly, with scarring of the bronchioles resulting in air-trapping and decreased blood flow to the affected lung. Chest radiograph is notable for a unilateral hyperlucent lung with normal or reduced volume during inspiration and air-trapping during expiration (Muller and Miller, 1995).

Some medications have been implicated as etiologic agents in the development of bronchiolitis obliterans. Both gold and penicillamine have been suspected; however, it is difficult to determine if the bronchiolitis obliterans results from the medication or the underlying disease (Geddes et al., 1977).

Idiopathic Pulmonary Fibrosis

Several environmental factors have been investigated for an etiologic role in IPF. The premise of an environmental stimulus that leads to repeated lung injury followed by abnormal wound healing fits nicely into one theory of the pathogenesis of IPF (see below). The search for these stimuli is challenging because the offending agent may be different between individuals based on individual differences in genetic susceptibility. Nevertheless, epidemiologic studies have identified links between occupational exposures, medications, and infectious agents and IPF.

Four separate case-controlled studies have looked at the association between occupational exposure and IPF. Although these studies are limited because of recall bias, there were some consistent observations. Metal dust exposure was significantly associated with IPF in every study and in a dose-response relationship (Hubbard et al., 1996; Iwai et al., 1994; Baumgartner et al., 1997; 2000). Two studies showed a significant association with livestock exposure, farming, and agricultural exposure (Baumgartner et al., 2000; Iwai et al., 1994). Paraquat, a herbicide used in agriculture, has been found to cause fatal pulmonary fibrosis in humans and experimental animals after oral, inhalational, or cutaneous exposure (Schoenberger et al., 1984). Anecdotal case reports have linked cases of IPF with occupations that result in toxic dust or fume exposure such as diamond polishing, dairy work, welding, gold extraction, and dental work (Baumgartner et al., 1997).

Pulmonary fibrosis is a well-known side effect of several medications, most notably bleomycin, amiodarone, methotrexate, and nitrofurantoin (Holmberg and Boman, 1981; Schoenberger and Crystal, 1983; Martin and Rosenow, 1988; Israel-Biet et al., 1991; Sleijfer, 2001). It has also been found as a rare complication of more commonly used medications such as beta-blockers, antidepressants, anticonvulsants, and nonsteroidal anti-inflammatory

drugs. However, these associations have been difficult to prove given the ubiquity of these medications and the relative rarity of IPF (Coultas et al., 1994).

The effect of smoking on the natural history of IPF is controversial, but of four case–control studies examining the association of smoking with pulmonary fibrosis (Iwai et al., 1994; Hubbard et al., 1996; Baumgartner et al., 1997; 2000), three show a significant link between smoking and the development of IPF. Some studies have shown improved survival in smokers with IPF compared with nonsmokers (Cherniack et al., 1995; King, et al., 2001). However, this observation may be due to lead time bias in the smoking group, and simply reflect a greater severity of disease in the nonsmoking groups.

ANIMAL MODELS

Animal models of the classical human Mendelian genetic diseases are relatively easy to produce because the genotype typically involves one affected gene, and knockout models of that gene, in mice for instance, can usually approximate the phenotype. Generating an animal model of a complex polygenic disease poses far more challenges because it involves multiple genes each exerting a relatively small effect.

Idiopathic Bronchiolitis Obliterans

Most of the animal models for bronchiolitis obliterans are designed to mimic the transplant-associated form of the disease. One model frequently used is the heterotopic murine tracheal transplant, whereby grafts of trachea and main bronchi are placed subcutaneously into allogeneic mismatched recipients (Hertz et al., 1993). By 21 days, grafts demonstrate fibroproliferation in the airway lumen, a characteristic for the human chronic rejection process. Subsequent studies on this model have shown that this is mediated by cellular and humoral immunity (Kelly and Hertz, 1997). Although this model can successfully mimic the phenotypic changes of IBO, it has limited applicability to understanding IBO because the entire tracheobronchial graft is an immunogenic stimulus, which is not likely the case in the idiopathic or autoimmune associated forms of the disease.

Adams et al. (2000) demonstrated that by removing the airway epithelium in rat trachea isografts that were implanted into the omentum, the grafts would develop pathologic changes characteristic of obliterative airways disease. Interestingly, when the airway epithelium was reseeded, the amount of obliteration significantly decreased.

Idiopathic Pulmonary Fibrosis

There is no animal model for IPF that clearly represents human IPF. However, there are several animal models for susceptibility to developing experimental pulmonary fibrosis. The susceptibility to bleomycin-induced interstitial lung disease has been correlated with both immune related (Th2 type) and non-immune related genes in different strains of mice (Rossi et al., 1987). Transforming growth factor-β has been shown to induce pulmonary fibrotic changes when overexpressed via intratracheal administration of an adenoviral vector (Liu et al., 2001). Likewise, when mice are treated with an adenoviral vector expressing SMAD-7, an inhibitory regulator of TGF-β production, they appear to be protected against bleomycin-induced lung injury (Nakao et al., 1999).

Many different transgenic and knockout mice have also been developed to investigate the molecular pathways that lead to pulmonary fibrosis. One example is mice that overexpress TNF-α will develop pulmonary fibrosis and have some of the features of human IPF (Miyazaki et al., 1995). Knockout mice with targeted deletions of genes necessary for fibrosis (e.g., adhesion molecules, ICAM-1 and L-selectin, which facilitate the accumulation of leukocytes) show significantly decreased fibrosis in response to bleomycin (Hamaguchi et al., 2002).

Many of these models are focused on only a select number of candidate genes, which may or may not have relevance to human disease. While these studies have been useful to identify genes that may play a role in susceptibility, the actual human form of the disease is likely far more complex and polygenic, which may prohibit creating a comprehensive animal model that reflects the underlying pathogenesis.

PATHOGENIC MECHANISMS

Idiopathic Bronchiolitis Obliterans

The pathogenesis underlying bronchiolitis obliterans varies according to the clinical condition with which it is associated. Differences in the initial insulting agent, location of the insult, and length of exposure can account for the differences in pathology and severity. The general sequence of events, however, is believed to be similar in order to result in a histopathologic pattern of constrictive bronchiolitis.

Airway epithelial injury followed by an inflammatory cellular infiltrate, predominantly neutrophils, is believed to be the initiating event (King, 2003a). The subsequent release of inflammatory cytokines results in bronchiolar inflammation. If the offending agent is removed and the inflammation resolves, there may be clinical recovery and resolution. Conversely, repetitive stimuli followed by abnormal repair processes and fibrosis are what likely leads to bronchiole luminal fibrosis and the typical findings of constrictive bronchiolitis. This theory of fibrosis is derived from studies of bronchiolitis obliterans in the lung transplant population,

where the disease represents a form of chronic rejection. Transplant patients who develop bronchiolitis obliterans have been shown to have higher levels of neutrophils and IL-8 in bronchial lavage fluid (DiGiovine et al., 1996).

Idiopathic Pulmonary Fibrosis

The original theory for the pathogenesis of IPF rested on the premise that inflammation of the alveoli was followed by fibrosis (Crystal et al., 1976; 1981; 1984; Hunninghake et al., 1979). There are many observations that support this hypothesis. Early studies that used bronchial lavage demonstrated increased numbers of alveolar macrophages, neutrophils, eosinophils, and lymphocytes (Crystal et al., 1976; Reynolds et al., 1977; Weinberger et al., 1978). Gallium scans, which are nonspecific markers of inflammation with macrophages and neutrophils, are positive in about 70% of all patients with IPF (Crystal et al., 1976; Line et al., 1978). Biopsies that are performed in early stages of the disease reveal large amounts of inflammation and alveolar wall derangement compared with biopsies taken in the later stages of disease where fibrosis predominates (Carrington et al., 1978). Alveolar macrophages are believed to play a central role in the inflammatory process through the release of cytokines that affect other cells. Alveolar macrophages from patients with IPF have been shown to secrete neutrophil chemotactic factor, which does not occur in normal non-activated alveolar macrophages (Hunninghake et al., 1980; 1981). Animal models have shown the presence of inflammation preceding fibrosis and the suppression of the inflammatory response attenuates the progression to fibrosis (Snider, 1986).

More recently, there has been a focus on the fibrotic aspect of the disease as also playing an important role. These theories about the pathogenesis of IPF involve the idea of recurrent, ongoing stimulus and injury to the lung, with abnormal wound healing. The abnormal wound healing is believed to result from a complex interplay of the genetic background of the individual, the predominant inflammatory phenotype (Th1 or Th2), and the environmental triggers. The stimulus that acts as the driving force remains a mystery, as does the mechanism that promotes a pathologic fibrotic response instead of the normal reparative response.

The lung parenchyma regulates its immune and fibrotic processes through cytokine signaling between the cells of the interstitium, including epithelial cells, endothelial cells, fibroblasts, and macrophages, and it is likely that these cells contribute to the pathogenesis of IPF (Martinet et al., 1987; Standiford et al., 1991; Selman et al., 2001). Although the exact sequence of chemokine signaling that leads to the progression of fibrosis is not understood, it has been shown that cytokines are responsible for the cell-to-cell communication and fibroblast activation, proliferation, and collagen production.

One theory is that an imbalance in inflammatory phenotype, shifted towards a Th2 response, is responsible for the fibrotic phenotype. Support for this theory comes from the observation that IL-4 and IL-13, major Th2-type cytokines, have been shown to be major stimuli for fibroblast-derived extracellular matrix deposition (Furuie et al., 1997; Hancock et al., 1998). Interferon-γ, one of the major Th1-type cytokines, has been shown to suppress the production of collagen and fibronectin by fibroblasts (Goldring et al., 1986). The increased presence of eosinophils, which have been associated with Th2 cytokine expression in asthma and parasitic infections, in association with fibrotic changes in IPF is consistent with the concepts of the Th2 paradigm of abnormal healing. Davis et al. (1984) demonstrated that eosinophils represented greater than 5% of the cells in the lavage fluid of 20% of patients with IPF compared with less than 1% of the normal controls. These eosinophils were shown to have collagenase activity and have the capacity to injure lung parenchymal cells.

The pathogenetic mechanisms that lead to the development of pulmonary fibrosis associated with rheumatic diseases have been most extensively studied in systemic sclerosis. The most common theory, which may or may not be applicable to the idiopathic form, is that an initial environmental injury triggers an ongoing, amplified immune response in the lung. TNF-α and TGF-β have both been shown to be upregulated early in the course of the disease (Bolster et al., 1997; Corrin et al., 1994) and there is a cytokine shift from Th1 to Th2 in helper T cells (Bolster et al., 1997). Bronchoalveolar lavage fluid from patients with scleroderma has increased levels of several inflammatory cytokines such as IL-8, TNF-α, and macrophage inflammatory protein (Southcott et al., 1995). The lavage is also believed to have prognostic value in patients with systemic sclerosis. Scleroderma patients with a neutrophil and eosinophil predominant bronchoalveolar lavage have been associated with more extensive pulmonary fibrosis seen on CT and more rapid clinical deterioration (Rossi et al., 1987; Silver et al., 1990; Behr et al., 1996; Friedman et al., 1996; Witt et al., 1999).

The stimulus that leads to the inflammatory response in the lungs of patients with scleroderma is also unknown, but one hypothesis suggests that aspiration of refluxed esophageal and gastric contents may be the cause. The premise behind this theory arises from the fact that many patients with systemic sclerosis have both esophageal dysmotility and pulmonary fibrosis. This association was initially observed in a relatively small cohort of 12 patients (Johnson et al., 1989a). Subsequent studies have found conflicting results when trying to correlate pulmonary function parameters meant to be a surrogate marker of pulmonary fibrosis (such as total lung capacity and diffusion capacity) with esophageal manometry (Troshinsky et al., 1994; Lock et al., 1998). These studies are limited by confounding ele-

ments because both esophageal dysmotility and pulmonary fibrosis may be independent markers of systemic sclerosis disease severity, without having a causal link.

TREATMENT AND OUTCOME

Idiopathic Bronchiolitis Obliterans

The prognosis is poor for patients with idiopathic or rheumatic disease-associated bronchiolitis obliterans, and there are no proven effective medical therapies for these conditions. These patients tend to not respond to corticosteroids, though a 3-month trial of high-dose prednisone (1 mg/kg) is often used. Lung transplantation is sometimes considered for individuals with bronchiolitis obliterans who continue to decline in pulmonary function and are refractory to medical therapy.

The one exception to this rule is in bronchiolitis obliterans secondary to inhalational injury, where corticosteroids are useful in both the acute and chronic phase of the disease (Milne, 1969; Horvath et al., 1978). Steroids should be started as soon as respiratory dysfunction occurs following a toxic inhalation, and be continued for at least 8 weeks to prevent recurrence (Tse and Bockman, 1970).

Given the dramatic effect that macrolides have in diffuse panbronchiolitis—a disorder related to bronchiolitis obliterans characterized by chronic sinobronchial disease and interstitial inflammation of the respiratory bronchioles—some investigators have recommended a trial of macrolides in the treatment of IBO (Ryu et al., 2003). Diffuse panbronchiolitis had a 26% 5-year survival rate in 1984 before the use of macrolides. Since the introduction of macrolides as the mainstay therapy for this disease, it now has a 10-year survival rate of 94% (Kudoh, 1998). Long-term efficacy and safety was demonstrated in 10 patients with diffuse panbronchiolitis who were treated with clarithromycin 200 mg/day for 4 years (Kadota et al., 2003). Most patients will experience a clinical and physiologic improvement within the first month of treatment. Bronchial lavage fluid from these patients has demonstrated a reduction in the number of neutrophils, neutrophil-derived elastolytic activity, IL-8, and other proinflammatory cytokines (Ichikawa et al., 1992; Sakito et al., 1996). Macrolides have not been extensively studied in bronchiolitis obliterans that is idiopathic or associated with rheumatic disease.

Idiopathic Pulmonary Fibrosis

Idiopathic pulmonary fibrosis usually portends a poor prognosis and is typically poorly responsive to therapy. Early diagnosis and treatment have traditionally been advocated so that therapy can be initiated and, hopefully, prevent irreversible fibrosis. Therefore, the typical medications used to treat IPF work through anti-inflammatory and immunosuppressant mechanisms. However, these traditional approaches have failed to show that the inflammatory or fibrotic process can be altered or reversed. As the understanding of the pathogenesis of the disease improves, newer agents are being developed based on cellular mechanisms to inhibit fibrogenesis. No therapy for IPF has been shown in a prospective, randomized double-blind, placebo controlled trial to improve survival.

Prior studies have suggested that the prognosis may be favorable for patients with pulmonary fibrosis associated with systemic sclerosis (Wells et al., 1994). However, Hubbard and Venn (2002) demonstrated with actuarial data that the mortality rates for patients with pulmonary fibrosis associated with all rheumatic disorders, predominantly RA in their study, are remarkably similar to those that are idiopathic in origin.

Corticosteroids

The most common medications used to treat IPF are corticosteroids, despite the fact that they have not been properly evaluated in a large clinical trial. Early studies showed that 10–30% of patients with IPF appear to improve or survive longer when treated with corticosteroids (Stack et al., 1972; Turner-Warwick et al., 1980). Unfortunately, these studies likely included other forms of idiopathic interstitial pneumonia, such as NSIP or COP, which tend to have a more favorable prognosis than IPF. When histopathologic criteria are used for the diagnosis of IPF, the clinical response (0–16%) and survival rates are much worse than for the other pathologic patterns (Daniil et al., 1999; Ziesche et al., 1999; Nicholson et al., 2000). Despite the lack of evidence for a beneficial role of corticosteroids, many pulmonologists use a 3- to 6-month trial of corticosteroids with close monitoring for radiographic or physiologic improvement. Patients who improve with corticosteroids or who remain stable are then kept on a maintenance dose of 10–20 mg/day prednisone (ATS, 2002). Intravenous pulse corticosteroids for 3–5 days are generally recommended for an acute exacerbation of IPF, as Keogh et al. (1983) have shown that higher doses of corticosteroids can significantly reduce the neutrophil accumulation during an active alveolitis of IPF.

Cytotoxic Agents

Other anti-inflammatory and cytotoxic agents have been investigated for a beneficial role in IPF. Cyclophosphamide, when used in combination with corticosteroids, had promising results towards a survival advantage compared with corticosteroids alone in an early randomized control trial (Johnson et al., 1989b; Baughman and Lower, 1992). Cyclophosphamide has been shown to reduce the neutrophil

component of the active alveolitis after 3 and 6 months of therapy (O'Donnell et al., 1987). However, subsequent studies have shown cyclophosphamide to have limited efficacy and a high frequency of side effects when used to treat patients with IPF who failed to respond to corticosteroid therapy (Zisman et al., 2000). Cyclophosphamide may be particularly effective in patients with pulmonary fibrosis associated with systemic sclerosis, as it was shown to improve pulmonary function testing in this population. Patients with systemic sclerosis and a neutrophil-predominant bronchoalveolar lavage seemed to have the best outcomes, although these studies were limited by either small sample size, lack of a control group, or selection bias from retrospective review (Schnabel et al., 1998; Silver et al., 1990; White et al., 2000). It is currently considered as a second-line drug for patients with progressive IPF. Side effects include leukopenia, thrombocytopenia, and hemorrhagic cystitis.

Azathioprine has been shown to have some efficacy in the treatment for IPF in small prospective case series (Winterbauer et al., 1978; Raghu et al., 1991). Azathioprine exerts cytotoxic effects on lymphocytes and also suppresses the activity of natural killer cells and antibody production. It is also considered a second-line therapy for patients who fail corticosteroids, or may be given in conjunction with corticosteroids. A trial of 3–6 months is recommended for both cyclophosphamide and azathioprine to assess for clinical response.

Antifibrotic Agents

Colchicine has been postulated to have a role in the treatment of IPF because it inhibits collagen formation in vitro and suppresses the release of alveolar macrophage-derived growth factor (Rennard et al., 1988). Colchicine has been suggested in small randomized control trials to be as effective as corticosteroids in treatment of IPF, but has not been followed up with large, controlled studies (Peters et al., 1993; Douglas et al., 1998).

Penicillamine has been noted in several anecdotal case reports to be efficacious in both IPF and rheumatic disease-associated pulmonary fibrosis (Vallance et al., 1995; Selman et al., 1998). However, since there have been no controlled studies and the medication has several significant side effects (stomatitis, nephrotoxicity), penicillamine is not used in the treatment of IPF.

Interferon γ-1b was used by Ziesche et al. (1999) in a one year study of 18 patients with IPF randomized to receive interferon γ-1b and prednisolone, compared to prednisolone alone. Interferon-γ1b has been shown to downregulate the expression of TGF-β1 and inhibit the proliferation of fibroblasts, both of which are considered to have important roles in the pathogenesis of pulmonary fibrosis (Clark et al., 1989; Narayanan et al., 1992). Ziesche's study (Ziesche et al., 1999) suggested a significant improvement in total lung capacity and partial pressure of arterial oxygen; and a decrease in the level of transcription of TGF-α1 and connective-tissue growth factor in the individuals who received interferon-γ1b.

This led to a multicenter, double-blind, placebo controlled trial of interferon-γ1b in patients with IPF who failed to respond to corticosteroids. Interferon-γ1b did not improve any of the main outcomes—progression-free survival, pulmonary function, or quality of life (Raghu et al., 2004). Additionally, there were more adverse side effects in the group that received interferon-γ1b. There was a trend towards increased survival in the group that received interferon-γ1b (16 out of 162 patients in the interferon-γ1b group died compared with 28 out of 168 patients in the placebo group, absolute reduction of 7%). However, given the relatively short follow-up of 1 year, coupled with the fact that this was not a primary end-point of the trial, there are concerns that this trend may be misleading. At this time, interferon-γ1b should not be considered as a proven therapy for IPF, unless used as part of a clinical trial.

Many other novel strategies have been investigated in the treatment of IPF, including cyclosporine, methotrexate, pirfenidone, suramin, and prostaglandin E (King, 2003b). These therapies focus on different aspects of the pathogenesis of the disease, such as antioxidants; inhibitors of cytokines, proteases, and fibroblast growth factors. Unless adequate studies are done to demonstrate efficacy, these agents should not be recommended for general use. The recent joint statement by the American Thoracic Society (ATS) and European Respiratory Society (2002) (ERS) recommended combined therapy with corticosteroids and either azathioprine or cyclophosphamide for a 3-month trial in patients who possess features consistent with a more favorable outcome.

Lung transplantation should be considered for individuals who progress despite optimized medical management. Patients should be referred to a transplant center relatively early in their course since wait times on the list can exceed 2 years due to limited donor availability. Those who receive a successful transplant can experience significant improvement in arterial oxygenation, pulmonary hypertension, and right ventricular dysfunction. Unfortunately, the 5-year survival rates for lung transplant are only about 60%, with death frequently due to graft failure, infection, or bronchiolitis obliterans (Lu and Bhorade, 2004).

CONCLUSIONS

The presumed autoimmune disorders of the lung, notably IBO and IPF, have long been recognized as inflammatory and fibrotic processes that are associated with poor prognosis, whether idiopathic in nature or in association with the

multisystem autoimmune diseases. Both diseases appear to be mediated through repetitive cell-mediated injury, directed at the bronchioles and alveoli/interstitium, respectively, followed by abnormal wound healing. Despite intense efforts, there is currently no approved therapy for either disease. Recent advances in the classification and diagnostic testing for these diseases have improved our ability to study their incidence, prognosis, and response to therapy. While much progress has been made, the search for antigenic stimuli and genetic polymorphisms that are responsible for disease pathogenesis continues. Only through a better understanding of the disease process will we be able to offer new therapies for these devastating diseases.

Acknowledgments

We thank J. Kaplan and N. Mohamed for help in preparing this manuscript. These studies were supported, in part, by M01RR00047 and the Will Rogers Memorial Fund, Los Angeles, CA. BG, is supported, in part, by the Altana/Pfizer CHEST Foundation Clinical Research Trainee Award in COPD.

Paraneoplastic Neurologic Diseases: Autoimmune Responses to Tumor Antigens

BRUNO GIOMETTO, MARIKA VIANELLO, AND ROBERTA VITALIANI

Department of Neurosciences, University of Padova, Padova, Italy, and Department of Neurology, Azienda ULSS9, Treviso, Italy

Paraneoplastic neurologic diseases (PND) are a heterogeneous group of disorders associated with systemic malignancies but never related to invasion or compression of, nor metastasis to, the nervous system; in addition, diagnosis should rule out intoxications, infections, and metabolic causes for symptoms (Posner, 1995).

Oppenheim was probably the first to associate cancer and neurologic disease, considering the neurologic symptoms to be a result of toxic processes (Oppenheim, 1888).

Greenfield noted perivascular infiltration and inflammatory nodules in the brain and spinal cord (Greenfield, 1934), and Henson et al. (1965) coined the term "encephalitis with carcinoma," suggesting that the entity was indistinguishable from viral encephalitis because of the severity of inflammatory changes.

In a seminal publication, Henson and Urich (1982) described several clinicopathologic entities in association with cancer (encephalomyelitis, cortical cerebellar degeneration, peripheral neuropathy, muscular and neuromuscular disorders) and discussed the possible etiopathogenesis of PND. After hypothesizing an infectious viral and toxic cause, they considered the immunologic theory to be the most likely, "albeit supported by very slender evidence" (Henson and Urich, 1982)

In 1965, Wilkinson and Zeromski found antibodies in the serum of four individuals suffering from small cell lung cancer and sensory neuropathy. Trotter et al. (1976) detected antibodies reacting with human Purkinje cells in the serum of a 21-year-old woman with Hodgkin lymphoma, while Greenlee and Brashear (1983) described two patients with ovarian cancer and high titers of anti-Purkinje cell antibodies.

In the 1980s, specific autoantibodies (Ab) reacting with both tumors and the central nervous system (CNS) were characterized in the serum and cerebrospinal fluid (CSF) of patients with PND (Posner, 1995) and several antigens were identified. The discovery supports the hypothesis, already advanced by Russell Brain in 1951 (Brain et al., 1951), that most PND could be the result of an immunologic response triggered by a tumor antigen that cross-reacts with a similar protein expressed by the nervous system.

At present, the role of these Ab in the pathogenesis of the various syndromes is still unclear (Posner, 1992). Nevertheless, their detection has become a useful tool both in the diagnosis of neurologic disorders and in directing the search for underlying tumors, since some tumors are preferentially

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

associated with a particular neurological disorder (Posner, 1989, 1995).

CLINICAL AND PATHOLOGIC FEATURES

Paraneoplastic neurologic diseases are rare syndromes that present an estimated incidence of between 1 and 3% of cancer patients. The clinical picture reflects the damage to a single area or multiple regions of the nervous system.

Table 68.1 summarizes the PND according to level of involvement of the nervous system and the presence of Ab.

Paraneoplastic Encephalomyelitis/ Paraneoplastic Sensory Neuropathy (PEM/PSN)

The term encephalomyelitis was first introduced to cancer patients by Henson and Urich in 1965 to describe tumor patients presenting signs of multiple CNS involvement (Henson et al., 1965). Paraneoplastic encephalomyelitis (PEM) is one of the most frequent remote effects of cancer and is pathologically characterized by neuronal loss and inflammatory infiltrates in different areas of the CNS and dorsal root ganglia (DRG) (Henson and Urich, 1982).

Onset of the neurologic syndrome is often subacute with symptoms mostly developing within days or weeks, followed by slower progression and stabilization. Acute onset is seen in 20% and chronic progression of paraneoplastic encephalomyelitis/paraneoplastic sensory neuropathy (PEM/PSN) in 17% of cases (Dalmau et al., 1992b). Patients may present with different clinical pictures, as limbic or brainstem encephalitis, myelitis, cerebellar degeneration, and sensory neuropathy, which may be isolated or present together. Sensory neuropathy is the presenting symptom in 70%, and the predominant picture in 60% of cases, but may also be present as an isolated syndrome.

First described by Denny-Brown in 1948, PSN is characterized by asymmetrical, painful sensory neuropathy, which evolves into complete loss of proprioception.

The neurologic syndrome usually antedates diagnosis of the tumor. Mean time from onset of neurologic symptoms to discovery of a tumor varies from 4 to 12 months with a maximum of 6 years. In a minority of cases, no tumor is found even at autopsy (Lucchinetti et al., 1998). Small cell lung cancer (SCLC) is identified in approximately 80% of patients, usually as a limited disease, but other tumors such as prostate cancer, neuroblastoma, and sarcomas may be detected.

Radiologic studies are usually normal, but abnormalities of the temporal lobe have been observed on computed tomography (CT) or magnetic resonance imaging (MRI) in some case with limbic encephalitis.

Cerebrospinal fluid (CSF) examination may be normal or show mild pleocytosis and increased protein and oligoclonal bands. The majority of patients (85%) with PEM harbors an antineuronal antibody, referred to as anti-Hu, in the serum and CSF; consequently the term "Hu syndrome" is applied alongside the term PEM/PSN (Lucchinetti et al., 1998; Graus et al., 2001).

Limbic Encephalitis

Paraneoplastic limbic encephalitis (PLE) is characterized by acute or subacute onset of an organic brain syndrome, giving rise to severe-to-moderate neurologic deficit (Rankin score >3) in a period of days to weeks. The pathologic features consist of neuronal loss, perivascular inflammatory infiltrate, and gliosis, usually restricted to the limbic system, in particular to the hippocampus and amygdala. The clinical picture is defined by short-term memory loss, confusion,

TABLE 68.1 Paraneoplastic neurological syndromes*

Central nervous system	Peripheral nervous system and dorsal root ganglia	Neuromuscular junction and muscle
Encephalomyelitis	*Sensory neuronopathy*	*Lambert–Eaton myasthenic syndrome*
Limbic encephalitis	–	–
Brain stem encephalitis	–	–
Cerebellar degeneration		
Opsoclonus–Myoclonus	*Autonomic neuronopathy*	*Myasthenia gravis*
Pure cerebellar degeneration	Acute sensorimotor neuropathy	Polymyositis/dermatomyositis
Paraneoplastic visual syndrome	Chronic sensorimotor neuropathy	Acute necrotizing myopathy
Stiff-Person syndrome	Vasculitic neuropathy	Cachetic myopathy
Necrotizing myelopathy	*Neuromyotonia*	Myotonia
Myelitis	–	–
Motor neuron syndrome	–	–
Subacute motor neuronopathy	–	–

**Italics* indicate disorders associated with autoantibodies.

psychiatric symptoms, involvement of the limbic system, and seizures. In the majority of patients, the symptoms antedate the diagnosis of tumor by an average of 3–5 months. Paraneoplastic limbic encephalitis was found to preferentially associate with SCLC (50%), germ cell tumors of the testis (20%), and breast cancer (8%) (Gultekin et al., 2000)

Neuroimaging, electroencephalography (EEG), CSF examination, and antineuronal antibody detection are helpful in the diagnosis of this illness. Alterations on MRI are seen in about 60% of patients. The MRI features of limbic encephalitis are most evident on coronal section and typically consist of abnormal high-signal intensity on T2 sequences in one or both medial temporal lobe(s). On T1 sequences, the temporal-limbic area may be hypointense and atrophic and may sometimes enhance with contrast injection. No alterations are visible in the initial phase of the disease. FDG-PET studies have shown increased tracer activity in the medial temporal lobe, which may be present in the absence of MRI abnormalities and may reflect an acute stage of the inflammatory process (Provenzale et al., 1998).

In 45% of patients, EEG reveals epileptic abnormalities from the temporal lobe, but in the majority of patients it shows unilateral or bilateral temporal slow waves.

Examination of the CSF shows inflammatory signs (e.g., pleocytosis, oligoclonal bands) in about 60% of patients.

Antineuronal Ab may be found in the serum and CSF of approximately 60% of patients with PLE, particularly anti-Hu Ab in patients with SCLC, and anti-Ma2 Ab in patients with testicular and sometimes breast cancer. In PLE, symptoms tend to stabilize in 2–3 months, and the course rarely leads to rapid decline and early death.

Paraneoplastic Cerebellar Degeneration

Paraneoplastic cerebellar degeneration (PCD) is a rare complication of cancer, but the presence of cancer has to be expected in about 50% of middle-aged patients who develop acute or subacute pan-cerebellar disorders. On pathologic examination, the main characteristic is loss of Purkinje cells with little lymphocytic infiltrations.

The onset of disease progresses over a period of 1 day to 16 weeks followed by stabilization. In about one-third of patients, onset may be abrupt with severe ataxia, which may develop overnight. The syndrome is characterized by pan-cerebellar dysfunction, manifesting as truncal and limb ataxia, slurred speech, and nystagmus. Nausea and vertigo are infrequent but may be debilitating. In one-third of patients, bulbar involvement with dysphagia and facial weakness is present (Posner, 1995).

On radiologic studies cerebellar atrophy may be detected in the late stage of the disease. Examination of the CSF may show mild pleocytosis, increased protein, and oligoclonal bands.

All patients with PCD present the same clinical picture, but they can be subdivided into several subgroups by serologic analysis of the associated antineuronal Ab. These subgroups differ in associated cancer, course, and survival (Rojas-Marcos et al., 2003).

An antineuronal antibody directed against Purkinje cell cytoplasm, referred to as anti-Yo, can be detected in the serum of patients with PCD. This syndrome usually develops in women with gynecologic or breast cancer. The cerebellar syndrome is isolated and develops before discovery of the cancer (mean, 15 months). Paraneoplastic cerebellar degeneration often leads to severe handicap, and the average survival is 13 months.

Male patients with a history of Hodgkin's disease may develop PCD. In such cases, the PCD develops 1–54 months after diagnosis of the primary tumor; an antineuronal antibody called anti-Tr, can be detected in the serum of these patients. Survival from time of diagnosis is significantly higher than in PND (mean, >113 months) associated with anti-Yo.

Paraneoplastic cerebellar degeneration may also be detected in patients with SCLC as part of a more widespread encephalomyelitis, as in the Hu syndrome. In this case the clinical course is progressive and mean survival is 7 months (Shams'ili et al., 2003). Anti-VGCC and electrophysiology testing should be performed in patients with SCLC associated with PCD to establish the presence of an associated Lambert–Eaton myasthenic syndrome (LEMS).

Opsoclonus–Myoclonus Syndrome

Opsoclonus is an eye movement disorder characterized by involuntary arrhythmic and multidirectional conjugated saccades. The paraneoplastic variant should be differentiated from paraneoplastic cerebellar degeneration, viral encephalitis, post-viral ataxia, multiple sclerosis, metabolic disorders, and intoxications (Wolpow and Richardson, 1988).

In children, opsoclonus occurs with myoclonus and ataxia; associated signs of encephalopathy (such as impairment in verbal, motor, and intellectual functions) are sometimes present. Opsoclonus–myoclonus syndrome (OMS) in children may develop as a primarily self-limiting disorder following a viral brainstem infection. Approximately 50% of children with OMS harbor a neuroblastoma (Baker et al., 1985), but do have a better prognosis for long-term survival compared with neuroblastoma patients without OMS. An immune mechanism is suggested, though no specific antineuronal antibody has yet been recognized (Antunes et al., 2000; Pranzatelli et al., 2002).

In adults, OMS is recognized as a distinct paraneoplastic syndrome associated in 20% of cases with breast carcinoma (Wirtz et al., 2002), gynecologic cancer, or small cell lung carcinoma (Gennaula and Eidelman, 1995). Recently, other

cancers, such as bladder and neuroendocrine gastric carcinoma, have been reported (Pittok et al., 2003).

Patients usually develop opsoclonus associated with truncal ataxia, dysarthria, myoclonus, and vertigo. Both CT and MRI brain scans are usually normal, and CSF may occasionally show mild pleocytosis or increased proteins (Sutton et al., 2002).

A specific antineuronal antibody called anti-Ri has been identified in association with breast carcinoma (Luque et al., 1991). Paraneoplastic OMS has to be differentiated from idiopathic OMS. The latter is usually described in patients who are younger than patients with the paraneoplastic form, and is characterized by a more benign clinical evolution and response to immunotherapy (Bataller et al., 2001).

Testing sera from patients with several types of OMS (idiopathic, associated with SCLC, and associated with neuroblastoma) has revealed heterogeneous immunity to neuronal antigens, although a single specific antibody marker has not been found. The two main groups of autoantigens were: 1) proteins of the post-synaptic density (considered to be a source of novel autoantigens); and 2) proteins whose function is restricted to neurons (including RNA- or DNA-binding proteins and zinc-finger proteins) (Bataller et al., 2003).

Consequently, there is an extensive variety of antigens recognized by the sera of patients with OMS, suggesting that this syndrome probably derives from different immune mechanisms (Bataller et al., 2003).

Paraneoplastic Stiff-Person Syndrome

Stiff-person syndrome (SPS) is a rare disorder characterized by continuous motor unit activity at rest and painful spasms in response to sound, touch, or electric stimulation. Stiffness spasms later become continuous, precipitated by voluntary movements and preventing normal gait (Folli, 1998). Electrophysiological studies have shown involuntary motor unit firing at rest, while contraction of antagonist muscles fails to induce motor unit relaxation in the leg muscles (Meinck et al., 1995).

Both CT scan and MRI are unremarkable, but CSF examination may reveal an inflammatory profile.

In rare cases, an association of SPS and breast cancer has been reported; these patients harbored anti-amphiphysin Ab in their serum and CSF (Folli et al., 1993).

IMMUNOLOGIC MARKERS IN THE DIAGNOSIS AND AUTOIMMUNE FEATURES OF ANTINEURONAL ANTIBODIES

Different antineuronal Ab are associated with specific PND and can be detected by immunohistochemistry (IHC) on rat or human cerebellum and by western blot using neuronal proteins. The antigen involved in some PND has been identified and the genes responsible have been cloned to produce recombinant proteins, as summarized in Table 68.2.

Anti-Hu Antibody

In 1985, anti-Hu Ab were demonstrated in the serum and CSF of two patients with sensory neuronopathy and SCLC that reacted with the nucleus of all human neurons in the CNS and PNS (Graus et al., 1985). Anti-Hu Ab are polyclonal complement-binding IgG that react with antigens present in the nucleus of both neurons and SCLC cells, sparing the nucleolus and cytoplasm (Graus et al., 1985) (Figure 68.1).

On western blot, using either human or rat neuronal nuclear lysates, a triple band is usually detected in the 38–40 kDa region (Graus et al., 1986).

Hu Antigens

Two highly homologous genes, referred to as HuD (Szabo et al., 1991) and HuC (Sakai et al., 1994) were isolated by screening a human cDNA library with anti-Hu sera. HuD and HuC are members of a family of neuronal RNA-binding proteins homologous to the *Drosophila* embryonic lethal abnormal vision (ELAV) protein, which is involved in the normal development of the fly nervous system (Szabo et al., 1991; King et al., 1994b).

HuD, Hel-N1, and N2 (all similar to ELAV) (King, 1994a; Sekido et al., 1994; King and Dropcho, 1996) are all expressed by SCLC cells (Dalmau et al., 1992a; King and Dropcho, 1996).

The gene for HuD has been mapped to human chromosome 1p34 (Muresu et al., 1994). A recombinant HuD of 43 kDa that reacts with all anti-Hu-positive sera has been produced (Szabo et al., 1991). The use of recombinant proteins by western blotting always increases the sensitivity and specificity of assays to detect anti-Hu Ab compared with IHC alone (Giometto et al., 1997; Dropcho and King, 1994).

Anti-Yo Antibody

In 1983, a circulating autoantibody that reacted with a cytoplasmic antigen of Purkinje cells was described in two patients with PCD and ovarian carcinoma (Greenlee and Brashear, 1983). Serologic Ab reacting with Purkinje cells were later confirmed in those patients and called anti-Yo Ab (Jaeckle et al., 1985).

By using IHC on human or rat cerebellar sections, these polyclonal complement-fixing IgG exhibit coarse granular staining of Purkinje cell cytoplasm and proximal dendrites, sparing the nucleus (Jaeckle et al., 1985; Greenlee et al.,

TABLE 68.2 Classification of paraneoplastic neurologic diseases (PND) according to the specific antibody detected, neurologic syndrome, and the most frequently associated tumor

Antibody	Paraneoplastic neurologic syndrome	Most frequently associated cancers	Immunohistochemistry	Western immunoblot	Antigen
Anti-Hu/ANNA-1	Encephalomyelitis, sensory neuronopathy	SCLC, non-SCLC	Strong staining of all neuronal nuclei and weaker staining of cytoplasm	38–40 kDa reactive triplet bands on extracts of crude or isolated CNS neurons/nuclei and SCLC. Recombinant protein 43 kDa (HuD)	Neuron-specific RNA/DNA binding protein, role in RNA processing of neurons
Anti-Yo/PCA-1	Acute to subacute pan-cerebellar syndrome, dysarthria and upbeat nystagmus	Ovarian, breast, uterus	Purkinje-cell cytoplasm and axons, coarse granular staining	34 and 62 kDa band from Purkinje cell extracts and breast and ovary tumors of patients, reactive with recombinant CDR-34 and CDR-62 patients	DNA binding, gene transcription regulators, carry leucine-zipper and zinc-finger motifs
Anti-Ri/ANNA-2	Opsoclonus–myoclonus	Breast, SCLC	All nuclei of CNS	55 and 80 kDa neuronal protein; 55 kDa recombinant protein	RNA-binding protein, regulates metabolism in a subset of developing neurons
Anti-amphiphysin	Stiff-person syndrome	Breast	Synapses of CNS neurons	128 kDa protein on neuronal extracts	Amphiphysin synaptic vesicle protein, function unknown
anti-Tr	More slowly developing cerebellar syndrome, less frequent dysarthria and nystagmus	Hodgkin's disease	Purkinje cell cytoplasm, fine granular staining in the molecular layer	No reactive protein detected as yet	Not known
Anti-CV2	Subacute cerebellar ataxia, Lambert–Eaton myasthenic syndrome, limbic encephalitis, uveitis	SCLC, thymoma	Cytoplasm of oligodendrocytes	66 kDa protein	CRMP5 (Collapsine response mediator protein 5)
anti-Ta (Me 2)	Limbic encephalitis	Testicular tumors	Nucleus, perykarion	40 kDa	Unknown function

SCLC, small cell lung cancer.

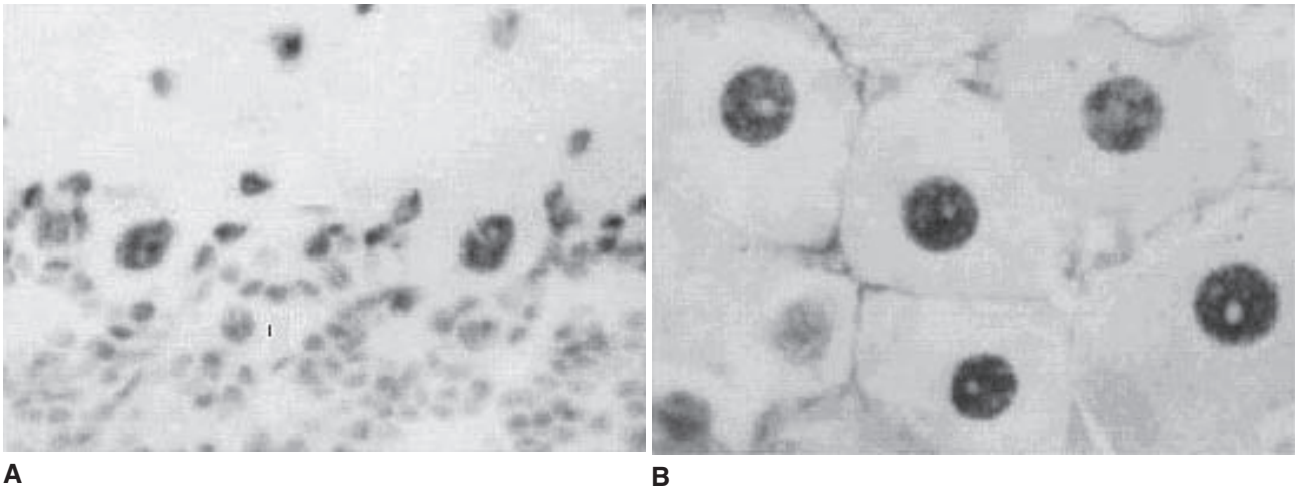

Figure 68.1 Anti-Hu antibody. *A,* rat cerebellar cortex showing homogeneous staining of neuronal nuclei of Purkinje, granular and molecular layer cells (×400). *B,* the autoantibody reacts also with rat dorsal root ganglia (DRG) nuclei (×800).

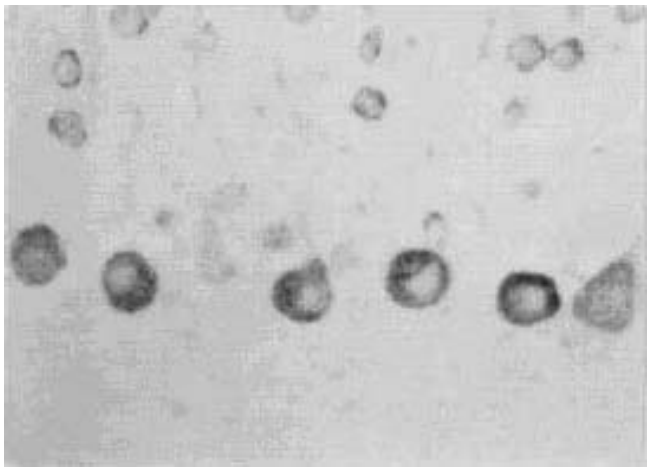

Figure 68.2 Anti-Yo antibody. Coarsely granular staining of the Purkinje and molecular layer cytoplasms sparing the nuclei in Purkinje cells of rat cerebellar cortex (×400).

1988) (Figure 68.2). Though anti-Yo reactivity is widespread in the rat cerebellum, no staining was demonstrated in human cerebral cortical neurons (Greenlee et al., 1988; Altermatt et al., 1991; Dalmau and Posner, 1996).

On western blot with Purkinje cell proteins or cerebellar extracts, anti-Yo Ab react with two bands at 32–34 kDa and 62–64 kDa (Greenlee, 1983; Jaeckle et al., 1985; Cunningham et al., 1986). The antigen is also selectively expressed in tumor tissue from patients with PCD (Furneaux et al., 1990).

The Yo Antigen

Using electron microscopy, it has been shown that the anti-Yo antibody binds to clusters of ribosomes, the Golgi apparatus and the granular endoplasmic reticulum of Purkinje cells (Peterson et al., 1992). The genes for the 34 kDa and 62 kDa Yo antigens have been cloned and the gene products are called cerebellar-degeneration-related proteins CDR1 (CDR-34) and CDR2 (CDR-62) (Fatallah-Shaykh et al., 1991). Two other Yo antigens of 58 kDa (CZF) and 52 kDa (PCD-AA) have been reported (Tanaka et al., 1996). However, anti-Yo Ab binding to 62 kDa, 58 kDa, and 52 kDa antigens tally to a single molecule of 58 kDa when tests are conducted under identical laboratory conditions; this underscores the usefulness of standardizing antibody detection methods to characterize PCD subgroups (Tanaka et al., 1996).

Unlike anti-Hu Ab, which are expressed in all SCLC, the CDR are only expressed in tumors of patients with anti-Yo-positive PCD (Furneaux et al., 1990; Sakai et al., 1992).

The function of these antigens is as yet unknown, although it is thought that they may regulate gene transcription by binding to DNA (Fatallah-Shaykh et al., 1991).

Anti-Ri Antibody

The antineuronal antibody called anti-Ri was identified in association with opsoclonus–myoclonus syndrome in patients with breast carcinoma in 1991 by Luque et al. It reacts on IHC with all neuronal nuclei of the CNS (except the dorsal root ganglia nuclei, thus differentiating it from anti-Hu) (Figure 68.3). On western blot using neuronal extracts, the antibody reacts with two separate bands of 55 and 80 kDa (Luque et al., 1991).

By screening a human cerebellar cDNA library using anti-Ri serum, a gene called NOVA-1 has been cloned. It encodes a 54 kDa protein (Buckanovich et al., 1993). The antigen NOVA-1 is a neuron-specific KH-type RNA-

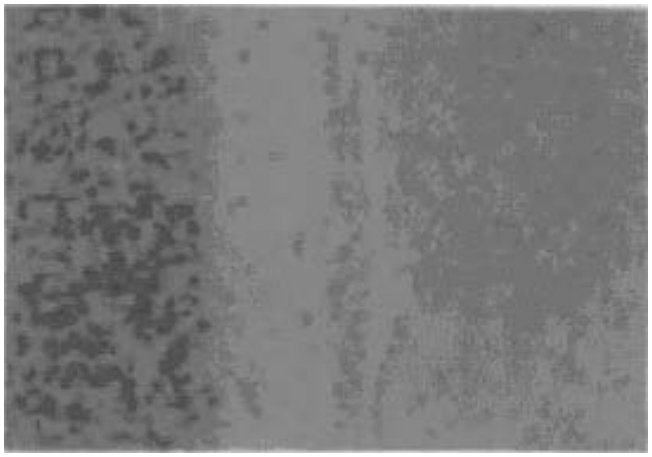

Figure 68.3 Anti-Ri antibody. Pattern of neuronal staining of spinal cord nuclei (bottom) sparing the dorsal root ganglia neurons (left) (×250).

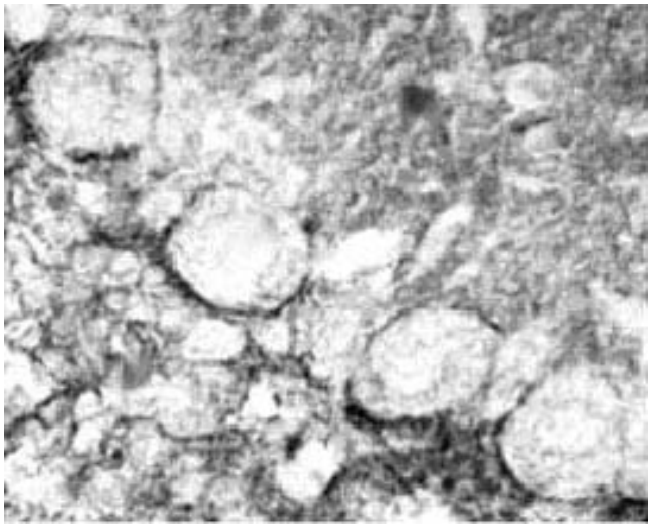

Figure 68.4 Anti-amphiphysin antibody. Staining of the neuropil of rat brain cerebellum in the molecular and granular layers of the Purkinje cell membrane sparing the nuclei and cytoplasms (×800).

binding protein. NOVA-1 transcripts are only present in specific regions of the CNS, as the midbrain and pontine tegmentum, optic tectum, and deep nuclei of the cerebellum (these localizations correlate with clinical symptoms in OMS).

The homology between NOVA-1 and hnRNPK suggests that NOVA-1 regulates metabolism in a specific subset of developing motor neurons (Buckanovich et al., 1993). *In vitro*, anti-Ri Ab can inhibit the RNA-binding activity of the NOVA-1 antigen (Buckanovich et al., 1996).

Anti-Amphiphysin Antibody

Anti-amphiphysin Ab were first described in patients affected by SPS and breast cancer (Folli et al., 1993). On IHC, anti-amphiphysin Ab react with the neuropil of rat brain cerebellum, sparing the neuronal nuclei and cytoplasm (Figure 68.4). On immunoblots of cerebral cortex, sera harboring anti-amphiphysin Ab react with a protein doublet of approximately 128 kDa (De Camilli et al., 1995).

Amphiphysin is a synaptic vesicle-associated protein (De Camilli et al., 1993) whose gene (AMPH) was mapped to the short arm of chromosome 7 (Yamamoto, 1995). Its function remains unclear. It binds to dynamin, involved in the internalization of synaptic vesicle membranes after exocytosis (De Camilli et al., 1995).

Anti-amphiphysin Ab have also been described in patients affected by PEM and SCLC (Dropcho, 1996; Dorresteijn et al., 2002). More recently, the spectrum of PND associated with anti-amphiphysin Ab was further enlarged to encompass limbic encephalitis (Dorresteijn et al., 2002), cerebellar degeneration and opsoclonus (Saiz et al., 1998; Antoine et al., 1999). In addition, anti-amphiphysin Ab are present, at a low frequency, in patients with SCLC without PND (Saiz et al., 1998). In such cases, patients' sera also harbored anti-Hu Ab. Considering the low incidence of the disease, no therapeutic approaches have yet been reported.

Anti-Tr Antibody

Anti-Tr Ab have been described in patients affected by PCD and Hodgkin disease (HD) (Graus et al., 1997). Cerebellar symptoms usually develop in middle-aged males after diagnosis of lymphoma and during remission of the tumor (Hammack et al., 1992).

Anti-Tr Ab label the cytoplasm of Purkinje cells of human and rat cerebellum. The molecular layer of rat cerebellum shows a characteristic dotted pattern suggestive of immunoreactivity by the dendritic terminals of Purkinje cells (Graus et al., 1997) (Figure 68.5). Immunoblots of human Purkinje cells or rat and mouse cerebellum are negative (Graus et al., 1997). Consequently, the corresponding antigen has not yet been identified.

Through laser confocal microscopy and immunoelectronmicroscopy, anti-Tr Ab immunoreactivity was found to be localized in the cytosol and outer surface of the endoplasmic reticulum of the perikarya of neurons of the molecular layer and the cell body and dendrites of Purkinje cells, without a particular concentration in the dendrite spines (Graus et al., 1998).

The antigen recognized by anti-Tr Ab probably appears at an early stage and is widely expressed in the developing rat brain (Graus et al., 1998).

Unlike other antineuronal Ab, anti-Tr Ab can be detected in the CSF but not in the serum and may spontaneously disappear during follow-up (Bernarl et al., 2003) or after improvement of clinical symptoms (Peltola et al., 1998).

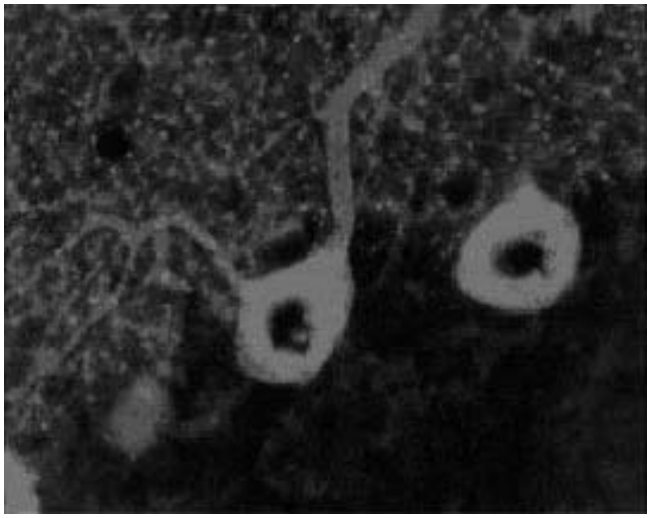

Figure 68.5 Anti-Tr antibody. Dotted staining of the molecular layer and Purkinje cell cytoplasm of rat cerebellum (immunofluorescence) (×800).

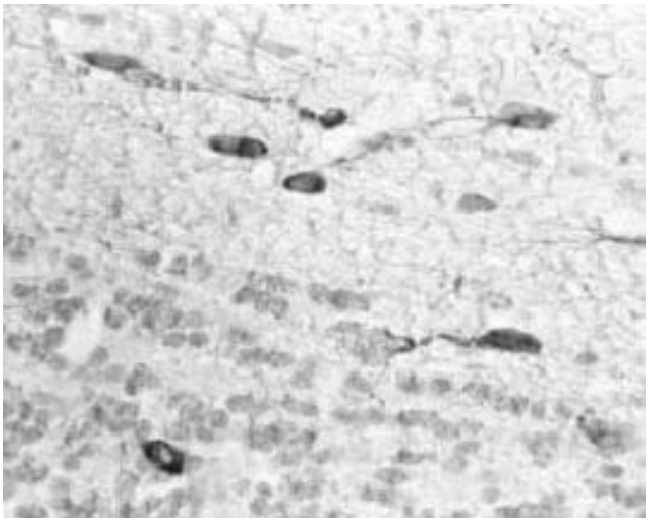

Figure 68.6 Anti-CV2 antibody. Cerebellar white matter (top) showing cytoplasmic labeling of oligodendrocytes (×400).

Anti-Tr Ab immunoreactivity has never been demonstrated in the tumor (Bernarl et al., 2003).

Anti-CV2 Antibody

Anti-CV2 Ab were first reported by Antoine et al. (1995) and Honnorat et al. (1996) in patients affected by subacute ataxia, SCLC, or thymoma. The main neurologic syndrome is a subacute cerebellar disease (66%) although a few cases presented with limbic encephalitis, LEMS, or uveitis (Honnorat et al., 1996). Most patients with anti-CV2 Ab develop SCLC; association with thymoma (Rogemond et al., 2000) and epidermoid carcinoma of the lung (Medrano et al., 2003) is rare.

The paraneoplastic origin of the disease seems to be confirmed by dramatic improvement after tumor excision (De La Sayette et al., 1998). In 20% of patients, anti-Hu Ab are also present. Patients with anti-CV2 Ab presented mixed axonal and demyelinating sensory-motor neuropathy, sometimes superimposed on a subacute sensory neuronopathy when both anti-CV2 and anti-Hu Ab were present (Antoine et al., 2001).

On adult brain tissue sections, anti-CV2 Ab label the cytoplasm of oligodendrocytes (Figure 68.6) and react with a 66 kDa protein of new-born rat brain on western blot (Honnorat et al., 1996).

The antigen (paraneoplastic oligodendrocyte protein of 66 kDa; POP66) is specifically expressed by a subpopulation of oligodendrocytes and not by neurons (Honnorat et al., 1998), in spite of the wide neuronal loss without demyelination pathologically reported in these patients. The involvement of POP66 in neuron survival via neuron/oligodendrocyte interactions has been postulated (Honnorat et al., 1998).

Recently, paraneoplastic chorea, mainly associated with SCLC and thymoma, has been described in patients testing positive for anti-CRMP-5 Ab (Yu et al., 2001; Vernino et al., 2002). CRMP-5 is a neuronal cytoplasmic protein, related to the collapsin response-mediator protein family, which migrates at 66–70 kDa under denaturing gel electrophoresis conditions. CRMP-5-IgG recognizes the neuronal nucleus and cytoplasm, and minor glial population on IHC.

Anti-CV2 Ab are hypothesized to constitute the same entity as CRMP-5-IgG since they react with at least four of the five known Ulip/CRMP (Unc-33-like phosphoprotein/collapsing response mediator protein) (Honnorat et al., 2001), a family of four homologous phosphoproteins considered crucial for brain development. The proteins recognized by anti-CV2 are Ulip3/CRMP1, Ulip4/CRMP3 (Honnorat et al., 1999), Ulip2/CRMP2, and Ulip6/CRMP5 (Ricard et al., 2001).

Anti-CRMP Ab reflect only one aspect of Ulip/CRMP recognition by anti-CV2 Ab (Honnorat et al., 2001).

Anti-Ma/Ta Antibody

Anti-Ta Ab recognize a 40 kDa neuronal protein present in the nucleus and cytoplasm of neurons. By IHC on acetone-fixed, frozen sections of human or rat brain, anti-Ta Ab produce discrete granular reactivity in the nucleus and perikaryon of rat neurons and nuclear staining in the

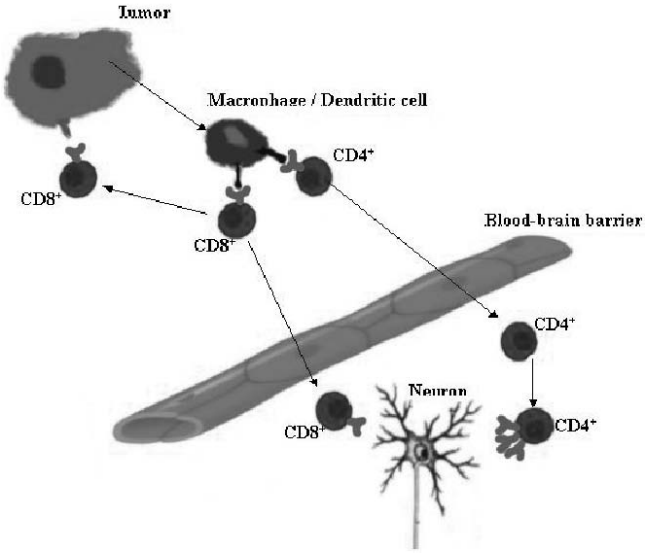

Figure 68.8 Autoimmune responses in paraneoplastic neurological diseases. Onconeuronal antigen expressed within the tumor when the cell dies is taken up by macrophages and presented to both cytotoxic and helper T cells. When these cells migrate through the blood–brain barrier they help B cells to produce specific antibodies. This microenvironment can induce MHC class I expression by neurons thus enabling the cytotoxic T cell to attack the neuron.

human cortex (Figure 68.7). Anti-Ta Ab are restricted to patients with limbic and brainstem encephalitis associated with testicular cancer (Voltz et al., 1998; 1999; Gultekin et al., 2000). Testicular cancer is the second leading neoplasm, after SCLC, to cause paraneoplastic limbic encephalitis.

Anti-Ta Ab has permitted the cloning of a protein called Ma2, which is expressed in the brain and testicular tumors of patients with paraneoplastic limbic encephalitis and anti-Ta Ab. The Ma2 function is unknown but shares homology with Ma1, an antigen expressed in normal brain and testis (Dalmau, 1998).

Antibodies directed against Ma1 are also known as anti-Ma Ab; they are usually harbored in the sera of patients affected by cerebellar and/or brainstem disease associated with breast, parotid, and colon cancer. Anti-Ma Ab react mainly with the nuclei and nucleoli of neurons and, to a lesser degree, with the cytoplasm; in addition, they recognize testicular germ cells. On western blot with neuronal proteins, anti-Ma Ab identified two distinct bands of reactivity at 37 and 40 kDa. As for Ma2, the function of Ma1 protein remains unknown (Dalmau et al., 1999).

Other Antibodies

Recently, other new antineuronal Ab have been characterized: Glutamate receptor (Sillevis-Smitt et al., 2000), and Zic4 (Bataller et al., 2004). However, these reactivities have only been confirmed by one laboratory.

PATHOGENIC MECHANISMS AND ANIMAL MODELS

The pathogenesis of PND is still unknown, but an immune-mediated mechanism is hypothesized. This theory is supported by the detection of antineuronal Ab in PND patients' CSF, which indicates intrathecal endogenous synthesis.

These syndromes seem to be the result of a cross-reaction mechanism in which antigens are expressed by both the tumor and neurons and called "onconeural antigens." The immune system is activated by these antigens, slowing tumor growth and causing the neuronal damage. A possible mechanism of the autoimmune responses is reported in Figure 68.8: onconeural antigens expressed within the tumor are taken up by macrophages and presented to both cytotoxic and helper T cells. When these cells migrate through the blood–brain barrier they help B cells to produce specific Ab. This microenvironment can induce MHC class I expression by neurons, thus enabling the cytotoxic T cell to attack the neuron.

The role of antineuronal Ab in the pathogenesis of PND has only been conclusively demonstrated in neuromuscular junction disorders, such as LEMS. Indeed, inoculation in rabbits of IgG from patients with LEMS was able to reproduce the disease (Lang and Vincent, 1996). This

mechanism occurs, however, irrespective of paraneoplastic etiology.

In the case of other PND, the discovery of specific Ab suggests a similar pathogenesis, although no *in vivo* or *in vitro* studies have been able to demonstrate that antineuronal Ab have a role in inducing the disease. Many onconeural antigens are nuclear or cytoplasmic, and it is, therefore, difficult to understand how Ab might target the neurons. Hu antigens, for example, are expressed in cell nuclei and not on the cell surface; this suggests that they are unavailable as a target for the immune system (Dalmau et al., 1991; 1992a). The only evidence that anti-Hu Ab may have a direct pathogenetic role comes from the finding that anti-Hu Ab destroy rat cerebellar granular cells *in vitro* (Greenlee et al., 1993).

However, anti-Hu-positive sera could be toxic to tumor cell lines even when cells do not express Hu antigens, suggesting that the effect on cells may not be Hu-mediated (Verschuuren et al., 1997).

Passive immunization of experimental animals with anti-Yo Ab has never reproduced the disease, as with anti-Hu Ab (Greenlee et al., 1988; Graus et al., 1991; Sillevis-Smith et al., 1994; Tanaka et al., 1995a; 1995b; René et al., 1996). This suggests involvement of an alternative cellular immune mechanism (for example cytotoxic T lymphocytes or other cytolytic killer cell activity). This hypothesis seems to be confirmed by the discovery of extensive infiltrates in the nervous system of PND patients (Verschuuren et al., 1996) and the detection of activated T-cells in the CSF of patients affected by PCD (Albert et al., 2000). Hence, cytotoxic T lymphocytes have become the candidate for holding the primary pathogenic role in PND. T-cell-receptor analysis in anti-Hu brain tissue revealed oligoclonal expansion of cytotoxic T cells, suggesting a primary immune reaction against onconeural antigens (see Figure 68.8). Very recently (Pellkofer et al., 2004) a model of paraneoplastic disease involving the central nervous system has been reported in which the adoptive transfer of T cells specific for an autologous onconeural antigen caused encephalomyelitis in rats with perivascular infiltrates in the regions affected in human disease.

TREATMENT WITH AUTOANTIBODIES

The rarity of PND has made it impossible to carry out controlled therapeutic studies, and currently available data are derived from limited cases. Correct clinical diagnosis is paramount but may be challenging since the neurologic symptoms sometimes have an acute onset and often antedate the discovery of the tumor. In any event, early cancer detection and treatment represent the gold standard for PND therapy. Indeed, in most cases, treatment of the neoplasm can lead to stabilization and even improvement of the neurologic syndrome, although cancer detection may sometimes be difficult. Moreover, patients may deteriorate in the months preceding diagnosis of the tumor, the neurologic disorder may progress even after achieving complete response to the tumor, or the PND can develop during cancer treatment. For all these reasons, cancer therapy cannot be the only approach to PND management. The use of immunomodulatory therapies, like steroids, intravenous immunoglobulin (Moll et al., 1993, Consuell, 1994; Uchuya et al. 1996), plasma exchange (Graus et al., 1992; Cher et al., 1995), immunosuppressive drugs (Graus and Delattre, 1993; Stark et al., 1995), and combination of these therapies (Keime-Guilbert et al., 2000) has been prompted by increasing evidence that many paraneoplastic syndromes are immunomediated. These therapies seem to be effective for PND with a proven immunomediated mechanism like LEMS (Bain et al., 1996). However, no immunomodulatory approach used to date has been very effective in treating other PND involving the central nervous system. In these cases, clinical symptoms could be caused by massive neuronal death (as in the case of Purkinje cells in PCD) or functional impairment of neuronal networks (as in OMS). In the former group, early treatment is recommended for stabilization of symptoms; in the latter group, complete remission is possible. Complete clinical remission was reported in patients affected by limbic encephalitis (LE) associated with anti-Ma Ab (Rosenfeld et al., 2001); all were treated with antitumor therapy, in some cases in combination with immunosuppression. In these cases a reversible imbalance of the neuronal network seems to be involved, rather than neuronal loss (as in the case of OMS). In addition, LE with anti-Ma Ab is usually associated with radically treated testicular cancer. An argument against the use of immunomodulatory therapy is that it might affect evolution of the neoplasm. There are no data to support this hypothesis; it has, instead, been shown that, in patients with PEM, SCLC outcome was similar in patients who received immunotherapy and those who did not (Keime-Guibert et al., 2000); in addition, long-term outcome of PCD and anti-Yo Ab is also not affected by immunotherapy (Rojas et al., 2000).

CONCLUDING REMARKS

Although categorization of the major PND by 1965 was supported by the detection of antineuronal Ab by 1980, strict diagnostic criteria have only recently been developed (Graus et al. 2004). The diagnosis of PND is still difficult because not all patients with paraneoplastic disorders harbor antineuronal Ab and a neoplasm is not detected in all patients with antineuronal Ab. These criteria divide PND into "definite" and "possible" based upon clinical and immunologic data. We believe that these new criteria will allow classifi-

cation of newly identified paraneoplastic syndromes and should now permit the development of standardized research protocols and multicentric therapeutic trials.

Lymphoma and Autoimmune Disease

KATHERINE MORLAND HAMMITT*
**Sjögren Syndrome Foundation, Bethesda, Maryland*

ELAINE L. ALEXANDER†
†Aeolus Pharmaceuticals, Inc., San Diego, California

Lymphoid malignancies occur with increased frequency in autoimmune disease *vis-á-vis* the general population. Lymphomas have long been linked with chronic stimulation of the immune system (Armstrong et al., 1970), so their occurrence in an autoimmune disease setting is not unexpected. The actual development of lymphoma in autoimmune disease, however, is complex and multifactorial. Autoimmune disease per se, with its inherent chronic inflammation and stimulation of the immune system, contributes to the development of lymphoma, and, in addition, genetic and environmental factors influence the transition.

Lymphomas and autoimmune diseases demonstrate a close correlation from several aspects. Thus, lymphomas, especially B-cell non-Hodgkin lymphomas (NHLs), occur with increased frequency among autoimmune diseases, and features of autoimmune diseases occur in lymphoma even without any evidence of autoimmunity. Environmental provocation, including infections (mainly viral) and chemical exposures, is coming under increasing scrutiny in the development of lymphoma in autoimmune disease. Also, information is expanding as sequencing of the human genome progresses, and genetic profiling is providing opportunities in diagnosis, prognosis, improved classification, and treatment of lymphoma.

The increased prevalence of lymphoma in autoimmune diseases is clearly established in some disorders, while it appears less clearly established and is based primarily on case studies or animal models in others. Our understanding of both non-Hodgkin B-cell lymphoma and autoimmune disease has increased substantially in the last couple of decades. Formerly categorized solely by grade as *low, intermediate,* and *high*, new classifications for non-Hodgkin B-cell lymphoma were devised starting in 1994 with the "Revised European American Classification of Lymphoid Neoplasms" and published by the International Lymphoma Study Group, and most recently modified in 1999. These discussions led to designations based on genetic features, morphology, immunophenotype, and clinical features (Harris et al., 1999; Jaffe et al., 1999).

Increased knowledge about pathogenesis will translate into better avenues for research and therapies. The clinical setting already is rapidly changing with newer knowledge of risk factors, diagnostic procedures, and regimens of treatment. With these opportunities, though, come the disappointments as some new biologic agents, while improving symptoms in many autoimmune diseases, can be accompanied by induction of lymphoma in the autoimmune diseases that these agents were meant to treat. However, the advances in such areas as cytokine treatments (including antagonists of tumor necrosis factor [TNF] and B-cell activating

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

factors), apoptosis, immunogenetics, and environmental provocations hold exceptional promise in moving forward the autoimmune-lymphoma field connection.

OCCURRENCE OF LYMPHOMA IN AUTOIMMUNE DISEASES

The occurrence of lymphoma in autoimmune disease is illustrated most clearly in Sjögren syndrome, autoimmune thyroiditis, and autoimmune hemolytic anemia (Mackay and Rose, 2001). A connection with lymphoma also has been proposed in rheumatoid arthritis, systemic lupus erythematosus (SLE), celiac disease, and Henoch–Schönlein disease, and has been suggested in a broad range of additional autoimmune disorders.

Autoimmune Diseases Having the Clearest Association with Lymphoma

Certain autoimmune diseases have been historically recognized as associated with lymphoproliferation, which can remain benign or transform into a frank lymphoma. The term "lymphoproliferative disease" was used as early as 1959 by Dameshek to describe this association (Dameshek and Schwartz, 1959). Diseases in this category include autoimmune hemolytic anemia, Sjögren syndrome, and autoimmune thyroiditis, described in Chapters 41, 31 and 35, with a prominent histologic feature in the latter two being ectopic lymphoid hyperplasia in the affected tissue and prominent germinal centers. Additional autoimmune diseases having a clear association with lymphoma are rheumatoid arthritis, SLE, and celiac disease.

Sjögren Syndrome

The link between Sjögren syndrome and lymphoma was the first to be identified among autoimmune diseases (Talal and Bunim, 1964). Sjögren syndrome, among all autoimmune diseases, carries the greatest risk for lymphoma development, the highest incidence of transformation, and clearest progression from autoimmunity to lymphoproliferation to malignancy. In 2001, an International Workshop on Autoimmunity and Lymphoma concluded that Sjögren syndrome best illustrated the transformation from a benign autoimmune process to malignancy (Mackay and Rose, 2001). The risk generally has been stated at 5% of those with Sjögren syndrome developing lymphoma over their lifetime, or a 44-fold increased risk compared with the general population, but some studies place the risk as high as 10%, and a realistic figure would be in a range from 6–10% (Ramos-Casals et al., 2000). In those individuals with a disease onset before age 45 years, the risk is estimated at a 60-fold increase over that of the general population (Kassan et al., 1978).

The most common type of lymphoma occurring in Sjögren syndrome is a B-cell NHL of the mucosa-associated lymphoid tissue (MALT) type. The salivary glands are the most common initiating site, but lymphomas also develop in the cervical nodes, lungs, and elsewhere, including the gastrointestinal tract.

Autoimmune Thyroid Disease

Hashimoto's thyroiditis is a lymphoproliferative autoimmune disease that often coexists with Sjögren syndrome, rheumatoid arthritis, SLE, or other autoimmune disorders and confers an increased risk of lymphoma. Thyroid lymphomas in a Denmark population cohort showed an incidence of 2 cases in 1 million per year, with 66% of those having pre-existing Hashimoto's thyroiditis (Pedersen and Pederson, 1996), and a risk of 40–80 times that of the general population. Numbers derived from a Swedish Cancer Register concur with a clear correlation and also note a relatively low overall risk of developing thyroid lymphoma for those with Hashimoto's thyroiditis, at less than 1% (Holm et al., 1985). While thyroid lymphoma is an unusual neoplasm, it most often is seen in patients with Hashimoto's thyroiditis (Hyjek and Isaacson, 1988). Similar to the lymphomas found more frequently in Sjögren syndrome, those with autoimmune thyroid disease are identified as B cell and of the MALT type. They also share a histologic feature in which centrocyte-like (CCL) B cells surround reactive follicles forming lymphoepithelial lesions (Hyjek et al., 1988; Isaacson, 1992; Mackay and Rose, 2001).

Autoimmune Hemolytic Anemia

A clear association with B-cell lymphomas is also evident in autoimmune hemolytic anemia (Sokol et al., 1981). Autoimmune hemolytic anemia (AIHA) may be marked in some patients by diffuse and extensive lymphadenopathy, a risk factor for development of lymphoma. In one cohort of AIHA patients, 18% developed malignant lymphoproliferative disorders, and development of serum monoclonal IgM protein was noted as a significant predictive factor (Sallah et al., 2001).

Rheumatoid Arthritis

Patients with rheumatoid arthritis (RA) face an increase in relative risk for lymphoma of 1.5–8.7 that of the general population (Prior, 1985; Ehrenfeld et al., 2001). The risk is cited as much higher for men than women. An hypothesis recently put forward on this disparity suggests that a lack of genetic protection against development of autoimmune

disease in such men might contribute to their susceptibility to develop lymphoproliferation and malignancy (Whelan and Scadden, 2004). However, gathering data on the prevalence of lymphoma in RA patients has become increasingly complicated because of use of treatments such as TNF inhibitors and immunosuppressive drugs that may themselves increase the risk of lymphoma.

Rheumatoid arthritis is associated with a range of hematologic and other malignancies, including NHL, Hodgkin's disease, and lung cancer, but conversely has a negative association with colorectal cancer (Mellemkjaer et al., 1996). Rheumatoid arthritis is notably correlated with development of diffuse large B-cell lymphoma (DLBCL) (Baecklund et al., 2003), and with acute nonlymphoblastic leukemia and chronic myelogenous leukemia (Gridley et al., 1993). A large database from Sweden disclosed that, while its patients with RA (76,527) did have an increased risk of lymphoma, this overall risk was not evident in first degree relatives (70,290), giving little indication of notably co-inherited risk factors or of environmental effects. This lymphoma was seen as the direct consequence of the inflammation or the treatment of RA (Ekström et al., 2003).

Systemic Lupus Erythematosus

Systemic lupus erythematosus shares with other autoimmune disorders some pathogenic mechanisms that can induce lymphoma development. In addition, lymphadenopathy is a common feature in lupus, further increasing the risk. The risk of developing NHL in SLE has been commonly cited at 5.2% (Mellemkjaer et al., 1997). Non-Hodgkin lymphoma is the most prevalent malignancy in SLE (Abu-Shakra et al., 1996). In patients with SLE, the occurrence of all types of malignancy lies within a broad range of 2.5–13.8% of affected individuals (Abu-Shakra et al., 2002).

Celiac Disease

Patients with celiac disease experience a higher incidence of malignant diseases, 8.4%, and this is even higher, 22.2%, in older patients (Freeman, 2004). Most of the malignancies are NHLs (Catassi et al., 2002). However, these are dissimilar from the B-cell lymphomas that most commonly occur in other autoimmune diseases, since the most prevalent malignancy is a small bowel T-cell lymphoma (Green and Jabri, 2003; Smedby et al., 2005). This enteropathy-associated T-cell lymphoma (EATL) has several notable features (Catassi et al., 2005). It is a substantial clinical problem, as the outcome is poor, although the relative risk for intestinal lymphoma conferred by celiac disease (<5.0) is less than hitherto thought. It accounts for some 35% of all small bowel lymphomas and occurs after many years of latency, and hence mostly in older adults. The immunophenotype of EATL is $CD3^+$, $CD4^-$, $CD8^-$ and $CD103^+$; immunophenotyping suggests a clonal proliferation of intraepithelial lymphocytes derived from $\alpha\beta$ rather than $\gamma\delta$ T cells. A gluten-free diet seems protective. Thus, as for autoimmune-based B-cell lymphomas, chronic antigenic stimulation (of T cells) is presumably provocative. A genetic anomaly, germline or somatic, has not been implicated.

Other Autoimmune or Immune-Mediated Diseases Associated with Lymphoma

A high frequency of hematologic malignancies has been reported in patients diagnosed with Henoch–Schönlein purpura after the age of 40 years. In one study, more than one-third of such patients developed a hematologic malignancy, and 10% of those were lymphomas, either of the non-Hodgkin or Hodgkin type (Pertuiset et al., 2000).

Non-Hodgkin lymphoma is reported in association with other autoimmune diseases, but large-scale epidemiological studies and further mechanistic investigations are necessary to sustain such associations. Those cited in coincident case reports or small-scale epidemiology studies but that remain inconclusive include Crohn's disease (Mellemkjaer et al., 2000; Raderer et al., 2004); Wegener's granulomatosus (Cohen et al., 2004); eczema and psoriasis (Zhang et al., 2004); polymyositis and dermatomyositis (Leandro and Isenberg, 2001; Varoczy et al., 2002); and Addison's disease and autoimmune hepatitis (Varoczy et al., 2002). Hematopoietic cancers, and especially myeloid leukemia, are increased by 20% in patients with inflammatory bowel disease, with a moderately increased risk of lymphoma found in Crohn's disease (Askling et al., 2005). Cancer in general, including NHL, is reported to occur more frequently in systemic sclerosis (scleroderma) (Rosenthal et al., 1995; Leandro and Isenberg, 2001; Varoczy et al., 2002; Pearson and Silman, 2003). Interestingly, in a recent review of 421 patients with NHL, as many as 7.6% had evidence of an autoimmune disease, most frequently Sjögren syndrome, and the autoimmune disease preceded the diagnosis of lymphoma in 70% of the associated cases (Varoczy et al., 2002).

Types of Lymphoma in Autoimmune Diseases

It is the non-Hodgkin B-cell type of lymphoma that is most closely linked with autoimmune disease, and MALT-type lymphomas are especially correlated with Sjögren syndrome and Hashimoto's thyroiditis. However, Hodgkin disease also appears in the context of autoimmune disease, and additional hematologic malignancies have been cited as occurring in an autoimmune disease setting, including multiple myeloma, B-cell chronic lymphocytic leukemia

(B-CLL), and Waldenstrom macroglobulinemia. T-cell lymphoma is unusual among autoimmune diseases except for celiac disease.

An interesting comparison was made by Bende et al. (2005) of amino-acid sequences of the IgV_H-CDR3 of B-cell lymphomas with sequences in GenBank. The repertoire expressed by lymphomas aligned with that of normal B cells except for salivary and gastric MALT lymphomas wherein there was strong CDR3 homology to rheumatoid factors, indicative of selection for reactivity to autologous Fc of IgG; this did not pertain however for MALT lymphomas with the (11;18) translocation. This supports the idea of lymphomagenic effects of chronic antigenic stimulation (Mackay and Rose, 2001) in the above examples, by Fc of IgG in complexes of IgG-ANA (salivary glands), or of IgG-*Helicobacter pylori* (stomach).

PATHOGENIC MECHANISMS

Lymphoma can develop in the context of chronic antigenic stimulation initiated or prolonged by autoimmune disease and/or infection. Viral or bacterial influences have a suspected etiologic role, and genetic aberrations also are involved.

Autoimmunity and Chronic Inflammation

A basic characteristic of autoimmune disease is long-term stimulation of the immune system and chronic inflammation, which augment the potential for development of lymphoma.

Viral and Bacterial Associations

Viruses and bacteria are linked with the development of numerous autoimmune, rheumatic, and related diseases and are also linked with the development of lymphoma. Therefore, infection has become a prime target in searching for an autoimmune-lymphoma link. Particularly in the past 15 years, investigators have recognized and legitimized the role that viruses and bacteria might play in either autoimmune disease or lymphoma (Parsonnet et al., 2004). Viruses and bacteria with a noted link with lymphoma cross a broad range of organisms.

The herpes-type Epstein–Barr virus (EBV) was the first human virus to be associated with malignancy, specifically Burkitt's lymphoma, and later with Hodgkin disease and primary central nervous system lymphoma. Epstein–Barr virus has also been investigated in the etiology of autoimmune diseases, but no direct link has been proven yet, either with autoimmunity itself or with lymphoma in autoimmune disease. Links with other herpes viruses have been established, such as human herpes virus (HHV8), which has been linked with lymphoma and lymphoid hyperplasia in autoimmune disease.

Hepatitis C virus (HCV) is a single-stranded RNA virus that has demonstrated a clear correlation with both autoimmune features and malignancy. In fact, identification of HCV in autoimmunity and lymphoma underlines the triple association between autoimmunity, infection, and cancer (Ramos-Casals et al., 2004). This association is clearest in specific geographic areas in which HCV is prevalent. Hepatitis C virus is most closely associated with B-cell lymphoproliferative disorders, and specifically with B-cell NHL, and also with type II mixed cryoglobulinemia (Ramos-Casals et al., 2004; 2005b).

Simian virus 40 has been linked to non-Hodgkin's lymphoma (Vilchez et al., 2004). *H. pylori* is another microorganism, a bacterium, that is clearly established in the etiology of malignancy, specifically gastric MALT lymphoma (Wotherspoon et al., 1991). *H. pylori* can lead to B-cell lymphocytic infiltration of the epithelium, a characteristic of MALT. The bacterium *Borrelia burgdorferi* causes Lyme disease and is also associated with MALT lymphoma.

In addition to specific infection being linked with immune dysfunction, persistent infection leads to chronic immune stimulation, which influences the development of lymphoma. Chronic stimulation of B cells, such as rheumatoid factor synthesizing B cells, most likely launches the process of lymphomagenesis in autoimmune disease as well as chronic infection (Marietta, 2001).

Potential Role of Apoptosis and the Tumor Necrosis Factor Family

Current research into how the immune system malfunctions and promotes development of autoimmune disease and malignancy centers on apoptosis, or programmed cell death, and the impact on apoptosis of the TNF family. The TNF-associated ligands and receptors for those ligands play a powerful role in maintaining or disrupting immune homeostasis.

The autoimmune lymphoproliferative syndrome (ALPS) is a classic example of how dysregulated apoptosis can lead to autoimmune disease and potentially to malignancy (see Chapter 70). In ALPS, gene mutations result in defective apoptosis, leading to abnormal lymphocyte accumulation and survival of lymphocytes that would normally be eliminated, including autoreactive lymphocytes and those that might transform into malignant cells. Lymphocytic accumulation in ALPS causes lymphadenopathy and splenomegaly, and supervening complications include autoimmune hemolytic anemia, thrombocytopenia, and neutropenia, and in some cases lymphoma. The etiopathogenesis in ALPS depends on mutations of CD95 (Fas) and CD178 (Fas ligand) genes, the specific involvement of

heterozygous mutations in CD95, and survival of an increased number of double-negative αβ $CD3^+CD4^-CD8^-$ T cells (Straus et al., 1999; 2001; Bleesing, 2003; Bleesing et al., 2001).

Defective apoptosis may likewise participate in other autoimmune diseases and in the development of lymphoma, and, in these cases, TNF family molecules are critical to dysregulation. The B-cell activating factor (BAFF; also referred to as B-lymphocyte-stimulator or BLyS) is one such member of the TNF family and promotes the survival and maturation of B cells, and, as such, is vital to normal B-cell development. However, excess BAFF results in impaired apoptosis and allows too many of the wrong kinds of B cells to survive, including those that are autoreactive and those predisposed to neoplasia. The critical checkpoint for BAFF activity most likely occurs during B-cell maturation in the spleen (Groom et al., 2002; Batten et al., 2004). Besides allowing potentially malignant B cells to survive at this vital point at which they should be eliminated, excess BAFF can be produced by malignant cells (Mackay and Tangye, 2004) and so would continue to promote the development of both B-CLL and NHL. The level of BAFF increases as malignancy becomes more aggressive (Novak et al., 2004).

Elevated serum levels of BAFF are evident in B-cell non-Hodgkin lymphoma (Briones et al., 2002; Batten et al., 2004). Similar high levels are seen in some autoimmune diseases, particularly those in which autoantibodies and lymphoproliferation are key features. Particular examples include Sjögren syndrome, SLE and RA (Groom et al., 2002; Mariette et al., 2003; Batten et al., 2004; Szodoray et al., 2004; Mackay et al., 2005). In contrast, normal levels of BAFF were found in primary biliary cirrhosis and autoimmune adult-onset type 1 diabetes, diseases in which B-cell proliferation is less evident (Mackay et al., 2002). B-cell-activating factor is implicated in the polyclonal activation of B cells, a characteristic of Sjögren syndrome (Lavie et al., 2004), and, not surprisingly, BAFF levels in Sjögren syndrome increase according to the severity of disease and the degree of systemic involvement, with levels linked to hypergammaglobulinemia (Szodoray et al., 2004), lymphoproliferation, and higher levels of autoantibodies (Mariette et al., 2003).

Another TNF family member related to BAFF is an apoptosis-inducing ligand known as APRIL. This member shares receptors with BAFF, of which three have been identified to date (Jelinek and Darce, 2005), but BAFF and APRIL maintain different functions. APRIL is involved in T-cell survival and T-independent antigen responses, has been discovered in some tumor cell lines and tissue, and can induce proliferation of non-lymphoid cells (Mackay and Ambrose, 2003; Mackay et al., 2003). Both BAFF and APRIL promote the growth and survival of some B-cell malignancies (Jelinek and Darce, 2005). In some non-Hodgkin lymphomas, BAFF and APRIL further contribute to the survival of malignant cells by upregulating c-Myc, which promotes cell proliferation by downregulating p53, which is an inhibitor of cell proliferation, and increasing Bcl-6 which arrests B-cell differentiation (He et al., 2004). Our knowledge and opportunities in research will certainly expand greatly as additional members of the TNF family are identified and their roles established in immune tolerance, autoimmunity, and malignancy (Mackay and Kalled, 2002).

In RA, BAFF is found not only in the serum but in the synovial fluid, and, in Sjögren syndrome, excess BAFF is also upregulated in the affected salivary glands and is expressed in T-cells at the site of salivary gland damage (Lavie et al., 2004). The appearance of BAFF in sites where autoimmune damage occurs in these diseases suggests a potential role for BAFF in their pathogenesis.

Marginal zone (MZ) B-lymphocytes also appear to have a role in autoimmunity, inflammation, and tissue damage (Mackay et al., 2005) (see Chapter 11). They form a separate spleen compartment, which most likely becomes a reservoir for autoreactive B cells (Groom et al., 2002). In addition to the spleen, MZ B cells also have been detected in the lymph nodes, blood, and salivary glands of BAFF-transgenic (TG) mice (Batten et al., 2004), with MZ-like infiltrates present in the salivary glands of this mouse model (Groom et al., 2002). Similar cells have also been detected among B-cell infiltrates in the thyroid gland of patients with Graves' disease (Segundo et al., 2001).

It is becoming increasingly apparent that the balance of many elements is critical to immune homeostasis. Tumor necrosis factor of itself provides a protective element in preventing B-cell proliferation, while TNF family members BAFF and APRIL, in usual amounts, are important for normal apoptosis. However, when BAFF and APRIL are produced in excess, they cause B-cell proliferation. Interestingly, in a recent study, TNF-deficient BAFF-TG mice developed autoimmune disease in spite of the lack of TNF, and B-cell lymphoma increased in those mice by 35% (Batten et al., 2004). These findings demonstrate that TNF might not necessarily be involved in the mediation of autoimmune disease, but it certainly does have a crucial role in preventing malignancy. Further study of the TNF family molecules and interactions among these members holds great potential for developing new therapeutics and understanding the complications of others.

Genetics

Genes and their products can affect the way the immune system functions and reacts to environmental triggers, so it is not surprising that genetic factors contribute to the susceptibility of developing autoimmune disease as well as cancer. Key research areas in disease development involve the complex interaction of susceptibility genes and defects

in the regulation of those genes. New frontiers include the potential role of genetic aberrations to cause dysregulation of apoptosis and so influence oncogenic events, such as p53 mutations and Bcl-2 chromosomal translocations, and the runt-related family (RUNX) of genes associated with autoimmunity.

Genetic Aberrations of p53 and Bcl-2

Genetic irregularities are linked with defective apoptosis, which has been shown to determine malignancy and autoimmunity. These aberrations appear to promote apoptosis via the cell-surface receptor for CD95 (Fas) (Hale et al., 1996) and include inactivation of tumor suppressor gene p53 and overexpression of Bcl-2.

Mutations of the p53 gene can induce abnormal cell growth and increase cell survival and can promote progression of certain B-cell lymphomas. Such mutations are frequently found in connection with human tumors, and anti-p53 antibodies appear in sera of patients with a variety of malignancies, occurring in about half of all human cancers (Ichikawa, 2000). In one study, p53 dysfunction was evident in 22% of cases of aggressive B-cell lymphoma (Ichikawa et al., 1997). MALT lymphoma and its progression from low-grade to high-grade have also been linked to p53 mutations (Du et al., 1995). Interestingly, cancer patients can develop features of autoimmune diseases with production of autoantibodies targeted to autoantigens involved in oncogenesis such as p53 (Abu-Shakra et al., 2001).

Further evidence of the interplay between genetics, malignancy, and autoimmunity is seen in p53 recognition of DNA damage (Herkel et al., 2000). Patients with SLE may produce antibodies to p53, and, together with anti-DNA antibodies often found in SLE, can block p53 function, thereby affecting apoptosis in those patients (Herket et al., 2001). Finally, additional research into the impact of p53 is expanding to other p53 family members and target genes of p53, which are also involved in regulation of apoptosis (Fridman and Lowe, 2003; de Stanchina et al., 2004; Rosenblum et al., 2004).

Bcl-2 is another genetic protein involved in apoptosis and malignancy and contributes to development of NHL when overexpressed. It is specifically correlated with B-cell NHL and later stage disease, with evidence of Bcl-2 activation in 51% of cases of B-cell NHL, compared with 17% of T-cell NHL, and with evidence that 44% of the patients had stage III-IV disease (Hermine et al., 1996).

Aberrations in Chromosomal Translocations

A clear correlation between MALT lymphoma and three chromosomal translocations has been established, providing additional evidence that genetic aberrations can permit lymphoproliferation by allowing malignant cells to evade apoptosis. Those translocations include t(11;18)(q21;q21); t(1;14)(p22;q32); and t(14;18)(q32;q21). The occurrence of each translocation appears to be mutually exclusive and identified with specific primary sites, t(11;18)(q21;q21) being connected with those lymphomas originating in gastric and pulmonary sites, and t(14;18)(q32;q21) with those appearing in ocular adnexa, salivary glands, and the skin (Streubel et al., 2004c). When the t(11;18)(q21;q21) translocation is associated with gastric MALT lymphoma, it is also closely correlated with *H. pylori* infection of the stomach; in fact, the translocation aberrations are influenced by the disease or infection that precedes transformation to malignancy (Ye et al., 2003).

Development of lymphoma most likely involves a complex interplay between the chromosome translocations, MALT1, nuclear factor κB (NFκB), and BCL10, and may also involve p53 regulation. The t(11;18)(q21;q21) chromosomal abnormality leads to fusion between AP12 and MALT1 genes, which is known to activate NFκB and in turn inhibit p53, thereby establishing a link between NFκB signaling pathways and inhibition of p53-mediated apoptosis (Stoffel and Levine, 2004; Stoffel et al., 2004). The role of NFκB in apoptosis is clearly an emerging area for study in this intricate interaction. Another MALT lymphoma-associated molecule, BCL10, may be deregulated by t(1;14)(p22;q32) (Isaacson, 2005) and t(14;18)(q32;q21) (Ye et al., 2005). The MALT1 gene is an important regulator of BCL10 (Ruland et al., 2003), which is essential for NFκB activation and, when overexpressed, interferes with normal apoptosis (Zhang et al., 1999).

Finally, microvascular endothelial cells in B-cell lymphomas may have a genetically close relationship with the lymphoma and display tumor-related characteristics. The endothelial cells in such lymphomas often display lymphoma-specific chromosomal translocations, although the precise mechanisms for this are not clear (Streubel et al., 2004a).

A Role for the Runt-Related Proteins

The runt-related proteins (RUNX) have been linked with both autoimmune disease and cancer. These proteins are transcription factors that regulate genes and include the RUNX1, RUNX2, and RUNX3 members that are each linked with malignancy (Ito, 2004). RUNX1 is associated with acute myelogenic leukemia (Yamada et al., 2004) and RUNX3 with gastric cancer. It is likely, however, that more than a single RUNX member may be involved in etiology. For example, two RUNX members in addition to RUNX3 have recently been linked with gastric cancer (Sakakura et al., 2005), demonstrating a role for multiple RUNX members in malignancy and an even more complex and widespread involvement of RUNX members than previ-

ously thought. Additional evidence demonstrates that the interaction of one or another RUNX members can impact others, creating an additional mechanism for influencing disease development (Spender et al., 2005).

It is of particular interest that significant associations have been found between RUNX1 and development of at least three autoimmune diseases: psoriasis, SLE, and RA (Alarcón-Riquelme, 2004). RUNX1 is correlated with defective regulation of genes linked to these autoimmune disorders. In psoriasis, strong suspicion has been cast on RUNX1 as a cause of defective regulation of two genes, SLC9A3R1 and NAT9, which are linked to this disease (Helms et al., 2003). Similarly, dysregulation by RUNX1 of a gene associated with RA, SLC22A4, likely contributes to the development of that disease (Tokuhiro et al., 2003; Yamada et al., 2004). Systemic lupus erythematosus is associated with RUNX1 and the programmed cell death 1 gene (PDCD1) (Prokunina et al., 2002); PDCD1 has also been associated with development of RA (Prokunina et al., 2004).

How does RUNX cause dysregulation? Regulatory single nucleotide polymorphisms (rSNPs) are believed to affect the binding site for RUNX and thereby regulate the expression of genes (Alarcón-Riquelme, 2003). These rSNPs are involved in loss of the binding site, which influences the autoimmune disease-linked genes and leads to disease progression. In the case of psoriasis, five rSNPs have been identified as likely candidates for affecting RUNX binding sites, whereas in RA, specific rSNPs have not yet been identified, although the RUNX1 link is clear. Much remains to be learned, but the role of RUNX in autoimmunity and malignancy provides numerous potentially fruitful avenues for research.

THE CLINICAL SETTING

Risk Factors

Immune impairment of itself creates a risk for malignancy. Therefore, individuals with any autoimmune or rheumatic disease, or even with rheumatoid factor, or undergoing immunosuppressive therapy, should be assessed for additional risk factors and actual development of lymphoma. Age, disease duration and severity, and environmental influences confer a higher risk. In addition, particular symptoms or laboratory findings, medications used, and genetic profiling can predict susceptibility to lymphoma.

The risk of lymphoid malignancy increases with age (Mackay and Rose, 2001; Sallah et al., 2001). The younger the individual at the onset of autoimmune disease, the higher will be the risk (Kassan et al., 1978; Ramos-Casals et al., 1998). The propensity to develop lymphoid malignancy also increases with autoimmune disease duration. This link is well documented in Sjögren syndrome (Ioannidis et al., 2002), rheumatoid arthritis (Gridley et al., 1993; Mellemkjaer et al., 1996), and in ALPS (attributed to Elaine Jaffey, Bethesda, MD, by Mackay and Rose 2001). The diagnosis of the associated autoimmune disease usually precedes that of NHL, implying that the sustained antigen drive associated with autoimmune disease predisposes to malignancy. Severity of disease generally appears to correlate with a risk for lymphoma, but the link between severity and lymphoproliferation in the case of SLE was not established (Ehrenfeld et al., 2001).

Serologic results found in autoimmune disease can also be a feature of malignancy. Thus antinuclear antibody (ANA) can indicate a risk for non-Hodgkin lymphoma. Also, ANA may be increased in patients with NHL following treatment, and, more importantly, they are found in a substantial number of patients with NHL prior to treatment for malignancy and hence are independent of treatment factors. Among NHL patients, 19% had evidence of ANA before any treatment, with the highest incidence in marginal zone MALT lymphomas (Guyomard et al., 2003). Laboratory tests often performed in autoimmune disease and correlating with risk of development of NHL include positive results for cryoglobulins, hypergammaglobulinemia, monoclonal gammopathy, Coombs' antiglobulin test, antibodies to neutrophils and platelets, and complement deficiency.

Cryoglobulinemia is correlated with palpable purpura, often secondary to cutaneous vasculitis and a risk factor for NHL. In addition, when evidence of HCV, of itself linked with malignancy, is coupled with cryoglobulinemia, it can herald transformation from benign lymphoproliferation to a malignant process. When records of patients with cryoglobulinemia were examined in one study, 5% developed a hematologic malignancy; of those, HCV was evident in 52% and both HCV and autoimmune disease in 48% (Trejo et al., 2003). While monoclonal immunoglobulins can occur in the absence of lymphoma, they are linked with development of lymphoma. More patients with Sjögren syndrome, compared with those with SLE or RA, have evidence of mixed monoclonal IgM immunoglobulin (Tzioufas et al, 1986, 1996). Monoclonal gammopathy is increased in 25% of those with autoimmune hemolytic anemia, which increases their risk of lymphoma as well as affecting survival (Sallah et al., 2000).

Non-standard laboratory tests also can forecast risk of malignancy. Such correlations with B-cell lymphoma include increased levels of Blys/BAFF in serum or synovial fluid (Cheema et al., 2001), and this is also indicative of reduced survival (Novak, 2004); increased levels of serum β2-microglobulin or Bcl-2 (Hermine et al., 1996); or presence of anti-p53 antibodies (Maxwell and Roth, 1994; Ichikawa, 2000). Genetic profiling will become increasingly used in the future, in helping with diagnosis, risk assessment, and prognosis. It is already known, for example, that

the chromosomal translocations t(11;18)(q21;q21) lead to fusion between AP12 and MALT1 genes, and these factors, in addition to evidence of t(1;14)(p22;q32) and t(14;18)(q32;q21), can be of prognostic value in MALT lymphoma (Okabe et al., 2003; Isaacson, 2005).

Comorbid factors linked with development of lymphoma should prompt close monitoring and scrutiny of treatment protocols. These factors include evidence of specific viral or bacterial infections, as mentioned in the section on pathology, such as HCV or *H. pylori*; exposure to ultraviolet radiation (Fisher and Fisher, 2004); and use of immunosuppressive drugs (Ehrenfeld et al., 2001; Zhang et al., 2004).

Specific symptoms can identify patients at increased risk of developing lymphoma. Evidence of lymphoproliferation, lymphadenopathy, splenomegaly, vasculitis, and palpable purpura in autoimmune disease are correlated with risk for lymphoma. In Sjögren syndrome, an additional risk factor is persistent parotid enlargement; a recent study found that 84% of patients with Sjögren syndrome who developed lymphoma had bilateral parotid gland swelling (Jonsson et al., 2001). The presence of anti-SSA (or Ro) autoantibodies is a serologic marker for Sjögren syndrome (and also SLE) and increases the likelihood of developing those symptoms that are predictive of lymphoma, such as peripheral neuropathy (Voulgarelis et al., 1999). In Sjögren syndrome, lymphoproliferative disease (LPD) and the likelihood of progression to lymphoma are significantly higher in those patients with palpable purpura and low C4 levels early in the disease (Ioannidis et al., 2002); in fact, all patients in the Ioannidis study who developed lymphoma had palpable purpura and low C4 during their first clinic visit and others also report that low complement levels in Sjögren syndrome, including low C3, C4 and/or CH50, are linked with a higher probability of systemic disease and lymphoma (Ramos-Casals et al., 2005a).

Treatment

The long-term goal is to prevent the development of lymphoma in the first place. The first line then is to control the autoimmune disease and reduce the hyperactivity of autoreactive B cells (Mariette, 2001). The newest biologic response modifiers used to treat autoimmune disease include inhibitors of TNF, a class of drugs that includes etanercept and infliximab. Anti-TNF has proven successful in some autoimmune disorders and specifically approved for use in rheumatoid arthritis and Crohn's disease (Feldmann and Maini, 2001; Maini et al., 2002). It may also be beneficial in a broader range of autoimmune disorders, since successful trials have already been reported for ankylosing spondylitis, psoriasis, and psoriatic arthritis (Feldmann et al., 2004; Taylor et al., 2004). Sometimes, TNF inhibitors are combined with more conventional therapies for autoimmune disease to obtain better results (Lipsky et al., 2000). When an environmental agent is implicated in NHL development, its eradication may result in resolution of the malignancy, e.g., resolution of MALT lymphoma when *H. pylori* is eliminated (Arima and Tsudo, 2003). *H. pylori,* however, is less amenable to treatment in the setting of gastric autoimmune disease (Raderer et al., 2001; 2003), likely because chromosomal aberrations as in MALT lymphoma have occurred (Streubel et al., 2004b).

Therapy for NHL most recently has entailed a combination of chemotherapeutic drugs, with optimal combinations, amounts, and schedule of delivery still being sought. Chemotherapy with ACVBP (dose-intensified doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone) has been found to be more effective than CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) in a study of 747 patients with localized aggressive B-cell lymphomas (Reyes et al., 2005). Current breakthroughs in genetically engineered human-mouse chimeric monoclonal antibodies (MAbs) and radioimmunotherapy offer additional options and may be combined with one another and with chemotherapy. The first MAb to become available, rituximab (Rituxan), was approved by the U.S. Food and Drug Administration (FDA) in 1997, and seven MAbs have quickly followed. Rituximab, an anti-CD20 MAb, rapidly depletes B cells and downregulates Bcl-2 expression, rendering malignant cells more sensitive to chemotherapy (Alas et al., 2002; Bosly et al., 2002; Chanan-Khan et al., 2004). Bcl-2 regulation is especially critical in view of the connection between Bcl-2 overexpression and an aggressive clinical course, resistance to therapy, and ultimately a poor disease outcome (Chanan-Khan et al., 2004). Combinations of MAbs and chemotherapy may be even more effective than either alone, as is the case with CHOP plus rituximab in diffuse large B-cell lymphomas (Czuczman et al., 1999; 2005; Vose et al., 2001; Coiffier et al., 2002; 2004; Feugier et al., 2005).

The use of rituximab and other MAbs in treating autoimmune diseases (see Chapter 76) may not only control the disease but also prevent the lymphoproliferative overlay and complications that predispose to lymphoma. While rituximab has proven effective in many autoimmune disorders (Specks et al., 2001; Gorman et al., 2003; Gottenberg et al., 2004; Rastetter et al., 2004), costs and adverse effects (immunosuppression) could preclude its routine use.

One of the latest therapeutic approaches combines a MAb with radioimmunotherapy, which allows the targeting of radiosensitivity of malignant B cells (Connors, 2005; Kaminski et al., 2005). The first radioimmunotherapy, and first conjugated antibody accepted for NHL treatment, is Yttrium-90 (^{90}Y) ibritumomab tiuxetan (Zevalin), approved by the FDA in 2002 (Grillo-Lopez, 2002) and in Europe in 2004. It is primarily used for low-grade or follicular NHL and in relapsed B-cell NHL (Grillo-Lopez, 2002; Witzig,

2004). Additional therapeutic developments have followed, including tositumomab (Bexxar), a chimeric anti-CD20 antibody that has been coupled with a radionucleotide and is selective for follicular lymphoma (Kaminski et al., 2005), and the radiolabeled monoclonal ^{90}Y-epratuzumab or ^{90}Y-DOTA humanized anti-CD22 IgG, also promising for NHL treatment (Sharkey et al., 2003). These therapies are clearly a work in progress with much remaining to be learned about each, the effectiveness of various combinations, and the additional interplay of knowledge brought by new therapies that will be developed and new concepts and understanding of NHL brought by changing concepts of staging in NHL (Armitage, 2005).

LYMPHOMA AS A COMPLICATION OF BIOLOGIC TREATMENT OF AUTOIMMUNE DISEASE

Treatment of autoimmune disease may be implicated in causing or modulating the development of lymphoma. Therefore, benefits and risks must be weighed according to the specific autoimmune disease, patient, and proposed therapy. It has been long suspected that use of immunosuppressive drugs can increase the risk of lymphoma (Ehrenfeld et al., 2001), so a relation between cumulative exposure to immunosuppressive agents and malignancy is not surprising (Asten et al., 1999). Such publicized links have been reported recently with two ointments approved for eczema and used in other autoimmune skin disorders. In 2005, the U.S. FDA issued warnings for pimecrolimus (Elidel) and tacrolimus (Protopic), linking their use to lymphoma and skin cancer. Both are immunosuppressants, and the FDA states that the incidence of malignancy likely increases with the amount of medication given (FDA, 2005).

Patients with RA treated with nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, are at greater risk of developing NHL than patients not treated with those drugs. One study reported the highest increased risk with use of NSAIDs excluding aspirin but still found a significant risk in those taking aspirin alone (Cerhan et al., 2003). Comparatively, osteoarthritis patients had no evidence of increased risk of lymphoma in those taking NSAIDs or aspirin.

Concern has arisen over development of malignancy following the use of cytotoxic (anticancer) drugs, methotrexate, and anticytokine therapies such as TNF and interleukin 1 (IL-1) inhibitors. A 10-fold increase in RA patients taking the cytotoxic drug azathioprine has been reported, compared with a 5-fold increase in RA patients not taking the drug (Silman et al., 1988). Suspicion centers on the possibility that the drug might induce chromosomal abnormalities or reactivate latent viral infections (Ehrenfeld et al., 2001). The disease modifying antirheumatic therapy (DMARD), methotrexate, is tentatively linked with lymphoproliferative disease and lymphoma, although a link is not certain (Salloum et al., 1996). Some reports demonstrate no clear connection between immunosuppression and lymphoma, with the exception of a small group of patients with RA or polymyositis who developed EBV-linked NHL while taking methotrexate (Mariette et al., 2002; Feng et al., 2004). Overall, however, little support exists for an increased risk of malignancy with use of methotrexate (Baecklund et al., 2004; Wolfe and Michaud, 2004).

Similar questions have been raised about TNF inhibitors and lymphoma. Patients with RA were reported as having a 4.9% increased risk of lymphoma when taking anti-TNF agents compared with those not taking the drug in one study, although the investigators cited a need for additional studies (Geborek et al., 2005), and no increased risk was found in another study (Askling et al., 2005b). The TNF blockers infliximab (Remicade), etanercept (Enbrel), and adlimumab (Humira), as well as the IL-1 inhibitor anakinra (Kineret), have been linked to lymphoma and include this risk in prescribing warning labels (Fleischmann et al., 2004).

While an increased risk of lymphoma appears evident with these medications, a clear and definite relationship remains to be proven. Patients with autoimmune disease already are predisposed to malignancy, use of immunosuppressive agents increase this predisposition, and the anti-TNF and anti-IL-1 agents bring additional immunosuppression into the equation. It is difficult to determine cause when natural predilection, medication history, and use of new biologics are involved. Only additional and larger studies will elucidate the possible association between particular therapies and the subsequent development of lymphoma.

A LOOK TO THE FUTURE

We are on the verge of an exciting and new generation of therapeutics for lymphoma. The future for treatment of non-Hodgkin lymphomas will build on what we are just beginning to learn about specific molecular targets and methods of delivery. In addition to creating new anticytokine agents and monoclonal antibodies and improving radioimmunotherapy, other areas of current and future interest will continue to evolve. These include STAT3 pathway inhibitors that might lead to a new class of targeted therapeutics (Alas and Bonavida, 2001; 2003; Alas et al., 2001) and the continuous search for different mechanisms to inhibit TNF and suppress overexpression of Bcl-2. Vaccines provide another potential treatment strategy to prevent relapses in those who have developed lymphoma. Vaccines can use the patient's own immune system against malignancy and provide a less toxic therapy (Hsu et al., 1997; Bendandi et al., 1999; Dar and Kwak, 2003).

Ultimately, the goal for the future is to tailor the therapy directly to the disease and the patient. As we learn more about pathogenesis of autoimmune disease and lymphoma, we can better understand how autoimmunity transforms from a benign to a malignant state so that this transformation might be prevented. Gene microarrays may lead to our ability to better predict susceptibility to lymphoma in autoimmune disease. New methods of examination providing a precise molecular diagnosis will allow us to recognize the differences among lymphomas that appear similar in histopathology but are indeed quite different (Cheson, 2004). These advances will lead to better classification of lymphoma and enable us to determine those therapies that have the greatest chance of success.

Gene expression profiling will be used increasingly in the future to help predict outcome and determine treatment. Already, the identification of ZAP70 in diffuse large B-cell lymphoma has provided a prognostic marker for that disease and can establish who might benefit from a specific chemotherapy treatment and who might not (Rosenwald, 2003; Rosenwald and Staudt, 2003; Rosenwald et al., 2002). As we continue to develop and better understand genetic microarrays and how specific genetic profiles might affect response to different treatments and overall prognosis, we can modify treatment protocols to fit the individual patient. The future should bring greater understanding of the pathogenesis of autoimmune disease and lymphoma, the impact of genetic profiling, and the promise of new biologics or other agents in treating these diseases.

Apoptosis and Autoimmunity: Lymphoproliferative Syndromes

DAVID L. VAUX

The Walter and Eliza Hall Institute, 1G Royal Parade, Parkville, Victoria, Australia

Autoimmune lymphoproliferative syndrome (ALPS), also known as Canale–Smith syndrome, is a genetically determined disease characterized by accumulation of lymphoid cells, increased numbers of $CD4^{-}CD8^{-}$ (double negative) $CD45R^{+}$ T cells, hypergammaglobulinemia, and autoimmunity. It is caused by mutations in genes encoding components of the cell death pathway that is activated by the ligation of Fas (CD95/APO1/TNFRSF6), a member of the tumor necrosis factor (TNF) receptor family. Although ALPS is very rare, study of this disease and its murine counterpart has revealed much about the roles and mechanisms of cell death in the immune system.

HISTORIC BACKGROUND

Canale–Smith syndrome was described in 1967 by Virgina Canale and Carl Smith who examined five children with a benign generalized lymphadenopathy and autoimmune disease (Canale and Smith, 1967). During the following years, the syndrome has also been called ALPS, chronic lymphadenopathy simulating malignant lymphoma, chronic pseudomalignant immunoproliferation, benign immunoproliferative syndrome, and lymphoproliferative syndrome with autoimmunity.

A similar disease was observed in the MLR strain of mice bearing the *lpr* (lymphoproliferative) mutation in 1978 (Andrews et al., 1978), and mice with the *gld* (generalized lymphoproliferative disease) mutation in 1984 (Roths et al., 1984). Unaware of the earlier report of Canale–Smith syndrome, Sneller et al. described two patients with ALPS, and recognized the similarity to the murine *lpr* and *gld* diseases (Sneller et al., 1992).

In 1992, Nagata and coworkers (Watanabe-Fukunaga et al., 1992) showed that *lpr* disease of mice was due to mutations in Fas (CD95), a member of the TNF receptor family that gives a pro-apoptotic signal when ligated (Yonehara et al., 1989). Two years later, they cloned the gene for the *gld* mutation, and showed it encoded the ligand for Fas (Takahashi et al., 1994).

Mutations of components of the Fas pathway in humans with ALPS were observed by Rieux-Laucat et al. in France in 1995 (Rieux-Laucat et al., 1995), and a short time later by Fisher et al. in the United States (Fisher et al., 1995). The formal demonstration that ALPS, *lpr* disease, *gld* disease and Canale–Smith syndrome were all manifestations of loss-of-function mutations in the same pathway came with the identification of mutations in the Fas gene of patients with Canale–Smith syndrome by Drappa et al. in 1996 (Drappa et al., 1996).

Because it has become the most frequently used term, this chapter will use the acronym ALPS, even though it was predated by the term Canale–Smith syndrome, and this disease is associated with accumulation of lymphocytes, rather than their proliferation.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.

CLASSICAL AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME—CLINICAL AND AUTOIMMUNE FEATURES

Autoimmune lymphoproliferative syndrome is a very rare syndrome, with an approximate total of 100 cases described to date worldwide. There are four classical features: a defect in the Fas-induced apoptotic pathway; a polyclonal, non-malignant accumulation of unusual $CD4^{-}CD8^{-}CD45R^{+}$ T-lymphocytes; hypergammaglobulinemia; and autoimmunity. Similar features are seen in mice homozygous for loss-of-function mutations in Fas (i.e., the *lpr* mutant mice) or FasL (i.e., *gld* mutant mice).

Autoimmune lymphoproliferative syndrome is usually seen in young children (0–5 years), although some cases have only been diagnosed in adulthood (Deutsch et al., 2004). Affected individuals usually present with afebrile lymphadenopathy and splenomegaly. The majority also exhibit signs of autoimmunity, most commonly autoimmune hemolytic anemia, thrombocytopenia, or neutropenia, but involvement of other organs such as the kidneys and liver has also been observed (Sneller et al., 1997; Rieux-Laucat et al., 1999). Levels of IgG and IgA in the blood are increased, often with autoantibodies to red blood cells, platelets, nuclear antigens, and IgG (rheumatoid factor), whereas antibodies to DNA are not seen, unlike the mouse *lpr* disease.

Although the lymphadenopathy and splenomegaly resemble those of malignant lymphoma, ALPS is not a neoplastic disease. Elevated numbers (more than 1% of circulating lymphocytes) of a peculiar subset of T-lymphocytes can be found in the blood. These T-receptor-positive cells lack both of the T-cell markers CD4 and CD8, but express the CD45R (B220) antigen, which is usually only seen on B-lineage cells. The origin of these cells, which also accumulate in the mouse form of the syndrome, remains enigmatic. Presumably in normal individuals these cells are removed by Fas-signaled apoptosis, but persist and accumulate when Fas pathways are interrupted.

The disease can be confirmed *in vitro* by demonstrating insensitivity of peripheral blood lymphocytes to Fas-induced apoptosis. This can be carried out either by activating the cells with antibodies to the T-cell receptor-associated antigen CD3, and measuring the amount of activation-induced cell death, which is dependent on Fas–FasL interactions (Wu et al., 1996), or by incubating the lymphocytes with antibodies that cross-link Fas, and determining the amount of apoptosis (Sneller et al., 1997).

GENETIC INHERITANCE

Autoimmune lymphoproliferative syndrome is caused by a failure of the Fas pathway. This can result from recessive inheritance of two nonfunctional genes for a component of the pathway, or due to a dominant interfering mutation, which would lead to a dominant inheritance pattern.

In the mouse *gld* disease (due to mutation to the genes for Fas ligand) and *lpr* disease (due to low or absent expression of Fas) are recessively inherited. While three cases of homozygous null mutations to Fas have been reported in humans (ALPS 0), the great majority of human ALPS, about 100 cases, exhibit a partially penetrant dominant inheritance pattern (ALPS Ia), and are heterozygous for mutations to Fas. It is thought that the mutant Fas proteins act in a dominant negative manner by interfering with the ability of the normal molecules to form trimers that are capable of efficiently activating the death-inducing signaling complex (Kischkel et al., 1995) comprised of FADD, caspase 8, and caspase 10.

Genotyping of family members of ALPS patients for Fas mutations usually reveals a dominant pattern of inheritance, but relatives that share the mutation often have no history of lymphadenopathy or autoimmune disease, even though their lymphocytes are resistant to apoptosis following ligation of Fas (Sneller et al., 1997). This illustrates the great variation in the penetrance of the disease.

FAS ACTIVATED SIGNALING PATHWAYS

Fas (CD95/APO1/TNFRSF6) is a member of the TNF receptor family that exists as a homotrimer in the plasma membrane of several cell types, including T- and B-lineage cells. The extracellular aminoterminal half of Fas can be bound by Fas ligand (FasL), leading to formation of higher order multimers (Holler et al., 2003) and activation of signaling (Kischkel et al., 1995). The intracellular carboxy-terminal half of Fas bears a protein interaction motif termed a death domain (DD) that allows it to interact with the DD in the adaptor protein FADD (Chinnaiyan et al., 1996, Boldin et al., 1996). The cytoplasmic adaptor molecule FADD can, in turn, bind to latent forms of caspase 8 and caspase 10, leading to activation of these proteases (Boldin et al., 1996; Muzio et al., 1996). Once active, these caspases can cleave proteins within the cell, and activate other caspases, resulting in death of the cell by apoptosis.

By interacting with other DD-bearing adaptor proteins such as RIP (Ting et al., 1996), in some cells Fas can activate other signal transduction pathways including the NFκB and Jun transcription factor pathways (Duckett, 2002). Modulation of Fas signaling by another adaptor molecule, termed FLIP, can determine whether ligation of Fas leads to apoptosis or the activation of other biochemical pathways (Irmler et al., 1997; Lens et al., 2002).

Binding of Fas by FasL can, therefore, set in train a signal transduction pathway that leads to apoptosis, but it does not always proceed that far, and signals emanating from ligated

Fas do not only lead to activation of the cell death mechanism, but may result in other cellular responses.

ANIMAL MODELS AND PATHOGENIC MECHANISMS

Loss of Fas expression in the *lpr* mice is due to integration of a transposable element into intron 2 of the Fas gene, leading to markedly reduced Fas expression (Adachi et al., 1993). Mice with a point mutation in the cytoplasmic domain of Fas that prevents signaling (*lpr*^{cg} mice) (Adachi et al., 1993), and Fas null mice generated by gene targeting (Adachi et al., 1996) exhibit similar phenotypes, characterized by accumulation of $CD4^-CD8^-CD45R^+$ T lymphocytes in the lymph nodes and spleen. The blood contains increased levels of IgG, anti-DNA antibodies, rheumatoid factor, and immune complexes, and the mice often develop glomerulonephritis and arthritis. A similar syndrome is seen in Fas ligand mutant (*gld*) mice and FasL gene-targeted mice (Karray et al., 2004), although the disease in the latter is slightly more severe.

The severity of lymphocyte accumulation and autoimmunity in *lpr* mice is strongly affected by the background genotype; for example, on the MRL background, it is much more severe than when the same mutation is on a C57BL6 background. This demonstrates that several other genes can influence the clinical manifestations of the disease (Vidal et al., 1998).

Although mutations in Fas and its ligand result in ALPS-like syndromes in mice, mutations to other components of the pathway, such as FADD and caspase 8, do not. Deletion of the FADD genes in mice results in embryonic lethality, and transgenic mice expressing a dominant negative FADD construct in their T cells do not develop an ALPS-like phenotype, but have defects in T-cell proliferation (Newton et al., 1998).

Mice do not have a gene homologous to human caspase 10, and deletion of caspase 8 genes results in embryonic lethality. Transgenic mice expressing the caspase 8 inhibitor CrmA in T-lineage cells (Smith et al., 1996) did not develop autoimmunity or accumulate $CD4^-CD8^-CD45R^+$ lymphocytes, even though the cells were profoundly resistant to Fas-induced apoptosis. Mice in which caspase 8 was deleted only in the T lineage, which rendered the cells completely resistant to induction of apoptosis following ligation of Fas (Salmena et al., 2003), had normal thymocyte development, but numbers of peripheral T cells were reduced, and they were immunodeficient. There was no accumulation of $CD4^-CD8^-CD45R^+$ T-lymphocytes or autoimmunity. These experiments suggest that the development of the disease manifestations associated with ALPS in mice, such as accumulation of lymphocytes and autoimmunity, requires interruption of Fas-signaling pathways upstream of caspases and FADD.

Autoimmune lymphoproliferative syndrome results from loss of signals from ligated Fas on both B and T lymphocytes. These signals include activation of NFκB and Jun transcription-factor pathways, processing of caspase 8, and apoptosis. MLR *lpr* mice expressing transgenic Fas in just the T-lineage did not develop splenomegaly or lymphadenopathy, but still generated autoantibodies and developed glomerulonephritis, whereas transgenic expression of Fas in both B and T lineages prevented both lymphocyte accumulation and autoantibody production (Fukuyama et al., 1998; 2002). This suggests that loss of Fas on T-lineage cells leads to persistence of the $CD4^-CD8^-CD45R^+$ T cells, but Fas signaling must be lost from B lymphocytes for autoimmunity to occur.

NONCLASSICAL FORMS OF AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME

Classical ALPS is due to either homozygosity for a null mutation to Fas (ALPS 0, which has been observed in three cases) or heterozygosity for a dominant negative mutation to Fas (ALPS Ia, found in approximately 100 cases). These mutations are usually found in the DD. There are a number of other classes of ALPS, namely ALPS Ib, ALPS II and ALPS III in which the cause of the syndrome is less well established.

The ALPS Ib form is due to mutations in the gene for FasL in humans, analogous to the gld mutation in mice. Only a single instance has been reported: a patient heterozygous for an 84 base-pair deletion in the gene for FasL (Wu et al., 1996). This patient, who presented with features typical of systemic lupus erythematosus (SLE) rather than classical ALPS, did not have severe lymphadenopathy or increased $CD4^-CD8^-CD45R^+$ T cells. Furthermore, because the defects in function of FasL expressed on the patient's lymphocytes were partial, it is not certain that the FasL deletion was the cause of his disease.

Patients with ALPS II have the classical clinical features of ALPS, and their lymphocytes are resistant to apoptosis caused by Fas ligation, but they have normal Fas and FasL genes. Mutations to caspase 10 have been found in two kindreds (Wang et al., 1999), but at this stage it has not been proven beyond doubt whether the nucleotide changes observed cause the disease, or whether these patients have some other abnormality. One of the genetic changes was subsequently found to occur in 0.5% of the Danish population, so might represent a polymorphism, rather than a loss of function mutation (Gronbaek et al., 2000).

If mutations in caspase 10 are indeed the cause of ALPS II it will be important to determine the mechanism by which they do so, but, because mice do not have genes for caspase 10, it is not possible to examine the analogous mutations in mice. The mechanism proposed is that the mutant caspase

10 molecules, which bear missense point mutations, act in a dominant negative way to interfere with caspase 8 function (Wang et al., 1999). Because complete loss of caspase 8 causes immunodeficiency rather than an ALPS phenotype (Chun et al., 2002; Salmena et al., 2003), if they are acting in a dominant negative way, the mutant caspase 10 proteins cannot inhibit all caspase 8 function.

Some patients with ALPS II have normal genes for caspase 10 (Rieux-Laucat et al., 2003), raising the possibility that other molecules involved in Fas-signaling pathways are involved in these, and possibly all, cases of ALPS II.

Approximately 20 patients with ALPS III have been described. They show mild clinical features of ALPS, including increased numbers of $CD4^-CD8^-CD45R^+$ T cells in the blood, but have no mutations in their genes for Fas or FasL. Some are reported to have lymphocytes with normal sensitivity to ligation of Fas *in vitro*, whereas in others it is reduced (Ramenghi et al., 2000). No errors have been found in genes for FADD, TNF receptors 1 and 2 (TNFR1, TNFR2), caspase 8, or caspase 10 (Chun and Lenardo, 2001; van der Werff ten Bosch et al., 2001; Rieux-Laucat et al., 2003). Suspicion now falls on other members of the TNFR family, such as receptors for the TNF-like cytokine TRAIL. However, to date, there have been no mutations reported, and mice engineered to have mutations in genes such as TRAIL do not exhibit an ALPS-like phenotype (Sedger et al., 2002).

Six children initially classed as having ALPS III, because they had autoimmunity, increased $CD4^-CD8^-$ T cells, and hypergammaglobulinemia, but normal sensitivity of their lymphocytes to Fas-induced apoptosis, were subsequently found to have Fas mutations in their $CD4^-CD8^-$ T cells, but not in DNA from their hair or skin cells (Holzelova et al., 2004). These investigators proposed that somatic mutations to the Fas gene (similar to those in ALPS Ia) arose in a hematopoietic precursor cell, resulting in mosaicism, and suggested that patients be denoted as belonging to ALPS type Im.

AUTOIMMUNITY

In ALPS, the autoimmunity is chiefly antibody mediated, with the usual autoantibodies found being antibodies to red blood cells, platelets, nuclear antigens, and rheumatoid factor. Although the major abnormal cell types are of the T lineage (namely the $CD4^-CD8^-CD45R^+$ T cells), and the defects in Fas-induced death are usually demonstrated in T lymphocytes, B cells are clearly important for development of the autoimmune manifestations. For autoimmunity to develop in *lpr* mice, the B cells must bear the mutation (Fukuyama et al., 1998; 2002). How then does loss of Fas signaling lead to production of autoantibodies?

It has been proposed that Fas is required for elimination of autoreactive B cells (Rathmell et al., 1995), creating a defect in peripheral tolerance. This possibility could be confirmed by expressing the gene for the caspase 8 inhibitor CrmA in the B cells of transgenic mice. It seems clear that, whatever the mechanism leading to autoimmunity, it will be complicated and influenced by many genes. In humans, the partial penetrance observed in families with ALPS demonstrates the effects of other genes, as do differences in the severity of autoimmune disease in mice with different genetic backgrounds. Mutations to many different genes that affect the number or survival of B cells in mice can lead to autoimmune syndromes. For example, transgenic expression of the antiapoptotic gene Bcl-2 (Strasser et al., 1990; 1991), or deletion of the genes for BIM (Bouillet et al., 2002) or IL-2 (Suzuki et al., 1997) develop SLE-like autoimmune syndromes when on certain genetic backgrounds.

TREATMENT AND OUTCOME

Autoimmune lymphoproliferative syndrome usually spontaneously decreases in severity (Fischer et al., 1999), and is compatible with normal life expectancy (Infante et al., 1998), so the treatments are conservative. Lymphadenopathy, splenomegaly, and autoimmune manifestations often regress without treatment, even though elevated IgG and increased numbers of $CD4^-CD8^-CD45R^+$ T cells often persist. Acute episodes of autoimmune disease such as hemolytic anemia and thrombocytopenia may occur, and lymphoma has developed in some patients. Management is, therefore, based on regular monitoring and treatment of acute exacerbations of disease.

To treat the more severe autoimmune disease manifestations a number of regimens have been tried, including steroids, mycophenolate mofetil (Alvarado et al., 2004), rituximab, and vincristine (Heelan et al., 2002), splenectomy, or bone marrow transplantation (Sneller et al., 1997; Sleight et al., 1998).

CONCLUDING REMARKS—FUTURE PROSPECTS

For researchers, the significance of ALPS has been from the insights it has provided into the mechanisms of apoptosis and autoimmunity, but because it is such a rare disease there is little incentive to develop specific therapies. The main burdens of disease faced by ALPS patients are due to the accumulation of lymphoid tissue and the flare ups of autoimmune disease. Recent discoveries of the role of the TNF-related cytokine BAFF as a B-cell growth and survival factor that is elevated in a number of SLE-like autoimmune syndromes (Vaux, 2002) provides hope that BAFF-blocking

agents might one day be also useful for the treatment of the autoimmune manifestations of ALPS.

CHAPTER

71

Cameos

IAN R. MACKAY

Department of Biochemistry and Molecular Biology, Monash University, Victoria, Australia

The previous edition (3rd) of 1998, Chapter 37, described various "contender" autoimmune diseases of which many now appear as full chapters in this edition. Here are presented (alphabetically) further diseases as cameos, either by reason of their rarity, controversial evidence on causation, or autoimmunity being just one of several elements in pathogenenesis.

ANOREXIA NERVOSA AND BULIMIA

Anorexia nervosa (AN) and bulimia are eating disorders that affect up to 3% of women in their lifetime (Walsh and Devlin, 1998), and are characterized by aversion to food, cachexia and amenorrhea (AN) or food aversion with bouts of overeating (bulimia). Since AN is usually interpreted as a behavioral disorder, patients often come into psychiatric care, although a neuropsychiatric basis has not been ascertained. The incidence in young women could prompt consideration of autoimmunity despite absence of other features. Fetissov et al. (2002) reported an analysis of serum autoantibodies from 57 women with eating disorders: AN, 28; bulimia, 22; and combined AN and bulimia, 7. The assay used was immunohistochemical labeling by serum of cells of rat pituitary gland and hypothalamus. Of the 57 sera, 42 (74%) had autoantibodies that bound to melanotropes and/or corticotropes in the pituitary gland, and certain of the sera were selectively reactive with hypothalamic neuronal cells and projections that expressed melanocyte-stimulating hormone. Further technical details are given by Fetissov et al. (2002). There has been no direct confirmation of these data.

ATHEROSCLEROSIS

Atherosclerosis is discussed in Chapter 64 in this volume with emphasis on autoimmune reactivity to heat shock protein 60 (hsp60), but the complexity of this multifactorial inflammatory disorder warrants a "second look." Schwartz and Mitchell (1962) illustrated mononuclear cell infiltrations, mainly lymphocytic, in the vascular adventitia in

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

atheroma, with surprise that "such prominent cellular accumulations should have received so little attention." They cited several antecedent reports on the frequency of these infiltrations, and tabulated data indicating that adventitial cellular infiltrations correlated with coronary arterial plaque severity and with recent arterial thrombosis. In an immunoepidemiologic study of 3407 adult residents of Busselton, Western Australia, in 1973, it was found that the prevalence of routinely tested autoantibodies not only increased with age, but also proved to be an independent risk factor for mortality and morbidity from coronary/cerebrovascular disease (Mathews et al., 1973); postulated mechanisms included reactivity of autoantibodies with antigens on the vascular surface. Subsequently, the presence of lymphocytes, predominantly T cells, in atherosclerotic plaques is repeatedly cited (Jonasson et al., 1986; Emeson and Robertson, 1988; Van der Wal et al., 1989; Xu et al., 1990; Libby and Hansson, 1991). Also the vascular lesion seen in long-standing human allografted organs—kidney, liver, or heart—as a thickening of the wall of medium-sized arteries with inflammatory features, and interpretable on the basis of a chronic host-versus-graft cellular immune attack, simulates atherosclerosis. Finally, there is the occurrence of accelerated atherosclerosis in multisystem autoimmune diseases, earlier interpreted as myocarditis (Mackay and Burnet, 1963), and recently well documented for systemic lupus erythematosus (SLE) (Asanuma et al., 2003; Roman et al., 2003) and rheumatoid arthritis (Kaplan and McCune, 2003).

Animal models have been developed to examine the immunopathogenesis of atherosclerosis. In rabbits with hypercholesterolemia, atherosclerotic lesions contain autoreactive T cells that respond to hsp60 (Wick et al., 1995; see Chapter 64). Mice with a "knockout" of the gene encoding apolipoprotein E, apoE$^{-/-}$ (Zhou et al., 1996), as for low density lipoprotein (LDL)-receptor deficient mice, are hypercholesterolemic and develop severe atherosclerosis with morphologic features very similar to the human counterpart (Lichtman et al., 1996). The lesions in these mice show numerous T lymphocytes, predominantly of the CD4^{+} phenotype with expression of the activation marker CD25, high expression of MHC class II molecules on adjacent tissue cells indicative of release of cytokines, e.g., interferon-γ (IFN-γ) from the infiltrating T cells, lipid-filled macrophages (foam cells), and hypertrophy of the smooth muscle of the arterial wall.

Studies in humans, have been directed to defining specific immune reactants that could promote atherogenesis, either directly or via immune complexes. These could include 1) pro-inflammatory oxidized phospholipids (Berliner and Watson, 2005; Piarulli et al., 2005; Tsimikas et al., 2005), and noting the reactivity of antibodies to phospholipids in SLE (Vaarala et al., 1993); 2) malondialdehyde which is an adduct formed on low density lipoprotein during oxidation (Salonen et al., 1992; Lopes-Virella and Virella 1996); or 3) hsp60, the mammalian equivalent of bacterial hsp65, when hyperexpressed on stressed arterial intimal cells (see Chapter 64). Laman et al. (1997) implicated an interrelationship between foamy macrophages and activated T cells via expression of coreceptor molecules, CD40 on the former and its ligand CD154 on the latter, so promoting inflammatory responses and cytokine release. Antigen dependence of CD154 expression by T cells in the lesion might be expected, but could occur in an inflammatory milieu independent of antigen presentation (Phipps, 2000). A further factor is infection, particularly with *Chlamydia pneumoniae*, by which induction of an anti-hsp60 response may occur (Benagiano et al., 2003). A contemporary assessment of the likely interrelated contributions to atherosclerosis of metabolism, infections, inflammation, and immunity is presented by Hansson (2005).

There is much work ahead on the immunopathology of atherosclerosis noting several studies implicating T cells of the Th1 subset (Benagiano et al., 2003), and findings in mice that a deficiency in T-bet signaling results in a switch to Th2 responsiveness that is atheroprotective (Buono et al., 2005). Other interesting leads that are being followed, or could be worth, following include effects in atherosclerosis-prone mice of hypo- or hyper-expression of pro-inflammatory cytokines or chemokines (MIF, GM-CSF, MCP-1, and others), and effects of depletion of regulatory T cells.

AUTOINFLAMMATORY DISEASES

"Autoinflammatory" is a term of convenience to describe intrinsic cytokine-mediated activation of inflammatory pathways independent of adaptive immune responses. The term is admittedly gray-edged and the perimeters for inclusion of diseases as autoinflammatory are indefinite. A prototypic disease would be familial Mediterranean fever (FMF) that mainly affects populations derived from the Mediterranean basin, and is characterized by periodic self-limited attacks of fever with features of serosal membrane inflammation. A culprit gene (*MERV*) that maps to the short arm of chromosome 16 encodes a regulator of leukocyte- and monocyte-specific inflammatory activity. Deficiency mutants of *MERV* result in unrestrained activity of predominantly Th1 polarized cytokines such as tumor necrosis factor-α (TNF-α) and IFN-γ (Centola et al., 2000). There is evidence for subclinical activation of inflammatory pathways even in symptom-free individuals (Musabak et al., 2004). While T cells are essential participants in FMF, there are no indicators for antigen-specificity in their activation.

As other examples, there are genetically less well-defined inflammatory pathways that can be activated in some way by lipids (or derivatives of these), examples being inflammatory responses associated with obesity (Wellen and

Hotarmisligil, 2005), or with triglyceride deposition in the liver. In the latter instance, non-alcoholic steatohepatitis (NASH) is emerging as a threatening variant of benign hepatic steatosis wherein the presence of lipid in liver cells provokes a progressive cytokine-dependent necroinflammatory response with fibrogenesis and cirrhosis. The factors that determine lipid accumulation in the liver in the first place, whether in NASH or the more familiar alcoholic liver disease, are reviewed by Browning and Horton (2004). These include metabolic shifts, oxygen species, mitochondrial dysfunction, and others and, superimposed on these, is the propensity in individuals at risk for NASH for T lymphocytes to be chemotactically attracted, and to release inflammatory cytokines, particularly TNF-α. Superimposed, there may be genetically dependent pathways that enhance fibrogenesis (Wynn, 2004). Extending yet further, tissue injury may be associated with abnormal cytoplasmic inclusions or misfolded proteins that are inadequately disposed of by chaperone molecules, ubiquination or autophagy, with cytotoxic consequences. Thus, in serpinopathy exemplified by deficiency of α1-antitrypsin, progressive inflammatory liver injury may supervene and, in certain CNS diseases, accumulations of beta amyloid or polyglutamine repeats may provoke cytotoxicity and a microglial-dependent inflammatory response (Taylor et al., 2002).

The extent to which autoinflammatory diseases require consideration in this present text is debatable, given the meager evidence for antigen-specific adaptive autoimmune responses in pathogenesis, yet a form of self-reactivity is seen as a contributory cause in at least some of these diseases.

BIRDSHOT RETINOPATHY

The slender reasons, additional to the piquancy of the title, for consideration of this rare ocular disease is the likely dependency on retinal S antigen in pathogenesis, and the remarkably high disease association with a class 1 MHC molecule, HLA A29. Considering inflammatory eye diseases in general (see Chapter 49), these take in responses to antigens in various of the ocular tissues, but mainly uvea and retina, although a serologic response to a well-characterized antigenic molecule is not so readily demonstrable as for autoimmune diseases of most other tissues. Birdshot retinopathy affects predominantly individuals of Northern European extraction and occurs usually in mid-adult life, with a slight female excess; it accounts for only about 1% of all cases presenting clinically as "uveitis." Birdshot retinopathy is seen ophthalmologically as multiple separate cream-colored spots on the post-equatorial fundus. Opportunity for pathologic examination is most infrequent but, from one study by Gasch et al. (1999), the retina was predominantly affected with a T-lymphocytic and granulomatous infiltrate. Serologic reactivity *in vitro* to retinal S antigen is not well documented. The risk conferred by the MHC allele HLA A29 (50- to 224-fold) is higher than that for any other disease, and is greater for the A29.1 than the A29.2 subtype. The only other human diseases with an HLA class 1 rather than a class II association are spondyloarthropathies with B27 (see Chapter 33) and psoriasis with Cw6 (see Chapter 58). Birdshot retinopathy presumably results from specific reactivity of $CD8^+$ cytotoxic T cells against retinal S antigen, but the provocation for this is unknown.

CHRONIC FATIGUE SYNDROME

This peculiar syndrome had its origin in 1955 from an outbreak of an illness affecting 292 hospital staff members with features of malaise, neck stiffness, lymphadenopathy, and fever (Medical Staff Royal Free Hospital, 1955). At that time, the term myalgic encephalomyelitis (ME) was proposed by someone described as "an unusually uncritical Lancet editorialist" (Byrne, 1988). Features include severe unexplainable fatigue, loss of energy, poor exercise tolerance with muscle discomfort, fibromyalgia, and various other nonspecific symptoms. A preceding viral illness is often implicated. "Myalgic encephalomyelitis" faded from use, but the syndrome continued to attract attention from various medical specialties and patient support groups, with protagonists for a functional basis and others for some unknown organic basis. By the 1980s, the syndrome was accepted as a real entity, and in 1987 was renamed chronic fatigue syndrome (CFS), with recommended diagnostic criteria by the Centers for Disease Control (CDC) in Atlanta, Georgia (Holmes et al. 1988). The two major criteria for diagnosis were 1) a new onset of fatigue lasting 6 months and reducing activity to less than 50%; and 2) any other condition usually producing fatigue ruled out, and the 11 minor criteria (of which eight should be fulfilled) included eight symptomatic criteria, and three physical criteria that comprised mild fever, nonexudative pharyngitis, and palpable cervical or axillary lymph nodes up to 2 cm in diameter. Claimed causes of CFS have included chronic viral infections, allergies, responses to unusual environmental exposures, or psychosomatic disorder. Despite evidence for immune activation and/or impaired indices of cell-mediated immunity in CFS (Lloyd et al., 1989, 1990; Buchwald and Komaroff, 1991), indications of inflammatory activity or tissue destruction are inconspicuous. Effects of immunomodulatory treatment with intravenous immunoglobulins, of clear efficacy in autoimmune disorders, are controversial, endorsed by some (Lloyd et al., 1990), and refuted by others (Peterson et al., 1990).

Analysis of an autoimmune component in CFS is beset by problems such as specifying a clear diagnosis, the overall

scarcity of affirmative reports indicative of a number of unpublished negative studies, and the occurrence of fatigue as a symptom of various well-defined autoimmune disorders. The question then is whether, among cases fulfilling CDC criteria for CFS, there can be identified a highly raised level of any autoantibody species, particularly antinuclear autoantibody (ANA). Among positive studies are those of Behan et al. (1985) (50 cases studied), and of Konstantinov et al. (1996) and von Mikecz et al. (1997) from the one laboratory (60 cases studied). The latter group cited frequencies of autoantibodies of up to 83% versus 17% in the control group, predominantly of ANA specificity, and directed to the nuclear envelope, together with various subspecificities, and the cytoplasmic staining patterns observed were of intermediate filament-vimentin type, indicative of viral infection (see Chapter 53). On the other hand, negative results for ANA in CFS were reported by Skowera et al. (2002), and only modestly positive results by Vernon and Reeves (2005).

The conclusions are that autoimmunity is unlikely to provide an overall explanation for CFS, and that autoantibodies, when present, may well be secondary to some other more basic cause. Perhaps autoimmunity is just one among a conglomerate of causes for CFS.

CONGENITAL HEART BLOCK

The observation was made in 1977 that newborn infants with congenital heart block (CHB) were delivered by mothers with an autoimmune disease, usually SLE or Sjögren syndrome, and with antibodies to the Ro/La (SS-A/SS-B) autoantigens, cited by Buyon et al. (2001) and Buyon and Clancy (2003). This remarkable experiment of nature provides striking examples of passive (transplacental) transfer of an autoimmune disease, and the pathogenic potential of humoral antibody even though the anti-Ro-bearing mother herself is spared. The fetal risk of CHB with an anti-Ro-positive mother is low (about 2%), but still immensely higher than that for all births. Other interesting features of anti-Ro-related CHB are the "window of susceptibility" between 18 and 24 weeks of gestation, an increased risk of recurrence in subsequent pregnancies, up to 18%, and a curiously low concordance in twin pregnancies (Buyon and Clancy, 2003). There is a gradation in degree of heart block from minor conduction defects to a state requiring replacement of the dysfunctional fibroinflammatory atrioventricular (AV) tissue by a permanent artificial pacemaker: in fact, the latter is the usual outcome.

While the complicity of transferred autoantibody in CHB is well established, the detailed pathogenesis is not so. The culprit autoantigen is the 52 kDa isoform of Ro (see Chapter 31), identified as a transcriptional regulator that is located intracellularly in all cells including ventricular cardiomyocytes, AV node, and impulse-conducting tissues. Possibly anti-Ro-positive sera contain another antibody species reactive with an accessible surface-expressed autoantigen, an L-type calcium channel (see Chapter 17), or development of the fetal heart involves remodeling by physiologic apoptosis that can generate autoantigenic fragments (see Chapter 15) that become translocated to the cell surface. However, neither of these ideas accounts for the subsequent over first pregnancy risk of anti-Ro for CHB. The likelihood that a specific antibody population is accountable arises from the finding of antibodies to an epitope sequence within the Ro 52 kDA protein (residues 200–239 called p200) that is contained within the leucine zipper region: these antibodies are highly associated with CHB (Salomonsson et al., 2005). Experimentally, female DA rats immunized with regular boostings with the p200 sequence of Ro52 developed a stable anti-p200 response without epitope spreading and, after mating, produced offspring among which the occurrences of AV block was 20% (Salomonsson et al., 2005). Highly focused monoclonal antibodies to the p200 region were used to test for binding to primary myocyte cultures from neonatal rat heart, so allowing for the identification of a particular subset of anti-p200 antibodies that bound directly to voltage-gated calcium channels on cardiomyocytes causing calcium overload and, eventually, apoptotic cell death (see Chapter 17). Otherwise stated, the pathogenic subset of autoantibodies does not primarily recognize apoptosis fragments, but rather induces apoptosis and thereby initiates a chain of events culminating in CHB. Consequently, there is now a means to identify pregnancies at high risk for CHB, and strategies can be visualized to prevent this.

ERYTHROID (PURE RED CELL) APLASIA

Erythroid or pure red cell aplasia (PRCA) describes severe anemia with a low blood reticulocyte count and scarce-to-absent erythroid precursors in the bone marrow. Pure red cell aplasia differs from aplastic anemia (see Chapter 44) wherein there is hypercellularity affecting all lineages in the bone marrow. Reports on PRCA go back to the 1950s, cited by Casadevall et al. (1996), some with varying solidity of evidence for an autoimmune basis, based on bioassays showing interference by disease serum of erythroid cell growth *in vitro*. Other cases seem clearly associated with infection by parvovirus of erythroid precursors (see Chapter 44). A further and intriguing association in some 15% of cases of spontaneously occurring PRCA is thymoma, sometimes with cure effected by thymectomy (Goldstein and Mackay, 1970; Dessypris, 1991). Currently, most cases can be attributed to autoantibodies to erythropoietin, the growth factor necessary for erythroid develop-

ment. Immunoassays show undetectable levels in blood of erythropoietin, and bioassays show absence of erythroid precursor cell growth in the presence of disease serum. In most cases, the patient usually has renal failure and is receiving hemodialysis and a preparation of recombinant erythropoietin (rEPO). Selected batches of rEPO have been incriminated in autoimmunogenicity, perhaps explained by differences in degree of glycosylation (Guest and Levitt, 2003).

The occurrence of an autoimmune reactant (anti-EPO) after repetitive adjuvant-free injection of a self antigen that is presumably only slightly modified, if at all, is interesting, and is reminiscent of autoantibody inhibitors of factor VIII after treatment of congenital hemophilia with preparations of recombinant factor VIII (see Chapter 45), or neutralizing antibody to type 1 interferons after therapy with such interferons. This could be regarded as induction of autoimmunity by a process somewhat akin to molecular mimicry and in the apparent absence of any elements of "damage-danger."

FOLATE DEFICIENCY SYNDROME

Maldevelopment of the embryonic neural tube resulting in spina bifida, anencephaly, or other defects occurs in infants at a prevalence of about 1 in 1000. It has been widely ascertained that periconceptual folic acid supplements to mothers strikingly alleviate this, even though the mothers usually do not have evident folate deficiency (Rothenberg et al., 2004). The observation was made that antiserum to folate receptors in pregnant rats resulted in embryonic maldevelopment, and this prompted the search for autoantibodies to folate receptors in women in whom a pregnancy had been followed by an infant affected with a neural tube defect (Rothenberg et al., 2004). The procedure used was the specific blocking of (^{3}H) folic acid to folate receptors on placental membranes and to indicator cell lines. The results were that 9 of 12 (versus 2 of 20 controls) of women with affected children had a receptor blocking antibody. In a further study (Ramaekers et al., 2005), the same authors investigated infantile-onset cerebral folate deficiency that develops 4–6 months after birth and is expressed as mental and psychomotor retardation, cerebellar ataxia, dyskinesis, seizures, visual disorder, and autism. There were low levels of 5-methyl tetrahydrofolate (5-MTHF) in the cerebrospinal fluid but normal levels in serum, and lack of evidence of extracerebral folate deficiency. Serum from 25 of 28 affected children, versus none of 28 controls, contained high-affinity blocking autoantibodies against membrane-bound folate receptors on the choroid plexus, indicating impediment to the passage of folic acid from serum to brain. This could be normalized by oral calcium folinate that led to clinical improvement. Notably, none of five tested mothers had autoantibodies. Perhaps the induction of the anti-folate receptor antibodies in these affected children was due to soluble folate-binding proteins in milk, or to other unknown antigens (Ramaekers et al., 2005). This story is indeed a true "cameo" in the universe of autoimmunity: anti-folate receptor autoantibody generated either in the pregnant mother or the newborn child with neural developmental disorders, prompting Schwartz (2005) to comment that "autoimmunization lurks behind every pillar"! And there is the added point that catastrophic consequence in this particular example can be alleviated by a very simple therapy, folic acid.

INTERSTITIAL CYSTITIS

Hunner (1914) reported eight cases of chronic recurrent edematous ulceration of the bladder in young women, but possible earlier descriptions of the disease are cited by Sant (1991). Subsequently, the term *interstitial cystitis* was introduced to accommodate the accompanying diffuse fibrosis of the bladder wall. Hand (1949) reported on 223 cases, 204 women and 19 men, who accounted for almost 5% of all urologically investigated patients, and Oravisto et al. (1970) on 54 cases from a urology unit over a 10-year period, of whom all were females aged 16–80 years, mean 59 years. Symptoms include urinary frequency and urgency, suprapubic pain, and hematuria. Cystoscopy reveals a greatly reduced bladder capacity and a bladder wall with stellate scars, clusters of granulations, and multiple punctuate hemorrhages, likened to an "angry scratch." Microscopy of the bladder wall shows bladder mucosal ulceration, edema, lymphoid-plasma cell infiltrations, and prominence of mast cells (Sant and Theoharides, 1994) and, in long-standing cases, pronounced fibrosis. The idea of autoimmunity as a cause of interstitial cystitis gained impetus from disease associations, particularly SLE (Fister, 1938; Shipton, 1965; Boye et al., 1979), Sjögren syndrome, and autoimmune thyroiditis (Oravisto, 1980). Other disease associations among 129 cases studied by Peeker et al. (2003) included hypersensitivity/allergic disorders, rheumatoid arthritis, and inflammatory bowel disease.

Present data on interstitial cystitis suggest a population frequency of approximately 1–2 in 1000, with a high predominance among women (90%). Sufficient interest in the condition exists for the creation in the USA of a support group (Interstitial Cystitis Association), and the development by the National Institute of Diabetes and Digestive and Kidney Diseases of the NIH (USA) of formal criteria for diagnosis. Subtypes of interstitial cystitis sometimes used in case classification are ulcerative (typical) or nonulcerative, and primary (sole disorder) or secondary (associated with some other immune-mediated disease, often SLE) (de la Serna and Alarcon-Segovia, 1981; Alarcon-Segovia, 1984).

Currently biomarkers are being sought to increase the reliability of diagnosis and assess efficacy of treatment.

Serologically, a finding of bladder-specific autoantibodies by Silk (1970) has not been confirmed. The frequency of ANA is controversial. Initially, raised frequencies were reported by Oravisto et al. (1970) and Jokinen et al. (1972). In the more modern era, the frequency of autoantibodies was assessed by Ochs et al. (1994) in 96 patients using immunofluorescence on tissue sections and the HEp-2 cell line, and a bladder epithelial cell line, and by western blotting. Specific autoantibodies to bladder cells were not demonstrable, but there was a clearly increased frequency of non-tissue-specific autoantibodies (cut-off titer 1:40), 36% versus 8% in female controls, mostly ANA, but antimitochondrial in three cases. The ANA patterns of the positive sera were speckled or nucleolar, unlike what pertains in SLE. Ochs et al. (1994) reasonably interpreted their findings as a consequence of chronic inflammation rather than a primary immune attack on the bladder wall, albeit with some potential to augment secondarily the inflammatory process.

Experimental models of autoimmune cystitis have been induced in mice and rats by immunization with bladder extracts. In a BALB/c-derived mouse strain, BALB/cAN, cystitis was induced, and histologic features included edema, fibrosis, and lymphocytic and mast cell infiltrations; specific reactivities of antibodies or T cells were not cited but disease was transferable adoptively by lymphoid cells (Bullock et al., 1992). In the Lewis rat, cystitis was similarly inducible, and could be adoptively transferred with splenocytes (Luber-Narod et al., 1996).

In conclusion, interstitial cystitis remains in the penumbra of autoimmunity. Neither pathogenic nor even marker autoantibodies are reliably demonstrable, earlier suggestions of damage by pathogenic immune complexes now seem speculative, and well-controlled studies showing sustained benefit from corticosteroid or immunosuppressive drugs are lacking. Hence, consideration is required of a pathogenesis other than autoimmunity, e.g., an adverse response to a constituent of urine to which the bladder wall is exposed.

IPEX SYNDROME

The immune dysregulation-polyendocrinopathy-X-linked syndrome (IPEX), the generic equivalent of scurfy disease in mice, is a usually lethal disease of male infants with florid autoimmune expressions. There is recessive inheritance of a mutant FOXP3 gene and disease expressions of IPEX/scurfy depend on a non-functional FOXP3 transcriptional factor (scurfin in mice) that is essential for proper development of CD4+CD25+ Treg cells. Results of molecular genetic analyses on IPEX/scurfy published in 2001 by Wildin et al. and Bennett et al. are cited in references to Chapter 9. The particular interest of IPEX/scurfy is that it could be a pointer to a dysfunctional FOXP3 as a genetic element in later-in-life autoimmune disease.

NEUROIMMUNOPATHIES

There are various "minor" autoimmune neurologic diseases that claim our attention yet cannot be accommodated under the major headings of multiple sclerosis, peripheral neuropathy, myasthenia gravis, or paraneoplastic disease. Some of these are described below.

Autonomic Neuropathy

Autonomic nerve fibers innervate cardiovascular, gastrointestinal, urogenital, thermoregulatory, sudomotor and pupillary structures. There exists a group of peripheral neuropathies of disparate cause that affect unmyelinated autonomic nerve fibers or ganglionic structures, with the clinical presentation of autonomic failure (dysautonomia). Paraneoplastic dysautonomia has been associated with a variety of other paraneoplastic expressions (Freeman, 2005), and with autoantibodies to the Hu antigen (see Chapter 68), nicotinic acetylcholine receptors in autonomic ganglia (Versino et al., 2000) and presynaptic voltage-gated calcium channels as in Lambert–Eaton syndrome (see Chapter 48) In some instances, autonomic neuropathy is "spontaneous," and apparently not associated with neoplasia (Vernino et al., 2000). Particular components of dysautonomia may be more prominent, for example, intestinal hypomotility seen as gastric stasis or constipation. In a case of severe gastric stasis associated with type 1 diabetes (T1D), histologic examination showed complete, and presumably autoimmune, depletion of the interstitial cells of Cajal of the myenteric plexus (He et al., 2001). In a model counterpart, rabbits immunized with the α3 subunit of the acetylcholine receptor developed an autonomic neuropathy (Lennon et al., 2003), with passive transfer to mice demonstrable with serum from affected rabbits and also, albeit with limited data, with sera from diseased humans (Vernino et al., 2004).

GADA-Associated Neuropathies

The discovery of the glutamic acid decarboxylase 65 kDa isoform (GAD65) as a diabetes autoantigen (see Chapter 36) arose from the detection of antibody to GAD65 (GADA) in a case of stiff-person syndrome (SPS, also known as stiff-man disease) with T1D. GAD65 is most abundant in neuroendocrine cells in pancreatic islets and the CNS, wherein it catalyzes the production of the inhibitory neurotransmitter, γ-aminobutyric acid (GABA). Exactly how GAD65 as an intracellular enzyme is implicated in neuroendocrine autoimmunity is uncertain, although immunohistochemical staining shows GAD present at GABA-ergic nerve terminals

(Peltola et al., 2000). Several curious if not exotic diseases qualify as GADA-associated neuronopathy (GAN), of which the prototypic example is SPS (see Chapter 48). Interestingly, serum levels of GADA are substantially higher in GAN than in T1D, perhaps explaining selective positivity by immunoblot in the former, and there is often a different epitope selection including a short sequence in the N-terminal region of GAD65 rather than (or as well as) the highly conformational epitopes in the mid- and C-terminal regions typically engaged by T1D antisera (Myers et al., 2000). Further, as evidence for intrathecal synthesis of GADA, the CSF may contain monoclonal bands and have specific immunoreactivity (Peltola et al., 2000). Other examples of GAN include cerebellar ataxia that can be associated with high levels of GADA and polyendocrine autoimmunity (Saiz et al., 1997) and therapy-resistant epilepsy (Peltola et al., 2000); these expressions of GAN seem linked to the fact that the cells affected are GABA-ergic neurons that contain cellular reservoirs of GAD required to meet demands for GABA-dependent synaptic transmission.

Batten disease, a real curiosity, is a recessively inherited fatal neurodegenerative disease of children due to a mutation in both copies of a gene *CLN3*, thus leading to ceroid lipofuscin accumulation in neurons. A gene-disruption mouse model revealed altered expression of enzymes required for the synthesis of the neurotransmitter glutamate, and circulating antibodies to brain proteins including GAD65. This prompted a search for GADA in Batten disease itself, with positive results (Chattopadhyay et al., 2002). As yet, the role of GADA in the overall pathogenesis is uncertain.

Movement Disorders

There is a miscellaneous group of movement disorders marked by basal ganglion autoantibodies (BGA). These include Sydenham's chorea (jerky movements), Tourette syndrome (motor and vocal tics), and PANDAS, which is an acronym for pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (Shulman, 1999). Speculative extensions have included obsessive–compulsive and attention-deficit disorders. The (weak) evidence for autoimmunity includes antecedent streptococcal infection with analogy drawn to rheumatic carditis (see Chapter 62), autoantibodies of various specificities but particularly to basal ganglia neurons, and capacity of sera for passive transfer of disease after direct injection into the striatum of rats. Not surprisingly, such claims are contested, and their validity remains an open question (Giovannoni, 2005).

Sandhoff Disease

Sandhoff disease (SD) is yet another genetic-metabolic autoimmune curiosity. It is a recessively inherited lysosomal storage disease of infancy in which neuronal cell death results from an enzyme deficiency that causes accumulation of GM2 gangliosides in lysosomes of brain cells. There is a murine equivalent created by knockout of the *hexb* gene that encodes the hexosamidase enzyme. It is claimed that anti-ganglioside antibodies in SD accelerate premature neuronal death, perhaps as complexes of antibody and ganglioside that cause inflammatory activation of microglial cells. Similar events are postulated for the human counterpart (Yamaguchi et al., 2004).

Epilepsy and Rasmussen Disease

Considerable interest was aroused in the early 1990s by suggestions that a severe form of childhood encephalitis with seizures (Rasmussen disease, RD) was attributable to antibodies to excitatory glutamate receptors in the CNS. Reminiscent of the serendipitous observations on experimental myasthenia gravis in rabbits immunized merely to raise an anti-acetylcholine receptor reagent (see Chapter 48), rabbits that were immunized to raise antibodies to the glutamate receptor subunit 3 (GluR3) developed seizures and histologic encephalitis, and this prompted a successful search for autoantibodies to glutamate receptors in RD (Barinaga, 1995). Thus some cases of idiopathic epilepsy could be due to autoimmunity affecting receptors for Glu3, so causing increased neuronal excitability; this idea remains current, but far from substantiated (see Chapter 48).

Narcolepsy

Narcolepsy is a sleep-wake disorder with onset during adolescence in which there is irresistible daytime sleepiness attributed to deficient neurotransmission dependent on orexin, a transmitter that promotes wakefulness. Prima facie this would seem hardly likely as an autoimmune disease, yet there is an extremely (and puzzlingly) high association with the class II MHC allele, HLA DQB1*0602. An autoantibody relevant to narcolepsy has never been demonstrated by conventional assays, but Smith et al. (2004) obtained such evidence by a bioassay based on passive transfer of IgG to mice, the readout being increased contractile responses of detrusor muscle strips to cholinergic stimulation; however, this research group considers that their data do not yet provide definitive evidence for an autoantibody-mediated loss of wakefulness, and are "very preliminary" (Gordon, T. personal communication, 2005).

Neuromyelitis Optica, Devic's Disease

Neuromyelitis optica (NMO) is an inflammatory demyelinating disease that is more frequent among Asian than white populations. The selective effects of the disease on optic nerves, and longitudinally extensive spinal cord lesions, distinguish NMO from multiple sclerosis (MS),

which it otherwise resembles (see Chapter 46). The CSF contains inflammatory cells, but lacks oligoclonal bands as seen in MS. Since a routinely demonstrable marker autoantibody in MS has long been awaited, it is notable that serum in NMO is reactive by immunofluorescence on sections of mouse CNS tissue, specifically with the abluminal face of microvessels exclusive to the CNS (Lennon et al., 2004). The sensitivity of the assay was 58% and the specificity 100% for the clinical diagnosis of NMO, and sensitivity may well be enhanced by adaptations of the assay. The identity of the NMO autoantigen for which the presumed origin is astrocytic foot processes and the blood–brain barrier, has been defined as the widely distributed aquaporin-4 water channel (Lennon et al., 2005). Since the Ig reactant in NMO is likely generated extrathecally, and can be causally implicated, logical therapies would include plasma exchange or IVIG, followed by corticosteroids and azathioprine. The question remains open as to whether NMO represents a subcategory of MS or is an independent autoimmune CNS disorder.

OMENN SYNDROME

This eponym was applied to infantile familial reticuloendotheliosis with eosinophilia (Omenn, 1965), and is now expanded to cover intestinal and cutaneous expressions, absence of B lymphocytes in blood and lymphoid tissues and infiltration of oligoreactive T cells in skin, gut, liver, and spleen (Aleman et al., 2001). Omenn syndrome is the result of deficiency mutations of recombinase-activating genes (RAGs). A similar phenotype can ensue with a mutant allele of the gene encoding ARTEMIS, a DNA repair protein (Ege et al., 2005). There may be hypomorphic mutations that allow for some residual V(D)J recombination, such that T cells with restricted receptor specificity can expand in peripheral tissues, and it is these that cause the cutaneous and intestinal lesions. This scenario however implies a defect also in tolerance processes and T-cell regulation, and this was duly shown in two patients in whom there was additionally a greatly limited expression of the AIRE protein consequent on dysfunction of the *AIRE* gene (Cavadini et al., 2005). Omenn syndrome is thus an extraordinarily compound "experiment of nature" that vividly illustrates the complexities of establishment and maintenance of natural immune tolerance.

OSTEOARTHRITIS

Osteoarthritis (OA) is prototypically a degenerative articular disease with a late-in-life onset and a relationship to articular stresses, although an early inflammatory phase with an apparent acute onset is recognized. Cases of OA are routinely used as "disease controls" in tests for specificity of serologic reactants for the diagnosis of RA; however when citrullinated peptide or native collagen type II (CII) is used as the test antigen, some degree of reactivity in OA is usually observed. Xiang et al. (2004) noted that sera from cases of OA, unlike RA, react more with denatured than native CII, although, sera from RA, OA and relapsing polychondritis all do react with native CII. Accordingly, specific epitopes of CII were investigated in OA by Burkhardt et al. (2002), and the result was that, in contrast to RA sera, OA sera tended to engage a different epitope, CII-F4, that is localized to the C-terminal region of native CII, rather than the RA-related epitopes, C1 and M2.139. Notably, in mice, an anti-CII-F4 monoclonal antibody (MAb), in contrast to other epitope-specific MAbs, is not pathogenic on passive transfer; in fact, anti-CII-F4 inhibits the matrix-disruptive effects of antisera with other CII epitope specificities (Burkhardt et al., 2002). Xiang et al. (2004) further found that OA sera, as well as having anti-CII-F4 reactivity, also recognize another antigen identified as triose phosphate isomerase (TPI). Perhaps in OA, as for other conditions discussed herein, autoimmunity can develop in the setting of tissue injury of diverse cause and be associated with multiple reactants that perhaps contribute to clinical expressions.

PARATHYROID DYSFUNCTION

An autoimmune basis for hypoparathyroidism, proposed over 40 years ago by Solomon and Blizzard (1963), was consolidated by Seeman (1967) in a histologic study that revealed lymphocyte-plasma cell infiltrates, and hence it was called lymphocytic parathyroiditis. In the first edition of this text in 1985, Maclaren and Blizzard discussed the autoimmune polyendocrine syndrome (APS) types 1 and 2 and, for type 1, noted that three major components existed and appeared usually in a uniform order: candidiasis, hypoparathyroidism, and Addison's disease. Moreover, autoimmune hypoparathyroidism, albeit a characteristic feature of APS type 1, did not occur in any of their 224 cases of APS type 2. However serologic reactivity with parathyroid tissue was insufficiently convincing to generate clinical laboratory assays, although autoantibodies were reported to bind to the cell surface of human parathyroid cells and to inhibit parathyroid secretion. An autoimmune basis was clinched when Li et al. (1996) demonstrated reactivity with the calcium-sensing receptor (Ca-SR) on the cell surface in both APS1-associated and sporadic cases of hypothyroidism, and an immunoprecipitation assay showed that the extracellular domain of the Ca-SR contained the reactive epitopes. Notably this autoimmune reactivity, in 56% of 25 cases, was far more frequent among females than

males. In a further turn of events, cases were recognized wherein antibodies to the parathyroid Ca-SR had an inactivating effect, so rendering the glands insensitive to ambient calcium; the ensuing oversecretion of parathyroid hormone had effects akin to those seen with parathyroid adenomas, causing hypocalciuric hypercalcemia (Pallais et al., 2004). These antibodies were functionally active but nondestructive and, interestingly, were of the IgG4 subclass and associated in one case with autoimmune pancreatitis in which there are raised levels of IgG4 (see Chapter 56). Thus the clinical expressions of autoimmune parathyroiditis with anti-Ca-SR reactivity may be either hypoparathyroidism if the antibodies are non-blocking or if the glands are subject to lymphocytic destruction, or hyperparathyroidism if the antibodies are blocking and the glands retain functional activity.

PULMONARY ALVEOLAR PROTEINOSIS

Pulmonary alveolar proteinosis (PAP) moves us still closer to the fringes of autoimmunity. As reviewed by Trapnell et al. (2003), the three forms of PAP include *congenital* (gene mutations), *secondary* (macrophage deficiencies with pulmonary alveolar injury), and *acquired* (idiopathic), which is now suspected as autoimmune. Pulmonary alveolar proteinosis is rare (0.37 cases in 100,000) and is mostly of the acquired type. Symptoms include a history of smoking, breathlessness, cough, fever, chest pain, and hemoptysis; and diagnosis depends on suggestive radiologic findings, abnormal pulmonary function tests, a milky bronchoalveolar lavage fluid containing alveolar macrophages and lymphocytes, and lung biopsy findings of abundance of surfactant proteins. A clue to the nature of PAP was the unexpected occurrence of a similar disease in knockout mice deficient in granulocyte-macrophage colony-stimulating factor (GM-CSF) (Stanley et al., 1994). The pathogenesis was shown to be impaired clearance of surfactant proteins from the lung due to deficiency of GM-CSF, and GM-CSF replacement was efficacious. Further studies showed that the critically affected cell was the pulmonary alveolar macrophage, which failed to undergo maturation by reason of the presence in serum and pulmonary fluid of an inhibitor that proved to be an IgG class autoantibody with neutralizing capacity for the binding of GM-CSF to alveolar macrophages. A latex agglutination test for detection of this autoantibody had a sensitivity of 100% and specificity of 98% for the diagnosis of PAP (Trapnell et al., 2003). Also, current therapy with whole-lung lavage can now be rationally supplemented by various regimens of GM-CSF supplementation, with prospects for the eventual waning of autoimmunity to GM-CSF, i.e. "desensitization" (Schoch et al., 2002).

RELAPSING POLYCHONDRITIS

Relapsing polychondritis (RP) was so named by Pearson et al. (1960) to designate recurring inflammatory damage to cartilage throughout the body, but particularly nasal, auricular, tracheobronchial, and audiovestibular, rather than articular cartilage. There is clustering in some 30% of cases with other autoimmune diseases that include rheumatoid arthritis and SLE, mononuclear cell accumulation at affected sites, association with HLA DR4, and benefit from prednisolone (McAdam et al., 1976). Specific antibodies to cartilage were detected by immunofluorescence by Dolan et al. (1976) and Foidart et al. (1978), using indirect immunofluorescence and cartilage substrate from mouse leg, or human costochondral and tracheal cartilage with preincubation with hyaluronidase to remove masking proteoglycan. Autoantibodies were detected mostly in the acute stages of RP, were of IgG class and non-complement-binding, levels correlated with clinically assessed disease severity, and absorption exclusively with type II collagen removed reactivity from serum. In a study on a single case, Bergfeld (1978) detected deposits *in vivo* of IgG, IgA, and C3 in affected cartilage using immunofluorescence. In a further study on cartilage antibodies by immunofluorescence (Ebringer et al., 1981), positive results were obtained in six of nine patients, and there was clustering with organ (thyroid)-specific autoantibodies. Results of studies on T-cell-mediated immunity to cartilage in relapsing polychondritis, cited by Foidart et al. (1978) and Ebringer et al. (1981), were indecisive.

Sera of cases of RP are reactive with CII. Terato et al. (1990) studied 202 Japanese patients with RA, 26 with RP, and 92 with other rheumatic diseases for antibodies to human CII by ELISA, with positive results in 11 (42%) of the cases of RP, in contrast with 11% in RA and 0.3% in controls. Tests using peptides derived by cyanogen bromide (CB) digestion of CII indicated that RP sera reacted preferentially with the CB 9.7 peptide, unlike the anti-CII reactivity of sera from other diseases. However, subsequent studies have indicated that in RP the primary reactant might not be CII, since reactivity of T cells and serum antibodies was greater with collagens IX and XII (Yang et al., 1993). Also, NOD DQI transgenic mice that were immunized with CII developed an auricular chondritis simulating human RP, with reactivity to CIX as well as to CII (Taneja et al., 2003). Thus, anti-CII in RP may occur secondarily by epitope spreading. Also, the species of anti-CII detectable does not have the epitope specificity associated with erosive articular inflammation (Burkhardt et al., 2002). Moreover, there is a further candidate autoantigen in RP, the cartilage protein matrilin I (Hansson et al., 2004), which is abundant in cartilage at sites affected in RP (trachea, ears) but sparse in sites that are spared (joints). A model of RP could be induced in mice by active immunization with matrilin I, with intact B cells and complement factor V being

required for disease expression, and transfer of disease by a MAb to matrilin I indicated that RP is indeed an antibody-mediated autoimmune disease (Hansson et al., 2004).

REPERFUSION INJURY AUTOIMMUNITY

When interest recently became refocused on innate immunity as a first line of immune defense based on invariant recognition of pathogen-associated molecular patterns, this would have seemed an unlikely contributor to autoimmunity. However, innate immunity can not only promote adaptive immune responses (see Chapter 2) but of itself may directly participate in autoimmune reactions, exemplified by reperfusion injury (RI). This curious syndrome is due to acute inflammation provoked by tissue ischemia, usually a thrombotic infarction followed by restoration of blood flow. It has been studied experimentally after ischemia of intestine or skeletal muscle (Carroll and Holers, 2005), with findings that RI requires a source of natural IgM autoantibody produced by B-1 B-cells and integrity of complement pathways, since mice deficient in RAG-1 and complement are protected. The use of a panel of MAbs derived from hybridomas developed in RAG-1-deficient mice with RI enabled the identification of a single injury-reconstituting IgM with a specificity for an auto-(neo)-antigen generated by ischemic intestine. In other examples, such as renal ischemia-reperfusion, complement pathways alone appeared sufficient. It will be of interest to ascertain the molecular identity of the RI autoantigen, and ascertain its role in the human counterpart.

SARCOIDOSIS

An early suspicion that sarcoidosis could have an autoimmune connection (Mackay and Burnet, 1963) was not sustainable, although no other credible pathogenesis has emerged. The disease expressions depend on noncaseating granulomatous lesions in multiple sites—skin, lymph nodes, lung, liver or CNS—and pathogenicity depends either on inflammatory fibrosis as in the lungs, or pressure effects of lesions as in the CNS. The immune system is clearly implicated as judged by the granulomatous histopathology, but how? Ho et al. (2005) drew on the known Th1-biased $CD4^+$ T-cell response in sarcoidosis, together with possible involvement of the natural killer (NK) T-cell system. The NKT cells are activated by glycolipid antigens presented by CD1 molecules on antigen-presenting cells (APCs) (see Chapter 2). A particular class of CD1 (CD1d), after interaction with NKT cells with an invariant receptor (Vα24/JαQ, paired with Vβ11) exerts regulatory effects. In mice at least, the CD1-restricted repertoire includes autoreactive T cells (Park et al., 2001). Ho et al. (2005) ascertained in sarcoidosis a deficiency (for unknown reason) of Vα24 NKT cells, with ensuing loss of their normal regulatory effect on CD1d-dependent reactivity. However, for sarcoidosis to be ascribed to autoimmunity, the depletion of Vα24 NKT cells would need to be associated with persistent stimulation of the Th1 T-cell pathway by an endogenous autoantigen, for which there is meager evidence. In fact epidemiologic data implicate an environmental influence, with possible person-to-person transmission, or a shared response to a provocative agent.

BENEFICIAL (PROTECTIVE) AUTOIMMUNITY

It seems appropriate to conclude these cameos with brief comments on beneficial effects of autoimmunity. Earlier on, it was proposed by Grabar (1975) that "natural" autoantibodies existed, and served beneficially as *transporteurs* of products of tissue degradation. But there are now other intriguing examples of beneficial autoimmunity. One is the production of antibodies to cytokines. Such antibodies are well recognized as an unwanted complication of therapy of certain autoimmune diseases with recombinant cytokines such as type 1 interferons for multiple sclerosis, with ensuing loss of efficacy, comparable with effects of unwanted antibodies during therapy with the growth factor erythropoietin, or factor VIII, resulting in loss of efficacy. Now, surprisingly, there is reported the natural occurrence of beneficial autoantibodies to the pro-inflammatory mediator TNF-α, akin to what is attempted therapeutically with MAb to TNF-α in rheumatoid arthritis. These spontaneous autoantibodies to TNF-α were demonstrable during the course of adjuvant arthritis in rats, and also in patients with RA at much greater frequency than in cases of OA (Wildbaum et al., 2003). A further example may be neuroprotective autoimmunity. It was observed in rats that passive transfer of autoimmune T cells reactive with myelin basic protein reduced neuronal loss after injury to the CNS (Kipnis et al., 2002). Hence, it was presumed that the immune repertoire naturally contains CNS-reactive (myelin-reactive) T cells that promote the disposal of products of neural injury and thereby facilitate recovery from neural injury. Of interest, depletion of $CD4^+CD25^+$ regulatory T (Treg) cells enhanced this myelin-reactive T-cell protection, while augmentation of Treg effects had the opposite effect (Kipnis et al., 2002). Whether these findings can be extended more generally, beyond CNS injury is uncertain, as are the prospects for extension towards development of a vaccine to ameliorate effects in humans of traumatic or ischemic damage to the CNS (Hauben et al., 2001). So, like the contents of Pandora's box, the baneful diaspora of autoimmu-

nity may be accompanied by a glimmer of hope, namely benefit to the organism under particular circumstances, such as damping down inflammatory mediators, or facilitating recovery after tissue injury.

CHAPTER

72

Autoantibody Assays, Testing, and Standardization

MARVIN J. FRITZLER*
**Faculty of Medicine, University of Calgary, Calgary, Canada*

ALLAN WIIK†
†Statens Serum Institut, Copenhagen, Denmark

The first description of human autoantibodies and the development of the Wassermann test for syphilis that was initially based on agglutination and complement fixation dates to 1906 (Wassermann et al., 1906). In the early 1940s, the active component of the Wassermann test was found to be a phospholipid, which was subsequently named "cardiolipin" and the antibodies reactive to cardiolipin were named "reagin" (Pangborn, 1941; 1942). Serum reagins were detected by a flocculation or immunoprecipitation (IP) that employed a mixture of cardiolipin, cholesterol, and phosphatidylcholine in an assay that was referred to as the Venereal Disease Research Laboratory (VDRL) test. Early in the history of the application of the VDRL test, it became clear that some individuals, including certain systemic lupus erythematosus (SLE) patients, had a positive test without any other evidence for syphilis (Moore and Mohr, 1952; Moore and Lutz, 1955). Subsequent studies showed that this reactivity was due to the presence of phospholipid antibodies, and in particular anticardiolipin antibodies (Harvey and Shulman, 1966; Koike et al., 1984) (see Chapter 30). The importance of the false positive VDRL test in the diagnosis and classification of SLE was underscored by the inclusion of the false-positive VDRL test as one of the criteria in the original American Rheumatism Association's criteria (Cohen et al., 1971).

In 1948, just as the VDRL test was achieving some interest in its relationship to SLE, Hargraves and colleagues published the seminal paper on the lupus erythematosus (LE) cell (Hargraves et al., 1948). The identification of the LE cell, the development of the LE cell assay and the introduction of indirect immunofluorescence (IIF) and immunodiffusion (ID) assays stand as a historical pivotal point because it led to the development of other new diagnostic techniques and the rapid expansion of medical literature that documented numerous autoantibodies in a variety of conditions (Van Venrooij and Maini, 1993; Krapf et al., 1996; Peter and Shoenfeld, 1996). In the five decades that followed the development of the LE cell assay, the detection of autoantibodies in human sera has become an increasingly important approach to the diagnosis and management of patients with autoimmune conditions. At the outset, most laboratories prepared many of their own reagents for these assays, but increasing requests and a widening spectrum of autoantibodies heightened the need for supplies and a wide variety of reagents to perform these assays. This became an entry point for manufacturers and commercial vendors to develop and market a wide variety of diagnostic kits. Although some diagnostic laboratories still use assays that are developed in house, commercial kits have gained a significant foothold in many areas of autoimmune serology. The use of commercial kits has become so widespread because they are cost-effective, easy to use and can satisfy criteria for accreditation.

The discovery of autoantibodies also had an important impact on progress in the fields of basic and applied immunology. The mechanisms that led to the generation

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

of autoantibodies created an understanding of immune regulation. In addition, the ongoing identification of novel autoantibodies strengthens the foundation of disease-related autoantibody markers while adding new conditions to an expanding list of autoimmune diseases. Although autoantibodies are thought to be relevant in B-cell dominant conditions; autoantibodies are also found where T-cell-mediated processes are thought to predominate (Rose, 1996).

Many autoantibodies have become central to the practice of clinical immunology and immunopathology. For example, the diagnostic and classification criteria for many autoimmune diseases, such as rheumatoid arthritis (RA) (Arnett et al., 1988), SLE (Tan et al., 1982), mixed connective tissue disease (MCTD) (Kasukawa, 1987), and proposed criteria for type 1A diabetes mellitus (Seissler et al., 1998) have included autoantibodies as key components of their respective diagnostic algorithms. Taken together, the detection of autoantibodies has achieved a prominent role in clinical practice, particularly as an approach to the diagnosis of autoimmune conditions, and recently as markers of disease prognosis.

Box 72.1
Considerations regarding the clinical interpretation and application of autoantibody testing

- Normal sera contain autoantibodies
- Disease-specific autoantibodies can antedate disease
- Definition of a positive test is based on an empirically defined threshold
- Some assays such as indirect immunofluorescence are based on subjective interpretation
- Lack of standardized antibodies and reagents
- Variety of assays and diagnostic assay platforms
- Adoption of high throughput assays before validation of local performance
- Impact of short-term cost and budget restraints
- Long-term impact on total health care costs are mostly unknown

SPECTRUM OF AUTOANTIBODIES

The spectrum of autoantibodies in autoimmune diseases is continually expanding and the reader is referred to the relevant chapters in this book. Table 72.1 lists and summarizes some of the autoantibodies that are widely used as an approach to diagnosis and treatment of autoimmune and related conditions. To be sure, the list of autoantibodies found in these conditions is much wider. For example, in autoimmune conditions with multi-organ involvement such as SLE, more than 100 different autoantibodies have been described (Sherer et al., 2004) and over 20 have been found in systemic sclerosis (SSc) (Fritzler, 1993; Ho and Reveille, 2003). In most organ-localized diseases, the autoantibodies tend to be directed to only one or a few antigens harbored in the affected organ (see Table 72.1).

ASSAYS AND TECHNOLOGIES FOR AUTOANTIBODY TESTING

Many laboratories rely on commercial autoantibody assay kits that employ a variety of technologies, including IIF, ID, IP, immunoblotting (IB) and line immunoassays, enzyme-linked immunosorbent assays (ELISA), and, more recently, addressable laser bead assays (ALBA) and antigen arrays (Fritzler, 2002; Robinson et al., 2002). The use and application of these kits has been attended by certain limitations that are not always apparent to the clinician (Box 72.1). One of the more popular assay platforms is based on the ELISA or enzyme immunoassay (EIA) because it offers sensitivity, high throughput, and relatively low cost on the background of only modest equipment needed to perform the assay. Unfortunately, there has been little done to standardize these kits (Feltkamp, 1996) and post-marketing surveillance and quality assurance is largely left to the manufacturers (Fritzler et al., 2003a). Although the ELISA and EIA kits are constantly being improved, some high-titer antibodies to a variety of autoantigens (e.g., fibrillarin, PM/Scl, centromere, nuclear envelope) are often not detected. Hence, a report that indicates a "negative EIA or ELISA" screen should not be interpreted as "negative for all relevant autoantibodies" that might otherwise be detected by IIF and other diagnostic technologies.

A number of studies have evaluated the performance characteristics of kits for detecting ANA using IIF and EIA (Jansen et al., 1987; Avina-Zubieta et al., 1995; Jaskowski et al., 1995; Vancheeswaran et al., 1996; Bizzaro et al., 1998; Emlen and O'Neill, 1997; Cordiali et al., 1998; Fawcett et al., 1999; Bossuyt, 2000; Kern et al., 2000; Ulvestad et al., 2000; Fritzler et al., 2003b). Other studies focused on kits for antineutrophil cytoplasmic antibodies (ANCA) detection (Csernok et al., 2002). Studies that compared EIA kits from different manufacturers with conventional assays such as IIF and ID concluded that there was significant discordance between conventional assays and EIA (Jaskowski et al., 1996; Fawcett et al., 1999) and between kits from different manufacturers (Emlen and O'Neill, 1997). In one study, EIAs were found to be more sensitive than ID (Jaskowski et al., 1995) and another study that used a cross-section of serum referred to a rheumatology laboratory found moderate-to-good agreement between IIF and anti-DNA results with two commercial EIA kits (Ulvestad et al., 2000). Analysis of the design of some studies suggests that lack of agreement between EIA and conventional assays may

TABLE 72.1 Autoantibodies used in diagnosis of autoimmune diseases

Autoantibody	Disease	Sensitivity (%)/Specificity (%)	Assay
dsDNA	SLE DIL*	45–60/80–90	IIF, ELISA, IP
Sm (U2-U4-6 RNP)	SLE	10–20/95	ELISA, ID.IP
U1RNP	MCTD SLE	90/90–95 40/30	ELISA, ID, IP
SS-A/Ro 60	SjS SLE	50–70/80 45/25	ELISA, ID, IP
SS-B/La	SjS SLE	40/70–90 15/10	ELISA, ID, IP
Histone/chromatin	SLE DIL	70/20 80/20	ELISA, IB
Topoisomerase I/Scl-70	SSc	20/90	ELISA, IB, IP
U3 RNP/fibrillarin	SSc	15/95	IIF, IP
Centromere	SSc	50–60/90	IIF, ELISA, IB
Jo-1/histidyl tRNA synthetase	PM/DM	20–30/90–95	ELISA, IB
Citrullinated peptides and proteins	RA	65–85/85–95	ELISA
Proteinase 3	Wegener's granulomatosis	60–70/90–95	ELISA, IB, IIF (cANCA)
Myeloperoxidase	MPA	65/80	ELISA, IIF (pANCA)
Pyruvate dehydrogenase complex (M2)	PBC	75–80/85	IIF, IB, ELISA, IP
Smooth muscle F-actin	Chronic active hepatitis	70/25	IIF, ELISA
Intrinsic factor	Pernicious anemia	90/70	IIF, ELISA
Human tissue transglutaminase	Celiac disease	85/90	IIF, ELISA
Cardiolipin complex	APS	80/50	ELISA
β2-glycoprotein I	APS	80/90	ELISA
Basement membrane (α3 domain of type IV collagen)	Anti-GBM disease (Goodpasture syndrome)	80/80	IIF, ELISA
Acetylcholine receptor	Myasthenia gravis	80/90	ELISA, IB
Thyroid microsomes (thyroid peroxidase)	Hashimoto's thyroiditis	90/75	IIF, ELISA
Cadherins	Pemphigus vulgaris	90/90	IIF
Skin basement membrane zone	Bullous pemphigoid	80/80	IIF
Yo/Purkinje cell	PCD	70/95	IIF, IB
Hu	PEM	70/90	IIF, IB, IP

APS, antiphospholipid syndrome; cANCA and pANCA, cytoplasmic and perinuclear antineutrophil cytoplasmic antibodies; DIL, drug-induced lupus; ELISA, enzyme-linked immunoassay; IB, immunoblot; IIF, indirect immunofluorescence; IP, immunoprecipitation; MCTD, mixed connective tissue disease; MPA, microscopic polyangiitis; PBC, primary biliary cirrhosis; PCD, paraneoplastic cerebellar degeneration; PEM, paraneoplastic encephalomyelitis; PM, polymyositis; RNP, ribonucleoprotein; SjS, Sjögren syndrome; SLE, systemic lupus erythematosus; SSc, systemic sclerosis; TNF, tumor necrosis factor.

*Some RA patients treated with anti-TNF or sulfasalazine develop features of drug-induced lupus and anti-dsDNA antibodies.

depend on the diagnosis and/or the selection bias of the control patients under study (Jaskowski et al., 1995; Jaskowski et al., 1996; Emlen and O'Neill, 1997; Ulvestad et al., 2000).

A study by Tan et al. (1999) focused on nine different commercial EIA kits for the determination of antibodies to a number of nuclear and cytoplasmic autoantigens and highlighted deficiencies in intrinsic properties of these kits (sensitivities and specificities). A more recent study focused on the clinical laboratories themselves and, although one might expect academic laboratories to be rather proficient in the implementation of the EIA kits, that was not the case (Fritzler et al., 2003b). As in other studies (Feltkamp, 1996), it was suggested that quality-control procedures for daily performance of tests in the clinical laboratory setting should not be ignored, and that a minimal performance of EIA assays should be established (Fritzler et al., 2003b).

In the field of neutrophil-specific autoantibodies (NSA), which are found in many diseases where the chronic inflammation involves ongoing recruitment of neutrophils to the

inflammatory site (Wiik, 1980), the main emphasis has been on the study of ANCA (Hoffman and Specks, 1998; Wiik, 2001). Antineutrophil cytoplasmic antibodies are rather specifically directed against one of the two main azurophilic granule enzymes, proteinase 3 or myeloperoxidase, and thus fulfill criteria for being called ANCA, whereas the NSA found in RA, ulcerative colitis, primary sclerosing cholangitis, and autoimmune hepatitis are polyspecific, directed to a whole host of autoantigens that are not yet well known. It is important to mention that ANCA are found at high and intermediate levels in patients with small vessel necrotizing vasculitides, whereas borderline positivity can be found in many chronic inflammatory diseases and long-standing infections. Therefore, it is imperative to adjust positive cut-off of assays for proteinase 3 ANCA and myeloperoxidase ANCA at a sufficiently high level to assure sufficiently high diagnostic specificity for systemic vasculitis (Hagen et al., 1998). Results are best secured when both IIF of ANCA and ELISA quantitation of ANCA are studied and reported together (Hagen et al., 1998; Savige et al., 1999). Just a few studies have been undertaken to look at commercial assays for the determination of ANCA (Csernok et al., 2002).

Since there is considerable variation in the sensitivity of the various commercial diagnostic kits, the particular assay used to generate the test result should be made available to the clinician. In addition, because of the growing trend to use automated immunoassay systems with quantitation, these laboratories should follow standards of chemistry instrumentation and require analytical measured ranges and periodic calibrations. Clinical laboratories that adopt multiplexed assays (e.g., ALBA) must establish reference ranges and cut-off values for each analyte, and the sensitivity and specificity must be established with care as the laboratory findings may present a difficult interpretation problem. In the future, instrumentation may be developed for automated quantitation with measurement of avidity (affinity) and isotype profile of the specific autoantibody, which will help in determination of specificity and significance of the autoantibody.

CLINICAL APPLICATIONS OF AUTOANTIBODY TESTING

Before considering the application of autoantibody testing in the clinical setting, it is important to appreciate certain limitations to the interpretation and application of these tests (see Box 72.1) that may be understood by considering a number of features of autoimmunity and assays used to detect autoantibodies. First, any given human serum contains a wide range of autoantibodies of varying concentrations (Rose, 1996). Second, it is important to understand that the measurement and assignment of an abnormal or elevated autoantibody test requires an empirically defined threshold that is dependent on numerous factors (Fritzler et al., 2003a; Wiik et al., 2004). Third, some disease-specific autoantibodies can antedate overt disease by many years. For example, antibodies to centromere proteins (CENPs) may antedate the clinical diagnosis of SSc by many years (Wigley et al., 1992; Kallenberg et al., 1988) and antibodies to Scl-70 (topoisomerase I) were linked to the development of pulmonary fibrosis and higher mortality (Kuwana et al., 1994; Scussel-Lonzetti et al., 2002). In harmony with this, a large study of non-SLE patients harboring anti-dsDNA antibodies as detected by the Farr immunoassay were found to develop SLE within the course of 4 years (Swaak and Smeenk, 1985). Similarly, in 115 of 130 SLE patients, at least one autoantibody related to SLE could be traced back to a mean of 3.3 years before the clinical onset of SLE (Arbuckle et al., 2003). Recent evidence showed that antibodies to cyclic citrullinated peptide (CCP) are seen in patients with joint symptoms that antedate sufficient diagnostic criteria for RA (Kroot et al., 2000; Rantapää-Dahlqvist et al., 2003; Van Gaalen et al., 2004). It has been suggested that the appearance of type IA diabetes mellitus (DM) related autoantibodies also commonly antedates the clinical diagnosis (Atkinson and Eisenbarth, 2001). A sequential appearance and peak of antibodies to insulin (IAA), glutamic acid decarboxylase (GADA), and islet cell antigens ICA512/IA2A has been observed in children between the ages of 9 months and 3 years who then go on to develop DM. These autoantibodies tend to be persistent and most of the individuals that progress to overt diabetes express multiple anti-islet autoantibodies by the time of diabetes onset.

Although the detection of autoantibodies in human sera has become an important tool for experienced clinicians, the clinical application and validation of autoantibody testing has been hampered by a lack of standardized assays, divergent technologies, cost constraints, and subjective interpretation of results. New autoantibody assays are continually being developed and adopted with the anticipation that they will lead to better reproducibility and to higher sensitivity and specificity. If the ultimate goal is to improve patient care, it is imperative that the accuracy of autoantibody testing be validated by studies of sufficiently large patient populations before a new assay is accepted for clinical use. Since very few prospective, unbiased, and multicenter studies have been published, the clinical accuracy of many autoantibody tests is still uncertain. Studies based on literature review and meta-analysis have been published as "evidence-based guidelines" (Kavanaugh and Solomon, 2002; Solomon et al., 2002; Reveille and Solomon, 2003) but the translation of this information is hampered because of the wide variety of newer assays and assay parameters that may not apply to contemporary technologies used in many laboratories.

To achieve significant clinical utility, it is important that the ability of autoantibody testing to discriminate between disease and the absence of disease, or between disease and confounding clinical conditions is understood. The performance characteristics of each test must be known in order to avoid misinterpretation, incorrect diagnosis, and potentially harmful treatment. To aid in patient follow-up and the introduction of therapeutic strategies, the prognostic significance of a given autoantibody in a patient who may have a subclinical autoimmune disease should also be considered. For example, the finding of an autoantibody that indicates a poor prognosis in the context of early disease should lead to appropriate follow-up and monitoring for emerging organ involvement that would place the patient at risk for increased morbidity or mortality. Attention to these factors requires the close collaboration and cooperation between patients, dedicated clinicians, laboratory scientists, and the diagnostics industry (Fritzler et al., 2003a; Wiik et al., 2004). Once a diagnostic assay has been established and is widely utilized in a clinical setting, standardized postmarketing surveillance and quality assurance by manufacturers and laboratories alike should be mandatory (Tan et al., 2002).

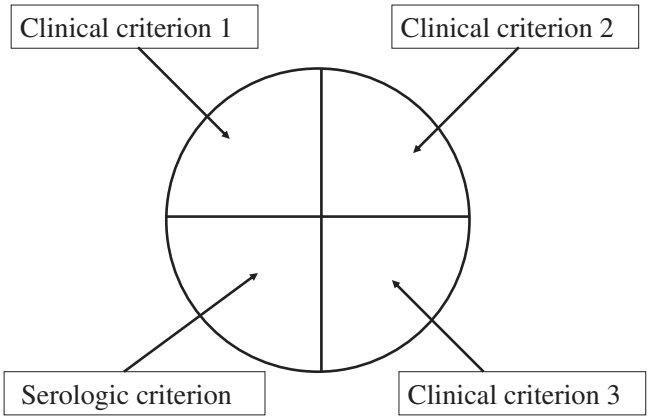

Figure 72.1 Relationship between clinical criteria and autoantibody results, illustrated as a situation where a positive antinuclear antibody is used as a disease criterion, but a specific antibody is indicative of a certain subtype of disease and, hence, prognosis. The fewer the clinical criteria, the more helpful is the addition of a serologic criterion or support for diagnosis.

AUTOANTIBODIES AND CLINICAL DIAGNOSTICS

Years of accumulated clinical experience and research have led to the development of clinical criteria to support a given diagnosis of a number of autoimmune diseases (Masi et al., 1980; Kasukawa, 1987; Alarcon-Segovia and Cardiel, 1989; Cassidy et al., 1989; Leavitt et al., 1990; Jennette et al., 1994; Savige et al., 1999; Wilson et al., 1999). Since systemic rheumatic diseases frequently involve multiple organ systems, multiple criteria are required to confirm a diagnosis. As a consequence, it is rare that a single pathognomonic criterion be translated into certainty that a given diagnosis is correct. To ensure that results from the immunology laboratory gain maximum utility for clinicians, it is important to study the performance of each assay as a diagnostics aid in early disease, since that is the time at which a serologic result will impact diagnostic and prognostic considerations the most (Fenger et al., 2004). This is best done by building a particular serum bank containing samples from patients at an early stage of disease, often drawn at a time when diagnosis has not yet been set with certainty due to lack of some clinical criteria. The clinical diagnosis then has to be established after months or years of clinical follow-up. The impact of adding a serologic criterion at a stage where clinical criteria are insufficient for diagnosis is illustrated in Figure 72.1. Although autoantibodies are included as a criterion in many diseases, the diagnosis of SSc stands out as one disease where the inclusion of disease-specific autoantibodies is lacking (Masi et al., 1980; LeRoy and Medsger, 2001). A recent study suggested that there is clinical value in including topoisomerase I and centromere autoantibodies in criteria for the classification of SSc (Nadashkevish et al., 2004). The more knowledgeable the clinician is with regard to the clinical and laboratory characteristics of diseases, the greater the chance that a diagnosis is correct. Many of the diseases listed in Table 72.1 have clinical subgroups with somewhat dissimilar manifestations and, hence, prognosis. Of relevance to this discussion, these subgroups are often associated with different autoantibody profiles and specificities (Permin et al., 1978; Cervera et al., 1993; Kuwana et al., 1994; Mustila et al., 2000; Wiik, 2001; Cervera et al., 2002; Scussel-Lonzetti et al., 2002; Targoff, 2002). Therefore, an autoantibody may be a valuable marker of a prognostic subgroup and used to tailor follow-up and therapeutic strategies (Franssen et al., 1998).

Autoantibodies with high disease specificity, regarded as disease-specific markers, tend to be rare (von Muhlen and Tan, 1995). Unfortunately, some data related to certain autoantibodies and their disease specificity relied on outdated technology and on studies published several decades ago. With the introduction and adoption of newer diagnostic technology platforms, autoantibodies that were thought to be specific for one disease may subsequently turn out to be associated with a variety of autoimmune diseases (van Eenennaam et al., 2002). The presence of multiple disease-related autoantibodies occurring in a single serum has strengthened the importance of autoantibody profiles, and changes of autoantibody expression in individual patients may be more indicative that a certain diagnosis is correct

than the presence of a single antibody (von Muhlen and Tan, 1995; Blass et al., 1999; Vasiliauskiene et al., 2001; Visser et al., 2002). Hence, multiplexed and autoantigen array technologies that are now emerging will provide even more extensive autoantibody and autoepitope profiles in a given patient, which in turn may alter approaches to diagnosis and therapeutics (Schachna et al., 2002; Robinson et al., 2002; Fritzler, 2002).

New technologies often focus on achieving high diagnostic sensitivity rather than on reaching high diagnostic specificity of specific autoantibodies. In addition, new assays are frequently released before the ability of the assay to accurately predict a specific diagnosis is fully known. Diagnostic specificity of an assay generally decreases when high sensitivity is achieved. Thus, when a new test is introduced, clinicians may overlook the loss of diagnostic specificity and focus on the improved sensitivity in predicting a disease. Evaluation of new assays is necessary to demonstrate that the diagnostic specificity of new assays does not suffer because of attempts to increase sensitivity. To achieve this, it is important that sera from local control patients with inflammatory autoimmune diseases are tested in order to measure the predictability of any given assay. This testing needs to be attended by consent from patients whose sera is being used in such studies and by close collaboration with experienced clinicians who are willing to monitor and record the clinical manifestations of each patient who donated serum for these studies. It is evident that a highly sensitive automated assay can be used for selection of sera that should be further tested using a very specific assay, since this may save time and money by focusing attention to few candidate positive sera (Wiik et al., 2004).

As laboratory equipment becomes more sophisticated and, as noted above, assays become more sensitive, adjustment of cut-off or screening titers to achieve higher specificity should be undertaken. New recommendations were recently suggested regarding IIF testing for ANA, using HEp-2 cell substrates (Tan et al., 1997). For years, the cut-off for normal results was considered to be at a serum dilution of 1:40 or 1:80. This multicenter international study revealed that 32% of normal individuals were positive at serum dilutions of 1:40. Thus, a titer of 1:160 was recommended as a more acceptable cut-off between normal and abnormal sera. Unfortunately, despite the best efforts of international committees to provide these recommendations, subsequent cursory surveys and review of subsequent literature suggest that these guidelines have not been widely applied. While it is appreciated that a value of screening at a dilution of 1:40 is to rule out a disease such as SLE, Sjögren syndrome (SjS) and SSc (Griner et al., 1981; Homburger, 1995), the disadvantage is the generation of a significant health care cost through referral and investigation of people that have a "positive" ANA but do not have a systemic rheumatic condition.

CLINICAL PRACTICE GUIDELINES

Because of the complexity of modern autoimmune serology, there is a pressing need for guidelines that outline the appropriate and economic use of serologic testing. If a limited number of clinicians are involved in ordering diagnostic testing and the laboratory serves a finite number of departments, it is easier to achieve an understood consensus on testing strategies. However, as exemplified by current trends, regional and national laboratories provide service to more extensive areas or populations and to family practitioners as well as specialists, and in these situations written guidelines may be required to develop screening criteria, and then a rational testing scheme that limits unnecessary testing (Wiik et al., 2004). Another strategy is to develop order forms in such a way that the doctor can choose between a tentative diagnosis, after which a few rational tests are done, or choose just one or two tests from this testing panel (Figure 72.2). A positive screening test may lead to the referral of a patient to a specialist, who will then plan the further investigation program including further serologic testing. It is important to realize that the pretest probability to detect a useful diagnostic laboratory result increases dramatically with each clinical feature that has been incorporated into the tentative diagnosis (Keren and Nakamura, 1997). Some clinics have agreed with laboratory specialists on the use of post-test algorithms to alleviate appropriate use of positive and negative laboratory results in relation to tentative diagnoses.

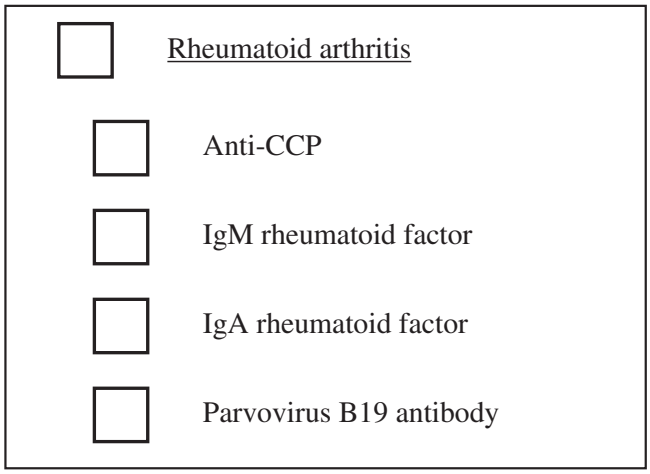

Figure 72.2 Example of a test order hierarchy from a laboratory order form based on tentative diagnosis or on single test(s).

LABORATORY REPORTS, INTERPRETATION, AND COST ANALYSIS

When an autoantibody is found, the positive result is usually communicated as a printed report that is mailed directly to the requesting physician. Unfortunately, in some jurisdictions, current regulatory constraints (Health Protection Acts and Freedom of Information Protection Acts) prohibit the transmission of a digital report directly to the doctor's personal computer or other digital device. Perhaps an international effort to develop consensus on the electronic medical record and the digital transmission of clinical data would help alleviate concerns about this technology (Vogt et al., 2004). A description of the most common diagnostic associations related to an autoantibody found in diagnostic testing is included with the result, for example: "Anticentromere antibodies are found in about 25% of patients with SSc. This antibody is most commonly seen in the limited form (CREST) subset of the disease."

To aid in interpretation of the results, information related to the sensitivity and specificity of a positive result should be tabulated and made accessible in a printed form and on the internet. Also the level of the antibody or the strength of expression should be mentioned together with cut-off towards disease control patients and the range of credible measurements. Some laboratories routinely accompany reports on positive findings with a short written comment on the most frequent clinical association(s) to help direct further diagnostic work-up.

Many laboratories use an algorithm that includes a rapid and inexpensive screening test followed by more specific tests as an approach to rationally screen for the presence of autoantibodies. For example, the IIF test or the whole cell ELISA is often used to detect autoantibodies in systemic rheumatic and other diseases. This serves three purposes: first, it serves as a triage for further testing; second, if the IIF or screening ELISA test is negative, unless there is a compelling clinical evidence to do so, no further testing is required and the result is reported accordingly; third, many autoantibodies can be accurately identified solely by this IIF screening approach. Examples include anticentromere antibodies that are seen primarily in patients with a limited subset of SSc or in a subpopulation of SjS patients (Vlachoyiannopoulos et al., 1993) and antibodies to parietal cells seen in pernicious anemia (see Table 72.1). If the IIF test is positive, the samples can be processed by more specific tests that include ELISAs, line assays that detect a variety of autoantibodies, or an addressable laser bead assay that has the ability to detect up to 100 different autoantibodies in a single serum sample (Fritzler, 2002; Robinson et al., 2002).

It is very important that all laboratory results can be validated and, in this context, borderline (low positive) results can be especially troublesome. It is recommended that borderline positive results must be confirmed or refuted by use of a second well-established independent technique to ensure that only certified positive results are reported to the physician or clinic. If controversy about the result persists, the laboratory should add a note of caution to the clinician that the result may have little significance in supporting a diagnosis and/or may recommend retesting a new serum sample in 1 to 3 months. Some regulatory agencies mandate that borderline positive tests should be reported as positive until proven otherwise through repeat or follow-up testing at appropriate intervals. High and intermediate positive results of a single credible technique can be reported without independent confirmation by a second technique. To aid in the interpretation of laboratory results, the chosen limit for positivity is stated on the report and ranges of low, intermediate, and strong positivity should be indicated.

A significant problem is that easy to perform and high throughput techniques are being adopted without proper clinical validation. Screening for autoantibodies by use of ELISA plates that have adsorbed complex mixtures of native and/or recombinant autoantigens or nuclear extracts is now used by many laboratories instead of ANA screening by IIF. This practice continues despite data showing that many patients with SjS, SSc, polymyositis/dermatomyositis, and juvenile RA score negative for ANA using such composite ELISA techniques (Keren and Nakamura, 1997; Fawcett et al., 1999). HEp-2-IIF screening of these "false-negative" sera reveals that most of these sera contain antibodies to nucleoli, nuclear matrix, nuclear envelope, nuclear pores, coiled bodies, PML domains, cell-cycle-specific antigens such as proliferating cell nuclear antigen or mitotic spindle apparatus components, or other cytoplasmic organelles and structures such as mitochondria, Golgi apparatus, signal recognition particles, or ribosomes (Bayer et al., 1999; Wiik, 2003a; 2003b; Stinton et al., 2004). Studies have shown that these autoantibodies are readily recognized by experienced technicians (Wiik and Lam, 2001) but are missed by ELISAs for ANA screening (Bayer et al., 1999). Some of these autoantibodies have defined clinical associations and should be identified as such (Table 72.2). On the other hand, autoantibodies that lack proven clinical value should not be reported until their diagnostic specificity and value have been clearly established. This approach mandates rigorous, multicenter studies of newly discovered autoantibodies to establish their clinical relevance or value. One of the most important aspects of autoantibody test results is the impact the result has on clinical decision making such as prognosis, follow-up strategy, and therapeutic intervention, since these factors are the ones that impact on the long-term outcome of disease.

There is a serious deficiency in our knowledge of the actual costs incurred through inappropriate laboratory testing, although the actual costs of laboratory diagnostic

TABLE 72.2 Antinuclear antibodies determined by indirect immunofluorescence patterns that may be useful in clinical diagnostics

Cellular structure	Molecular target	Disease associations
Coiled bodies	p80 coilin	Localized SSc, Raynaud syndrome
Golgi complex	Golgins, giantin	SLE, SjS, RA overlap syndromes, malignancy, viral infection
Mitotic spindle apparatus:		
Centrioles	Enolase, pericentrin, ninein	SSc, SjS, post-viral syndromes
NuMa pattern	NuMa 235	*Mycoplasma* infection
Spindle microtubules	HsEg5	SLE
Multiple nuclear dots	Sp-100, PML protein	Primary biliary cirrhosis
Nuclear envelope	Lamins A/C, B1, B2, LAP1/2	SLE, SjS, AIH, APS, SNP
Nuclear pore complex	p62, gp-210, Tpr	PBC, SjS
GW bodies	GW182	SjS, sensory/motor neuropathy

AIH, autoimmune hepatitis; APS, antiphospholipid antibody syndrome; NuMA, nuclear mitotic apparatus; PBC, primary biliary cirrhosis; RA, rheumatoid arthritis; SjS, Sjögren syndrome; SLE, systemic lupus erythematosus; SNP, seronegative polyarthritis; SSc, systemic sclerosis; Tpr, translocated promoter region.

Data from Peter and Shoenfeld, 1996; Bayer et al., 1999; Wiik, 2003a; Fritzler et al., 2003c; Stinton et al., 2004.

studies can easily be calculated. In Scandinavia, the estimated cost of all types of *in vitro* diagnostic testing in laboratories is between 2% and 3% of the total budget for healthcare. Diagnostic imaging techniques are now being used much earlier in spite of their much higher expense. Frequently, their clinical value with regard to the long-term prognosis has not been clearly elucidated. In the light of this significant expense, it is difficult to explain why low-cost and high-quality autoimmune serology is not given a higher priority by healthcare economists. The prospects for healthcare financing are very intimately linked to an accurate early diagnosis and treatment. Inappropriate laboratory testing (e.g., panel testing) is both costly and potentially misleading in the diagnostic workup. An estimation of long-term costs related to early accurate diagnosis and therapeutic intervention compared to a missed or a wrong diagnosis, with or without treatment, has to be performed to highlight the value of high-quality laboratory diagnostics. Factors that impact costs related to chronic diseases include the number of visits to clinics, length, and cost of stays in clinics, readmission rate, working days lost to patient and family, and productive years gained.

STANDARDIZATION AND QUALITY ASSURANCE

A set of standardized sera provided by the IUIS/AF/WHO/CDC Serology Committee (*www.ucalgary.ca/IUIS/index.htm*) is made available through the CDC in Atlanta (Smolen et al., 1997). The set of reference sera available through this program is continuously monitored and is currently being expanded to include antibodies to cardiolipin, β2-glycoprotein 1, fibrillarin, RNA polymerase I/III, ribosomal P proteins, proteinase 3 and myeloperoxidase (c- and p-ANCA, respectively). Sera used as standards for a particular methodology or technology platform need to be reviewed from time to time as exemplified by the re-evaluation of AF/CDC reference sera for immunoblotting purposes (Smolen et al., 1997). Although it would likely improve inter-laboratory variation in performance, standardized secondary antibodies are not widely available.

All clinical laboratories should participate in quality assurance and quality improvement programs such as the one administered by the College of American Pathologists (*www.cap.org*). The Clinical Laboratory Improvement Amendments of 1988 set standards for all laboratories engaged in clinical testing. These standards include requirements for trained and competent supervisory and testing personnel, record keeping and instrument maintenance, daily quality control practices, result reporting, and laboratory inspection and maintenance. It is not clear that these standards are being met in routine practice. In Europe the most widely used quality assurance and management program (DS/EN ISO/IEC 17025:2000) additionally sets laboratory standards aimed to prove that an assay actually gives results that are useful for clinical diagnostics.

SUMMARY

In contemporary medical practice, changes in laboratory diagnostics and new technologies are being introduced at a rapid pace. This is attended by concerns that certain key

matters (such as clinical utility) are not debated thoroughly between clinical and laboratory directors. It is important to avoid alienation of users and deliverers of potentially important information that should be used to set an early and precise diagnosis and estimate a likely prognosis. In many autoimmune diseases, autoantibodies are considered reporters of overt or subclinical organ or tissue damage. The detection of autoantibodies can serve as an indicator that focuses the clinician's attention to involved tissues or organs using classical diagnostic tools such as histopathology, imaging techniques, and organ function testing. Clinical guidelines to facilitate the communication between clinicians and laboratories can be formulated, mutually accepted algorithms for test ordering can be used, rules for reporting results must be agreed upon, and algorithms for optimal use of laboratory results should be adopted. A trade-off between sensitivity and diagnostic specificity always is ideally established before a test is made widely available, since cut-off values for a positive test, which are usually furnished by manufacturers, mainly separate a certain nosographic entity from the healthy population. This is not an ideal approach for differentiating between clinically related and overlapping autoimmune diseases.

The accuracy (sensitivity, specificity), reliability, and quality of many commercial kits have been a topic of study and concern. In many cases, the manufacturer has been assumed to be the root cause for these shortcomings; however, the use of commercial kits and their appropriate application in a clinical setting involves a rather complex chain of constituencies and events (Fritzler et al., 2003a). It has been suggested that a higher level of commitment and partnership between all of the participants is required to achieve the goal of improving the quality of patient care through the use of autoantibody testing and analysis (Wiik et al., 2004).

T Cell Assays

BART O. ROEP

Division of Autoimmunity, Leiden University Medical Center, Dept. of Immunohematology and Blood Transfusion, E3-Q, NL-2300 RC Leiden, The Netherlands

T cells play a critical role in the vast majority of autoimmune diseases. Although it is often not proven whether the actual tissue destruction is mediated by autoreactive T cells or by T-cell hyper-reactivity leading to loss of tolerance to self-determinants by other effector immune cells, efforts to identify and characterize the role of T cells in the pathogenesis of autoimmune diseases have focused on T-cell autoreactivity. Measuring T-cell reactivity in autoimmune disease is a different league compared with that in infectious diseases and transplantation. In marked contrast to T-cell reactivity against pathogens and allodeterminants, the targets of T-cell autoreactivity are often not known precisely, and the list of candidate autoantigens is endless. Many of the autoantigens are not target-tissue specific, and the reactivity against them is not disease specific. Moreover, T-cell autoreactivity is conceivably hampered by factors such as low precursor frequencies in circulation, no access to sites of inflammation, counteracting regulatory immune reactivities, ectopic expression of target autoantigens, and lack of appropriate co-stimulation. This chapter will focus on T-cell assays in human autoimmune disease, using type 1 (insulin-dependent) diabetes (T1D) mellitus as a model, which results from a T-cell-mediated autoimmune destruction of the pancreatic β cells in genetically predisposed individuals (see also Chapters 5, 36) (Roep, 1996; 2003). Therapies directed against T cells have been demonstrated to halt the disease process (Chapters 36, 76) and prevent recurrent β-cell destruction after islet transplantation. Less is known about the nature and function of these T cells, the cause of the loss of tolerance to islet autoantigens, why the immune system apparently fails to suppress autoreactivity, and whether (or which) autoantigen(s) are critically involved in the initiation or progression of disease.

ASSAYS TO DETECT T CELL AUTOREACTIVITY

Proliferation Assay

T-cell autoreactivity is not exclusive for any autoimmune disease. Consequently, efforts to determine T-cell autoreactivity linked with autoimmune diseases have been hampered by the false expectation that sensitive and specific technology exists that allows reproducible measures for disease activity (Box 73.1). Multiple and sometimes conflicting studies have identified a variety of aberrations in the cellular immune response to autoantigens in persons with the disease. Potential explanations for these discrepancies include incomparable techniques or culture conditions, diversity in the populations of patients or controls tested, and differences in autoantigen preparations.

Appreciative of the above notion, international workshops on T-cell autoreactivity are organized under the auspices of the international Immunology of Diabetes Society (IDS) to standardize immunoassays to allow comparison between different studies (Roep, 1999; Roep et al., 1999a; Peakman et al., 2001). First, the islet autoantigen quality

Box 73.1
Issues affecting progress in T-cell research in type 1 diabetes

- Lack of sensitive and reproducible detection assay
- Quality of recombinant autoantigens; choice of target autoantigen or peptide epitope
- Choice of control subjects
- Discordance between experimental models and human disease
- Inaccessibility to inflammatory lesion
- Relevance of circulating autoreactive T cells
- Potential hyper-responsive immune status in recent-onset patients
- Low precursor frequencies of circulating autoreactive T cells
- Limited diagnostic value (in cross-sectional studies) due to prevalence of autoreactive T cells in patients and controls.
- Immunoregulation
- Discordance between cellular and humoral autoimmunity
- Lack of technologies to detect autoreactive T cells
- False expectations
- Required expertise

control analyses indicate that the quality of recombinant autoantigen preparations requires improvement. For example, several T-cell clones specific for glutamic acid decarboxylase (GAD65) were unable to cross-react with GAD65 expressed in baculovirus, yeast, or bacteria. Nonetheless, responses could be measured to all autoantigen preparations evaluated in the workshop. Second, all participating centers were able to reproducibly measure T-cell responses to two identical samples of tetanus toxoid, but there was significant interlaboratory variation in sensitivity and extent of the proliferative response measured. Third, the results using candidate autoantigens indicated that although a few laboratories could distinguish patients with T1D from non-diabetic controls in proliferative responses to individual islet autoantigens, in general, no differences in T-cell proliferation between the two groups could be identified. This first T-cell workshop on T-cell autoreactivity in T1D confirms that this is a difficult area for interlaboratory investigations, but it provided insight towards future efforts focused on standardizing autoreactive T cell measurements.

Assay Standardization

At present, it is clear that measuring T-cell autoreactivity requires different skills, and higher sensitivity and specificity than standard assays suitable for measuring alloreactivity or T-cell responses against pathogens. Assay standardization has become essential. Some previously reported conflicting results can in part be explained by the observed interlaboratory variability. The inability to discriminate normal controls from patients suggests that measuring proliferative responses in peripheral blood mononuclear cells (PBMC) represents an incomplete picture of the immune response, perhaps complicated by difficulties in identifying suitable antigens and assays for standardized use. There is an excellent track record on standardization of assays for the detection of diabetes-associated autoantibodies (see also Chapter 36) (Bingley et al., 2001). Unfortunately, the experience gained in the latter efforts could not easily be translated to T-cell assay standardization studies in humans. Disappointment that may have arisen from the slow progress achieved in the standardization efforts could be attributable to unrealistic expectations, and lack of recognition of multiple and sometimes unique limitations associated with human T-cell assays (Atkinson et al., 2000).

Limitations to Measure T-Cell Autoreactivity

The most obvious limitation is the inability (for ethical and practical reasons) to conduct experiments *in vivo*. Inaccessibility to the target organ severely hampers the *in vitro* studies and limits our efforts to define surrogate markers of insulitis in cases of T1D. Yet, in other autoimmune diseases such as rheumatoid arthritis (Chapter 32), autoimmune thyroiditis (Chapter 35) and celiac disease (Chapter 51), the site of inflammation is accessible, while in other cases (e.g., multiple sclerosis, Chapter 46), immune samples can be isolated from cerebrospinal fluid (CSF) yielding relevant surrogate markers of disease activity. Levels of autoreactive T cells in circulation are much lower than those in inflammatory lesions. This contrasts the situation with autoantibodies. Unfortunately, the *in vitro* manipulation may introduce misleading artifacts that are associated with factors like the isolation procedure, antigen concentration, and source of serum in culture medium, etc. In addition, unlike autoantibody molecules, T cells cannot be frozen and thawed without affecting their functional capacities. In addition to these factors, simple enumeration of T cells before and after antigen stimulation is in many cases not mathematically feasible because the responding cells are present in very small frequencies in peripheral blood (i.e., less than 1 in 100,000 cells in the total cell population). Finally, the purity of the antigen preparations needed for detection of autoreactive T cells has been proven to be a critical variable to allow or prevent accurate measurements of circulating autoreactive T cells (Roep, 1999; Roep et al., 1999a; Peakman et al., 2001).

Perspectives for Assay Improvement

Due to the lack of technologies to determine T-cell autoreactivity, the insufficient quality of antigen preparations, and the difficulty of defining relevant immunogenic synthetic peptide epitopes of islet autoantigens, progress has been slow. In addition, the need for appropriately selected control subjects for comparison with diabetic individuals seems underestimated. Appreciating the contribution of HLA polymorphism in T-cell repertoire selection, tolerance induction, and antigen presentation, and the experience that autoimmunity becomes less pronounced with age, it is critical to choose HLA- and age-matched control subjects as references to determine the disease association of a given T-cell response. In fact, non-diabetic siblings of T1D patients have frequently been shown to respond more similar to their T1D relatives than unrelated controls. Considering the possibility that clinical onset of autoimmune disease may be accompanied by a generalized hyperimmune response, it should also be considered to include control subjects suffering from chronic inflammation unrelated to the autoimmune disease of study (Roep et al., 1995).

The T-cell committee of the Immunology of Diabetes Society has recommended a sensitive and reproducible assay for the detection of autoreactive T cells (Table 73.1). This assay provided useful surrogate markers for insulitis. Autoreactive T-cell reactivity against islet granules was associated with presence of insulitis in recent-onset diabetes, while established T1D and healthy controls showed intermediate and low reactivity, respectively. Reactivity against the non-diabetic recall antigen Tetanus Toxoid was comparable for the three groups (Figure 73.1). This T-cell assay was able to distinguish between control and T1D patient groups (Roep et al., 1995). However, on the individual basis, T-cell proliferation assays did not qualify as diagnostic, due to the lack of reactivity in a considerable proportion of new-onset patients (i.e., poor sensitivity), and increased responses to islet autoantigen in non-diabetic subjects (i.e., insufficient specificity) that are inherent to this type of technology. Nonetheless, due to the limited interassay variation of the assay in a given individual, this methodology was shown to provide useful and interpretable information when applied longitudinally in the context of islet reconstitution therapy (Roep et al., 1999b).

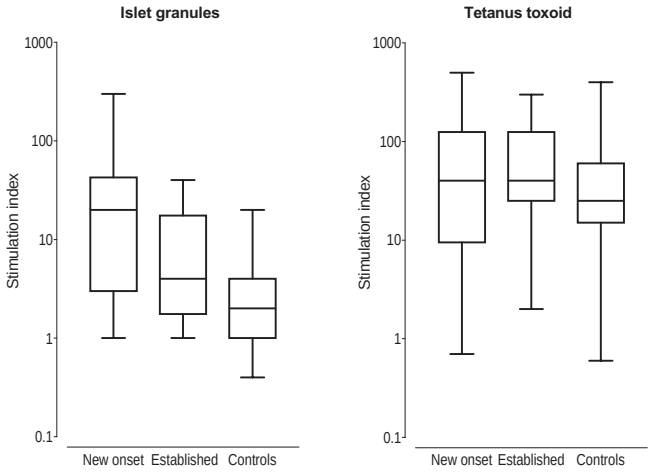

Figure 73.1 Proliferation Assay. T-cell proliferation provides a surrogate marker for the presence of autoimmune insulitis. *Left,* Children with newly diagnosed type 1 diabetes (T1D) have increased proliferative responses in peripheral blood mononuclear cells (PBMC) against insulin-secretory granule membrane preparations, compared with non-diabetic children with unrelated chronic inflammations. T1D patients with the disease for 6 months or more (with presumably no insulitis) still express increased autoimmunity, albeit less than patients at diagnosis. *Right,* T-cell responses to the recall antigen tetanus toxoid are not different between these three groups of subjects. T-cell responsiveness to antigen is indicated in stimulation indices (proliferactive (counts per minute of ^{3}H-thymidine in DNA) of PBMC to antigen divided by proliferation of PBMC in medium alone)

Modified from Roep et al., 1995.

Limiting Dilution Assay

One of the factors determining the magnitude of an immune response is the number of antigen-specific lymphocytes available to respond at the time of an antigenic challenge. Unlike regular proliferation assays that provide the total reactivity as a readout for mixed cell populations, culturing the T cells by limiting dilution can be used to estimate the actual number (frequency) of reactive T cells to various autoantigens. Limiting dilution analysis (LDA) is an established technique to assess immune response in humans in a quantitative manner at the level of the cell. It is a powerful *in vitro* tool for investigating the expressed human T-cell repertoire. Historically, LDA was developed to permit enumeration of cells induced to proliferate by *in vitro* exposure to antigen (Lefkovits and Waldmann, 1984). Past a certain cell dilution, an all-or-none response is seen, depending on the presence or absence of one type of cell, critical for reactivity. The application of Poisson statistics on the number of negative wells per cell concentration can be used to estimate the frequency of precursor T cells (cells undergoing clonal expansion and proliferation in response to a specific antigenic stimulus). Limiting dilution analysis also bears the advantage of relatively short culture periods *in vitro* and, consequently, results likely reflect the situation *in vivo* rather than T-cell clones that have undergone extensive stimulation *in vitro*.

Equal numbers of $CD4^{+}$ T cells recognizing myelin basic protein (MBP) and proteolipid protein (PLP) have been found in the circulation of normal individuals and multiple sclerosis (MS) patients (Zhang et al., 1994) (Chapter 46). While there were no differences in the frequencies of MBP- and PLP-reactive T cells after primary antigen stimulation,

TABLE 73.1 Protocol for proliferation assay for autoreactive T cells in peripheral blood mononuclear cells (PBMC)

Step	Details	Comments
Draw blood	B&D vacutainer system; Na or Li Heparin; 170 IU.	Shake tubes gently to avoid clotting
Ship sample	Room temperature	Heparin does not work at 4°C; make sure that the assay is performed within 24 hours after blood draw. Ship blood in heparin; do not ship Ficoll interphase
Ficoll gradient	Dilute up to 20 mL of blood to 35 mL in Hanks' balanced salt solution (HBSS) in 50 mL tube. Put 10 mL-pipet filled to top (~14 mL) with Ficoll (density 1.077 g/mL) under blood solution and release Ficoll passively under blood. Spin for 20 min at RT, 350 g, no brake.	Make sure that all solutions (Ficoll, media) are at RT. Keep blood >1 hour in heparin tube at RT before putting on Ficoll.
Remove interphase and wash interphase twice with HBSS and resuspend in IMDM supplemented with HS (20%)	280 g, RT, brake 2 mL IMDM/20% HS per 10 mL of heparinized blood	IMDM is not appropriate for cryopreservation (use RPMI 1640 w/o Hepes). Check each individual serum before pooling in mixed lymphocyte culture to ensure that sera qualify for proliferation assays. Also check pooled serum in MLR. HS is heterogeneous; reserve single pool for longitudinal and comparative studies.
Count mononuclear cells; dilute cells to 1.5×10^6/mL IMDM/20% HS	Dilute cells 1:10 in Türk solution, which lyses erythrocytes and stains nuclei	Counting of thawed cells is recommended in eosin, to exclude dead/dying (i.e., red) cells. ***N.B. cryopreservation affects monocytes, T-cell blasts and autoreactivity, and removes IL-10 from system.***
Add antigen preps to round-bottom 96 well plate.	Concentrate Ag prep 2 × in 100 µL per well; Ag medium: IMDM (no serum). Test dose response (final concentration of most recombinant antigens: 5–10 µg/mL; peptides: 2–10 µg/mL) Use tissue-coated plates.	Round-bottom plates are required for primary assays to ensure optimal cell–cell contact, while flat-bottom plates are recommended after initial *in vitro* stimulation. Adding Ag to wells first prevents spillover of cells (round-bottom!), and ensures that cells are kept under unfavorable conditions (pH, humidity, temperature) for minimum time. Include IL-2 triplicate as control for viability of T cells, PHA for control for APC function and proliferative capacity, and recall antigen (e.g., tetanus toxoid) for Ag-specific T-cell response.
Add cells to plate	100 µL ~150,000 cells/well	Add cells quickly with repetition pipette and move plate immediately to incubator.
Incubate	5 days, 37°C, 5% CO_2, 90% humidity.	Do not pile up more than 5 plates, to ensure gas exchange for medium buffering.
Add 0.5–1.0 µCi ^{3}H-thymidine; incubate overnight.	In 50 µL RPMI 1640.	
Harvest DNA	Semi-dry glass fiber filters are recommended for optimal signal/noise ratio (e.g., Wallac 1295–004) Betaplate™ 96-well Harvester (Pharmacia).	Ensure water is completely removed to prevent quenching of scintillation signal.
Measure cpm	E.g., Wallac 1205 liquid scintillation counter	

Ag, antigen; APC, antigen-presenting cell; cpm, counts per minute; HS, human pool serum; IL-2, interleukin 2; IMDM, Iscove's modified Dulbecco's medium; MLR, mixed lymphocyte reaction; RT, room temperature.

the frequency of MBP or PLP but not tetanus toxoid-reactive T cells generated after primary recombinant interleukin (rIL-2) stimulation was significantly higher in MS patients compared with control individuals. In the CSF of MS patients, MBP-reactive T cells generated with primary rIL-2 stimulation were 10-fold more frequent than in paired blood samples. In contrast, MBP-reactive T cells were not detected in CSF obtained from patients with other neurologic diseases (Zhang et al., 1994). These results provide definitive *in vitro* evidence of an absolute difference in the

activation state of myelin-reactive T cells in the central nervous system of patients with MS and provide evidence of a pathogenic role of autoreactive T cells in the disease.

In T1D, a progressive decrease in the number of negative cultures at increasing cell concentrations that was represented by a low goodness of fit (GoF, low chi square), was seen with the tetanus toxoid-response in new-onset patients, their siblings and parents; precursor frequencies and GoF were similar in all three groups. Reactivity to insulin, however, showed low precursor frequencies in patients and siblings, and the LDA to insulin demonstrated dramatic decreases in the number of positive cultures at higher cell concentrations leading to a high GoF in patients and siblings compared with parents (Naik et al., 2004). This saw-toothed pattern of reactivity to insulin is indicative of multiple hit kinetics and implies that the response is regulated. Consequently, the precursor frequency of insulin autoreactive cells in patients and their siblings are probably much higher than calculated.

Other Proliferation Assays

Recently, a novel assay was developed for antigen-specific human T-cell proliferation (Mannering et al., 2003). Peripheral blood mononuclear cells were labeled with the fluorescent dye 5,6-carboxylfluorescein diacetate succinimidyl ester (CFSE) and cells that proliferated in response to antigen, with resultant reduction in CFSE intensity, were measured directly by flow cytometry. This assay appeared more sensitive than ^{3}H-thymidine incorporation, and detected the proliferation of rare antigen-specific $CD4^+$ T cells at lower antigen concentrations. Using the CFSE assay, the investigators could measure directly the proliferation of human $CD4^+$ T cells from healthy donors in response to the T1D autoantigens glutamic acid decarboxylase (GAD) and proinsulin (PI), implying that this approach may not (yet) distinguish between affected and unaffected subjects.

HLA Tetramers

Fluorochrome-labeled major histocompatibility complex tetramers may enable investigators to enumerate antigen-reactive T cells. Soluble HLA-DR tetramers containing a peptide epitope from human GAD65 were used to analyze peripheral blood T cells of newly diagnosed T1D patients and at-risk subjects (Reijonen et al., 2002). Peripheral blood mononuclear cells were expanded on APCs presenting GAD65 peptide and subsequently activated with specific plate-bound class II-peptide monomers. T-cell activation defined in flow cytometry by CD4(high) and/or CD25 markers were observed in all T1D patients and some at-risk subjects, but not in normal control subjects. The activated T cells stained positive with tetramers containing the selected GAD65 epitope. Tetramer-positive cells were CD4(high) T cells with high avidity for an immunodominant GAD65 T-cell epitope. These results demonstrated that phenotyping of T cells utilizing HLA class II tetramers provides a new tool to characterize the autoimmune response in T1D. Shortcomings of this approach for identifying class II restricted cells are that the studies can only be done in individuals with certain HLA types, with reactivity to specific antigen peptides, and that it is necessary to expand the cells *in vitro* because of the low precursor frequency in the peripheral blood. Alternative assays using soluble MHC-multimers have also proven to be valuable tools for the stimulation of as well as the analysis of antigen-specific T cells *in vitro*. Dimeric major histocompatibility complexes coupled to immunoglobulin (HLA-Ig) and loaded with peptide epitopes have been used to visualize antigen-specific T cells and potentially stimulate immune responses as part of an artificial APC (Fahmy et al., 2002).

Cytokine Assays

Cytokines and chemokines are essential components in the communication between different components of the immune system, as well as in directing leukocytes to inflammatory lesions (see Chapter 18). Much interest has focused on the phenotype of the T-cell response that differentiates after activation (Chapter 7). Little is known of which cytokines and chemokines are associated with the pathogenesis of autoimmune diseases in humans, and to what extent they could reflect attempts of the immune system to counteract immune abnormalities including autoimmunity. There is a common belief that T1D, rheumatoid arthritis, autoimmune thyroiditis, and myasthenia gravis are Th1-associated diseases, i.e., associated with or accompanied by pro-inflammatory cytokines and chemokines, while Th2 cells could be beneficial or at least benign in fighting β-cell destruction. According to the quality of response they mediate, autoreactive T cells recognizing autoantigenic peptides could represent both disease effectors in the development of autoimmune disease and directors of tolerance in healthy individuals or those undergoing preventative immunotherapy. The rarity of these cells, inadequate technology, and poorly defined epitopes, however, has hampered examination of this paradigm.

Enzyme-Linked Immunospot Assays

The identification of sensitive assay formats capable of distinguishing islet autoreactive T cells directly *ex vivo* in blood is a major goal in autoimmunity research. Recently, much interest has been shown in the cytokine-enzyme-linked immunospot (ELISPOT) assay. The ELISPOT provides a highly sensitive assay to detect single cells secreting cytokines (Figure 73.2). The higher sensitivity of the ELISPOT compared with an ELISA is due to the plate-

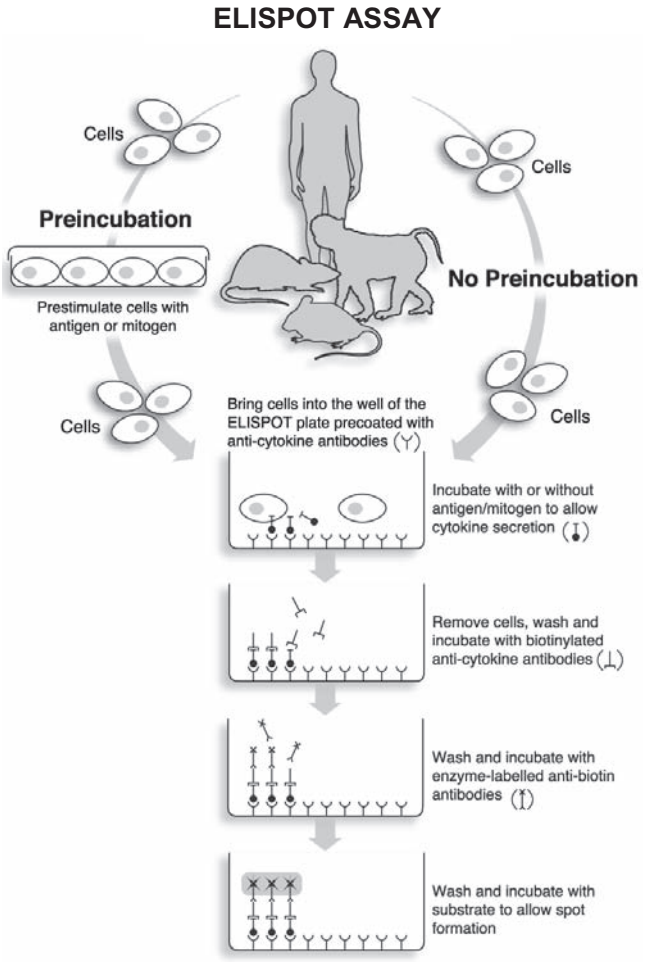

Figure 73.2 Flow diagram of the enzyme-linked immunospot (ELISPOT) assay. Cells are incubated for a defined length of time in the wells of the ELISPOT plate precoated with a high-affinity monoclonal antibody to which the cytokine, produced during incubation, will bind. Subsequently, cells are lysed and debris is washed away. Areas in which the cytokine has been captured by the coating antibody are detected with a combination of biotinylated anticytokine detector antibodies and enzyme-labeled streptavidin or antibiotin antibodies. The last step in the assay is the addition of a substrate yielding a colored zone ('spot'), which reveals the site of cytokine secretion. Numbers and sizes of spots can be read by light microscopy or through designated spot-readers followed by computer microimaging and analysis (Arif et al., 2004).

This diagram was kindly provided by Dr. Peter H. van der Meide, U-CyTech, Utrecht University, The Netherlands.

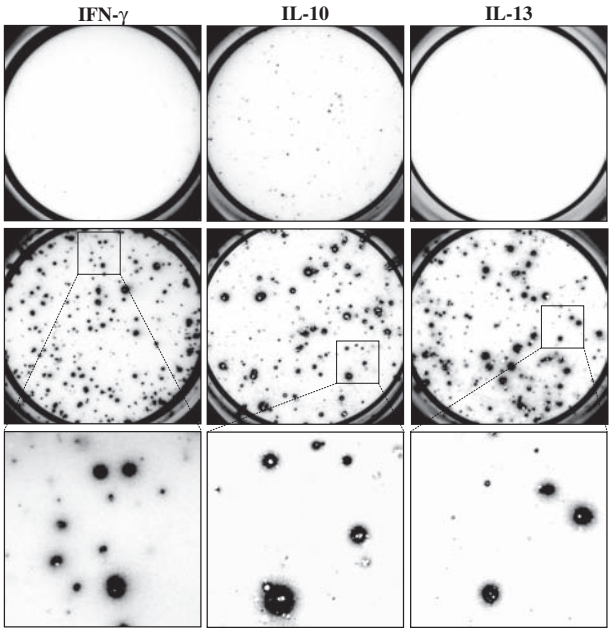

Figure 73.3 The ELISPOT Assay. Examples of interferon-γ *(left)*, IL-10 *(middle)* and IL-13 *(right)* specific spots produced by 2.5×10^4 human PBMC of a healthy subject (preincubation: 42 hours; incubation ELISPOT: 5 hours). *Top,* no stimulus (magnification 25×). *Middle,* concanavalin A stimulation (magnification 25×). *Bottom,* concanavalin A stimulation (magnification 140×).

Data provided by Dr. Peter H. van der Meide, U-CyTech, Utrecht University, The Netherlands.

bound antibodies directly capturing the cytokine secreted in the immediate vicinity of the cell before it is diluted in the supernatant, trapped by high-affinity receptors, or degraded by proteases (Figure 73.3).

A recent breakthrough that allowed distinction between T1D patients and non-diabetic controls was achieved by applying the ELISPOT assay using a panel of naturally processed islet epitopes by direct elution from APCs bearing HLA-DR4 (Arif et al., 2004; Herold, 2004). The quality of autoreactive T cells in patients with T1D showed extreme polarization toward a proinflammatory Th1 phenotype. Furthermore, rather than being unresponsive, the majority of non-diabetic, HLA-matched control subjects also manifested a response against islet peptides, but one that showed extreme bias to T regulatory cell (Treg, IL-10-secreting) bias. Development of T1D depends on the balance of autoreactive Th1 and Treg cells, which may be open to favorable manipulation by immune intervention (Chapters 9 and 10). The interferon-γ (IFN-γ) responses to combined pro-insulin and IA-2 peptides allowed for the first time to discriminate between T1D patients and control subjects. Moreover, the cells from the control subjects did not produce an IFN-γ response to the proinsulin peptides. IL-10 is a likely regulatory cytokine and would thus affect the cells recruited to the inflammatory site. The specificity of the immune regulation is imparted by the specificity of the responding T-cell receptor.

These recent findings also imply that a difference between healthy subjects and T1D patients is not in the repertoire and quantity of T-cells but is in the quality of the response, i.e., pathways of differentiation activated in response to antigen. Since the ELISPOT assay enumerates the number of cells producing a given cytokine, rather than

the total amount of this cytokine being produced, this approach did not allow for assessment of quantitative differences in terms of amounts of cytokine produced in responses to the antigens, so the full extent of differences in cytokine production between individuals with different rates of disease progression cannot be entirely determined. Yet, the qualitative differences suggest the mechanism described above.

Other Cytokine Assays

Given the low precursor frequencies of autoreactive T cells as evidenced by proliferation assays, limiting dilution assays, HLA tetramer studies, and ELISPOT analyses, it may prove very difficult to detect autoantigen-specific T cells after intracellular staining of cytokines after *in vitro* stimulation of PBMC by FACS analysis. Nonetheless, this approach has been reported to be applicable in infectious disease, tumor therapy, and transplantation to identify adaptive immune responsiveness. Preliminary studies suggested that new techniques such as the cytokine bead assay may turn out to be more useful to provide relevant surrogate markers of autoimmune disease. The advantage of such assays is that they require relatively small numbers of PBMCs, are less laborious, fast, and sensitive, while they can provide information on multiple cytokines and chemokines in small aliquots of supernatants of stimulated PBMCs.

T Regulatory Cells

The mechanisms involved in maintenance of peripheral tolerance and suppression of autoimmunity include a specialized subset of Treg within the $CD4^+CD25^+$ T-cell population. Recent interest has focused on these Tregs that represent a naturally occurring $CD4^+$ T-cell population expressing CD25 that arises from the thymus and seeds into the periphery, creating a cohort of cells with profound T-cell immunosuppressive qualities. No single phenotypic marker exists that is specific for Treg. $CD4^+CD25^+$ cells can be detected in peripheral blood in humans (Baecher-Allan et al., 2001) and are able to suppress proliferation and cytokine production from both $CD4^+$ and $CD8^+$ T-cells *in vitro* in a cell contact-dependent manner. Measuring the frequency and function of Treg might provide helpful information regarding the immunopathogenesis of the disease process. Hopefully, it will be a matter of time that testing of the frequency and function of circulating Treg becomes an important test parameter in clinical research involving patients. Recent studies indicate that the function and phenotype of these cells in human autoimmune diseases may differ from their counterparts in infection or alloreactivity, since their immune suppressive function *in vitro* appears to be impaired (Viglietta et al., 2004; Lindley et al., 2005).

Box 73.2
Perspectives for T-cell studies in autoimmune disease

- Unraveling of immunopathogenesis
- Definition for targets for immunotherapy
- Monitoring of immunologic and clinical efficacy of immunointervention trials
- Identification of triggers initiating autoimmune disease process
- Development of appropriate immunotherapy
- Guidance of immune regulatory therapy
- New technologies (ELISPOT assays, HLA tetramers, CFSE staining, LDA)

APPLICATION

Autoreactive T cells have proven to be valuable targets to study pathogenic or autoimmune disease related processes (Box 73.2). Measuring T-cell autoreactivity also provided critical information to determine the fate of islet allografts transplanted to T1D patients. Furthermore, these studies have provided proof of operational immunologic tolerance to islet allografts as well as valuable information to improve and customize immunosuppressive therapy. Presently, technologies to detect T-cell auto- and alloreactivity in T1D recipients of islet allografts are applied to monitor islet allograft survival in relation to various immunosuppressive therapies, and to guide tapering of these therapies after successful restoration of insulin production.

With the development of new technologies, such as ELISPOT assays and HLA tetramers that allow quick detection of peptide-specific T cells in the context of their restriction element, the stage has been set to improve the qualitative and quantitative detection of autoreactive T cells in autoimmunity. This will help to understand the cause of autoimmune diseases, and design and monitor immunotherapeutic intervention strategies. Although it is generally appreciated that studies on cellular auto- and alloimmunity are hampered by the complex nature of such immune responses and the required technical and physical skills, it has been a worthwhile quest to unravel the role of T cells in the pathogenesis of autoimmune disease.

CHAPTER

74

Prediction of Autoimmune Disease

JENNIFER M. BARKER AND GEORGE S. EISENBARTH

Barbara Davis Center for Childhood Diabetes, University of Colorado Health Sciences Center, 4200 E. 9th Avenue B-140, Denver CO 80262

Many autoimmune diseases are chronic in nature with a long asymptomatic preclinical period marked by laboratory abnormalities (e.g., the presence of autoantibodies; Table 74.1). Therefore, individuals with asymptomatic disease can be identified prior to developing tissue destruction with immunologic and immunogenetic testing. Given the prevalence of autoimmune disorders, immunologic and immunogenetic testing is likely to become an important component of what has been termed "personalized medicine." Accurate prognostication is dependent upon sensitive and specific assays in combination with an understanding of pathophysiology and the natural history of disease. In this review, we will emphasize studies of endocrine autoimmunity, especially type 1 diabetes (T1D) where techniques for disease prediction have developed since the mid-1980s.

OVERVIEW OF PREDICTION

Understanding of key concepts such as positive predictive value (PPV) and negative predictive value (NPV), sensitivity and specificity, and Bayes' theorem is essential to prediction of disease.

Sensitivity is the probability of a positive test, given that the individual has disease. Specificity is the probability of a negative test given that the individual does not have the disease. Sensitivity and specificity are generally thought of as independent of disease prevalence. The PPV is the probability of disease given that the test is positive. Conversely, the NPV is the probability of no disease given a negative test result (Table 74.2). Both PPV and NPV are influenced by disease prevalence.

Table 74.3 demonstrates the influence of disease prevalence on PPV and NPV. In this table, assume a test with sensitivity of 90% and specificity of 99% with a low prevalence state of 0.3% and a high prevalence state of 5% in a hypothetical population of 100,000 individuals. Prevalence was chosen to approximate T1D in the general population (0.3%) and for first-degree relatives of patients with T1D (5%). Prevalence highly influences the PPV of a study. As the prevalence of a disease increases the proportion of positives that are "true positives" increases. Therefore, when attempting to predict disease, it is essential to understand the prevalence of the disease in the population of interest and the ability of a test to identify those with disease correctly (the sensitivity and specificity of the test).

Bayes' theorem mathematically relates the probability of a disease in an individual after a study is performed (post-test probability) to the probability of a disease before the study is performed (pre-test probability), the sensitivity and

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

specificity of a study and disease prevalence by the following equation:

$$\text{Post-test probability} = \frac{\text{Pre-test probability} \times \text{test sensitivity}}{(\text{Pre-test probability} \times \text{test sensitivity}) + (1 - \text{disease prevalence}) \times (1 - \text{specificity})}$$

When the pre-test probability of disease is the prevalence of disease, this equals the PPV of a test.

It should be noted that Bayes' theorem is a simplification of complex probabilities. It assumes a binary study outcome and independence of study results and pre-test probability. Predicting post-test probability with the use of a test is most helpful in cases of intermediate pre-test probability where a positive or negative study will influence diagnosis. In a diagnostic algorithm that incorporates multiple studies, the probability of disease increases with each positive test.

It is sometimes thought that to increase sensitivity one must decrease specificity. That is correct for any given specific test or algorithm of tests but, in the real world of clinical testing, we can change the test (e.g., a new method that increases sensitivity and specificity) and apply a different testing algorithm. An example is the analysis of three anti-islet autoantibodies, rather than a single autoantibody for prediction of T1D. The presence of two or more anti-islet autoantibodies has a very high sensitivity and specificity compared with single positive anti-islet autoantibody.

TABLE 74.1 Representative disease-associated autoantibodies

Disease	Autoantibodies
Type 1 diabetes	Islet cell autoantibodies
	Insulin, GAD65, IA-2
Thyroid disease	Anti-thyroid peroxidase
	Anti-thyroglobulin
Addison's disease	Anti-21-hydroxylase
Celiac disease	Anti-tissue transglutaminase
Multiple sclerosis	Anti-myelin oligodendrocyte glycoprotein
	Anti-myelin basic protein (MBP)
Rheumatoid arthritis	Rheumatoid factor (IgM anti-IgG)
	Anti-cyclic citrullinated peptide

TYPE 1 DIABETES MELLITUS AS A MODEL FOR PREDICTION OF AUTOIMMUNE DISEASE

The chronic disease model for T1D (Figure 74.1) is a useful model for the prediction of T1D. In this model, the mass of insulin-producing pancreatic β-cells is depicted on the y-axis and time on the x-axis (Eisenbarth, 1986). As the disease progresses, the β-cell mass decreases and markers of autoimmunity such as autoantibodies against islet-specific proteins and islet-specific T cells emerge. As the β-cell mass diminishes, metabolic abnormalities develop and ultimately clinical diabetes manifests. Studies can be performed at each step along the way to identify individuals at risk for clinical diabetes.

Genetics

Although more than 85% of individuals with T1D do not have a family history of T1D, the risk for diabetes in a first-degree relative of an individual with T1D is approximately 15 times greater than that of individuals from the general population (6% vs. 0.4%) (Tillil and Kobberling, 1987). The major histocompatibility complex (MHC) located on chromosome 6 (6p21.3) is thought to contribute 50% of the genetic risk for T1D (Nerup et al., 1974). Noble et al. (1996)

TABLE 74.2 Sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV)

Study	Disease present	Disease absent
Positive	A (true positive)	B (False positive)
Negative	C (false negative)	D (True negative)
Sensitivity = A/(A+C)	PPV = A/(A+B)	
Specificity = D/(B+D)	NPV = D/(C+D)	

TABLE 74.3 Effect of disease prevalence on positive predictive value (PPV) and negative predictive value (NPV) with identical test specificity (99%) and sensitivity (90%)

	Low prevalence (0.3%)			High prevalence (5%)		
Test	**Disease present**	**Disease absent**	**N**	**Disease present**	**Disease absent**	**N**
Positive	270	997	1267	4500	950	5450
Negative	30	98703	98733	500	94050	94550
Total	300	99700	100000	5000	95000	100000
PPV	270/1267 = 21.3%			4500/5450 = 82.6%		
NPV	98703/98733 = 99.97%			94050/94550 = 99.5%		

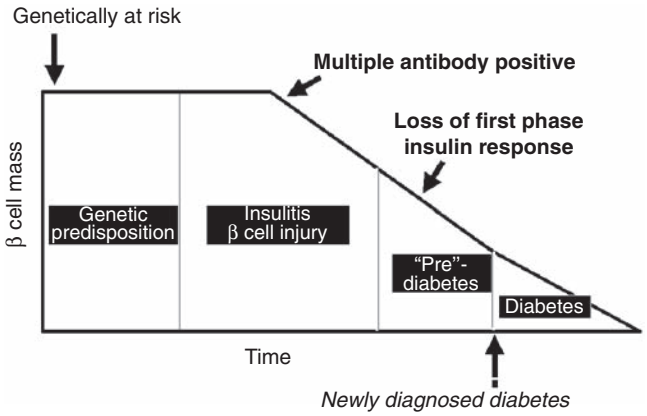

Figure 74.1 Stages in the development of type 1 diabetes. A model for the natural history of the autoimmunity leading to type 1A diabetes. Individuals who are genetically susceptible to disease are triggered to initiate insulitis or β cell injury. This is marked by the production of autoantibodies against the pancreas. As loss of β cell mass continues, metabolic abnormalities such as a loss of first-phase insulin response begin, and ultimately when enough β cells are lost, diabetes develops.

and Erlich et al. (1993) have shown that both DQ and DR alleles have been associated with T1D. The HLA haplotypes associated with the highest risk for T1D are DR3-DQ2 (DQA1*0501, DQB1 *0201) and DR4-DQ8 (DQA1*0302 DQB1*0302) (Ziegler et al., 1991).

It is estimated that approximately 6% of the population with DR3-DQ2/DR4-DQ8 will develop T1D. However, the risk of diabetes in first-degree relatives with these high-risk HLA haplotypes is much higher. Approximately 40% of first-degree relatives with DR3-DQ2/DR4-DQ8 will develop T1D. This suggests that other genetic loci within the MHC may also contribute to risk of T1D in that relatives with these fixed class II alleles usually share complete MHC haplotypes. These high-risk genotypes also impact the age at which T1D develops. Approximately 50% of those who develop T1D prior to 5 years of age are heterozygotes for DR3-DQ2/DR4-D8 compared with 2.4% of Colorado newborns (Redondo et al., 2001).

Specific HLA haplotypes protect individuals from disease. Similar to many studies, Pugliese et al. (1995) have reported that DR2 (DRB1*1501, DQA1*0102, DQB1*0501) and DR7 with DQA1, DQB1*0301, and DRB1*1401 are protective for the development of T1D.

Additional genetic loci such as the insulin gene (Bell et al., 1984; Bennet et al., 1997), CTLA-4 (Nistico et al., 1996; Lowe et al., 2000), lymphocyte specific tyrosine phosphatase (gene-*PTPN22*) (LYP) (Bottini et al., 2004) and other loci with as yet undetermined gene products have also been associated with risk for the TID.

HLA haplotypes and, to a lesser extent, insulin gene polymorphisms are the only genetic markers that have been used to identify individuals from the general population at high-risk for the development of T1D. Studies such as the Diabetes Autoimmunity Study in the Young (DAISY) in Denver, Colorado, USA (Rewers et al., 1996) and the Finnish Type 1 Diabetes Prediction and Prevention project (DIPP) (Kupila et al., 2001) follow children from the general population who are at high-risk for the development of T1D based upon the presence of moderate- or high-risk HLA genotypes.

The presence of high-risk HLA genotypes increases the likelihood of T1D by an order of magnitude. Individuals with the highest-risk HLA haplotypes and no family history of diabetes have a risk for T1D of approximately 6%, compared with a risk of 0.4% in the overall population (Tillil and Kobberling, 1987). In first-degree relatives this risk increases from approximately 6% to approximately 40% in those with the highest-risk HLA genotypes. Therefore, knowledge of HLA genotype improves predictive ability. However, risk is not absolute, with a significant subset of individuals with high-risk HLA genotypes never developing islet autoimmunity. Further evaluation, including the use of anti-islet autoantibodies will refine prediction.

Laboratory Markers of Autoimmunity (Including Autoantibodies and T-cell Assays)

Since the discovery of islet-cell autoantibodies (ICA), detected by incubation of serum with sections of frozen human pancreas (Lendrum, 1975; Bottazzo et al., 1980), autoantibodies have been used to identify individuals at risk for T1D. The ICA level is measured in Juvenile Diabetes Foundation (JDF) units with positive often defined as ≥10 JDF units. Bonifacio et al. (1990) and Chase et al. (1991) have shown that the risk for diabetes increases as the ICA level increases. In first-degree relatives, the risk for T1D increases from 40% with a low cut-off (≥4 JDF units) to 100% (in one study) with a high cut-off (≥80 JDF units) (Bonifacio et al., 1990). The relationship between ICA level and PPV for diabetes has also been observed in cohorts without an affected first-degree relative (Chase et al., 1991).

The specific antigens of ICA include the 65 kDa form of glutamic acid decarboxylase (GAD65) and the protein tyrosine phosphatase ICA512 (IA2). Insulin autoantibodies are not detected with the staining of frozen pancreas. These three autoantibodies are the current so-called "biochemical autoantibodies." Sensitive and specific radioimmunoassays (RIAs) have been developed for autoantibodies to insulin, GAD65, and IA2. When ICA are present in the company of biochemical autoantibodies, the risk for T1D increases. Individuals who expressed ICA alone were at a much lower risk for T1D (5%) compared with those positive for ICA and biochemical autoantibodies (66.2%) (Maclaren et al., 1999). Yu et al. (2001) demonstrated that higher levels of ICA are associated with expression of one or more biochemical

autoantibodies. Therefore, the risk conferred by ICA can also be identified through testing for biochemical autoantibodies.

Life-table analysis has shown that expression of multiple biochemical autoantibodies is associated with a greater risk for T1D (Figure 74.2). Individuals who express three anti-islet autoantibodies are at an approximately 70% risk for T1D after 5 years, compared with 12% for those who express one anti-islet autoantibody (Verge et al., 1996).

Studies from the USA and Finland have shown that autoantibody production can begin in the first year of life (Rewers et al., 1996; Kimpimaki et al., 2001). Individuals can persist with positive autoantibodies many years prior to the development of T1D (Bingley et al., 1994; 1997). The risk for T1D does not appear to dissipate over time for individuals with multiple autoantibodies. Gardner et al. (1999) followed first-degree relatives with multiple autoantibodies and found a progressive increase in incidence of T1D over time, such that at 15 years 66% had developed diabetes. The development of diabetes did not appear to be decreasing at the end of the study. This has led to the hypothesis that all individuals who express multiple autoantibodies will develop diabetes given enough time. In contrast, the expression of a single biochemical autoantibody is associated with a long-term risk of approximately 20% in relatives of patients with T1D. Transient expression of autoantibodies in the DAISY study was not associated with high-risk genotypes or family history of diabetes (Yu et al., 2000) and the development of T1D (Barker et al., 2004a). Conversely, Pietropaolo et al. (2002) have observed first-degree relatives with high-risk HLA genotypes developing classic insulin deficiency and diabetes without the presence of autoantibodies, suggesting that there are immunologic abnormalities that are not captured with standard autoantibody assays.

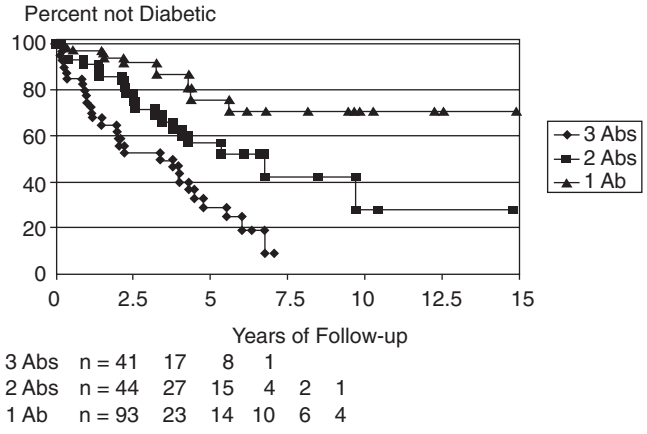

Figure 74.2 Progression to diabetes versus number of autoantibodies (GAD, ICA512, insulin). First degree relatives of individuals with T1D were followed for development of diabetes. Those relatives who expressed more than 2 or 3 autoantibodies were at a greater risk for the development of diabetes compared with those who expressed one autoantibody. The numbers along the bottom of the figure indicate the numbers of subjects in each group still followed at that time period.

Adapted from Verge, et al., 1996.

LaGasse et al. (2002) have used biochemical autoantibodies to screen school children in Washington State, USA. Approximately 4500 school children were screened, 12 children were found to have two or three positive autoantibodies. Six children developed diabetes during the 8-year follow-up. All expressed at least two autoantibodies. None of the children with zero or one autoantibody developed diabetes. This indicates that autoantibodies can be used in a large population to screen for disease.

The DAISY study has identified children with biochemical autoantibodies and followed them for the onset of diabetes. Children diagnosed with this intensive screening program tend to be found at an earlier stage of disease and have less diabetic ketoacidosis (Barker et al., 2004b). These children also have lower blood glucoses at the time of diagnosis (Figure 74.3).

The use of autoantibody assays has identified individuals previously classified as type 2 diabetics as having an autoimmune process associated with a faster progression to insulin dependency compared with autoantibody-negative individuals. Approximately 45% of such adults positive for ICA required insulin at 6 years post-onset of diabetes compared with 5% of those with no autoantibodies. This so-called "latent autoimmune diabetes of adults (LADA)" was analyzed in the UKPDS study (Turner et al., 1997). Similarly, Fuchtenbusch et al. (1997) have demonstrated that, in women with gestational diabetes, the presence of one, two, or three autoantibodies conferred a risk for insulin dependency of 17%, 61%, and 84%, respectively, during follow-up of approximately 2 years. Autoantibodies can be used in adults diagnosed with diabetes as a prognostic factor for insulin dependency.

Multiple international workshops evaluating different assay formats for islet autoantibodies in mouse models of T1D and in humans indicate that standard ELISA formats

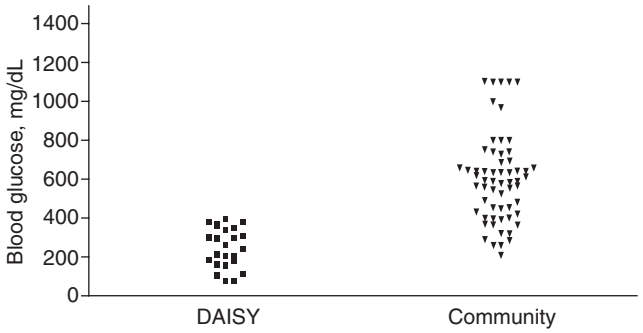

Figure 74.3 Blood glucose levels at diagnosis in children diagnosed with diabetes through an intensive screening program (Diabetes Autoimmunity Study in the Young [DAISY]) compared with those diagnosed from the community.

are inadequate in contrast to fluid phase radioassays. For example, ELISA anti-insulin autoantibody assays could detect insulin antibodies following subcutaneous insulin therapy but could not detect pre-diabetic insulin autoantibodies (Greenbaum et al., 1992) (Figure 74.4). A recent GAD65 atypical autoantibody enzyme-linked immunosorbent assay (ELISA) was configured with a very low density of GAD65 on the plate so that only a single binding site of the autoantibody reacted. The presence of autoantibody was detected by "fluid-phase" reaction of tagged GAD65 and performed as well as fluid-phase radioassays in the 2004 Diabetes Autoantibody Standardization Program (oral communication workshop results). A similar format for detection of IA2 autoantibodies was not as sensitive. In general, fluid-phase radioassays utilizing specific precipitants (e.g., protein A) provide the best sensitivity and specificity and can be performed in 96-well formats. It is relatively easy to develop such assays for protein antigens, with *in vitro* transcription and translation of cDNA to produce labeled autoantigen.

Type 1 diabetes is known to be a T-cell-mediated disease. Autoantibodies are likely only a marker of the autoimmune process and are not themselves directly pathogenic. Therefore, efforts are underway to develop reliable T-cell assays for T1D (see Chapter 73). Tetramer analysis has allowed for the detection of T cells that react to β cell antigens. Tetramer analysis employs the use of multimeric peptide-MHC complexes to detect T cells. Using this technology, soluble HLA-DR401 or DR404 tetramers with a GAD65 epitope were found to react with T cells of newly diagnosed T1D and individuals at risk for T1D (Reijonen et al., 2002; 2003). Further refinement of the tetramer assay is necessary in order to use these assays for disease prediction. Enzyme-linked immunospot (ELISPOT) assays are also being evaluated. In particular, a $CD8^+$ T-cell response to a peptide of islet amyloid polypeptide (IAPP) has been described (Panagiotopoulos et al., 2003).

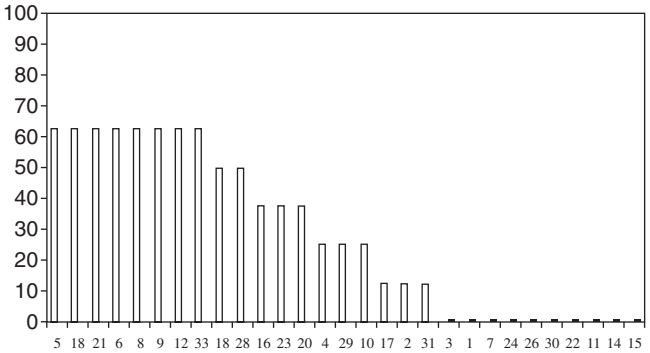

Figure 74.4 Percentage of positive insulin autoantibodies (IAA) (defined as ≥3 SD above the mean) by laboratory in healthy individuals who became diabetic (n = 8). Numbers along the y-axis indicate different laboratories. Open bars are laboratories using radioimmunoassay (RIA) and closed bars are those using enzyme-linked immunosorbent assay (ELISA).

Metabolic Studies

Metabolic abnormalities begin to appear as the β cell mass diminishes to the point where it cannot appropriately respond to a glucose load. The first metabolic abnormality identified is the loss of the first-phase insulin response (FPIR) on the intravenous glucose tolerance test (IVGTT). The FPIR is the sum of the insulin levels at 1 and 3 minutes after an intravenous glucose load. In the presence of islet autoantibodies, levels that are less than the first percentile of age-matched normal controls identify individuals that are at a 50% risk for the development of overt diabetes at 5 years and 90% at 10 years (Bleich et al., 1990; Bingley et al., 1992). This relationship remains true in individuals who are positive for anti-islet autoantibodies (Bleich et al., 1990). In the DIPP study, Keskinen et al. (2002) have followed children with multiple anti-islet autoantibodies and shown that they have lower FPIR than children with ICA only (Figure 74.5), and that half of the children with abnormal FPIR developed overt diabetes during the time period of the study. The metabolic state of an individual at risk for T1D is dynamic and β cell loss may be ongoing, so repeat evaluation is necessary in order to be maximally sensitive. In addition to being able to correctly identify individuals at risk for overt diabetes, a FPIR greater than the 10th percentile has a

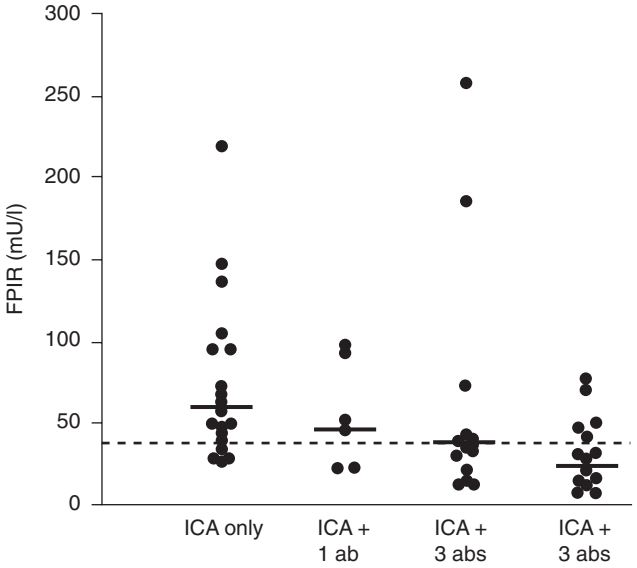

Figure 74.5 The level of first-phase insulin secretion (FPIR) is associated with the number of positive autoantibodies (abs), children with three autoantibodies expressed the lowest FPIR. The dotted line represents the first percentile in age-matched normal controls. (ICA, islet-cell autoantibodies.)

Adapted from Keskinen et al., 2002.

good NPV. Relatives with FPIR greater than the 10th percentile rarely progress to T1D over a 3-year period. Using the FPIR in addition to autoantibody data led to the development of a model of risk for T1D. In this model, the time remaining before the development of T1D was dependent upon the FPIR and insulin autoantibodies (IAA) level (Jackson et al., 1988).

The FPIR is not without problems. It is a measure of β cell function, and, therefore, only an indirect measure of β cell mass. As such, situations that increase insulin resistance such as puberty and obesity may affect the results. In addition, there is significant intra-subject variability with coefficients of variation ranging between 4 and 36% (Smith et al., 1988; Allen et al., 1993; Arslaninan and Austin, 1993). The timing of loss of FPIR differs in the progression to T1D in different groups. For example, in young children who express autoantibodies, the FPIR may already be lost at the time of first autoantibody expression (Keskinen et al., 2002) and some individuals maintain FPIR into their first year of diagnosis of T1D.

As the β cell mass continues to diminish, the metabolic abnormalities become more pronounced and may be detected in routine oral glucose tolerance testing, initially with impaired glucose tolerance (glucose 2 hours after oral glucose ≥140 mg/dL and <200 mg/dL). It is of note that early in the time course of T1D, the metabolic abnormality may not be observed in the fasting state. At this point, the individual is not symptomatic but may rapidly progress to symptomatic diabetes.

ORGAN-SPECIFIC AUTOIMMUNE DISEASES

Thyroid

Autoimmune thyroid disease (AIT) manifested as either hypothyroidism or hyperthyroidism is very common in the general population. Approximately 5% of the population is hypothyroid and 1.3% hyperthyroid (Hollowell et al., 2002). Autoimmune thyroid disease occurs at an increased frequency in individuals with T1D (28% [Umpierrez et al., 2003]), Addison's disease (AD) (14–21% [Betterle et al., 2002; Zelissen et al., 1995; Kasperlik-Zaluska et al., 1998]), celiac disease (CD) (up to 12% [Ansaldi et al., 2003]), and other autoimmune diseases. Therefore, the first step in prediction requires knowledge of the individual's medical history. Routine screening for thyroid disease is generally recommended in these individuals as there is a high pre-test probability of disease and the studies are relatively non-invasive.

Risk for AIT is weakly related to HLA genotypes that vary dependent upon the population. Sanatamaria et al. (1994) reported that *DRB1*0201* increased the risk for AIT in T1D. Kim et al. (2003) reported that *DQB1*0401* increased the risk in the Korean diabetic population. *DQB1*0302* has been associated with AIT in the Czech diabetic population (Sumnik et al., 2003). DR3 and DR5 have been associated with thyroid autoimmunity in German blood donors (Boehm et al., 1993).

Autoimmune thyroid disease is accompanied by autoantibodies to thyroid antigens thyroid peroxidase (TPO) and thyroglobulin (TG) (Vakeva et al., 1992). These autoantibodies are positive in approximately 10% of the general population (Hollowell et al., 2002) and in around 90% of the hypothyroid population (Vakeva et al., 1992). Prospective follow-up by Vanderpump et al. (1995) in the Whickham study has shown that women with positive TPO autoantibodies and normal thyroid stimulating hormone (TSH) have a 2.1% per year risk of developing hypothyroidism with an overall risk of 27% of hypothyroidism at 20 years.

In high-risk populations such as T1D, progression to AIT is related to the presence of TPO and TG antibodies, with approximately 80% of individuals with T1D who are positive for TPO antibodies progressing to AIT compared with 15% of those who are TPO-negative (Umpierrez et al., 2003) (Figure 74.6). Of note, individuals negative for TPO autoantibodies still progressed to AIT but at a much lower rate.

Similar to T1D in which abnormalities of glucose metabolism identify individuals at a greater risk for clinical diabetes, individuals who have abnormalities of thyroid metabolism are at an increased risk for the development of overt hypothyroidism. Of those with an elevated TSH and normal thyroid hormone, 55% were hypothyroid at 20 years, with a 4.3% yearly incidence.

Screening for thyroid autoimmunity in high-risk populations such as T1D with TPO and/or TG autoantibodies may

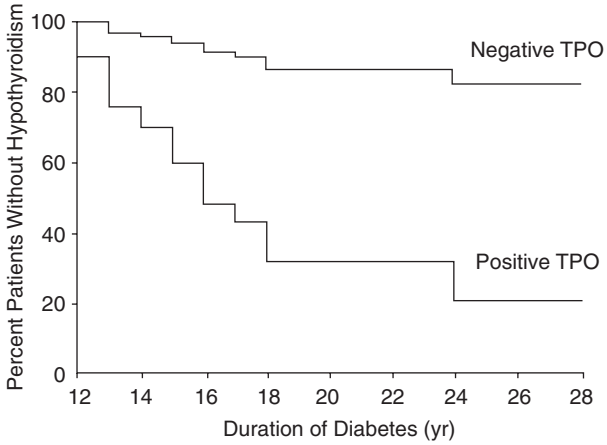

Figure 74.6 The development of hypothyroidism in the diabetic population is dependent upon the production of thyroid autoantibodies. Individuals who express autoantibodies to thyroid peroxidase (TPO) are at a much higher risk for hypothyroidism compared with those who do not.

Adapted from Umpierrez et al., 2003.

identify individuals at an increased risk for autoimmune thyroid disease for closer monitoring. The efficacy of this screening has not been fully evaluated.

Addison's Disease

Addison's disease is an autoimmune endocrine disease resulting in primary adrenal insufficiency. It is a rare disease in the general population, occurring in approximately 1 in 10,000 individuals. However, it does occur with other autoimmune endocrine diseases including T1D and AIT. The combination of two of the three autoimmune diseases (T1D, AD, and/or AIT) is known as autoimmune polyendocrine syndrome II (APS-II).

Genetic risk for AD is conferred by the MHC on chromosome 6. This includes the HLA class II region. AD is associated with DRB1*0404 DQ8 (Yu et al., 1999). Gambelunghe et al. (1999) and Park et al. (2002) have independently shown that polymorphisms of other loci within the MHC including MIC-A are associated with AD both in the diabetic and nondiabetic populations. Follow-up of individuals with T1D and 21-hydroxylase has shown that homozygosity for the MIC-A5.1 polymorphism is associated with an increased progression to clinical AD (Barker et al., in press). MIC-A encodes a ligand for a receptor found on T cells. This interaction may be important in thymic maturation of T cells (Hue et al., 2003) providing an attractive hypothesis for the importance of MIC-A in the development of autoimmune disease.

Addison's disease is accompanied by the production of autoantibodies against the adrenal cortex (Anderson et al., 1957). Since this report, Winqvist et al. (1992) and Baumann-Antczak et al. (1992) have identified the cytochrome p450 enzyme 21-hydroxylase as the major antigen for these antibodies. Falorni et al. (1997) have shown that 21-hydroxylase autoantibodies are highly sensitive and specific for AD. Reflecting the increased risk for AD in people with T1D, individuals with T1D express adrenal autoantibodies at a rate of 1–2% (Brewer et al., 1997; Peterson et al., 1997; Yu et al., 1999).

Adrenal function is tested using tetracosactide (cortrosyn; ACTH) stimulation. Baseline blood work consisting of ACTH, cortisol and plasma renin activity (PRA) are obtained and then a stimulatory dose of tetracosactide is given and cortisol levels are measured 30–60 minutes later. Boscaro et al. (1994) have proposed a sequence of events starting with the expression of adrenal autoantibodies and culminating in full-blown adrenal insufficiency. In their cohort, the first metabolic abnormality detected was an elevated baseline PRA. In our group of patients with T1D and 21-hydroxylase autoantibodies, elevated ACTH was a sensitive and specific predictor of abnormalities of stimulation testing (Barker et al., in press).

Celiac Disease

Celiac disease is an autoimmune disease characterized by gluten insensitivity. Symptoms range from malabsorption, diarrhea, and stunted growth to less specific symptoms of fatigue and malaise. Celiac disease can be found in the company of T1D and AIT, occurring in as many as 10% of individuals with T1D (De Vitis et al., 1996) and AIT (Ansaldi et al., 2003).

Celiac disease occurs in association with specific HLA genotypes. In individuals with T1D who are homozygous for HLA DQ2, approximately one-third are positive for autoantibodies to tissue transglutaminase (tTG) (Bao et al., 1999). Ninety-five percent of individuals with CD have HLA DQA1*0501, DQB1*0201, compared with 36% of the general population (Hall et al., 1991). DQA1*0501, DQB1*0201 generally occurs with DR3-DQ2 (DQA1*0501 DQB1*0201) and DR5, DR7 heterozygotes (DRB1*0701 DQA1*0501). Hoffenberg et al. (2003) have prospectively followed neonates from the general population with the high-risk DR3-DQ2 HLA haplotypes in Denver, Colorado. Children with high-risk haplotypes were enrolled and followed for the development of autoantibodies to tTG. At age 5 years, 3.2% of children DR3/3 homozygous developed positive tTG compared with 3.4% of heterozygotes and 0.3% of children negative for DR3 (Figure 74.7).

Celiac disease is associated with the expression of autoantibodies. Antibodies against gliadin (IgG and IgA) are sensitive but not specific and, therefore, have a low PPV. In contrast, anti-endomysial autoantibodies (EMA) are highly sensitive and specific; they are detected with indirect immunofluorescense against human umbilical cord.

Figure 74.7 Percentage of the general population with tissue transglutaminase by HLA DR type. The production of tissue transglutaminase autoantibodies is highly dependent on the presence of HLA DR3. The numbers along the bottom of the figure indicate the numbers of subjects in each group still followed at that time period.

Adapted from Hoffenberg et al., 2003.

Recently tissue transglutaminase (TG2) has been identified as the autoantigen of EMA and highly sensitive and specific assays have been developed to detect TG2 autoantibodies (Dieterich et al., 1997; Fasano and Catassi, 2001; Gillett et al., 2001) (see Chapter 51).

Diagnosis is made by biopsy of the small intestinal mucosa showing the characteristic pathologic changes and confirmed with resolution of these findings on biopsy after institution of a gluten-free diet. Because of the invasiveness of the procedure, biopsy should be performed only in individuals with a high likelihood of being positive. Factors that increase the pre-test probability of disease include individuals who are symptomatic of disease and individuals with higher levels of autoantibody as measured by the radioimmunoassay. Liu et al. (2003) have shown that higher levels of TG2 in a radioimmunoassay had a higher PPV for biopsy positivity. The standard cut-off of 0.05 (99% specificity) had a PPV of 76% compared with 96% with a cut-off of 0.5. In addition, the level of TG2 autoantibody has been shown to correlate with severity of findings on biopsy (Tursi et al., 2003). Therefore, level of autoantibody can be incorporated in an algorithm to decide whether or not to perform the biopsy. The autoantibody levels also decrease on a gluten-free diet and are used to monitor compliance with therapy.

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic autoimmune disease resulting in neurologic deficits. It occurs in the setting of specific HLA alleles. DRB1*1501 has consistently been shown to predispose to MS (Allen et al., 1994; Laaksonen, et al., 2002). In a large group of patients, this has been shown to have a dose effect with two copies of the susceptible haplotype associated with a higher risk of MS compared with one or none. Those individuals who express DRB1*1501 on both HLA DRB1 alleles tend to have a more severe disease course (Barcellos et al., 2003).

Autoantibody determinations in these groups are less well defined compared with the other autoimmune disease discussed. Berger et al. (2003) have used western blot analysis looking for antibodies against the autoantigens myelin oligodendrocyte glycoprotein (MOG) and myelin basic protein (MBP) to predict "clinically definite multiple sclerosis" after a first demyelinating event. Individuals who were positive for anti-MOG and anti-MBP had a quicker relapse (7.5 ± 4.4 months) compared with those who were positive for only one autoantibody (14.6 ± 9.6 months) and those positive for neither (45.1 ± 13.7 months). In addition, a much higher proportion of individuals positive for one (83%) or two (95%) autoantibodies progressed to clinically evident MS compared with those who were negative for both antibodies (23%). This initial report requires confirmation, as determination of disease-specific autoantibodies with western blot assays in MS has proven difficult.

NON-ORGAN-SPECIFIC DISEASE

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a systemic autoimmune disease. It is characterized by joint inflammation, ultimately leading to joint destruction and disability. At diagnosis, individuals often show signs of advanced joint destruction. Landewe et al. (2002) have shown that early treatment decreases disease severity. Therefore, the ability to predict disease and diagnose individuals early would have high clinical utility.

Rheumatoid arthritis is associated with HLA-DR4 (HLA-*DRB1* 0401* and *DRB1*0404*) with the strongest association to *DRB1*0404* (Silman and Pearson, 2002).

Rheumatoid arthritis is accompanied by the production of autoantibodies. Rheumatoid factor (RF) and anti-cyclic citrullinated peptide (CCP) autoantibodies are commonly identified. Rheumatoid factor is an IgM (rarely IgG) autoantibody directed against the Fe piece of IgG. Citrulline is an amino acid that is generated by post-translational modification of arginine by the enzyme peptidylarginine deiminase (PAD) (Vossenaar et al., 2003); polymorphisms of the gene PAD4 are associated with RA (Vossenaar et al., 2004). Cyclic citrullinated peptide autoantibodies are detected in 80% of patient with RA and are produced within the synovium and may have some impact on disease processes (Suzuki et al., 2003). Molecular modeling has shown that *DRB1*0401* binds citrullinated peptides (Hill et al., 2003) and the presence of *DRB1*0401* is correlated with autoantibodies to CCP (Goldback-Mansky et al., 2000). Hill et al. (2003) have associated the genetic risk for RA to the presence of anti-CCP.

Rheumatoid arthritis is thought to have a long preclinical phase that is marked by the presence of autoantibodies without the symptoms of arthritis. Aho et al. (1991) followed over 7000 Finnish individuals over the age of 30 years for the development of RA. Twenty-one individuals developed RA, 15 of whom had positive RF in serum samples prior to the development of disease (Aho et al., 1991). Halldorsdottir et al. (2000) have prospectively determined that persistently positive RF is associated with development of disease. Nielen et al. (2004) retrospectively studied frozen serum samples obtained prior to the diagnosis of RA. Approximately 50% of individuals were positive for either RF or anti-CCP for a median of 4.5 years prior to symptom onset compared with approximately 1% of the general population control. The sensitivity of positivity for RF or CCP was 36.5%, with a specificity of 98.1%. The PPV for a high-risk population positive for either autoantibody positive was 43.8%.

Rantapaa-Dahlqvist et al. (2003) have shown similar findings. However, the PPV of CCP autoantibodies with an estimated population prevalence of 1% is 16%. Therefore, the majority of individuals positive for these autoantibodies

in the general population will not progress to disease and may not be candidates for early therapy. Majka and Holers (2003) have postulated that these autoantibodies may have a better utility in individuals with a high pre-test probability of disease such as those with high risk HLA haplotypes or those with a family history of disease.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease characterized by multiorgan involvement. The disease can have a relapsing remitting course or become persistent with fulminant organ involvement.

Genetic risk is conferred by HLA class II alleles in particular DR2 or DR3. In addition C4 null alleles occur in increased frequency in individuals in many ethnic groups (Christiansen et al., 1991).

Autoantibodies are produced in SLE and are characteristic of the disease. However, many of the autoantibodies are also produced in individuals who never develop disease. The antinuclear antibody is a good screening test for disease, in that 95% of individuals with SLE will be positive for this antibody. However, as many as 5% of the general population will also be positive for this autoantibody, albeit at a low titer. Therefore, it is a sensitive but not specific marker of disease. Anti-double stranded DNA antibodies are more disease specific. Specific autoantibodies and quantification using radioimmunoassays have been associated with disease activity. For example, Yamamoto et al. (2000) have described a radioimmunoassay for ribonuclear proteins (RNPs) and found that in individuals with SLE 44% were positive and there was a correlation with SLE nephritis. The use of combinations of autoantibodies can improve sensitivity and specificity for SLE, and levels of autoantibodies can be associated with disease activity scores (Ignat et al., 2003).

CONCLUSION

Effective prediction of autoimmune disease requires an understanding of the epidemiologic concepts of sensitivity, specificity, PPV, NPV, and Bayes' theorem and usually requires assays with specificities ≥99%. Though assays and algorithms for T1D are routinely set at this level, for most rheumatologic disorders immunohistochemical or ELISA assays with lower specificities are standard. It is likely that newer fluid-phase methodologies would also improve prediction for these disorders. Using laboratory studies in populations that are at a high risk for disease, defined by family history or the presence of a high-risk HLA haplotype, may also help improve prognostication for these individuals.

Prediction of disease is especially important when early diagnosis and intervention positively impact the patients. For RA, early treatment modifies the disease course and portends a better outcome in those patients. For T1D, the early identification of individuals at risk for disease by positive autoantibodies decreased the hospitalization for ketoacidosis compared with controls (Barker et al., 2004). As effective prevention measures are developed for autoimmune diseases, the ability to correctly identify individuals at a high risk for disease will become very important.

Autoimmune diseases are often accompanied by the production of autoantibodies. Certain characteristics of autoantibody production such as level, affinity, duration of positivity, and epitope recognition may be associated with disease development. Autoantibody assays can be used in a cohort of susceptible individuals to identify people at an increased risk for the development of disease. Autoantibody production can precede the development of disease for many years and some individuals who are autoantibody positive may never develop disease. Therefore, precise prognostication for a single individual is difficult. For T1D, the presence of two or more anti-islet autoantibodies is associated with very high risk of progression.

The presence of one autoimmune disease identifies an individual at a high risk for a second autoimmune disease (Pearce and Leech, 2004). The heightened risk for disease in this group increases the pre-test probability of disease. Therefore, using autoantibody assays and/or T-cell assays in this group will be more efficacious. A positive result will have a high post-test probability of disease in a single individual.

Many autoimmune diseases are T-cell dependent. The development of reliable T-cell assays that are sensitive and specific for autoimmune disease will be a major advance in the ability to predict disease. When used in combination with autoantibody assays, the T-cell assays may refine our diagnostic ability and improve PPV and NPV.

The use of predictive algorithms that incorporate genetic risk expressed by HLA haplotypes or family history of disease, autoantibody production, and early physiological changes such as abnormal FPIR (T1D), mildly elevated TSH (AIT), or elevated PRA, ACTH (AD) will identify individuals at different points along the natural history of disease with increasing risk for disease development. These algorithms can be used to identify individuals who might benefit and be willing to participate in intervention studies that could change the course of disease. We believe it is likely that most autoimmune disorders are preceded by a long prodrome and that waiting for clinical presentation can be associated with irreversible morbidity (bone erosions at diagnosis of patients with RA, osteoporosis with CD or presentation with T-cell lymphoma) or even mortality (e.g., death at diabetes onset from cerebral edema, hypotensive crisis of AD). As the field of "personalized" medicine progresses, utilizing knowledge of personal risk factors (genetic, laboratory, clinical) to guide individual care, we believe that early detection of autoimmune disease risk will

be increasingly important and will depend on improved tests as well as development of preventive therapies.

CHAPTER

75

Prevention of Autoimmune Disease: Type 1 Diabetes as a Paradigm

LEONARD C. HARRISON

Autoimmunity and Transplantation Division, The Walter and Eliza Hall Institute of Medical Research, 1G Royal Parade, Parkville 3050, Victoria, Australia

Insulin-dependent or type 1 diabetes (T1D) is an autoimmune disease in which cell-mediated immunity destroys the insulin-secreting beta cells in the pancreatic islets (see Chapter 6). Type 1 diabetes is genetically-determined but its expression is modified by environment. In most cases the disease process begins months to years before major loss of beta-cell function heralds symptoms of hyperglycemia, a natural history that has clear implications for prevention (see Chapter 36). Increasing knowledge of the mechanisms of beta-cell destruction and the ability to identify individuals at risk for T1D, together with proof-of-principle for therapeutic intervention in the non-obese diabetic (NOD) mouse model, are platforms for T1D prevention in humans. Indeed, T1D can be seen as a paradigm for the preclinical diagnosis and prevention of autoimmune disease in general. Preventing T1D applies not only to people at risk but also to those with clinical diabetes, in order to preserve residual beta-cell function, allow possible beta-cell regeneration and prevent recurrent autoimmune disease after therapeutic beta-cell replacement or regeneration.

Ideally, T1D would be eradicated by primary prevention aimed at avoiding or averting the environmental factors that are thought to precipitate disease in genetically at-risk individuals, but these factors have not been clearly identified and may be ubiquitous. Without knowing these environmental factors (and not being able to modify genetic susceptibility), the prospects for primary prevention are uncertain. Secondary prevention, after the disease process has started, has received considerable attention for over two decades, with a range of candidate therapeutic agents being evaluated, predominantly in people with recent-onset clinical diabetes. Prevention is, however, mostly applicable to subclinical disease, rather than to clinical disease when beta-cell destruction is end-stage.

Prerequisites for a human therapeutic are efficacy and safety in animals. The most widely used animal model of T1D is the NOD mouse, which has contributed substantially to our understanding of the disease process and the expectation that T1D should be preventable (Leiter et al., 1987). The NOD mouse shares features with human T1D, including polygenic inheritance dominated by genes for antigen-presenting molecules in the major histocompatibility complex (MHC), autoimmunity to (pro)insulin and glutamic acid decarboxylase (GAD), transfer of disease by bone marrow and a protracted subclinical stage (Adorini et al., 2002). Many immune and other interventions modify the incidence of diabetes in NOD mice (Atkinson and Leiter, 1999); indeed, some would say too many, questioning whether this inbred mouse is in fact a good surrogate for the evaluation of candidate therapeutic agents in humans. However, most interventions prevent disease in only a proportion of NOD mice, some merely retard disease and others have no effect (and, therefore, are not reported), and many of the reported disease modifiers have not been tested in humans.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Secondary prevention strategies are summarized in Table 75.1. The emphasis has recently shifted from nonspecific modalities to more disease-specific immunoregulatory agents. Apparent preservation of C-peptide secretion in the first year after diagnosis has been reported in many randomized trials (e.g., Harrison et al., 1985; Feutren et al., 1986; Canadian-European Randomized Control Trial Group, 1988; Cook et al., 1989; Assan et al., 1990; Goday et al., 1993; Bjork et al., 2001; Raz et al., 2001; Herold et al., 2002), but has not been sustained. Autoantigen-specific immunotherapy—the "Holy Grail"—is safe and effective in animal models of autoimmune disease but has still not been shown to be clinically effective in at-risk humans. Prevention trials would be greatly facilitated by better assays for mechanistic immune and metabolic markers, especially for islet autoantigen-reactive T cells, and by non-invasive means of assessing islet pathology.

While the focus has been on beta-cell immunopathology leading to insulin deficiency, the level of blood glucose reflects a carefully-regulated balance between both insulin secretion and insulin action. Recently, insulin resistance has been shown to be a major, independent risk factor for progression to diabetes in individuals with islet autoantibodies (Fourlanos et al., 2004). Hence, promotion of insulin action must also be considered for the secondary prevention of T1D. The prevention of T1D will occur incrementally, with targeted agents being evaluated, often in combination, according to disease stage and risk, analogous to the evolving treatment regimens for cancer or HIV infection.

PREVENTION—WHY?

Complications of T1D can be reduced but not prevented by intensive blood glucose control with injectable insulin. In the Diabetes Control and Complications Trial (DCCT), even intensively-treated, motivated subjects in a study situation developed significant complications over a 10-year follow-up: neuropathy in 5%, retinopathy in 10%, and nephropathy in 15%. Moreover, intensive treatment was accompanied by 2–3-fold increase in severe, symptomatic hypoglycemic episodes (Diabetes Control and Complications Trial Research Group, 1993). Hence, retaining some beta-cell function or delaying the onset of clinical disease would significantly reduce the burden of T1D, because patients with residual beta-cell function require lower doses of insulin and have better blood-glucose control. In our experience of screening first-degree relatives, approximately 3% of whom are positive for one or more islet autoantibodies (Colman et al., 1998), the cost of detecting one relative with a 25–50% risk of diabetes within 5 years is approximately twice the annual cost of treating someone with T1D. Thus, a relatively inexpensive means of prevention would need only to delay the onset of diabetes by 2–3 years for screening to be cost-effective. The Finnish IDDM Prediction and Prevention Project (DIPP) found that neonatal screening for HLA genetic risk was cost-effective compared with autoantibody screening of the whole population (Hahl et al., 1998). If a safe and effective intervention were to be available, genetic risk-based screening at birth would be economic in populations with a high incidence of T1D.

PREVENTION—WHO?

Candidates for prevention are those with genetic and/or immune markers of risk and, less strictly, those with recent-onset diabetes in whom residual beta-cell function might be preserved or even regenerated. Most studies of people at risk have centered on first-degree relatives of a T1D proband identified as positive for autoantibodies to one or more of the islet autoantigens (pro)insulin, GAD and tyrosine phosphatase-like insulinoma antigen 2 (IA2) (Verge et al., 1996; Bingley et al., 1999; Colman et al., 2000; Harrison, 2001). A critical prerequisite for intervention in asymptomatic individuals is the ability to predict development of clinical disease. This can be achieved by measuring immune and metabolic markers of T1D (Box 75.1). In young, first-degree relatives the 5-year risk of diabetes is of the order <25%, 25–50%, and >50% if they have autoantibodies to one, two, and three islet auto-antigens, respectively; for single autoantibodies, those to insulin (IAA) are the most predictive, and to GAD (GAD Ab) the least predictive. The addition of measures of insulin secretion and insulin action further refine risk. Thus, first-phase insulin response (FPIR) to intravenous glucose at or below the first percentile signifies end-stage preclinical disease. More importantly, among autoantibody-positive relatives with a normal FPIR years before clinical onset, the highest risk is conferred by insulin resistance (Fourlanos et al., 2004). This finding has impor-

Box 75.1
Markers of risk for diabetes in an islet autoantibody-positive relative

- Number of antigen specificities of islet autoantibodies
- Antigen specificity of islet autoantibody
- Level of islet autoantibody
- Age at detection of islet autoantibody
- First-phase insulin response (FPIR) to I.V. glucose
- Insulin resistance, e.g., estimated as HOMA-R
- HLA alleles for risk or protection
- HLA haplotype sharing with proband
- Kinship with proband

Table 75.1 Trials for prevention of type 1 diabetes

	Subjects (n)	Follow-up (months)	Outcome	Reference
Primary prevention				
Non-antigen-specific immune modulation				
Cow's milk elimination (TRIGR)	HLA at-risk infants (2032)	120	Ongoing	Akerblom H.
Gluten elimination	AR (7)	24	No effect on islet antibody levels	Hummel et al., 2002
Secondary prevention				
Nonspecific immune suppression				
Azathioprine (2 mg/kg/day)	RD (24)	12	Higher basal and glucagon-stimulated C-peptide, and more remissions	Harrison et al., 1985
Cyclosporine (7.5 mg/kg/day)	RD (122)	9	More remissions	Feutren et al., 1986
Azathioprine (2 mg/kg/day) + prednisolone (reducing dose)	RD (46)	12	Higher meal-stimulated C-peptide and lower insulin dose	Silverstein et al., 1988
Cyclosporine (20 mg/kg/day)	RD (188)	12	Higher glucagon C-peptide and more remissions. Greater benefit in most recently diagnosed	Canadian-European Randomized Control Trial Group 1988
Azathioprine (2 mg/kg/day)	RD (49)	12	Higher meal-stimulated C-peptide	Cook et al., 1989
Azathioprine & thymostimulin	RD (45)	12	Higher glucagon-stimulated C-peptide and more remissions	Moncada et al., 1990
Cyclosporine	RD (219)	24	Higher meal-stimulated C-peptide and more remissions	Assan et al., 1990
Cyclosporine (10 mg/kg/day, 4 months)	RD (43)	36	No difference in glucagon-stimulated C-peptide, HbA1C, insulin dose	Chase et al., 1990b
Prednisolone (15 mg/day, 8 months); Indomethacin (100 mg/day, 8 months)	RD (25)	24	Lower insulin dose and higher urine C-peptide in prednisolone group	Secchi et al., 1990
Cyclosporine (10 mg/kg/day)	RD (23)	12	Higher meal- but not glucagon- or glucose-stimulated C-peptide. No difference in insulin dose.	Skyler and Rabinovitch, 1992
Anti-CD5/ricin A chain (unblinded)	RD (15)	12	Higher meal-stimulated C-peptide	Skyler et al., 1993
Glucocorticoid	RD (32)	12	Higher glucagon-stimulated C-peptide, but no remissions	Goday et al., 1993
Anti-CD4 + glucocorticoid	RD (12)	12	No difference in insulin dose, or islet antibody titers.	Kohnert et al., 1996
Methotrexate (unblinded)	RD (10)	36	No effect on basal or meal-stimulated C-peptide. Insulin dose higher.	Buckingham and Sandborg 2000
Anti-CD3 (hOKT3) (unblinded)	RD (18)	12	Increase in meal-stimulated C-peptide in first year. IL-10 detected in serum.	Herold et al., 2002
Anti-CD3	RD (80)	48	Ongoing	Gorus F. and Chatenoud L.
Mycophenolate mofetil ± daclizumab (anti-IL-2 receptor) (MMF/DZB)	RD (180)	48	Ongoing	Gottlieb P.A.

Table 75.1 (Continued)

	Subjects (n)	Follow-up (months)	Outcome	Reference
Daclizumab	RD (40)	24	Ongoing	Rodriguez H.
Rituximab (anti-CD20)	RD (?)	?	Pending	Pescovitz M.
IL-2 + rapamycin	RD (?)	?	Pending	Rabinovitch A.
Nonspecific immune stimulation				
BCG vaccine	RD (26)	18	No effect on glucagon-stimulated C-peptide, insulin dose or HbA1C	Elliott et al., 1998
BCG vaccine	RD (94)	24	No effect on mixed meal-stimulated C-peptide, insulin dose or HbA1C	Allen et al., 1999
Q fever vaccine	RD (39)	12	No effect on glucagon-stimulated C-peptide or insulin dose	Schmidli R.
Oral IFN-α	RD (120)	12+	Ongoing	Brod S.A.
Nonspecific immune regulation				
Thymopoietin	RD (32)	6	Lower insulin antibodies and insulin dose. More remissions. No difference in C-peptide or HbA1c.	Giordano et al., 1990
Gammaglobulin	RD (16)	6	Higher basal C-peptide Lower insulin dose, unchanged HbA1c	Panto et al., 1990
Linomide	RD (63)	12	Lower HbA1c, insulin dose. No difference in glucagon-stimulated C-peptide.	Coutant et al., 1998
HSP60 p277 peptide (DiaPep)	RD (35)	10	Decrease in glucagon-stimulated C-peptide and insulin dose in placebo but not treated group.	Raz et al., 2001
1,25-dihydroxy vitamin D3	RD (40)	18	Ongoing open	Walter M. and Ziegler A.
1,25-dihydroxy vitamin D3	RD (20)	18	Ongoing placebo-controlled	Walter M. and Ziegler A.
Antigen-specific immune regulation				
Parenteral insulin (IV vs. SC 2 weeks)	RD (26)	12	Higher meal-stimulated C-peptide, lower HbA1c	Shah et al., 1989
Parenteral insulin	RD (49)	60	Higher glucagon-stimulated C-peptide and improved insulin sensitivity and glycemic control.	Linn et al., 1996
Parenteral insulin (IV vs. SC 2 weeks)	RD (19)	12	Higher meal- and glucagon-stimulated C-peptide and lower HbA1c	Schnell et al., 1997
Parenteral insulin	RD (10)		Higher C-peptide response to oral glucose, HbA1C unchanged	Kobayashi et al., 1996
Parenteral insulin and sulphonylurea (glipizide)	RD (27)	12	Higher basal and glucagon-stimulated C-peptide, more remissions	Selam et al., 1993
Oral insulin	RD (80)	12	No effect on basal C-peptide, HbAIC, insulin dose or insulin antibodies	Pozzilli et al., 2000

Oral insulin	RD (131)	12	No effect on basal, glucagon- or meal-stimulated C-peptide, HbAIC, insulin dose or islet antibody levels	Chaillous et al., 2000
Parenteral insulin	AR (14)	84	Delay in onset of diabetes. No effect on islet antibody levels.	Füchtenbusch et al., 1998
Parenteral insulin (DPT-1)	AR (339)	44	No effect on diabetes development.	Diabetes Prevention Trial-Type 1 Diabetes Study Group, 2002
Intranasal insulin (INIT I)	AR (38)	48	Increased antibody and decreased T-cell responses to insulin. Stable first-phase insulin response to I.V. glucose.	Harrison et al., 2004
Oral insulin (DPT-1)	AR (372)	52	No effect on diabetes development.	www.nih.gov/news/pr/jun2003/niddk-15.htm
Parenteral insulin B chain in incomplete Freund's adjuvant	RD (12)	24	Ongoing	Orban T.
Parenteral insulin B chain 9-23 "altered peptide ligand" NBI-6024-0101 ("Neurocrine")	RD (188)	25	Ongoing	Gottlieb P.A.
Intranasal insulin (DIPP)	AR (200+)	?	Ongoing	Simell O.
Parenteral GAD65 (Diamyd™)	RD (160)	?	Pending	www.diamyd.com
β cell protection				
Nicotinamide	RD (20)	12	Higher glucagon-stimulated C-peptide at 45 days, then decline. No difference in remissions.	Mendola et al., 1989
Nicotinamide	RD (23)	9	Higher basal and glucagon-stimulated C-peptide	Vague et al., 1989
Nicotinamide	RD (35)	12	No difference in basal or glucagon-stimulated C-peptide	Chase et al., 1990a
Nicotinamide	RD (56)	12	Higher glucagon-stimulated C-peptide in subjects >15 years old	Pozzilli et al., 1995
Nicotinamide ± cyclosporine	RD (90)	12	Lower insulin dose. No difference in remissions	Pozzilli et al., 1994
Nicotinamide ± parenteral insulin	RD (34)	12	No difference in glucagon-stimulated C-peptide	Vidal et al., 2000
Nicotinamide versus vitamin E (no control group)	RD (84)	12	No difference in basal or glucagon-stimulated C-peptide, HbA1c or insulin dose	Pozzilli et al., 1997
Nicotinamide (DENIS)	AR (55)	36	No effect on diabetes development	Lampeter et al., 1998
Nicotinamide (ENDIT)	AR (552)		No effect on diabetes development	Philips et al., 2002
Octreotide	RD (20)	12	Higher glucagon-stimulated C-peptide at 6 and 12 months; no difference in HbA1c or insulin dose	Grunt et al., 1994
Diazoxide	RD adults (40)	18	Higher basal C-peptide	Bjork et al., 1996
Diazoxide	RD children (56)		Higher(?) stimulated C-peptide at 12, not 24, months	Bjork et al., 2001
Antioxidants	RD (46)	30	No difference in meal-stimulated C-peptide, insulin dose or HbA1c	Ludvigsson et al., 2001

AR, islet autoantibody-positive first-degree relative; DENIS, Deutsche Nicotinamide Intervention Study; DIPP, Diabetes Prediction and Prevention Project; DPT-1, Diabetes Prevention Trial Type 1; ENDIT, European Nicotinamide Diabetes Intervention Trial; IFN-α, interferon-α; IL-10, interleukin 10; INIT I, Melbourne Intranasal Insulin Trial; RD recently-diagnosed diabetic; TRIGR, trial to reduce IDDM in the genetically at-risk.

tant implications for new preventative approaches (to improve insulin action), as well as for the selection of autoantibody-positive subjects for prevention trials.

Several caveats apply. Approximately 10% of patients have no detectable antibodies at diagnosis. In addition, while first-degree relatives, with shared susceptibility genes and environmental risk factors, have at least a 10-fold higher prevalence of T1D than the background population, they still represent no more than 15% of people diagnosed with T1D. The risks in first-degree relatives cannot be directly extrapolated to the general population because the predictive value of a risk marker reflects the population prevalence of disease, according to Bayes' theorem. The prevalence and predictive value of islet autoantibodies in the general population has not been widely investigated but will be an important issue once effective means of secondary prevention are found. In Finland, which has the highest incidence of T1D in the world, neonatal screening for high-risk HLA class II susceptibility genes can identify over half of those destined to develop T1D (Kimpimäki et al., 2001). Neonatal screening to identify genetically at-risk populations is a basis for primary prevention, but its modest predictive value would only justify an intervention that was simple and safe, for example, diet modification or vaccination.

The case for intervention in asymptomatic, at-risk individuals, earlier when prediction is less accurate as against later or just after the onset of diabetes, hinges on considerations of safety and likely efficacy (Figure 75.1). Some agents, such as potentially toxic immunosuppressive drugs, cannot be given rationally in asymptomatic individuals, many of whom are children, whereas others such as agents that might promote protective immune homeostasis, while relatively safe, are likely to be ineffective in end-stage disease. Prevention should be more effective early in the natural history of preclinical disease, yet at the same time, prediction is less exact. In individuals with recent-onset diabetes the consideration of safety versus efficacy would appear to be less of a dilemma, but the major loss of beta-cell function at this time militates against efficacy. Nevertheless, in NOD mice treatment with anti-T-cell receptor (CD3) monoclonal antibody (mAb) at the onset of diabetes surprisingly resulted in reversal of diabetes (Chatenoud, 2003; see Chapter 76). A subsequent pilot trial of anti-CD3 monoclonal antibody in humans with recent-onset diabetes revealed preservation of residual β-cell function for at least a year but not reversal of diabetes (Herold et al., 2002). Removing the burden of pathogenic, effector T cells at this stage is an important strategy to allow the emergence or induction of protective, regulatory T cells, with potential for β-cell recovery and possible regeneration. Finally, it is important to note that about 10% of adults with diabetes have what appears to be a slowly-progressive form of T1D, associated mainly with GAD Ab, that initially is non-insulin-requiring (Hagopian et al., 1993; Tuomi et al., 1993; Gottsater et al., 1995; Turner et al., 1997). These patients have, on average, higher residual β-cell function at diagnosis than younger patients with classical T1D (Gottsater et al., 1993), implying a wider therapeutic window for secondary prevention spanning the onset of symptoms.

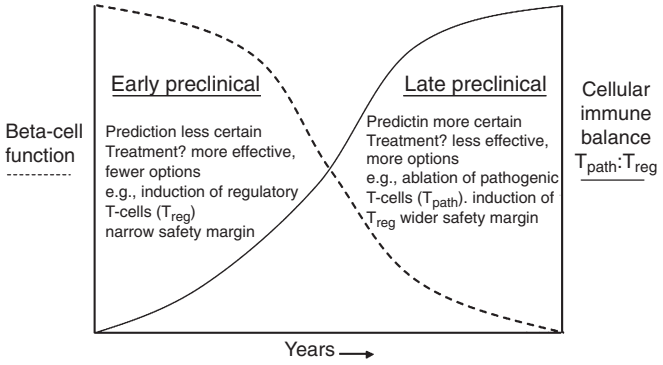

Figure 75.1 Preventing type 1 diabetes: early versus late intervention.

PREVENTION—HOW?

The number of candidate agents that meet scientific and ethical criteria for use in at-risk individuals is limited, and the identification of these individuals is a major logistic exercise. Consequently, the majority of the more than 60 clinical trials for "prevention" of T1D (Table 75.1) have been conducted in people with recent-onset diabetes, beginning with trials of glucocorticoids, azathioprine, and cyclosporine in the 1980s. No intervention, however, has yet demonstrated efficacy in the longer-term. Trials in recent-onset patients (see Table 75.1), including earlier trials of azathioprine and cyclosporine and more recent trials of heat shock protein (HSP) 60 peptide p277 ("DiaPep") vaccine and humanized anti-CD3 mAb, yielded a beneficial effect as judged by clinical remission and/or preservation of β-cell function, but significant differences between control and treatment groups have generally been restricted to the first year after diagnosis. Residual β-cell function is usually measured by the glucagon- or mixed meal-stimulated increase in plasma C-peptide, which is secreted in equimolar proportions to insulin following cleavage of proinsulin in the β cell and is a surrogate for insulin when exogenous insulin or insulin antibodies could interfere with the measurement of endogenous insulin levels. Failure of the "first-year effect" to be sustained could be due to only a transient effect of the agent, or to bias in participant selection. Individuals with recent-onset diabetes must be carefully stratified according to age, HLA gene status, autoimmune

status including number and level of islet autoantibodies, residual β-cell function, and insulin resistance, any of which may influence the natural history of declining beta-cell function after diagnosis (Greenbaum and Harrison, 2003). Greenbaum (2002) noted that the mean age of subjects (22 vs. 15 years, $p < 0.01$) was higher in nine trials yielding an initial positive outcome than in another 10 trials yielding a negative outcome. Furthermore, the proportion of trials reporting a positive outcome has decreased from the 1980s, along with a shift in the primary outcome measure away from mere clinical remission to the more rigorous measure of residual insulin (stimulated C-peptide) secretion. Standardization of trial design is critical and would facilitate comparative analysis of trials. To this end, the Immunology of Diabetes Society (IDS) has published guidelines for prevention trials in recent-onset T1D (Greenbaum and Harrison, 2003).

Not all trials have been based on animal data for efficacy or safety or have incorporated surrogate disease markers. Interventions, particularly in asymptomatic, at-risk individuals, must be safe and should ideally be based on proof-of-concept in animal studies. The primary outcome of trials is to attenuate or prevent diabetes. However, measures of beta-cell function such as the oral glucose tolerance test (OGTT) or the mixed meal tolerance test in subjects with diabetes, or the intravenous glucose tolerance test (IVGTT) to measure FPIR in at-risk subjects, may provide critical interim information on efficacy. How well immune markers, islet autoantibodies, and T-cells reactive to islet autoantigens inform on the nature and outcome of islet pathology is unknown, but these markers should be incorporated into trials in order to find out.

Although humans at high risk for T1D have a relatively restricted set of HLA susceptibility genes they are, in contrast to inbred NOD mice, likely to display significant heterogeneity in response to any therapeutic intervention. Prevention trials in T1D provide an opportunity to gain insight into pharmacogenomics. An example pertinent to the therapeutic application of (pro)insulin as an immune tolerizing agent, e.g., administered via mucosal routes (Harrison et al., 2004) is the *IDDM2* susceptibility locus for human T1D. *IDDM2* maps to a variable number of tandem repeats (VNTR) upstream of the proinsulin gene; long (class III) and short (class I) *VNTR* alleles are associated, respectively, with lower and higher susceptibility to T1D (Bennett et al., 1995). The length of the VNTR correlates with the level of proinsulin gene transcription in the thymus (Pugliese et al., 1997) and in a peripheral population of myeloid cells (Narendran et al., 2004), which in turn could determine the extent of deletion of proinsulin-specific T-cells during their intrathymic development. Thus, the immune response to (pro)insulin, which is likely to be key to understanding beta-cell destruction (Narendran et al., 2003), may be predetermined by *IDDM2*.

PRIMARY PREVENTION

Primary prevention can be targeted at environmental factors that could precipitate islet autoimmunity. The evidence for an etiological role of environment in T1D is persuasive: in discordant identical twin pairs the lifetime risk of diabetes for the nondiabetic twin is 50–70% (Gale et al., 2001; Redondo et al., 2001); the incidence of T1D has increased over the last 15 years in many countries, particularly in the very young (Green and Patterson, 2001; Gale, 2002); in both hemispheres of the world an effect for infectious agents is suggested by a peak in spring–summer births of children who will develop T1D (Laron, 2000; Willis et al., 2002) and a peak in winter in diagnosis of T1D (Douglas et al., 1999; Green and Patterson, 2001; Willis et al., 2002); Type 1 diabetes occurred after exposure to rubella virus *in utero* (Forrest et al., 1971) and to the toxin "Vacor" (Karam et al., 1980). Interest in specific environmental agents is centered mostly on dietary components and viruses.

Diet and the Role of the Intestinal Mucosa

The hypothesis that early exposure of the infant to cow's milk and/or the lack of breastfeeding predisposes to T1D dates from the 1980s. It has important implications but remains controversial because the evidence on which it is based is indirect and open to criticism (Harrison and Honeyman, 1999). Two meta-analyses of multiple studies in which diabetes prevalence was associated retrospectively with infant feeding revealed only a marginal increase in relative risk (Gerstein, 1994; Norris and Scott, 1996). In the Denver-based Diabetes Autoimmunity Study in the Young (DAISY), infant feeding patterns retrospectively analyzed up to 6 months of age were not found to be related to the development of islet autoantibodies up to 7 years of age (Norris et al., 1996). In the Australian BabyDiab Study (Couper et al., 1999) and the German BabyDiab Study (Hummel et al., 2000), there was no association between infant feeding patterns and the development of islet autoantibodies. Nevertheless, to answer whether cow's milk exposure is a risk, the Trial to Reduce IDDM in the Genetically at-Risk (TRIGR), a multicountry study has been initiated. Newborns with a T1D first-degree relative and with HLA risk alleles, initially exclusively breastfed, are being randomized to either a casein hydrolysate formula ("Neutramigen") or a conventional cow's milk-based formula until at least 6 months of age, and will be followed for up to 10 years. The "cow's milk hypothesis" depended in part on reports that children with T1D have an increased immune response to cow's milk proteins (reviewed in Harrison and Honeyman, 1999). However, scrutiny of the literature indicates that, rather than being disease-specific, this reflects genetic predisposition to increased immunity to dietary proteins in general, associated with the HLA haplotype A1-B8-

DR3-DQ2, which also predisposes to celiac disease and selective IgA deficiency (Harrison and Honeyman, 1999). In the two rodent models of T1D, the NOD mouse and the BioBreeding (BB) rat, evidence has emerged that plant rather than milk proteins promote the development of islet autoimmunity (Beales et al., 2002). Antibodies to wheat gluten proteins are found in a proportion of T1D patients at the time of diagnosis (MacFarlane et al., 2002) and in one report the prevalence of autoimmune diseases, including T1D, in individuals with celiac disease was related to the duration of exposure to gluten (Ventura et al., 1999). However, in a small, unblinded pilot study 1 year of gluten-free diet had no effect on the natural history of islet autoimmunity in offspring of parents with T1D (Hummel et al., 2002).

We sought to reframe the cow's milk hypothesis around mucosal immune function in T1D (Harrison and Honeyman, 1999). The essential role of a normal mucosal immune system in maintaining immune homeostasis is illustrated by the effect of a germ-free versus conventional "dirty" environment on diabetes incidence in NOD mice. The incidence of spontaneous diabetes in NOD mice differs greatly between colonies around the world and appears to be inversely correlated with exposure to microbial infection (Pozzilli et al., 1993). The high incidence of diabetes in NOD mice housed under pathogen-free conditions is reduced by conventional conditions of housing and feeding (Suzuki, 1987; Funda et al., 2005). Under such conditions, bacterial colonization of the intestine is accompanied by an increase in number of intra-epithelial lymphocytes (Imaoka et al., 1996) and maturation of mucosal immune function (Kawaguchi-Miyashita et al., 1996). The increase in recent years in the prevalence of autoimmune and allergic disorders in the first world has been attributed to "clean living" conditions—the "hygiene hypothesis" (Strachan, 1989; Holt, 1994). Supplementary to the effects of microbial environment, breast milk contains growth factors, cytokines, and other immunomodulatory agents that promote functional maturation of the intestinal mucosa and mucosal immune system. Breast milk also contains endogenous insulin (Shehadeh et al., 2001), which could induce "oral tolerance" to insulin and so protect against the development of T1D, as described below. Thus, rather than cow's milk promoting T1D, human milk could be protective, by immune maturational effects and/or by delivering human insulin to the "tolerogenic" mucosal immune system.

Epidemiologic evidence has emerged for a protective role of vitamin D, a steroid with pleiotropic immune and non-immune effects. Vitamin D is synthesized in the skin after ultraviolet radiation exposure and the only other major source is diet supplementation. The recommended daily intake of vitamin D has fallen and increased awareness of skin cancer has reduced sun exposure. Children in Finland who received vitamin D supplementation had a lower incidence of T1D (Hypponen et al., 2001), and children in Norway had a lower incidence of T1D if their mothers took cod liver oil (a source of vitamin D) during pregnancy (Stene et al., 2000). In a multinational European case–control study, the odds ratio for T1D was significantly reduced in children given vitamin D (EURODIAB Substudy 2 Study Group, 1999). Trials of vitamin D supplementation are in progress in subjects with recent-onset T1D.

Viruses

Viral mechanisms could include direct infection of β cells, infection of the exocrine pancreas with bystander death of β cells, molecular mimicry between T-cell epitopes in a virus and those in β-cell autoantigens, superantigen stimulation of T cells, or combinations of these. If a particular virus was clearly implicated, vaccination of children early in life, if generally safe, would be protective, but with disease induction by molecular mimicry being a possible caveat.

The first virus to be associated with T1D was rubella (Forrest et al., 1971). Children with congenital rubella born to mothers who contracted rubella early in pregnancy had evidence of infection in the brain, pancreas, and other tissues, and 20% developed insulin-dependent diabetes (Menser et al., 1978). Subsequently, almost twice this proportion of such children were reported to develop islet-cell antibodies (Ginsberg-Fellner et al., 1985). Children with congenital rubella and ensuing diabetes were noted to have a higher frequency of the T1D susceptibility haplotype HLA-A1-B8-(DR3-DQ2) (Menser et al., 1974). More recently, evidence for molecular mimicry between rubella and GAD has been reported (Ou et al., 2000). Rubella vaccine has virtually eliminated congenital rubella and may represent the first example of primary prevention of T1D. Clearly, many other environmental factors are involved, because the incidence of T1D has continued to increase in "first world" countries. Despite the report of rubella-GAD mimicry (Ou et al., 2000), strengthened by the finding of islet autoantibodies in children infected with rubella virus (Lindberg et al., 1999), there is no evidence from multiple studies (Hummel et al., 2000; DeStefano et al., 2001) that the vaccination with attenuated rubella virus is associated with islet autoimmunity (see Chapter 24). Only 4% of girls receiving live attenuated rubella vaccine developed islet-cell antibodies, and these were transient and of low titer (Bodansky et al., 1990).

Mothers infected during pregnancy with some enteroviruses, including coxsackie and echoviruses were more likely to deliver children who developed T1D early in life (Dahlquist et al., 1995; Hyoty et al., 1995), but more recent studies have negated this (Füchtenbusch et al., 2001; Viskari et al., 2002). Enterovirus RNA was isolated from peripheral blood mononuclear cells of 50% of recent-onset

T1D cases in Scandinavia, and 26% of siblings and 0% of age- and sex-matched controls (Yin et al., 2002). In Germany and Australia, coxsackie B virus infections were noted to be more common in infants and children with preclinical T1D than in controls but were not coincident with the detection of islet autoantibodies (Füchtenbusch et al., 2001; Honeyman M.C., in preparation). Evidence for induction of T1D by mimicry by enteroviruses remains unconvincing (Marttila et al., 2001; Roep et al., 2002). The circumstantial nature of their association with T1D makes enteroviruses less promising as a vaccine target. Furthermore, there are 72 recognized serotypes and many thousands of enterovirus strain variants, and no vaccines except for polio virus yet exist. However, if diabetes-associated strains such as coxsackie B3, B4, or echo 6 were to be clearly implicated, they would become candidate vaccines for genetically at-risk children.

Mumps virus epidemics have been associated with onset of T1D 2–4 years later (Khakpour and Nik-Akhtar, 1975; Hyoty et al., 1988). Intriguingly, the introduction of a mumps vaccine was associated with a plateau in the rising incidence of T1D in Finland (Hyoty et al., 1993), but this was temporary, and mumps vaccination is unlikely to be of value for preventing T1D. Cytomegalovirus (CMV) can damage β cells (Jenson et al., 1980) and contains a peptide sequence mimic of a T-cell epitope in GAD recognized by a T-cell clone from a subject with stiff person syndrome (Roep et al., 2002). However, evidence for CMV infection in T1D is weak (Hiltunen et al., 1995). Furthermore, although CMV is now a major cause of congenital defects, development of a vaccine is problematic because of latency and possible carcinogenicity of an attenuated virus.

The discovery of strong sequence similarities between T-cell epitopes in IA2 and GAD and the VP7 protein of rotavirus in islet antibody-positive relatives (Honeyman et al., 1998) suggested that molecular mimicry with rotavirus might precipitate islet autoimmunity. Rotavirus epidemics occur each winter particularly in kindergartens and are the most common cause of gastroenteritis in children. Rotavirus provides a profound inflammatory stimulus to the gut until sufficient IgA develops, by about 5 years of age. In the Australian BabyDiab Study, rotavirus infections were temporally associated with increases in islet autoantibodies in 24 children before they developed diabetes (Honeyman et al., 2000). It was then shown that rotavirus could infect β cells in islets from mice, pigs, and monkeys (Coulson et al., 2002). Recently, it has been shown (Honeyman M.C., in preparation) that both a majority of children at-risk for T1D, and HLA-matched controls, have T-cell responses to the similar peptide sequences in rotavirus VP7, and IA2, and GAD. This indicates that while ubiquitous rotavirus infections may drive cross-reactive immunity to islet autoantigens, this alone is not diabetogenic. Mimicry could, however, complement and sustain the immune response to direct infection of β cells. Rotavirus vaccines have been developed, but were withdrawn because of safety concerns following cases of intestinal intussusception. Whether a rotavirus vaccine would alter the incidence of T1D is unanswerable without vaccination of the population. The outcomes of infections in infants may be complex. Infection by rotavirus and other diabetogenic viruses in a non-inflammatory context, such as during breastfeeding, could conceivably be protective against the development of T1D.

SECONDARY PREVENTION

The approach to prevention that comes closest to the ideal for early preclinical disease, or even primary prevention, is autoantigen-specific immune tolerance induction. This involves, paradoxically, administration of an autoantigen to induce protective autoimmunity (also referred to as "negative vaccination"). The concept is that self-antigen-specific immunoregulatory mechanisms are physiological and can be boosted or restored to prevent pathological autoimmunity. Strategies to achieve this include the delivery of autoantigen by a "tolerogenic" route (e.g., mucosal), cell type (e.g., resting dendritic cell), mode (e.g., with blockade of costimulation molecules), or form (e.g., as an "altered peptide ligand"), all of which can prevent or suppress experimental autoimmune diseases in rodents (Faria and Weiner, 1999; Harrison and Hafler, 2000; Krause et al., 2000). They operate either by deleting and/or inducing anergy in potentially pathogenic effector T cells or by inducing regulatory T cells (Treg). Autoreactive T cells that are driven strongly by antigen may undergo apoptotic cell death and deletion, while those that survive or respond "partially" may become anergic (von Herrath and Harrison, 2003). Of potential importance clinically is the ability of Treg to exert antigen-nonspecific "bystander suppression" in response to specific antigen (Faria and Weiner, 1999; Harrison and Hafler, 2000; von Herrath and Harrison, 2003). Thus, some Treg respond to antigen by secreting anti-inflammatory cytokines such as interleukin 10 (IL-10) or transforming growth factor-β (TGF-β) that may then impair the ability of dendritic cells to elicit T helper 1 (Th1) T-cell or cytotoxic T-cell responses to any antigen locally at the site of the lesion or in the draining lymph nodes. Bystander suppression obviates the need to know if the autoantigen used to induce tolerance is necessarily the major or primary pathogenic autoantigen.

Mucosa-Mediated Antigen-Specific Therapy

Numerous experiments have shown that it is possible to partially protect NOD mice from diabetes by the mucosal administration of islet autoantigen. Zhang et al. (1991) initially reported protection after oral porcine insulin. Bergerot

et al. (1994) then showed that human insulin induced $CD4^+$ Treg that could transfer protection to naïve mice. Protection following oral insulin was later found to be associated with decreased expression of interferon-γ (IFN-γ)-secreting Th1 T cells in the pancreas and pancreatic lymph nodes (Hancock et al., 1995; Ploix et al., 1998). Oral insulin-induced CD4 Treg have also been shown to prevent immune-mediated diabetes induced by lymphocytic choriomeningitis virus (LCMV) infection of mice expressing the viral nucleoprotein of LCMV under control of the rat insulin promoter in their β cells (Homann et al., 1999). The majority of T cells in the islets of oral insulin-treated mice without diabetes secreted the Th2 (IL-4, IL-10) and Th3 (TGF-β) cytokines, in contrast to IFN-γ-secreting Th1 cells in islets of mice developing diabetes. The protective effect of oral insulin was enhanced by simultaneous feeding with IL-10 (Slavin et al., 2001), bacterial component OM-89 (Bellmann et al., 1997; Hartmann et al., 1997) or schistosome egg antigen (Maron et al., 1998), all of which promote Th2 responses. Fusion of insulin to cholera toxin B-subunit (CTB) significantly improved the ability of oral insulin to prevent diabetes (Bergerot et al., 1997). Oral CTB-insulin conjugates in NOD mice induced a shift from a Th1 to a Th2 immunity associated with the induction of regulatory $CD4^+$ T cells (Ploix et al., 1999). NOD mice were protected from diabetes by feeding potatoes that transgenically express CTB-insulin conjugates (Arakawa et al., 1998). Oral GAD has also been shown to suppress diabetes development in NOD mice (Ma et al., 1997). Although it is generally believed that neonates are less susceptible to mucosal tolerance induction, oral administration of insulin, insulin B-chain, or GAD peptide during the neonatal period still suppressed diabetes development in NOD mice (Maron et al., 2001). This suggests that mucosal delivery of islet autoantigen (e.g., in milk) could be used to treat very young infants at risk of developing T1D.

Protection against diabetes in NOD mice can also be achieved by nasorespiratory administration of islet autoantigens. This route of direct delivery to the mucosa avoids antigen degradation. When insulin was administered as an aerosol to NOD mice at 8 weeks of age, after the onset of subclinical disease, insulitis and diabetes incidence were both significantly reduced (Harrison et al., 1996). Aerosol insulin induced novel anti-diabetic CD8 γδ T cells that suppressed the adoptive transfer of diabetes to nondiabetic mice by T cells of diabetic mice. The type of Treg induced by (pro)insulin depends on the route and form of antigen. Nasorespiratory insulin, nondegraded and conformationally intact, induces CD8 γδ Treg, whereas oral insulin degraded to peptides, or intranasal or oral (pro)insulin peptides, induce CD4 Treg (Hänninen and Harrison, 2000; Martinez et al., 2003). Intranasal administration of the insulin B-chain peptide (amino acids 9–23), an epitope recognized islet-infiltrating $CD4^+$ T-cell clones capable of adoptively transferring diabetes to naïve mice, induced $CD4^+$ Treg and protected NOD mice from diabetes (Daniel and Wegmann, 1996). A peptide that spans the B–C chain junction in proinsulin also induces $CD4^+$ Treg after intranasal administration (Martinez et al., 2003). This peptide, like insulin B9-23, binds to the NOD mouse class II MHC, I-A^{g7} (Harrison et al., 1997) and is a T-cell epitope in NOD mice (Chen et al., 2001) and humans at risk for T1D (Rudy et al., 1995). T-cell epitope peptides from GAD administered intranasally were also protective, and associated with the induction of regulatory $CD4^+$ Treg and with reduced IFN-γ responses to GAD (Tian et al., 1996). Islet autoantigen proteins or peptides that induce Treg are potential "vaccines" for intranasal delivery to prevent T1D in humans, but this promise remains to be fulfilled (see below).

Hematopoietic Stem Cell-Mediated Antigen-Specific Therapy

Autoimmune diabetes in the NOD mouse can be transferred to non-susceptible NOD F1 recipients by allogeneic bone marrow transplantation (BMT) (Serreze et al., 1988; Wicker et al., 1988; LaFace and Peck, 1989). This demonstrates that the mechanisms of disease development operate within the hematopoietic compartment and implies that autoimmune diabetes may be prevented by manipulating hematopoietic cells. Indeed, replacement of the NOD mouse hematopoietic compartment with that from diabetes-resistant mouse strains by BMT blocks development of diabetes (Ikehara et al., 1985; LaFace and Peck, 1989; Beilhack et al., 2003). However, complete replacement is not required as generation of mixed-allogeneic hematopoietic chimeras is equally effective (Li et al., 1996; Kaufman et al., 1997; Mathieu et al., 1997). Autoimmune diabetes is prevented in mixed chimeras most likely by the introduction of thymic and/or peripheral tolerance-inducing antigen-presenting cells that express diabetes-nonsusceptible MHC molecules. This would be analogous to the protection afforded by transgenic introduction into NOD mice of diabetes-resistant MHC molecules such as I-E and alternative I-A molecules (Nishimoto et al., 1987; Lund et al., 1990; Singer et al., 1993; 1998), which may act by enhancing thymic selection of T cells (Schmidt et al., 1997; Luhder et al., 1998) or by inducing Treg (Singer et al., 1993). Induction of Treg, however, does not appear to account for diabetes prevention in mixed chimeras (Mathieu et al., 1997). Introduction of other genes (non-MHC for diabetes resistance) into the hematopoietic compartment could also contribute.

Allogeneic or mixed-allogeneic BMT strategies are being trialled for severe autoimmune diseases (Burt et al., 2002). However, they are unlikely to be suitable for T1D due to the requirement for cytotoxic conditioning of the host, and the risks of graft rejection (Castro-Malaspina et al., 2002) and

graft-versus-host disease (Ratanatharathorn et al., 2001). A much safer approach would be to use autologous, genetically-engineered hematopoietic stem cells to introduce molecules into the hematopoietic compartment that could prevent autoimmune disease. Adopting this approach, we found that transfer to young, irradiated NOD mice of 10^3 syngeneic hematopoietic stem cells that encoded proinsulin expression in antigen-presenting cell progeny totally prevented diabetes (Steptoe et al., 2003). This dramatic effect appears to depend on proinsulin expression by "resting" immature dendritic cells (Steptoe et al., 2004). The application of this "cell therapy" to humans faces two obstacles related to safety—introducing genes into stem cells without the risk of oncogenesis and avoiding toxic conditioning regimens in the host.

Trials of Islet Autoantigen-Specific Therapy in Humans

The large multicenter Diabetes Prevention Trial 1 (DPT-1) was launched in the United States in 1994 to determine whether antigen-specific therapy with either systemic or oral insulin would delay or prevent the onset of diabetes in at-risk relatives. Previously, intensive systemic insulin therapy had been reported to prolong the "honeymoon phase" after diagnosis (Shah et al., 1989), and a pilot study of prophylactic systemic insulin had suggested that this approach might be of benefit in at-risk relatives (Keller et al., 1993). In DPT-1, low-dose systemic insulin (annual intravenous insulin infusions and daily subcutaneous injections) was given to a high-risk group of relatives (>50% risk of diabetes over 5 years), matched with an untreated but closely monitored control group. Unfortunately, this treatment had no effect on diabetes incidence (Diabetes Prevention Trial-Type 1 Diabetes Study Group, 2002). The more recent randomized control DPT-1 of oral insulin recruited relatives with a 25–50% 5-year risk of developing diabetes, but again the primary analysis revealed no effect (*http://www.nih.gov/news/pr/jun2003/niddk-15.htm*). Two trials of oral insulin (up to 7.5 mg daily for 12 months) in recently-diagnosed patients showed no protective effect on residual β-cell function (Chaillous et al., 2000; Pozzilli et al., 2000).

Why have these trials failed? There are probably several answers: selection of subjects with end-stage disease; inadequate dose or bioavailability of the agent, possibly related to the route of administration; and co-induction of pathogenic T-cells. Regarding stage of disease, induction of antigen-specific immunoregulation, without concomitant inactivation or deletion of pathogenic effector cells, is likely to be relatively ineffective in end-stage disease. If a balance between pathogenic and protective T cells determines clinical outcome, then antigen-specific immunoregulation should be most effective in early preclinical disease; later, it might be complementary to a limited course of treatment aimed at reducing the burden of pathogenic effector T cells. Regarding route of administration, oral delivery may not be optimal for mucosa-mediated tolerance, because proteins are generally degraded after ingestion, whereas, even in the case of a small peptide, responses are seen after nasorespiratory but not oral delivery (Metzler and Wraith, 1993). In the mouse, nasal delivery of the model antigen, ovalbumin, elicited antigen-specific T-cell responses in cervical, mediastinal, and mesenteric mucosal lymph nodes, whereas oral delivery elicited responses only in the mesenteric nodes (Hänninen et al., 2001). Moreover, irrespective of route, mucosal delivery of ovalbumin was a "double-edged sword," inducing both tolerance and pathogenic $CD8^+$ cytotoxic T cells (Hänninen et al., 2002). To achieve a clinical effect from tolerance induction, it was necessary to block induction of pathogenic T cells by transient co-administration of systemic anti-CD40 ligand monoclonal antibody (Hänninen et al., 2002). Whether mucosal insulin is also a double-edged sword is unknown. However, the proinsulin B–C chain peptide that induces $CD4^+$ Treg in NOD mice is a "combitope" of $CD4^+$ ($I\text{-}A^{g7}$-restricted) and $CD8^+$ (K^d-restricted) T-cell epitopes, and is significantly more protective after intranasal administration if the C-terminal p9 anchor residue for binding to K^d is either deleted or mutated (Martinez et al., 2003). These findings underscore the necessity to evaluate immune responses to mucosal autoantigens in human trials.

The rationale for the DPT-1 trial of oral insulin was the induction of "oral tolerance" in the NOD mouse. In the mouse, milligrams of gavaged insulin were required to induce "regulatory" anti-diabetogenic $CD4^+$ T cells and partially suppressed development of diabetes (Zhang et al., 1991; Bergerot et al., 1994). Yet, the daily dose of insulin given orally in the human trials was only 7.5 mg, which, on a body-weight basis, equates to only a few micrograms in the mouse. Oral insulin is degraded and its bioavailability to induce mucosa-mediated immune tolerance in the upper small intestine is unpredictable. Despite this, dose-ranging studies in humans to determine a bioavailable dose of oral insulin were not undertaken, raising the question whether such a major trial was judicious without reassurance that the dose of insulin used would have had an immune effect. Insulin antibodies are a readout of bioavailability observed after aerosol insulin in NOD mice (Harrison et al., 1996) and intranasal insulin in humans (Harrison et al., 2004). Irrespective of whether such antibodies are a marker of immunoprotection, their induction demonstrates that the dose used was bioactive. Because insulin autoantibodies are a risk marker for T1D, the increase in insulin antibodies after administration of nasorespiratory insulin would seem to conflict with immunoprotection. However, this observation, together with the concomitant decrease in the T-cell-proliferative response to insulin after intranasal insulin

(Harrison et al., 2004), is entirely consistent with mucosal tolerance. Reciprocal cellular and humoral immune responses, originally termed "immune deviation" by Parish (1996), and later popularized in terms of the Th1/Th2 paradigm, are a feature of the earliest descriptions of mucosal tolerance. This was confirmed in landmark but overlooked human studies with the experimental antigen keyhole limpet hemocyanin (KLH). When KLH was administered orally (Husby et al., 1994) or nasally (Waldo et al., 1994) to human volunteers, subsequent antibody and T-cell responses to systemic immunization with KLH increased and decreased, respectively.

Enthusiasm to translate mucosal tolerance from rodents to humans has been tempered by failure to show clinical benefit not only of oral insulin but also of oral myelin basic protein in multiple sclerosis (Weiner et al., 1993) and oral collagen in rheumatoid arthritis (Trentham et al., 1993; McKown et al., 1999). As suggested, these failures could be due to an inability of mucosal tolerance to counteract pathogenic T cells in end-stage autoimmune disease or to the coinduction of a pathogenic immune response. In addition, as with the oral insulin trials, none of these trials reported an immune effect of the oral antigen. Without this evidence, it is not clear that the dose used was bioavailable and immunoactive. Therefore, major trials of mucosal antigens in future should not be undertaken without fore-knowledge that the dose is at least bioactive. At the same time, there is an urgent need for the measurement of potentially relevant biomarkers, particularly pro-inflammatory (potentially pathogenic) and anti-inflammatory (regulatory) T cells, to be rigorously standardized and incorporated into trials.

The Melbourne intranasal insulin trial I (INIT I) (Harrison et al., 2004) was a randomized controlled crossover pilot trial of intranasal insulin vaccine in young T1D relatives (median age 10.8 years; n = 38) with islet autoantibodies. Two 400 μg doses of insulin per nostril were self-administered daily for 10 days, then on two consecutive days each weekend, for 6 months. The aim was to determine if intranasal insulin was safe and would induce changes in surrogate immune and metabolic markers consistent with an immunoprotective effect. No local or systemic adverse effects were observed. Diabetes developed in 12 subjects who had negligible β-cell function at entry, after a median of 1.1 years. β-cell function in the remaining 26, the majority of whom had antibodies to 2 or 3 islet autoantigens and FPIR outside the first percentile at entry, generally remained stable over a median follow-up of 3.0 years. Intranasal insulin was associated with an increase in anti-insulin antibody and a decrease in T-cell responses to (denatured) insulin. This trial identified a dose of intranasal insulin that was safe and which induced changes in immunity to insulin as previously reported in NOD mice. Because INIT I was a crossover trial in which all subjects received treatment with intranasal insulin for 6 months, it could not determine if intranasal insulin prevents loss of β-cell function and diabetes. This will be answered in a follow-up trial.

In adults with autoimmune diabetes there has been only one published clinical trial of prophylactic insulin. This small study by Kobayashi et al. (1996) demonstrated that low doses of subcutaneous insulin improved the C-peptide response to oral glucose and decreased HbA1c at 6 and 12 months after diagnosis, compared to treatment with oral sulfonylurea drugs. Whether the beneficial effect of insulin treatment was due to metabolic or immunoregulatory mechanisms is not known. A randomized controlled-phase 2 trial of intranasal insulin (INIT III) in adults with recent-onset autoimmune diabetes is nearing completion in Melbourne. A phase 2 trial of subcutaneous GAD, sponsored by Diamyd Medical AB, is also underway in adults with recent-onset T1D.

PREVENTION OF TYPE 1 DIABETES IN THE THIRD MILLENNIUM

The rate at which knowledge about T1D accumulated at the end of the second millennium provides strong hope that the disease will be preventable early in the third. This will occur only incrementally and will involve a combination of interventions suited to genotype, risk level and disease stage. Environmental agents that precipitate or exacerbate islet autoimmunity are likely to be ubiquitous and, therefore, a single intervention (e.g., vaccination against a virus) is unlikely to be the ultimate solution. Antigen-specific immunotherapy applied rationally to enhance natural mechanisms of protective immune homeostasis promises to be a safe and widely-applicable intervention in early subclinical disease. In end-stage disease, combinatorial treatment that not only enhances immune homeostasis but suppresses pathogenic immunity is likely to be required. Advances in manipulating gene expression safely in stem cells will open new avenues for antigen-specific tolerogenic therapy. T1D is likely to be the first preventable autoimmune disease. This will facilitate replacement or regeneration of pancreatic islet β cells in people with established diabetes. The lessons learnt from the preclinical diagnosis, prediction and prevention of T1D should be applicable to the prevention of other autoimmune diseases.

Acknowledgments

The author is supported by the National Health and Medical Research Council of Australia and by a Center Program Grant from the Juvenile Diabetes Research Foundation. He is indebted to his colleagues and students in clinical medicine and laboratory research, and to people and families with diabetes, for much support and inspiration. Catherine McLean provided excellent administrative assistance.

CHAPTER

76

Emerging Therapies for Autoimmune Diseases

LUCIENNE CHATENOUD

Université René Descartes Paris 5, INSERM U580 Paris, France

Autoimmune diseases represent a major therapeutic challenge. In many cases, the disease is severe enough to significantly reduce longevity. In other cases, the disease causes major handicaps and discomfort that justify the usage of aggressive treatments generating their own hazards. Present treatments are palliative (substitutive), anti-inflammatory, or immunosuppressive without any specificity for the pathogenic mechanisms of the disease. With few exceptions [anti-tumor necrosis factor (TNF) antibodies in rheumatoid arthritis [RA0]] the treatment of autoimmune diseases has not significantly evolved from the mid-1980s. Therefore, much attention is drawn to modern technologies that have made new agents available. These approaches have been the matter of extensive experimental studies in the numerous and diversified animal models of autoimmune diseases. Some of them have already been tested in the clinic and even approved by regulatory authorities. The aim of this chapter is to review these strategies with particular emphasis on agents or methods that have entered the clinical arena. In addition, it is interesting to discuss how lessons drawn from the development of novel therapeutic strategies in one particular autoimmune disease may be translated into beneficial therapies for other autoimmune conditions.

LIMITATIONS OF CURRENT TREATMENTS

In some autoimmune diseases there is benefit from a substitutive treatment. This is typically the case in type 1 diabetes (use of insulin), thyroiditis (use of thyroid hormones), or pernicious anemia secondary to autoimmune gastritis (use of vitamin B12). In some cases, the approach is satisfactory; the treatment is fully efficient with minor constraints and side effects, as for thyroid hormones or vitamin B12. In other cases, such as type 1 diabetes, chronic insulin therapy is not an optimal treatment since it is associated with major constraints (multiple daily parenteral administration, need for self-monitoring of glycemia, serious risks linked to hypoglycemic episodes) and lack of effectiveness in preventing severe degenerative complications.

The treatment may aim at combating inflammation. Although many autoimmune diseases have a strong inflammatory component, it is fair to recognize that, with a few exceptions (RA), conventional anti-inflammatory drugs usually show limited efficacy and their chronic usage is associated with significant toxicity, notably renal and digestive.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

In diseases with a severe outcome, patients are given immunosuppressive agents such as cyclophosphamide, cyclosporine, or FK506, and more recently mycophenolate mofetil. These drugs are often (but not always) efficacious. Their usage, however, is curtailed by major difficulties. First, the drugs have a direct toxicity for humans, such as cyclosporine-induced nephrotoxicity or cyclophosphamide-induced bone marrow depression and carcinogenesis. Second, they must generally be used chronically at relatively high dosages, since disease relapse occurs when the treatment is stopped, thus exposing patients to over-immunosuppression leading to opportunistic infections and tumors. The risk can be minimized by adequate selection of drug dosage depending on a careful monitoring of blood levels and immune functions. Whatever the precautions taken, particularly when patients are not monitored by specialized centers, the long-term risks may become hardly acceptable in autoimmune patients.

Corticosteroids, which associate anti-inflammatory and immunosuppressive properties, are widely used in autoimmune diseases. They are frequently very effective but not satisfactory, however, due to their severe side effects, particularly when they are administered long-term at high dosages.

NEW GOALS FOR IMMUNOTHERAPY OF AUTOIMMUNE DISEASES

The first and most ambitious goal is that of inducing or, in the case of established autoimmune diseases, of restoring immune tolerance to target autoantigens. This may be defined operationally as the possibility to harness the pathologic immune response following a short-term treatment while keeping intact the capacity of the host to respond normally to exogenous antigens. Autoimmune diseases are the result of the rupture of tolerance to self-antigens. In most cases, notably in organ-specific autoimmune diseases, the breakdown of tolerance essentially involves the autoimmune response to the autoantigens of the target organ, which may represent a limited number of specificities. One must then attempt to restore tolerance to the corresponding autoantigen(s). In other cases, particularly in non-organ-specific autoimmune diseases such as systemic lupus erythematosus (SLE), the rupture of tolerance is more diffuse and may involve autoantigens that are present in many cell types, notably antigens expressed in apoptotic cells. Restoration of self-tolerance has the major advantage of avoiding the side effects linked to chronic immunosuppression. Since most autoimmune diseases are a chronic and/or relapsing/remitting process, for the effect to be long lasting one will probably need to repeat the tolerogenic treatment.

The second aim is the limitation of side effects of the tolerogenic treatment, either due to drug toxicity or over-immunosuppression. Biotechnology-derived products show a range of side effects, which are, however, often intrinsically different from those of conventional immunosuppressants. These side effects must be carefully evaluated, which is often difficult in preclinical studies because of the strict specificity of the products to humans (see below). One can study the mouse-specific equivalent of these products, but the conclusion drawn from these experiments is indirect since the drug tested is not the very same drug that will be used in the clinic. In some rare cases, the drugs may be tested in animal models when the human target molecule is transgenically expressed in the mouse.

The third aim is to achieve a medical benefit, which requires that the patients are still fully sensitive to the treatment, i.e., still showing a good function of the target organ at the initiation of therapy.

A last issue is that of the sensitization to the therapeutic protein, be it a humanized monoclonal antibody, a hormone, a cytokine, or an antigen. If neutralizing antibodies are produced, the therapeutic effect is lost. Additionally, if the hormone or the cytokine has an important biologic function, the sensitization may have serious consequences.

THE THERAPEUTIC ARMAMENTARIUM DERIVED FROM BIOTECHNOLOGY

Monoclonal Antibodies

Murine monoclonal antibodies (MAbs) produced by mouse or rat hybridomas (Kohler and Milstein, 1975) specific for immune cell receptors were introduced in clinical practice more than 25 years ago and their use initially developed in the field of solid organ transplantation. Two major side effects—namely, the sensitization against the xenogeneic molecule and the cytokine-releasing potential observed with some particular specificities—explain why the use of rodent MAbs remained initially mostly confined to transplantation with only very few attempts in autoimmunity. The advent of humanized MAbs that are less immunogenic and better tolerated has completely changed the picture and allowed a more widespread use of these interesting therapeutic tools. In fact, at variance with conventional immunosuppressants, MAbs specific for relevant lymphocyte receptors are unique in their capacity to induce, under adequate circumstances, immune tolerance to soluble proteins, foreign tissue alloantigens and autoantigens.

Conventional chemicals mostly act through removal and/or the functional inhibition of their targets. In contrast,

MAbs display a wide spectrum of pharmacologic and biologic activities highly relevant to their capacity to "reprogram" the immune system. Thus, depending on their fine specificity, MAbs will remove target cells, inhibit or block the functional capacity of the target without depleting it, neutralize major cytokines, and/or serve as receptor agonists triggering activation signals for specialized T-cell subsets, e.g., regulatory T cells.

The Problem of Sensitization can be Partly Overcome with Humanized and Human Monoclonal Antibodies

The repeated administration of murine MAbs invariably triggered a humoral immune response, of which the major clinical consequence was the neutralization of the antibody's therapeutic activity. Interestingly, this was not a global anti-mouse or anti-rat response; it was very restricted in its specificity with essentially anti-isotypic and anti-idiotypic antibodies being produced (Benjamin et al., 1986; Chatenoud, 1986; Chatenoud et al., 1986a). Anti-idiotypic antibodies that compete with the therapeutic antibody for antigen binding represent the neutralizing component of the response while anti-isotypic antibodies are mostly non-neutralizing (Baudrihaye et al., 1984). Another peculiarity of this humoral response is its oligoclonality (Chatenoud et al., 1986b), which explains why, at variance with what was observed in patients immunized to polyclonal antilymphocyte globulins, serum sickness was a rare consequence of sensitization to MAbs since the amount of immune complexes formed would be insufficient to elicit a generalized reaction. Antimonoclonal IgE responses associated with symptoms of anaphylaxis were reported but remained a very uncommon observation (Abramowicz et al., 1992; Abramowicz et al., 1996).

Until humanized MAbs or, more recently, fully human antibodies became available, the only way to cope with the problem of sensitization was to associate adequate doses of chemical immunosuppressants (Hricik et al., 1990). Two types of humanized antibodies have been derived from molecular engineering. Chimeric MAbs express intact rodent variable regions linked to human immunoglobulin constant domains (Elliott et al., 1994a). In fully reshaped or complementarity determining region (CDR)-grafted antibodies, the rodent hypervariable regions interacting with the antigen (i.e., CDRs) are included within human heavy and light chain immunoglobulin frameworks (Riechmann et al., 1988).

Humanized MAbs have significantly reduced, though not totally avoided, the risk of deleterious anti-idiotypic responses. The clinical data available indicate that both chimeric and reshaped humanized MAbs may be immunogenic when administered alone, without associated immunosuppressants, and after more than 2–3 repeated antibody courses (Elliott et al., 1994b). It has been the general experience that combining low doses of chemical immunosuppressants was an efficient way to overcome such sensitization (Nashan et al., 1997; Vincenti et al., 1998; Feldmann, 2002).

Fully human MAbs that are already used in clinical practice have been produced by different means. First, mice have been invalidated for the expression of endogenous (mouse) immunoglobulin genes and concurrently made transgenic for sufficient human constant and variable immunoglobulin-encoding sequences to provide for antibody diversity; B cells from these immunized mice will produce human antibodies that can be used in conventional fusions to obtain hybridomas yielding high-affinity MAbs derived from *in vivo* antigen-driven selection.

Second, there is a fully *in vitro* approach using cDNA libraries expressed on filamentous phages to derive high affinity antibodies to a wide variety of antigens, including those for which the conventional hybridoma technology fails due to poor immunogenicity (Marks et al., 1991). Third, human-mouse chimeras can be established using normal mice irradiated and reconstituted with bone marrow cells from SCID mice; after human lymphocytes from presensitized donors are inoculated, these mice are boosted with the antigen of interest, and sensitized human B cells are recovered and used for conventional fusions (Lubin et al., 1994).

Further Opportunities are Offered by Genetic Engineering

Engineering Fc Regions of Monoclonal Antibodies to Avoid Side Effects and Prolong Half-Life

Antibody engineering allows the design of tailor-made antibodies to fit at best therapeutic indications. Antibodies expressing human Fc portions have a significantly prolonged half-life. The choice of the human Fc portion will influence the antibody effector capacities, i.e., its activity in terms of complement fixation, opsonization and antibody-dependent cell cytotoxicity (ADCC). In addition, in the case of anti-CD3 antibodies, humanization can circumvent problems due to their intrinsic mitogenic and cytokine-releasing capacity that leads *in vivo* to a "flu-like" syndrome. This syndrome was regularly observed with murine anti-CD3 MAbs such as OKT3, and, although transient, it represented a major and troublesome side effect that totally precluded the use of CD3 MAbs for indications other than organ transplantation (Abramowicz et al., 1989; Chatenoud et al., 1990; Chatenoud, 2003). This mitogenic capacity is linked to the ability of the Fc portion of CD3 MAbs to interact with monocyte Fc receptors (Chatenoud, 2003). Thus "non-mitogenic" CD3 antibodies were obtained by inserting

adequate mutations into the Fc domains to hamper Fc receptor binding (Bolt et al., 1993; Alegre et al., 1994; Chatenoud, 2003). Phase I trials, using the two Fc-mutated CD3 MAbs presently available, OKT3γ1Ala-Ala and ChAglyCD3, in renal allograft recipients who presented with acute rejection episodes, confirmed that their use was free of major side effects (Friend et al., 1999; Woodle et al., 1999).

Engineering Variable Regions of Monoclonal Antibodies to Increase Affinity

X-ray crystallography has illuminated the nature of antigen–antibody interactions. The six CDRs do not contribute equally to the interactions for antigen-binding. Usually, a minimum of four CDRs are used, and the orientation of the CDR loops is critical for antibody specificity and affinity. Mutations within a CDR may create structural changes that, due to their close proximity, may influence other CDRs and greatly impact antigen binding. In addition, inadequate CDR/CDR interactions at the VL/VH interface may prevent domain assembly and antibody expression. This explains why antibody humanization requires detailed molecular modeling of antibody structures to achieve accurate structural predictions. It relies on computer-assisted three-dimensional models to predict the effects of point mutations or of perturbations in the position of the CDR loops during humanization. In this way it has been possible to obtain humanized CDR-grafted antibodies that show minimal reduction in their antigen-binding affinity compared to the parental rodent antibody.

In case the affinity of a given MAb is too low for *in vivo* use, phage display technology is an interesting approach to generate a better and improved fully human reagent with no requirement for prior immunization or use of hybridoma technology. The use of large phage libraries increases the possibility of isolating high-affinity antibodies. In case of failure, phage display can also be used to mimic artificially the processes used *in vivo* by the immune system to generate high-affinity antibodies. This has been achieved by shuffling the heavy or light chains by random or directed mutagenesis of CDRs (Barbas et al., 1994), as done by error-prone polymerase chain reaction (PCR) (Gram et al., 1992). Using such artificial affinity maturation of phage antibody repertoires, affinities of MAbs in the nanomolar to picomolar range have been generated that are perfectly suitable for therapeutic use (Barbas, 1995; Foote and Eisen, 1995).

PEGylation

The use is described of covalent attachment of polyethylene glycol (PEG) to various proteins including antibodies, antibody fragments, and cytokines essentially to prolong their half life (Choy et al., 2002; Yang et al., 2003; Torriani et al., 2004).

Main Targets

T-cell Antigens

CD3 Antibodies

The story of CD3 MAbs is paradoxical and remarkable. They were the first therapeutic antibody introduced in clinical practice in 1981, about 4 years before the molecular complexities and the key functional role of the CD3 molecule were discovered (Clevers et al., 1988; Davis and Chien, 1999). The OKT3 MAb, a mouse IgG2a (Kung et al., 1979), was initially used to treat and prevent renal allograft rejection (Cosimi et al., 1981a; Vigeral et al., 1986; Debure et al., 1988). This occurred without much *in vivo* preclinical data available due to the tight species-specificity of anti-T-cell MAbs in general and CD3 antibodies in particular. Chimpanzees are the only nonhuman primates harboring T lymphocytes that cross-react with MAbs to human CD3. In addition, antibodies to mouse CD3 were difficult to produce, the first one being characterized by Leo et al. in 1987 (Leo et al., 1987). Through the 1980s, controlled studies clearly demonstrated that MAb OKT3 was a potent immunosuppressant very efficient at reversing early acute renal allograft rejection episodes (Cosimi et al., 1981b; Ortho, 1985), an indication for which this MAb was rapidly licensed, both in the USA and Europe. Through the study of OKT3-treated patients, an enormous amount of knowledge was gained on the mode of action of murine anti-T-cell MAbs and their side effects, well-illustrated by over 3000 manuscripts published on the topic. These studies have been invaluable for the design of more refined approaches especially using humanized MAbs.

Over the last 10 years, as other immunosuppressants developed, the use of OKT3 was almost completely abandoned, essentially because of its cytokine-releasing potential (Chatenoud et al., 1986a; 1989; 1990; Cosimi, 1987; Abramowicz et al., 1989; Eason and Cosimi, 1999; Chatenoud, 2003).

CD3 MAbs used *in vitro* in functional studies and *in vivo*, both in the experimental and the clinical setting, are specific for the ε-chain of the CD3 complex. The experimental work conducted in different rat and mouse models suggested that, more than simply depressing all immune responses, CD3 MAbs could also induce immune tolerance to both alloantigens and autoantigens (Hayward and Shreiber, 1989; Nicolls et al., 1993; Plain et al., 1999) and, perhaps more impressively, could restore self-tolerance in established autoimmunity (Chatenoud et al., 1994; 1997; Belghith et al., 2003; Chatenoud, 2003). Based on these data, CD3 MAbs have again entered the clinical arena but now as well-tolerated humanized nonmitogenic MAbs (Bolt et al., 1993; Alegre et al., 1994) used not only in transplantation, but also in autoimmunity in protocols aimed at antigen-specific long-term effects rather than just immunosuppression.

CD3 MAbs and Autoimmune Diabetes

Trials are presently being conducted using anti-CD3 to treat patients with recent-onset type 1 diabetes based on our earlier data on diabetes-prone non-obese diabetic (NOD) mice. Short-term (5 days) treatment of overtly diabetic NOD mice with low-doses (5–20 μg/day) of CD3 MAbs, in either their mitogenic (whole 145 2C11) or nonmitogenic version [F(ab′)2 fragments of 145 2C11], induces disease remission by restoring self-tolerance (Chatenoud, et al., 1994; 1997; Belghith et al., 2003; Chatenoud, 2003). The effect is long-lasting and specific to β cell autoantigens (Chatenoud et al., 1994; 1997). Immune mechanisms mediating this tolerogenic capacity evolve in two distinct consecutive phases (Chatenoud, 2003). The first induction phase coincides with antibody administration and results in clearing of insulitis, explaining the rapid return to normoglycemia, with a transient Th2 polarization that is irrelevant to the long-term effect since there is prolonged remission of disease after anti-CD3 treatment of IL-4 deficient NOD mice (NOD IL-4$^{-/-}$) (Belghith et al., 2003; Chatenoud, 2003). The second maintenance phase results in upregulation and/or appearance of specialized subsets of CD4$^+$CD25$^+$ and CD4$^+$CD62L$^+$ regulatory T cells that mediate transferable active tolerance, and that effectively control pathogenic effector cells as shown by co-transfer experiments in immunodeficient NOD SCID mice (Chatenoud et al., 1994; 2001; Belghith et al., 2003). The proportions of regulatory CD4$^+$CD25$^+$ T cells increase in pancreatic and mesenteric lymph nodes of anti-CD3-treated tolerant mice (Belghith et al., 2003). Interestingly, CD4$^+$CD25$^+$ regulatory T cells induced by anti-CD3 may not be derived exclusively from "conventional" natural suppressor CD4$^+$CD25$^+$ T cells but also, and perhaps even essentially so, from peripheral CD4$^+$CD25$^-$ precursors (Belghith et al., 2003; see Chapters 9 and 10). In fact, CD3-specific MAb treatment induces diabetes remission also in NOD mice that are deficient for the co-stimulation molecule CD28 (NOD CD28$^{-/-}$), and are devoid of the thymic natural suppressor CD4$^+$CD25$^+$ population (Belghith et al., 2003). Also important, the immunoregulatory cytokine-transforming growth factor-β (TGF-β) appears to be a key player in this T-cell-mediated regulation, although its precise role, whether as a mediator of regulation or a growth and/or differentiation factor for regulatory T cells, is not yet determined. Thus, CD4$^+$ T cells from mice tolerant after anti-CD3 consistently produce high levels of TGF-β, and *in vivo* neutralization of TGF-β after injection of specific MAbs fully prevents anti-CD3-specific-induced remission (Belghith et al., 2003).

Clinical trials are underway to ascertain adequate modalities that will reproduce this remarkable effect. Results from an open trial using the OKT3γ1 Ala-Ala MAb in patients who present with recent-onset type 1 diabetes were very encouraging (Herold et al., 2002). Thus, at 1 year after a short-term treatment, a significant preservation of the β cell mass was observed in treated patients compared with controls (Herold et al., 2002). The results of a European multicenter randomized placebo-controlled trial using the ChAglyCD3 MAb, also in autoimmune type 1 diabetes, which we are conducting in collaboration with diabetology centers in Belgium (Belgium Diabetes Registry; Clinical coordinator Prof. B. Keymeulen) and Germany (Prof. A. Ziegler, Munich), fully confirmed the expectations. In fact, results obtained at 18 months of follow-up show not only a significant preservation of the β cell mass in ChAglyCD3-treated versus placebo-treated patients but also an impressive decrease in the insulin needs (Keymeulen et al., 2005). Interesting data have also been reported using the OKT3γ1Ala-Ala MAb in psoriatic arthritis (Utset et al., 2002) and in recipients of islet allografts (Hering et al., 2004).

CD4 Antibodies

The tolerogenic capacity of anti-CD4 MAbs in mice was highlighted from the outset, since, at variance with other xenogeneic MAbs, anti-CD4 did not elicit the usual antiglobulin response. In addition, humoral responses to foreign soluble protein antigens were specifically inhibited if delivery was under the cover of brief treatment with anti-CD4. The effect was obtained with both depleting and non-depleting CD4 antibodies, and it could be maintained long term merely by repeating antigen administration at regular intervals in absence of any further anti-CD4 treatment. Importantly, identical results were recently obtained in non-human primates using a humanized MAb specific for human CD4 and cross-reacting with monkey cells (Winsor-Hines et al., 2004). In this system CD4$^+$ T cells, but not B cells, are rendered tolerant, and effectively transfer such tolerance to naïve hosts. The single caveat is that only high CD4 MAb dosages are tolerogenic. In the mouse, anti-CD4 affords tolerance also to alloantigens (anti-CD4 MAbs are effective alone in the case of cardiac or islet allografts but must be combined to anti-CD8 MAbs in the case of skin allografts) and also often in the case of autoantigens (Wofsy and Seaman, 1987; Shizuru et al., 1988; Qin et al., 1993; Bushell et al., 1995; 2003; Waldmann and Cobbold, 2001; Cobbold et al., 2003). Effective treatment of an ongoing autoimmune disease was demonstrated for murine lupus in NZB/NZW F1 mice (Wofsy and Seaman, 1987), and in established diabetes in NOD mice (Maki et al., 1992), but only when using depleting CD4 antibodies.

The first pilot trials that used mouse MAbs to human CD4 were applied to patients presenting long-standing RA, psoriasis, inflammatory bowel disease, and uveitis (Goldberg et al., 1990; 1991; Emmrich et al., 1991; Horneff et al., 1991; Reiter et al., 1991; Wendling et al., 1991; Morel et al., 1992; Bachelez et al., 1998). In these trials, partial and short-term disappearance of circulating CD4$^+$ cells was observed,

together with coating of $CD4^+$ T-cells and dose-dependent saturation of CD4-binding sites. Results in terms of therapeutic effectiveness were encouraging but short-lasting, and were obscured by the antiglobulin response that rapidly developed and prompted trials of humanized CD4 MAbs.

The chimeric cM-T412 MAb (human IgG1), a depleting antihuman CD4 MAb, was used in RA with encouraging results in open studies, especially with high cumulative doses, ranging from 350–700 mg (Moreland et al., 1993; Van Der Lubbe et al., 1993; 1994); these, however, were not confirmed in a large randomized double-blind placebo-controlled study (Van Der Lubbe et al., 1995). Mild sensitization was reported in a majority of the patients (Moreland et al., 1993; Van Der Lubbe et al., 1993; 1994). Of major concern was the persisting $CD4^+$ cell depletion observed with MAb cM-T412, up to 60% from baseline for over 18–30 months (Moreland et al., 1994), contrary to what had initially been reported with the parental mouse M-T151 anti-CD4 MAb (Reiter et al., 1991). Apoptosis could mediate, at least in part, this massive depletion (Choy et al., 1993). The disappointing clinical results in ongoing RA are not necessarily surprising, since they are fully in keeping with preclinical data. In fact, in collagen-induced arthritis, a murine model for human RA, anti-CD4 in contrast to MAbs to TNF (discussed below) were effective for prevention but not for treatment of ongoing disease (Marinova-Mutafchieva et al., 2000). The cM-T412 MAb has also been used in patients with multiple sclerosis, but here again without any evident clinical benefit (van Oosten et al., 1997).

The nondepleting humanized MAb to CD4, OKT4cdr4A (the CDR-grafted version of OKT4A), was used in patients with severe psoriasis; one open pilot study and another placebo-controlled one were conducted, with promising data (Bachelez et al., 1998; Gottlieb et al., 2000).

Results from open-pilot studies suggested that CD4 MAb therapy, especially in combination with antibodies to CD52, could be effective in treating severe forms of vasculitis (Mathieson et al., 1990; Lockwood et al., 1993).

It is fair to conclude this section on anti-CD4 MAbs by pointing out that their development was seriously hampered by non-scientific considerations linked to patenting and marketing, explaining the incredible gap between the wealth of experimental data accrued and the paucity of controlled clinical trials conducted. It is hoped that CD4 antibodies will soon be made available for trials especially designed on the lessons drawn form preclinical studies.

CD25 Antibodies

CD25, the α-chain of the interleukin 2 (IL-2) receptor, is expressed on activated T cells (Waldmann, 1989), which explains the interest in it as a therapeutic target. Experimental data suggested an immunosuppressive capacity of anti-CD25 that significantly delayed rejection of heart allografts in the mouse (Kirkman et al., 1985) and of renal allografts in nonhuman primates (Reed et al., 1989). In autoimmunity anti-CD25 MAb prevented onset of collagen-induced arthritis (Banerjee et al., 1988), insulitis, and diabetes in NOD mice (Kelley et al., 1988) and lupus nephritis in NZB/NZW F1 mice (Kelley et al., 1988). In diabetes-prone Bio Breeding (BB) rats there was reversal of established disease after treatment with anti-CD25 and low-dose cyclosporine (Hahn et al., 1987).

Murine MAbs to human CD25 were effective for prevention but not for reversal of renal allograft rejection (Soulillou et al., 1990; Kirkman et al., 1991; Kriaa et al., 1993). By the late 1990s, two humanized MAbs to CD25—one chimeric [basiliximab (Simulect)] and one CDR-grafted (daclizumab [Zenapax])—were shown to be well-tolerated and effective as part of induction regimens to prevent organ allograft rejection, and were approved for use as induction therapies in organ transplantation (Nashan et al., 1997; Vincenti et al., 1998; Waldmann and O'Shea, 1998; Bumgardner et al., 2001). Moreover humanized CD25 antibodies appear beneficial for treatment of established rejection (Adu et al., 2003) and of some severe autoimmune diseases, uveitis in particular (Guex-Crosier et al., 1997; Nussenblatt, 2002).

Last but not least, none of the studies support a tolerance-promoting activity of anti-CD25 perhaps because CD25 is also expressed on a subset of T-cells endowed with regulatory/suppressor capacities that are critical in maintaining immune tolerance (Belghith et al., 2003; Sakaguchi, 2004). Thus, elimination or inhibition of the functional capacity of this subset using anti-CD25 MAbs might be counterproductive if the aim is tolerance induction.

Targeting Co-stimulatory Pathways

The CD28/CD80, 86 (B7.1, B7.2) Pathway

Delivery of activation signals through the T-cell receptor/CD3 pathway is insufficient to activate naïve T cells. Co-stimulation signals are required that are transduced through the specialized receptor CD28, which interacts with its specific ligands CD80 (B7.1) and CD86 (B7.2) at the surface of the antigen presenting cell (APC). Fusion proteins have been produced using the cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4, CD152) molecule that is homologous to CD28 and expressed on T cells following activation (Linsley et al., 1991). CTLA-4 is also constitutively expressed on the specialized regulatory/suppressor T-cell subset $CD4^+CD25^+$ (Read et al., 2000; Takahashi et al., 2000). CTLA-4Ig is a fusion protein including the extracellular domain of CTLA-4 combined to the Fc domain of a

human IgG1 (Linsley et al., 1992), and shows higher avidity for CD80 than CD86. LEA29Y is a CTLA4-4Ig derived molecule with two amino-acid mutations that confer higher avidity for both CD80 and CD86. This explains why LEA29Y is more potent *in vitro* than CTLA-4Ig.

Treatment *in vivo* with CTLA-4Ig effectively blocked immune responses to alloantigens (Lin et al., 1993; Lakkis et al., 1997; Onodera et al., 1997), xenoantigens (Lenschow et al., 1992), and autoantigens. In NZB/NZW mice, treatment with CTLA-4Ig blocked autoantibody production and prolonged mouse half-life (Finck et al., 1994). Mostly CTLA4-Ig was more effective for preventing than reversing established immune responses and generally a robust and long-standing tolerance was not the general rule.

In the clinic, in a phase I open-label study on 43 patients with psoriasis, CTLA-4Ig resulted in >50% sustained (>6 months) improvement in disease activity in 46% of patients (Abrams et al., 1999). CTLA-4Ig also appeared promising in RA, according to a pilot, escalating dose, double-blind placebo-controlled study on 214 patients, given CTLA-4Ig, LEA29Y, or placebo I.V., four infusions in all. Patients were assessed at 2.5 months after the first injection. Both agents had an excellent safety profile, and clinical efficacy was superior to placebo (Moreland et al., 2002). These good results were confirmed in a second controlled study using CTLA-4Ig or placebo in combination with methotrexate, again with significant improvement for the CTL4-4Ig-treated group (Kremer et al., 2003).

The CD40/CD154 (CD40) Ligand Pathway

CD40 is a member of the TNF receptor superfamily and is constitutively expressed by various cell types including B lymphocytes and APCs. CD40 interacts with CD154 (CD40L), a member of the TNF superfamily exclusively expressed at the surface of activated T lymphocytes. The CD40/CD154 co-stimulation pathway is essential for both T–B and T–T cooperation. CD40/CD154 interactions lead to germinal-center formation and immunoglobulin class switching. Severe immunodeficiency is caused by disruption of this pathway in mice due to gene knockout, or spontaneous mutations in humans. Concerning T–T cooperation, studies in the mouse and in nonhuman primates using *in vivo* administration of antibodies to CD154, either alone or in combination with CTLA-4Ig, showed great promise in prolongation of allograft survival and prevention of autoimmune disease (Larsen et al., 1996; Larsen and Pearson, 1997; Niimi et al., 1998; Kirk et al., 1999), albeit rapidly tempered when the first clinical trials in renal allograft recipients and in patients with SLE showed severe thromboembolic events (Boumpas et al., 2003) with one of the MAbs used. While such events were not observed with the IDEC-131 MAb, this proved ineffective in patients with SLE (Davis et al., 2001; Kalunian et al., 2002; Kuwana et al., 2004).

Adhesion Molecules

The $\alpha 4\beta 1$ Integrin VLA-4

Integrins are adhesion molecules of fundamental importance to the recruitment of leukocytes in inflammation. The $\alpha 4\beta 1$ integrin VLA-4 is a leukocyte ligand for endothelial vascular cell adhesion molecule-1 (VCAM-1), fibronectin, and osteopontin. The interaction between VLA-4 at the surface of activated lymphocytes and monocytes with its ligand VCAM-1 is essential for cell migration into inflamed parenchyma. Promising data in experimental models of blockade of VLA-4 prompted use of a specific humanized monoclonal antibody (natalizumab) in randomized placebo-controlled trials, first in multiple sclerosis (MS) (Miller et al., 2003). In 213 patients with relapsing-remitting or relapsing secondary progressive MS given natalizumab or placebo every 28 days for 6 months, there was a marked reduction in the number of new brain lesions [gadolinium-enhanced magnetic resonance imaging (MRI)] in treated patients (Miller et al., 2003). The same antibody was applied in Crohn's disease (Ghosh et al., 2003). Similarly in 248 patients with moderate to severe Crohn's disease, two infusions of MAb given 4 weeks apart induced higher remission rates than did placebo and significant improvement in the Crohn's disease activity index, together with improved quality of life (Ghosh et al., 2003). Unfortunately, recent reports indicate that, upon chronic administration, this antibody exposes the risk of opportunistic brain infection caused by the JC virus. The first two cases were observed in MS patients receiving natalizumab associated with interferon-β (IFN-β). The last reported case affected a patient with Crohn's disease treated with natalizumab alone.

Leukocyte Function-Associated Antigen 1

A humanized MAb, efalizumab, specific for the CD11a subunit of leukocyte function-associated antigen 1 (LFA-1), has been tested in psoriasis. When administered subcutaneously once a week, improvement was observed within 2–4 weeks, and lasted for up to 2 years (Leonardi, 2004). Results from three randomized, placebo-controlled trials in patients exhibiting moderate-to-severe plaque psoriasis likewise showed promising results (Menter et al., 2004); here the follow-up lasted for 12 weeks as a double-blind trial, and there was an additional 12 weeks of extended treatment phase (Menter et al., 2004).

B-Cell Antigens (CD20)

Rituximab (Rituxan) is a human–mouse chimeric MAb specific to CD20, a B-cell antigen, which causes rapid depletion of B lymphocytes. Rituximab was approved in the

United States of America in 1997 and in Europe in 1998 (MabThera) to treat severe refractory CD20-positive non-Hodgkin B-cell lymphoma. The use of anti-CD20 has now been extended to first-line therapy and maintenance therapy in lymphoma, stem-cell transplantation procedures, and, recently, for autoimmune disorders, including RA, immune thrombocytopenic purpura, autoimmune hemolytic anemia, SLE, vasculitis, dermatomyositis, and MS (De Vita et al., 2002; Leandro et al., 2002; Silverman and Weisman, 2003; Looney et al., 2004a; 2004b; 2004c; Rastetter et al., 2004). A phase II randomized, double-blind, placebo-controlled trial in RA showed that treatment with anti-CD20 was safe and led to major and sustained clinical responses (Edwards et al., 2004). At the more fundamental level, these results highlight the pathogenic role of B-lymphocytes, not only as antibody producing cells but also as APCs, which hitherto had long been considered of marginal importance in some of these autoimmune diseases.

Leukocyte Antigens (CD52)

Antibodies to CD52 target a small (12 amino acids) glycosylphosphatidylinositol (GPI)-anchored protein of undefined function expressed at the surface of human B and T cells and monocytes/macrophages. Anti-CD52 MAbs are highly depleting and have potent efficacy in long-term acceptance of organ allografts and maintaining remission in established and otherwise intractable autoimmune diseases, notably MS, vasculitis, and RA (Mathieson et al., 1990; Lockwood et al., 1993; Lockwood et al., 1996; Calne et al., 1999).

The first rat MAb to CD52, Campath-1M, was characterized in 1983. A fully reshaped humanized version, Campath-1H (human IgG1) was derived by genetic engineering (Riechmann et al., 1988) and is marketed as alemtuzumab. Its depleting capacity has led to its extensive use *in vivo* to treat $CD52^+$ hematologic malignancies, and *in vitro* to purge bone marrow transplants to prevent graft-versus-host disease (GvHD). Upon the first injection, Campath-1H triggers an acute self-limited cytokine release that causes a transient "flu-like" syndrome.

Campath-1H has been given to patients with RA, of whom, after 3 and 6 months, 50% showed improvement in the Paulus score (Isaacs et al., 1992). It also proved very effective in severe systemic small-vessel vasculitis in which the pathogenesis depends mainly on T-cell-mediated mechanisms (see Chapter 65) (Mathieson et al., 1990; Lockwood et al., 1993; 1996). The long-term remissions that were obtained when combining antibodies to CD52 and CD4 were particularly impressive (Mathieson et al., 1990; Lockwood et al., 1993; 1996).

Results with anti-CD52 in MS are also promising (Moreau et al., 1994; Coles et al., 1999a; 1999b). The initial trials included patients with long-standing relapsing/remitting MS that was unresponsive to conventional treatments. Long-term follow-up showed a marked decrease in the appearance of new lesions in the CNS, assessed by MRI, that correlated with the persisting and significant depletion of peripheral $CD4^+$ T lymphocytes (Moreau et al., 1994; Coles et al., 1999a; 1999b; 2004). An unexpected adverse effect was the appearance of Graves' disease in a significant proportion (33%) of successfully treated patients (Coles et al., 1999b). Interestingly, current multicenter trials that include patients with MS of more recent onset do not appear to expose to this adverse event (A. Coles, personal communication).

In general, Campath-1H seems unique in its capacity to promote long-lasting remission of life-threatening autoimmune diseases that are unresponsive to conventional treatments, but results from trials in progress are needed for more definite conclusions especially the risk/benefit ratio.

Cytokines

Blocking Tumor Necrosis Factor Pathways

Humanized MAbs to TNF proved a major breakthrough in the treatment of RA, consequent to the pioneering experimental and clinical work of the groups of Feldmann and Maini (Brennan et al., 1989; Elliott et al., 1994a; Feldmann, 2002). The seminal finding was that neutralizing antibodies to TNF significantly decreased the production of most of the pro-inflammatory cytokines (i.e., IL-1, IL-6, IL-8, GM-CSF) normally produced in *in vitro* cultures of cells that infiltrate synovial membranes in RA (Brennan et al., 1989; Brennan and Feldmann, 1992; Feldmann, 2002). The relevance of this finding to events *in vivo* was validated in mice that express a human TNF transgene and develop a form of chronic arthritis fully preventable by MAbs to TNF (Brennan and Feldmann, 1992; Feldmann, 2002). In addition, in CIA, neutralizing antibodies to murine TNF given at the onset of disease decreased the severity of objective and histopathologic features (swollen joints and bone erosions) (Piguet et al., 1992; Williams et al., 1992; 1994). An unexpected but potentially relevant observation was that, in established arthritis, combination of a suboptimal dose of anti-TNF (which had no significant effect per se) with anti-CD4 greatly improved joint inflammation and helped heal paw-swelling and bone erosions (Williams et al., 1994; Marinova-Mutafchieva et al., 2000). Thus neutralizing inflammation, as with anti-TNF, effectively "sensitizes" the immune system to T-cell-directed immunointervention: this could be relevant to various autoimmune diseases other than RA.

The first randomized placebo-controlled double-blind study showing effectiveness of the chimeric neutralizing antibody to TNF, cA2 (human IgG1, now termed infliximab [Remicade]) in long-standing RA was reported in 1994 (Elliott et al., 1994a); there was significant therapeutic benefit lasting for several weeks after the end of treatment. Some patients with relapse of RA underwent two or more

courses of treatment; the mean duration of remissions progressively diminished due to sensitization to the MAb (Elliott et al., 1994b). In further studies, anti-TNF was combined with methotrexate, thus avoiding sensitization and obtaining longer-lasting remissions (Maini et al., 1998; Feldmann and Maini, 2001; Feldmann, 2002). Data from a phase III trial showed that anti-TNF arrested joint damage in more than 50% of patients; the effect was noted by 6 months after beginning of treatment and lasted for the 2 years of the study (Maini et al., 1999; Lipsky et al., 2000). Infliximab was, therefore, approved for use, in combination with methotrexate, both in the USA and Europe.

Given these results with infliximab, other biologic agents against TNF were developed. Another chimeric anti-TNF MAb named CDP571 also was clinically effective (Rankin et al., 1995), as were two fusion proteins linking the TNF receptor molecules p55 or p75 to a human IgG constant region [lenercept and etanercept (Enbrel), respectively] (Moreland et al., 1996; 1997; Furst et al., 2003). However, only etanercept was actively developed in the clinic and became approved. Other interesting candidates are on the way, one being the fully human D2E7 antibody (adalimumab) that has shown efficacy in phase II and III trials (Kempeni, 1999; den Broeder et al., 2002).

Also MAbs to TNF were used successfully in severe Crohn's disease and have been approved for this use (Van Dullemen et al., 1995; Present et al., 1999). Although the pathophysiology of Crohn's disease remains unclear (see Chapter 52) inflammatory cytokines are significantly involved (Van Deventer, 1997). The therapeutic benefit derived from anti-TNF treatment correlated with a decreased production of IFN-γ by mononuclear cells infiltrating the lamina propria of the colon (Plevy et al., 1997). Interestingly, at variance with what is observed in RA, TNF receptor fusion proteins were not effective in Crohn's disease.

Subsequently data from trials using anti-TNF in juvenile idiopathic arthritis (juvenile RA) (Lovell et al., 2000), ankylosing spondylitis (Brandt et al., 2000), psoriatic arthritis (Mease et al., 2000) and psoriasis have been published (Chaudhari et al., 2001).

One adverse effect reported, especially in patients undergoing repeated treatments with infliximab, was the increased incidence of tuberculosis (both pulmonary and extrapulmonary disease) (Keane et al., 2001; Gomez-Reino et al., 2003). This is one reason why combination therapy with drugs aimed at neutralizing TNF and IL-1 has been recently disallowed by the Food and Drug Administration in the USA. Other side effects that have been related to TNF blockers include the induction of autoantibodies and the occurrence of non-Hodgkin lymphoma (Brown et al., 2002; Wolfe and Michaud, 2004). Autoantibody formation is commonly seen in patients receiving prolonged treatment with infliximab (Louis et al., 2003; Caramaschi et al., 2004). These include antinuclear antibodies, anti-Sm, anti-RNP, and, in few cases, anti-double-stranded DNA autoantibodies; their presence is usually not associated with clinical signs of multisystem autoimmune disease. Concerning the occurrence of lymphoma Wolfe and Michaud recently reported an extensive study on 18,572 patients with RA who were enrolled in the National Data Bank for Rheumatic Diseases (Wolfe and Michaud, 2004). The overall standardized incidence ratio for lymphoma in RA patients not receiving methotrexate or biologics was 1.0 [95% confidence interval (CI) 0.4–2.5], and it was 2.9 (95% CI 1.7–4.9) in patients treated with TNF blockers, 2.6 (95% CI 1.4–4.5) in patients receiving infliximab (with or without etanercept), and 3.8 (95% CI 1.9–7.5) in patients receiving etanercept, with or without infliximab (Wolfe and Michaud, 2004). The authors concluded that current data are insufficient to firmly establish a causal relationship because lymphomas are increased in RA independently from the treatment. Although the risk appears higher when TNF blockers are administered, differences between therapies are slight, and confidence intervals for treatment groups overlap.

Antibodies to Interferon-Gamma

Treatment with antibodies to IFN-γ has been attempted in several experimental autoimmune diseases on the rationale that the central effects of IFN-γ in Th1-mediated immune responses include macrophage activation and upregulation of major histocompatibility complex molecules. MAbs to IFN-γ successfully prevented autoimmune diabetes in BB rats and NOD mice (Nicoletti et al., 1990; Debray-sachs et al., 1991). In (NZB × NZW) F1 mice, anti-IFN-γ treatment when started early (by 4 months of age) delayed the onset of glomerulonephritis and significantly prolonged survival; anti-IFN-γ appeared to act by inhibiting production of anti-DNA autoantibodies rather than affecting immune complex formation.

In patients with RA, a randomized double-blind trial compared the effectiveness of treatment with anti-IFN-γ versus anti-TNF or placebo (Sigidin et al., 2001). Promising data were obtained by 4 weeks post-treatment but longer term studies are needed.

Other Soluble Receptors and Protein Fusion Conjugates

The use of soluble receptors to TNF and CTLA-4Ig has already been discussed. Another human fusion protein was recently developed by coupling LFA-3 to human IgG1 to provide an agent (alefacept) that binds to CD2 on T lymphocytes; in controlled multicenter studies, this agent was used weekly in patients with chronic plaque psoriasis for one or two 12-week courses. The drug was well-tolerated, and a minimal 75% reduction of the disease score (PASI index) was observed 2 weeks from the last dose, lasting for 7 months (Krueger, 2003; Lebwohl et al., 2003).

Alefacept has been approved by regulatory authorities in the USA for this indication. There was a reduction of memory T cells ($CD45R0^+$ that include pathogenic cells) in treated patients that correlated with measurements of disease activity; lymphocytes expressing a naïve phenotype were spared (Krueger, 2003; Lebwohl et al., 2003).

A recombinant human IL-1 receptor antagonist (IL-1Ra), anakinra, has been tested in severe rheumatic diseases with encouraging results in patients with juvenile idiopathic arthritis resistant to other drugs (Verbsky and White, 2004). Data were also reported in refractory SLE (Moosig et al., 2004). In RA large placebo-controlled trials including international multicenter studies have demonstrated safety of the drug as well as a sustained clinical improvement (Nuki et al., 2002; Fleischmann et al., 2003). Importantly, data also suggested that IL-1Ra significantly reduced radiologic progression of bone erosions (Jiang et al., 2000).

A new strategy aimed at producing a massive though selective apoptosis of recently activated T cells has been developed by Strom and colleagues. They constructed cytolytic chimeric IL-2/Fc and IL-15/Fc fusion proteins that specifically bind with high affinity and kill cells bearing IL-2 and IL-15 receptors by complement-dependent and antibody-dependent cytotoxicity (Zheng et al., 1999; 2003a; 2003b; Ferrari-Lacraz et al., 2004). When administered alone, these IL-2/Fc and IL-15/Fc fusion proteins prevented autoimmune diabetes in NOD mice, and also CIA (Zheng et al., 1999; 2003a; 2003b; Ferrari-Lacraz et al., 2004). Moreover, combining these two agents together with rapamycin provided an extremely efficient means of restoring self-tolerance in NOD mice presenting with recent-onset disease, and inducing transplant tolerance in a particularly stringent model, i.e., implantation of allogeneic islets in overtly diabetic NOD mice (Zheng et al., 2003a; 2003b). Mechanistic studies showed that, while limiting the early expansion of activated T-cells and forcing their apoptosis, this regimen nevertheless preserved regulatory $CD4^+CD25^+$ T cells (Zheng et al., 2003a; 2003b).

Soluble Autoantigens

Immunologic tolerance to a wide spectrum of antigens (and autoantigens) can be induced by parenteral, nasal, or oral delivery of a soluble antigen. This approach has proven to be successful in several animal models of autoimmune diseases, either spontaneous or experimentally induced by immunization against autoantigens. Thus the onset of diabetes in NOD mice can be prevented by administration of insulin or GAD using various routes of administration subcutaneous, I.V., nasal, or oral. Similarly, experimental allergic encephalomyelitis (EAE) is preventable by administration of the soluble myelin antigen which is ultimately used to induce the disease.

The details of the underlying mechanisms are the subject of another chapter (see Chapter 75), but mention can be made that autoantigen-induced tolerance, whether using proteins, peptides, or altered peptide ligands, is beset by a number of difficulties. These include limitation of the treatment to early disease stages; loss of therapeutic effectiveness as disease progresses; a long lag time to achieve efficacy, which may represent a problem in the case of acute autoimmune responses; risk of disease acceleration by triggering rather than downregulating the autoimmune response; sensitization with potential risks of anaphylaxis and/or production of neutralizing antibodies leading to serious problems when the autoantigen molecule (e.g., insulin) is physiologically relevant.

Bone Marrow Transplantation

Autoimmune diseases include genetic components expressed in the lymphoid and macrophage lineages and thus qualify as stem-cell disorders (Ikehara et al., 1990). Hence, patients with serious autoimmune diseases can be considered for high-dose immunosuppression followed by hematopoietic stem-cell transplantation (HSCT) (Marmont et al., 1997; Tyndall et al., 1997; Ikehara, 1998). This strategy was initially based on clinical observations in patients with malignancies and concurrent autoimmune diseases (McAllister et al., 1997), as well as results of HSCT in experimental models (Karussis et al., 1992; 1993; van Bekkum, 1998). The latter showed that all types of HSCT, whether allogeneic or autologous, may induce high remission rates provided adequate conditioning regimens are administered. For example, excellent results were obtained in murine models of spontaneous autoimmunity such as autoimmune diabetes in the NOD mouse or BB rat, and lupus in (NZB × NZW) F1 mice (Ikehara et al., 1985). The mechanisms involve both central and peripheral chimerism. Although successful, the strategy is however hardly applicable in humans, due to the hazards associated with conditioning regimens and potential GvHD disease.

More attention has been given in serious autoimmune diseases to transplantation of autologous bone-marrow-derived stem cells, with the initial aim to induce very deep immunosuppression by reason of the protection afforded by bone marrow cell reconstitution, to reduce the disease activity, or even provide a cure. Other modes of action may be operative, such as the resetting of immunoregulatory circuits. Thus, regulatory T cells may recover before effector cells, or benefit may come from the initial elimination of the latter. There is also the possibly useful role of granulocyte-colony-stimulating factor (G-CSF), usually administered pretransplant to mobilize stem cells or post-transplant to accelerate reconstitution, which could be beneficial by downregulating effector cells as shown for NOD mice (Kared, 2004) and mice with EAE (Zavala et al., 2002).

The First International Symposium on Haemopoietic Stem Cell Therapy in autoimmune diseases took place in 1996 (Tyndall et al., 1997), and inaugurated collaborations

including publication by the European Group for Blood and Marrow Transplantation (EBMT), European League Against Rheumatism (EULAR), and the European Charcot Foundation of consensus reports of guidelines for autologous HSCT in autoimmune diseases, and for reports by participating centers on their results to the EBMT registry.

The source of the stem-cell transplant is mostly mobilized cells from peripheral blood, as these appear to afford a faster and more complete recovery compared with bone-marrow-derived stem cells. Mobilization of blood stem cells is performed using cyclophosphamide in combination with hematopoietic growth factors, G-CSF alone, or combined with GM-CSF. According to different studies, the grafts are either purged of mature T cells, which may contain autoreactive effectors, by selection of $CD34^+$ cells with or without additional MAb-dependent T-cell-depletion, or are not manipulated. Pretransplant conditioning regimens, for which the aim is to ablate as completely as possible the diseased (autoreactive) component of the immune system, include chemotherapy-based regimens, such as BEAM [BCNU (carmustine), etoposide, cytarabine, melphalan], cyclophosphamide with or without antilymphocyte globulins and with or without other drugs, or total body irradiation and busulfan.

Recent reports provide a conspectus of results on HSCT in rheumatic diseases and MS. Farge et al. reported on 57 patients with systemic sclerosis in European phase I/II studies from 1996 to 2002, with a response in two-thirds of these over a follow-up of 36 months, which was durable and with an "acceptable" morbidity/mortality risk (Farge et al., 2004). At 5 years, the progression probability was 48% and the projected survival was 72% (Farge et al., 2004) leading to randomized trials now in progress. In another report, Van Laar and Tyndall reviewed the results of recent phase I/II studies and data from the EBMT/EULAR registry on more than 400 patients with autoimmune diseases including RA, SLE, systemic sclerosis, and juvenile idiopathic arthritis (Van Laar and Tyndall, 2003). Treatment-related mortality was low in RA (1.4%) but relatively high (>10%) in patients with juvenile idiopathic arthritis, SLE, and systemic sclerosis, possibly related to visceral involvement. With the application of uniform and strict criteria, safety has improved. Long-term remissions of up to 4 years have been observed in systemic sclerosis and juvenile idiopathic arthritis, while relatively more relapses have occurred in patients with SLE and RA although sensitivity to antirheumatic drugs was restored in these patients thus resulting in improved disease control (Van Laar and Tyndall, 2003). Data from a multicenter retrospective study assessing autologous HSCT in the treatment of poor-risk patients with MS (Fassas et al., 2002) indicated possible benefit as judged by a confirmed progression-free survival probability of 74% at 3 years post-transplant; progression-free survival rates were higher in patients below 40 years of age (89%) and for those not suffering from permanent progressive MS (78%). Treatment-related mortality was high (6%), though not significantly different from that after autologous HSCT in lymphoma. It remains to be determined what level of risk is acceptable for patients with an autoimmune disease that is seldom life-threatening. In fact, autologous HSCT seems justified only if this will confer a clear-cut benefit compared with what can be achieved by existing treatments.

Cell Therapy and Gene Therapy

Cell Therapy

The culture *in vitro* of specialized subsets of immune cells that can be re-infused into a subject with an autoimmune disease is another emerging therapy that has benefited from experience with tumor immunology. Two cell types in particular have elicited interest—tolerogenic dendritic cells and regulatory T cells.

Dendritic cells are potent stimulators of immune responses but, when appropriately manipulated *in vitro*, express powerful tolerogenic properties shown by suppression *in vivo* of alloimune and autoimmune responses. Several factors influence this tolerogenic capacity of dendritic cells, including the precise subset of dendritic cell considered, and the degree of differentiation/maturation: immature or "semi-mature" dendritic cells are tolerogenic whereas mature dendritic cells are immunogenic. Several *in vitro* procedures have been described to derive tolerogenic dendritic cells, including treatment with CTLA-4Ig (Ben-yedidia et al., 1999), IL-10 (Takayama et al., 1998), vitamin D3 (Adorini, 2004), or TGF-β (Alard et al., 2004). The cellular and molecular mechanisms that drive the modulatory capacity of such tolerizing dendritic cells vary, depending on the model, and although only partly understood, these mechanisms mostly rely on a capacity to trigger states of peripheral tolerance, either anergy, immune deviation, or the induction of regulatory T cells.

The culture of regulatory T cells is another option. According to recent data, *in vitro* expanded $CD25^+$ regulatory T cells were highly effective in reversing established diabetes in NOD mice (Bluestone and Tang, 2004; Tang et al., 2004).

Gene Therapy

It is tempting to treat autoimmune diseases by administration of immunoregulatory cytokines. Although there have been some data from experimental models including use of IL-4 and IL-10 in NOD mice (Rapoport et al., 1993) and IL-10 in EAE (Rott et al., 1994), clinical application appears problematic with the possible exception of IL-10 in Crohn's disease (Tilg et al., 2002).

An alternative way of administering recombinant proteins or autoantigens is based on the principles of gene therapy with the advantage of a targeted delivery of high amounts of the selected therapeutic protein.

Gene therapy has successfully been used in several settings for the treatment of autoimmune diseases in animal models. Transduction with genes for regulatory cytokines, notably IL-4 (Yamamoto et al., 2001), IL-10 (Moritani et al., 1996), and TGF-β (Piccirillo et al., 1998) has been shown to protect mice from autoimmune diabetes (NOD), and also from EAE (Tarner et al., 2003). In some cases, immune cells were transduced, with the idea that these cells would deliver the cytokine *in situ* after they had homed to the target organ (Tarner et al., 2003; Yamamoto et al., 2001). It has also been possible to inhibit the progression of advanced diabetes in NOD mice by genetic induction of large amounts of an intracellular adhesion molecule (ICAM-1) fusion protein (Bertry-Coussot et al., 2002).

The difficulties associated with clinical application of gene therapy are considerable. These include the selection of an efficacious and safe vector, long-term maintenance of the expression of the transduced gene, difficulties in controlling the amount of protein produced with risks of uncontrollable hyperproduction, and uncertainty about the site of delivery of the expressed protein (see Bottino et al., 2003 for review). Ingenious procedures are being developed in genetic diseases, and in cancer, where the need for gene therapy is urgent. Perhaps only when the problems are solved in these settings will gene therapy become applicable to human autoimmune diseases. Meanwhile use should be encouraged in animal models of autoimmunity to provide original information on disease mechanisms and prepare for future clinical applications.

There are as yet early experimental studies aiming at promoting target cell reconstitution, applicable to islet cells in diabetes, by antecedent administration of precursor cells and subsequent genetic manipulation to commit them to the β-cell lineage. There is a double caveat: the intrinsic difficulty of the procedure, and the likelihood of relapse of the autoimmune process on newly generated cells (Bottino et al., 2003).

CONTRASTED APPLICATIONS OF EMERGENT IMMUNOTHERAPIES IN HUMAN AUTOIMMUNE DISEASES

It may seem surprising that the emergent therapies discussed above are not in fact being applied to various autoimmune diseases, but there are some good reasons for this. First, some autoimmune diseases are antibody-mediated (e.g., SLE or myasthenia gravis) whereas others are T-cell-mediated (e.g., type 1 diabetes and psoriasis). Of course B-cell-targeted therapies should be limited to the former and T-cell-targeted strategies more to the latter; this is not absolute, however, since antibody production requires T-cell help, and T-cell responses may depend on B-cell-mediated antigen presentation. Second, primary effector mechanisms vary considerably among autoimmune diseases since TNF appears to be of crucial importance in RA and Crohn's disease, whereas $CD4^+$ and $CD8^+$ T cells are main effectors in type 1 diabetes. Third, some autoimmune diseases will be more used to establish proof of principle because of their easy qualitative and report readout, as for psoriasis, which is often selected for phase I study even though not qualifying as a *bona fide* autoimmune disease and perhaps not truly representative of all autoimmune diseases. Rheumatoid arthritis is often primarily selected because of the large consumer market it represents even though it is a very difficult disease for early evaluation of drug efficacy, and also is not necessarily representative of other autoimmune diseases at the pathophysiologic level. On the other hand, trials in MS can only provide significant data after laborious long-term study, although the introduction of MRI has accelerated and improved the clinical evaluation.

All these issues point to differences among the various autoimmune diseases. It is necessary, though, to consider the following points: that IFN-β has essentially been developed for treatment of MS, but its immunomodulatory properties could probably benefit patients with other autoimmune diseases; that anti-TNF antibodies have so far been used in RA, spondyloarthropathies, Crohn's disease, and more recently psoriasis, yet this cytokine is probably involved in many other autoimmune diseases; and that anti-T-cell antibodies have been used in a rather limited fashion (e.g., anti-CD3 in type 1 diabetes, anti-CD52 in MS and RA, anti-CD4 in RA), although T cells are involved in the majority of autoimmune diseases.

Similar comments can be made for other agents: CTLA-4Ig has been limited to use in psoriasis and RA, LFA3-Ig to psoriasis, anti-CD25 to uveitis, and anti-VLA-4 to MS and Crohn's disease, even though there is no logical reason whatsoever for the preferential usage of these agents in any of these diseases.

One, therefore, hopes that, despite the commercial or ethical difficulties connected with the application of these biologic therapies in a multitude of diseases, the remarkable results achieved should ensure that these effective agents become accessible to all patients who could benefit from them.

WHAT ARE THE PERSPECTIVES FOR THE FUTURE?

In addition to policies based on disease severity (risk-to-benefit ratio), the overall policy will vary according to the phases of progression of a particular disease and the perception of urgency at the onset of the autoimmune response. When there is urgency, as pertains in the case of recently-diagnosed type 1 diabetes or MS, the hope is that the auto-

immune destruction can be halted before irreversible lesions develop. This is not done at present because patients with MS are usually given high-dose corticosteroid treatment at the time of diagnosis, which may not be optimal. Patients with type 1 diabetes are not given any immunotherapy because of the availability of a substitutive treatment, insulin. Here, anti-T-cell MAb, of which the most promising is anti-CD3, is an attractive approach: anti-CD3 acts rapidly (within 24 hours) and the effect is long-lasting after a short therapeutic course (Herold et al., 2002; Keymeulen et al., 2005).

When inflammation is more prominent, consideration should be given to new anti-inflammatory methods exemplified by MAbs to TNF or IL-1 RA. It should be realized, however, that these methods of countering inflammation have only short-term effects and should supplement rather than replace the many other approaches discussed above, notably in RA.

When the autoimmune disease exposes the patient to a lethal risk, or major morbidity, examples being MS, very severe SLE, vasculitis, or rapidly progressing juvenile RA, high-risk treatments must be considered such as high-dose nonspecific chemical immunosuppression associated with autologous bone marrow transplantation.

At the end of this discussion it may be wondered where precisely therapy with corticosteroids and chemical immunosuppressants fits in for the management of autoimmune disease. Currently, these drugs still represent the best-established method of managing an autoimmune disease, particularly so for corticosteroids, which are still impossible to replace in many autoimmune diseases. However, their lack of specificity for the underlying autoimmune responses, and the exposure of patients to the risks of over-immunosuppression and direct drug toxicity should lead to a progressive reduction in their usage. As a conclusion, it is hoped, if not anticipated, that emergent therapies based on the progress of biotechnology, including gene and cell therapy, will progressively complement and perhaps replace conventional treatments. The rapidity with which anti-TNF antibodies have become accessible to patients with RA and Crohn's disease is more than encouraging. Nevertheless, there are still numerous problems concerning the development and evaluation of the various drugs being studied. The multitude of these drugs and their potential clinical applications are remarkable. Major efforts should be made to identify the best applications and promote their development for the benefit of patients beyond commercial constraints.

Advocatus Diaboli: What is not known about Autoimmune Disease

JAMES W. GODING

Department of Immunology and Department of Physiology, Monash University, Clayton 3800, Victoria, Australia

WHY IS AUTOIMMUNITY STILL IN SUCH A MUDDLE?

It is a challenging privilege to conclude *The Autoimmune Diseases, 4th edition* by setting out what remains unknown. Perhaps a scientist who is not at the center of autoimmunity might be hesitant in listing gaps in knowledge that must be painfully obvious to those in the field. But, as befits the title, I will argue that we remain in a state of deep ignorance concerning the nature of autoimmunity and its induction, maintenance, and effector mechanisms. We are even uncertain of where the perimeters of autoimmune disease begin and end.

It is sometimes argued that scientists should mount a frontal attack on the so-called "big questions." In biology, this approach is rarely successful, and often delusional. I doubt whether many immunologists realized just how complex the question of tolerance would turn out to be. The "military concept" of a frontal attack seems eerily reminiscent of the ubiquitous "mission statement" that is currently so fashionable in the business world. It usually fails because essential but apparently unrelated information is missing, or simply because the necessary technology is not yet available. The time has to be ripe. Technological progress may make a question suddenly tractable, as witnessed by the occasional simultaneous appearance of a batch of papers on the same hitherto intractable subject. Sometimes major advances are unexpected, unplanned, and even initially unbelievable, coming as the result of asking a totally different question. Such was the case for the discovery of the relevant autoantigen of myasthenia gravis—the acetylcholine receptor (Patrick and Lindstrom, 1973; Lennon et al., 1975).

WHAT WE DO KNOW

Many of the central questions in immunology have been answered. The clonal selection theory continues to underpin our thinking. It has been intermittently under attack, but not fatally (Melchers, 2004). The revolutions that have flowed from the discovery of T and B cells, MHC restriction, and DNA rearrangements to create receptor genes seem comfortably embedded in the past. We now have a fairly clear idea of the mechanisms of antigen recognition by both B- and T cells, and of the genetic mechanisms by which clonal diversity is achieved. It might, therefore, be felt that immunology has reached maturity, and that the functioning of the immune system is reasonably well understood (see Chapter 2). Yet even this would be an overstatement. A glance backwards for just a few years will reveal that immunology is continuing to undergo quite revolutionary changes. Indeed, the rate at which discoveries are being made makes it clear that we should expect more radical discoveries to be just around the corner.

The Autoimmune Diseases, edited by Noel R. Rose and Ian R. Mackay.
ISBN-13: 978-0-12-595961-2 ISBN-10: 0-12-595961-3

Let me take some examples. First, suppressor T cells have reappeared, renamed "regulatory T cells." This is a most unfortunate term, because all T cells are regulatory. We still need to ask what regulates the regulators. If all that this population does is suppress, we should "bite the bullet" and call them suppressors, and hope that we are on more solid footing the second time around (Shevach, 2004; Schwartz, 2005; von Boehmer, 2005). But clearly, for the present, there are many unknowns regarding regulation and the T cells contributing to it (see Chapter 9).

Second, the innate immune system that until a few years ago was seen as "yesteryearish" and boring, has suddenly become the focus of renewed interest and excitement. It has been found to possess a recognition system of sophistication far greater hitherto imagined (Janeway and Medzhitov, 2002). Moreover, in hagfish, the "innate" system has a diversification system involving DNA rearrangements that previously appeared to be exclusive to the adaptive immune system in vertebrates (Pancer et al., 2004). Is this really an adaptive system rather than a "fixed" system, and has nature invented adaptive immunity twice? It is too early to say whether similar gene rearrangements occur in vertebrates.

Third, the renewed interest in the innate immune system has forced us to rethink some cherished concepts. The intractability of the problem of autoimmunity reflects our incomplete understanding of the normal functioning of the immune system, particularly how immune responses are initiated and how mechanisms of self-tolerance operate–opposite sides of the same coin. It is now apparent that mere recognition of antigen by lymphocyte surface receptors is insufficient to activate the adaptive immune system: it needs a "kick start" from the innate system (Medzhitov and Janeway, 1999). Given the well-documented existence of self-reactive albeit low avidity T and B cells in normally healthy individuals, this is just as well (Andre et al., 1996).

WILL THE "REAL" AUTOANTIGEN PLEASE STAND UP?

Autoimmune processes can be analyzed with much greater clarity if they are divided into initiation, maintenance, and effector mechanisms. But let us begin by considering autoantigens, which must be common to all three stages.

The topic of autoimmunity has no shortage of antigens. In most cases, it is not clear whether any individual autoantigen is involved in the pathogenesis of the associated disease, or is merely an innocent bystander. A "real" autoantigen would be one wherein there is definitive evidence that autoimmune attack against it causes disease in humans, either as an initiator or a final target or both.

This requirement is most readily met for diseases in which the damage is mediated by antibodies, such as those demonstrable in myasthenia gravis, Graves' disease, autoimmune hemolytic anemia, autoimmune thrombocytopenic purpura, pemphigus vulgaris, and various more uncommon diseases, including those associated with autoantibodies to growth factors such as granulocyte/macrophage colony-stimulating factor (Trapnell et al., 2003) and erythropoietin (Guest and Levitt, 2003), and the folate receptor (Ramaekers et al., 2005). On the other hand, the "real" antigens that determine tissue damage in many common human autoimmune diseases including type I diabetes mellitus, systemic sclerosis, rheumatoid arthritis, and multiple sclerosis remain unidentified, and the relevance to human disease of autoantigens identified or studied in corresponding animal models remains uncertain.

The technology required to identify antigens that are recognized by autoantibodies is well established and relatively straightforward. In marked contrast, the identification of autoantigens recognized by T cells is very much more of a challenge, particularly for those that are restricted by MHC class I and recognized by $CD8^+$ T cells. In particular, the entire role and activities of $CD8^+$ T cells in autoimmune disease is near to a "closed book." Numerous T-cell antigens that are centrally involved in pathogenesis probably remain to be identified, and many mysteries of autoimmunity probably stem from this technological difficulty.

What should we make of the plethora of serologically detectable autoantigens, many of which are intracellular? These reactivities have considerable utility as diagnostic markers, but do they have anything to do with pathogenesis? It is possible to have high levels of many such antibodies and yet be perfectly healthy. Could they merely represent fortuitous cross-reactions with the "real" antigen? Claims that antibodies can penetrate cells and cause damage by binding to intracellular autoantigens remain perennially controversial. The main reason why T cells are so important for defense of the body is because every cell in the body displays on its surface in the MHC groove a more or less random sample of all the proteins that the cell is making. This allows T cells to "see inside" other cells, while B cells and antibodies cannot, and is only possible because of a very complex set of mechanisms involving intracellular proteolysis, transport of peptides across cell membranes, and machinery to load the MHC groove with endogenous or exogenous peptides.

It is interesting but poorly understood why so many intracellular autoantigens recognized by autoantibodies are multi-subunit proteins or protein/nucleic acid complexes. The conventional explanation, which seems convincing, is that the entire multimeric complex is dragged by one subunit into an antigen-presenting cell, perhaps via the membrane immunoglobulin receptors of B cells that are part of the inflammatory component of autoimmunity. Endocytosis is

followed by fragmentation and presentation of peptides from all subunits in the groove of class II MHC molecules on the B-cell surface, ultimately leading to activation of additional helper T cells and consequent "epitope spreading." In many such instances where there are autoantibodies to intracellular molecular complexes, the disease process is multiorgan and multisystem, and may reflect the relatively nonspecific inflammatory effects of circulating antigen/antibody complexes.

Sometimes an autoantigen is ubiquitous, yet the tissue damage is localized to discrete tissue sites. The most dramatic example is primary biliary cirrhosis (Ichiki et al., 2004; see Chapter 54). It is very difficult to see how the antimitochondrial antibodies could be involved in pathogenesis of highly localized tissue damage affecting bile ducts alone. Is the "real" antigen something else? Or are the tissues and cells that are damaged unusually susceptible to some form of effector phase?

INDUCTION OF AUTOIMMUNITY

The strong association of almost all, or perhaps even all, autoimmune diseases with particular HLA alleles is a very clear pointer towards a primary involvement of T-cells in the initiation of disease (see Chapter 20). It also strongly suggests that autoimmunity must be initiated by a single antigen, or at the most by a very small number of antigens that bind preferentially to the relevant HLA allelic product. However, even for diseases with the highest risk HLA alleles, penetrance of risk is incomplete, and the great majority of individuals with the high risk allele do not develop autoimmune disease. Why? It seems all too easy to invoke environmental factors. Incomplete penetrance could result from other mechanisms, such as low probability pathogenic somatic mutations. Somatic mutations are now extremely well documented as playing a causative role in cancer, and the time-dependent buildup of somatic mutations is widely accepted as explaining the dramatic increase in the incidence of cancer with aging. A similar process may well be a part explanation for the age-specific increase in incidence of certain autoimmune diseases. Autoimmune disease does occur in younger age groups, but so does cancer. Somatic mutations are a normal physiologic process in B cells during affinity maturation in secondary responses. They do not seem to be involved in normal T-cell development, but I can see no reason why pathogenic somatic mutations could not occur in lymphocytes in a similar way to those that cause cancer in any somatic cell type. We are just beginning to see evidence in support of a role for somatic mutations in autoimmunity, and it seems very likely that many more examples will be found in the next few years (Clementi et al., 2004; Holzelova et al., 2004; Puck and Straus, 2004).

Mutations in the germline are easy to detect because they are amplified by massive cell division. Cells are extremely small; there are extremely large numbers of them, and mutations are rare events that take place in single cells. Accordingly, the vast majority of somatic mutations would not be expected to have detectable biologic consequences. It has been reasonably argued that the only way that somatic mutations would reveal themselves would be if they caused cancer or autoimmunity. The "Clonal Selection Theory" introduced the concept of the "forbidden clone" as a general explanation for autoimmunity. This hypothesis was formulated long before the mechanisms of receptor diversification were understood or even imagined, and it now seems likely that the great majority of initially arising receptor specificities are forbidden (i.e., autoreactive). Such clones could persist due to failure of deletion, or could arise *de novo* by somatic mutation.

Somatic mutations in genes for lymphocyte receptors for antigen are obvious candidates to make them autoreactive. However, the appeal of this simple hypothesis is greatly diminished by the clear evidence that autoreactive T and B cells are widespread in the body, yet most of the time they do no damage. The term "forbidden clone" has disappeared from the lexicon, although it does aptly describe the regulation-resistant memory-type "autoaggressive" T cell characteristic of organ-specific autoimmunity.

Mutation of genes encoding receptors for antigen is not the only way in which somatic mutations could cause autoimmunity. Somatic mutations in genes encoding any of the pathways involved in immune responses, such as costimulatory molecules, regulation of apoptosis, or signaling pathways in lymphocytes or antigen-presenting cells, could lower the threshold of activation and thereby cause the development of a destructive effector phenotype.

There is considerable evidence, both in humans and in mice, that autoimmunity can be the result of an unfavorable genotype caused by inherited germline mutations that affect the threshold of lymphocyte activation (Bach, 2005; Lang et al., 2005; McGaha et al., 2005). Such germline mutations might be expected to be expressed in large numbers of cells and cause generalized disease such as systemic lupus erythematosus (SLE) by inducing polyclonal activation. I can see no reason why a similar process could not occur for somatic mutations that lower the activation threshold in individual T or B cells. Because the specificity of lymphocytes is clonally distributed, such somatic mutations would be expected to cause antigen-specific tissue damage.

If, as I strongly suspect, a rogue T-cell clone is the most common cause of autoimmunity, how could such a clone be identified? It will probably be necessary to enrich for the culprits, but this will not be easy. I envisage the initiating event to be a single adverse mutation in a single cell, although a multistep process similar to oncogenesis is also

possible. It is clear that the infiltrating population of attackers in naturally occurring autoimmunity is not monoclonal, perhaps due to recruitment of other T- and B-cell clones and resultant epitope spreading. Will "rounding up the usual suspects" be sufficient to apprehend the culprit? What seems to be required is a massive program of amplifying, cloning, and sequencing cDNA from enriched populations. Sequencing of genes for antigen receptors has generally been unrewarding. A more promising target may be the numerous genes encoding molecules involved in setting their threshold of activation, such as kinases, phosphatases, and many others. Such a brute force approach may seem inelegant, but at least it is now technically feasible. If the abundance of particular mRNAs in these pathways change in a selective way, microarrays might help focus the search, but the final answer will probably come from DNA sequencing.

What about environmental factors as an explanation of the incomplete penetrance of high-risk HLA alleles? In spite of massive searches for a "smoking gun," there are extremely few instances where an environmental villain has been unmasked at a molecular level. We have known for well over half a century that beta hemolytic streptococci cause rheumatic fever. Some progress has been made in identifying the relevant microbial antigen molecules (see Chapter 62), but we still have a very inadequate understanding of how these proteins trigger autoimmunity, and we have even less understanding of the mechanism of damage to the heart. It seems quite unlikely that it is due to antibodies. The case for an environmental trigger is also strong for spondylarthropathies including reactive arthritis, but the molecules and mechanisms by which autoimmunity is triggered are not understood at all (see Chapter 33).

A rare but fascinating example of what is almost certainly autoimmunity provoked by an external antigen is the case of pure red cell aplasia associated with autoantibodies to erythropoietin that appear to have been provoked by therapy with recombinant erythropoietin (Bennett et al., 2004). This seems to be a case in which autoimmunity is induced by an external agent that is very closely related to self, but which presumably has some critical differences that make it immunogenic. Possible candidates include aggregation, which is known to increase immunogenicity, and oxidation damage, which could render the protein "non-self." It may be significant that changes in the preparation and storage of recombinant erythropoietin to minimize damage by aggregation and oxidation seem to have reduced the incidence of such autoimmune reactions. It seems unlikely that the case of pure red cell aplasia points to any general principle regarding the provoking of autoimmunity by an external antigen that is closely related to "self" because it is possible to make anti-allotype antibodies that are specific for an allelic product of self that differs by only a single amino acid, and yet these antibodies do not react with the "self" allele (Warner et al., 1977; see below).

The case in which an environmental factor in a naturally occurring autoimmune disease seems best understood at the molecular level is celiac disease (McManus and Kelleher, 2003; see Chapter 51). Peptides from the wheat protein gliadin bind to the relevant HLA class II allelic products, triggering T-cell activation and thereby initiating local disease in the duodenum. The gliadin peptides are covalently modified by tissue transglutaminase, increasing their affinity of binding to the relevant HLA molecules. Transglutaminase is a serologically detectable autoantigen in the disease, although it is not clear whether it also represents an important target in the effector phase. The identification of an environmental trigger for celiac disease raises hopes that other autoimmune diseases may likewise have identifiable environmental triggers. In the vast majority of other cases, the initiating antigen for autoimmune disease remains unknown, and it is not even clear whether it is environmental, or intrinsic to the patient.

Returning to celiac disease, this is not without difficulties as a general model for induction of autoimmunity. Is it a true autoimmune disease or merely an example of cell-mediated hypersensitivity to foods? There is little evidence that such autoantibodies or T-cell reactivity to transglutaminase are involved in generating tissue damage.

A similar mechanism to that of celiac disease, also involving covalent post-translational modification of self proteins and peptides, has been proposed for rheumatoid arthritis, where some autoantigenic peptides have been found to have a covalent modification involving conversion of arginine to citrulline (Meyer, 2004). However, the case for involvement of this process in pathogenesis of the disease is less clear than for celiac disease, even though with refined assays the specificity of autoantibodies to cyclic citrullinated peptides is remarkably high (Rantapaa-Dahlqvist et al., 2003).

Does inflammation play a role in initiation of autoimmunity? The hypothesis is attractive because the activation of the innate immune system induces inflammation and maturation of dendritic cells, which are key events in the initiation of immune responses. This concept has been given many colorful names, particularly the "danger hypothesis" (Matzinger, 1994). The need for adjuvants to provoke strong immune responses is probably a reflection of the same requirement, which Janeway has termed "immunologists' dirty little secret" (Medzhitov and Janeway, 1999). To some extent these terms have been overtaken by a more precise understanding of the role of dendritic cells and Toll-like receptors in the initiation of T-cell responses (see Chapter 4).

Activation of lymphocytes must occur in stages. In some mouse models of type I diabetes mellitus, pancreatic islets become surrounded by a cuff of lymphocytes without any apparent damage. A distinct additional signal or event seems to be required for them to enter the islets and destroy

them. Is activation of the innate immune system and inflammation all that is required to change "sleeper" autoreactive T cells into active assassins (Poirot et al., 2004; Lang et al., 2005)?

Inflammation is clearly not a general provoker of autoimmunity. A popular hypothesis is that autoimmunity results from a combination of an inflammatory stimulus and a high-risk genotype. This is unlikely to be the complete answer, because all individuals with "high-risk" HLA alleles will encounter injuries and infection throughout life, yet few will develop autoimmunity. On the contrary, the "clean environment" of modern Western life is associated with rising incidence of autoimmune disease (Feillet and Bach, 2004). Similarly, nonobese diabetic (NOD) mice are highly prone to type 1 diabetes mellitus caused by autoimmune destruction of their pancreatic beta cells, but, contrary to the danger hypothesis as a cause for autoimmunity (see above), the cleaner the mice, the higher the incidence of diabetes (Zaccone et al., 2004). Moreover, the provocation of autoantibodies to erythropoietin by the recombinant hormone seems to have occurred in the absence of any adjuvant or obvious inflammatory stimulus (Bennett et al., 2004; see above).

In summary, we can say with confidence that HLA antigens and T cells must be of primary importance in the induction of autoimmunity. We must acknowledge our ignorance concerning the role of environmental triggers and inflammation. We can suspect that somatic mutations in T cells that influence specificity by setting the threshold of activation may provide an explanation for the incomplete penetrance of the known genetic risk factors.

MAINTENANCE OF AUTOIMMUNITY

Is autoimmunity antigen-driven? This would seem to be the case in general, and certainly for celiac disease where removal of gluten from the diet results in the intestinal mucosa returning to normal: but is this autoimmunity? The widely assumed premise that most cases of autoimmunity are driven by endogenous antigen is supported by fading levels of autoantibodies in organ-specific diseases when the relevant autoantigen is completely eliminated ("burn out") as exemplified by thyroiditis, gastritis, and type 1 diabetes, but in other examples definite proof of autoantigen requirement is lacking. For B cells at least, there is a further reason to believe that the process of autoimmunity is autoantigen-driven, because autoantibody-secreting B cells usually have mutated antibody genes that are typical of antigen-driven secondary responses. The situation for T cells is less clear, but lesions do depend on the presence of T cells of the "activated/memory" phenotype.

The ideal experimental model to test whether autoimmunity is driven by endogenous antigen would be a disease in which all the tissue bearing the relevant autoantigen could be removed without killing the animal. The "classical" experiment that is frequently cited in this regard is that of Triplett (1962), in which removal of the pituitary from embryonic frogs was claimed to prevent the induction of tolerance to this organ, as evidenced by rejection of autologous pituitary grafts after the frogs had matured. In view of its potential importance, it is remarkable that it took 20 years before attempts to repeat it were made, and it was found to be irreproducible (Rollins-Smith and Cohen, 1982).

In mice, some organs that are subject to autoimmune attack are not required for life, such as the ovary, thyroid, or even the stomach. They could be removed and life maintained. Two key questions could be asked. If a mouse had evidence of an autoimmune attack against an organ, and that organ were *completely* removed, would the autoimmune process fade away? Even if it did, would autoimmune memory cells persist? And if the relevant organ were removed sufficiently early in life, would this prevent the development of autoimmune attack against that organ? Suppose, for example, that NOD mice that have begun to produce autoimmune attack on the pancreatic islet cells were pancreatectomized and maintained on insulin, would the autoantibodies disappear? And would they return if the mice were reconstituted with syngeneic pancreas at a later stage?

But would removal of the organ that bears the brunt of immunologic attack be enough to remove all the sites of antigen expression? Probably not, because low-level "ectopic" antigen expression in other tissues is very common. Ectopic antigen expression may even help establish and maintain self-tolerance, particularly if it is in the thymus or the bone marrow, or possibly anywhere, since regulatory T cells can be induced peripherally (see Chapter 9). Many self antigens are expressed at low levels in the thymus, driven by the AIRE (autoimmune regulator) gene, and germline mutations of this gene cause autoimmunity (Chapters 37 and 38; Finnish-German APECED Consortium, 1997; Nagamine et al., 1997; Ramsdell and Ziegler, 2003).

EFFECTOR MECHANISMS IN AUTOIMMUNITY

The instances where the mechanisms of tissue damage are well characterized are almost entirely confined to antibody-mediated effects. These are generally diseases where the "real" autoantigen is clearly defined, such as myasthenia gravis, Graves' disease, autoimmune hemolytic anemia, autoimmune thrombocytopenic purpura, acquired hemophilia, and pemphigus vulgaris. In a few cases, autoantibodies have been found to neutralize growth factors such as erythropoietin or granulocyte-macrophage colony-

stimulating factor, presumably by direct binding, which prevents their association with the cognate cellular receptors. Antibodies may mediate damage by direct binding, activation of complement, facilitation of phagocytosis, or a combination of these. We also have some, but still insufficient, understanding of autoimmune tissue damage due to circulating antigen–antibody complexes, such as lupus and various forms of vasculitis (see Chapters 27, 28, 65).

However, much less clear are the instances where demonstrable autoantibodies cannot be implicated as a cause of damage, such as type 1 diabetes mellitus, primary biliary cirrhosis, and autoimmune hepatitis, and in some diseases of suspected autoimmune etiology such as multiple sclerosis where the role of autoantibodies remains controversial (Berger et al., 2003; Hafler et al, 2005). There is considerable evidence that damage is mediated by the direct action of T-cells, either as cytotoxic $CD8^+$ T cells or by the secretion of cytokines from $CD4^+$ cells and probably $CD8^+$ cells as well. In nearly all these cases, the "real" antigen in humans has not been definitively identified, nor has the precise mechanism of tissue damage been established. We know even less about the mechanism of tissue damage in rheumatic heart disease, systemic sclerosis, rheumatoid arthritis, or polymyositis.

Not all damage comes from antibody or T cells. Recent evidence has pointed to a significant role for natural killer (NK) cells in the destructive infiltration of the pancreatic islets in NOD mice (Poirot et al., 2004). NKT cells also seem to play a major role in downmodulating the susceptibility to autoimmunity in some animal models, although evidence for a role of these cells in human disease is far less clear (Godfrey, 2000; Esteban et al., 2003).

WE STILL DON'T UNDERSTAND TOLERANCE

Sometimes it is argued that "tolerance is dead," and that the key to understanding self/non-self discrimination lies at the level of the dendritic cell and its state of activation. This seems no more justified by the facts than Ehrlich's often misinterpreted "*horror autotoxicus*" that came to be taken to mean that autoimmunity was impossible.

There is abundant and very strong evidence that the initial repertoire of specificity of T and B cells is random and, therefore, includes anti-self specificities, and that many of these are deleted in the thymus and bone marrow, respectively, a process known as "central tolerance" (see Chapters 8, and 13). Few immunologists would doubt the existence of this process. Equally well, most would acknowledge that central mechanisms cannot be the whole story because it seems unlikely that each and every self antigen is expressed in the primary lymphoid organs, and there is good evidence that some self-reactive cells slip out. There is also good evidence for B cells that somatic mutations that drive affinity maturation in secondary responses are likely to generate anti-self reactivities (see Chapters 8, and 13). Mechanisms of "peripheral tolerance" must exist to deal with these potential sources of autoimmunity.

There has been a tendency in recent times to downplay the importance of structural differences between self and non-self, and to emphasize other factors in making the choice for the immune system of whether to respond or not. I take the traditional view of non-self as being structurally different from self, and that this is the main driving force for immune responses.

At least in the case of B cells, the further the phylogenetic distance between self and non-self proteins the greater the sequence divergence and the stronger the immune response to them. The reason is obviously that the closer the sequence of the antigen is to that of the corresponding self protein, the greater the fraction of self-reactive cells that can be silenced via self tolerance. The fact that it is sometimes possible to generate autoantibodies to self proteins does not negate this basic fact.

If there is any doubt about this point, consider the case of IgM allotypes in the mouse. There are two allelic forms of μ-chain, which differ by only one amino acid in the constant region, out of a total of 434 amino acids (Schreier et al., 1986). Immunization of mice with IgM of the non-self allele in the absence of adjuvants generates antibodies that react with the non-self allele but not the self allele (Warner et al, 1977). This tells us several things. It demonstrates the ability of the immune system to discriminate between self and non-self is extremely precise. It also tells us that the lymphocyte repertoire does not respond to the self allele when challenged with the non-self allele. If we accept the notion that the activation signal delivered by helper T cells to B cells is not antigen-specific, it follows that B cells with specificity for the self allele must be either absent or silenced.

The situation for T cells is considerably more complex, because, when the antigen comprises living cells such as transplanted organs or the mixed lymphocyte reaction, allogeneic interactions are generally stronger than xenogeneic. However, these situations are highly artificial. Their relevance to naturally occurring immune reactions is still unclear, and the reasons for the strength of alloreactivity are still not well understood.

There have been many experimental models of tolerance, some with more rationale than others. One very popular model, the rationale of which I have never understood, has been the induction of "tolerance" by intravenous injection of large doses of de-aggregated human IgG in mice. If these experiments purport to reveal a universal truth, it would seem logical that administration of high doses of mouse IgG to humans would also induce unresponsiveness. This experiment has been done unintentionally in countless attempts to

use monoclonal antibodies as therapeutic agents. Administration of large quantities of pure, de-aggregated endotoxin-free mouse monoclonal antibodies to humans always induces an anti-mouse response, in the absence of any overt inflammatory co-stimulus. This is why therapeutic mouse monoclonal antibodies must be humanized for successful use as therapeutic agents. So much for the de-aggregated IgG tolerance model.

Experiments in which autoantibodies can be induced by immunization with self antigens almost always involves the use of complete Freund's adjuvant, and their relevance to naturally occurring tolerance and autoimmunity must be evaluated taking this into account. These experiments certainly prove that self tolerance can sometimes be broken under extreme conditions, and that self tolerance is not always complete (see below).

In recent years, the attention of many immunologists has shifted from central tolerance to the periphery. One of the most important recent insights has been the appreciation of the central role of dendritic cells in the initiation of T-cell responses. However, we should not forget that many other cell types, notably B cells and macrophages, also play an important role in presentation of antigen to T cells, albeit perhaps more importantly once a primary response has been established.

It is agreed that under some circumstances dendritic cells can induce activation of T cells, while under others they can induce tolerance. It has become orthodoxy to explain the decision on the basis that encounter of the T cell with antigen in the absence of costimulation from activated dendritic cells leads to tolerance, while activation of dendritic cells induces T-cell activation (Abbas and Sharpe, 2005). This model seems too simplistic. To give one example of the inadequacy of this model, recent work has shown that induction of T cell tolerance by resting dendritic cells requires engagement of the costimulatory molecules PD-1 and CTLA-4 on T cells (Abbas and Sharpe, 2005; Probst et al., 2005). Much remains to be learned about decision-making of activation, non-response, or tolerance at the synaptic interface between the dendritic cell and the T cell.

To summarize, the field of self/non-self discrimination and tolerance abounds with paradoxes. The mere presence of non-self is not necessarily sufficient for an immune response to occur. There is abundant evidence that, in addition to the presence of antigen, activation of dendritic cells is essential for the initiation of T-cell responses. And yet, the strong human anti-mouse antigen response to mouse IgG in the absence of adjuvants seems to argue that activation of inflammation is not essential for initiation of immune responses. This should not be taken to imply that activation of the innate immune system is not important for initiation of immune responses. There seems little doubt that inflammation potentiates the induction of immune responses. This is almost certainly a key factor in how adjuvants work. However, the role (if any) of inflammation in the induction of human autoimmune disease is still unclear. Obviously, we still don't understand all the rules of the game.

SELF TOLERANCE IS NOT ABSOLUTE, AND IS INCOMPLETE

The immune system evolved to produce a workable but imperfect defense system involving a series of compromises between the conflicting demands of destroying non-self but not self. Given the enormous diversity of biologic structures and the corresponding diversity of immune receptors, the distinction between self and non-self cannot be absolute. It must depend on choices based on thresholds of affinity of recognition and setting the sensitivity of signaling mechanisms to optimize survival for populations as a whole. In genetically diverse populations it seems inevitable that some individuals will have these thresholds set too far at one or other extreme. A system capable of defending the body against an almost infinite diversity of external threats would be expected to set the threshold for activation at a level where some individuals would succumb to autoimmunity.

There are many reasons why self-tolerance may be incomplete. Sequestration of a particular self antigen away from the immune system would be expected to result in immunologic ignorance. Presentation of soluble antigens in monomeric forms can induce anergy rather than deletion of B-cells with cognate receptors. There is also no reason to think that there would be evolutionary pressure to select for mechanisms of robust and unbreakable tolerance to self antigens that are unlikely to cause trouble in most individuals. Accordingly, the numerous examples of induction of autoantibodies by immunizing with autologous antigens in complete Freund's adjuvant do not invalidate the general concept of self tolerance any more than the concept of "*horror autotoxicus*" rules out the possibility of autoimmune disease.

THE HOLY GRAIL: INDUCTION OF ANTIGEN-SPECIFIC TOLERANCE

> ". . . evolution is selecting . . . to maintain the probability of debilitating autoimmunity acceptably low and of an effective ridding response acceptably high. What medicine is trying to do is alter these probabilities." (Cohn, 2002).

The triumph of vaccination as a means to prevent disease is a reflection of the ease of turning on specific immune responses. Much of this knowledge was obtained empirically, with little understanding of the underlying

mechanisms. Preventing or turning off immune responses has been more challenging. Apart from tissue matching involving ABO blood groups and HLA tissue antigens, there have been very few instances where immunologic knowledge has been successfully applied to implement antigen-specific non-responsiveness in clinical medicine. The only example that I can think of is in the prevention of Rh sensitization of mothers at childbirth by the administration of anti-Rh antibodies. This highly effective procedure has been in use for many decades, but it is still not clear how it works. It could be as simple as the rapid clearance of antigen from the body before there is time for an immune response to be activated, although more complex mechanisms have not been ruled out.

Given all these uncertainties, it is not surprising that treatment remains unsatisfactory. We still rely almost entirely on drugs that suppress immune responses non-specifically. The challenge facing treatment of autoimmunity is to be able to prevent immune responses from occurring in an antigen-specific way. This form of treatment would be expected to have far fewer side effects than non-specific immunosuppression. What are the prospects?

Antigen-specific intervention in autoimmune disease seems most promising at the level of prevention. It has been possible to prevent autoimmune disease in mice by expressing the relevant autoantigen in the thymus from early embryonic development (Alderuccio et al., 1993; see Chapter 39), but it is difficult to see how this successful strategy could be applied to autoimmune disease in humans. However, some attempts are currently being made to prevent the onset of autoimmune disease in high-risk individuals. For example, clinical trials are under way to try to prevent type 1 diabetes mellitus by intranasal administration of proinsulin. This intervention seems to lack a convincing rationale, and there is a risk that it could provoke the disease instead of preventing it. Nonetheless, preliminary results are encouraging (see Chapter 75).

Turning off an immune response that has already been initiated is an even greater challenge. In the vast majority of cases, once an immune response gets going, the only known way to stop it is by nonspecific immunosuppression. Some success in modifying ongoing immune responses has been claimed in the area of desensitization for allergy, but this traditional procedure still requires examination in the context of contemporary immunology. In any event, this is a special case and its relevance to treatment of autoimmunity is uncertain.

Wouldn't it be wonderful if we could indeed turn off autoimmunity by antigen-specific means? Success would seemingly demand the identification of the "real" antigens that are driving the process, finding a way to turn off the response in an antigen-specific manner. However, the diseases in which we most wish to achieve this, such as multiple sclerosis, the "real" autoantigen remains unknown. Moreover, we still do not understand the rules that govern whether encounter of a naïve or activated T-cell with cognate antigen will be ignored, or will induce activation or tolerance. Until we do, the induction of antigen-specific tolerance will remain a dream.

At the present time, the goal of cure or even amelioration of autoimmune disease by antigen-specific means seems a long way off, but it would be scarcely appropriate to conclude this book on a note of pessimism. The history of medicine is littered with pronouncements that a seemingly distant goal is "impossible," but with the pronouncement becoming refuted, sometimes not long after the pessimist has spoken. It is now half a century since the first successful renal transplant (Morris, 2004). An ability to induce antigen-specific tolerance would revolutionize both transplantation and autoimmunity. Given the current pace of immunologic research, who can say that such a goal is impossible?
