Although the multimodal approach to perioperative pain management is to be applauded, we need to display caution when combining multiple pharmaceutical agents with different mechanisms of action (“poly-pharmacy”) for fear of eliciting unacceptable side effects. The ideal multimodal drug combination should enhance analgesia while at the same time decrease drug-related adverse side effects. It is the general consensus that the gabapentinoids are opioid-sparing and effective in attenuating immediate postoperative pain; however, these drugs can also increase the risk of postoperative sedation, so great care should be taken when dosing these drugs, particularly in combination with opioid analgesics. Unfortunately, the optimal perioperative dosing regimen and treatment duration remain unclear. Preoperative dosing of gabapentin as high as 1,200 mg orally has been recommended; however, this may place the patient at an increased risk for postoperative respiratory depression. Patients at increased risk for postoperative respiratory depression include the elderly, the morbidly obese, and patients with OSA. In a recent retrospective study<sup>52</sup> involving patients undergoing total hip and knee arthroplasty, the authors suggest that premedication of patients with greater than 300 mg of gabapentin, as part of a multimodal analgesic regimen, is associated with an increased risk of postoperative respiratory depression. Unfortunately, these patients had also received a preoperative dose of sustained release oxycodone, which likewise put them at an increased risk for postoperative respiratory depression. In another placebo-controlled crossover study, the effects of pregabalin and remifentanyl, alone and in combination, on analgesia, ventilation, and cognitive function were examined.<sup>53</sup> The authors concluded that the combination of the two drugs produced *additive* analgesia but *potentiated* respiratory depression and produced greater cognitive side effects. Prudence therefore dictates that great care should be taken when dosing gabapentinoids in combination with opioids. In the opioid-naive patient, the preoperative dose of gabapentin should rarely exceed 300 mg orally. In addition, gabapentinoids should not be combined with a preoperative dose of sustained release opioid. Only in rare circumstances, such as in the opioid-dependent patient or in the patient at increased risk for chronic postsurgical pain (e.g., thoracotomy), should higher doses of gabapentinoids be contemplated.<sup>49</sup>

**Figure 55-14** Hypothesized mechanisms of action of gabapentin. Gabapentin binds to the  $\alpha$ -2 $\delta$  subunit of voltage-gated P/Q type calcium channels. This binding appears to modulate the function and traffic of these channels, which appear on the synaptic bulb of presynaptic neurons. Calcium influx through these channels after a pain-evoked action potential is believed to trigger the fusion of synaptic vesicles with the neuronal membrane and consequent release of neurotransmitters in the dorsal horn of the spinal cord. Gabapentin may exert its analgesic effect by inhibiting or modulating this process. In addition, gabapentin may exert an analgesic effect by activating descending inhibitory noradrenergic pathways that regulate neurotransmission of pain signals in the dorsal horn of the spinal cord. (Reprinted with permission from Schmidt, PC, Ruchelli G, Mackey SC. Perioperative gabapentinoids: choice of agent, dose, timing, and effects on chronic postsurgical pain. *Anesthesiology*. 2013;119(5):1215–1221.)

Dosing of the gabapentinoids may be initiated preoperatively, intraoperatively, or postoperatively with equal efficacy. However, because it takes gabapentin and pregabalin 4 to 6 hours and 8 hours, respectively, to reach peak cerebrospinal fluid levels dosing of the drug the evening prior to surgery may ultimately prove to be the most beneficial method of administration.<sup>49</sup> Unfortunately, side effects such as dizziness, sedation, and confusion may preclude this approach. The postoperative dosing of the gabapentinoid may therefore be titrated based on side effects, with larger doses being prescribed during the evening. Dosing should be adjusted accordingly based on the patient's age, weight, and comorbidities (e.g., renal function). The ideal gabapentinoid dosing regimen that can optimize

immediate postoperative pain and minimize the risk of postoperative respiratory depression, while reducing the development of chronic postsurgical pain, has yet to be elucidated and merits further investigation.

Following intravenous administration, the *local anesthetic* lidocaine has been shown to be analgesic, antihyperalgesic, and anti-inflammatory.<sup>54,55</sup> In vitro studies indicate that the beneficial effects of intravenous lidocaine are mediated by inhibitory actions on voltage-gated sodium channels, voltage-gated calcium channels, potassium channels, G protein-coupled receptors, NMDA receptors, and the glycinergic system.<sup>56</sup> The perioperative infusion of lidocaine has been shown to not only improve postoperative analgesia in patients recovering from laparoscopic colectomy but also decrease postoperative opioid requirements, attenuate postoperative ileus, and accelerate time to discharge from the hospital.<sup>54,56</sup> The ideal dose of systemic lidocaine has yet to be clearly defined; however, a bolus dose of 1.5 to 2.0 mg/kg followed by an infusion of 1.5 to 2 mg/kg/hr has been recommended for the treatment of perioperative pain.<sup>56</sup> These recommendations result in serum concentrations in the therapeutic range, which is considered to be 1 to 5 µg/mL. Serum concentrations greater than 5 µg/mL are associated with cardiovascular and central nervous system toxicity. Lidocaine infusion is contraindicated in any patient with arrhythmia, heart failure, coronary artery disease, Stokes-Adams disease (cardiovascular syncope) and heart block. Future studies are warranted that will identify surgical indications and ideal dosing regimens that are both safe and efficacious.

Recent meta-analyses indicate that the perioperative administration of intravenous *magnesium* may also be an effective adjunct in the treatment of perioperative pain.<sup>57,58</sup> Intravenous magnesium infusion decreases pain scores and is opioid sparing in the first 24 hours following surgery and is devoid of any serious adverse effects. In a recent trial of 50 patients undergoing scoliosis surgery, the combination of intraoperative intravenous magnesium (bolus dose: 50 mg/kg over 30 minutes, maintenance dose: 8 mg/kg/hr) with low-dose ketamine (bolus dose: 0.2 mg/kg, maintenance dose: 0.15 mg/kg/hr) versus low-dose ketamine alone, decreased postoperative morphine consumption, and improved sleep and patient satisfaction scores.<sup>59</sup> The mechanism of analgesia is thought to be mediated by NMDA receptor antagonism as well as regulation of calcium influx into the cell, resulting in suppression of neuropathic pain and inhibition of central sensitization, potentially making this drug useful in the opioid-tolerant patient.

The *glucocorticoids* are well known for their analgesic, anti-inflammatory, and antiemetic effects. Inhibition of cytosolic phospholipase A<sub>2</sub> upstream from the lipoxygenase and COX enzymes in the prostaglandin cascade most certainly accounts for both their anti-inflammatory and analgesic effects by inhibiting leukotriene and prostaglandin production. The mechanism of the

antiemetic effect of the corticosteroids is less clearly understood but appears to be centrally mediated.<sup>60</sup> In combination with a gabapentinoid, acetaminophen, and an NSAID, dexamethasone is considered a useful component of a multimodal drug strategy to effectively attenuate postsurgical pain. The recommended preoperative intravenous dose is 0.11 to 0.2 mg/kg. Because the drug has been reported to cause perineal irritation in 50% to 70% of individuals following rapid administration, prudence dictates that the drug be diluted in 50 mL of normal saline and injected over 10 minutes prior to surgery.<sup>61</sup> In the opioid-tolerant patient, acute perioperative pain management can be challenging, and high dose intravenous dexamethasone, combined with a proton pump inhibitor, has been recommended as a useful therapeutic option.<sup>62</sup> Dexamethasone has also been administered via the perineural route as part of a four-drug cocktail. The perineural dose of dexamethasone should never exceed 1 mg per plexus!<sup>63</sup>

## Methods of Analgesia

### *Patient-controlled Analgesia*

PCA is any technique of pain management that allows the patients to administer their own analgesia on demand. We will highlight some important aspects of PCA as a complete review of PCA is beyond the scope of this chapter; we refer the reader to the comprehensive review by Macintyre on this topic.<sup>64</sup> In the United States, the most commonly used drugs are morphine, hydromorphone, and fentanyl. Hydromorphone is recommended as an alternative in renal failure; however, fentanyl might be a better choice as it has no active metabolites. Meperidine is not recommended for use in an intravenous PCA secondary to accumulation of its potentially toxic metabolite normeperidine.

8

**Table 55-15** Usual Intravenous Opioid Patient–controlled Analgesia Regimens in the Opioid-naïve Adult Patient<sup>64,192</sup>

Opioid	Demand Dose	Lockout (min)	Basal Infusion
Morphine	1–2 mg	6–10	0–2 mg/hr
Hydromorphone	0.2–0.4 mg	6–10	0–0.4 mg/hr
Fentanyl	20–50 µg	5–10	0–60 µg/hr
Sufentanil	4–6 µg	5–10	0–8 µg/hr
Tramadol	10–20 mg	6–10	0–20 mg/hr

The five variables associated with all modes of PCA include (1) bolus dose, (2) incremental (demand) dose, (3) lockout interval, (4) background infusion

rate, and (5) 1- and 4-hour limits. A typical PCA regimen in an otherwise healthy adult would be an incremental dose of 1 to 2 mg of morphine with an 8- to 10-minute lockout (Table 55-15). The authors do not recommend a background infusion of opioid in the opioid-naive patient. A background infusion should be reserved for the patient with chronic malignant or nonmalignant pain who is opioid-tolerant or in patients with persistent pain who have failed a trial of incremental PCA dosing. In the elderly, the dose of the PCA should be decreased. The relative risk factors for use of an opioid PCA are listed in Table 55-16. If more than two risk factors exist, you may want to avoid using a PCA in the standard dosing regimen and administer opioids only as needed.

Opioid-related side effects include nausea and vomiting, pruritus, sedation, and confusion. Consensus guidelines for the treatment of nausea and vomiting include prescribing various combinations of dopamine antagonists, serotonin antagonists, and glucocorticoids.<sup>65</sup> In addition, the perioperative systemic administration of an  $\alpha_2$ -agonist (e.g., dexmedetomidine), which is both analgesic and opioid sparing, has been shown to reduce the incidence of postoperative nausea and vomiting.<sup>66</sup> Pruritus can be ameliorated with the use of diphenhydramine, hydroxyzine, or a low dose of an opioid antagonist (e.g., naloxone) or mixed agonist–antagonist (e.g., nalbuphine). Excessive sedation may respond to a change in the opioid; however, use of a multimodal analgesic technique, which incorporates the use of a regional anesthetic (e.g., epidural or peripheral nerve blockade), an NSAID, acetaminophen, or other nonopioid analgesics such as an NMDA receptor antagonist or an  $\alpha_2$ - $\delta$  subunit calcium channel ligand, will have an opioid-sparing effect, which should attenuate opioid-induced sedation.

**Table 55-16** Relative Risk Factors Associated with the Use of Patient-controlled Analgesia

Pulmonary disease  
Obstructive sleep apnea  
Renal or hepatic dysfunction  
Congestive heart failure  
Closed head injury  
Altered mental status  
Lactating mothers

## **Neuraxial Analgesia**

Although opioid analgesics have been prescribed to patients for many centuries, the exact mechanism of action was not completely understood until 1971, when the opioid receptor was discovered. Within 5 years' time, Yaksh reported that morphine could produce spinally mediated analgesia in a rat

model. Soon thereafter, in 1979 and 1981, respectively, Wang and then Onofrio reported significant pain relief following the neuraxial administration of morphine in patients with severe cancer-related pain. Since these discoveries, the intrathecal administration of opioids and the epidural administration of opioids plus a local anesthetic has produced significant comfort for our patients.

**9** *Epidural analgesia* is a critical component of multimodal perioperative pain management and improved patient outcome. Meta-analysis investigating the efficacy of epidural analgesia found epidural analgesia to be superior to systemically administered opioids.<sup>67</sup> The efficacy of an epidural technique is determined by numerous factors that can include (1) catheter incision site congruency, (2) choice of analgesic drugs, (3) rates of infusion, (4) duration of epidural analgesia, and (5) type of pain assessment (rest versus dynamic). Ideally, the epidural catheter is positioned congruent with the surgical incision (Fig. 55-15). Thoracic epidural catheter placement is recommended for both thoracic and upper abdominal surgical procedures because of the observed improvement in coronary artery blood flow, attenuation of pulmonary complications, and the reduction in the duration of postoperative ileus. Combining a local anesthetic plus an opioid in the epidural space is believed to have a synergistic effect.<sup>67</sup> The optimal duration of epidural analgesia has not been determined, but recommendations are that the infusion be continued for at least 2 to 4 days. Other than analgesia, epidural infusions lasting less than 24 hours do not appear to offer any clear cardiovascular advantages.

Epidurally administered opioids have the distinct advantage of producing analgesia without causing significant sympatholytic effect or motor blockade. Analgesia occurs by way of a *spinal mechanism* and through a *supraspinal mechanism* following systemic adsorption. The spinal mechanism occurs following diffusion of the drug into the spinal fluid, and is determined by meningeal permeability. Opioids with intermediate lipophilicity (e.g., hydromorphone, alfentanil, and meperidine) have the ability to easily move between the aqueous and lipid regions of the arachnoid membrane and therefore have high meningeal permeability, which potentially confers higher bioavailability in the spinal cord. However, in a comprehensive review of the topic Bernards et al.<sup>68</sup> concluded that morphine has greater bioavailability in the spinal cord than alfentanil, fentanyl, and sufentanil.

In general, the epidural administration of hydrophilic opioids tends to have a slow onset, long duration, and a mechanism of action that is primarily spinal in nature. The epidural administration of lipophilic opioids, on the other hand, has a quick onset, short duration, and a mechanism of action that is primarily supraspinal, secondary to rapid systemic uptake. However, the data are controversial and the site of action of lipophilic opioids such as

fentanyl may primarily be determined by the mode of administration. Bolus administration of fentanyl appears to have a segmental analgesic effect whereas epidural infusion of fentanyl appears to have a nonsegmental (systemic) effect. There are some data, however, that suggest that there can be significant spinal mechanisms of action of the lipophilic opioids, particularly with the thoracic epidural infusion of fentanyl. In the opioid-tolerant patient taking more than 250 mg/day of oral morphine, sufentanil may be considered to be the epidural opioid of choice because of its high intrinsic activity.

**Figure 55-15** Dermatome guide for placement of epidural catheters.

As previously mentioned, local anesthetic–opioid combinations are the most common form of epidural infusion because the combination is considered to be synergistic. Local anesthetics have the unique ability to block the stress response by blocking afferent input to the spinal cord. Although bupivacaine plus fentanyl may be the most common combination, bupivacaine plus morphine makes more sense from a bioavailability point of view.

Hydromorphone plus bupivacaine also makes very good sense as this combination has all the advantages of a hydrophilic opioid with excellent meningeal permeability but less risk of pruritus. Remember, epidural infusions may consist of just a hydrophilic opioid if the patient cannot tolerate side effects from the local anesthetic or if the epidural is incongruent with the surgical incision. Likewise, an epidural infusion may consist simply of a local anesthetic if the patient cannot tolerate opioid-related side effects, provided that the epidural is correctly placed and is congruent with the surgical incision. [Table 55-17](#) contains epidural dosing guidelines.

Adjuvant medications, which may enhance analgesia, include clonidine and ketamine. Clonidine (2 µg/mL) can be combined with an opioid and a local anesthetic and is usually infused at a rate of 5 to 20 µg/hr. Side effects that limit its clinical usefulness include hypotension, bradycardia, and sedation. An epidural infusion consisting of ropivacaine 0.2%, fentanyl 5 µg/mL, and clonidine 2 µg/mL infused at a rate of 3 to 7 mL/hr following a TKA has been reported to cause no significant sedation in this dosage range.<sup>69</sup> The safety of epidurally administered ketamine has not been determined, and routine use cannot be recommended at this time.

A novel approach to postoperative pain control is extended-release epidural morphine (Depodur). The system consists of morphine encapsulated within a liposome delivery system, which provides controlled release of morphine for up to 48 hours. Double-blinded studies indicate that the epidural administration of liposomal morphine has proven to be efficacious in the treatment of postoperative pain associated with total hip arthroplasty (THA), TKA, and cesarean section. Depodur is approved only for lumbar epidural administration.

*Intrathecal analgesia* with a variety of drugs is a widely accepted practice for the treatment of both acute and chronic pain. Rathmell et al.<sup>70</sup> have thoroughly reviewed the role of intrathecal analgesia for acute pain. Opioid analgesics, including morphine, hydromorphone, meperidine, methadone, fentanyl, and sufentanil, are the most commonly administered drugs for this purpose. Their distribution within the intrathecal space following administration is complex. Hydrophilic opioids (e.g., morphine) penetrate the spinal cord and bind to specific pre- and postsynaptic receptors within the dorsal horn. They traverse the dura slowly, bind to epidural fat poorly, and slowly enter the plasma. They tend to have a slow onset of action, long duration, and provide a broad band of analgesia. Delayed respiratory depression is more common with hydrophilic opioids secondary to rostral spread.<sup>70</sup> Lipophilic opioids (e.g., fentanyl), on the other hand, tend to bind to nonspecific receptors in the white matter. They rapidly cross the dura and are quickly sequestered into epidural fat and swiftly enter the systemic circulation. As a general rule lipophilic opioids tend to have a rapid onset of

action, short duration, and a narrow band of analgesia. Delayed respiratory depression is less of a problem with the lipophilic opioids. Other side effects associated with intrathecal opioids include nausea and vomiting, urinary retention, and pruritus. The incidence of pruritus with intrathecal hydromorphone is reported to be significantly less than with morphine (refer to [Table 55-18](#) for dosing guidelines).

**Table 55-17** Guidelines for Adult Epidural Catheter Dosing Regimen<sup>a,b</sup>

Catheter Placement	Surgical Dermatome		
	Lumbar (e.g., total knee arthroplasty or lower extremity bypass surgery)	Low thoracic (e.g., exploratory laparotomy, xiphopubic incision)	Mid-to-high thoracic (e.g., thoracotomy, sternotomy)
Lumbar T <sub>12</sub> –caudal	Catheter congruent with incision! Bupivacaine 0.05–0.1% or ropivacaine 0.1–0.2% with Fentanyl 2–5 µg/mL or morphine 0.1 mg/mL or hydromorphone 0.02 mg/mL	Catheter/incision incongruency! <sup>c</sup> May consider bupivacaine or ropivacaine with a hydrophilicopioid. <i>This is not ideal!</i> <sup>d</sup> Hydrophilic opioids are required! Morphine 0.1 mg/mL or hydromorphone 0.02 mg/mL	Not applicable
Low thoracic T <sub>8</sub> to T <sub>12</sub>	Not applicable	Catheter congruent with incision! Bupivacaine 0.05–0.1% or ropivacaine 0.1–0.2% with Fentanyl 2–5 µg/mL or morphine 0.1 mg/mL or hydromorphone 0.02 mg/mL	Catheter/incision incongruency! May consider bupivacaine or ropivacaine with an opioid but <i>this is not ideal!</i> Lipophilic Fentanyl 2–5 µg/mL. <i>This is not the ideal opioid!</i> <sup>d</sup> Hydrophilic opioids are a better choice! 1. Morphine 0.1 mg/mL or 2. hydromorphone 0.02 mg/mL
Mid-to-high thoracic T <sub>4</sub> to T <sub>8</sub>	Not applicable	Not applicable	Catheter Congruent with incision! Bupivacaine 0.05–0.1% or ropivacaine 0.1–0.2% with fentanyl 2–5 µg/mL or morphine 0.1 mg/mL or hydromorphone 0.02 mg/mL

<sup>a</sup>Rate of infusion, 2–10 mL/hr. Recommended adult dose for epidural bupivacaine. Do not exceed 400 mg/24 hr!

<sup>b</sup>May consider Clonidine 1–2 µg/mL in the epidural. Remember hypotension, bradycardia, and sedation are common at doses greater than 14 µg/hr.

<sup>c</sup>Local anesthetic efficacy is diminished if the catheter placement is not congruent with the incision!

<sup>d</sup>Hydrophilic opioids provide a broad band of analgesia! Morphine is the gold standard. Epidural hydromorphone may cause less pruritus.

Other useful analgesic additives include the  $\alpha_2$ -agonists, NSAIDs, NMDA receptor antagonists, acetylcholinesterase inhibitors, adenosine, epinephrine, and benzodiazepines. The  $\alpha_2$ -agonists alter pain transmission by binding to pre- and postsynaptic receptors within the dorsal horn of the spinal cord. Evidence suggests that intrathecal clonidine is synergistic with spinal local anesthetics, prolongs sensory and motor blockades, and causes less urinary retention than intrathecal morphine.<sup>70</sup> Intrathecal clonidine does not cause respiratory depression or pruritus. Intrathecal doses of 150 µg, however, are reported to increase the incidence of hypotension, bradycardia, and nausea<sup>70</sup> (refer to [Table 55-19](#) for additional dosing recommendations). Anecdotal reports suggest that the neuraxial administration of an NSAID, either accidentally or intentionally, is both safe and effective. Further investigation

for the treatment of postoperative pain is required to define the role of intrathecal NSAIDs as well as the acetylcholinesterase inhibitors, NMDA receptor antagonists, adenosine, and benzodiazepines.

**Table 55-18** Intrathecal Analgesia Dosing Guidelines<sup>a,30,70</sup>

Surgical Procedure	Intrathecal Drug Dose
Labor analgesia	Sufentanil 2.5–5 µg
Cesarean section (C-section)	Morphine 100 µg. The addition of clonidine 60 µg is synergistic and can increase the duration of spinal analgesia after C-section but also increases intraoperative sedation.
Outpatient knee arthroscopy	Fentanyl 10–25 µg will improve intraoperative analgesia without prolonging postoperative motor blockade.
Total knee arthroplasty	Morphine 100 µg
Total hip arthroplasty	Morphine 100 µg
Thoracotomy and major abdominal surgery	Morphine 500 µg. The incidence of side effects such as nausea and vomiting, urinary retention, pruritus and respiratory depression increase significantly with doses >300 µg.

<sup>a</sup>50–100 µg of intrathecal hydromorphone approximates 100–200 µg of intrathecal morphine.

**Table 55-19** Intrathecal Analgesia: Other Dosing Guidelines<sup>70,193</sup>

Intrathecal Drug	Dosing	Comments
Clonidine	15–45 µg improves the quality of spinal blockade in outpatient surgery	Side effects increase significantly at intrathecal doses >150 µg
Epinephrine	0.1–0.6 mg Dose-related increase: 1. Return of motor function 2. Return of micturition	Not recommended for outpatient surgery
Neostigmine	6.25–50 µg Dose-related increase: 1. Motor blockade 2. Time for resolution of the block 3. Nausea and vomiting	Further studies of the appropriate intrathecal dose that optimizes analgesia while minimizing side effects are warranted

## Peripheral Nerve Blockade

Single-injection peripheral nerve blockade has been shown to provide pain control that is superior to opioids with fewer side effects.<sup>71</sup> Single-injection techniques are limited in duration but continuous peripheral nerve block (CPNB) techniques can extend the benefits of peripheral nerve blockade well into the postoperative period. CPNB has proven to be an effective technique for postoperative pain management; it is superior to opioid analgesia with fewer opioid-related side effects and rare neurologic and infectious complications.<sup>72,73</sup> The benefits of CPNB in the ambulatory setting include prolonged postoperative analgesia, facilitated discharge from the hospital, fewer opioid-related side effects, and greater patient satisfaction.<sup>74</sup> Since the previous iteration of this chapter, ultrasound-guided regional anesthesia (UGRA) has clearly become the primary peripheral nerve localization technique. Advantages of UGRA include not only decreased block performance time, block onset time, and local anesthetic requirements but also improved sensory block onset as well as improved block success. Likewise, UGRA has reduced the incidence of the dreaded complication of local anesthetic systemic toxicity (LAST).<sup>75</sup> Tables 55-20, 55-21, and 55-22 present indications and contraindications for specific peripheral nerve blocks. Table 55-23 has recommended dosing guidelines for CPNB.

## The Brachial Plexus

### *Above the Clavicle*

The *interscalene block (ISB)* is the ideal peripheral nerve block for painful orthopedic procedures on the shoulder and upper arm such as repair of a rotator cuff or labral tear, acromioclavicular joint reconstruction, Bankart Procedure, proximal humerus fracture, and total shoulder arthroplasty. It is also indicated for vascular procedures performed on the shoulder and upper arm, but is a poor choice for forearm and hand surgery because the ulnar nerve is commonly spared. It is the most cephalad approach to the brachial plexus and was originally described by Winnie in 1970.<sup>76</sup>

**Table 55-20 Brachial Plexus Blockade**

Peripheral Nerve Block	Indications	Contraindications	Comments
Interscalene	Total shoulder arthroplasty and hemiarthroplasty Open rotator cuff repair Open anterior reconstruction Open reduction, internal fixation (ORIF) and joint fusion	Refusal by the patient, infection, or hematoma in the vicinity of the block, allergy to local anesthetics, and progressive neuropathy or lesion of unknown etiology  In the anticoagulated patient follow the recommendations set forth for neuraxial blockade until practice guidelines for peripheral nerve blocks are promulgated	UGRA results in the following beneficial outcomes: <ul style="list-style-type: none"> <li>• Faster block performance</li> <li>• Fewer needle passes</li> <li>• Decreased risk of vascular puncture</li> <li>• More rapid sensory block onset</li> <li>• Improved block success</li> </ul>
Supraclavicular	Provides anesthesia to the entire upper extremity with a single injection of local anesthetic	See above	The incidence of pneumothorax with the use of US guidance is low.
Infraclavicular	This approach is ideally suited for surgery on the distal upper arm, the entire forearm, wrist, and hand Surgery distal to the elbow: Arteriovenous fistula, Colles' fracture, Dupuytren contracture release, wrist fusion, and ORIF Surgery on the forearm, wrist, and hand	See above Also chest deformities and healed but dislocated fractures of the clavicle	Ultrasound guidance can significantly improve the safety and effectiveness of this block. Catheter techniques can be useful.
Axillary	Hand surgery	See above	

**Table 55-21 Lumbar and Sacral Plexus Blockade**

Peripheral Nerve Block	Indications	Contraindications	Comments
Femoral nerve	Total knee arthroplasty (TKA) Anterior cruciate ligament repair, femoral neck fractures, and saphenous vein stripping Muscle biopsies involving the ventral, medial, or lateral thigh	See Table 55-20	Good choice for TKA May be combined with a sciatic nerve block for TKA Catheter techniques are useful. Ultrasound guidance confirms placement of the needle tip between the fascia iliaca and the iliopsoas muscle.
Adductor canal block	Total knee arthroplasty Any surgery on the medial aspect of the ankle		UGRA targets the saphenous nerve within the adductor canal.
Sciatic nerve	Above-the-knee amputation Combine with a lumbar plexus block Ankle joint replacement Ankle arthrodesis Calcaneal osteotomy Achilles tendon repair	See above	Numerous approaches have been described. The <i>parasacral approach</i> is the most cephalad. The <i>infragluteal parabiceps approach</i> is useful. Catheter techniques are useful for prolonged analgesia. Ultrasound guidance can confirm needle placement in the subgluteal space.
Popliteal fossa	Below-the-knee amputation Combine with a saphenous nerve block <i>Ankle surgery:</i> Triple arthrodesis, arthroscopy, and Achilles tendon repair <i>Foot surgery:</i> Bunion surgery and transmetatarsal amputation	See above	Lateral and posterior approaches have been described. Catheter insertion following ambulatory foot surgery can provide prolonged analgesia. Ultrasound guidance is very useful. Use the "seesaw" sign to confirm identification of the common peroneal and tibial nerves. May be combined with an adductor canal block to provide analgesia to the medial aspect of the ankle.

**Table 55-22** Truncal Blocks

Peripheral Nerve Block	Indications	Contraindications	Comments
Paravertebral block	Breast surgery, thoracic and abdominal surgery, fractured ribs, postherpetic neuralgia	In the anticoagulated patient follow the recommendations set forth for neuraxial blockade	Numerous US guided approaches have been described.
Pectoralis block			
I	Breast expanders		
II	Mastectomies and sentinel node dissection		
Anterior serratus	Latissimus dorsi flap reconstruction and multiple rib fractures		
Transversus abdominis plane (TAP) block	Abdominal wall surgery		<i>Unilateral TAP</i> for surgery that does not cross the midline (e.g., renal transplant or appendectomy)
Subcostal TAP	Supra-umbilical incisions		<i>Bilateral TAP</i> for incisions that cross the midline (e.g., laparoscopic procedures)
Lateral TAP	Infra-umbilical incisions		
Posterior (QL) TAP	T5 to T10 spread		
Rectus sheath block	Midline abdominal surgical incision		
Transversalis fascia plane	Iliac crest bone graft		
Ilioinguinal/iliohypogastric nerve	Inguinal hernia repair		

Using ultrasound (US) guidance this is a relatively straight forward peripheral nerve block to perform. Although this block can be carried out using an in-plane or out-of-plane technique, the most common technique is a posterior in-plane approach with the transducer in an axial oblique plane. The needle tip is advanced under real time and is positioned adjacent to or within the brachial plexus sheath. The ideal position of the tip of the needle is unclear; however, Spence and colleagues<sup>77</sup> investigated this and suggest that conservative (periplexus) injection of local anesthetic adjacent to the brachial plexus sheath is as effective as aggressive (intra-plexus) injection of local anesthetic within the brachial plexus sheath. Needle tip positioning within the brachial plexus sheath, however, does offer the advantage of using smaller volumes of local anesthetic while maintaining efficacy. When performing this block direct needle-to-nerve contact is not required for an effective interscalene block (ISB).<sup>78</sup> By avoiding direct needle-to-nerve contact you can maximize efficacy and minimize the risk of nerve injury. US-guided ISB has the advantage of minimizing vascular puncture and allows for multiple injections around the plexus, resulting in smaller volumes of local anesthetic and decreasing the risk of toxicity. Your end point for injection is real-time observation of hydrodissection of local anesthetic around the nerves.

**Table 55-23** Recommended Dosing Regimen of Local Anesthetics for Continuous Peripheral Nerve Blockade<sup>194,195</sup>

Catheter	Agent	Rate of Infusion	PCA Bolus (mL)	Lockout (min)
Interscalene Infraclavicular	Ropivacaine 0.2% or bupivacaine 0.15–0.2%	5–8 mL/hr	2–4	15–20
Femoral	Ropivacaine 0.2% or bupivacaine 0.15–0.2%	5–10 mL/hr	5–10	30–60
Popliteal		5–8 mL/hr	2	15–20
Paravertebral	Ropivacaine 0.2%	0.1–0.2 mL/kg/hr	—	—
	Bupivacaine 0.25% with 1:400,000 epinephrine	0.1 mL/kg/hr	—	—

PCA, patient-controlled analgesia.

Single-injection interscalene blockade for shoulder surgery reduces postoperative VAS pain scores, total opioid consumption, postoperative nausea and vomiting, time for request of first dose of analgesic, time to discharge, and unplanned hospital admissions.<sup>79</sup> Interscalene blockade provides postoperative analgesia, which is superior to subacromial bursae blockade, suprascapular nerve blockade, infusion of intra-articular local anesthetic, and parenteral opioids. To extend the period of postoperative analgesia, continuous catheter techniques have been successfully employed in both the inpatient and outpatient settings.

The *supraclavicular approach* to the brachial plexus provides anesthesia to the entire upper extremity with a single injection of local anesthetic. Indications for this block include arm, elbow, forearm (arteriovenous fistula creation), and hand (scaphoid fracture, trapeziectomy) surgeries. The supraclavicular approach is carried out at a point where the plexus is reduced to its fewest component parts, the superior, middle, and inferior trunks, as they pass under the clavicle and over the first rib.

In the now “classic” Kulenkampff description,<sup>80</sup> of this peripheral nerve block, needle insertion is 1 cm above the midpoint of the clavicle in a plane that is parallel to the patient’s head and neck. This approach requires the elicitation of multiple paresthesias and multiple injections, and the incidence of pneumothorax has been reported to be as high as 0.5% to 5% with this technique. With the introduction of ultrasound guidance, however, the safety of this approach has improved dramatically. Real-time imaging of the needle tip in order to optimize its position not only decreases the risk of pneumothorax but also increases the quality and shortens the onset time of the block.<sup>81,82</sup> Single, double, and triple injection techniques have been described for this block.<sup>83–85</sup> It is unclear which technique is superior. The evidence to date, however, suggests that it is imperative that the advancing needle puncture the brachial plexus sheath, which can be appreciated as a palpable “fascial click.” Local anesthetic can then be injected in divided doses within the perineural space, which can create a safe conduit for advancement

of the needle into the space referred to as the “corner pocket,” which is bordered by the subclavian artery medially, the first rib inferiorly, and the divisions of the brachial plexus superiorly and laterally. The ulnar nerve is commonly spared with the supraclavicular approach; however, the “corner pocket” technique (Fig. 55-16) is reported to block the ulnar nerve in at least 85% of cases when performed correctly.<sup>83</sup> Although ultrasound guidance has facilitated the performance of this block, unusual sonoanatomy (sonopathology), such as an aberrant transverse cervical artery, a dilated subclavian vein (secondary to elevated central venous pressure) and atypical locations of the brachial plexus can make this a challenging block to perform.<sup>86,87</sup> Although the supraclavicular approach is amenable to continuous catheter techniques, the literature on this subject is meager.

### *Below the Clavicle*

The *infraclavicular block* is ideally suited for surgical procedures below the midhumerus such as the hand, wrist, forearm, or elbow.<sup>88</sup> The block targets the brachial plexus at the level of the cords where it is in close proximity to the axillary artery.<sup>89</sup> The popularity of this approach has been less than enthusiastic because of unreliable surface landmarks and the potential risks of pneumothorax and vascular puncture. Ultrasound guidance has, however, dramatically improved both the safety and efficacy of the infraclavicular approach and success rates are reported to be in the 90% to 100% range.<sup>90</sup>

**Figure 55-16** Ultrasound-guided supraclavicular nerve block. The long arrows highlight the brachial plexus at the level of the supraclavicular fossa. SA, subclavian artery; LA, local anesthetic. (Reprinted with permission from Soares LG, Brull R, Lai J, et al. Eight ball, corner pocket: the optimal needle position for ultrasound-guided supraclavicular block. *Reg Anesth Pain Med.* 2007;32:2.)

With the patient in the supine position the block is performed with the transducer placed below the clavicle in the delto-pectoral groove in a parasagittal plane, which provides a short axis view of the axillary artery. Although this block may be performed with the arm adducted or abducted, the ideal position of the patient's arm is abducted to 90 degrees with the elbow flexed. This maneuver significantly displaces the clavicle in a cranial-posterior direction, and allows the needle to be inserted 2 to 4 cm cephalad to the transducer and anterior to the clavicle, resulting in a shallower approach with the needle, which optimizes the ultrasound image.<sup>91</sup> Use of an echogenic needle should facilitate performance of this peripheral nerve block, particularly if the angle of insertion becomes too steep. The optimal injection site is cranioposterior and adjacent to the axillary artery.<sup>92</sup> This area is closest to all three cords and potentially optimizes local anesthetic spread. A prospective randomized trial comparing ultrasound-guided infraclavicular blockade, with and without neurostimulation, has confirmed that the "U-shaped" distribution of local anesthetic around the posterior, medial, and lateral aspects of the axillary artery will reliably produce complete blockade

of the brachial plexus (Fig. 55-17).<sup>89</sup>

A recent large-scale study documented the analgesic benefit and favorable safety profile of single-injection infraclavicular nerve blockade.<sup>93</sup> Placement of continuous infraclavicular nerve catheters has the advantage of providing prolonged analgesia for several days following surgery. Benefits include improved pain scores, decreased opioid requirements, less sedation, and less sleep disturbance with continuous infraclavicular nerve blockade.<sup>94</sup> Although abduction of the arm is recommended the block can be performed with the arm *abducted* or *adducted*. This flexibility in positioning can be advantageous particularly in the trauma patient who has significant pain and limited mobility. Placement of continuous infraclavicular catheters provides the advantage of a secure point of insertion that will not dislodge easily with patient movement. It is also relatively easy to keep clean and sterile, particularly if the patient is to be discharged home with the catheter in situ to be removed at a later date.

## The Lumbar Plexus

The lumbar plexus is formed from the ventral rami of the L1 to L4 spinal nerve roots, with a small contribution from T12 in some patients. The plexus lies within the substance of the psoas muscle in between the anterior and posterior masses and gives rise to the femoral (saphenous), obturator, lateral femoral cutaneous, ilioinguinal, iliohypogastric, and genitofemoral nerves. The nerves provide sensory innervation to the abdomen and groin, the

anterior, lateral, and medial aspects of the thigh, the knee joint, and the medial part of the calf. Motor innervation is supplied to the abdominal muscles, the hip flexors, thigh adductors, and the quadriceps muscles. Numerous posterior and anterior approaches for lumbar plexus blockade (LPB) have been described<sup>95</sup> and the block is indicated for major surgeries of the hip and knee.

### *Posterior Approach (Psoas Compartment Block)*

The posterior approach to the lumbar plexus reliably blocks the femoral, lateral femoral, and obturator nerves.<sup>96</sup> The block is performed with the patient in the lateral decubitus position, usually with the operative side in the uppermost (independent) position. The advantage of this position is that the block can be combined with a sciatic nerve block. The disadvantage, however, is the increased risk of epidural spread. When combined with sciatic nerve blockade, virtually any surgical procedure can be performed on the lower extremity. Although ultrasound-guided LPB has been described in the literature, it has not been studied extensively. Complications associated with the placement of a psoas compartment block includes epidural spread, spinal anesthesia, systemic toxicity, unilateral sympathectomy, renal subscapular hematoma, and neurologic injury.<sup>97</sup> Psoas compartment blockade should be avoided in the anticoagulated patient. The depth of the plexus in adults can make ultrasound guidance more challenging particularly in the obese patient, which will preclude its use, unless current ultrasound technology improves dramatically; however, in children ultrasound-guided LPB may prove to be efficacious.<sup>98</sup>

### *Anterior Approach (Femoral Nerve Block)*

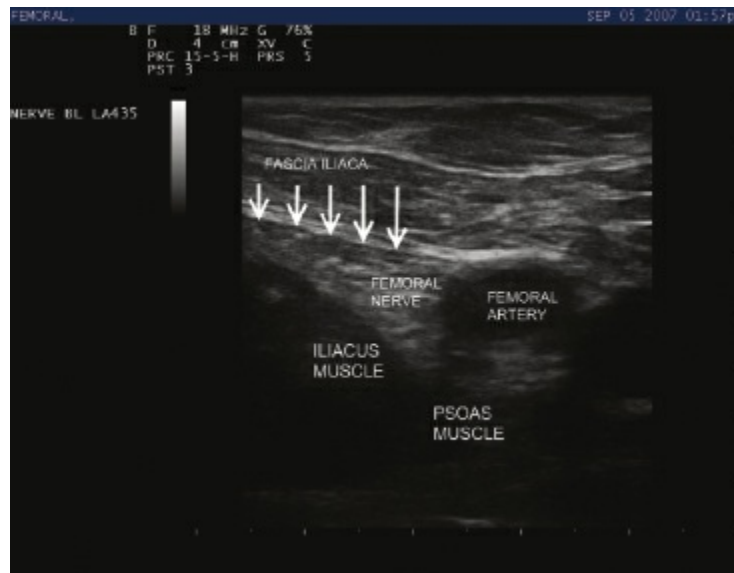

The femoral nerve is formed from the posterior divisions of the ventral rami of L2 to L4 and is the largest terminal branch of the lumbar plexus. The nerve emerges from the lower lateral border of the psoas muscle and passes beneath the inguinal ligament in the groove between the iliacus and psoas muscles. In the inguinal region the nerve is covered by two fascial layers, the fascia lata and fascia iliaca, and whereas the fascia lata separates the subcutaneous tissue from the muscle and vessels, the fascia iliaca completely envelopes both the iliopsoas muscle and the femoral nerve, physically separating the nerve from the femoral artery and vein.<sup>99</sup> Although the nerve can be visualized with ultrasound, both above and below the inguinal ligament, it is ideally visualized at the level of the inguinal crease, and at this level, the nerve is positioned approximately 0.5 cm lateral to the femoral artery. The nerve provides motor innervation to the quadriceps femoris, sartorius, and pectineus muscles as well as sensory innervation to the anterior thigh, knee, and the

medial aspect of the lower extremity terminating as the saphenous nerve. Recent ultrasound-guided evidence indicates that the topographic relationship of the femoral nerve at the inguinal crease is *medial and lateral* to each other rather than *anterior and posterior* and both divisions are in close proximity to each other under the fascia iliaca.<sup>100</sup>

*Femoral nerve block* (FNB) is indicated for any surgery on the anterior aspect of the quadriceps muscle (biopsy or tendon repair), patella, TKA, anterior cruciate ligament repair or ankle surgery involving the medial aspect of the foot. Ultrasound-guided FNB is performed at the level of the femoral (inguinal) crease using a transverse cross-sectional (short-axis) view of the nerve as described by Ilfeld and colleagues.<sup>101</sup> Using an in-plane approach the needle is carefully advanced through the fascia iliaca and, while taking care to avoid direct needle-to-nerve contact, the needle is positioned either anterior or posterior to the nerve. Care must be taken to place the tip of the needle within the space between the fascia iliaca and the iliopsoas muscle lateral to the femoral artery (Fig. 55-18). Using incremental injection local anesthetic is administered into the perineural space and hydrodissection of local anesthetic around the nerve is confirmed.

Following TKA, ultrasound-guided FNB has been shown to provide analgesia that is superior to intravenous PCA alone and analgesia that is similar to epidural analgesia but without the hypotension associated with epidural analgesia.<sup>102</sup> Although both single shot and continuous catheter techniques have been described, a recent Cochrane Review indicates that continuous blockade may be superior to a single shot technique.<sup>103</sup> Evidence suggests, however, that continuous blockade of the femoral nerve can precipitate weakness of the quadriceps muscle, potentially increasing the risk of inpatient falls (IFs) following surgery.<sup>104</sup> Other independent risk factors for IF, completely unrelated to FNB, include advanced age, and increasing comorbidity burden such as sleep apnea, psychosis, obesity, and anemia.<sup>105</sup> The Centers for Medicare and Medicaid Services (CMS) have designated IF as a hospital-acquired condition that is a potentially avoidable event and they may not necessarily reimburse for related expenses. Comprehensive, multidisciplinary fall-prevention programs can eliminate the risk of IFs.

**Figure 55-18** Ultrasound-guided femoral nerve blockade: Short axis ultrasound image of the infrainguinal structures. Femoral nerve blockade can be performed with a needle approach that is either in-plane or out-of-plane. The needle tip must be positioned within the space between the fascia iliaca and the iliopsoas muscle before local anesthetic is injected in order to achieve a successful block of the femoral nerve.

*Saphenous nerve blockade* is frequently combined with a lateral popliteal block or sciatic block for procedures involving the lower leg. The saphenous nerve is the only branch of the lumbar plexus below the knee and is the largest sensory terminal branch of the femoral nerve. The nerve provides sensory innervation to the medial, anteromedial, and posteromedial parts of the knee, leg, and medial malleolus and, in some people, the medial aspect of the large toe. Several approaches have been described at the level of the patella and medial malleolus; however, blockade of the nerve within the adductor canal (AC) has proven to be very popular. The AC is bounded by the sartorius, vastus medialis, and adductor muscles and contains the femoral vessels, saphenous nerve, the motor nerve to the vastus medialis, and occasionally the obturator nerve. The AC extends from the apex of the femoral triangle to the adductor hiatus.

Ultrasound-guided *adductor canal block* (ACB) is indicated for TKA, anterior cruciate ligament repair, medial meniscectomy, and any surgery on the medial aspect of the ankle (total ankle arthroplasty and triple arthrodesis). The potential advantage of the ACB over the FNB is analgesia without significant motor blockade, theoretically decreasing the risk of IFs.<sup>106</sup> Although continuous AC catheters preserve quadriceps strength better than continuous femoral catheters there is evidence that femoral catheters may provide superior dynamic analgesia.<sup>107</sup> Generally speaking the ACB is performed at the mid-thigh level; however, the literature is confusing about what constitutes “mid-thigh”!<sup>108</sup> Nevertheless, ultrasound-guided ACB is performed with the patient in the prone position with the operative leg

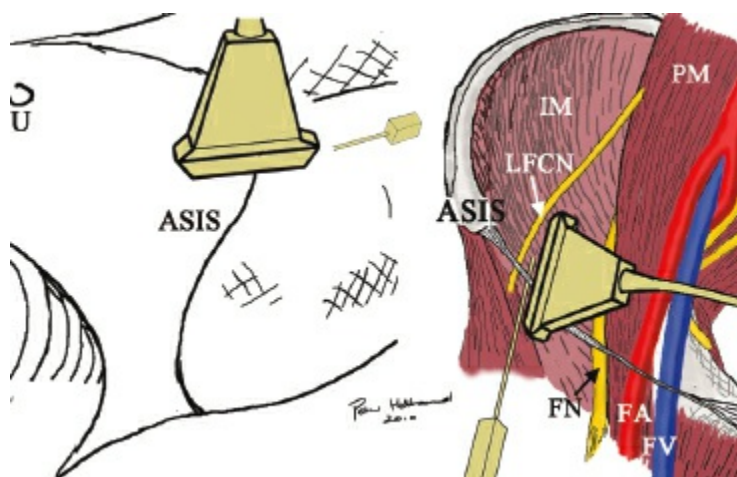

externally rotated and the leg slightly flexed. In a transverse axial plane place a high-frequency linear transducer positioned on the medial aspect of the thigh to identify the femoral vessels coursing deep to the sartorius muscle. As the transducer is advanced caudally the femoral artery dives deep through the adductor hiatus. If the purpose of the ACB is to anesthetize both the saphenous nerve as well as the nerve to the vastus medialis then the ideal needle entry point should be the distal thigh, within the AC, approximately 2 to 3 cm proximal to the adductor hiatus<sup>109,110</sup> or at the midpoint of the AC as defined by the ultrasound image of both the proximal and distal ends of the AC.<sup>111</sup> Injection at this point should provide analgesia to the anteromedial aspect of the knee joint, joint capsule, and retinaculum.<sup>111</sup> Needle insertion is in-plane using an anterior-lateral to posterior-medial direction.

Another very successful approach to femoral nerve blockade is the *fascia iliaca compartment block* (FICB). The injection site is distant from any neurovascular structures and therefore does not require neurostimulation to be successful.<sup>97</sup> The block has been described in both children and adults and is reported to be more successful than the 3-in-1 block. It is a large volume (30 to 60 mL) fascial plane block that targets both the femoral and lateral femoral cutaneous nerves, and is considered to be both a safer alternative to a lumbar plexus block and a critical component of a multimodal opioid-sparing technique for analgesia in the elderly patient with hip fracture. Advantages of this block, in the hip fracture patient, include (1) analgesia that allows positioning of the patient for neuraxial block, (2) opioid-sparing analgesia, (3) decreased length of hospital stay, and (4) less delirium.<sup>112-114</sup> The three techniques that have been described in the literature include the “landmark technique”<sup>115</sup> the supra-inguinal para-sagittal approach,<sup>116</sup> and the transverse approach in the inguinal crease.<sup>117</sup> When performing the suprainguinal parasagittal approach it is recommended that you inject as proximally as possible to guarantee cephalad spread of local anesthetic into the pelvis (Figs. 55-19 and 55-20).<sup>118</sup>

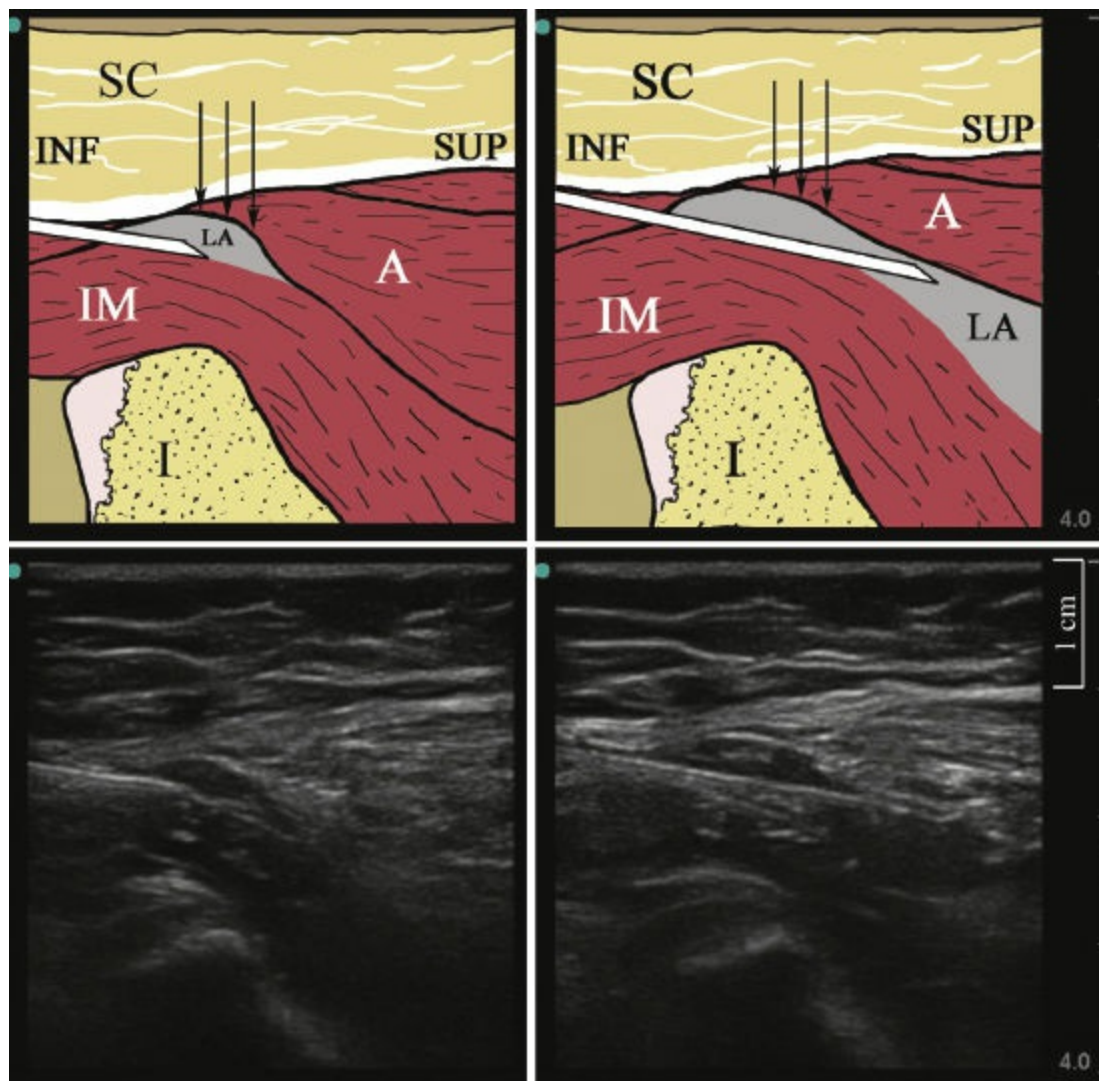

## Sacral Plexus

The sciatic nerve originates from the sacral plexus and is derived from the ventral rami of the fourth lumbar to the third sacral nerve roots. The three major components of the sciatic nerve include the tibial and common peroneal nerves and the posterior femoral cutaneous nerve to the thigh. The sciatic nerve provides sensory, motor, and some sympathetic innervation to the lower extremity, and its blockade, in combination with a femoral or saphenous nerve block, can provide complete anesthesia and postoperative analgesia for lower extremity surgery. Sciatic nerve blockade has been proven useful in numerous surgical procedures, including THA and TKA, anterior

cruciate ligament repair, complex outpatient knee surgeries, above- and below-the-knee amputations, as well as ankle and foot surgery. Although numerous proximal and distal techniques, using anterior, posterior, and lateral approaches to the sciatic nerve with the patient in the supine, prone, lateral, and lithotomy positions, have been described, patient comfort is the key factor determining the optimal approach.

**Figure 55-19** Probe and needle position and diagram of dissected iliac fossa showing anatomy for the suprainguinal fascia iliaca block. Ultrasound-guided suprainguinal fascia iliaca block: a cadaveric evaluation of a novel approach. *Anaesthesia*. 2011;66:300–305.)

Sciatic nerve blockade within the popliteal fossa is probably one of the most common approaches. Sciatic nerve blockade at this level typically spares the posterior cutaneous nerve to the thigh, thus preserving hamstring function. This approach therefore has the added benefit of being less restrictive on ambulation, which is useful following ambulatory surgery. Compared with subcutaneous local anesthetic infiltration and ankle blockade, popliteal sciatic nerve blockade provides significantly longer postoperative analgesia and has a high degree of patient satisfaction.

Although single-shot sciatic nerve blockade can provide short-term analgesia, continuous popliteal sciatic nerve blockade with a peripheral nerve catheter can significantly extend the duration of postoperative analgesia and

has been successfully implemented in both the inpatient and outpatient settings using an electronic infusion pump or a disposable elastomeric pump. Pain-related sleep disruption is less, and hospital LOS is shorter, which can potentially lead to a reduction in health-care costs.<sup>119</sup> Risks associated with at-home perineural infusions of local anesthetic include catheter site infection, nerve injury, and catheter migration with subsequent local anesthetic toxicity. Complications are relatively rare.<sup>74,120</sup>

Over the previous 5 years, ultrasound guidance has become the predominant technique for identifying the sciatic nerve within the popliteal space. It has significantly improved the accuracy of needle placement through real-time imaging of the nerve and has increased the rate of sensory block success through targeted circumferential spread of local anesthetic around the nerve.<sup>121</sup> The image of the sciatic nerve in the popliteal space varies  depending on the type of transducer used, but the linear 5- to 12-MHz transducer provides the highest resolution image.<sup>122</sup> With the posterior approach and a short-axis (transverse cross-sectional) view, active or passive dorsiflexion of the foot can produce external rotation of the sciatic nerve around its central axis (seesaw sign) which facilitates its identification.<sup>123</sup>

In cadaveric models it has been demonstrated that a paraneural sheath envelopes the sciatic nerve.<sup>124</sup> Using high-definition ultrasound the paraneural sheath appears as a hyperechoic fascial layer between the epineurium of the nerve and the epimysium of the surrounding muscle (Fig. 55-21).<sup>125</sup> An injection deep to the paraneurium, within the paraneural space (“subparaneural” compartment), will, therefore, facilitate spread of local anesthetic along the length of the nerve and improve sensory blockade.<sup>125</sup> Likewise, subparaneural injection of local anesthetic at or above the bifurcation of the sciatic nerve in the popliteal fossa has been shown to accelerate the onset time and increase the duration of sensory blockade.<sup>126,127</sup>

**Figure 55-21** Sequence of transverse sonograms (distal to proximal) demonstrating the spread of the local anesthetic in both the subepimyseal and subparaneural compartments after an ultrasound-guided popliteal sciatic nerve block above its bifurcation. The paraneural sheath (*white arrow heads*) is interposed between the epimysium of the surrounding muscles and the outer surface (epineurium) of the sciatic nerve and its divisions. Note the extensive distal spread of the local anesthetic (LA), deep to the paraneural sheath, to encompass both the common peroneal (CPN) and tibial (TN) nerves. The individual paraneural sheath and subparaneural compartment of the CPN and TN are clearly delineated in **(C)**. Circumferential spread of the LA is also seen around the tibial nerve in **(D)**. (Reprinted with permission from Karmakar MK, Shariat AN, Pangthipampai P, et al. High-definition ultrasound imaging defines the paraneural sheath and the fascial compartment surrounding the sciatic nerve at the popliteal fossa. *Reg Anesth Pain Med.* 2013;38(5):447–451.

## Truncal Blocks

*Thoracic paravertebral block* (TPB) can provide segmental analgesia for numerous surgical procedures including thoracotomy, mastectomy, nephrectomy, cholecystectomy and rib fractures, spinal surgery, and video-assisted thoracoscopic surgery, as well as inguinal and abdominal procedures. The paravertebral space (PVS) does not actually exist but is considered to be a potential space created by fluid distention of the tissues.<sup>128</sup> The PVS is defined anteriorly by the parietal pleura, posteriorly by the costotransverse ligament, superiorly by the occiput, inferiorly by the alar of the sacrum, and medially by the vertebral body, intervertebral disc, and the intervertebral foramen. Laterally, the PVS is contiguous with the intercostal space.<sup>128</sup> The PVS contains the anterior and posterior ramus of the spinal nerve root and the white and grey rami communicantes. Injection of local anesthetic into this

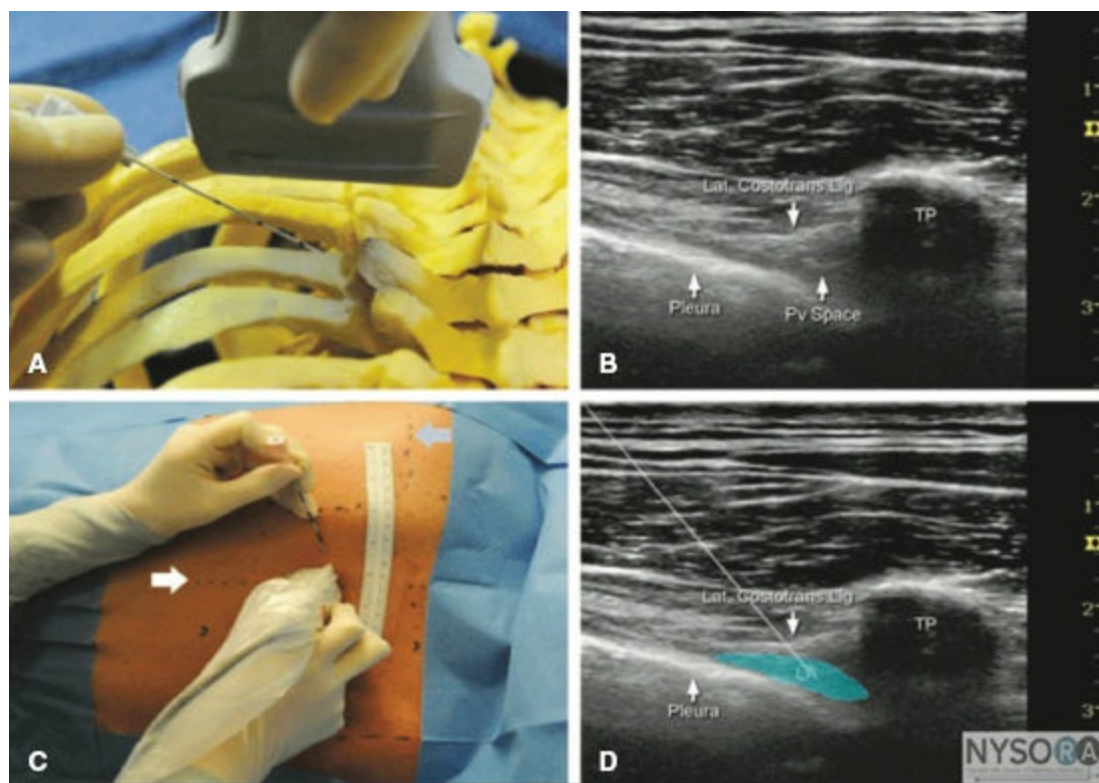

potential space will therefore produce a dense sensory and sympathetic block resulting in unilateral segmental analgesia. Generally speaking, TPB is performed at the thoracic level. When performed in the lumbar region it is better known as a *psoas compartment block* and when performed at the cervical level it is referred to as a *deep cervical plexus block*.<sup>128</sup> TPB can be performed in the seated, prone, or lateral decubitus position. Although TPB has been performed using a blind percutaneous approach, the introduction of ultrasound guidance has improved the precision and decreased the complications associated with this procedure.

Different combinations of transducer positioning (transverse versus sagittal) and needle insertions (in-plane vs. out-of-plane) have resulted in the description of at least nine different ultrasound-guided approaches for TPB, the discussion of which is beyond the scope of this chapter.<sup>129</sup> Although the physician may have a preference for a specific transducer position it is recommended that a scout scan be performed utilizing both sagittal and transverse positioning prior to the performance of any block so important anatomic landmarks such as the pleura, superior costotransverse ligament (SCTL), and transverse process can be identified. The in-plane transverse technique (Fig. 55-22) is a tangential approach that inserts the needle in a lateral to medial direction that minimizes the risk of pleural puncture. However, there is a risk of epidural spread if the needle is advanced too close to the intervertebral foramen. The risk of epidural spread may be minimized by using an in-plane sagittal approach; however, this technique requires a steep insertion angle, which can make it difficult to image the tip of the needle.<sup>129</sup>

The advantages of TPB include lower postoperative VAS pain scores, a reduction in postoperative opioid consumption, and, therefore, less opioid-induced postoperative nausea and vomiting, less pain with movement, and shorter hospital stays. Continuous TPB compares favorably with thoracic epidurals for postthoracotomy analgesia. Continuous TPB provides analgesia that is equivalent to thoracic epidural blockade but without the side effects of hypotension, postoperative nausea and vomiting, and urinary retention<sup>130</sup> and may therefore be a reasonable alternative to a thoracic epidural catheter for postoperative analgesia.

Risks associated with the performance of TPB include pneumothorax, inadvertent entry of the block needle through the intervertebral foramen, epidural spread, and sympathetic blockade. Consequently, many practitioners may be uncomfortable performing this block and a reasonable alternative for chest wall analgesia would be the less invasive *pectoral nerve block*. Pectoralis nerve blockade is an interfascial plane block, originally described by Blanco et al.<sup>131</sup> that deposits local anesthetic between the various muscle layers that consist of the pectoralis major, pectoralis minor, anterior serratus, and

intercostal muscles. As part of a multimodal pain regimen pectoral nerve blockade has been demonstrated to significantly lower VAS pain scores and shorten the hospital stay for patients following modified radical mastectomy.<sup>132</sup> Ultrasound guidance has not only facilitated the performance of these blocks but also decreased the risk of inadvertent pneumothorax during execution of the block. All thoracic wall blocks are performed with the patient in the supine position with the arm abducted. The needle is inserted in-plane with the transducer in a medial-to-lateral direction.<sup>131,133</sup>

**Figure 55-22** Ultrasound-guided thoracic paravertebral block. **A:** Transducer position and needle orientation. **B:** Corresponding ultrasound image. **C:** Patient is in oblique lateral position. >, spinous processes; gray arrow, left scapula; white arrow, paramedian line 3 cm (transverse processes). **D:** Needle insertion path and correct injection of local anesthetic. TP, transverse process. (Reprinted with permission from Vandepitte C, Pintaric TS, Gautier PE. Thoracic paravertebral block. NYSORA website. <http://www.nysora.com/techniques/neuraxial-and-perineuraxial-techniques/ultrasound-guided/3277-thoracic-paravertebral-block.html>. Published September 9, 2013.)

The *pectoralis I block* (PEC I) is indicated for any surgery on the pectoralis major muscle such as the insertion of breast expanders and subpectoral prosthesis. This block targets the lateral and median pectoral nerves within the fascial plane defined by the pectoralis major and pectoralis minor muscles at the level of the third rib. A total of 10 mL of local anesthetic is deposited at this level (Fig. 55-23).

The *pectoralis II block* (PEC II or modified PEC block) is indicated for more

extensive chest wall surgery such as insertion of breast expanders and subpectoral prosthesis, tumorectomies, mastectomies, and sentinel node dissection. This block targets the lateral branches of the intercostal nerves that exit at the level of the mid-axillary line to innervate the breast and the skin from T2 to T6 as well as the long thoracic nerve. At the level of the third rib a total of 20 mL of local anesthetic is deposited between the serratus anterior muscle and either the pectoralis minor or the external intercostal muscle. This block is always combined with a PEC I block for extensive chest wall surgery such as mastectomy combined with placement of a tissue expander.

The *serratus plane block* is a relatively new block that is indicated for latissimus dorsi flap reconstruction and multiple rib fractures. The block is performed at the level of the fifth rib in the mid-axillary line and a total of 40 mL of local anesthetic is injected in the fascial plane defined by the latissimus dorsi and serratus anterior muscles.

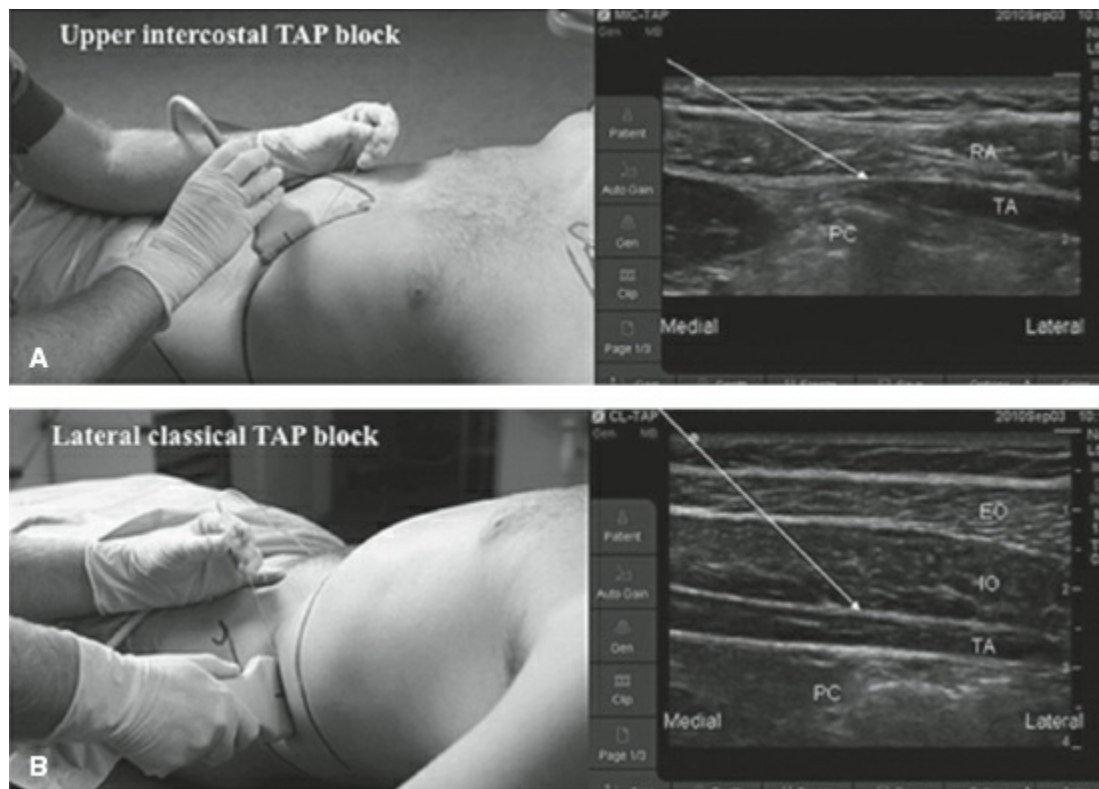

The *transversus abdominis plane (TAP)* block is a volume-dependent compartmental field block that anesthetizes the anterior rami of the thoracolumbar spinal segmental nerves T7-L1 as they travel between the internal oblique (IO) and the transversus abdominis (TA) muscles. The TAP block provides both sensory and motor blockade of the abdominal wall and works best when postoperative pain is primarily of somatic and not visceral origin. This block can provide adequate postoperative analgesia in patients undergoing major abdominal surgery such as colorectal and renal transplant surgery, cesarean section, cholecystectomy, hysterectomy, inguinal herniorrhaphy, appendectomy, nephrectomy, bariatric surgery, gastrectomy, liver transplantation, and prostatectomy. Current evidence suggests that the TAP block is an essential component of multimodal analgesia, which can be opioid-sparing and is a reasonable alternative to epidural analgesia when placement of an epidural catheter is contraindicated.<sup>134</sup>

The TAP block was originally described in 2001 by Rafi<sup>135</sup> using a landmark method at the triangle of Petit (TOP), which is defined by the latissimus dorsi muscle posteriorly, the external oblique (EO) muscle anteriorly, and the iliac crest caudally. This is a blind approach that uses a “double-pop” technique to advance the needle into the appropriate fascial plane. Reliable identification of the TOP using the landmark approach can be difficult, particularly in the obese patient. Incorrect needle placement can result in positioning of the needle in the peritoneal cavity, which increases the risk of damage to visceral organs. The introduction of the ultrasound-guided TAP block has the advantage of real-time imaging of the EO, IO, and TA muscles with needle placement that can improve both the safety and efficacy of the TAP block when compared to the landmark technique. To date the three approaches that have been described in the literature include the lateral

(“mid-axillary”) approach, the “oblique subcostal” approach, and the posterior approach (aka the “quadratus lumborum” [QL] block) (Figs. 55-24 and 55-25). Current recommendations suggest that the lateral TAP technique is well suited for infraumbilical (T10 to T12) incisions, and an oblique subcostal TAP for supraumbilical (T7 to T9) incisions. The role of the posterior TAP is unclear; however, it appears to provide better coverage of dermatomes<sup>136</sup> and more prolonged analgesia<sup>137</sup> compared to the lateral approach. Larger case series are recommended to better clarify the role of this novel block.

**Figure 55-24** The bilateral dual (BD) TAP block. **A:** Upper intercostal TAP block. The needle is inserted above the rectus abdominis (RA) muscle and advanced in-plane to the transducer in a medial-to-lateral direction. The end point is beneath the RA and between the posterior rectus sheath and the transversus abdominis (TA) muscle. PC indicates peritoneal cavity; TAP, transversus abdominis plane. **B:** Lateral classic TAP block. The needle is inserted into the anterior axillary line beneath the thoracic cage and above the iliac crest. The needle is advanced in-plane to the transducer, and the end point is between the internal oblique (IO) and the transversus abdominis (TA) muscles. EO indicates external oblique muscle. (Reprinted with permission from Børglum J, Jensen K, Christensen AF, et al. Distribution patterns, dermatomal anesthesia, and ropivacaine serum concentration after bilateral dual TAP block. *Reg Anesth Pain Med.* 2012;37[3]: 294–301.)

**Figure 55-25** Photograph and ultrasonographic images demonstrating siting of the TAP block. **A:** Photograph of needle and transducer. **B:** Before injection of local anesthetic (LA). **C:** After injection of LA. The ultrasound transducer is placed in the transverse plane between the 12th rib or costal margin and the iliac crest. The end point of injection is 1 to 2 cm anterior to thoracolumbar fascia. The left side of the image is oriented medially, and the skin is at the top of the images. The needle is marked with *arrowheads*. PC indicates peritoneal cavity; CM, costal margin; IIC, iliac crest; AAL, anterior axillary line; MAL, medial axillary line; EO, external oblique; IO, internal oblique; TA, transversus abdominis. (Reprinted with permission from Støving K, Rothe C, Rosenstock CV, et al. Cutaneous sensory block area, muscle-relaxing effect, and block duration of the transversus abdominis plane block: a randomized, blinded, and placebo-controlled study in healthy volunteers. *Reg Anesth Pain Med.* 2015; 40[4]:355–362.)

The *rectus sheath block* (RSB) is a regional anesthetic technique for use in adults to provide relaxation of the anterior abdominal wall during laparotomy. The RSB has been described in both adults and children and can provide effective postoperative analgesia for both umbilical and midline surgical incisions. The block is performed by depositing local anesthetic in the

potential space between the rectus abdominis muscle and the posterior rectus sheath using an ultrasound-guided, in-plane, medial-to-lateral or lateral-to-medial approach. Complications associated with the block include intraperitoneal injection of local anesthetic, perforation of the bowel, and puncture of a mesenteric vessel.<sup>134</sup>

The *ilioinguinal/iliohypogastric (II/IH)* nerve block is indicated for analgesia following hernia repair in both adults and children and following orchidopexy and hydrocele repair in children. Both a landmark technique (two fascial “clicks”) and a US-guided technique have been described; however, the US technique has been shown to be more reliable and potentially safer. Risks associated with this block include bowel puncture, bowel or pelvic hematoma, femoral nerve blockade, and elevated serum levels of local anesthetic. For the US-guided approach the patient is placed in the supine position and the anterior superior iliac spine (ASIS) is palpated. With a linear transducer positioned in the transverse plane with its lateral edge positioned at or above the ASIS the EO, IO, and TA muscles as well as the II and IH nerves and the deep circumflex iliac artery (DCIA) can be identified. Using an in-plane lateral-to-medial approach the block needle is carefully advanced into the neurovascular plane between the IO and TA muscles and with intermittent aspiration local anesthetic is carefully injected. Significant reduction of pain at rest and with mobilization has been demonstrated in adults who have received US-guided IL/IH nerve blockade prior to inguinal hernia repair.<sup>138</sup>

The *transversalis fascia plane (TFP)* block was designed to anesthetize the lateral cutaneous branches of the T12 and L1 nerves deep to the transversus abdominis muscle and anterior to the QL muscle. The block is indicated for patients undergoing iliac crest bone harvest, open appendectomy, and inguinal hernia repair. Complications, such as peritoneal puncture, are relatively rare because the peritoneum does not lie directly under the transversalis plane.<sup>136</sup>

## Wound Infiltration

Recently, there has been an interest in continuous *intra-articular* and *periarticular* infiltration of local anesthetic with or without opioid for TKA. The advantage of the approach is that quadriceps strength can be maintained, thus facilitating ambulation and possibly earlier discharge from the hospital. A major disadvantage of this approach relates to reports of chondrolysis that may limit its usage. Other major disadvantages include the potential for large wound effusions and an increased risk for infection with a catheter in place. The *periarticular soft tissue injection* of local anesthetic combined with an NSAID (e.g., ropivacaine and ketorolac) combined with an intra-articular catheter for 24 hours has been described.<sup>139</sup> This technique appears to be safe

and effective, and the risk of infection is minimized by removing the catheter on postoperative day 1.

*Local infiltration analgesia (LIA)* can be a useful technique for sustained reduction of perioperative pain following soft tissue and orthopedic surgeries. Multimodal analgesia that incorporates LIA is clearly superior to monotherapy-based regimens and has the advantage of being opioid sparing, and can reduce the number of opioid-related adverse events.<sup>140</sup> The efficacy of LIA has been compared to other popular modalities for perioperative analgesia following TKA with favorable results. A recent prospective, randomized, double-blind study compared LIA to intrathecal morphine in patients receiving a TKA and the authors concluded that LIA with ropivacaine provided better postoperative analgesia, earlier mobilization, and shorter hospital stay than intrathecal morphine.<sup>141</sup>

Both LIA and FNB demonstrate excellent perioperative analgesia following TKA; however, at the present time there is insufficient data supporting the superiority of one technique over the other.<sup>103</sup> Some orthopedic surgeons, however, prefer LIA because it is relatively easy and safe to perform intraoperatively and, unlike FNB, it has the advantage of preserving quadriceps strength, which can facilitate ambulation and potentially shorten the patients' hospital LOS. Direct infiltration of the wound with local anesthetic also has the potential advantage of decreasing inflammation and preventing central sensitization and ultimately neuropathic pain. The *periarticular* infiltration of a local anesthetic is technique dependent and requires careful administration of the drug into the posterior, inferior medial, superomedial, and superolateral capsules of the knee, as well as the periosteum, fascia, and subcuticular tissue.<sup>142</sup> Complications associated with LIA include systemic toxicity, infection, and wound dehiscence.

Although the perioperative administration of bupivacaine for acute perioperative pain control using LIA has proven to be quite efficacious, the duration of analgesia, unfortunately, is relatively short (<12 hours).<sup>143</sup> In an attempt to prolong the duration of analgesia a novel approach has been developed that encapsulates bupivacaine into microscopic lipid-based spherical particles (Depofoam). This *liposomal formulation of bupivacaine (Exparel)* is designed to release bupivacaine over a period of about 72 hours and in a recent efficacy analysis of 10 randomized, double-blind, single-dose wound infiltration studies, involving patients undergoing hernia repair, TKA, bunionectomy, breast augmentation, and hemorrhoidectomy, liposomal bupivacaine was shown to lower pain scores and reduce opioid consumption.<sup>144</sup>

Liposomal bupivacaine has been recommended as a superior alternative to bupivacaine HCl for LIA in TKA and in a recent phase II randomized dose-ranging study comparing various doses (133 mg, 266 mg, 399 mg, and 532

mg) of liposomal bupivacaine (Exparel) to bupivacaine HCl 150 mg, using LIA, liposomal bupivacaine (532 mg) was found to provide significantly greater analgesia for patients at rest.<sup>140</sup> Unfortunately, this dose of liposomal bupivacaine exceeds, by twofold, what is considered to be both safe and efficacious and is not FDA approved. Subsequently, a retrospective cohort study compared the periarticular injection of liposomal bupivacaine (266 mg) to the traditional periarticular injection of ropivacaine 400 mg (with morphine 5 mg and epinephrine 0.4 mg) for TKA and liposomal bupivacaine was found to provide pain control that was inferior to the less-expensive traditional periarticular injection.<sup>142</sup> Finally, a recent investigation compared liposomal bupivacaine (LIA) to single-injection FNB and found that both techniques provided comparable pain relief, and although the FNB group displayed greater postoperative knee flexion, the group that received LIA with liposomal bupivacaine demonstrated improved early ambulation and decreased LOS.<sup>145</sup>

Liposomal bupivacaine (Exparel) is intended for single-dose administration only and although the drug has been shown to be well tolerated at doses up to 532 mg, in five different surgical models, the maximum recommended dose, per the package insert, is 266 mg (20 mL). Combining liposomal bupivacaine with other drugs prior to administration is not recommended. The ideal multimodal, opioid-sparing, analgesic protocol following TKA has yet to be defined; however, it will more than likely consist of some combination of the aforementioned techniques. Further investigation is recommended to better define both the safety and efficacy of liposomal bupivacaine.

## **Continuous Peripheral Nerve Blockade Caveats**

Interest in CPNB increased following the FDA warning in 1997 on the risk of spinal hematoma in patients who received epidural placement and low-molecular-weight heparin concurrently.<sup>146</sup> Although bleeding complications can be associated with the placement of CPNB catheters, the actual risks related to this technique are not well defined. Hemorrhagic complications, rather than neurologic deficits, appear to be the predominant risk associated with the performance of peripheral nerve blockade in the anticoagulated patient.<sup>147</sup> Major hemorrhage can occur following performance of psoas compartment blockade (e.g., LPB) and lumbar sympathetic blockade.<sup>147</sup> Special risk seems likely in any patient who may be anticoagulated perioperatively.<sup>147</sup>

Practice-based guidelines for the performance of *neuraxial techniques* in the anticoagulated patient are available online at the ASRA Web site at <https://www.asra.com/advisory-guidelines>. At the time of this publication, however, no consensus statement has been promulgated by the society

outlining practice guidelines for the performance of *peripheral nerve blocks* in anticoagulated patients. Until guidelines are developed for the performance of peripheral nerve blockade in the anticoagulated patient, Horlocker et al.<sup>147</sup> recommend a conservative approach by adapting the guidelines set forth by ASRA (third edition) for the performance of neuraxial blockade, which they acknowledge may be overly restrictive. While work progresses on the Fourth Edition of the Practice Advisory, ASRA has developed a medical app that provides up to date, drug-specific guidelines, for antithrombotic and thrombolytic therapy use in the setting of regional anesthesia procedures. The app is available for your cell phone and can be downloaded from iTunes or Google Play.

## Complications from Regional Anesthesia

The opinion of some that regional anesthesia is safer than general anesthesia may be based on the fact that regional anesthesia has been associated with reduced postoperative mortality secondary to thromboembolic phenomenon and myocardial infarction.<sup>148,149</sup> Nonetheless, data from the American Society of Anesthesiologists Closed Claims Project database suggests that the comparative safety of regional anesthesia in comparison to general anesthesia cannot be accurately determined. In a review of Closed Claims data, however, death is more common with claims involving general anesthesia and permanent-disabling and nondisabling temporary injuries are more often associated with regional anesthesia.<sup>150</sup> Serious complications associated with regional anesthesia include cardiac arrest, radiculopathy, cauda equina syndrome, and paraplegia. Fortunately, the incidence of severe anesthesia-related complications is rare (<0.1%); however, the incidence of cardiac arrest and neurologic complications is higher following spinal anesthesia than after all other types of regional procedures. The incidence of cardiac arrest following spinal anesthesia is  $6.4 \pm 1.2/10,000$  versus  $1.0 \pm 0.4/10,000$  for other forms of regional anesthesia. The incidence of neurologic injury after spinal anesthesia ( $6 \pm 1/10,000$  cases) is greater than all other regional techniques (e.g., epidural, peripheral nerve block, and intravenous regional anesthesia) combined ( $1.6 \pm 0.5/10,000$  cases).

**11** Should a perioperative nerve injury occur, it is the responsibility of the physician to determine which combination of anesthetic, surgical, and patient risk factors are involved in any nerve injury and not assume a priori that the regional anesthetic is the reason. The risk factors for nerve injury are listed in [Table 55-24](#). *Patient risk factors* for perioperative nerve injury may include any pre-existing systemic neuropathy (e.g., diabetes mellitus) or drug-induced neuropathy (e.g., vincristine or cis-platin). Risk factors for ulnar nerve injury include male sex, prolonged hospitalization, increasing age, extremes of body

habitus, and diabetes. Diabetics, for example, has a decreased requirement for local anesthetic yet an increased risk for local anesthetic-induced nerve injury. This phenomenon has been described as the “double-crush” syndrome and proposes that axons injured at one site have an increased susceptibility to injury distally. Interestingly enough, in spite of this risk, regional anesthesia has been safely performed on patients with pre-existing ulnar neuropathy who underwent ulnar nerve transposition.<sup>151</sup>

**Table 55-24** Risk Factors for Nerve Injury during the Performance of Regional Anesthesia

Variables	Risk Factors
Patient	Body habitus Pre-existing neurologic disorder (e.g., diabetes mellitus or patients who have received chemotherapy in the recent past) Male gender Advanced age
Surgical	Direct surgical trauma or stretch trauma Prolonged tourniquet time Hematoma Infection Tightly applied casts or surgical dressings Patient positioning
Regional anesthesia	Mechanical injury from the needle or catheter Chemical neurotoxicity from the local anesthetic Ischemic injury to the nerve

**Table 55-25** Advantages of Ultrasound-guided Regional Anesthesia<sup>152,196</sup>

- Hastened block performance
- Fewer needle passes resulting in less patient discomfort and potentially a decreased risk of vascular puncture and hematoma formation in the anticoagulated patient
- Faster initial onset of the block
- Decreased dose of local anesthetic
- Preprocedural scanning can reveal anticipated as well as unanticipated structures such as hemodialysis catheters, ventriculoperitoneal shunts, vascular and neurologic anomalies

Over the past quarter century ultrasound has become the preferred **12** nerve localization technique that has truly transformed the practice of regional anesthesia. Direct visualization of the needle and the associated anatomic structures and real-time hydrodissection of local anesthetic around target nerves has been shown to hasten the onset of sensory and motor blockade, decrease performance time and the number of needle passes.<sup>152</sup> Although UGRA has not significantly reduced the incidence of **13** postoperative neurologic symptoms, as compared to peripheral nerve

stimulation technique, it has most definitely decreased the incidence of LAST and has had a meaningful impact on reducing the incidence of pneumothorax following supraclavicular nerve blockade.<sup>152</sup> Advantages associated with the use of UGRA are listed in [Table 55-25](#). Relevant patient safety issues are listed in [Table 55-26](#). See [Chapters 22](#) (Local Anesthetics), [35](#) (Epidural and Spinal Anesthesia), and [36](#) (Peripheral Nerve Blockade) for additional details on the reported complications of regional anesthesia.

**Table 55-26** Ultrasound-guided Regional Anesthesia (UGRA) and Patient Safety<sup>75,152</sup>

1. Peripheral nerve injury
  1. The incidence of peripheral nerve injury with UGRA is similar to reports of nerve injury following the use of peripheral nerve stimulation (PNS).
2. Local anesthetic systemic toxicity
  1. Compared to PNS, UGRA decreases the risk of unintended vascular puncture but does not necessarily decrease the risk of local anesthetic toxicity.
3. Hemidiaphragmatic paresis (HDP)
  1. Low-volume UGRA of the brachial plexus can decrease the risk of HDP following an interscalene approach and almost eliminate it following a supraclavicular approach.
4. Pneumothorax (PTX)
  1. Because UGRA allows the anesthesiologist to directly visualize the pleura this should decrease the risk of PTX; however, PTX has been reported following the performance of UGRA.

## Perioperative Pain Management of the Opioid-dependent Patient

Although this discussion focuses on the patient with chronic pain syndromes, these strategies for perioperative pain management are easily adaptable to other opioid-dependent populations. Chronic pain is defined as “pain without apparent biologic value that has persisted beyond the normal tissue healing time usually taken to be three months” (International Association for the Study of Pain) and “pain of a duration or intensity that adversely affects the function or well-being of the patient” (American Society of Anesthesiologists). Chronic pain is often associated with anxiety and depression, which may require treatment with various anxiolytics, antidepressants, anticonvulsants, antiarrhythmics, and skeletal muscle relaxants in addition to opioids. Symptoms unique to chronic pain include tight musculature, limited range of motion, and lack of energy, sleep disturbance, irritability, and social withdrawal. Associated psychiatric diagnoses may include hypochondriasis and psychosis.

Over the past decade, the percentage of patients with chronic pain for whom chronic opioids have been prescribed has increased dramatically. The

United States has led the world in opioid prescribing for chronic pain. With only 4.6% of the world population the United States consumes 80% of the licit global supply of opioids.<sup>153</sup> The reason for this is twofold: (1) the more aggressive and compassionate treatment of chronic pain of malignant origin in cancer patients who are surviving longer and (2) to a much larger extent, the willingness of the medical community to treat pain of nonmalignant origin, such as osteoarthritis, with opioids.<sup>154</sup>

The goal of opioid therapy for chronic pain is improvement of pain, function, and quality of life. Unfortunately, recent evidence suggests that in spite of the increased use of opioids for chronic nonmalignant pain there have been no corresponding reductions in the rates of disability or improvements in health status.<sup>155</sup> Unacceptable opioid side effects and concerns about adverse hormonal effects and immune modulation from long-term exposure can cause patients to abandon therapy. Finally, long-term opioid use results in physical dependence, the potential for withdrawal symptoms on abrupt discontinuation of the opioid, and the development of OIH and tolerance. The U.S. FDA defines opioid tolerance as the use of the oral morphine equivalent of greater than or equal to 60 mg a day for 7 days or longer.<sup>156</sup> Recent evidence suggests that the opioid-tolerant patient can potentially have a complicated hospital course resulting in an increased LOS and high readmission rate.<sup>156</sup> A multimodal approach to pain management is highly recommended.

*Physical dependence* is a “physiologic state of adaptation to a specific psychoactive substance characterized by the emergence of a *withdrawal syndrome* during abstinence, which may be relieved in total or in part by re-administration of the substance.” Opioid *withdrawal* is characterized by an increased sympathetic and parasympathetic response that results in hypertension, tachycardia, diaphoresis, abdominal cramping, and diarrhea. *Tolerance* is a rightward shift of the dose–response curve and by definition is “a state in which an increased dosage of a psychoactive substance is needed to produce a desired effect.” Escalating doses of opioid may also be explained by an underlying progression of the disease state or by the development of OIH. Tolerance can be innate or acquired. Innate tolerance is a genetically predetermined sensitivity to a drug, whereas acquired tolerance can have a pharmacokinetic, learned, or pharmacodynamic basis. Pharmacokinetic tolerance involves a diminution in the effects of a drug because of changes in distribution and metabolism usually secondary to enzyme induction of the CYP450 system, which results in accelerated metabolism. Learned tolerance refers to compensatory behavior that masks intoxication. Pharmacodynamic tolerance refers to neuroadaptive changes that occur following chronic exposure to opioids, which may involve receptor desensitization secondary to receptor downregulation, internalization, and uncoupling of opioid receptors

from G proteins. Opioids exhibit *cross-tolerance* to each other but the degree of cross-tolerance varies widely and is often incomplete.<sup>157</sup> Clinicians use incomplete cross-tolerance to their advantage to restore analgesic sensitivity in highly tolerant patients through opioid rotation.<sup>157</sup> Because cross-tolerance is incomplete, analgesia is restored with the new opioid at more than 50% below the predicted equianalgesic dose.<sup>157</sup> It must be stressed that the development of tolerance or physical dependence in no way implies that the patient is addicted to an opioid. *Addiction* is a biopsychosocial disease characterized by dysfunctional behavior that involves craving, compulsive use, loss of control, and the continued use of a drug in spite of adverse consequences. Finally, addiction should not be confused with *pseudoaddiction*, which, by definition, describes the patient who has behavioral features of addiction secondary to undertreatment of the pain syndrome. Pseudoaddiction is usually diagnosed retrospectively because once the dose of opioid is increased, pain resolves and aberrant behavior abates.

The onus for the identification of the opioid-dependent patient rests with the patient's surgical team, preoperative evaluation staff, and the anesthesia team.<sup>158</sup> Ideally the patient and the health-care teams will formulate a perioperative pain management plan prior to surgery, and the chronic pain service, if available, should be consulted. Often, however, the opioid-14 dependent patient is identified just moments prior to surgery and the anesthesia team needs to be innovative. The ideal perioperative pain management strategy, in the opioid-dependent patient, will involve a multimodal approach that employs regional analgesia techniques (neuraxial or peripheral nerve blockade) in conjunction with systemic nonopioid medications. Opioids, however, remain the mainstay of perioperative pain management, and an adequate dose of opioid needs to be maintained to avoid precipitating withdrawal symptoms ([Table 55-27](#)).

*Preoperative management* of the patient involves determining the patient's "baseline" opioid requirement, and on the day of surgery the patient should be instructed to take their normal opioid dose. If for some reason the patient neglects to take the opioid on the day of surgery, the anesthesiologist can administer an equivalent dose preoperatively. The opioid-dependent patient has increased opioid requirements, which are reported to be 30% to 100% greater than an opioid-naive patient<sup>154</sup>; therefore, during the preinduction period, the dose of fentanyl, morphine, or hydromorphone should be increased accordingly. Patients prescribed transdermal fentanyl patches are usually instructed to maintain their fentanyl patch into the operating room and this can serve as their baseline opioid requirement. Occasionally, however, in the case of major surgery, in which the risk of major blood loss or sepsis is significant, patients may be instructed to discontinue their transdermal patch, and an intravenous fentanyl infusion can be initiated to

maintain adequate plasma concentrations. Patients maintained on methadone should continue their baseline dose throughout the perioperative period. In the United States, methadone is available for both oral and intravenous administration. The reader is reminded that patients receiving more than 200 mg of methadone per day can develop a prolonged QT interval, which places them at risk for Torsades de pointe. It is therefore recommended that a baseline electrocardiogram be obtained for comparison. Patients who are maintained on the partial opioid agonist buprenorphine may continue to receive the drug for postoperative pain control, and morphine, hydromorphone, or fentanyl may be administered to supplement analgesia if required.<sup>159</sup> Full antagonists (e.g., naloxone and naltrexone) and the partial agonists–antagonists (e.g., nalbuphine, pentazocine, and butorphanol) should be avoided because they will precipitate withdrawal symptoms in opioid-

**15** dependent patients.

**Table 55-27** Suggested Guidelines for Perioperative Pain Management in the Opioid-tolerant Patient

**Preoperative**

1. Evaluation: Evaluation should include early recognition and high index of suspicion.
2. Identification: Identify factors such as total opioid dose requirement and previous surgery/trauma resulting in undermedication, inadequate analgesia, or relapse episodes.
3. Consultation: Meet with addiction specialists and pain specialists with regard to perioperative planning.
4. Reassurance: Discuss patient concerns related to pain control, anxiety, and risk of relapse.
5. Medication: Calculate opioid dose requirement and modes of administration; provide anxiolytics or other medications as clinically indicated.

**Intraoperative**

1. Maintain baseline opioids (oral, transdermal, intravenous).
2. Increase intraoperative and postoperative opioid dose to compensate for tolerance.
3. Provide peripheral neural or plexus blockade; consider neuraxial analgesic techniques when clinically indicated.
4. Use nonopioids as analgesic adjuncts.

**Postoperative**

1. Plan preoperatively for postoperative analgesia; formulate primary strategy as well as suitable alternatives.
2. Maintain baseline opioids.
3. Use multimodal analgesic techniques.
4. Patient-controlled analgesia: Use as primary therapy or as supplementation for epidural or regional techniques.
5. Continue neuraxial opioids: Intrathecal or epidural analgesia.
6. Maintain continuous neural blockade.

**After Discharge**

1. If surgery provides complete pain relief, opioids should be slowly tapered, rather than abruptly discontinued.
2. Develop a pain management plan before hospital discharge. Provide adequate doses of opioid and nonopioid analgesics.
3. Arrange for a timely outpatient pain clinic follow-up or a visit with the patient's addictionologist.

Data from Mitra S, Sinatra RS. Perioperative management of acute pain in the opioid-dependent patient. *Anesthesiology*. 2004;101:212.

Because it is well documented that the use of systemic nonopioid analgesics are opioid sparing in the opioid-naive patient it is reasonable to apply this experience to the opioid-tolerant patient. Drugs that should be part and parcel of any multimodal protocol for the perioperative care of the opioid-tolerant patient should include some combination of gabapentin or pregabalin, an NSAID or selective cyclooxygenase (COX-2) inhibitor, acetaminophen, dexamethasone, an NMDA receptor antagonist,  $\alpha_2$ -receptor agonists, lidocaine, and magnesium.

Both *gabapentin* and *pregabalin* bind to the  $\alpha$ -2 $\delta$  subunit of voltage-gated P/Q-type calcium channels in the dorsal horn of the spinal cord and, by

modulating the release of excitatory neurotransmitters from activated nociceptors, these drugs are believed to inhibit pain transmission and central sensitization.<sup>49</sup> They are both recommended for the treatment of perioperative pain in the opioid-tolerant patient.<sup>62</sup> Although gabapentin and pregabalin have similar mechanisms of action, pregabalin may be the preferred drug because of superior bioavailability and better diffusion into the central nervous system.<sup>62</sup>

The *NSAIDs* (e.g., ibuprofen and naproxen) have displayed proven efficacy for the treatment of postoperative pain and their opioid-sparing effect accounts for a significant reduction in opioid-related side effects, especially postoperative nausea and vomiting. Likewise, the analgesic effects of the *selective COX-2 inhibitors* are analogous to the NSAIDs. The recommended dose of celecoxib that reduces both postoperative pain and decreases opioid requirement is 400 mg orally 2 hours prior to surgery.<sup>62,160</sup>

*Acetaminophen* is an effective adjuvant in the treatment of postoperative pain, has an opioid-sparing effect, and decreases postoperative nausea and vomiting. The mechanism of action of the drug is elusive but is thought to involve inhibition of the COX enzyme via interaction at the peroxidase site, modulation of the descending inhibitory serotonergic pathways, and opioid agonist effects. There is also evidence that the drug interacts with the endocannabinoid system, TRPV<sub>1</sub>, and NMDA receptors,<sup>161</sup> which may make this drug particularly efficacious in the opioid-tolerant patient; however, more research into this intriguing area is warranted. The drug may be administered orally or intravenously; however, the intravenous route offers the advantage of earlier and higher peak plasma levels compared to oral acetaminophen, resulting in superior cerebrospinal fluid levels. The recommended adult dose in patients above 50 kg is 1,000 mg intravenously q 6 hours. The first dose may be administered just prior to surgery and continued postoperatively for as long as the patient is non per os (npo). In a single systematic qualitative review of 21 trials,<sup>39</sup> the authors conclude that the combination of an NSAID with acetaminophen demonstrates analgesia that is superior to either drug alone. Finally, dexamethasone may be beneficial, in the opioid-dependent patient, secondary to decreased neurotransmitter release and decreased production of the NMDA receptor antagonist kynurenic acid.<sup>62</sup> Although the recommended preoperative intravenous dose is 0.11 to 0.2 mg/kg<sup>61</sup> doses as high as 0.2 mg/kg have been administered as part of a multimodal analgesic strategy.<sup>62</sup> Future research strategies should focus on procedure-specific analgesic drug combinations, which can be specifically tailored to the patient that will provide optimal pain relief while minimizing side effects.

*Intraoperative management* of the opioid-dependent patient requires the prudent use of fentanyl, morphine, or hydromorphone in order to provide effective intraoperative anesthesia, postoperative analgesia, and to prevent

opioid withdrawal. This requires the administration of the patients' baseline opioid requirement plus their intraoperative requirements secondary to surgical stimulation. Exact opioid dosing guidelines do not exist but because of receptor downregulation secondary to chronic opioid administration, opioid doses may need to be increased 30% to 100% vis-à-vis the opioid-naive patient. Because of receptor downregulation an alternative opioid may be useful in this setting. Opioid rotation takes advantage of the fact that the new opioid will bind a different opioid receptor subtype and be metabolized differently. Following the cancer pain model, the dose of the new opioid is less than 50% of the calculated equianalgesic dose because of incomplete cross-tolerance.<sup>157</sup> Although the alternative opioid may be administered for several days postoperatively, prudence dictates that a physician or pharmacist well versed in pain management convert the patient to the appropriate oral opioid regimen for discharge from the hospital.

The optimal intraoperative dose of opioid varies considerably from patient to patient; therefore, monitoring intraoperative vital signs such as heart rate, pupil size, and respiratory rate can be useful and allows the clinician to avoid the negative consequences of overdosing or underdosing the patient with opioid. Reversing neuromuscular blockade toward the end of a general anesthetic and allowing the patient to breathe spontaneously can be a prudent technique. Patients with a respiratory rate greater than 20 breaths per minute and significantly dilated pupils require additional opioid. Titrating fentanyl, morphine, or hydromorphone to a respiratory rate of 12 to 14 breaths per minute and a moderately miotic pupil is recommended. It is also recommended that patients who are receiving chronic methadone therapy may receive an additional intraoperative dose of 0.1 mg/kg intravenously, which can be titrated to hemodynamic effect and pupillary response.

Activation of the NMDA receptor by the second messenger protein kinase C (PKC) is reported to play a critical role in the development of opioid tolerance.<sup>62</sup> Inhibition of the NMDA receptor with the NMDA receptor antagonist ketamine can be a useful strategy in this patient population because it is reported to be effective at reversing morphine tolerance and restoring its effectiveness as an analgesic.<sup>154</sup> The recommended intraoperative dose of ketamine for the opioid-tolerant patient is 0.5 mg/kg as a bolus dose at the beginning of the case, followed by 10 µg/kg/min as an infusion for the duration of the case.<sup>162</sup> Low-dose ketamine may be continued into the postoperative period for up to 48 hours without any serious complications.

The  $\alpha_2$ -adrenoreceptor agonists (e.g., dexmedetomidine and clonidine) have moderate analgesic effects and opioid-sparing effects in the opioid-naive patient. In the perioperative setting, they are sedating and anxiolytic and can decrease the stress response to surgery and postoperatively mitigate shivering, nausea and vomiting, and agitation. It is unclear at this time,

however, what role, if any, this drug class would have specifically in the perioperative management of the opioid-tolerant patient, but they may be particularly valuable in the treatment of the opioid-tolerant patient because they attenuate opioid withdrawal symptoms and can reduce postoperative opioid requirements and pain.<sup>158,163</sup>

Intravenous lidocaine has been gaining acceptance as a drug that may be useful in a multimodal approach to perioperative pain management, particularly in the patient receiving abdominal surgery or in the patient in whom regional anesthesia is contraindicated. Systemic lidocaine displays analgesic, anti-inflammatory, and anti-hyperalgesic properties, which are mediated by inhibition of voltage-dependent sodium channels, NMDA receptors, and G protein-coupled receptors (GPCRs). Indirect blockade of the NMDA receptor through inhibition of PKC potentially makes this a useful drug in the opioid-tolerant patient.<sup>164</sup>

*Like ketamine, intravenous magnesium is an NMDA receptor antagonist that can suppress neuropathic pain, potentiate morphine analgesia, attenuate morphine tolerance,<sup>57</sup> and has the ability to abolish the development of hyperalgesia and central sensitization,<sup>165</sup> which suggests that this drug would be particularly effective in the treatment of acute perioperative pain in the opioid-tolerant patient.<sup>166</sup> Because magnesium and ketamine bind to different sites on the NMDA receptor it has been posited that the combination of the two drugs may enhance analgesia through a “super-additive effect.”<sup>167</sup> Future studies should focus on the ideal dosing regimen that maximizes analgesia while decreasing drug-related side effects.*

*Postoperative management of the opioid-dependent patient can be very challenging. Ideally, the optimal amount of opioid has been administered to the patient during the intraoperative period, allowing them to emerge from anesthesia comfortably sedated and pain-free. On arrival to the recovery room, intravenous opioids may be administered on an “as-needed” basis; however, initiation of an intravenous PCA opioid with both a basal and an incremental (bolus) dose will minimize the risk of breakthrough pain. The recommended basal infusion should equate to the patient’s hourly preoperative oral opioid dose requirement as this will avoid precipitating withdrawal symptoms, and the bolus dose, as calculated from the background infusion, is the 1-hour dose of the background infusion. For example, a patient taking 90 mg of oral morphine per day equates to 30 mg of intravenous morphine per day, which can be administered as a basal morphine in fusion of 1.25 mg/hr. The bolus dose would be equivalent to 1.25 mg with a lockout interval of 6 to 10 minutes. Basal infusions are not required for patients who are maintained on their transdermal fentanyl patches as these provide adequate basal analgesia. Therefore, a fentanyl PCA with a bolus dose and an appropriate lockout interval is all that is required. Patients recovering from*

same-day surgery will be initially treated with intravenous doses of opioids in the recovery room; however, they can be quickly transitioned to an oral regimen consisting of their baseline opioid requirement plus an appropriate amount of short-acting opioid for breakthrough pain consistent with the invasiveness of the surgery.

Nonopioid coanalgesics are opioid-sparing and should be part and parcel of any multimodal perioperative pain management strategy in the opioid-dependent patient. Low-dose intravenous ketamine may be continued into the postoperative period; however, specific dosing recommendations are not available at this time. Please refer to the section on NMDA receptor antagonists for dosing guidelines. In a single case report, however, which involved an opioid-dependent trauma patient, ketamine was administered, postoperatively, at a starting dose of 10 µg/kg/min and then gradually tapered to 2.5 µg/kg/min over 45 minutes. This particular regimen provided significant pain control and was opioid sparing. The ketamine infusion was continued for 7 days without any adverse sequelae.<sup>168</sup>

The combination of both acetaminophen and a selective COX-2 inhibitor provides superior analgesia and is opioid-sparing. The administration of dexmedetomidine may also be particularly beneficial in the perioperative pain management of these patients. Likewise, the gabapentinoids, gabapentin, and pregabalin, display antihyperalgesic properties, have opioid-sparing effects in the opioid-naive patient, reduce OIH, and have been shown to reduce the incidence of postsurgical pain. The evidence suggests that it would be prudent to administer a gabapentinoid postoperatively for 10 to 14 days. Although both gabapentin and pregabalin are indicated, pregabalin is the preferred drug because of its superior pharmacokinetic profile. The recommended dosing regimen of pregabalin following TKA that reduces chronic pain is 300 mg 1 hour prior to surgery and for 14 days thereafter as a tapering regimen (150 to 50 mg twice daily).<sup>169</sup>

Regional anesthesia is highly recommended in this patient population. Peripheral nerve blockade as a single-injection technique or as a continuous catheter can be very useful. Likewise, if indicated, epidural analgesia should be part and parcel of the multimodal pain regimen for these patients. During the perioperative period, however, the epidural and systemic requirements for morphine have been reported to increase three to fourfold. Epidural infusions that have been recommended include a combination of fentanyl (2 to 5 µg/mL), morphine (0.1 to 0.2 mg/mL), or hydromorphone (0.02 to 0.04 mg/mL) combined with a local anesthetic such as bupivacaine (0.05% to 0.2%) or ropivacaine (0.1% to 0.2%). Switching to an opioid with high intrinsic efficacy may be useful. A combination of sufentanil (2 µg/mL) with 0.1% bupivacaine has been shown to be quite efficacious in an opioid-tolerant patient refractory to the analgesic effects of epidural morphine. The neuraxial

administration of opioid is usually a very small fraction of the patient's baseline opioid requirement. Notwithstanding the fact that patients obtain excellent analgesia from the epidural, opioid serum levels and supraspinal receptor binding may not be totally adequate at preventing opioid withdrawal symptoms. It may therefore be necessary for the patient to receive at least part of their baseline opioid dose either orally or intravenously (PCA) to prevent opioid withdrawal symptoms. A physician well versed in chronic pain management and comfortable in the equianalgesic dosing of opioids via different routes of administration should ideally be involved in the care of the patient. Careful monitoring of the patient for excessive sedation or respiratory depression is mandatory, and caregivers in the recovery room and on the postsurgical units should be alerted to the potential risk for respiratory depression when parenteral and neuraxial opioids are combined.

## **Organization of Perioperative Pain Management Services**

There is a growing recognition in the health-care industry that the undertreatment of pain is a widespread problem that cuts across all phases of patient care. The effective management of pain is a crucial component of good perioperative care and recovery from surgery. Unrelieved pain and inadequate pain relief have detrimental physiologic and psychological effects on patients by slowing recovery and creating burdens for patients and their families, and by increasing costs to the health-care system. Although the acute postoperative pain service plays an integral role in the pain management of the surgical patients, there are considerable barriers that challenge the establishment and/or effectiveness of acute pain teams in managing patients across the continuum of care. There is good evidence that the overall incidence of moderate-to-severe pain in surgical patients is about 25% to 40% despite the availability of pain treatment.<sup>170</sup> A major obstacle to the establishment of postoperative pain services is its cost in a privatized health system wherein limited reimbursement for postoperative care discourages the establishment of a service. The value of an acute pain service, apart from its benefit for patient care, also comes from the added value of reducing hospital costs by improving surgical outcome and by facilitating patient recovery and early discharge.<sup>171</sup> While providing direct patient care along previous lines such as the management of continuous epidural and regional catheter infusions and other modalities, the perioperative pain management service must also play a leading role in patient education and the education of other physicians, nurses, and caregivers to ensure their competence in effectively assessing, managing, and meeting a patient's needs. The success of a perioperative pain management team can be established not only in the context of the direct patient care that the team provides but also through its

role in educating other health-care professionals and services as physician leaders responsible for setting clinical standards and practice guidelines in the health-care system.

The key components to establishing a successful perioperative pain management service begins with an institutional commitment to support the service. The team must be built around a physician leader with training and experience in pain medicine. There must be other anesthesiologists available to support the service. The institution must support the service, which may be manifest through support of a nurse coordinator or the availability of a pharmacist to consult on the many pharmaceutical issues that arise in patients on preoperative medications that may conflict with the perioperative pain management plan. The perioperative pain management chief is responsible for the development and implementation of clinical pathways and protocols that effectively enhance recovery following surgery. These protocols must include pain assessment tools that are adopted across the continuum of care by all caregivers. 16

Although it is convenient to regard postoperative pain primarily as acute pain caused by tissue injury associated with surgery, this may exclude other important factors that contribute to a patient's suffering following surgery. Acute postsurgical pain can also be caused by prolonged patient positioning or pressure effects from prolonged immobility. Many patients presenting for elective surgery may also suffer chronic pain from underlying illness or injury (e.g., degenerative diseases or malignancy) that may contribute significantly to the intensity of the postoperative pain experienced by the patient. Postoperative pain remains a substantial problem that is often masked by a patient's acceptance of pain as a natural consequence of surgery. Other common patient barriers include cultural and language barriers, stoicism and/or opiophobia, and personal experience or the experiences of friends and relatives. For these reasons, postoperative pain management begins preoperatively with patient education to alleviate the attendant anxiety, apprehension, and fear of surgery, to understand the patient's fears and concerns, and to come to an agreement with the patient that pain control is an expected goal of care. Education is also the key to changing attitudes of other caregivers to more effectively treat their patient's pain. In developing a perioperative pain service it is important to bear in mind that the importance of effective perioperative pain management extends well beyond the mere establishment of dedicated personnel; it must also encompass a leadership role in transforming the institutional culture to elevate the relief of pain and suffering to its place as a primary goal of patient care.<sup>172</sup>

## **Special Considerations in the Perioperative Pain Management of Children**

Acute pain management in children undergoing surgery or invasive procedures offers several specific and unique challenges for the anesthesiologist. The challenges include the importance of support from the child's parents and siblings, preoperative fear and anxiety in the child, developmental and communication issues, difficulties in evaluating pain and the effectiveness of treatment, and the child's reaction to pain, surgery, and the environment, including crying and resistance to care. These problems all summate to emphasize the importance of a holistic approach to pain management that focuses on family-centered care wherein significant efforts are made to reduce preoperative stress and anxiety and to engage the parents in gaining the cooperation of the child.<sup>173</sup> There is also good evidence that the level of preoperative anxiety and stress adversely impacts postoperative pain and recovery from surgery. A number of methods can be used to reduce preoperative anxiety in children. They include preoperative parental education and counseling about the operative experience,<sup>174</sup> distraction techniques including videos and music, handheld video games, game-playing with the support of the family and/or child life specialists, and parental presence coupled with oral midazolam (0.5 mg/kg) administration to ease anxiety associated with the transition to the induction of anesthesia. As parental behavior and attitudes can be major determinants of a child's behavior during the inhalational induction of anesthesia, the anesthesiologist is obliged to counsel and inform parents as to the importance of modulating their fear and anxiety should they want to be present during anesthetic induction.

Effective pain management in the postoperative period depends on effective assessment and the precision of the evaluation tools used to measure pain intensity.<sup>175</sup> A child's responses to pain may be variable and unpredictable because of their age and development, verbal communication skills, fear and anxiety, withdrawal, prior experiences, parental presence or absence, and the parent's reactions to the care.<sup>176</sup> A comprehensive approach to assessment that employs multiple assessment tools including behavioral responses offers the best option for success. The use of visual analogue "faces" pain scales referenced to the appropriate cultural identity of the patient can be useful in assessing postoperative pain severity. There is some question as to the value of parental or practitioner evaluation of a child's pain intensity relative to the visual analogue scale, but parents can play a key role in the assessment and management of their child's pain in the postoperative period, particularly when their child is reluctant to communicate or suffers from a cognitive disorder.<sup>177</sup>

## ***Nonparenteral Analgesics***

## Nonopioid Analgesics

The use of nonopioid analgesics administered orally or by rectal suppository are important adjuvant analgesic therapies under a wide variety of circumstances. The release of intravenous acetaminophen (Ofirmev) in November 2011 has progressively replaced nonparenteral administration of acetaminophen in pediatric perioperative practice. See [Table 55-13](#) for dosing guidelines in children. Intravenous acetaminophen can be used across a wide spectrum of surgical procedures and may be sufficient for outpatient procedures. Nonparenteral administration of acetaminophen either by oral administration (10 to 20 mg/kg) or by rectal suppository (20 to 40 mg/kg) after induction of anesthesia remains an acceptable alternative to parenteral administration. Although the short-term use of the NSAIDs (e.g., ibuprofen and ketorolac) are equipotent with acetaminophen and can be used with safety, the overall convenience and fewer side effects of acetaminophen have favored its use in children. Oral clonidine (4 µg/kg) given as a preoperative medication has also been used with good effect for sedation and postoperative pain management in children undergoing adenotonsillectomy. The greater degree of postoperative sedation with clonidine relative to other analgesics may limit its universal acceptance.

## Opioid Analgesics

Codeine in combination with acetaminophen is commonly used with good effect for the management of moderate postoperative pain in the ambulatory patient.<sup>178</sup> Unfortunately, deaths have occurred post-operatively in children with obstructive sleep apnea who received codeine for pain control following tonsillectomy or adenoidectomy. Codeine is metabolized to morphine by the hepatic enzyme, CYP2D6, and ultra-rapid metabolizers of codeine appear to be at increased risk for unanticipated respiratory depression secondary to potentially fatal amounts of morphine in the body. Consequently, the FDA (Food and Drug Administration), has advised against the use of codeine in children and infants until additional clinical research can be performed to develop safer alternatives. The atypical opioid tramadol (3 mg/kg) has also been used as an oral preparation, usually in combination with midazolam (0.5 mg/kg) prior to the induction of anesthesia in children undergoing adenotonsillectomy. Oral tramadol can also be used for postoperative analgesia in children undergoing oral or dental procedures.<sup>179</sup> Intranasal sufentanil (0.2 µg/k) can also be used to manage preoperative anxiety and postoperative analgesia in children and may be more effective than oral tramadol.<sup>179</sup>

## *Patient-controlled Analgesia*

PCA is established as an important postoperative pain management tool in adults and is increasingly used in older children to good effect.<sup>180,181</sup> There are safety concerns with the use of PCA in children that mandate a high level of surveillance with respect to the functioning of the equipment and careful patient monitoring that may be a limitation to its use in infants. PCA by proxy is a safety risk as there is no complete assurance that parents will be competent in assessing the intensity of their child's pain or be able to regulate the bolus dosages in order to avoid opioid overdose.<sup>182</sup>

## *Epidural Neuraxial Analgesia*

The use of epidural neuraxial analgesia either as a single-shot technique or as a continuous catheter technique has become a key component of the perioperative pain management plan for infants and young children undergoing abdominal, urologic, or orthopedic procedures.<sup>183</sup> The use of a single-shot “kiddy” caudal using a local anesthetic with morphine is effective in relieving pain associated with minor procedures in the outpatient setting. Although the overall morbidity is low, there is serious risk associated with epidural analgesia in children related to the systemic toxicity of the local anesthetic and the need to place the epidural under general anesthesia. The risk of irreversible cardiac toxicity, although primarily associated with the use of bupivacaine, can also occur with the ropivacaine and levobupivacaine at an incidence of about 30% to 50% relative to bupivacaine. The risks are increased in children with hepatic dysfunction or when large volumes of local anesthetic are injected into the epidural space through a small, sharp, immobile needle. In the rare event that cardiac toxicity occurs, the anesthesiologist must be prepared to initiate chest compressions and lung ventilation to minimize the risk of anoxic injury and immediately start an intravenous bolus infusion of 20% intralipid (1 to 2 mL/kg) followed by a continuous infusion (0.25 to 0.5 mL/kg/min) until normal cardiac rhythm and the circulation is restored.<sup>184</sup> Although the use of lipid emulsions can be successful in reversing cardiac arrest, their immediate availability does not excuse the anesthesiologist from taking all precautions to prevent systemic injection or absorption when performing the procedure.

## *Peripheral Nerve Blocks in Children*

The introduction of small stimulating needles and ultrasound imaging along with long-acting local anesthetics and continuous catheter techniques in selected cases has resulted in an increase in the use of peripheral nerve blocks

in children undergoing orthopedic extremity procedures.<sup>185</sup> The use of stimulating needles permits the anesthesiologist to place the injection after the child is anesthetized.<sup>186</sup> Because the child is unresponsive, it is important that the initial injection meets no resistance in order to avoid intraneural injection. Combined ilioinguinal and iliohypogastric nerve blocks performed under ultrasound guidance to reduce the volume of the injection have gained increasing interest for effective pain management in children undergoing inguinal herniorrhaphy.<sup>187</sup>

## Conclusion

In October 2000, the U.S. Congress designated the decade beginning January 1, 2001, as the Decade of Pain Control and Research. The onus is on dedicated health-care professionals to provide our patients with the best care possible when it comes to pain and suffering, which applies directly to the perioperative state. Accomplishing this requires integration of information and systems from disparate disciplines within medicine. It challenges physicians to acquire a patient-focused perspective that provides the patient with a pleasant perioperative experience and enhanced recovery following surgery. In doing so, clinicians will be challenged to construct systems within hospitals to support such endeavors but will be able to show objective and meaningful outcomes with positive benefits to patients and to health-care organizations. The cost of ignoring pain and suffering has been widely cited to be in the billions of dollars each, but the cost in suffering is immeasurable. Anesthesiology has led the way in improving the overall pain care of the surgical patient and is positioned to lead medicine into a new era in which perioperative pain management is better, safer, more assured, and consistently available at the highest levels to all.

# 56 Chronic Pain Management

HONORIO T. BENZON • ROBERT W. HURLEY • SALIM M. HAYEK

## **Anatomy, Physiology, and Neurochemistry of Somatosensory Pain Processing**

Primary Afferents and Peripheral Stimulation

Neurochemistry of Peripheral Nerve and the Dorsal Root Ganglion

Neurobiology of the Spinal Cord and Spinal Trigeminal Nucleus

Neurobiology of Ascending Pathways

Neurobiology of Descending Pathways

Neurobiology of Supraspinal Structures Involved in Higher Cortical Processing

Transition from Acute to Persistent or Chronic Nociception

## **Management of Common Pain Syndromes**

Low Back Pain: Radicular Pain Syndromes

Low Back Pain: Facet Syndrome

Buttock Pain: Sacroiliac Joint Syndrome and Piriformis Syndrome

Myofascial Pain Syndrome and Fibromyalgia

## **Neuropathic Pain Syndromes**

Herpes Zoster and Postherpetic Neuralgia

Diabetic Painful Neuropathy

Complex Regional Pain Syndrome

Human Immunodeficiency Virus Neuropathy

Phantom Pain

## **Cancer Pain**

Neurolytic Blocks for Visceral Pain from Cancer

## **Pharmacologic Management of Pain**

Opioids

Pharmacologic Treatments of Neuropathic Pain

## **Interventional Techniques**

Discography

Thermal Annular Procedures

Minimally Invasive Lumbar Decompression Procedure

Vertebroplasty and Kyphoplasty

Spinal Cord Stimulation

Peripheral Nerve Stimulation

Dorsal Root Ganglion Stimulation

## Occipital Nerve Stimulation Intrathecal Drug Delivery

### Summary

#### KEY POINTS

- 1 A delta and C fibers, under normal conditions, transmit nociceptive (pain) information to the spinal cord from their free nerve endings in the periphery. In chronic pain conditions, the A beta fibers, which normally transmit nonnoxious information, also participate in nociceptive transmission.
- 2 Most randomized studies on the efficacy of epidural steroid injections show temporary relief of radicular pain. Studies on thermal rhizotomy of the medial branches, for relief of facet syndrome, show benefit that lasts 3 to 12 months. This relief avoids the usage of addicting opioids.
- 3 Injection of epidural local anesthetics and methylprednisolone, when performed three to four times during the acute stage of herpes zoster, may prevent the development of postherpetic neuralgia. Postherpetic neuralgia is mostly managed pharmacologically, although interventional techniques may be used in resistant cases.
- 4 Antidepressants and anticonvulsants are effective for treatment of neuropathic pain syndromes. Use of antidepressants is limited because of their side effects. Anticonvulsants have a more favorable side-effect profile and speed of therapeutic effect, which makes them the first line of treatment for these syndromes. Their efficacy is improved when combined with an opioid or an antidepressant.
- 5 Complex regional pain syndrome that does not respond to nerve blocks, physical therapy, and/or pharmacologic management may respond to spinal cord stimulation.
- 6 Opioids are the mainstay for cancer pain management and are effective in neuropathic pain, although at higher doses.
- 7 The majority of pain secondary to cancer is effectively managed pharmacologically with opioids, anticonvulsants, and antidepressants. Neurolysis of the visceral sympathetic system for pain secondary to abdominal or pelvic cancer relieves pain, decreases opioid consumption, and improves the patients' quality of life.
- 8 Vertebroplasty and kyphoplasty are indicated for vertebral compression fractures, although some studies question their efficacy.
- 9 Spinal cord stimulation is effective in patients with failed back syndrome and complex regional pain syndrome and may be effective in angina and critical limb ischemia.
- 10 Intrathecal drug delivery (IDD) systems are valuable options in cancer

pain patients in whom opioids are ineffective at high doses or cause unacceptable side effects; however, noncancer pain patients seem to do best if they are on no- or low-doses of opioids prior to initiation of IDD.

## Anatomy, Physiology, and Neurochemistry of Somatosensory Pain Processing

### *Primary Afferents and Peripheral Stimulation*

A variety of mechanical, thermal, electrical, or chemical stimuli can result in the sensation and perception of pain. Information about these painful or noxious stimuli is transmitted to higher brain centers by receptors and neurons that are often distinct from those that carry innocuous somatic sensory information. The mammalian somatosensory system is subserved by four groups of afferent fibers differentiated by their anatomy, rate of transmission, and sensory modality transduced (Table 56-1).

The heavily myelinated large-diameter A beta ( $A\beta$ ) fibers have specialized encapsulated nerve endings, which transduce innocuous or low-threshold mechanical stimulation. The activation of  $A\beta$  fibers has been invoked as a part of the mechanism for the production of pain relief by transcutaneous electrical nerve stimulators.<sup>1</sup> As well, it is becoming increasingly apparent that in chronic pain states, these fibers may indeed participate in pain signaling by adopting a “phenotype” similar to that of a C fiber (*vide infra*).<sup>2</sup>

**1** The next groups of fibers represent the specialized sensory neurons that respond to actual or potential tissue damage, the *nociceptors*. The lightly myelinated medium-diameter A delta ( $A\delta$ ) fibers and the unmyelinated small-diameter C fibers have free nerve endings that transduce noxious or high-threshold thermal, mechanical, and chemical stimulation. Patients with a mutation of the tyrosine kinase protein A, which is a component of the nerve growth factor receptor, fail to develop  $A\beta$ ,  $A\delta$ , or C fibers and have no ability to sense pain.<sup>3</sup> Unlike receptors in the  $A\beta$  fibers, the  $A\delta$  and C fibers respond to stimulation of their receptive fields in a characteristic manner with slow adaptation and residual firing following the withdrawal of the stimulus. Although these two fiber groups respond similarly to stimulation, they mediate different aspects of pain sensation. The rapidly conducting  $A\delta$  fibers mediate the “first” pain or *epicritic pain*, which is well localized and is characterized as sharp or prickling. The slowly conducting C fibers mediate the “second” pain or *protopathic pain*, which temporally follows the epicritic pain and is poorly localized or diffuse and is characterized as burning or dull.<sup>4</sup>

The majority of  $A\delta$  and C nociceptors are polymodal and therefore are responsible for the transduction of noxious stimuli of different modalities.

Nociceptive nerve endings are also located in muscle, the fascia, and adventitia of blood vessels, the knee joint, the dura, and the viscera. The primary afferent peripheral (distal) terminals express a variety of specific transducer channels that are sensitive over a range of stimulus intensities. When they are activated by the appropriate stimulus (thermal, chemical, or mechanical) these channels activate voltage-sensitive cation channels (NaV and CaV) and initiate an action potential. The sodium channel is of special interest following the discovery of its involvement in patients who are insensitive to pain. An epidemiologic study identified three Pakistani families with congenital insensitivity to pain. All were found to possess nonsense mutations of the *SCN9A* gene, resulting in truncation of the Nav1.7 isoform of the sodium channel.<sup>5</sup> Other mutations of this gene result in the impaired inactivation of this channel, which causes paroxysmal extreme pain disorder or hyperexcitability resulting in erythromelalgia.<sup>6,7</sup>

The understanding of the molecular underpinning of the sensory processing of pain has primarily come from studying the transient receptor potential (TRP) channels. The cloning and characterization of the “capsaicin” receptor of the TRP family of nonselective cation channels expanded the field immensely.<sup>8</sup> Members of this molecular family transduce thermal, mechanical, and chemical information in the periphery. The capsaicin receptor named *TRP vanilloid 1* (TRPV1), which responds to capsaicin and other vanilloid compounds and is also activated by acid and heat, provides an excellent example of the integration of multiple sensory modalities within a single neuron and is localized to nociceptors.<sup>8</sup> Furthermore, acidic environments can lower the activation threshold of the channel to heat stimuli. Therefore, the TRPV1 receptor may represent an important therapeutic target in inflammatory (acidic) pain conditions. Mice lacking the TRPV1 receptor are deficient in their response to thermal but not mechanical or other noxious stimuli.<sup>9</sup> These data suggest that this member of the family of TRP channels may play a role in the integration of noxious chemical and thermal stimuli while having relatively less to do with mechanical transduction.

**Table 56-1** Primary Afferent Fibers and Their Function

Modality	Receptor	Fiber Type	Conduction Velocity and Diameter	Rate of Adaptation	Function
Proprioceptive	Golgi and Ruffini endings, muscle spindle afferents	A $\alpha$	70–120 m/s 15–20 $\mu$ m	Slow and rapid	Muscle tension, length, and velocity
Mechanosensitive	Meissner, Ruffini, Pacinian corpuscles, and Merkel disc	A $\beta$	40–70 m/s 5–15 $\mu$ m	Rapid (slow—Merkel)	Touch, flutter, motion, pressure, vibration
Thermoreceptive	Free nerve endings	A $\delta$	10–35 m/s 1–5 $\mu$ m	Slow	Innocuous cold
	Free nerve endings	C	0.5–1 m/s <1 $\mu$ m	Slow	Innocuous warmth
Nociceptive	Free nerve endings	A $\delta$	10–35 m/s 1–5 $\mu$ m	Slow	Sharp pain
	Free nerve endings	C	0.5–1 m/s <1 $\mu$ m	Slow	Burning pain

### Neurochemistry of Peripheral Nerve and the Dorsal Root Ganglion

The nociceptive primary afferents, the A $\delta$  and C fibers, represent the principal target of pharmacologic manipulation by the physician treating pain. Glutamate receptors, as well as opioid, substance P, somatostatin, and vanilloid receptors, have been identified on the peripheral endings of these nerve fibers. Although the transmission of acute nociceptive information is primarily by the A $\delta$  and C fibers, a subset of the A $\delta$  and C fibers are “thermoreceptors” that transduce innocuous cold and warm information, respectively. The cell bodies of primary afferents, regardless of the structure they innervate, make up the *dorsal root ganglia* (DRG) located just outside the spinal cord within the bony foramen.

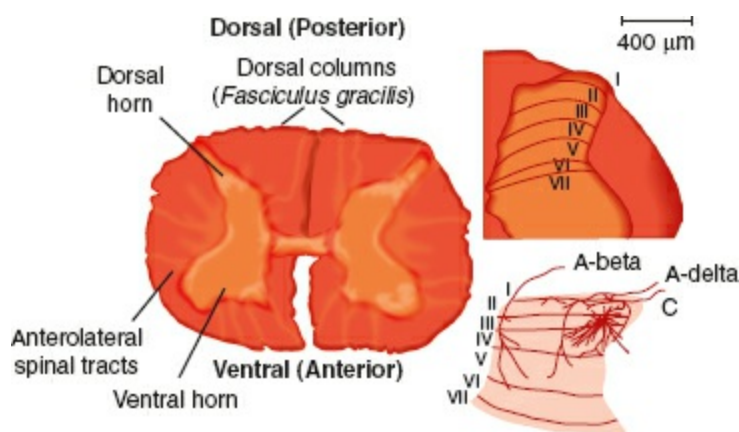

Primary afferent activation results in a postsynaptic excitatory event in the spinal cord. Glutamate is the primary neurotransmitter serving this function. Acute activation events are mediated by the  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptor present on the dorsal horn neurons. This receptor produces a robust but short-lasting depolarization of the postsynaptic membrane by increasing sodium conductance and augmenting the activation of the *N*-methyl-D-aspartate (NMDA)-type glutamate receptor. In addition to glutamate, populations of primary afferents contain and release a variety of neuropeptides, including substance P, calcitonin gene-related peptide, adenosine triphosphate, adenosine, galanin, and somatostatin and growth factors, including brain-derived nerve growth factor.<sup>10</sup>

### Neurobiology of the Spinal Cord and Spinal Trigeminal Nucleus

Primary afferent fibers enter the gray matter of the spinal cord through the *dorsal root entry zone* and innervate the spinal cord. The majority of heavily

myelinated primary afferent fibers ( $A\alpha$ ,  $A\beta$ ) carrying sensory information, including tactile, pressure, and vibratory sense, enter in dorsal roots, traverse across the top of the dorsal horn of the spinal cord (Lissauer tract), and ascend ipsilaterally within the dorsal column and provide collateral branches into the gray matter of the dorsal horn. The small-diameter, lightly myelinated and unmyelinated fibers transmitting temperature and nociceptive information enter Lissauer tract and innervate the gray matter of the spinal cord. Unlike the heavily myelinated fibers, these fibers may also ascend rostrally or descend caudally through Lissauer tract before they innervate adjacent spinal levels.

The gray matter of the spinal cord is made up of synaptic terminations of primary afferents and the second-order neurons that form the first stage of processing and integration of sensory information. The gray matter of the spinal cord is divided into 10 laminae on the basis of histologic appearance. The dorsal horn includes laminae I to VI and represents the primary sensory complement of the spinal cord (Fig. 56-1). The ventral horn, including laminae VII to IX and lamina X, is involved in somatic motor and autonomic functions, respectively. *Somatic* C-fiber nociceptive afferent endings primarily terminate in the laminae I and II of the same and/or one to two adjacent spinal segments from which they entered from the periphery, whereas *visceral* C-fiber nociceptive afferents can terminate in the dorsal horn more than five segments rostrally or caudally. They terminate in the ipsilateral laminae I, II, V, X, and also in contralateral laminae V and X. Therefore, visceral afferents have a wider branching pattern and the nociceptive information they transmit is less localizable to a particular area of the body.

**Figure 56-1** Histologic sections and schematic diagrams of the spinal dorsal horn. The histologic section at left is from the lumbar segment of the spinal cord. It is labeled to show the relationship between the major spinal somatosensory structures. The histologic section at right is from the rat lumbar spinal cord. The *outer heavy lines* show the boundary of the spinal gray matter and the *inner heavy lines* show the boundaries of Rexed laminae. These boundaries are established by the histologic characteristics of each zone, and the layers are identified by the Roman numerals. The drawing at the

bottom illustrates the pattern of primary afferent innervation to the nonhuman primate spinal dorsal horn. The large myelinated (A-beta) fibers segregate to the dorsal aspect of an entering root and then track medially in the dorsal horn and terminate in layers III to V. The small myelinated (A-delta) fibers and C fibers that carry nociceptive information segregate ventrally in the entering roots, course laterally in the dorsal horn, and then largely terminate in the superficial layers (I and II) of the dorsal horn. (Adapted with permission from Raja SN, Dougherty PM. Anatomy and physiology of somatosensory and pain processing. In: Benzon HT, Raja SN, Molloy RE, et al., eds. *Essentials of Pain Medicine and Regional Anesthesia*. 2nd ed. Philadelphia, PA: Elsevier-Churchill Livingstone;2005:3.)

In addition to the primary afferent endings, neurons of the descending pathways and local interneurons also innervate the superficial dorsal horn (laminae I and II). The outer marginal layer or lamina I contain interneurons and cells that send axonal projections to the brainstem and midbrain structures. The substantia gelatinosa, or lamina II, also contains excitatory and inhibitory interneurons but fewer projection neurons. Laminae III and IV contain interneurons and the second-order neurons that make up the dorsal column pathways relaying nonnociceptive sensory and proprioceptive information. Laminae IV to VI contain interneurons and a modest portion of nociceptive projection neurons that distribute input to the brainstem and thalamus.

Nociceptive somatic input is primarily transmitted by second-order lamina I, IV, and V projection neurons as the contralateral spinothalamic tract (STT) pathway traveling to numerous brainstem regions and the thalamus.<sup>11</sup> There is a nociceptive visceral processing area in laminae III, IV, V, VII, and X. The visceral nociceptive input is relayed by second-order neurons whose axons travel within the dorsal column. Like the fibers transmitting nonnoxious sensory information, these fibers remain uncrossed until relayed with the crossed medial lemniscal fibers to the thalamus. The visceral pain information transmitted by the ventral STT is likely originating from cells also receiving somatic nociceptive input. Nociceptive and nonnociceptive sensory information from the head, neck, and dura transmitted via the trigeminal nerve innervates the dorsal horn of the spinal trigeminal nucleus in the caudal medulla. The organization and neurotransmitter complement of the spinal trigeminal nucleus is similar to that of the spinal dorsal horn.

## ***Neurobiology of Ascending Pathways***

### **Dorsal Column Tracts**

The dorsal column contains the axons of second-order spinal cord projection

neurons in addition to the ascending axons of primary afferent neurons relaying touch, pressure, and vibratory sensation. Second-order dorsal column cells in the central visceral processing region of the spinal cord around lamina X also respond to noxious visceral stimulation and converge on some of the thalamic cells receiving nociceptive information from the skin and other somatic structures.

## **Spinothalamic Tract**

Spinothalamic tract (STT) neurons are the primary relay cells providing nociceptive input from the spinal cord to supraspinal levels. The axons of STT cells cross the midline of the spinal cord through the anterior white commissure and ascend primarily in the contralateral and anterolateral tracts. The axons of STT cells terminate primarily in the posterior complex of the thalamus, including the ventral posterior lateral and ventral posterior medial nuclei. Nonnoxious sensory input from the same body region converges on the same target thalamic neurons providing somatotopic encoding for localization of the input onto the cortical representation of the specific body region, allowing the ability to locate the source of the nociceptive input. The STT cells receiving noxious somatic input are predominantly situated in lamina I and the lateral aspect of the dorsal horn in laminae IV to V.<sup>11</sup> However, other STT neurons are scattered throughout the deep dorsal horn, intermediate region, including lamina X, and even in lamina VII of the ventral horn. These STT cells receive both somatic and visceral nociceptive information.

## **Spinohypothalamic, Limbic, and Cortical Connections**

Pain is a sensory experience but also has an affective component to the perception of noxious stimuli. Pain can provoke fear, anxiety, and depression, resulting in autonomic responses, including increased heart rate and blood pressure as well as the endocrine stress response. These responses to noxious stimuli are mediated by the spinohypothalamic and spinoamygdalar pathways. In addition to their affective function, these regions are also thought to be involved in antinociception. Ascending axonal projections of these pathways arise predominantly from the spinal cord laminae I and X.

## ***Neurobiology of Descending Pathways***

The primary components of this descending pain inhibition system, but certainly not all-inclusive, is the “triad” of the periaqueductal gray (PAG), the rostral ventral medulla (RVM), and the dorsolateral pontine tegmentum (DLPT).<sup>12</sup> The PAG is an important site for the production of antinociception

following electrical or chemical activation, or the injection of opioid receptor agonists. The endogenous opioid enkephalin is present within this nucleus, and opioid receptors of each subtype are present in this region. The PAG provides dense projections to the RVM, the locus coeruleus, and A7 nuclei.<sup>13</sup> Although the RVM can function as a relay nucleus in the production of antinociception by more cephalad midbrain structures, including the PAG, it also has a primary role in the suppression of nociceptive transmission at the level of the spinal cord. The suppression of nociceptive reflex behavior is mediated by the axons of RVM neurons that descend within the dorsolateral funiculus and terminate bilaterally in laminae I, II, V, VI, and VII of the spinal cord. Anatomic studies have shown that these axons terminate coincident with interneurons of the dorsal horn that are related to nociceptive transmission.<sup>14</sup> Consistent with the anatomic terminations of the RVM axons, physiologic studies have shown that stimulation of the RVM results in the inhibition of a population of nociceptive-specific neurons within the dorsal horn as well as selective inhibition of the nociceptive responses of wide-dynamic range neurons.<sup>15</sup> The DLPT is also an important component of spinal cord nociceptive modulation. It contains all of the noradrenergic neurons that project to the RVM and the spinal cord, and electrical stimulation of the DLPT sites produces spinal cord  $\alpha_2$ -adrenergic receptor-mediated analgesia.<sup>16</sup>

### ***Neurobiology of Supraspinal Structures Involved in Higher Cortical Processing***

Higher cortical centers play a role in the perception of painful stimuli as well as the integration of the sensory-discriminative and affective components of the noxious stimulation. The localization of the neural structures involved in this perception and integration is still in its adolescence. The development of positron emission tomography and functional magnetic resonance imaging technologies has moved this research forward. These imaging technologies produce indirect evidence of neural activity related to pain stimulation. The primary and secondary somatosensory cortexes, the anterior cingulate gyrus, the insula, and the prefrontal cortex appear to be involved in the higher processing of somatic and visceral pain.<sup>17</sup> As the primary and secondary cortexes are known to be somatosensory processing regions, the imaging studies are consistent with a sensory-discriminative role of these structures. The insula and frontal cortex may contribute to memory and learning of events related to painful stimuli. The anterior cingulate cortex is thought to be involved in the analysis of the emotional significance of the painful input.

### ***Transition from Acute to Persistent or Chronic Nociception***

Pain sensation is unique among the somatosensory modalities in that it does not rapidly adapt to prolonged stimulation as do the other sensory modalities, such as fine touch. In fact, continued stimulation may produce greater noxious sensation or reduce the stimulus threshold or intensity that is necessary for the appreciation of the sensation as noxious. For instance, previously innocuous thermal or mechanical stimulation (e.g., warm water of a shower or the light touch of a towel) may be perceived as painful following a prior noxious stimulus (e.g., sunburn). This is termed *allodynia*. Another example of an altered pain state that may follow an acute injury is that of *hyperalgesia*, in which a previously noxious stimulus is perceived as more painful. The sensation of increased intensity of noxious stimulation at the site of the injury is the result of the sensitization of the peripheral nociceptors.

Persistent C fiber, but not A $\beta$  fiber, the primary afferent activation of lamina I and lamina V (as occurs with tissue injury and inflammation), has been shown to enhance the response to subsequent stimulation and augment the size of the receptive field of the respective dorsal horn neuron. Therefore, afferent input from adjacent dermatomal areas now produces neuronal excitation. Furthermore, nonnoxious stimulation becomes increasingly able to activate these neurons. This general phenomenon has come to be termed *wind-up* or *central sensitization*.<sup>18</sup> This activation is thought to explain the allodynia and hyperalgesia observed surrounding the site of injury.

In addition to the alteration of the chemical milieu surrounding the primary afferent distal terminal that results from injury or persistent high-intensity stimulation, axonal sprouting and the formation of neuroma may occur. The neuroma may have an altered complement of ion channels, including an upregulation of sodium channels or a downregulation of potassium channels, which has the net result of increasing neuronal excitability and increasing nociceptive transmission. It has been shown that, following nerve damage, an increase in the expression of sodium channels occurs in the neuroma and the DRG. Numerous sodium channels exist on primary afferents; Nav1.8 and 1.9 subtypes are primarily found on C-fiber DRG cells. Genetic “knock-down” or removal of the Nav1.8 channel had no effect on baseline pain thresholds; however, it reversed nerve injury–evoked nociception.<sup>19</sup> Also following nerve damage, potassium currents have been shown to be reduced, suggesting a reduction in these channels contributing to spontaneous nociceptive activity. Consistent with this notion, it has been observed that potassium channel antagonists increase and potassium channel agonists decrease ectopic firing after peripheral nerve injury.<sup>20</sup>

Neuromas of injured primary afferents have altered sensitivity to a number of humoral factors, including cytokines, prostaglandins, and catecholamines. These factors are released from a variety of cell types, including inflammatory cells and neuronal support cells. Cytokines directly

activate the nerve and neuroma through receptors that become expressed in the membrane after the nerve injury. A molecule that has been shown to have a prominent role following nerve damage is tumor necrosis factor subunit *alpha* (TNF- $\alpha$ ).<sup>21</sup> Shortly after injury, TNF- $\alpha$  decreases potassium conductance, increasing neuronal excitability, whereas the long-term changes may be produced through the activation of second messenger systems, resulting in altered protein production. Application of TNF- $\alpha$  to the peripheral nerve results in hyperalgesia and systemic delivery of antibodies to TNF- $\alpha$  or TNF- $\alpha$ -binding protein reduces neuropathic pain.

Prostaglandins are also released from inflammatory cells following nerve and tissue damage. They can enhance the opening of Nav1.8 channels by acting through receptors on the afferent terminal.

Although acute noxious stimuli are transmitted to the spinal cord via A $\delta$  and C fibers, the presence of allodynia is thought to be mediated by the activation of large-diameter A $\beta$  fibers through what has been termed a *phenotypic* switch.<sup>2</sup> Prior to this peripheral injury, the A $\beta$  fibers, unlike the C fibers, do not express substance P. However, following injury these fibers were able to express this neuropeptide.<sup>22</sup> These data therefore implicate A $\beta$  fibers in the transmission of noxious peripheral stimulation and provide further support for the involvement of somatic A $\beta$  fibers in at least some form of the allodynic pain states. Furthermore, the blockade of A $\beta$  fibers results in a reduction in light-touch-evoked allodynia.<sup>23</sup> This phenotypic switch of A $\beta$  fibers may represent another avenue for therapeutic intervention; however, the difficulty will be in differentiating between those A $\beta$  fibers involved in noxious versus nonnoxious sensory information.

## Management of Common Pain Syndromes

### *Low Back Pain: Radicular Pain Syndromes*

The common causes of low back pain include radicular pain/radiculopathy from herniated disc or spinal/foraminal stenosis, facet syndrome, and internal disc disruption. Myofascial pain syndrome also causes back pain, whereas sacroiliac joint syndrome and piriformis syndrome cause mostly buttock pain but can present as low back pain or radicular pain. Radicular symptoms of pain, paresthesias, and numbness in a typical dermatomal distribution in the presence of objective signs of weakness, diminished reflexes, and positive straight-leg raise are secondary to pathology or dysfunction of the sensory spinal nerve roots. Low back pain, with or without radicular pain, is mostly due to lesions of the intervertebral discs and degenerative spinal disorders. Other causes include spinal metastasis, vertebral body fractures, infections, abdominal aortic aneurysm, and chronic pancreatic lesions.

Low back and radicular pain secondary to a herniated disc is due to mechanical nerve root compression and the subsequent inflammatory process. The presence of a herniated disc does not necessarily result in pain. Up to 36% of the general population <sup>24</sup> and up to 53% of pregnant women<sup>25</sup> can have an asymptomatic herniated disc. Follow-up studies on patients with a herniated disc show spontaneous regression without treatment, absence of symptoms in the presence of more abnormalities, and partial or complete resolution with treatment that includes medications, bed rest, physical therapy, traction, or epidural steroids.<sup>26</sup> If symptomatic, the patient usually presents with low back pain and radicular symptoms that include paresthesias as well as numbness and weakness in the distribution of the involved nerve root. Gait disturbances, loss of sensation, reduced muscle strength, and diminished reflexes involve the appropriate affected dermatomal distribution.

Inflammation in the spinal canal secondary to a herniated disc plays an important role in the causation of back and radicular pain. Herniated nucleus pulposus results in local release of cytokines and other inflammatory mediators that cause a chemical radiculitis. High levels of phospholipase A<sub>2</sub> activity were noted in human disc fragments removed at surgery from patients with symptomatic radiculopathy. Increased levels of the inflammatory cytokines interleukin-6 and interleukin-8 were noted from disc material taken from patients with known disc disease.<sup>27</sup> The application of disc material onto spinal nerve roots can induce functional and morphologic changes in the nerves. Disc cells express TNF- $\alpha$ , which, when applied to spinal nerve roots, causes changes similar to those seen after application of disc material; selective inhibition of TNF- $\alpha$  may reduce the intraneural edema.<sup>28</sup> A double-blind, placebo-controlled study showed that an intradiscal injection of 1.5 mg of etanercept, a TNF- $\alpha$  inhibitor, in a pain-generating disc did not reduce the pain scores or disability scores of patients with chronic discogenic pain or lumbosacral radiculopathy.<sup>29</sup> The use of the potent disease-modifying antirheumatic drugs, either intravenously or epidurally, in patients with low back pain is in its infancy. A review of the literature on the subject showed some studies to be of low quality, results that were inconclusive, or efficacies that were short-term.<sup>30</sup>

For patients with radicular symptoms who do not respond to conservative management, epidural steroid injections (ESIs) may be useful. Epidural **2** steroids have an anti-inflammatory effect related to inhibition of phospholipase A<sub>2</sub> activity. In addition, steroids have an antinociceptive effect. The local application of methylprednisolone blocks transmission of C fibers but not the A $\beta$  fibers. Several prospective randomized controlled studies have demonstrated short-term efficacy of ESIs for treatment of lumbar spine radiculopathy whereas others have not.<sup>31,32</sup> Another study demonstrated less leg pain and sensory deficit with ESI, but the incidence of surgery was the

same between the steroid and the control groups.<sup>33</sup> For cervical ESIs, the few studies that have been done are mostly descriptive and their results were the same as in lumbar ESIs, that is, transient relief from the injections. The transient efficacy, that is, no more than 3 months, has to be viewed against the natural history of patients with herniated disc and spinal stenosis as these patients seem to do well over time with conservative management. The transient relief provided by ESIs may minimize the need for opioids and potent anti-inflammatory medications and their related side effects.<sup>34</sup> ESIs should be a component, but not the sole modality, of the conservative management of radicular pain.

A transforaminal approach can be employed to deposit steroid in the anterolateral epidural space, where the herniated disc is located, through the intervertebral foramina, and distally along the nerve root (Fig. 56-2). This approach is especially indicated in radicular pain specific to a single nerve root. Prospective randomized studies on transforaminal ESIs show the same results as with the interlaminar approach, that is, short-term efficacy of the injection.<sup>35,36</sup> The transforaminal approach has a better rationale than the midline interlaminar approach, and studies that compared the two approaches show better efficacy with the transforaminal approach.<sup>37,38</sup>

It is advisable that fluoroscopy be used in ESI, especially with the transforaminal approach, to assure insertion of the needle at the affected vertebral level and document the flow of the contrast medium (and the drug). Reassessment should be carried out 2 to 3 weeks after the initial injection. The use of multiple ESIs in a patient, with a short interval between injections, is not advised. If there is no response to an initial injection, it can be repeated once because some patients require a second injection before they respond. If there is partial response, up to three injections can be performed.

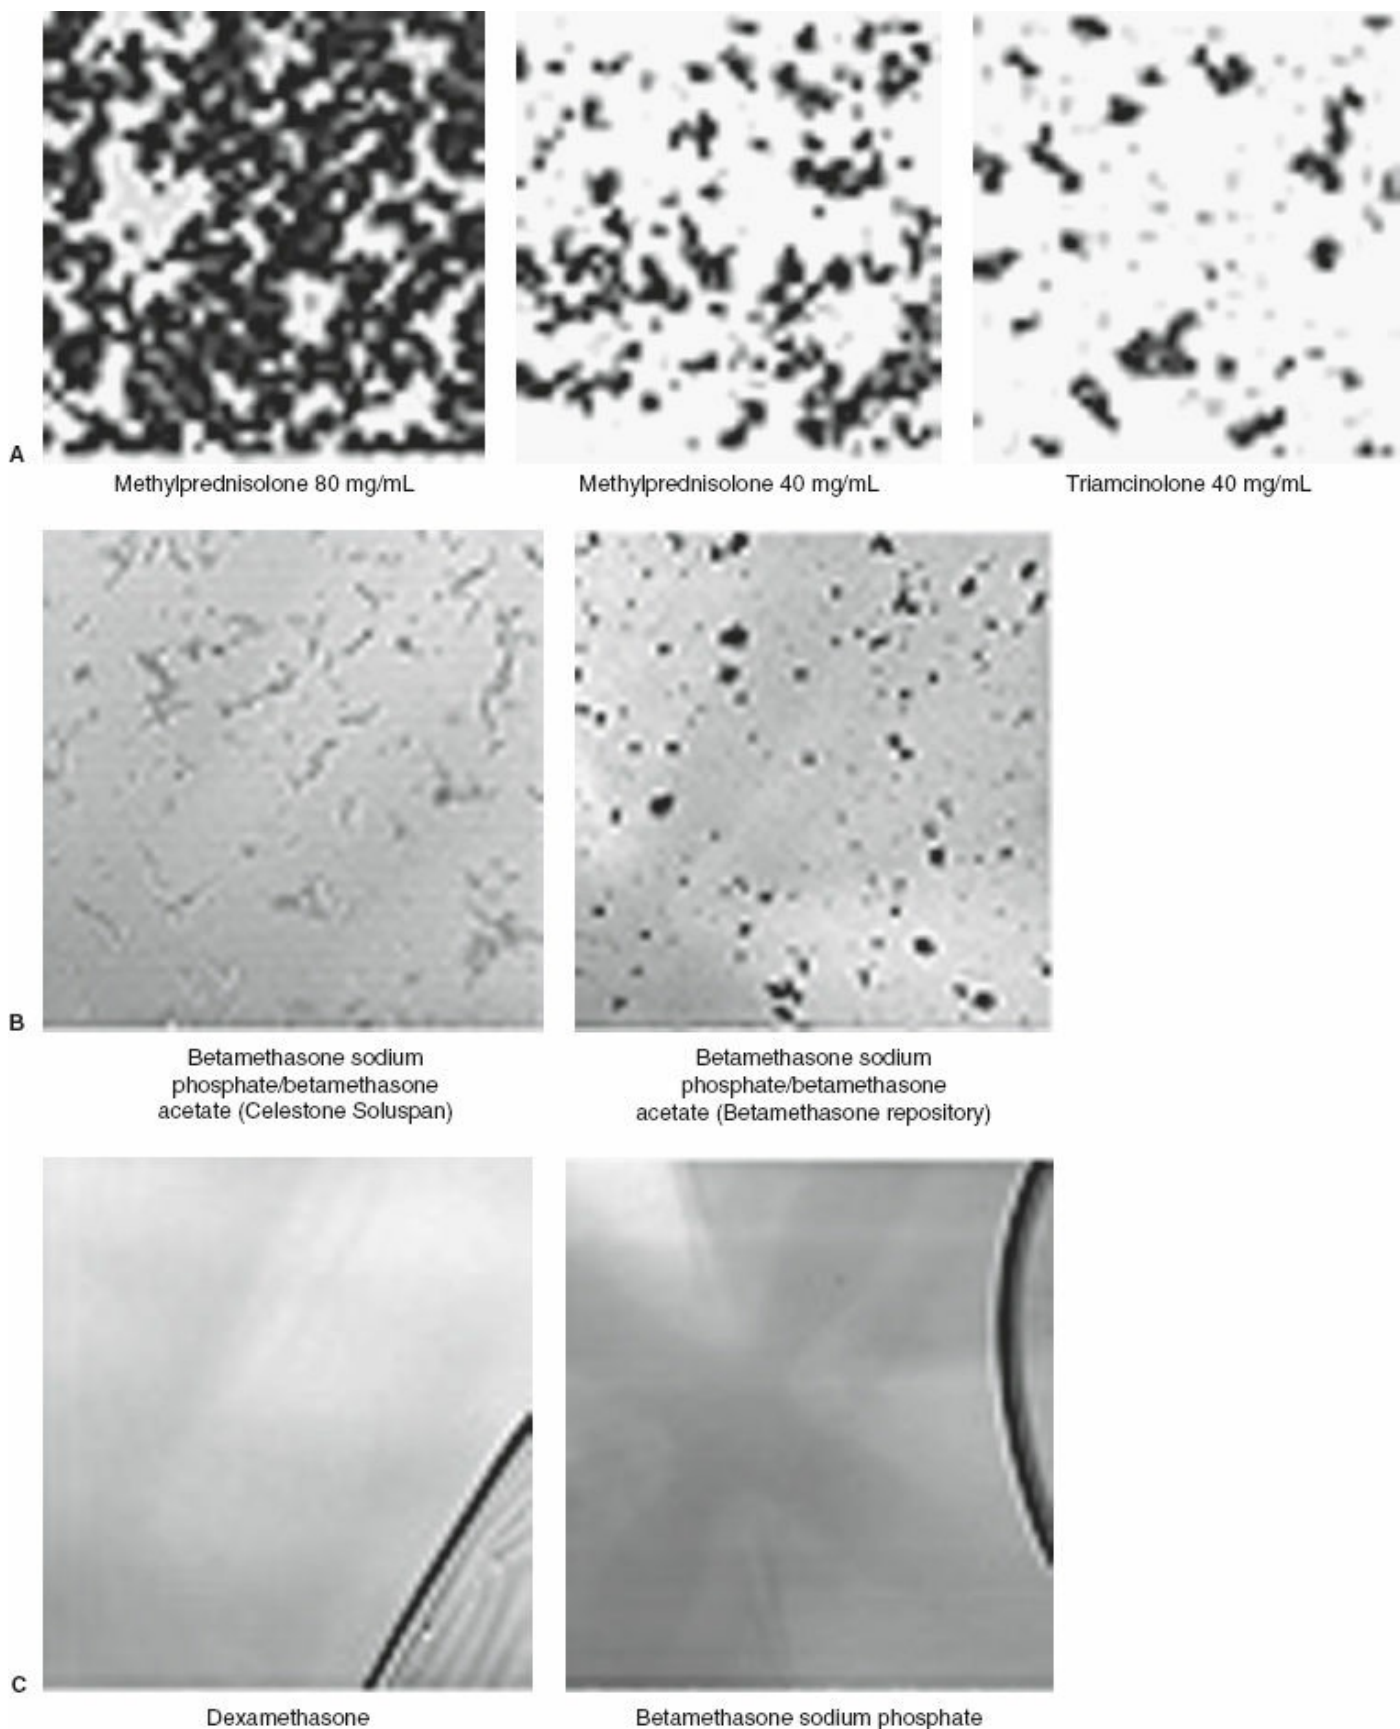

The complications of ESI may be due to the technique or from the injected drug, as well as the vehicle and additives. Complications related to the technique include needle trauma, vasospasm, and infection. Glucocorticoids reduce the hypoglycemic effect of insulin and interfere with blood glucose control in patients with diabetes mellitus. Insulin sensitivity may be impaired, there may be no change in the glycated hemoglobin (HbA<sub>1c</sub>) levels, or the blood glucose can be increased for 1 week after ESIs. A single dose of 80 mg of methylprednisolone can suppress plasma cortisol levels and the ability to secrete cortisol in response to synthetic corticotropin for up to 3 weeks. Epidural triamcinolone, 80 mg, can suppress serum cortisol and corticotropin levels for up to 7 days after injection. The median recovery to normal levels occurs within 1 month after the last injection, and full recovery is at 3 months.<sup>39</sup>

Injury to the brain or spinal cord can occur with transforaminal ESIs.<sup>40</sup> The cerebral/cerebellar events can be ascribed to trauma to the vertebral artery,

vasospasm from the injected steroid or dye, or embolism of the particulate steroid via the vertebral artery.<sup>41,42</sup> The spinal cord injuries can be ascribed to injury to the radicular artery accompanying the nerve root, spasm of the radicular artery from the injected dye or steroid, or embolism of the particulate steroid. The occurrence of adverse events at the lumbar level has been ascribed to intra-arterial injection into an abnormally low-lying artery of Adamkiewicz. These adverse events have also been described after injection of local anesthetic or dye, without steroid.<sup>42</sup> Huntoon<sup>43</sup> noted that the vertebral, ascending cervical, and deep cervical arteries supply segmental medullary vessels and that the ascending and deep cervical arteries are within 2 mm of the site of insertion of the needle for cervical transforaminal ESIs. The proximity of these arteries to the site of needle placement makes these blood vessels vulnerable to trauma or unintentional sites of injection of the steroid. Occlusion of the vessels occurs from the particulate steroids. Methylprednisolone acetate has the largest particle size, betamethasone the smallest particles, and triamcinolone acetonide is in between (Fig. 56-3).<sup>42</sup> Dexamethasone has no identifiable particles. Dexamethasone appears to be ideal for transforaminal ESIs; however, it is easily washed out from the epidural space, and preliminary studies showed its efficacy to be of shorter duration than particulate steroids. Recent studies showed the efficacy of the nonparticulate dexamethasone to be the same as the particulate steroids.<sup>44,45</sup>

**Figure 56-2** Right L5 transforaminal epidural injection. Note the spread of the contrast medium proximally into the lateral epidural space and distally along the nerve root.

**Figure 56-3 A:** Typical microscopic appearances of methylprednisolone, 80 mg/mL and 40 mg/mL, and triamcinolone 40 mg/mL. The particles are amorphous in appearance. **B:** The particles of commercial betamethasone (Celestone Soluspan) are rodlike and lucent, whereas those of the compounded betamethasone (betamethasone repository) are amorphous. **C:** Note that dexamethasone is pure liquid. (Adapted with permission from Benzon HT, Chew TL, McCarthy R, et al. Comparison of the particle sizes of the

different steroids and the effect of dilution: a review of the relative neurotoxicities of the steroids. *Anesthesiology*. 2007;106:331.)

A multispecialty working group, together with several national organizations, has made recommendations to improve the safety of ESIs.<sup>46</sup> These include the following:

1. Interlaminar ESIs should be performed using image guidance with appropriate anteroposterior, lateral, or contralateral oblique views, and contrast media.
2. Cervical interlaminar ESI should be performed at C6-C7 or C7-T1 but not higher.
3. Transforaminal ESIs should be performed by injecting contrast medium under real-time fluoroscopy and/or digital subtraction imaging, using an AP view, before injection.
4. Particulate steroids should not be used in therapeutic cervical transforaminal (TF) ESIs.
5. Nonparticulate steroid (dexamethasone) should be used in initial TF ESIs.
6. There are situations where a particulate steroid can be used in lumbar TF ESIs.<sup>46</sup>

ESIs are more effective in patients with acute radicular symptoms; they are not effective in patients with chronic lumbar radiculopathy.<sup>47</sup> The efficacy of ESIs in spinal stenosis has not been established. It has been shown not to be better than an epidural local anesthetic.<sup>48</sup> However, local anesthetic may not be the appropriate control intervention because it also relieves back pain.<sup>49</sup> To have a long-term effect in spinal stenosis, ESIs should be part of a multidisciplinary approach.

Gabapentin appears to be effective in treating lumbosacral radicular pain.<sup>50</sup> However, ESIs resulted in greater reductions in worst leg pain and the patients experienced a positive outcome compared to gabapentin. Duloxetine was noted to be superior to placebo in treating the neuropathic component of chronic low back pain.<sup>51</sup>

### **Low Back Pain: Facet Syndrome**

Patients with low back pain secondary to facet pathology have pain in the low back that radiates to the ipsilateral posterior thigh and usually ends at the knee. On physical examination there is paraspinal tenderness and reproduction of pain with extension–rotation maneuvers of the back. The diagnosis of facet syndrome is arrived at by a combination of the patient's history, physical examination findings, and a positive response to diagnostic medial branch blocks or facet joint injections (Fig. 56-4). For medial branch

blocks, some investigators recommend the use of local anesthetics with different durations of effect (e.g., lidocaine and bupivacaine) and to correlate the duration of relief with the known duration of effect of the drug.

Some patients may have a prolonged response to facet joint injections, that is, up to 3 to 6 months. If the patient has a prolonged response, it is best to wait for recurrence of the pain. If the relief is short-lived, especially after medial branch blocks, then thermal radiofrequency (RF) rhizotomy of the medial branches should be performed. It appears that there is no relationship between the mean sensory stimulation threshold (which denotes proximity of the electrode to the nerve) during lumbar facet rhizotomy denervation and treatment outcome.<sup>52</sup> Randomized controlled studies have shown improvements after thermal RF of the lumbar medial branches that lasted 3 to 12 months.<sup>53–55</sup> For cervical facet syndrome, a systematic review of eight publications showed that a majority of the patients were pain free at 6 months and over one-third were pain-free at 1 year.<sup>56</sup> Regarding the overall effectiveness of RF for facet syndrome, a Cochrane review of 12 studies noted moderate evidence supporting facet joint RF compared to placebo over the short term and low quality evidence supporting the efficacy of RF over steroid injections.<sup>57</sup> A best evidence synthesis publication concluded there was level 2 evidence for effectiveness of lumbar and cervical RF neurotomy.<sup>58</sup>

### ***Buttock Pain: Sacroiliac Joint Syndrome and Piriformis Syndrome***

The pain of sacroiliac joint syndrome is located in the region of the affected sacroiliac joint and the medial buttock. The pain may radiate to the groin, posterior thigh, and occasionally below the knee. Physical examination usually reveals tenderness over the sacroiliac sulcus, reduction in the joint mobility, and reproduction of the pain when the affected sacroiliac joint is stressed. The most commonly used tests for sacroiliac joint dysfunction include the FABER (flexion, abduction and external rotation), or Patrick, test, and the Gaenslen, Yeoman, sacroiliac shear, and Gillet tests. The FABER (Patrick) and the Yeoman test do not rule out hip pathology, whereas the Yeoman and the shear tests are more specific for sacroiliac joint syndrome. The presence of symptoms and physical examination findings suggestive of sacroiliac (SI) joint syndrome, pain on three of the provocative tests, and a positive response to SI joint injection are adequate to make the diagnosis of SI joint syndrome.

**Figure 56-4** Left L4 to L5 facet joint injection. The injection of 5 mL of contrast medium demonstrates the extent of the joint capsule.

**Figure 56-5** Sacroiliac joint injection. Note the spread of the contrast medium along the joint. (Adapted with permission from Benzon HT, Nader A. Hip, sacroiliac joint, and piriformis injections. In: Benzon HT, Rathmell J, Wu C, et al., eds. *Raj's Practical Management of Pain*. 4th ed. Philadelphia, PA: Mosby Elsevier;2008:1070.)

The treatments for SI joint syndrome include physical therapy, manipulation, intra-articular steroid injections (Fig. 56-5), RF denervation, and surgical fusion of the joint. Physical therapy and chiropractic manipulations are used extensively for the treatment of SI joint disease; however, there is no large outcome study validating their use. Intra-articular

injections of steroid (40 to 80 mg of methylprednisolone or other depot steroid) and local anesthetic into the SI joint may result in a few months of pain relief, but again, no prospective controlled studies support their use.

Denervation of the lower portion of the SI joint may be achieved by the creation of bipolar RF strip lesions along the dorsal border of the SI joint in a leapfrog manner. It has been demonstrated that the use of a multilesion probe (Simplicity III, NeuroTherm) along the posterior sacral plate lateral to the foraminas can be effective for at least 6 months in approximately 50% of patients.<sup>59</sup> Local anesthetic blockade of the sensory innervation of the dorsal portion of the SI joint—the medial branch of the dorsal rami of L5 and the lateral branches of the dorsal rami of S1 to S3—can be performed when the relief from the SI joint injection is temporary. Relief from the local anesthetic block may last weeks to months when combined with physical therapy. Thermal RF lesioning of the lateral branches is performed for a more lasting relief. The bigger lesions created by the water-cooled RF technique (Fig. 56-6)<sup>60</sup> are inherently more effective because it accommodates for the variations in the location of the lateral branches along the lateral border of the sacral foraminas.

## Piriformis Syndrome

Piriformis syndrome, another pain syndrome that originates in the buttocks, comprises 5% to 6% of patients referred for the treatment of back and leg pain. It occurs after trauma, surgery, and infection, or from compression of one of the components of the sciatic nerve as it runs between two divisions of the piriformis muscle.<sup>61</sup> Patients with piriformis syndrome complain of buttock pain with or without radiation to the ipsilateral leg. The buttock pain usually extends from the sacrum to the greater trochanter of the femur, whereas irritation of the sciatic nerve results in a buttock pain that radiates to the ipsilateral leg. Prolonged sitting, as in driving or biking, or getting up from a sitting position aggravates the pain. The pain is aggravated by hip flexion, adduction, and internal rotation. Neurologic examination is usually negative. There may be leg numbness when the sciatic nerve is irritated; the straight-leg test may be normal or limited. Three signs confirm the presence of piriformis syndrome<sup>61</sup>: (1) The *Pace sign*, wherein there is pain and weakness on resisted abduction of the hip in a patient who is seated with the hip flexed; (2) the *Lasègue sign*, wherein there is pain on flexion, adduction, and internal rotation of the hip in a patient who is supine (note that some clinicians also call pain on straight-leg raise the Lasègue sign); and (3) the *Freiberg sign*, wherein there is pain on forced internal rotation of the extended thigh. Note that the piriformis is an internal rotator of the flexed hip and an external rotator of the extended hip. The diagnosis of piriformis syndrome is

made on clinical grounds. Electromyography may detect myopathic and neuropathic changes, including a delay in the H-reflex, with the affected leg in a flexed, adducted, and internally rotated (FAIR) position as compared with the same H-reflex in the normal anatomic position.

**Figure 56-6** Target points (A) and expected lesions (B) from water-cooled radiofrequency denervation at the right L5 medial branch and the S1, S2, and S3 lateral branches. (Adapted with permission from Cohen SP, Hurley RW, Buckenmaier CC 3rd, et al. Randomized placebo-controlled study evaluating lateral branch radiofrequency denervation for sacroiliac joint pain. *Anesthesiology*. 2008;109:279–88.)

The treatments of piriformis syndrome include physical therapy combined with medications such as muscle relaxants, anti-inflammatory drugs, and analgesics to reduce the spasm, inflammation, and pain. Local anesthetic and steroid injections into the piriformis muscle may break the pain/muscle spasm cycle. Techniques involving identification of the piriformis muscle include the use of CT guidance, use of a nerve stimulator, or combined fluoroscopy–nerve stimulator guidance. A randomized study noted similar efficacy of the fluoroscopy- and ultrasound-guided piriformis injections.<sup>62</sup> There appears to be no difference between lidocaine and lidocaine with betamethasone.<sup>63</sup> If relief from the local anesthetic does not last, then the piriformis muscle is injected with 100 units of botulinum toxin A in 2 to 3 mL of local anesthetic.<sup>64,65</sup>

### **Myofascial Pain Syndrome and Fibromyalgia**

Myofascial pain syndrome is a painful regional syndrome characterized by the presence of an active trigger point in a skeletal muscle. The trigger point can be felt as a palpable taut band and manipulation of the trigger point by digital pressure or by penetration by a needle may induce a twitch response. There is spot tenderness in the taut band; pressure on the tender nodule induces pain that the patient recognizes as an experienced pain pattern, and there may be limitation to full passive range of motion of the affected muscle.

The management of myofascial pain syndrome includes repeated applications of a cold spray over the trigger point in line with the involved muscle fibers, followed by gentle massage of the trigger point and stretching of the affected muscle. Physical therapy includes improving posture, body mechanics, relaxation techniques, trigger point massage, postisometric relaxation, and reciprocal inhibition. A part of a multimodal treatment is local anesthetic injection or dry needling of the trigger point. Recent studies show that dry needling may be as effective as local anesthetic injection; however, the local anesthetic makes the procedure less painful. Several injections at 2- to 3-week intervals, followed by physical therapy, may result in a long-term benefit. Botulinum toxin injections have been recommended but the results of clinical studies have not been uniform. In a study using an enriched protocol design (two groups randomized into botulinum toxin and placebo groups after the patients responded to an initial botulinum toxin injection), better pain scores and a reduced number of headaches were observed in the patients injected with botulinum toxin.<sup>66</sup>

## Fibromyalgia

The American College of Rheumatology criteria for classification of fibromyalgia,<sup>67</sup> established in 1990, requires two components: a history of widespread pain for at least 3 months and allodynia to digital pressure at 11 or more of 18 anatomically defined tender points. The tender points are located in the occiput, the intertransverse spaces between C5 and C7, trapezii, supraspinatus, the second rib (just lateral to the costochondral junctions), lateral epicondyles, glutei, greater trochanters, and knees. In 2010, a new diagnostic paradigm was proposed that included a clinician-administered tool for widespread pain index (WPI) and the symptom severity (SS) scale of key characteristic signs and symptoms.<sup>68</sup>

There is a strong genetic and familial component to the development of fibromyalgia. Also, family members of fibromyalgia patients are more likely to have irritable bowel syndrome, temporomandibular disorders, headaches, and a host of other regional pain syndromes. They have higher concentrations of substance P and glutamate in cerebral spinal fluid (CSF) compared with

normal controls.<sup>69</sup>

Opioidergic activity is normal or increased in fibromyalgia, and levels of cerebrospinal fluid enkephalins are roughly twice as high in these patients compared to healthy controls.<sup>70</sup> The increased activity of endogenous opioidergic systems explains clinicians' observations that opioids are ineffective in this syndrome. On the other hand, the principal metabolite of norepinephrine, 3-methoxy-4-hydroxyphenethylene glycol (MPHG) is lower in the CSF of patients with fibromyalgia. This may explain the efficacy of drugs that raise levels of both serotonin and norepinephrine (tricyclic antidepressants [TCAs], duloxetine, milnacipran, tramadol).

The optimal treatment of fibromyalgia supports a multifaceted program comprising pharmacologic and nonpharmacologic therapy.<sup>71</sup> Efficacious medications for treatment of fibromyalgia include two serotonin and norepinephrine receptor inhibitors (SNRIs) (duloxetine and milnacipran),<sup>72,73</sup> pregabalin, amitriptyline, gabapentin, and gamma-hydroxybutyrate (sodium oxybate).<sup>74,75</sup> Effective nondrug treatment includes patient education, supportive therapy, exercise programs (specifically low-intensity low-impact programs), and cognitive-behavioral and operant-behavioral therapy.

## Neuropathic Pain Syndromes

### *Herpes Zoster and Postherpetic Neuralgia*

Some patients with acute herpes zoster have a prodrome of dermatomal pain before the skin eruptions. The pain of acute herpes zoster is usually moderate in severity and can be managed with analgesics, and the pain usually subsides with healing of the rash. About 10% to 15% of patients develop postherpetic neuralgia (PHN), or pain that persists more than 3 months after resolution of the rash; the incidence rises from 30% to 50% in the elderly. The risk factors for the development of PHN include increased pain during the acute stage, greater severity of the skin lesion, older age, and the presence of a prodrome. The use of antiviral drugs (acyclovir, famciclovir, or valacyclovir) has been shown to hasten the healing of the rash, reduce the duration of viral shedding, and decrease the increase of PHN.

Most of the studies on the efficacy of neuraxial and peripheral nerve blocks, performed during the acute stage of herpes zoster, have been either retrospective or case series. However, more reliable prospective randomized controlled studies provide conflicting results. A study in which epidural methylprednisolone and bupivacaine was compared with acyclovir and prednisolone showed the epidural steroid group to have less pain (1.6% vs. 22%) and less allodynia (4% vs. 12%) at 1 year.<sup>76</sup> Another study in which standard therapy with oral antiviral medications and analgesics was compared

with standard therapy and epidural methylprednisolone and bupivacaine noted less pain in the epidural group (48% vs. 58%) at 1 month but not at 3 months (21% vs. 28%).<sup>77</sup> The better results in this study may be related to the greater number of epidural injections (two to four vs. one). To be effective in preventing PHN, the blocks are preferably done within 2 weeks of the onset of rash.

The mainstay of treatment for PHN is pharmacologic management that includes anticonvulsants, opioids, and antidepressants. Although the antidepressants have been found to be effective, their use is precluded by the frequent occurrence of side effects. The side effects include anticholinergic effects such as tachycardia, dry mouth, constipation, and symptoms of prostatism in elderly males. Nortriptyline is preferred over amitriptyline because it is equally effective and better tolerated. Additional efficacious drugs include opioids and tramadol.<sup>78,79</sup> The anticonvulsants gabapentin and pregabalin are usually effective in the management of PHN.<sup>80,81</sup> The side effects of the drugs include somnolence, dizziness, and peripheral edema. Two studies showed that the combination of gabapentin and controlled-release morphine, and gabapentin and nortriptyline, were more effective and required lower daily dosages than when either drug was given alone.<sup>82,83</sup>

Based on efficacy, antidepressants are the first choice for neuropathic pain syndromes, followed by opioids, tramadol, and gabapentin/pregabalin. When quality of life, side effects, prevention of addiction, and regulatory issues are considered important in addition to pain relief, then gabapentin/pregabalin may be the first drugs of choice. For the allodynia that accompanies PHN, a lidocaine patch is recommended. Capsaicin 8% topical patch can be used for localized pain.

Interventional techniques may be performed if medications do not control the pain of PHN. Intrathecal methylprednisolone, 60 mg in lidocaine, given once a week for four times, has been observed by some to be more effective in relieving PHN compared with intrathecal lidocaine or no treatment.<sup>84</sup> However, a study that tried to confirm the efficacy of intrathecal steroid had to be stopped because of lack of efficacy.<sup>85</sup> Based on possible risks and the lack of studies confirming its efficacy, a group of experts failed to arrive at a conclusive recommendation regarding the efficacy of intrathecal steroid for PHN.<sup>86</sup> Other interventional techniques for PHN are intrathecal alcohol and spinal cord stimulation (SCS).<sup>87</sup> When a spinal cord stimulator was placed in 28 patients with intractable PHN for 2 years, long-term pain relief was achieved in 23 patients and the median pain score decreased from 9 to 1.<sup>88</sup>

### **Diabetic Painful Neuropathy**

Peripheral neuropathy may be present in approximately 65% of patients with

insulin-dependent diabetes, most commonly distal symmetric polyneuropathy, followed by median nerve mononeuropathy at the wrist, and visceral autonomic neuropathy. The incidence of diabetic neuropathy increases with duration of diabetes, age, and degree of hyperglycemia; neuropathies generally develop after persistence of hyperglycemia for several years. The pathophysiology of diabetic neuropathy includes the polyol pathway, microvascular, and glycosylation end-product theories. All pathways result in chronic ischemia of the nerve.

The management of diabetic painful neuropathy (DPN) includes tight control of the patient's blood glucose and pharmacologic therapy. The anticonvulsants gabapentin and pregabalin appear to be effective in the management of DPN, with the efficacy of gabapentin enhanced by the addition of controlled-release morphine or nortriptyline.<sup>82,83</sup> The TCAs are also effective in DPN whereas the selective serotonin reuptake inhibitors are not as effective. The antidepressant duloxetine appears to be effective<sup>89</sup> and, together with its favorable side effect profile compared with the tricyclics, is now widely used in treatment of DPN. The European Federation of Neurological Sciences Task Force and the International Association for the Study of Pain (IASP) Neuropathic Pain Special Interest group (NeuPSIG) now recommend the serotonin–norepinephrine reuptake inhibitors (duloxetine, milnacipran) as the first-choice drugs for the treatment of DPN.<sup>90,91</sup> Finally, the opioids and tramadol are also effective in the treatment of DPN.

## Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) consists of two types. *CRPS type I* was originally termed *reflex sympathetic dystrophy*, whereas *CRPS type II* represents *causalgia*. The risk factors for the development of CRPS include previous trauma, nerve injury (for causalgia), previous surgery, work-related injuries, and female sex. The signs and symptoms of CRPS include spontaneous pain, hyperalgesia, allodynia, plus trophic, sudomotor, vasomotor abnormalities, and, finally, active and passive movement disorders. The clinical features of CRPS type II are the same as in CRPS type I except there is a preceding nerve injury in CRPS II. The IASP proposed diagnostic criteria for CRPS but because the criteria had a high diagnostic sensitivity with a low specificity, it resulted in overdiagnosis. The Budapest criteria, with high sensitivity and improved specificity, have supplanted the IASP criteria.<sup>92</sup>

Treatments for CRPS include sympathetic nerve blocks, physical therapy, and medications. Oral therapy includes gabapentin, memantine (an NMDA blocker), and alendronate.<sup>93</sup> Intravenous infusions include ketamine and bisphosphonates.<sup>94</sup> Ketamine can be given either as a 4- to 5-day infusion at 1

to 7 µg/kg/min (5 to 30 mg/hr in a 70-kg patient) or for 4 hours daily for 10 days at an infusion rate of 0.35 mg/kg/hr (24 mg/hr in a 70-kg person).<sup>95,96</sup> If ketamine infusion is employed, serial determinations of liver enzymes should be serially determined.<sup>97</sup> Intramuscular or subcutaneous calcitonin can also be used.<sup>98</sup> SCS should be considered if the patient does not respond to any of these treatments.<sup>99,100</sup>

5

## *Human Immunodeficiency Virus Neuropathy*

Symptomatic neuropathy occurs in 10% to 35% of patients who are seropositive for human immunodeficiency virus (HIV), and pathologic abnormalities exist in almost all patients with end-stage AIDS. The sensory neuropathies associated with HIV include distal sensory polyneuropathy, the more common neuropathy related to the viral infection, and antiretroviral toxic neuropathy (ATN) secondary to the treatment. The clinical features of HIV sensory neuropathy typically include painful allodynia and hyperalgesia. The onset is gradual and most commonly involves the lower extremities. The neuropathy and dysesthesia progress from the distal to the more proximal structures. There is minimal subjective or objective motor involvement and this is generally limited to the intrinsic muscles of the foot.

The treatment of HIV sensory neuropathy is symptomatic and includes optimization of the patient's metabolic and nutritional status. Cessation or dose reduction of treatment with nucleoside reverse transcriptase inhibitors may improve the symptoms of ATN. The anticonvulsants, particularly lamotrigine (300 mg/day), can be effective therapy for HIV sensory neuropathy as well as ATN.<sup>101</sup> Gabapentin is also effective at doses of 1,200 to 3,600 mg/day.<sup>102</sup>

## *Phantom Pain*

Nearly all patients with amputated extremities experience nonpainful sensations in the absent, phantom limb. As many as 60% of them experience pain. The onset of pain may be immediate but commonly occurs within the first few days following amputation. Approximately 50% of patients experience a decrease of their pain with time, whereas the other 50% report no change or an increase in pain over time. Phantom pain is caused by both peripheral and central factors. Peripheral mechanisms include neuromas, an increase in C-fiber activity, and sodium channel activation. Central mechanisms include abnormal firing of spinal internuncial neurons and supraspinal involvement secondary to the development of new synaptic connections in the cerebral cortex.

Numerous prophylactic measures have, with variable success, been

undertaken in an attempt to reduce the incidence of phantom limb pain. These include perioperative epidural infusions of opioids and local anesthetics or clonidine, and continuous brachial plexus blockade with memantine. The treatment of phantom limb pain includes pharmacologic and nonpharmacologic measures. A systematic review noted level 2 evidence for the effectiveness of gabapentin, morphine, tramadol, intramuscular botulinum toxin, and epidural ketamine.<sup>103</sup> Nonpharmacologic measures include transcutaneous electrical nerve stimulation, spinal cord stimulators, and biofeedback. A combination of pharmacologic treatment with physical, psychological, or behavioral intervention is probably the most effective approach.

## Cancer Pain

Significant pain is present in up to 25% of patients with cancer who are in active treatment and in up to 90% of patients with advanced cancer. The pain of cancer can be somatic, visceral, or neuropathic. Somatic pain tends to be responsive to opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), or cyclooxygenase 2 inhibitors, and is also amenable to treatment with neural blockade. Visceral pain responds to sympathetic nerve blocks, and neuropathic pain is responsive to anticonvulsants, opioids, TCAs, serotonin–norepinephrine reuptake inhibitors, or combinations of these drugs.

Management of cancer pain should be multifaceted and include the following: (1) appropriate tumor-specific antineoplastic therapy, (2) pain medications, (3) interventional management, (4) behavioral and psychological management, and ultimately (5) hospice care. Pharmacologic therapies include opioids, antidepressants, anticonvulsants, NSAIDs, corticosteroids, oral local anesthetics, and topical analgesics. Opioids are the mainstay of treatment for cancer pain as approximately 75% to 95% of patients are responsive positively when appropriate guidelines are followed.

6 Continuous intravenous opioid infusions can be performed during the later stages of the disease. Interventional treatments include neurolytic sympathetic nerve blocks and intrathecal opioids. Vertebroplasty or kyphoplasty may be required for vertebral compression syndromes.

### *Neurolytic Blocks for Visceral Pain from Cancer*

#### **Celiac Plexus Block**

The celiac plexus innervates all of the abdominal viscera except the left side of the colon and the pelvic viscera. The plexus contains two large ganglia that receive sympathetic fibers from the greater, lesser, and least splanchnic

nerves. It also receives parasympathetic fibers from the vagus nerve. The splanchnic nerves are located retroperitoneally at the level of the T12 and L1 vertebrae, and the celiac plexus is anterior to the crura of the diaphragm and surrounds the abdominal aorta and the celiac and superior mesenteric arteries.

Blockade of the celiac plexus can be achieved by the classic retrocrural approach, an anterocrural approach, or by neurolysis of the splanchnic nerves.<sup>104</sup> For the fluoroscopy-guided procedure, the tip of the needle is directed toward the body of L1 (Fig. 56-7). In the retrocrural approach, the tip of the needle is advanced approximately 1 cm anterior to the anterior and upper border of L1. In the anterocrural or transaortic approach, the tip of the needle is advanced through the lower portion of L1 and the aorta on the left side until blood can no longer be aspirated through the needle. For splanchnic nerve block, the tip of the needle is placed at the anterior portion of the T12 vertebral body. There appears to be no differences in efficacy between the three approaches.<sup>104</sup> Some clinicians perform an initial diagnostic block with a local anesthetic whereas others proceed immediately to a neurolytic block because the results of the diagnostic and neurolytic blocks may not be the same. Better results are usually seen with local anesthetics because of better spread (phenol is viscous and its vascular absorption may relieve pain). Fifty percent alcohol or 6% to 10% phenol is employed for the neurolytic block. The dosages of the neurolytic agents are 30 to 40 mL for the retrocrural and anterocrural approach, and 10 to 15 mL on each side for splanchnic nerve blockade. Complications from the celiac plexus block include orthostatic hypotension, back pain, retroperitoneal hematoma, reactive pleurisy, hiccups, hematuria, transient diarrhea, abdominal aortic dissection, transient motor paralysis, and paraplegia. The paraplegia and transient motor paralysis may be due to spasm of the lumbar segmental arteries that perfuse the spinal cord, direct vascular or neurologic injury, or retrograde spread to the nerve roots or spinal cord.

**Figure 56-7** Retrocrural versus anterocrural approaches to neurolysis of the celiac plexus. Note that the tip of the needle is in the upper third of L1 and about 1 cm beyond the border of the vertebral body for the retrocrural technique; the spread of the contrast medium is cephalad. In contrast, the tip of the needle is the lower third of L1 and about 3 cm beyond the border of the vertebral body for the anterocrural technique; the spread of the contrast medium is caudad and in front of the aorta. (Adapted with permission from de Leon-Casasola OA. Neurolysis of the sympathetic axis for cancer pain management. In: Benzon HT, Rathmell J, Wu C, et al., eds. *Raj's Practical Management of Pain*. 4th ed. Philadelphia, PA: Mosby Elsevier;2008;918.)

The efficacy of celiac plexus neurolysis in relieving pain from cancer of the upper abdomen has been substantiated in randomized controlled trials.<sup>105,106</sup> **7** The end points of the studies were lower pain scores, less opioid consumption with a lower incidence of side effects, and equal or better quality of life. A meta-analysis of 21 retrospective studies in 1,145 patients concluded that adequate-to-excellent pain relief was achieved in 89% of the patients during the first 2 weeks following the block and partial-to-complete pain relief continued in 90% of the patients at the 3-month interval.<sup>107</sup> Using the GRADE (grading of recommendations assessment, development, and evaluation) level of evidence, a European collaborative group gave a strong recommendation for the use of celiac plexus block for treatment of pancreatic cancer pain.<sup>108</sup>

### **Superior Hypogastric Plexus Block**

Superior hypogastric plexus block is indicated for pelvic pain secondary to cancer and chronic nonmalignant conditions. The plexus is located in the retroperitoneum, bilaterally extending from the lower third of the fifth lumbar vertebra to the upper third of the first sacral vertebra. For blockade of the plexus, the patient is placed in the prone position and two 7-cm needles are inserted, under fluoroscopy, in medial and caudal directions until the tips lie anterior to the L5 to S1 intervertebral disc space. Alternatively, a single needle can be used through a transdiscal approach. After injection of contrast medium, 6 to 8 mL of local anesthetic is used for a diagnostic block while phenol or alcohol is employed for neurolysis. Anterior ultrasound-guided superior hypogastric plexus blocks appear to be effective for pelvic pain.<sup>109</sup> The factors associated with positive outcome include older age, and presence of bladder cancer.<sup>110</sup> The complications are minimal and include nerve root blockade secondary to retrograde spread of the injectate. Case reports support the efficacy of neurolytic superior hypogastric plexus block both in reducing pelvic pain secondary to cancer and in decreasing opioid consumption.

## Ganglion Impar Block

Pain in the perineal area associated with malignancies can be treated with neurolysis of the ganglion impar (Walther ganglion), a solitary retroperitoneal structure located anteriorly to the sacrococcygeal junction. Visceral afferents innervating the perineum, distal rectum, anus, distal urethra, vulva, and distal third of vagina converge at the ganglion. For the procedure, the patient is usually prone. The transsacrococcygeal approach is easier to perform; a 20-gauge, 1.5-in needle is inserted through the sacrococcygeal ligament until the tip of the needle is just anterior to the anterior portion of the sacrum. Four to 8 mL of local anesthetic is used for diagnostic block and 8% to 10% phenol or 50% alcohol is used for neurolysis. Similar to superior hypogastric plexus blocks, there are no controlled studies on its efficacy, although case reports confirm its effectiveness in relieving perineal pain secondary to cancer.

## Pharmacologic Management of Pain

### Opioids

Morphine is the standard for opioid therapy for cancer pain (see [Chapter 20, Opioids](#)). It has a variable oral bioavailability between 10% and 45%. The metabolites of morphine include morphine-6-glucuronide, which causes additional analgesia, and morphine-3-glucuronide, which can cause adverse effects. Controlled-release preparations are available, reducing the need to take the drug frequently. The *numbers needed to treat* or NNT for 10 mg of morphine for postoperative pain is 2.9 and its *numbers needed to harm* or NNH is 9.1. Hydromorphone, a  $\mu$ -receptor agonist, is three to five times more potent than morphine when given orally and five to seven times more potent when given parenterally. Its 3- to 4-hour duration of analgesic effect is similar to that of morphine. Pruritus, sedation, nausea, and vomiting occur less frequently compared with morphine. Its metabolite, hydromorphone-3-glucuronide, lacks analgesic property but possesses properties similar to that of morphine-3-glucuronide.

Methadone has a 60% to 95% bioavailability, high potency, and a long duration of action. It has ideal characteristics that include the lack of an active metabolite, additional salutary effects such as acting as an NMDA receptor antagonist and serotonin reuptake inhibitor, and it is inexpensive. Its potency compared with morphine ranges from 1:1 to 1:2 on acute dosing but can be 1:4 with chronic dosing. It has a long and unpredictable half-life of 8 to 80 hours that makes it difficult to achieve steady-state plasma concentrations, increasing the risk of accumulation and the need for careful and individualized dosing. There has been an “epidemic” of deaths due to

unintentional overdose from methadone<sup>111</sup> because many physicians do not appreciate the consequences of the drug's long and unpredictable half-life. Methadone also causes cardiac rhythm abnormalities, including QT prolongation and Torsade de pointes. Most reports are based on high-dose maintenance (>120 mg) for the treatment of addiction; however, such occurrences have also been reported with lower dosages. Experts recommend disclosure of the dysrhythmogenic property of the drug (especially for patients with cardiac disease), a screening electrocardiogram (ECG) before initiation of therapy, follow-up ECGs in patients who are taking over 100 mg daily, and risk stratification.<sup>112</sup> The risk should be discussed when the QTc interval is 450 to 500 ms and the methadone dose reduced or discontinued when the interval is greater than 500 ms.<sup>112</sup>

Oxycodone is mainly a prodrug, being active after conversion by the enzyme cytochrome P450 2D6 to oxymorphone (a  $\mu$ -opioid agonist). Noroxycodone is its inactive metabolite. It has a high bioavailability (60%) and is associated with a low incidence of itching and hallucinations. It has an NNT of 2.5 in neuropathic pain; the oxycodone-to-morphine ratio is 1:1.5. The controlled-release preparation (OxyContin, Purdue Pharma) has good analgesic characteristics but became a popular drug for abuse prior to its reformulation to include abuse-deterrent technologies. Oxymorphone has greater affinity to the  $\mu$ -receptor than morphine and has little or no affinity to the  $\kappa$ -opioid receptor. It is 10 times more potent than morphine when given intravenously. It has low histamine release, similar to fentanyl. Due to extensive first-pass hepatic metabolism, the bioavailability of oxymorphone is only 10%. However, its greater lipid solubility explains the rapid onset of analgesia. It should not be taken with alcohol because this increases its plasma concentration by as much as 300%. The efficacy of oxymorphone in chronic and cancer pain is similar to other opioids. Buprenorphine is a partial agonist at the  $\mu$ -receptor, a  $\kappa$ -antagonist, and a weak  $\delta$ -agonist. It has a rapid onset (30 minutes) when given orally and a long duration of action of 6 to 9 hours. Buprenorphine antagonizes the opioid effects of full agonists such as morphine or hydromorphone due to its partial opioid agonist pharmacodynamics.

The weak opioids include codeine, hydrocodone, tapentadol, and tramadol. Codeine is transformed to morphine via the enzyme cytochrome P450 2D6, and has an NNT of 16.7. Genetic factors can affect the effect of these drugs. Approximately 9% of Caucasians do not have the enzyme and do not experience analgesia from codeine.<sup>113</sup> Asians have a lower rate of codeine O-demethylation, resulting in less morphine formation. Children under 12 years of age lack maturity of the enzyme and cannot convert the drug to morphine, experiencing the drug's side effects with minimal analgesia.<sup>114</sup> Hydrocodone reaches peak serum concentrations within 1 to 2 hours and has

a half-life of 2.5 to 4 hours. An additive effect is noted when ibuprofen is combined with hydrocodone.

Tramadol is a weak opioid agonist and a monoaminergic drug. It has bioavailability of 80% to 90%, low abuse potential, low incidence of constipation, and minimal risk of fatal respiratory depression, which is possibly limited to patients with severe renal failure. It has a dose-dependent efficacy, with NNTs of 8.5 for 50 mg, 5.3 for 75 mg, 4.8 for 100 mg, and 2.9 for 150 mg. The maximum dose of tramadol is 400 to 500 mg/day. Tapentadol is similar to tramadol and also has a dual mode of action as a  $\mu$ -opioid agonist and a norepinephrine reuptake inhibitor. It is modestly stronger than tramadol. Tapentadol is FDA approved for moderate-to-severe acute pain, whereas its extended-release formulation is approved for moderate-to-severe chronic pain and diabetic neuropathy. Tapentadol has side effects and adverse reactions that are similar to those of tramadol, but has a higher risk of addiction and respiratory depression due to its opioid agonism. The oral equianalgesic doses of morphine 10 mg intravenously or 30 mg orally are (1) 200 mg of codeine, (2) 30 mg of hydrocodone, (3) 20 mg of oxycodone, (4) 150 mg of tramadol, and (5) 75 mg of tapentadol.

There is a public concern regarding the effect of opioids on driving performance. A 2013 study determined, contrary to older studies, that individuals receiving stable doses of 20 mg of morphine or equivalent are at increased risk for motor vehicle collisions and this risk increases substantially at doses above 120 mg.<sup>115</sup> Patients who have their opioid dose increased by greater than 30% over a period of 2 days show worsening of their cognitive performance.<sup>116</sup> Patients receiving stable low doses of opioids can probably drive, whereas those who are starting to take opioids, take moderate to high doses and those who had a recent increase in their dose should be warned about the hazards of driving.

Opioids are commonly used for cancer pain, with long-acting opioids supplemented by short-acting ones for breakthrough pain. Opioid monotherapy in cancer pain is rarely successful and adjuvants and procedural interventions are usually added for increased efficacy. The use of opioids for acute or short-term pain (<3 months) following surgery or traumatic injuries is well accepted and supported by the literature. The use of opioids for treatment of chronic (>3 months) noncancer pain is controversial. To date, there has been no randomized clinical trial establishing the efficacy of chronic opioid therapy for greater than 3 months.<sup>117</sup> Chronic opioid therapy is likely to be effective for long-term analgesia in a small subset of patients. Studies show them to be effective in the treatment of neuropathic pain, although at higher doses. Because of the undesirable issues associated with the use of opioids, such as addiction, aberrant behaviors, and regulatory issues, opioids are a third-line drug for neuropathic pain. The combination of a gabapentin

and an opioid has been shown to result in better analgesia, fewer side effects, and lower doses of each drug. It should be noted that although individual studies show the efficacy of opioids in low back pain in the short term, a meta-analysis did not show reduced pain when compared with a placebo or a nonopioid control group.<sup>118</sup> Opioids, in addition to NSAIDs and muscle relaxants, may be efficacious for the short-term relief of acute low back pain, but the long-term efficacy of opioids ( $\geq 16$  weeks) is unclear and cannot be recommended due to the established risks and harms of opioid therapy.<sup>117,118</sup> When treating fibromyalgia, tramadol, tapentadol, or a tramadol/acetaminophen combination are the only opioids that have been shown to be more effective than placebo. Other opioids, including pure opioid agonists, should not be used in the treatment of fibromyalgia and chronic widespread pain.

Opioids have significant risks and harm. The long-term use of opioids is associated with tolerance and physical dependence. The rates of substance-use disorders or opioid misuse reported in studies vary widely. A body of evidence suggests that among chronic pain patients receiving opioid therapy, 6% to 37% will exhibit aberrant drug-related behaviors, 8% to 16% will abuse their drugs, and approximately 2% to 14% may become addicted.<sup>117</sup> Factors predictive of increased risk for misuse included history of substance use disorder, history of sexual abuse, younger age, major depression, and use of psychotropic medications. Recent literature has supported the hypothesis that a subset of patients self-medicate with opioids to manage depression independent of pain.<sup>119</sup> This form of chemical coping is a factor to consider when opioid therapy is being considered.

## *Pharmacologic Treatments of Neuropathic Pain*

NeuP-SIG of the IASP recently published a meta-analysis of 229 randomized double-blind studies, including nonpublished trials, of oral and topical medications used for neuropathic pain. The quality of each study was rated using GRADE. First-line medication recommendations included gabapentin, pregabalin, SNRIs, and TCAs. Second-line recommendations included capsaicin 8% patches, lidocaine patches, and tramadol. Third-line medications were botulinum toxin A and opioids.<sup>120</sup>

### **Antidepressants**

TCAs have a serotonergic effect (interference with serotonin reuptake and alteration of serotonin binding to receptors in neural tissue), a noradrenergic effect (interaction with  $\alpha$ -receptors), an opioidergic effect, blockade of the NMDA receptor complex, inhibition of the uptake of adenosine, and blockade

of sodium and calcium channels. TCAs also have an anti-inflammatory effect in animal models of pain. The NNTs of antidepressants are comparable with those of opioids and anticonvulsants. Antidepressants also inhibit the histaminic, cholinergic, muscarinic, and nicotinic receptors, resulting in sedation, dry mouth, and urinary retention. TCAs, specifically amitriptyline and nortriptyline, have been shown to be effective in PHN.

Serotonin and norepinephrine receptor inhibitors (SNRIs) block the reuptake of serotonin and norepinephrine, with duloxetine having increased selectivity for serotonin. Venlafaxine has more serotonergic effects at lower doses but with greater noradrenergic activity at higher dosages. Duloxetine and milnacipran have preferential noradrenergic effect, have longer half-lives (12 and 8 hours respectively), and have no active metabolites. In addition to their antidepressant action, the SNRIs have an antinociceptive effect.<sup>121,122</sup> Duloxetine is effective in DPN and fibromyalgia and has a good safety profile for long-term use.<sup>123,124</sup> Patients with fibromyalgia have been shown to have improvements in fatigue, physical conditioning, and discomfort after milnacipran.<sup>125,126</sup> The efficacy of the SNRIs in DPN and fibromyalgia, coupled with the better side effect profile (free of cholinergic, histaminic, and  $\alpha$ -adrenergic receptor effects, and less potential for drug interactions) in comparison to the TCAs, are probably the reasons for their increased preferential usage.<sup>121</sup> As stated previously, the European Federation of Neurological Sciences Task Force and the IASP NeuPSIG recommend the SNRIs as the first-choice drugs for the treatment of DPN.

TCAs have an NNT of 2.1 to 2.8 for treatment of PHN, 1.3 to 3.4 for DPN, and 1.7 for central pain. The side effects of antidepressants include cholinergic effects such as dry mouth, sedation, and urinary retention. Venlafaxine may cause hypertension and mania, and may exacerbate seizures. A gradual withdrawal is recommended for duloxetine to prevent agitation, anxiety, confusion, and hypomania. TCAs are more likely to cause weight gain compared with SNRIs. TCAs impair driving ability during the first week of treatment or during dose escalation, but driving performance returns to baseline shortly thereafter.<sup>127</sup> No impairment of driving ability apparently occurs with SNRIs. The recommended doses for the commonly used antidepressants are shown in [Table 56-2](#). The serotonin specific reuptake inhibitors (SSRIs) (citalopram, paroxetine) show a limited effect on neuropathic pain.

## **Anticonvulsants**

Neuropathic pain is associated with changes in sodium and calcium channel subunit expression, resulting in functional changes. In chronic nerve injury, there is redistribution and alteration of subunit compositions of sodium and

calcium channels, resulting in spontaneous firing at ectopic sites along the sensory pathway. Sodium channel blockers inhibit spontaneous activities at neuromas, DRG, and at the dorsal horn of the spinal cord. Most anticonvulsants block sodium channels, explaining their efficacy in neuropathic pain syndromes. Other anticonvulsants act on ion channel systems, including GABA<sub>A</sub> receptor agonists (topiramate and felbamate), GABA<sub>A</sub> transaminase blockers (vigabatrin), GABA<sub>A</sub> transport blockers (tiagabine), and glutamate receptor antagonists (felbamate and topiramate). The other drugs directly block calcium channels (lamotrigine), T-type calcium channels (topiramate and zonisamide) and  $\alpha_2$ -delta subunits (gabapentin and pregabalin). Randomized controlled studies demonstrate the efficacy of the anticonvulsants in several neuropathic pain syndromes including trigeminal neuralgia, PHN, DPN, HIV polyneuropathy, phantom limb pain, spinal cord injury (SCI) pain, and central poststroke pain.

**Table 56-2** Dosages (mg/day) of the Commonly Used Antidepressants and Anticonvulsants<sup>a</sup>

Antidepressants	Anticonvulsants
Amitriptyline: 10–300	Gabapentin: 900–3,600, tid
Doxepin: 30–300	Lamotrigine: 50–150
Nortriptyline: 50–150	Mexiletine: 300–1,350, tid
Desipramine: 25–300	Oxcarbazepine: 300–900, bid
Fluoxetine: 5–40	Pregabalin: 150–600, bid
Paroxetine: 20–40	Topiramate: 50–200, bid
Venlafaxine: 37.5–300	
Duloxetine: 60–120, od or bid	
Milnacipran: 100–200 mg, 50–100 mg bid	

tid, three times a day; bid, twice a day; od, once daily.

<sup>a</sup>Unless indicated, dosing is once a day. Start with smallest possible dose and titrate to efficacy or side effects.

Gabapentin is an effective drug in neuropathic pain (PHN, DPN, and SCI), multiple sclerosis pain, neuropathic cancer pain, and fibromyalgia. It has few side effects and lacks drug–drug interactions. Its median effective dose is 900 to 1,800 mg/day. Compared to gabapentin, pregabalin has an improved linear pharmacokinetic profile. It has been shown to be effective in PHN, DPN, and SCI pain. The maximum dose of pregabalin is 600 mg/day in patients with creatinine clearance more than 60 mL/min or 300 mg in patients with clearance of 30 to 60 mL/min. The popularity of gabapentin and pregabalin relates to the lack of drug interactions and their perceived speed of onset.<sup>128</sup>

Lamotrigine has been shown to be effective in HIV polyneuropathy, pain from SCI, trigeminal neuralgia, and central poststroke pain.<sup>101</sup> The most common side effect is rash, and use of lamotrigine is limited by the risk of

Stevens–Johnson syndrome. Topiramate is effective in migraine prophylaxis, similar to divalproex. Oxcarbazepine is similar in chemical structure to carbamazepine and noted to be effective in trigeminal neuralgia with fewer side effects; its analgesic effect is fast and pain relief may be noted within 24 to 48 hours. The recommended doses of the commonly used anticonvulsants are in [Table 56-2](#).

The side effects of anticonvulsants include dizziness, fatigue, somnolence, weight gain, peripheral edema (gabapentin and pregabalin); rash (lamotrigine); paresthesia, cognitive effects, weight loss (topiramate); hyponatremia; and low thyroid concentrations (oxcarbazepine).

### **Lidocaine Patch, Capsaicin Patch, Mexiletine, and Intravenous Lidocaine**

The 5% lidocaine patch delivers lidocaine locally at the site of neuropathic pain generation, limiting its systemic effects and reducing its interactions with other concomitantly administered medications; analgesia is by local sodium channel blockade and not by its systemic effects. The patch contains 700 mg of lidocaine inside an adhesive. It is recommended that a maximum of three patches be applied for a maximum of 12 hr/day. Most patients experience pain relief within a few days of application. Others have a delayed response so it has been recommended that there should be a 2-week trial period. Some patients continue to experience relief between patch applications but others have pain when the patch is removed; clinicians recommend using the patch for 16 to 18 hours in these patients. The absorption of lidocaine is limited; only about 3% of the total dose applied is absorbed systemically.<sup>129</sup> The maximum plasma lidocaine concentration is usually achieved on the second day of a 12-hours-per-day patch application and is significantly lower than concentrations that are cardiotoxic. Clinical experience with the lidocaine patch has shown that it can be used effectively for patients with PHN.<sup>130</sup>

Capsaicin has been shown to defunctionalize TRPV1 nerve endings and reduce epidermal nerve fiber density.<sup>131</sup> The higher-concentration capsaicin 8% patch (Qutenza, Acorda Therapeutics) has been shown to be better than placebo and better than low-concentration (0.04%) capsaicin. It appears to be effective in PHN, DPN, and HIV neuropathy.<sup>132,133</sup> Its NNT, 30% relief, is 12 (6.4 to 70). Because of burning sensation during its placement, local anesthetic cream applied 60 minutes before the patch is applied for 60 to 90 minutes. The 60-minute application is better tolerated and is similar in efficacy. There is an increase in pain 20 to 30 minutes after application, which disappears 2 to 3 hours after removal of the patch. Relief can be up to 12 weeks after one application. A maximum of four doses can be given at intervals of 12 weeks.<sup>134</sup>

Mexiletine is an oral analogue of lidocaine and has been used for diabetic

neuropathy, thalamic stroke pain, spasticity, and myotonia but has been shown to only have modest efficacy. Its efficacy is similar to that of intravenous lidocaine, although a favorable response to intravenous lidocaine does not necessarily mean a similar response to mexiletine. The median recommended dose of mexiletine is 600 mg/per day.

## **Cannabinoids**

Cannabis has been studied for treating neuropathic pain. Seven of the nine reviewed studies of nabiximols, a cannabinoid-based oral mucosal spray, were negative for the primary outcome of 50% pain reduction. Cannabinoids were therefore given a weak recommendation against use.<sup>120</sup> Another meta-analysis reviewed five randomized controlled trials that looked at inhaled (smoked) cannabis for treatment of chronic neuropathic pain and showed an NNT for short-term reduction in neuropathic pain similar to that of TCAs, SNRIs, and gabapentin. These studies are limited in the sample size, dose variability, lack of functional outcome variables, and short duration.<sup>135</sup> Nabiximols, but not delta-9-tetrahydrocannabinol (THC), were modestly effective in the treatment of cancer-related pain.<sup>136</sup> As of December 2015, the prescription and consumption of medical marijuana was legal in 23 states and the District of Columbia, although federally illegal. Dronabinol and nabilone, synthetic cannabinoids approved for nausea treatment, had no pain benefit in acute postsurgical pain clinical trials. Dronabinol did improve pain intensity in chronic pain patients who were opioid tolerant.<sup>137</sup>

Based on original studies, review articles, and meta-analysis publications, the recommended drugs for several different chronic pain syndromes are listed in [Table 56-3](#).

## **Buprenorphine–Naloxone Therapy**

Buprenorphine–naloxone (bup/nal in 4:1 ratio; Suboxone, Indivior Inc.) is a semisynthetic, sublingual tablet consisting of buprenorphine and naloxone in fixed 4:1 ratio. It has been noted to be effective in outpatient-based opioid addiction treatment and offers several advantages over methadone maintenance programs. As opioids are associated with adverse and social consequences, buprenorphine/naloxone has been prescribed as an alternative. A review of the literature showed it to be inadequate to provide pain relief in patients without opioid dependence or addiction.<sup>138</sup> In patients with chronic pain with opioid dependence or addiction, studies showed the drug to have some efficacy.<sup>139,140</sup>

## **Interventional Techniques**

## Discography

The symptoms of discogenic pain are nonspecific and include nonradicular back pain that is worse in the sitting position and with lifting maneuvers. The neurologic examination is usually normal; the MRI may show a high-intensity zone on the T2 sagittal images, indicating an annular tear. Treatments include stabilization, core strengthening, exercise training, back education, activity modification, and occasional ESIs for managing symptom exacerbation.

Diagnostic discography remains a useful tool in identifying painful intervertebral discs.<sup>141</sup> Some of the indications include (1) evaluation of abnormal discs to assess the extent of abnormality or correlation of the abnormality with clinical symptoms, (2) assessment of patients with persistent severe symptoms in whom diagnostic tests have failed to reveal which suspected disc is the source of pain, (3) assessment of discs before fusion to determine which discs within the proposed fusion segment are symptomatic, and (4) confirmation of a contained disc herniation or investigation of contrast distribution pattern before intradiscal procedures. Discography can be performed on an outpatient basis with fluoroscopic guidance, under light sedation. Antibiotic prophylaxis is recommended and may be administered either intradiscally or intravenously. The specifics of the technique are discussed by Derby et al.<sup>142</sup> Nonionic contrast is injected into the disc, preferably with a controlled injection system with pressure readout. The patient is asked to rate his or her pain on a 0 to 10 scale before and during injection, and whether the pain is *concordant*, that is, similar to the pain for which the patient is being evaluated.<sup>143</sup> The suggested end points for injection include (1) pain severity of 6 out of 10 or greater, (2) intradiscal pressure of less than 50 psi above opening pressure, or (3) a total of less than 3.5 mL of contrast medium has been injected. Anteroposterior and lateral images are taken to record the distribution of contrast medium and whether the contrast leaked outside the disc through a fissure in the annulus fibrosis. After recovery, the patient is sent for a postdiscography computed tomography (CT) scan, preferably within 4 hours of the discography.

Discitis is the most feared complication of discography; it is considerably decreased with prophylactic antibiotic use.<sup>144</sup> The diagnosis of discitis includes worsening back pain the week after discography, and elevated erythrocyte sedimentation rate and C-reactive protein that usually peaks 53 weeks after the procedure. The most common causative organism in discitis is *Staphylococcus aureus*. The possibility of disc injury after discography, resulting in disc degeneration and/or herniation from such procedures,<sup>145</sup> as well as the procedure's poor prognostic value for success of surgical fusion,<sup>141</sup> may have decreased the frequency with which the procedure is performed.

**Table 56-3** Recommended Drugs for Chronic Pain Syndromes

Postherpetic Neuralgia	Diabetic Painful Neuropathy	Spinal Cord Injury	Fibromyalgia	Human Immunodeficiency Virus (HIV)
Pregabalin	Duloxetine	Pregabalin	Duloxetine	Lamotrigine
Gabapentin	Pregabalin	Gabapentin	Pregabalin	Gabapentin
Opioid	Gabapentin	Lamotrigine	Milnacipran	
Antidepressants	Antidepressants	IV lidocaine	Tramadol	
Tramadol		Mexilitine (±)		
Lidoderm patch (allodynia)				

### **Thermal Annular Procedures**

Intradiscal electrothermal therapy (IDET) is a procedure wherein a thermal resistance catheter is placed percutaneously in the posterolateral portion of the disc. Heat causes the collagen of the annulus fibrosis to contract. Two randomized sham-controlled studies examined IDET in discogenic pain patients, with one study showing significant improvements in pain scores and Oswestry Disability Index<sup>146</sup> and the other study demonstrating differences in pain or functional outcome between the IDET-treated and sham control groups.<sup>147</sup> The procedure was not approved by the Center for Medicare and Medicaid Services (CMS), leading to the near demise of its use in patients insured by commercial carriers and patients in the Veterans Administration system. Given the difficulty of navigating the IDET catheter in degenerated discs, a bilateral cooled RF approach—biacuplasty—was developed. A prospective sham-controlled study showed efficacy of biacuplasty compared to sham control at 6- and 12-months<sup>148</sup> and an open-label trial showed it to be superior to conventional medical management.<sup>149</sup> Similar to other thermal annular procedures, third-party insurance coverage remains extremely limited.

### **Minimally Invasive Lumbar Decompression Procedure**

Spinal stenosis is narrowing of the spinal canal with compression of the nerve roots as demonstrated with a magnetic resonance imaging (MRI) or CT scan. Such canal narrowing can be secondary to hypertrophy of the ligamentum flavum or the facet joint. Low back pain from spinal stenosis is located in the low back area, buttocks, thighs, and/or legs in combination with neurogenic claudication, especially with erect posture (due to smaller spinal canal diameter in this position) or walking.<sup>150</sup> The minimally invasive lumbar decompression (MILD) procedure is a minimally invasive method of spinal decompression. It is indicated in patients with low back pain and neurogenic claudication associated with MRI or CT evidence of central canal stenosis secondary to ligamentum flavum hypertrophy in the lumbar segments.<sup>151,152</sup>

The procedure involves limited percutaneous laminotomy and thinning of the ligamentum flavum to increase the critical diameter of the stenosed spinal canal. It can be performed under local anesthesia. A one- or, more usually, two-level decompression is performed. In contrast to surgical decompression with fusion wherein there is complete resection of the ligamentum flavum and bony posterior elements compressing the thecal sac and exiting nerve roots, the mild procedure only partially debulks the ligamentum flavum. Although initial reports were promising,<sup>153,154</sup> the procedure has not become commonplace because approval for payment by CMS (and subsequently commercial insurance carriers) was deferred pending a sham-controlled randomized trial.

### *Vertebroplasty and Kyphoplasty*

Vertebroplasty and kyphoplasty are percutaneous interventional modalities to treat vertebral compression fractures (VCFs), a condition usually secondary to osteoporosis in elderly patients. Most healed VCFs are asymptomatic; pain may be experienced in acute or subacute VCF with bending, lifting, prolonged sitting or standing, or when the patient attempts to stand from a seated position. The pain is usually a deep back pain and there may be intercostal neuralgic symptoms or radiculitis and paravertebral muscle spasm. Pain is relieved by bed rest and the recumbent position. Radiography shows osteopenia or decreased bone mass; MRI is the imaging modality of choice as it detects bony edema associated with acute fracture with a very high sensitivity.

Vertebroplasty involves the injection of polymethylmethacrylate (PMMA) into the affected vertebral body; kyphoplasty involves the insertion of a balloon prior to the injection of the cement. These procedures lead to restoration of some of the decreased vertebral height, improved strength of the vertebral body, and decreased stress placed on the adjacent vertebrae. Both procedures are performed under fluoroscopic guidance. Vertebral body access is obtained through a uni- or bipedicular approach. The entire vertebral body does not have to be filled with cement to achieve pain relief; 2 mL is adequate for the procedure (Fig. 56-8). The patient remains supine for 3 to 5 hours after the procedure for assessment of neurologic status and observation for the occurrence of bleeding and hematomas. A CT scan is usually performed afterward for assessment of cement distribution and the occurrence of complications such as bleeding and leakage of the cement. Kyphoplasty involves the percutaneous introduction of a balloon into the vertebral body, inflation of the balloon, then filling of the balloon with PMMA that is more viscous than that used for vertebroplasty.

The complications of percutaneous vertebral augmentation include leakage

of the cement and complications related to the procedure. The factors that contribute to cement leakage include the level of injection, severity of fracture, and the amount of cement injected. Neurologic complications include radiculopathy, spinal claudication, and paraplegia. Kyphoplasty may be associated with a lower rate of cement extravasation because of the higher viscosity of the PMMA that is used, the lower injection pressure employed, and the inflatable bone trap that seals pathways for cement leakage.<sup>155</sup> Complications related to the procedure include infection, bleeding, and allergic reactions from the PMMA or contrast medium.

**Figure 56-8** Vertebroplasty at T10 vertebral level. A total of 5 mL of cement was injected.

**8** Initial results after vertebroplasty and kyphoplasty were good and complications were minimal.<sup>156-160</sup> More recent randomized controlled studies have not confirmed the beneficial effects of vertebroplasty in that improvements in pain and pain-related disability were similar to the improvements in the sham control group.<sup>161,162</sup> Although the conduct of the studies was criticized appropriately, questions about the mechanism and the effectiveness of this procedure remain unanswered.<sup>163</sup> Two randomized controlled studies showed the superiority of balloon kyphoplasty for VCFs in patients with osteoporosis or cancer when compared with a control nonsurgical care group.<sup>164,165</sup> These two randomized studies were partly criticized, in that funding of the study came from the maker of the device, and one of the authors was affiliated with the company. Final conclusions on the efficacy of these procedures await additional randomized controlled

studies.

## Spinal Cord Stimulation

The analgesic effect of spinal cord stimulation (SCS) may involve the *gate control theory*, neurotransmitter modulation in the spinal cord affecting pain pathways and suppression of sympathetic activity, with antidromic and activity supraspinal mechanisms also playing important roles. It is hypothesized that SCS increases the input of the large nerve fibers, thus closing the “gate” at the substantia gelatinosa of the dorsal horn of the spinal cord. SCS may alter the local neurochemistry at the dorsal horn, and there may be a decrease of the hyperexcitability of the wide dynamic neurons. It is correlated with increased levels of the inhibitory neurotransmitter GABA and a decrease of the excitatory neurotransmitters glutamate and aspartate.<sup>166</sup> In ischemic pain, the analgesia may be secondary to alteration of the sympathetic tone with restoration of a favorable oxygen supply-and-demand balance.

In the United States, SCS is approved “as an aid in the management of chronic intractable pain of the trunk and/or limbs, including pain associated with failed back surgery syndrome, low back pain and leg.” Clinical indications for SCS implantation include patients with a diagnosis of post laminectomy syndrome, also known as failed back surgery syndrome (FBSS), CRPS, neuropathic pain syndromes, angina, and chronic critical limb ischemia and pain.<sup>167-173</sup> Many of these indications are considered off-label, including placement of all cervical spine stimulators. Patients who failed conservative therapy and had a temporary stimulation trial that has demonstrated pain relief after having passed a psychological evaluation generally proceed to permanent implantation. Many patients with chronic pain may have uncontrolled depressive symptoms and implantation should be avoided in patients with major psychological disorders. The general contraindications include systemic or local site of infection and abnormal coagulopathy. Complications include nerve and SCI, infection, hematoma, and lead breakage or migration.

Evidence supports the efficacy of SCS for treatment of persistent back and leg pain. In a randomized study, patients who were candidates for repeat laminectomy were randomized to either SCS or surgery.<sup>167</sup> At 6-month follow-up 67% of patients who had reoperation crossed over to SCS, but only 17% in the SCS group crossed over to repeat surgery. At the 3-year follow-up, the SCS group continued to have better outcomes compared with patients having repeat spine surgery. Overall, 47% of patients in the SCS group achieved 50% or more pain relief compared with 12% in the reoperation group ( $p < 0.01$ ). The patients randomized to reoperation used significantly

more opioids than those randomized to SCS. SCS is also superior to conservative medical management (CMM) in patients with FBSS. More recently, modifications to SCS parameters, in particular frequency rate and pattern, have shown improved efficacy in pain control. In particular, high frequency SCS at 10 kHz has shown superior pain relief in back and leg pain to conventional SCS (at low frequency 40 to 130 Hz) in long-term follow-up. Unlike conventional stimulation, SCS at 10 kHz is paresthesia free. In addition, sending packets of higher frequency stimulation at 500 Hz, in what has been referred to as burst SCS, has been shown to result in improved back and leg pain control compared to tonic stimulation, in a paresthesia-free fashion for the most part. Thus, there is sufficient evidence to support the efficacy of SCS for treating failed back syndrome in terms of sustained long-term pain relief with medication reduction, improvement in quality of life, increased patient satisfaction, increased ability to return to work, minimal side effects, and cost-effectiveness compared with alternative therapies; moreover the technique is reversible. Although the main indication for use of SCS in the United States is FBSS, it is a popular treatment for pain secondary to peripheral ischemia in Europe. 9

Studies examining the efficacy of SCS in CRPS have consisted of retrospective case series, prospective clinical studies, and a prospective randomized controlled study. In the randomized controlled study,<sup>169</sup> 54 patients with refractory CRPS who had failed previous therapies including surgical sympathectomy were randomized to either SCS with physiotherapy (SCS+PT) or PT alone. Using an intent-to-treat analysis at the 6-month follow-up, patients who were treated with SCS had a significantly greater reduction in pain, and a significantly higher percentage of patients graded their relief as much improved in terms of global perceived effect (a 7-scale outcome measure ranging from “worst ever” to “best ever”). These effects were maintained at 2 years but not at 5 years using an intent-to-treat analysis.<sup>170</sup> However, an as treated analysis of results at 5 years revealed significant improvement in the SCS+PT compared to the PT group. A meta-analysis<sup>168</sup> concluded that SCS is an effective tool in the management of CRPS and that a grade A level of evidence supports the efficacy of SCS in CRPS. A 12-year follow-up of a prospective cohort study showed SCS to provide an effective long-term pain treatment for 63% of the implanted patients.<sup>171</sup> For pain from peripheral ischemia and angina, most of the published literature consists of case series and case reports.

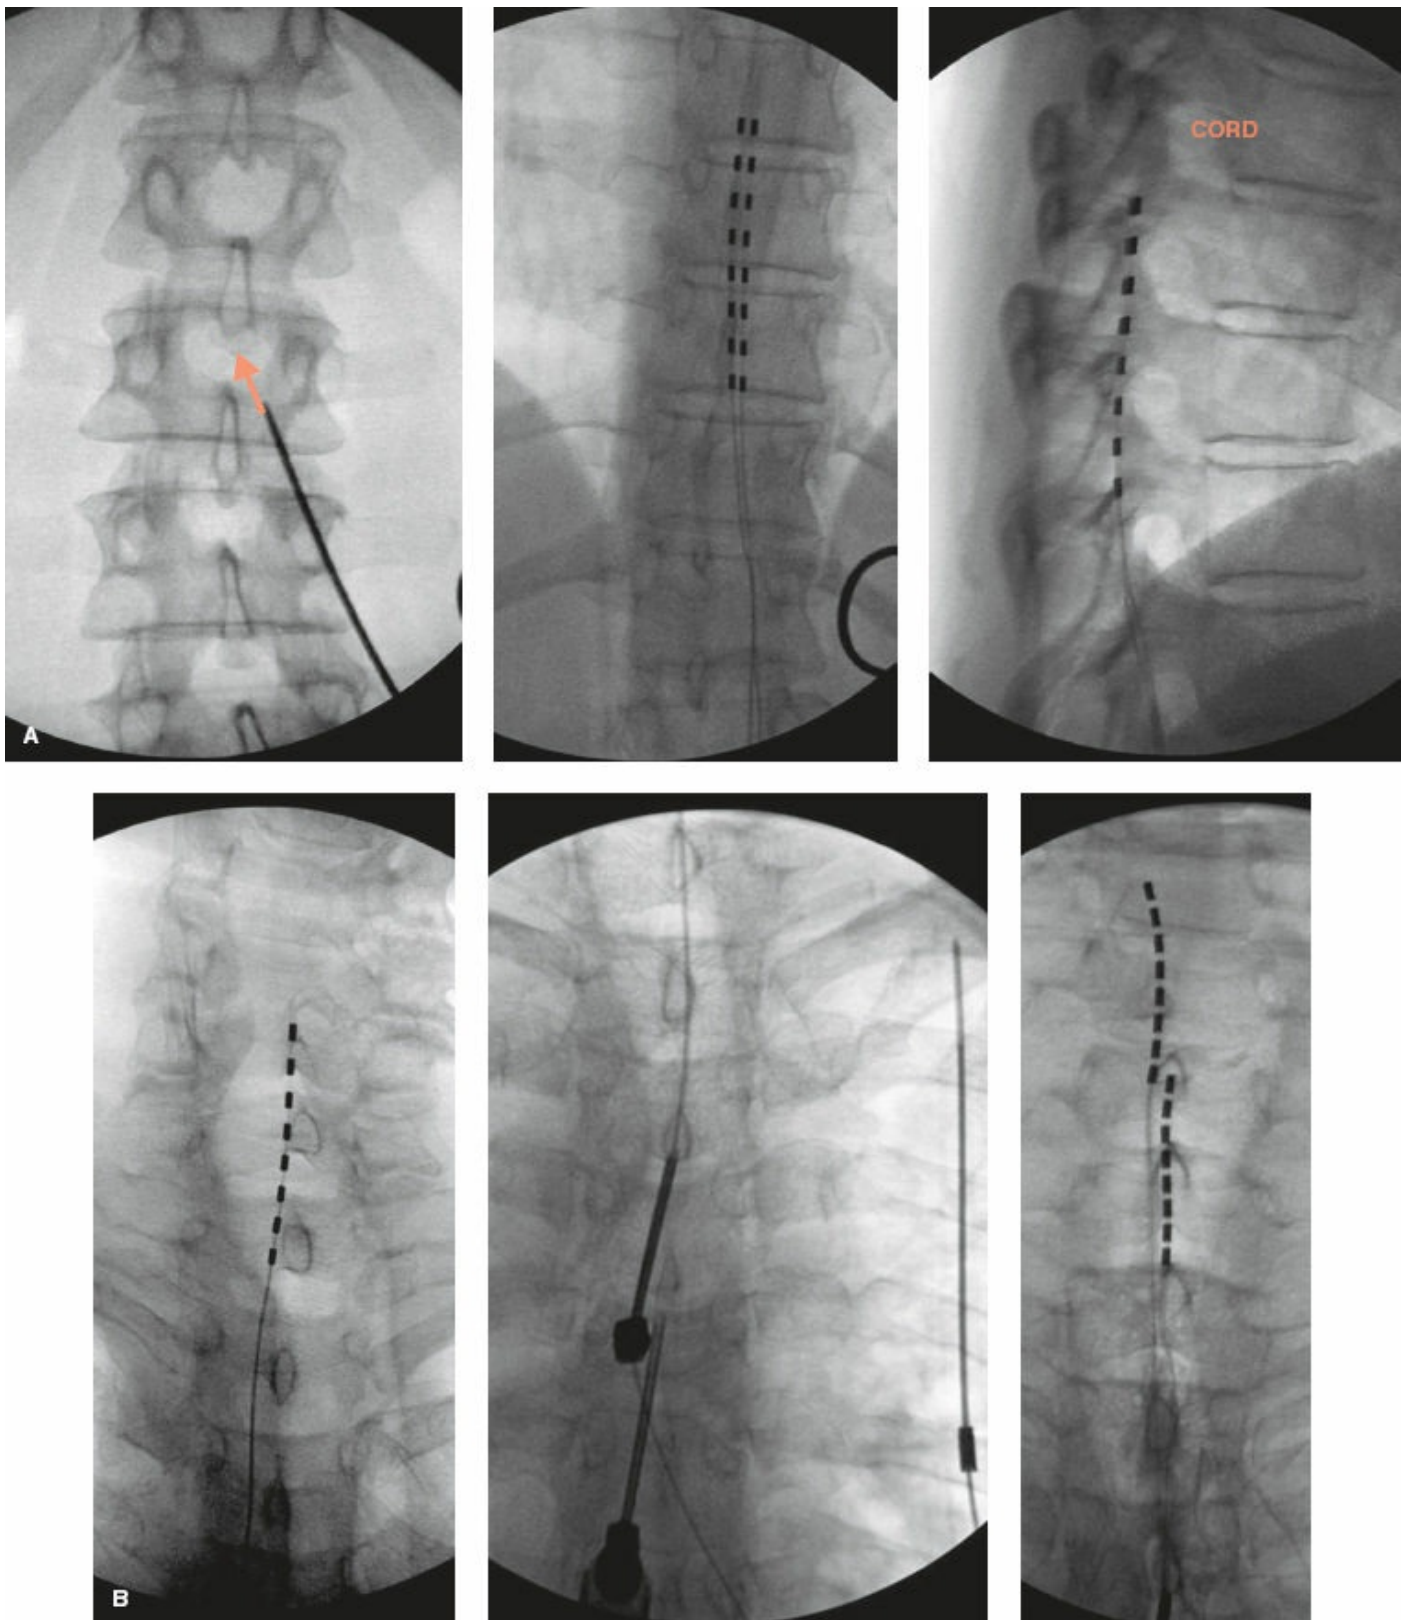

SCS electrodes are placed via a Touhy needle as shown in [Figure 56-9](#).

### **Peripheral Nerve Stimulation**

Electrical stimulation of a peripheral nerve can be used to treat neuropathic

pain, ideally arising from a single nerve. When considering peripheral nerve stimulation (PNS) it is important to distinguish between open and percutaneous PNS approaches. In open PNS, nerve stimulation is made feasible with a circumferential (cuff) electrode that requires a surgical exposure of the target nerve. Application of high frequency (10 kHz) alternating current using a cuff electrode around a peripheral nerve has been shown to result in reversible complete neuronal conduction block. PNS of the sciatic or tibial nerve has shown promise in treating postamputation pain, and is now the subject of a large multicenter study. On the other hand, PNS involves the use of cylindrical percutaneous lead (originally designed for SCS) in close proximity to the target nerve or in the subcutaneous field area supplied by the target nerve. The former percutaneous approach requires target specificity and may be subject to lead migration and unwanted motor stimulation in mixed nerves. The latter percutaneous approach is referred to as peripheral nerve field stimulation and is less target specific and less technically challenging. It has been used for managing focal neuropathic pain such as occipital neuralgia, facial neuralgias, and PHN, and various other conditions such as refractory angina, abdominal pain, pelvic pain, knee pain after arthroplasty, and low back pain (in combination with SCS). It should be noted that most PNS studies are limited by their observational nature and absence of a control arm. As with patients who are being evaluated for SCS, neuropsychological testing may be valuable. In addition, before permanent implantation of the internal pulse generator, patients should have undergone a successful trial of stimulation with a predetermined therapeutic benefit.

**Figure 56-9** Placement of the epidural needle and the spinal cord electrodes at the thoracic (A) and cervical (B) levels.

### ***Dorsal Root Ganglion Stimulation***

A hybrid between SCS and PNS involves DRG stimulation. In DRG stimulation, special percutaneous leads are introduced, initially in the interlaminar epidural space, and directed toward the adjacent target DRG.

Advantages of this technique involve targeting unique dermatomes and difficult-to-target areas, such as the foot, along with minimal-to-no positional changes in paresthesia intensity compared to conventional SCS. A recent comparative effectiveness study involving 152 CRPS patients randomized to DRG stimulation or paresthesia-based SCS showed a significantly greater proportion of patients achieving 50% or more pain relief with DRG stimulation.<sup>174</sup>

### *Occipital Nerve Stimulation*

Occipital neurostimulation (ONS), a form of peripheral nerve field stimulation, is an innovative technique for providing reversible and effective therapy for intractable headache. The technique is thought to work via inhibition of central nociceptive impulses by stimulation of the superficial nerve branches of C2 and C3. As in all forms of neurostimulation, lead migration represents a potential technical failure that can require surgical replacement; this incidence is particularly high with ONS.<sup>175</sup> Reliable evidence to support the efficacy of this therapy is, at this point, lacking.

### *Intrathecal Drug Delivery*

Intrathecal drug delivery (IDD) enables opioid to be directly deposited near the spinal cord receptors, resulting in analgesia at lower doses. An additional mechanism is the release of adenosine in the cerebrospinal fluid.<sup>176</sup> IDD systems are valuable options in chronic pain patients who have not responded to other modalities and in whom oral or transdermal medications/opioids are ineffective at reasonable doses, or cause unacceptable side effects. The main indications for IDD are cancer pain and pain of spinal origin, with the majority of pumps placed in the USA for FBSS. IDD allows the drug to be directly deposited near the spinal cord receptors, bypassing the blood–brain barrier and the first-pass effect encountered by systemic medications. Hence, medications that have limited blood–brain barrier permeability and medications whose target receptors are located in the spinal canal can be delivered more efficiently and at significantly lower doses. For pain applications, there are only two medications approved by the FDA for IDD: preservative-free morphine and the synthetic peptide ziconotide. Morphine, hydrocodone, or ziconotide are considered acceptable as first-line agents.<sup>177</sup> A number of other medications are commonly used off-label, including hydromorphone, fentanyl, the local anesthetic bupivacaine, and the  $\alpha_2$  adrenergic agonist clonidine. Baclofen is FDA-approved for management of spasticity but otherwise has a limited role in pain applications.

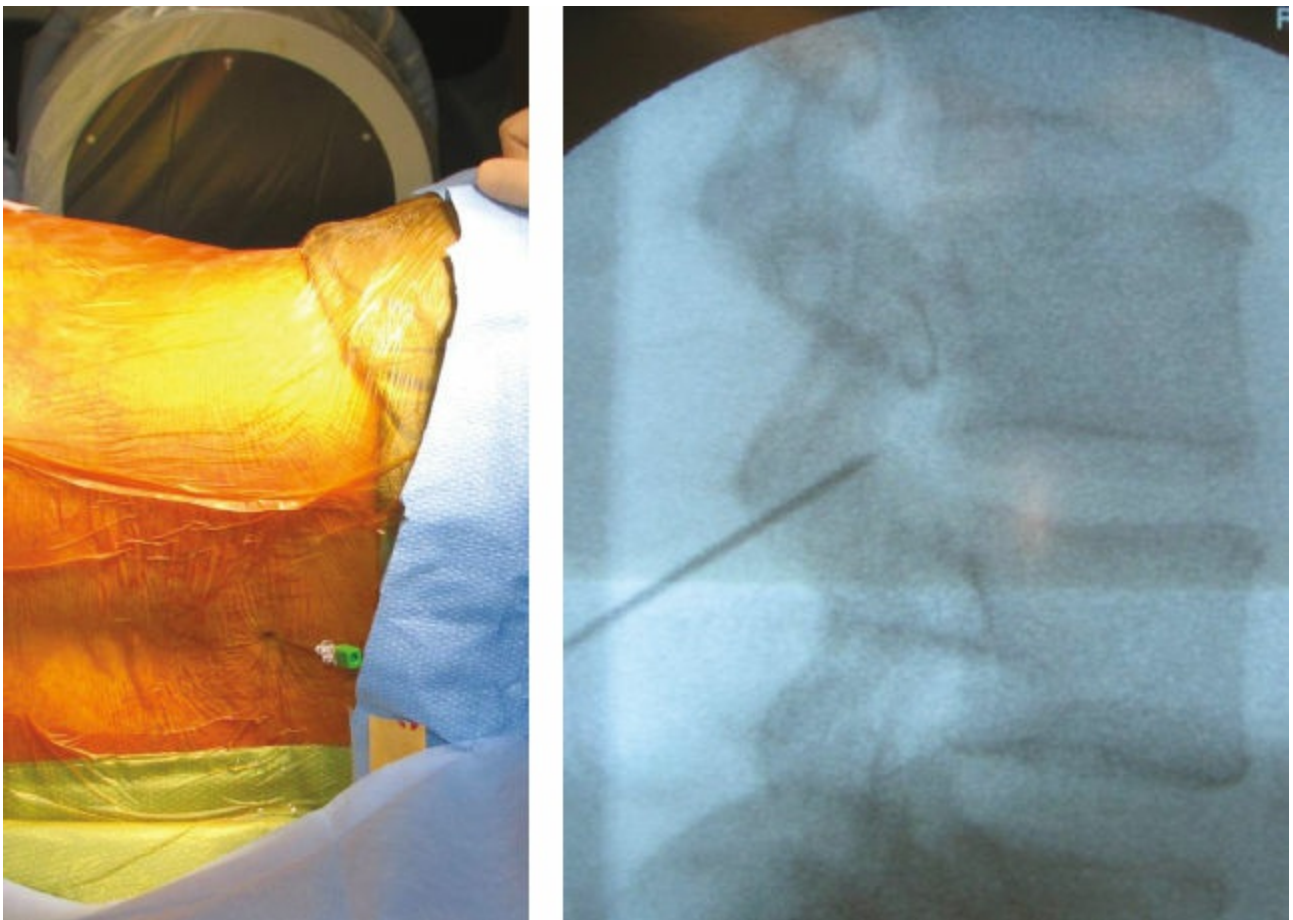

Patients receiving intrathecal opioids develop tolerance not unlike what is

seen with systemic opioids.<sup>178</sup> Side effects such as pruritus, urinary retention, and peripheral edema are more likely to occur with intrathecal than systemic administration of opioids. In addition, an 8% risk of developing an intrathecal catheter tip granuloma is unique to intrathecal opioid infusion. These are typically sterile inflammatory masses consisting of fibroblasts, macrophages, neutrophils, and monocytes.<sup>179</sup> Granuloma formation is increased with higher doses and concentrations of morphine and hydromorphone but not fentanyl. It is not mediated through opioid receptors and experiments suggest that granuloma formation may be related to dural mast cell degranulation occurring in response to morphine and hydromorphone but not fentanyl.

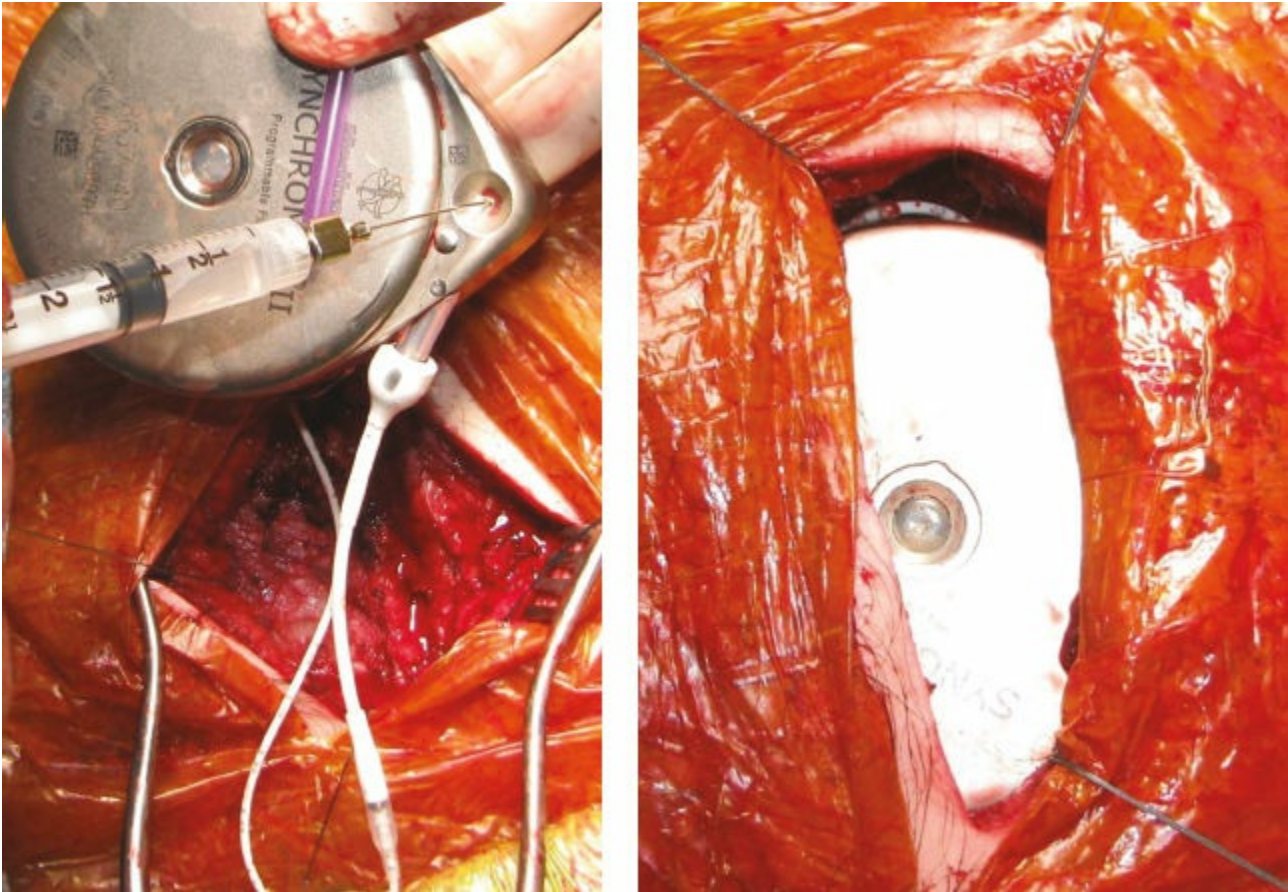

The overwhelming preponderance of IDD systems are placed for managing refractory chronic noncancer pain, primarily low back pain in the setting of previous lumbar spine surgery. In these cases, opioid dose escalation is concerning because it may predispose not only to intrathecal catheter tip granuloma but also to opioid-induced hyperalgesia. Several patient-related factors should be considered before instituting IDD systems for noncancer pain, including the patient's age, pain location, pain type and frequency, and baseline opioid consumption, as well as the patient's medical status. Patients with well-localized pain may be better candidates for IDD given the limited spread of intrathecal medications past the catheter tip; older patients are likely to have a slower rate of opioid dose escalation; a combination of bupivacaine with an opioid may slow the rate of opioid dose escalation; patients with neuropathic pain may escalate their opioid dose requirements more than other patients; and patients with neuropathic pain may respond to a combination of an opioid and bupivacaine.<sup>180</sup> Importantly, opioid consumption at baseline may be the most crucial determinant of opioid dose escalation and this has led to embracing the practice of low opioid dosing (sometimes referred to as "microdosing") whereby patients are weaned off systemic opioids prior to consideration of intrathecal administration.

A trial period is recommended before an intrathecal pump is permanently placed. A trial can be performed intrathecally or through the epidural space, by a single shot, intermittent bolus, or a continuous infusion. If a trial shows efficacy, then permanent implantation is performed. The placement of a permanent pump and catheter should be performed in the operating room under sterile conditions and intravenous antibiotics should be administered. Surgical considerations regarding IDD system implantation include choice of patient positioning (e.g., lateral decubitus vs. prone); type of anesthetic; intrathecal needle entry point (Fig. 56-10); eventual catheter tip location; site of pump placement; and a knowledge of the patient's lumbar spine anatomy, including prior spine surgery or pathology. A purse string suture should be placed in the fascia around the catheter to minimize cerebrospinal fluid leak. In the majority of patients, the only anatomical location that can reasonably

accommodate the size of the pump is the abdominal wall on either side. The anatomic constraints are the bony borders of the iliac crest, and the costal margin. None of these should come in contact with the pump when the patient is seated because of discomfort and risk of damage to the pump or catheter. The pump pocket incision should be made to approximate the size of the pump. The incision can be carried down to the rectus fascia in thin patients. This is followed by tunneling through the subcutaneous tissues between the pump pocket and the posterior incision (Fig. 56-11). This must be done carefully to prevent accidental puncture of the peritoneum or even the pleura.

**Figure 56-10** Placement of the intrathecal needle under fluoroscopy.

**Figure 56-11** Connection of the intrathecal catheter to the programmable pump and confirmation of cerebrospinal fluid prior to placement in the pocket.

Complications of IDD systems can be divided into those related to the procedure/device and those related to the medications infused. Procedure/device-related complications include wound dehiscence, skin erosion over the device, infection, bleeding, CSF leak, seroma or hygroma collection, pump malfunction, and catheter kink or shear. Opioid-related complications include androgen deficiency, decreased testosterone levels and hypogonadism with increased risk of bone mineral deficiency, peripheral edema with morphine and hydromorphone, pruritus, urinary retention, and formation of an intrathecal granuloma. Bupivacaine may cause sensorimotor deficits and urinary retention and clonidine may cause hypotension. Details regarding management of intrathecal complications may be found in books on interventional pain management.

## Summary

The proper treatment of pain, particularly chronic pain, is a unique field of medicine that is considered by some to be a specialty of its own, comparable to other major specialties such as medicine, surgery, and anesthesiology. The practice of chronic pain medicine involves a comprehensive knowledge of basic science, pharmacology, regional nerve blocks, and interventional

procedures. The practice of chronic pain medicine is multidisciplinary and the anesthesiologist's role should complement that of physicians in other specialties, including physical medicine and rehabilitation, psychiatry, radiology, and surgery.

## KEY POINTS

- 1 Simple and inexpensive interventions in the intensive care unit (ICU), such as the utilization of checklists, protocols, and care bundles can result in substantial improvements in patient outcomes.
- 2 The goal of resuscitation in brain injury is to prevent continuing cerebral insult after a primary injury has already occurred. This is accomplished by restoring cerebral blood flow, maintaining adequate cerebral perfusion pressure, reducing intracranial pressure, evacuating space occupying lesions, and avoiding fever, hyperglycemia, and hypoxia.
- 3 “Triple-H” therapy consisting of hypertension, hypervolemia, and hemodilution is no longer recommended for the treatment of cerebral vasospasm in subarachnoid hemorrhage. Instead, maintenance of euvolemia and a controlled stepwise trial of blood pressure augmentation in patients with suspected vasospasm is recommended.
- 4 Administration of thrombolytic therapy (rtPA) to patients presenting within 4.5 hours of onset of acute ischemic stroke results in improved neurologic outcome.
- 5 There are four general types of shock: hypovolemic, cardiogenic, distributive, and obstructive. The 28-day mortality for septic and cardiogenic shock, two of the most common types encountered in the ICU, are 20% to 40% and 70% to 80% respectively.
- 6 In patients with severe sepsis or septic shock, early and aggressive use of fluid resuscitation, appropriate antibiotics, infectious source control, and vasopressors/inotropes as needed improves survival.
- 7 Despite strong regional, local, and individual biases, there is little evidence to suggest that the mode of mechanical ventilation contributes significantly to any major outcome measure, and the choice of mode is largely one of clinician preference.
- 8 Separation from mechanical ventilation in patients who are recovering from respiratory failure is accelerated by respiratory therapy-driven protocols and daily trials of spontaneous breathing.
- 9 Ventilation with low tidal volume (6 mL/kg) in patients with acute lung injury and acute respiratory distress syndrome reduces mortality, compared to traditional tidal volumes (12 mL/kg).
- 10 Red blood cell transfusion in the ICU should be restricted (transfusion threshold hemoglobin <7 g/dL) with the possible exception of patients

with active bleeding, early septic shock, acute myocardial infarction, unstable angina, or primary neurologic or neurosurgical problems.

- 11 Available evidence suggests that practices favoring light sedation, bolus administration versus continuous infusion of sedatives, and daily trials of awakening in ICU patients result in a variety of benefits, including a shortened duration of mechanical ventilation, decreased time in the ICU, and reduced mortality.
- 12 Delay in treatment of nosocomial infections is associated with increased mortality. Treatment should not be delayed pending diagnostic evaluation; rather treatment should be started after culture specimens are sent, and antibiotics then “de-escalated” after 48 to 72 hours to ensure adequate initial antibiotic treatment, but avoid long-term overuse of antibiotics.
- 13 End-of-life care is an important aspect of ICU care, and good communication between medical teams, patients, and their family members is required to ensure that delivered care is consistent with patient values and preferences. Patients at high risk of death or severely impaired functional recovery should be offered care focused on comfort and not just curative treatment. Palliative care can also be offered in conjunction with curative care.

## Introduction

### *Anesthesiologists and Critical Care Medicine*

Historically, Critical Care Medicine (CCM) evolved as a specialty nearly simultaneously in Europe and North America, but has followed different models in regards to the involvement of anesthesiologists. The first intensive care unit (ICU) in Europe may have been located in Denmark in the 1950s, and concurrently the first critical care physician, or “intensivist,” may well have been an anesthesiologist.<sup>1</sup> Anesthesiologists continued to play a defining role in the development of CCM in most of Europe, Australia, New Zealand, Japan, and elsewhere, and comprise the majority of intensivists in many countries around the world today. In North America, anesthesiologists were also integral to the development of CCM as a specialty. However, in contrast to other countries, in the United States anesthesiologists have played a smaller role in the specialty, and today comprise a minority of the intensivist workforce.<sup>2</sup>

Although it has been suggested that the first ICU in North America was established at Johns Hopkins in 1923 to care for postoperative neurosurgical patients, it was not until the late 1950s and early 1960s that true multidisciplinary ICUs began to appear. Anesthesiologists played a natural

role in the evolution of ICUs, given their familiarity with surgical resuscitation and mechanical ventilation. Early on, however, the concept of “intensivists” did not exist, and patients were often managed by their primary physician (be it a surgeon or an internist) and nurses, with formal or informal consultation given by specialists, including anesthesiologists.

In the early 1960s, the first CCM training program was established at the University of Pittsburgh under the direction of an anesthesiologist, Peter Safar, and the concept of “intensivist” was born. As defined by Dr. Safar, the qualities and qualifications of such an individual should include inquisitiveness, thoughtfulness, and a high level of motivation, action orientation, diplomacy, and scientific training. In the late 1960s, a group including Dr. Safar and another anesthesiologist, Ake Grenvik, were instrumental in inaugurating the Society of Critical Care Medicine (SCCM). Anesthesiologists working through SCCM were instrumental in developing the board certification process for CCM, and in 1986 the first CCM Certification examination was administered by the American Board of Anesthesiology.<sup>3</sup>

### *Anesthesiology and Critical Care Medicine: The Future*

An increasing demand for intensivists is projected to continue through at least 2020,<sup>2,4</sup> driven largely by substantial evidence that intensivists increase the quality of ICU care and improve patient outcomes. In addition, the aging population is increasing the demand for critical care services. However, the supply of physician intensivists is not expected to keep pace, and instead is projected to decrease through 2025, leading to a worsening shortage of physician providers.<sup>5</sup> Anesthesiology as a specialty is ideally suited to help alleviate this shortage. Anesthesiologists are hospital-based, have sound fundamental training in physiology, pharmacology, invasive procedures, and monitoring, and have excellent historical and contemporary role models for the anesthesiologist as intensivist. In 2013 only 14% of new board certifications in CCM went to anesthesiologists, and less than 8% of graduating anesthesiology residents pursued critical care training.<sup>6</sup> Historically, economic and lifestyle considerations dissuaded many anesthesiology trainees from pursuing further training and careers in CCM. However, evolving reimbursement and staffing models are eliminating these disincentives in many practices. Furthermore, although the practice of CCM for anesthesiologists has historically been focused largely at academic centers, community practice opportunities are increasingly prevalent. While it seems certain that anesthesiologists will continue to play an important role in CCM worldwide, the current conditions in the United States are ideally suited for anesthesiologists wishing to pursue careers in CCM.

## **Critical Care Medicine: A Systems and Processes Approach**

Critical care encompasses all disciplines of medicine. It is clearly beyond the scope of a single chapter to provide detailed coverage of all aspects of critical illness, including physiology, pathophysiology, and management of disease. In addition, many critical care issues are commonly encountered by anesthesiologists who practice solely in the operating room and are covered in detail elsewhere in this text. Thus, this chapter will focus on topics that are relatively unique to the ICU, but are widely applicable to the care of critically ill or injured patients. The entire chapter focuses on evidence-based practices that may improve both patient outcomes and health-care system performance in the perioperative setting.

Grading of levels of evidence and practice guidelines in an effort to improve clinical care has become standard practice. Several different grading systems exist, with no clear evidence that one is superior to another. Furthermore, given uncertainty about the methodology of grading systems and their effects on patient outcomes,<sup>7</sup> we have chosen not to include “grades” or levels of evidence in this chapter.

### **Processes of Care in the ICU**

There is increasing pressure in medicine to deliver high quality care. With the passage of the Affordable Care Act (ACA) in 2010, the United States federal government provided a definition of high quality care and sought, among other things, to link quality care and reimbursement.<sup>8</sup> The six components of quality care according to the ACA are timely, effective, efficient, patient centered, equitable, and safe care. This legislation is rapidly changing many aspects of health-care delivery in the United States, and the ICU is no exception.<sup>9</sup>

A primary way to improve quality across a system is to reduce variability within the system. Processes of care are evidence-based organizational and individual practices that seek to improve the quality of care delivered by standardizing some aspects of health-care delivery. Although the number of potential process targets is nearly limitless, there are only a few that are widely agreed to improve the quality of care.

### **Staffing**

As advances in medical and surgical therapeutics have increased the complexity of care for an aging and increasingly ill population of patients, it has become increasingly clear that the involvement of intensivists in the management of the critically ill patient is desirable.<sup>10</sup> However, the level of

involvement is not clear. Numerous studies have suggested that mortality and other intermediate end points such as ICU length of stay, duration of mechanical ventilation, and cost can be reduced when “high-intensity” physician staffing models that mandate management or co-management by intensivists are used.<sup>11–13</sup> However, it does not appear that the addition of in-house nighttime attending physician intensivist staffing further improves outcomes compared to daytime only in-house attending physician staffing.<sup>14,15</sup> The best staffing model for a given ICU likely depends on many factors that are not yet fully understood.

Patient outcomes appear to be further improved by the addition of multidisciplinary providers to intensivist-led teams. Examples include pharmacist participation in daily rounds, as well as the inclusion of nurses, dietitians, and respiratory therapists. These practices significantly reduce costs and medication-related adverse events, and are also associated with decreased patient mortality.<sup>16,17</sup>

## Checklists

**1** Despite the improvement in communication and information transfer that occurs with multidisciplinary teams, the high stress and massive volume of information in the ICU environment can lead to errors. Checklists have been widely implemented on ICU rounds as cognitive aides that serve as daily reminders to evaluate a limited number of interventions, preventative measures, bundles, and processes of care that can improve outcomes. Their implementation is associated with a decrease in mortality and ICU length of stay, and they cost virtually nothing.<sup>18</sup> It has been suggested that a checklist prompting consideration of potential interventions is more important than the specific interventions or protocols that are subsequently enacted, especially in ICUs with high-intensity staffing models.<sup>19</sup> Considering these potential benefits and the minimal economic investment required for checklist implementation, their use is strongly recommended. In fact, many of the care processes in this chapter commonly appear on checklists and should be considered with every patient, every day. Suggested content for consideration and inclusion in a daily ICU checklist is listed in [Table 57-1](#). Content might be added or removed based on local ICU considerations.

## Protocols and Care Bundles

The use of standardized protocols and care bundles has targeted improved timeliness and appropriateness of treatment for a variety of common ICU diagnoses, as well as prevention of common complications. For example, implementing a standardized order set for patients with septic shock may

lower 28-day mortality.<sup>20</sup> Similarly, implementing a simple ventilator care bundle may reduce the incidence of ventilator-associated pneumonia (VAP) and antibiotic utilization.<sup>21</sup> Other studies have shown reduced rates of central line–associated bloodstream infections (CLABSIs) by implementing protocols and bundles.<sup>22</sup> An important additional benefit of utilizing standardized care processes is an improved ability to track outcomes and engage in quality assurance (QA) and quality improvement (QI) programs. As noted earlier, outcome tracking and reporting are now mandated and tied to reimbursement under the ACA.

**Table 57-1** Suggested Daily Intensive Care Unit Checklist

- Spontaneous awakening trial
- Spontaneous breathing trial
- Nutrition/diet ordered
- Adequate sedation and analgesia
- Deep-venous thrombosis prophylaxis initiated
- Glucose control adequate
- Unnecessary labs and imaging discontinued
- Antibiotics discontinued
- Foley catheter removed
- Central venous catheter and arterial line removed
- Plan of the day reviewed

## **Resource Management**

In 2014 the Critical Care Societies Collaborative (CCSC) released a list of “Five Things Physicians and Patients Should Question” in critical care as part of the Choosing Wisely campaign. The campaign is designed to reduce unnecessary interventions that lack cost-effectiveness, and has been supported by many medical specialties. At the top of the CCM list is a recommendation to not order diagnostic studies (chest x-rays, blood gases, blood chemistries, cell counts, and electrocardiograms) at regular intervals (e.g., daily) without clear clinical indications. Compared with a practice of ordering tests only to answer clinical questions, or when doing so will affect management, the routine ordering of tests increases costs, does not benefit patients and may in fact harm them.<sup>23</sup> Additional recommendations including restrictive transfusion thresholds, avoiding oversedation and parenteral nutrition unless clearly indicated, and discussing end-of-life issues are addressed in other sections of this chapter. This type of effort to minimize unnecessary interventions recognizes both the financial impact such practice decisions have on individual patients and the health-care system overall, as well as the physician’s role in providing not just effective, but efficient care.

## **Neurologic and Neurosurgical Critical Care**

## Neuromonitoring

There are many neuromonitoring techniques with both intraoperative and ICU applicability. Electroencephalogram (EEG), evoked potential monitors, near-infrared spectroscopy (NIRS), brain tissue oxygenation (PbrO<sub>2</sub>), cerebral microdialysis, intracranial pressure (ICP) monitoring, transcranial Doppler (TCD) ultrasonography and jugular venous saturation (SjO<sub>2</sub>) monitoring may all help in assessing pathophysiologic processes and adjusting therapy. These techniques are discussed in [Chapters 26, 37, and 53](#), and will not be discussed in detail here.

## Diagnosis and Clinical Management of the Most Common Types of Neurologic Failure

### Traumatic Brain Injury

Traumatic brain injury (TBI) is the leading cause of death from blunt trauma, with an incidence of approximately 10 per 100,000 per year, and is the leading cause of death between 5 and 45 years of age. The most powerful predictors of poor outcome from injury through resuscitation are age greater than 55, poor pupillary reactivity, postresuscitation Glasgow Coma Scale (GCS), hypotension, hypoxia, and unfavorable intracranial diagnosis as established by radiological features (e.g., computed tomography [CT]). In addition, early hyperglycemia (>200 mg/dL) is a reliable independent predictor of poor outcome.

The GCS (see [Chapter 53](#)) is the most widely used clinical measure of injury severity in patients with TBI. The advantages of this scale are that it provides an objective method of measuring consciousness, it has high intra- and inter-rater reliability across observers with a wide variety of experience, and it has an excellent correlation with outcome. However, the GCS is not measurable in up to 25% to 45% of patients at admission, and is inaccurate when only the partial score is used, such as in patients with tracheal intubation whose verbal response cannot be assessed. TBI qualifies as severe when the GCS is 8 or less. The predictive value of the GCS at admission is about 69% for good neurologic outcome and 76% for unfavorable outcome. After 7 days these figures approximate 80% for both favorable and unfavorable outcome.<sup>24</sup>

Pupillary dilatation and light reactivity are also useful predictors of neurologic outcome after TBI. When both pupils are dilated and unreactive the likelihood of poor neurologic outcome or death is as high as 90% to 95%. When both pupils are reactive, the likelihood of poor neurologic outcome is approximately 30% to 40%, and the probability of good outcome is 50% to 70%.

In contrast, hypotension is a strong predictor of poor outcome in TBI. In one report, there was a 15-fold increased risk of mortality in patients with early hypotension and an 11-fold increase in mortality in patients with late hypotension.<sup>25</sup>

Radiological imaging is important in the diagnosis and prognosis of patients with TBI. A number of CT-based scoring systems have been developed and correlated with outcome, but the amount of midline shift appears to be the single most predictive feature of outcome. Subarachnoid blood, intraventricular blood, and diffuse axonal injury patterns portend worse outcomes, but epidural hematomas generally have better outcomes.<sup>26</sup> In addition, it should be noted that about one-third to one-half of TBI patients present with no imaging lesion at admission, but develop delayed lesions, which are associated with substantially worse neurologic outcome.

The goal of resuscitation in traumatic and other types of brain injury is to prevent continuing cerebral insult after a primary injury has already occurred. The extent of the primary cerebral injury is usually determined by the mechanism of the trauma, the cause, and duration of cerebral ischemia. A primary insult is often associated with intracranial hypertension and systemic hypotension, leading to decreased cerebral perfusion and brain ischemia. Concomitant hypoxemia aggravates brain hypoxia, especially in the presence of hyperthermia, which increases brain metabolic demand. The combined effect of these factors leads to secondary brain injury characterized by excitotoxicity, oxidative stress, and inflammation. The resulting cerebral ischemia may be the single most important secondary event to affect outcome following a cerebral insult. Prevention of secondary injury is the main goal of resuscitative efforts.

**2** Traumatized areas of the brain manifest impaired autoregulation and disruption of the blood–brain barrier. If space-occupying lesions or edema are present, these will contribute to reduced brain compliance, leading to increased ICP and consequent reduction in cerebral blood flow. The rationale for attempting to optimize cerebral perfusion pressure (CPP) arises from the assumption that cerebral regions surrounding the primary lesion may be close to the ischemic threshold. Therefore, the goals of neuroresuscitation are to **1** restore cerebral blood flow by maintenance of adequate CPP, reduction of ICP, evacuation of space-occupying lesions, initiation of therapies for cerebral protection, and avoidance of hypoxia.

Unfortunately, the ICU treatment of TBI is hindered by a lack of rigorous, randomized, controlled trials to prove benefit for many of the management strategies utilized today. The Brain Trauma Foundation has published Guidelines for the Management of Severe Traumatic Brain Injury, and revised them as recently as 2016.<sup>27</sup> However, only one recommendation in 28 subject areas is a Level 1 recommendation based on high quality evidence.

Furthermore, even rigorous studies generate more debate than consensus, as exemplified by a recent randomized, controlled trial of ICP-guided therapy versus imaging and clinical examination-based treatment that found no benefit to ICP monitoring.<sup>28</sup> Thus, treatment remains largely based on pathophysiologic principles and uncontrolled trials. A general guideline for management of patients with severe TBI appears in [Table 57-2](#). Basic principles of acute TBI management, including osmotherapy, are discussed further in [Chapter 53](#); however, sedation, hyperventilation, hypothermia, corticosteroids, and anti-seizure prophylaxis are discussed in further detail later.

Sedation of neurologically impaired patients should typically be achieved with short-acting sedatives to allow for frequent assessment by neurologic examination.<sup>29</sup> Although no studies have investigated the effect of sedation on outcome in such patients, a common practice is to provide sedation with propofol, benzodiazepines, or dexmedetomidine in patients following TBI. These agents have favorable effects on cerebral oxygen balance, although propofol is more potent in this regard. Undesirable effects of sedatives can lead to a reduction in CPP due to hemodynamic depression, or to an increase in cerebral blood flow and a simultaneous increase in ICP.

Propofol rapidly penetrates the central nervous system and has rapid elimination kinetics. Despite the induction of systemic hypotension, propofol decreases cerebral metabolism resulting in a coupled decline in cerebral blood flow, with a consequent decrease in ICP. Propofol's favorable pharmacologic and neurophysiologic profile has led to its widespread use in neurointensive care, and high-dose propofol has been advocated as a substitute for barbiturate therapy in patients with refractory intracranial hypertension. However, prolonged (>24 hours), high-dose (>80 µg/kg/min) propofol administration has been associated with lactic acidosis, cardiac failure, and death (propofol infusion syndrome) in children and adults with TBI.<sup>30</sup> Thus, the use of high-dose propofol to control refractory intracranial hypertension is not recommended, and barbiturates should be considered if ICP is not controlled by moderate doses of propofol.

**Table 57-2** ICU Management of Patients with Severe Traumatic Brain Injury

Basic principles applied to all patients, assuming initial surgical management	<ul style="list-style-type: none"> <li>• Head elevation 30–45 degrees<sup>a</sup></li> <li>• CPP 60–70 Torr               <ul style="list-style-type: none"> <li>■ Euvolemia, vasopressors as needed</li> <li>■ ICP &lt;20 Torr</li> <li>■ Mannitol, hypertonic saline</li> <li>■ CSF drainage</li> </ul> </li> <li>• SaO<sub>2</sub> ≥95%; PaCO<sub>2</sub> 35–40 Torr</li> <li>• Temperature ≤37°C</li> <li>• Glucose               <ul style="list-style-type: none"> <li>■ &lt;180 mg/dL</li> </ul> </li> <li>• Sedation and analgesia</li> <li>• Early enteral nutrition</li> <li>• Seizure, stress ulcer, and DVT prophylaxis</li> </ul>
Refractory intracranial hypertension Consider one or all of these interventions, depending on individual circumstances	<ul style="list-style-type: none"> <li>• Optimized hyperventilation with SjO<sub>2</sub> and/or PbrO<sub>2</sub> monitoring</li> <li>• Barbiturate coma</li> <li>• Mild therapeutic hypothermia (33°–35°C)</li> <li>• Decompressive craniectomy</li> </ul>

<sup>a</sup>Unless contraindicated by spine injury, hemodynamic instability, or otherwise.

ICU, intensive care unit; CPP, cerebral perfusion pressure; ICP, intracranial pressure; CSF, cerebrospinal fluid; SaO<sub>2</sub>, arterial oxygen saturation; PaCO<sub>2</sub>, arterial carbon dioxide tension; DVT, deep venous thrombosis; SjO<sub>2</sub>, jugular venous oxygen saturation; PbrO<sub>2</sub>, brain tissue oxygen tension.

The mechanisms by which barbiturates exert their cerebral protective effect appear to be mediated by a reduction in ICP via alteration in vascular tone, reduction of cerebral metabolic rate, and inhibition of free radical peroxidation. Although barbiturates are effective at reducing ICP, their routine use in TBI does not appear beneficial, and may in fact result in excess mortality in patients with diffuse brain injury.<sup>31,32</sup> This effect may in part relate to the profound cardiovascular depressant effects of barbiturates. Based on one small randomized trial, barbiturates do appear to reduce mortality in patients with refractory high ICP.<sup>33</sup> Thus, high-dose barbiturate therapy may be considered in hemodynamically stable, severe TBI patients with intracranial hypertension refractory to maximal medical and surgical ICP-lowering therapy. In some patients pentobarbital may induce cerebral hypoxia by reducing cerebral blood flow (CBF) in excess of metabolism, and therefore SjO<sub>2</sub> monitoring may be considered during barbiturate therapy.

The centrally acting  $\alpha_2$  agonist dexmedetomidine has both sedative and analgesic effects. Its most desirable property is that it can allow for a more interactive and awake patient than other sedatives. (See section on Sedation, later.) Although it has not been studied specifically in brain-injured patients, it has been shown that cerebral blood flow–cerebral metabolic rate of oxygen (CMRO<sub>2</sub>) coupling remains intact in healthy volunteers during dexmedetomidine infusion.<sup>34</sup>

Although neuromuscular blockade may result in a fall in ICP, the routine use of neuromuscular blockade is discouraged because its use has been associated with longer ICU stays, a higher incidence of pneumonia, and a trend toward more frequent sepsis without any improvement in outcome.

Hyperventilation effectively reduces ICP by reducing cerebral blood flow. However, the role that hyperventilation should play in routine management of TBI is not clear. Primarily, there are concerns that hyperventilation may lead to critically low cerebral blood flow, resulting in worsening cerebral ischemia.<sup>35</sup> In small randomized trials, prophylactic hyperventilation has not proven to be beneficial in TBI.<sup>36</sup> Based on the available evidence, prolonged or prophylactic hyperventilation should be avoided after severe TBI, especially in the first 24 hours after the injury. Hyperventilation may be necessary for brief periods to reduce intracranial hypertension refractory to sedation, osmotic therapy, and cerebrospinal fluid (CSF) drainage, and should be guided by SjO<sub>2</sub> and/or PbrO<sub>2</sub>.<sup>37</sup> A marked fall in either of these values suggests a harmful effect of hyperventilation, and that it should be reduced or discontinued.

Experimentally, hypothermia causes a reduction in cerebral metabolism by decreasing all cell functions related to neuronal electric activity and those responsible for cellular integrity. In addition, mild hypothermia has been shown to decrease the release of substrates associated with tissue injury such as glutamate and aspartate. However, numerous randomized trials of therapeutic mild hypothermia (33° to 35°C) in patients with TBI published over two decades and enrolling more than 1,000 total patients have failed to demonstrate a mortality benefit or improvement in neurologic outcome with hypothermia. In addition, a recent randomized, controlled trial of induced mild hypothermia for the treatment of refractory high ICP found worse outcomes at 6 months in the group treated with hypothermia.<sup>38</sup> Thus, induction of mild hypothermia in patients with TBI, either prophylactically or to treat high ICP, cannot be recommended.

An additional second-tier therapy to control refractory elevated ICP is decompressive craniectomy. While one large randomized trial of decompressive craniotomy for refractory high ICP in TBI (Decompressive Craniectomy [DECRA] trial) showed worse outcomes in the craniectomy group, a more recent large randomized trial of the same intervention with slightly different inclusion criteria (Randomized Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of Intracranial Pressure [RESCUEicp] Trial) showed a survival benefit with craniectomy. The apparently contradictory results have not yet been incorporated into the guidelines.<sup>40</sup>

Corticosteroids to reduce posttraumatic inflammatory injury in TBI were advocated for 30 years or more, but without convincing evidence of benefit.

The Corticosteroid Randomization after Significant Head Injury (CRASH) study, published in 2004, prospectively randomized over 10,000 patients presenting with acute TBI to receive high-dose methylprednisolone or placebo for 48 hours after hospital admission. Methylprednisolone administration was associated with an approximately 20% increase in the relative risk of death at 2 weeks in the entire cohort, and this detriment was evident across subgroups divided by severity and type of injury.<sup>41</sup> Thus, high-dose corticosteroids should not be administered as therapy for acute TBI.<sup>37</sup> Likewise, intravenous magnesium administration did not improve outcomes in patients with TBI, and might even have a negative effect in the treatment of significant brain injury.<sup>42</sup>

Anticonvulsants are effective at preventing early posttraumatic seizures within 7 days following TBI. However, the evidence does not indicate that prevention of early seizures improves outcome following TBI.<sup>43</sup> Seizures should therefore be treated on an as-needed basis.

Finally, it should be noted that use of albumin as fluid replacement therapy in patients with TBI has been associated with increased mortality in a subgroup analysis of a randomized controlled trial comparing saline and albumin.<sup>44</sup> Routine albumin administration to patients with TBI should be avoided.

## **Subarachnoid Hemorrhage**

The incidence of subarachnoid hemorrhage (SAH) in the United States varies from 7.5 to 12.1 cases per 100,000 of population. The rupture of an intracranial aneurysm most commonly causes SAH. Other causes of SAH include trauma, vertebral and carotid artery dissection, dural and spinal arteriovenous malformations, mycotic aneurysms, sickle cell disease, cocaine abuse, coagulation disorders, and pituitary apoplexy. Aneurysmal SAH is associated with considerable morbidity and mortality, with one-third of SAH patients dead before receiving medical attention, and only one-third of patients being functional survivors.<sup>45,46</sup> The leading causes of death and disability are the direct effect of the initial bleed, cerebral vasospasm with resulting stroke, and rebleeding. Although the number of early deaths may not have changed substantially, the overall case fatality rate of aneurysmal SAH has fallen over time, and is reported in the 40% to 50% range in most studies.<sup>47</sup> Approximately 40% to 50% of survivors have good neurologic outcome after SAH, as measured by the modified Rankin scale.<sup>47</sup> Severity of the initial bleed is the most important determinant of SAH outcome.

At the time of aneurysm rupture, a large hemorrhage results in a critical reduction in cerebral blood flow due to an increase in ICP toward arterial diastolic values. The persistence of a no-flow pattern is associated with acute

vasospasm and swelling of perivascular astrocytes, neuronal cells, and capillary endothelia. After SAH, injury to the posterior hypothalamus may stimulate release of norepinephrine from the adrenal medulla and sympathetic cardiac efferent nerves. The release of norepinephrine has been associated with ischemic changes in the subendocardium (neurogenic stunned myocardium or stress cardiomyopathy), cardiac dysrhythmias, and pulmonary edema.

In survivors of the initial bleed, management emphasizes early aneurysm control with either surgery or interventional neuroradiology (coiling). Approximately 10% to 23% of unsecured aneurysms will rebleed in the first 2 weeks, with approximately 6% occurring within the first 24 hours after the initial hemorrhage. Rebleeding is associated with a mortality rate of over 50%.<sup>48</sup> Early aneurysm occlusion substantially reduces the risk of this complication, and it is recommended that aneurysms be secured within 72 hours of rupture, and perhaps earlier in high-risk cases.

With the improvement of the operative management, delayed neurologic deterioration (DND)—due to cerebral vasospasm and delayed cerebral ischemia (DCI), cerebral edema, hydrocephalus, and the effects of fever and electrolyte abnormalities—has become an increasingly important cause of death and disability. In addition, patients can develop a number of medical problems related to either the SAH or associated critical illness.

Cerebral vasospasm after SAH is identified by angiography in up to 60% of patients, and is correlated with the amount and location of subarachnoid blood. A subsequent reduction in cerebral blood flow is ultimately responsible for the appearance of DCI, which occurs in approximately one-third of patients suffering from SAH. A systematic review of the literature found an overall death rate of 31% (vs. 17% in patients without vasospasm), permanent deficits in 35%, and good outcome in 34% of the patients who developed symptomatic vasospasm.<sup>49</sup> DCI typically presents as altered consciousness and/or transient focal neurologic deficits beyond the first 3 days after aneurysm rupture, typically peaks in 7 to 10 days, and resolves over 10 to 14 days. If severe, vasospasm can result in cerebral infarction and persistent neurologic deficits, which contribute to considerable long-term morbidity.

TCD has been used to identify and quantify cerebral vasospasm on the basis that blood flow velocity increases as the diameter of the vessel decreases. Changes in measured velocities over time may be more reliable than absolute values in predicting symptomatic vasospasm. Velocities greater than 200 cm/s have been associated with a high risk of infarction; however, there is poor correlation between TCD velocities and angiographic findings, especially for the posterior circulation.

Oral nimodipine (60 mg every 4 h for 21 days) is recognized as an

effective treatment to improve neurologic outcome (reduction of cerebral infarction and poor functional outcome) and mortality in SAH patients with vasospasm.<sup>50</sup> Because angiographic studies do not demonstrate a difference in the frequency of vasospasm compared with a placebo-treated group, the benefits of nimodipine have been attributed to a cytoprotective effect related to the reduced availability of intracellular calcium and improved microvascular collateral flow. No other pharmacologic therapies to prevent or treat cerebral vasospasm have conclusively demonstrated effective results in clinical trials. Although earlier studies suggested that statins may have a protective effect in preventing cerebral vasospasm and DCI, subsequent randomized trials have not borne this finding out.<sup>51</sup>

Hypervolemia, hypertension, and hemodilution (triple-H) therapy is 3 historically one of the mainstays of prevention and treatment of cerebral ischemia associated with SAH-induced vasospasm, despite the lack of strong evidence for its effectiveness, especially for prophylactic use.<sup>52</sup> Triple-H therapy evolved from the observed association of hypovolemia with poor outcomes after SAH, cerebral blood flow dysregulation, and the beneficial rheologic effects of anemia on cerebral blood flow. However, current consensus guidelines recommend modification of this strategy to include maintenance of euvolemia, avoidance of intentional hemodilution, and a controlled trial of stepwise blood pressure augmentation in patients with suspected DCI.<sup>53</sup> In addition, discontinuation of nimodipine is recommended if its administration results in hypotension. Careful monitoring for cardiopulmonary complications of hemodynamic therapy is recommended.

Interventional neuroradiology with the use of balloon angioplasty can reverse or improve vasospasm-induced neurologic deficits if initiated early after the development of ischemic symptoms. Although observational data suggest a beneficial effect of angioplasty on long-term outcomes, these findings have not been confirmed in randomized, controlled trials, and the risks of angioplasty include intimal dissection, vessel rupture, ischemia, and infarction.

Hydrocephalus is another cause of neurologic dysfunction after SAH, occurring in 25% of patients surviving the hemorrhage. The presence of blood in the ventricular system obstructs ventricular drainage and CSF absorption sites (subarachnoid villi). Ventricular drainage is usually successful in improving neurologic symptoms due to hydrocephalus. A minority of patients will require a permanent ventriculoperitoneal shunt. Seizures also occur in 13% of patients with SAH, and are more common in patients with a neurologic deficit; thus, prophylactic anticonvulsant therapy may be considered.<sup>53</sup>

Hyponatremia occurs in 10% to 34% of patients after SAH. Hyponatremia usually develops several days after the hemorrhage and is attributed to two

main causes: (1) a syndrome of inappropriate antidiuretic hormone (SIADH), which is associated with euvoemia or mild hypervolemia and an excess of free water, or (2) cerebral “salt wasting” with depletion of sodium and water. The differentiation of these two entities is difficult but important, because SIADH is treated by free-water restriction, whereas cerebral salt wasting is treated with volume repletion and sodium administration. Thus, assessment of intravascular volume status is a key component when deciding on the treatment regimen for hyponatremia associated with SAH. Urine electrolyte analysis is not discriminative, as urine sodium is high in both disorders, particularly in association with intravenous saline administration.

Other medical complications are relatively common after SAH and include pneumonia, neurogenic pulmonary edema and acute lung injury (ALI), stress (Takotsubo) cardiomyopathy, sepsis, and venous thromboembolism (VTE). Fever is highly prevalent after SAH and is associated with poor outcomes. Although fever is often due to noninfectious causes after SAH, a rigorous search for infection is necessary. Fever control is recommended during the risk period for DCI, particularly in high-risk patients.<sup>53</sup>

## Acute Ischemic Stroke

Although the incidence of stroke has declined over the past few decades, stroke affects nearly 800,000 people annually, and was the fifth leading cause of death in the United States as of 2013.<sup>54</sup> Nearly 90% of strokes can be attributed to an ischemic mechanism such as atherosclerosis, thrombosis, cardio-embolism, or hypotension. Other major causes of stroke are intracerebral and subarachnoid hemorrhage. Unusual causes of stroke such as carotid artery dissection, hypercoagulation syndromes, or infective endocarditis should be considered in younger patients without apparent risk factors. Transient ischemic attacks may precede stroke and should be considered as a warning sign. The prognosis after stroke varies depending on the size and location of the lesion. In patients with acute ischemic stroke, the duration of coma appears to be the most important predictor of outcome and successful therapy.

**4** Rapid clot lysis and restoration of circulation via systemic thrombolysis limits the extent of brain injury and improves outcome after thrombotic stroke. American Heart Association/American Stroke Association (AHA/ASA) guidelines recommend systemic thrombolysis using intravenous alteplase (rtPA) to patients presenting with acute ischemic stroke within 3 hours of symptom onset (barring contraindications), and up to 4.5 hours after symptom onset in select individuals.<sup>55</sup>

Accumulating evidence suggests that mechanical thrombectomy as an adjunct to systemic thrombolysis offers additional outcome benefits to select

patients with ischemic stroke. Thus, the AHA/ASA guidelines recommend stent retrieval of clot in patients who have received intravenous alteplase within 4.5 hours of symptom onset, who have evidence of internal carotid or proximal middle cerebral artery (MCA) occlusion, and in whom treatment can be initiated within 6 hours of symptom onset.<sup>56</sup>

Neither unfractionated nor low-molecular-weight heparin have been shown to prevent progression or reduce the rate of stroke recurrence when administered within 48 hours of the acute event, and therefore are not recommended. In general, heparin is only recommended for early secondary prophylaxis in patients with suspected cardiac embolism. Aspirin 325 mg has been shown to reduce the risk of early recurrent ischemic stroke. It is recommended within 24 to 48 hours of stroke onset in most patients, but it does increase the risk of hemorrhagic stroke. The frequency of deep venous thrombosis in acute stroke is reduced by anticoagulants (e.g., low-molecular-weight heparin), but not by antiplatelet agents. However, it is unclear if the frequency of pulmonary embolism is also reduced.

The majority of patients with acute ischemic stroke present with severe arterial hypertension. In theory, permissive hypertension should be allowed after stroke because reduction of the CPP could compromise the viable brain surrounding the ischemic region (ischemic penumbra), although high-level evidence to support this recommendation is lacking. However, severe hypertension (blood pressure >220/120 mmHg) should be controlled because of increased risk of hemorrhagic transformation; a lower threshold is indicated after alteplase administration (blood pressure >185/110). If the stroke is accompanied by raised ICP due to cerebral edema, the principles of treatment of raised ICP discussed earlier for TBI similarly apply. Cytotoxic brain edema usually occurs 24 to 96 hours after acute ischemic stroke, and osmotherapy constitutes the basis of ICP reduction, and possibly hemicraniectomy in select patients (see later). Steroids are of no value in the treatment of ischemic stroke, and although some have advocated therapeutic hypothermia, there is insufficient evidence to recommend this approach in stroke outside of research settings. As with SAH, fever is associated with poor outcome after ischemic stroke, and close temperature monitoring and management are recommended. Hyperglycemia is also associated with poor outcome in ischemic stroke, and it is recommended to monitor and maintain blood glucose within the range of 140 to 180 mg/dL.<sup>55</sup>

Hemispheric MCA infarction with subsequent cerebral edema, increased ICP, and herniation (malignant MCA syndrome) is often fatal. Randomized trials demonstrate that hemicraniectomy improves survival in this setting.<sup>57</sup> However, this benefit may come at the expense of increased and often severe disability in survivors. This seems particularly true for patients greater than 60 years of age.<sup>57,58</sup> Cerebellar infarction can likewise result in fatal

brainstem compression due to local edema. Case series suggest that suboccipital craniectomy can be life-saving in this situation, and that patients can recover with acceptable functional outcomes.<sup>55,59</sup>

## **Anoxic Brain Injury**

Anoxic brain injury most commonly occurs as a result of cardiac arrest, either in- or out-of-hospital. Of patients who survive their initial cardiac arrest, in-hospital mortality ranges from approximately 50% to 90%, and a high percentage of survivors suffer brain injury with significant long-term disability. The pathophysiology of anoxic brain injury is multifactorial, and includes excitatory neurotransmitter release, accumulation of intracellular calcium, and oxygen free radical generation. Unfortunately, pharmacologic therapies aimed at several of these pathways, including barbiturates, benzodiazepines, corticosteroids, calcium channel antagonists, and free radical scavengers have failed to improve the outcome of anoxic brain injury.

Based largely on two small, single-center randomized trials published in 2002 that showed outcome benefits, mild therapeutic hypothermia (target temperature 33°C) has been widely applied to unconscious patients who survive initial resuscitation from cardiac arrest due to ventricular fibrillation or tachycardia.<sup>60</sup> However, a much larger, multicenter randomized trial published in 2013 found no benefit to targeting a temperature of 33°C compared to 36°C.<sup>61</sup> Based on this study, therapeutic hypothermia can no longer be recommended as routine therapy after cardiac arrest. Strict fever control with a target temperature of 36°C appears to result in similar outcomes.

## **Cardiovascular and Hemodynamic Aspects of Critical Care**

### **Types of Shock**

One of the most common and urgent requirements for critical care is the presence of shock. Shock is a state characterized by tissue oxygen 5 delivery that is inadequate to meet demand. Often this is associated with circulatory instability and severe systemic hypotension. Shock states are commonly classified according to the primary cause of circulatory failure. Distributive (sometimes called vasodilatory) shock results from a reduction in systemic vascular resistance (SVR), often associated with an increased cardiac output (CO) as may happen in sepsis, anaphylaxis, or spinal cord injury. Cardiogenic shock results from left or right (or both) heart failure and is characterized by low CO and increased SVR. Hypovolemic shock is also associated with low CO and increased peripheral resistance, most commonly

due to hemorrhage. Obstructive shock, as the name suggests, is characterized by an obstruction to forward flow such as may happen with a tension pneumothorax, pericardial tamponade, or pulmonary embolism. The most common form of shock encountered in the ICU depends on the type of ICU, but septic, cardiogenic, and hypovolemic shock are most common. Shock of all kinds is highly morbid and despite extensive research and aggressive management, the mortality from shock remains staggeringly high. Approximately 35% to 40% of patients die within 28 days of the onset of septic shock, and the mortality rate is 70% to 80% for patients with cardiogenic shock. The mortality from hypovolemic shock is highly variable and depends upon the etiology and the rapidity of recognition and treatment. Mortality from septic shock may be improving, as evidenced by the fact that control-group mortality in sepsis trials has decreased from 46% to approximately 20% between 2001<sup>62</sup> and 2014,<sup>63–65</sup> although this may reflect broader screening and inclusion of less sick patients than in past trials. Cardiogenic and septic shock are discussed in more detail in the following section, whereas the causes and treatment of hypovolemic and obstructive shock are discussed in [Chapters 39](#) and [53](#).

## **Cardiogenic Shock**

The hallmark of cardiogenic shock is primary pump failure, which itself may be caused by extensive myocardial infarction (MI), nonischemic cardiomyopathy, dysrhythmia, or mechanical complication (e.g., mitral regurgitation, ventricular septal defect). The pathophysiologic characteristics include a reduction in contractility, usually accompanied by dilatation of cardiac cavities and venous congestion. Determining the etiology of cardiogenic shock is of utmost importance because the treatment varies considerably based on the underlying mechanism. For example, the role of  $\beta$ -blockers in the management of nonischemic decompensated heart failure has evolved to be of increasing importance<sup>66</sup> and diuresis is frequently indicated, whereas in acute ischemic ST elevation MI (STEMI)  $\beta$ -blockers are critical and there is little role for acute diuresis. A 12-lead electrocardiogram (ECG), serum troponin measurements, B-type natriuretic peptide levels, and echocardiography should be obtained in all patients presenting with heart failure, and is helpful in differentiating between the various causes of heart failure.<sup>67</sup>

The onset of pump failure is associated with two compensatory mechanisms: a reflex vasoconstriction in systemic vessels causing an increase in left ventricle (LV) workload and myocardial oxygen demand, and a redistribution of blood volume toward the heart and the lungs.

Several studies have demonstrated that the incidence and severity of LV

failure complicating acute MI are directly related to the extent of ventricular muscle necrosis. Consequently, therapy should minimize myocardial oxygen demand and raise oxygen delivery to the ischemic area. This goal is complicated by the fact that many resuscitative approaches to correct hypotension increase myocardial oxygen consumption (e.g., preload augmentation, inotropes, and vasopressors, as discussed later). In patients without hypotension, pharmacologic vasodilatation using nitroglycerin or sodium nitroprusside may reduce myocardial oxygen consumption and improve ventricular ejection by reducing LV afterload, and may also produce a shift of blood from the lungs to the periphery by reducing venous tone. Synthetic B-type natriuretic peptide (nesiritide) and dopamine agonists such as fenoldopam have similar effects, but have shown inconsistent benefit in large randomized trials and are not recommended for routine management.<sup>68,69</sup> When pharmacologic interventions are not sufficient to restore hemodynamic stability, the use of mechanical support with the insertion of intra-aortic balloon pump counterpulsation and ventricular assist devices can help unload the ventricles (see [Chapter 39](#)).

In patients with MI, coronary reperfusion can be achieved with systemic thrombolysis or, preferably, primary percutaneous coronary intervention (PCI). The American Heart Association/American College of Cardiology guidelines recommend treatment of STEMI by PCI within 90 minutes of presentation to PCI-capable centers, by thrombolytic therapy within 30 minutes of presentation to non-PCI-capable centers, or by rapid transfer under certain conditions of favorable timing.<sup>70</sup> Guidelines clearly favor PCI over fibrinolysis when both are feasible within the appropriate time frame. For patients with ischemia and cardiogenic shock, the addition of intra-aortic balloon counterpulsation to PCI in acute STEMI does not reduce infarct size<sup>71</sup> or mortality.<sup>72</sup> Data on the use of LV assist devices (LVADs) in the setting of acute ischemic cardiogenic shock are limited, but these may be effective devices to bridge patients in shock until recovery or transplant.<sup>73</sup>

Management of cardiac failure related to specific valvular abnormalities is discussed in [Chapter 39](#).

## Septic Shock

Septic shock is a form of distributive shock associated with infection and the activation of the systemic inflammatory response. It is usually characterized by a high CO, low SVR, hypotension, and regional blood flow redistribution that result in tissue hypoperfusion. Other noninfectious causes of distributive shock include acute spinal cord injury, pancreatitis, burns, fulminant hepatic failure, multiple traumatic injuries, toxic shock syndrome, anaphylactic and anaphylactoid reactions, and drug or

toxin reactions, including insect bites, transfusion reactions, and heavy metal poisoning. Septic shock is the most common shock syndrome, accounting for roughly two-thirds of shock patients in broad critical care populations.<sup>74</sup> Severe sepsis and septic shock account for at least 10% of ICU admissions, and septic shock is more common in the very young and very old, in men than in women, and in black patients than in white patients.<sup>75</sup>

In patients with systemic infections, the physiologic response can be staged on a continuum from sepsis to severe sepsis and septic shock (Table 57-3).

The initiating event in septic shock appears to be the interaction between organism-specific ligands on pathogens and ligand-specific receptors (e.g., toll-like receptors, nucleotide-binding oligomerization domain–like receptors, and others) on cells of the innate immune system. The resulting release of immune mediators sets in motion a complex series of events that results in altered gene expression, T-cell differentiation, complement activation, elaboration of pro-coagulant processes, and the production and release of other immunomodulatory cytokines. Together, these events produce the septic phenotype (e.g., microthrombi, endothelial dysfunction, capillary leak, vasodilatation, effective hypovolemia, hypoperfusion, and organ failure).<sup>75,76</sup>

Although the calculated CO often increases, and echocardiography often shows hyperdynamic LV function in early sepsis, this may be secondary to the decrease in SVR that is a hallmark of septic shock. LV contractility itself is depressed in many patients. A global decrease in cardiac contractility, combined with relative hypovolemia, may reduce oxygen delivery to tissues. Even in the case of normal or seemingly adequate CO and oxygen delivery, metabolic needs are increased during sepsis, and the ability of the tissues to extract and utilize oxygen may be impaired. Thus, a metabolic acidosis may be present despite normal levels of oxygen transport.<sup>77</sup> A decrease in cellular oxygen extraction capacity may result from factors other than hypoperfusion, such as direct cellular damage by toxins and/or mediators or maldistribution of blood flow. The impact of impaired perfusion on organ function depends on individual susceptibility to hypoxia. Though hypoperfusion is the suspected cause of lactic acidosis in sepsis, various degrees of intermediary metabolic alterations may contribute to the increased lactate production independent of perfusion, or when tissue oxygen tension is normal.<sup>77</sup>

**Table 57-3** Definitions of Sepsis and Organ Failure

**Sepsis:** Evidence of infection (either documented or suspected) and some of the following:

- Core temperature  $<36^{\circ}\text{C}$  or  $>38^{\circ}\text{C}$
- Tachycardia  $>90$  beats/min
- Tachypnea  $>20$  breaths/min while breathing spontaneously, or  $\text{PaCO}_2 <XX$  mmHg
- White blood count  $>12,000$  cells/ $\text{mm}^3$ ,  $<4,000$  cells/ $\text{mm}^3$ , or  $>10\%$  immature forms
- Altered mental status
- Hypotension (SBP  $<90$  mmHg, MAP  $<70$  mmHg, XX  $>40$  mmHg below normal or greater than 2 standard deviations below normal for age)
- Hyperglycemia (serum glucose  $>140$  mg/dL in the absence of diabetes)
- Plasma C-reactive protein or procalcitonin elevation ( $>two$  standard deviations above normal)
- Arterial hypoxemia ( $\text{PaO}_2:\text{FiO}_2 <300$ )
- Coagulopathy (international normalized ratio  $>1.5$ )
- Creatinine increase (rise in serum creatinine  $>0.5$  mg/dL)

**Severe Sepsis:** Ongoing organ dysfunction attributed to infection that persists despite adequate fluid resuscitation:

- Acute lung injury ( $\text{PaO}_2:\text{FiO}_2 <250$  in absence of pneumonia as source of infection or  $\text{PaO}_2:\text{FiO}_2 <200$  in presence of pneumonia as source of infection)
- Lactic acid elevation (above the lab normal range)
- Acute oliguria (urine output  $<0.5$  mL/kg/hr for two or more hours despite adequate fluid resuscitation)
- Coagulopathy (international normalized ratio  $>1.5$ )
- Thrombocytopenia ( $<100,000/\text{mL}$ )
- Bilirubin elevation ( $>2$  mg/dL)

**Septic Shock:** Sepsis with hypotension, despite adequate fluid resuscitation

**Multiple Organ Dysfunction Syndrome:** Presence of several altered organ functions in an acutely ill patient such that homeostasis cannot be maintained without intervention

SBP, systolic blood pressure; MAP, mean arterial pressure.

6

The hallmark of treatment of septic shock includes early antimicrobial therapy and source control, restoration of organ perfusion by augmenting circulating volume, stroke volume, and/or oxygen carrying capacity, and the management of the expected consequences of sepsis, organ failure, and critical care (e.g., infections, acute kidney injury [AKI], and VTE). These have been thoroughly investigated and discussed in the Surviving Sepsis Campaign Guidelines (summarized in [Table 57-4](#)), which provide an excellent review of the evidence for various components of therapy.<sup>78</sup>

Active screening protocols and resuscitation algorithms have enjoyed immense popularity and have been adopted widely, despite the lack of consistent benefit in organized trials<sup>62–65</sup> and poor adherence in evaluations of the implementation of care bundles.<sup>79–81</sup> Nevertheless, the practice of systematic, early, and aggressive attention, treatment, and monitoring has

such tremendous face validity that these strategies are likely to remain the standard of care for some time.

**Table 57-4** Management of Severe Sepsis and Septic Shock

- Initiation of early goal-directed resuscitation during the first 6 h after onset of sepsis
- Blood cultures to identify causative organisms before starting antibiotic therapy, and prompt imaging studies performed to identify potential source of infection
- Administration of empiric broad-spectrum antibiotics within 1 h of diagnosis, and reassessment of appropriate therapy upon availability of microbiology results
- Control of source of infection
- Administration of crystalloids as initial fluid resuscitation with consideration given to adding albumin when large volumes of crystalloid are required
- Avoidance of hetastarch formulations
- Initial fluid resuscitation volume of at least 30 mL/kg with additional fluid challenges continuing as long as there is hemodynamic improvement as assessed by either static or dynamic variables
- Use of norepinephrine as first-line vasopressor for a target MAP  $\geq 65$  mmHg
- Epinephrine may be added when an additional agent is needed
- Vasopressin may be added at a fixed rate as an adjunct to catecholamines, but should not be used alone
- Use of dopamine is recommended only in highly selected circumstances and should generally be avoided
- Consideration for dobutamine in low cardiac output states despite fluid resuscitation

- Targeting supranormal values of oxygen delivery is not recommended
- Stress-dose steroid therapy for septic shock only if blood pressure is poorly responsive to fluid and vasopressors
- Targeting a hemoglobin of 7–9 g/dL in the absence of tissue hypoperfusion, coronary artery disease, or acute hemorrhage
- Appropriate use of fresh frozen plasma and platelets
- Use of low tidal volume, limitation of inspiratory plateau pressure, and application of at least a minimal amount of positive end-expiratory pressure for ALI patients
- Elevation of the head of the bed to a semirecumbent position unless contraindicated
- Avoidance of routine use of pulmonary artery catheter in patients with ALI
- Use a conservative fluid strategy for patients with ALI who are not in shock
- Use of protocols for ventilation weaning and sedation/analgesia, with daily sedation interruption if using continuous infusion sedation
- Avoidance of neuromuscular blockade
- Use of bicarbonate to correct arterial pH above 7.15 is not recommended
- Consideration of limitation of life support when appropriate

ALI, acute lung injury.

## Monitoring and Resuscitation in Shock States

The primary goal of monitoring patients in or at risk for shock is to identify and measure the presence of hemodynamic instability and inadequate tissue oxygen delivery, so that interventions can be undertaken to improve these perturbations. Invasive monitors used in shock states can be separated into those that assess hemodynamics and CO, and those that assess the degree to which the metabolic needs of the patient are being met.

### 3 Hemodynamic Monitoring

Adequate circulating volume is a necessary condition of adequate stroke volume and oxygen delivery, although assessing this volume is difficult. Intravascular pressure assessments such as the mean arterial pressure (MAP) and central venous pressure (CVP) have tremendous face validity, a historical track record, and are easy to measure and understand. However, these measures have their faults. Clinicians adhere poorly to MAP goals<sup>82</sup> and high-quality data linking active MAP management to improved outcomes remain elusive.<sup>83,84</sup> Moreover, given the typically poor correlation between various MAP measurement modalities,<sup>84</sup> its use as a proxy for hemodynamic information is suspect.<sup>85</sup> Similarly, the CVP is a poor predictor of whether a patient's stroke volume will respond to fluid.<sup>86–88</sup> Like monitoring CVP and MAP, the pulmonary artery catheter (PAC) has theoretical utility and is discussed at length in [Chapter 26](#). However, despite the theoretical benefits, there are few data to support a positive effect of PAC utilization on mortality or other substantive outcome variables. Patient populations, including those with acute respiratory distress syndrome (ARDS), congestive heart failure, septic shock and high-risk surgical patients, have all been the subject of investigations targeting the effect of PAC use on outcome.<sup>89,90</sup> These trials have all failed to show benefit, and PAC use has greatly waned.

### Echocardiography

Both transthoracic echocardiography (TTE), and transesophageal echocardiography (TEE) provide accurate diagnostic information with regard to dynamic ventricular function, valvular anatomy, pericardial anatomy, and intracardiac pressures. Although TEE has long been used in the operating room and is discussed in detail in [Chapter 27](#) and Appendix 7, TTE use is becoming more widespread in the ICU as the size and cost of the equipment are decreasing. The major limitation of focused cardiac ultrasound is that it does not provide continuous monitoring and requires a high standard of training and experience. However, a number of studies have now shown that

with limited training, critical care physicians can accurately and rapidly perform focused cardiac ultrasound examinations. In one study, intensivists were provided with 2 hours of formal didactic training followed by 4 hours of hands-on training in focused point-of-care cardiac ultrasound. Using formal TTEs obtained by professional sonographers and interpreted by attending cardiologists as a gold standard, the intensivists were able to correctly identify ventricular dysfunction over 80% of the time.<sup>91</sup> Moreover, the use of ultrasound in general, and cardiac ultrasound in particular, frequently identifies conditions that alter clinical management. The role of focused cardiac ultrasound in the management of the critically ill will likely expand in the future, because the availability of the equipment and the dearth of other noninvasive methods for answering the relevant clinical questions are simply too compelling. Both TTE and TEE applications are discussed in more detail in Appendix 7.

## **Dynamic Respiratory Indices**

Positive pressure ventilation (PPV) has predictable effects on stroke volume in both normal subjects and critically ill patients, inasmuch as it reduces venous return and increases right ventricular afterload. During PPV there is an inspiratory reduction in right ventricular stroke volume due to decreased venous return and a subsequent reduction in LV end-diastolic volume appearing during the expiratory phase of the respiratory cycle. Therefore, the LV stroke volume varies cyclically with ventilation and is paralleled by a similar variation in systolic blood pressure and pulse pressure. These effects are more pronounced in patients on the steeper part of the Frank–Starling curve where, by definition, patients will enjoy a larger increase in stroke volume for a given increase in LV end-diastolic volume (i.e., a fluid bolus).

The relationship between these respirophasic changes in stroke volume and position on the Frank–Starling curve can be exploited to make inferences about a patient's likely response to fluid administration. A number of metrics to approximate these changes in stroke volume variation have been identified. These include systolic pressure variation (SPV) and pulse pressure variation, both of which utilize analysis of arterial waveforms. Thresholds indicating abnormal variation vary by device, but are generally in the range of 10% to 15%. The higher the degree of variation, the more stroke volume is changing with respiration, and, ultimately, the more likely the patient is to experience an increase in stroke volume with fluid administration. Compared to static measures such as CVP, systolic and pulse pressure variations are superior predictors of fluid responsiveness in patients with a variety of critical illnesses, including septic shock and ARDS, and following cardiac surgery.<sup>86–88,92,93</sup>

It should be noted that the use of these metrics has only been validated in patients who are tracheally intubated and receiving PPV. Spontaneous or noninvasive ventilation is associated with a different set of hemodynamic effects, and their relationship to volume responsiveness is being examined.<sup>94</sup> Furthermore, the majority of data were collected in patients receiving tidal volumes of at least 8 mL/kg, which is at the higher end of the acceptable range for patients with ARDS. Patients also need to be in a sinus rhythm; atrial fibrillation and frequent ectopy will alter the variation in arterial waveform amplitude independent of respirophasic changes, thereby exaggerating variation. Finally, because such analysis requires patients be synchronous with mechanical ventilation, study patients were generally deeply sedated, if not paralyzed. These pitfalls may limit generalizability of findings to patients in current ICUs, where a more restrictive approach to sedation and tidal volumes is frequently employed. Another important pitfall to dynamic respirophasic indices is that these measurements do not predict fluid responsiveness in patients with an open chest,<sup>95</sup> which may be becoming more frequent after complex cardiac surgery.<sup>96</sup>

### **Less-Invasive Cardiac Output Monitors**

A host of less-invasive (relative to PAC) CO monitors have come to market in the last decade. Some exploit the analysis of the systemic arterial pulse contour, and a range of other modalities such as transesophageal Doppler and bio-reactance exist.

Pulse contour analysis (PCA) integrates the area under the curve of the arterial waveform to approximate stroke volume. Two commercially available devices utilize either lithium dilution (lithium injected through a peripheral IV—LiDCO [Lidco Ltd., London, UK]) or thermal dilution (saline injected through a central venous catheter—PiCCO [Pulsion, Feldkirchen, Germany]) for initial calibration. They then derive changes in CO using PCA. This approach correlates well with thermodilution CO derived from a PAC in a variety of conditions, and has the advantage of providing continuous measurement without necessitating the placement of a PAC.<sup>97–100</sup> The PiCCO device also allows for measurement of intrathoracic blood volume using transpulmonary thermodilution, and may be a more accurate reflection of preload than static CVP measurements. Although further validation of these techniques in critically ill patients is necessary, the use of PCA may obviate the need for PACs to measure CO, particularly if combined with the measurement of central venous oxygen saturation (ScvO<sub>2</sub>) as an indicator of the balance between oxygen delivery and consumption.

A third PCA device, the FloTrac/Vigileo (Edwards Lifesciences, Irvine, CA), incorporates respirophasic changes into its calculation of stroke volume

and, unlike the other two PCA devices, does not require a dilution calibration. Randomized trials of the device in high-risk surgical patients generally show a reduction in complications and improvement in surrogate markers (e.g., length of stay)<sup>101,102</sup>; however, controversy persists<sup>103</sup> and high-quality data in the ICU are lacking.

Transesophageal Doppler sonography utilizes a small esophageal probe to monitor descending aortic blood flow velocity continuously. When combined with the cross-sectional area of the aorta, the blood flow velocity allows for calculation of CO. Like the PCA devices discussed earlier, transesophageal Doppler shows good correlation with more traditional methods of CO measurement such as PAC, but its ability to alter meaningful outcomes in the ICU setting is not established.<sup>104</sup> The disadvantages of this technique are that it is inaccurate if not positioned correctly, is easily dislodged, and it does not measure the ascending aorta output or the aortic cross-sectional area directly, but instead uses nomograms to determine aortic cross-sectional area.<sup>105</sup>

Perhaps the least invasive of the CO monitors utilizes of the concept of bioimpedance. These devices exploit the differential absorption of electrical current by pulsatile blood over time to estimate stroke volume. Using just four surface electrodes, the NICOM (Cheetah Medical, Newton Center, MA) is easy to place and has a low risk of complications. Although immediately appealing because of the simplicity, ease of use, and noninvasiveness, the CO derived from the NICOM does not seem to track well with other measures like the PAC<sup>106,107</sup> or transesophageal Doppler,<sup>108</sup> and as a part of a broader fluid resuscitation algorithm, the use of the device was not associated with improvements in relevant clinical outcomes.<sup>109</sup>

## Metabolic Monitoring

Although an adequate circulation is necessary for resuscitation, occult hypoperfusion is possible in the setting of seemingly adequate hemodynamic conditions.<sup>110</sup> Once goals for an adequate circulation are met, metabolic goals can be addressed to detect and treat such cellular hypoperfusion, using lactate clearance and venous oximetry.

As the product of anaerobic metabolism, lactate is an indicator of insufficient oxygen delivery to cells. As elevated lactate level decreases, improved perfusion is assumed, and organ function should improve. Clearance of lactate as a goal of resuscitation has been studied recently in patients with septic<sup>111</sup> and undifferentiated shock.<sup>112</sup> Both studies randomized patients to resuscitation algorithms closely mimicking Rivers' early goal-directed therapy (EGDT) for severe sepsis, and showed that patients being treated according to lactate clearance did as well or better than those being treated according to traditional EGDT. Although the relationship between measured lactate and

tissue hypoperfusion may not be as direct as it is physiologically intuitive,<sup>77</sup> these results suggest that lactate clearance is a reasonable monitoring strategy for the detection and resolution of hypoperfusion.

Venous oximetry, or assessment of mixed venous oxygen saturation (SvO<sub>2</sub>), aims to measure postorgan bed oxygenation as a means to infer the oxygen extraction ratio and make further inference about adequacy of oxygen delivery. Measurement requires a PAC, which requires technical skill and carries risk of complications. SvO<sub>2</sub> and ScvO<sub>2</sub> reflect the relationship between oxygen delivery (DO<sub>2</sub>) and oxygen consumption (VO<sub>2</sub>). A somewhat less invasive and less costly alternative to placing a PAC for the measurement of SvO<sub>2</sub> is to measure ScvO<sub>2</sub> via a central venous catheter. ScvO<sub>2</sub> is approximately 5 mmHg higher than SvO<sub>2</sub> in critically ill patients, but appears to correlate well with SvO<sub>2</sub> during changes in hemodynamic status.<sup>113</sup> Because ScvO<sub>2</sub> approximates true SvO<sub>2</sub>, trends in ScvO<sub>2</sub> closely mimic trends in SvO<sub>2</sub>,<sup>114</sup> but this is somewhat controversial.<sup>115,116</sup> The use of venous oximetry gathered tremendous attention after the publication of EGDT using venous oximetry in patients with severe sepsis.<sup>62</sup>

The level of ScvO<sub>2</sub> has been associated with high mortality in sepsis. Supranormal levels, whether present at the outset of treatment or after treatment, may be a marker of altered oxygen utilization and are associated with a high mortality.<sup>117,118</sup> The impact of venous oximetry on outcome, however, is mixed. Achieving ScvO<sub>2</sub> more than 70% was independently associated with improved mortality in a retrospective analysis of sepsis care bundles (the only care factor positively associated with mortality),<sup>79</sup> although a much larger and similar analysis did not find the same favorable association between ScvO<sub>2</sub> and mortality.<sup>80</sup> Moreover, three recent, well-conducted attempts to replicate Rivers' initial trial have shown little benefit to EGDT, a central component of which is the assessment of ScvO<sub>2</sub>.<sup>63–65</sup>

An important observation about monitoring technology must be recognized. Any individual technique is vulnerable to bias, contraindications, and error. Given the high stakes complexity of hemodynamic and metabolic assessment, the wisest approach is to understand the strengths and weaknesses of many possible strategies, apply the techniques most appropriate to a given patient with an eye toward possible bias, and interpret the information generated within the broader context of the patient's history, exam, and ever-changing clinical status.

## Acute Respiratory Failure

Acute respiratory failure is characterized by a derangement in pulmonary gas exchange or an imbalance between the work of breathing and respiratory muscle capacity, and is usually accompanied by hypoxemia and/or

hypercapnia. Indeed, in some cases respiratory failure may be caused by “nonrespiratory” issues (e.g., coma that results in the inability to protect the airway). Acute respiratory failure is a common phenomenon. Depending on the type of ICU, the majority of patients may be mechanically ventilated at any given time, and virtually all critically ill patients are mechanically ventilated for some portion of their ICU stay. Suffice it to say that the treatment of acute respiratory failure is primarily supportive, typically necessitates supplemental oxygen, and often requires mechanical ventilation with or without tracheal intubation. Acute respiratory failure typically resolves when the initiating condition is adequately treated. The following subsections will discuss basic principles of mechanical ventilation, some of the more challenging types of respiratory failure, and potential therapeutic approaches to respiratory failure.

### *Principles of Mechanical Ventilation*

Mechanical ventilation in the ICU is provided through the application of **7** positive pressure to the airway. At its simplest, a preset tidal volume **5** (volume control) or inspiratory pressure (pressure control) and rate provide minimum minute ventilation. Any breathing that the patient does above this preset minute ventilation is either supported (continuous mandatory ventilation [CMV]) or not (intermittent mandatory ventilation [IMV]). However, ICU ventilators have become increasingly powerful and complex, capable of delivering high inspiratory flows, and utilizing microprocessors that simultaneously monitor and respond to multiple characteristics of the respiratory circuit. Thus, ventilatory modes used today include pressure support ventilation, pressure control ventilation, volume control ventilation, pressure-regulated volume control ventilation, high-frequency ventilation, proportional assist ventilation, airway pressure release ventilation, synchronous intermittent mandatory ventilation, and others. In reality, despite strong regional, local, and individual biases, there is little evidence to suggest that the mode of mechanical ventilation contributes significantly to any major outcome measure, and the choice of mode is at this point largely one of clinician preference. Thus, this discussion will not dwell on specific modes of ventilation.

Mechanical PPV has been traditionally considered supportive therapy that is applied until the initiating cause of respiratory failure improves sufficiently, such that the patient is able to breath without assistance. However, evidence suggests that mechanical ventilation may be injurious in certain settings. Traditionally, tidal volumes of 10 to 15 mL/kg were routinely used to ventilate patients in the ICU. The use of such “supraphysiologic” tidal volumes (normal resting tidal volumes are 5 to 7 mL/kg) evolved from the

observation that the use of smaller-sized volumes was associated with the development of atelectasis and hypoxemia in anesthetized patients in the operating room. However, large tidal volumes can result in cardiovascular compromise, barotrauma, ventilator-induced or ventilator-associated lung injury (VILI or VALI), and excess mortality, as discussed later.

PPV results in increased intrathoracic pressure, which reduces venous return, and in turn results in reduced CO and blood pressure. In addition, PPV can result in alveolar overdistention and alveolar rupture, which manifests as pneumothorax, pneumomediastinum, and subcutaneous emphysema (barotrauma). Both of these effects are amplified in patients with obstructive lung disease (asthma and chronic obstructive lung disease [COPD]). In these patients, limitation of expiratory flow leads to air trapping and the development of intrinsic positive end-expiratory pressure, or “auto-PEEP.” Air trapping results in alveolar overdistention and increases the risk of barotrauma, and auto-PEEP can contribute substantially to increased intrathoracic pressure and cardiovascular depression. Auto-PEEP cannot be measured without holding exhalation for a prolonged interval (expiratory pause) with both inspiratory and expiratory ventilator valves closed; thus, auto-PEEP may not be appreciated unless actively sought. Auto-PEEP can also be detected by observing a failure of expiratory flow to return to zero prior to initiation of the next breath.

The development of air trapping and auto-PEEP leads to significant morbidity and mortality in patients with obstructive lung disease. Thus, the ventilatory strategy in these patients should focus on prolongation of the expiratory time, limiting minute ventilation by using low tidal volumes (6 to 8 mL/kg or less) and a low rate (8 to 12 breaths per minute), and by reducing the inspiratory time of the respiratory cycle. Low minute ventilation is often associated with hypercapnia and respiratory acidosis (permissive hypercapnia); however, this does not appear to be harmful, and the benefits of reduced air trapping and auto-PEEP far outweigh any possible detriment. In order to decrease inspiratory time, the inspiratory flow rate must increase, and this results in increased peak airway pressure. However, most of the peak pressure is dissipated in the endotracheal tube and large airways, and more importantly, end-expiratory, static or plateau, and mean airway pressures will fall with increased expiratory time. In order to accomplish these goals, deep sedation is often required, and rarely neuromuscular blockade must be used. The adoption of this type of ventilatory strategy in the 1980s and 1990s was associated with a dramatic reduction in mortality due to acute, severe asthma and respiratory failure, from as high as 23% to less than 5%.<sup>119</sup>

In contrast to barotrauma, VILI or VALI refers to microscopic injury to the lung due to overdistention (volutrauma) and cyclic reopening of alveoli (atelectatrauma). VALI has been well-demonstrated in numerous experimental

models, and is histologically similar to the features seen in ALI of other causes, with diffuse alveolar damage (DAD) and increased microvascular permeability.<sup>120</sup> In addition, VALI is associated with the systemic release of inflammatory mediators that may contribute to multiple organ failure. Clinically, patients felt to be at risk for VALI are those with abnormally low recruitable lung volumes, in particular those with ARDS. Thus, a “lung-protective” ventilatory strategy utilizing low tidal volume ventilation has been shown to reduce mortality when applied to patients with ARDS (see later). In addition, accumulating evidence suggests that the use of low tidal volume ventilation may reduce the risk of developing ARDS in critically ill patients.<sup>121,122</sup>

In summary, although tidal volumes of 10 to 12 mL/kg may still be indicated for some patients, in most cases an initial tidal volume of 8 mL/kg is probably appropriate, and volumes as low as 4 mL/kg may be appropriate in some cases. In addition, because lung volumes correlate with height rather than weight, tidal volume selection should be based on predicted or ideal body weight, rather than actual weight to avoid lung overdistention. Predicted body weight (PBW) can be calculated from the formula:  $PBW = 50 + 2.3 (\text{height [inches]} - 60)$  (males), or  $45.5 + 2.3 (\text{height [inches]} - 60)$  (females).

Although mechanical ventilation generally implies tracheal intubation (translaryngeal or tracheotomy), noninvasive positive pressure ventilation (NPPV) or continuous positive airway pressure (CPAP) can be delivered via a tight-sealing nasal or full-face mask. NPPV is applied using either standard ICU ventilators (typically set to pressure support or pressure control modes, with or without PEEP) or specially designed ventilators that deliver CPAP or bi-level positive airway pressure (Bi-PAP). These dedicated noninvasive ventilators generate high gas flow, can cycle between a high inspiratory pressure and a lower expiratory pressure, and can sense and respond to patient inspiratory effort. Originally developed for home ventilation in patients with obstructive sleep apnea and chronic respiratory failure, newer models are targeted for use in the ICU and incorporate monitoring packages that allow assessment of delivered tidal volumes and respiratory patterns. However, there is no evidence that the type of ventilator used for NPPV affects patient outcome, and the choice of equipment is typically based on availability and familiarity.

NPPV compared to standard therapy has been associated with improved outcomes in a variety of causes of respiratory failure, including cardiogenic pulmonary edema, COPD, and ALI in immunosuppressed patients.<sup>123,124</sup> Improved outcomes include the avoidance of endotracheal intubation, a reduction in complications associated with intubation including VAP, and reduced mortality. However, NPPV is not without risk, and has been

associated with increased complications, including a higher rate of MI in patients with cardiogenic pulmonary edema, and increased mortality in patients with respiratory failure after extubation.<sup>125,126</sup> Therefore, NPPV is best and most safely utilized when patient characteristics are ideal, including an awake, cooperative patient (with the exception of rapidly reversible obtundation due to hypercarbia), a low risk for regurgitation and aspiration of gastric contents, and a high likelihood that the process resulting in respiratory failure is rapidly reversible. Further research including larger, randomized trials of NPPV is necessary to better define the particular subgroups of patients who will benefit from this approach.

Another alternative to tracheal intubation and mechanical ventilation for patients with acute hypoxemic respiratory failure is the provision of oxygen through high flow nasal cannulae (HFNC), wherein a high concentration of heated and humidified oxygen is delivered at flow rates from 40 to 60 L/min. This technique not only delivers high inspired oxygen fraction (FiO<sub>2</sub>) but also generates low levels of PEEP and may reduce the work of breathing. A number of studies, including two recent, moderately sized randomized controlled trials, have shown outcome benefits of HFNC for acute hypoxemic respiratory failure in comparison to NPPV and conventional therapy.<sup>127,128</sup> HFNC is thus a viable first-choice alternative to NPPV or tracheal intubation in select patients.

**8** “Weaning” from mechanical ventilation is better termed “liberation” or “separation” from ventilation, because weaning implies that ventilation must be gradually withdrawn in order to allow respiratory muscle and patient adaptation to the process. In reality, separation from mechanical ventilation is more a function of the resolution of the cause of respiratory failure, rather than the technique used to withdraw ventilatory support. This is supported by a study showing that daily trials of unassisted ventilation (T-piece trials) resulted in more rapid separation from ventilation than other more gradual approaches, in particular IMV “weaning.”<sup>129</sup> In addition, so-called “weaning parameters” are inadequate predictors of the success or failure of withdrawal of ventilatory support, and add little to routine management. Thus, the process of separation from mechanical ventilation is expedited when respiratory therapy-driven protocols are used that focus on daily assessment of the ability to breath without assistance, assuming improvement of the inciting process, adequate oxygenation, and hemodynamic stability.<sup>130</sup> Once the patient can breathe comfortably for 30 to 120 minutes without support, the trachea can be extubated, assuming that there are not other precluding factors such as airway abnormalities, coma, and so forth.

## **Acute Respiratory Distress Syndrome**

ARDS is a syndrome of acute, hypoxemic respiratory failure marked pathologically by DAD, with resulting increased lung permeability and diffuse alveolar edema.<sup>131</sup> ARDS can occur as a result of direct injury to the lung (e.g., aspiration or pneumonia), or in association with extrapulmonary infection (sepsis) or injury (e.g., multiple trauma). ARDS and DAD are associated with an inflammatory cell infiltration of the lung, increased systemic markers of inflammation, and progression through exudative, fibroproliferative, and fibrotic phases of injury over days to weeks.

In order to better standardize the definition of ARDS for epidemiologic and research purposes, in 1994 a joint American-European Consensus Conference (AECC) proposed criteria for characterizing ARDS according to the severity of gas exchange abnormality, and distinguished ALI as a less severe version of ARDS, at least in terms of gas exchange.<sup>132</sup> Another multinational consensus conference convened in 2011 to refine the definition of ARDS; the resulting “Berlin Definition” eliminates the “ALI” term, adds more explicit criteria for the timing and presentation of the syndrome, and stratifies ARDS into three grades of severity according to gas exchange criteria.<sup>133</sup> Although the Berlin Definition performs better than the prior AECC definition in predicting mortality due to ARDS, its predictive value is still poor.

ARDS is highly prevalent in the ICU population and accounts for 10% to 15% of all ICU admissions.<sup>134</sup> Of predisposing factors, sepsis carries the highest risk (approximately 30%) and is the most common cause of ARDS. Mortality associated with ARDS appears to have fallen over the past 20 years, although this observation is mainly confined to randomized, controlled trials versus observational studies.<sup>134,135</sup> Moreover, ARDS mortality varies greatly with the population of patients studied; for example, ARDS mortality in trauma patients is 10% to 15%, whereas mortality in medical ICU patients is as high as 60%. Patients with ARDS continue to die primarily as a result of associated conditions (sepsis, multiple organ failure, etc.), and uncommonly die of hypoxemia per se.

Clinically, ARDS is characterized by reduced static thoracic (lung and chest wall) compliance and severe impairment of gas exchange, including high intrapulmonary shunt and dead space fraction. These mechanics and gas exchange abnormalities create a challenge in terms of optimizing mechanical ventilation, because maintenance of adequate oxygenation and carbon dioxide elimination are both problematic. In addition, although the ratio of PaO<sub>2</sub> to FiO<sub>2</sub> (P/F ratio) does not appear to predict mortality, high dead space fraction does, and may reflect the extent of pulmonary vascular injury.<sup>136</sup> Pulmonary hypertension often develops as the syndrome progresses, and can complicate hemodynamic management.

Although ARDS appears to be a diffuse process by chest x-ray, lung

opacification is surprisingly heterogeneous when the lung is imaged by CT. Areas of dense opacification are frequently confined to the posterior, dependent portion of the lung, leaving a small, relatively normal, recruitable volume available for ventilation. This low recruitable lung volume has been termed the “baby lung,” and has important implications for ventilatory management in ARDS, as discussed later.<sup>120</sup>

The treatment of ARDS is largely supportive, and includes aggressive 9 treatment of inciting events, avoidance of complications, and mechanical ventilation. In regards to the latter, it is critical that tidal volumes and static ventilatory pressures are minimized in order to avoid further injury to the remaining relatively uninjured lung. A large, randomized, prospective trial found that a small tidal volume (6 mL/kg or less) and low static (plateau) airway pressure ( $\leq 30$  cm H<sub>2</sub>O) resulted in a relative mortality reduction of 22% when compared to a control group ventilated with tidal volumes of 12 mL/kg.<sup>137</sup> This approach was corroborated in a similar, smaller trial.<sup>138</sup> This is the only intervention that has been unequivocally proven to reduce mortality in patients with ARDS.

Because ARDS is marked by high intrapulmonary shunt, hypoxemia is relatively unresponsive to oxygen therapy. Thus, strategies to recruit collapsed lung are necessary. This is most commonly achieved by using PEEP. The optimal balance between PEEP and FiO<sub>2</sub> has been long debated, but at this point there is no strong evidence to favor either a “high PEEP, low FiO<sub>2</sub>” or a “minimal PEEP, high FiO<sub>2</sub>” strategy.<sup>139</sup> Other maneuvers to promote recruitment of lung include the use of esophageal manometry to titrate PEEP and tidal volume, recruitment maneuvers or sigh breaths, pressure controlled ventilation, airway pressure release ventilation, inverse ratio ventilation (prolonged inspiratory time), prone positioning, and high frequency ventilation. Of these techniques, prone positioning alone is associated with improved survival. A meta-analysis of seven randomized, controlled trials of patients with ARDS and ALI and a subsequent multicenter, randomized, controlled trial found a mortality benefit to prone positioning in patients with severe ARDS.<sup>140,141</sup> Unfortunately, the difficult logistics of prone positioning likely discourage early use of this potentially life-saving procedure. A number of studies have compared high frequency oscillatory ventilation to conventional ventilation for treatment of ARDS, including several multicenter, randomized controlled trials. However, this intervention is not associated with improved outcomes, as confirmed in a recent meta-analysis.<sup>142</sup>

Inhaled vasodilators such as nitric oxide (iNO) and prostaglandins also variably and transiently improve oxygenation in ARDS by improving blood flow to ventilated alveoli. However, several randomized, prospective trials have failed to show any relevant long-term outcome benefits associated with iNO administration to patients with ALI/ARDS.<sup>143,144</sup> Prostaglandins have not

been as rigorously studied. Inhaled vasodilators may be useful as “rescue” therapy in selected patients with severe, refractory hypoxemia, although outcome benefits have not been established.

Given that ARDS is marked by high permeability pulmonary edema, it is intuitive that administration of excessive fluids be avoided. Results from a randomized, controlled trial found that a conservative fluid management strategy that emphasized diuresis resulted in improved oxygenation, more ventilator-free days, and more days not in the ICU, but no significant difference in mortality compared to liberal fluid management.<sup>145</sup> Another intervention to facilitate reduction of lung water in ARDS is co-administration of albumin with diuretics.<sup>146</sup> Similar improvements in fluid balance and oxygenation were again demonstrated, but this study was underpowered to detect a more meaningful mortality difference. Although a small study suggested that administration of inhaled  $\beta$  agonists might also enhance lung water clearance in patients with ARDS, a subsequent large randomized, controlled trial failed to show benefit to this therapy.<sup>147</sup>

Multiple therapies have been tested in an effort to halt the inflammatory and proliferative phases of injury, with mixed success. Corticosteroid administration to patients with ARDS has been associated with reduced mortality in two small, randomized trials and smaller case series and cohort studies.<sup>148,149</sup> A large randomized controlled trial sponsored by the ARDS Network randomized patients between days 7 and 28 of ARDS onset to methylprednisolone versus placebo.<sup>150</sup> Although there was no difference in 28-day mortality in the intention-to-treat analysis, patients receiving steroids between 7 and 14 days after ARDS onset appeared to benefit, but those starting treatment more than 14 days after ARDS onset appeared to suffer harm. Furthermore, the group receiving methylprednisolone had more ventilator-free days and shock-free days at day 28, in addition to improved oxygenation and respiratory system compliance. Thus, it appears that patients with ARDS may benefit from corticosteroid treatment within a narrow time window, but further study is necessary before strong conclusions can be drawn.

Additional areas of controversy in the management of patients with ARDS include the use of neuromuscular blockade and extracorporeal membrane oxygenation (ECMO). Although the use of neuromuscular blockade to facilitate mechanical ventilation of patients with ARDS has generally been on the decline due to fears of increased risk of critical illness myopathy, a French multicenter trial that randomized patients with severe ARDS (P/F ratio <150) to early treatment with cisatracurium versus placebo questions these fears.<sup>151</sup> The cisatracurium-treated group had a reduction in the adjusted hazard ratio for death, compared to the placebo group, and there was no increase in ICU-acquired paresis. Subsequent experimental data suggest that

the benefits of neuromuscular blockade in ARDS may be due to anti-inflammatory effects of nicotinic receptor inhibition.<sup>152</sup> Reservations about this approach remain, however, and further research is necessary before routine neuromuscular blockade for severe ARDS can be recommended.

The use of ECMO to support patients with severe ARDS had resurgence during the influenza pandemic of 2009, with some observational data suggesting a survival benefit to ECMO.<sup>153</sup> In addition, a UK-based multicenter trial randomized patients with severe ARDS to consideration for ECMO at a specialized referral center versus conventional treatment at their originating hospital. Patients randomized to ECMO consideration had an increased likelihood of disability-free survival at 6 months.<sup>154</sup> Skepticism remains regarding the widespread use of ECMO for management of severe ARDS given the invasive nature of this approach, cost considerations, and need for transfer to specialized centers.

## Acute Kidney Injury

AKI is reported to occur in up to 66% of critically ill patients.<sup>155</sup> In 2004, a consensus group proposed standard criteria for classifying the severity of renal injury and the associated outcomes.<sup>156</sup> The criteria, known as the RIFLE (risk of renal dysfunction, injury to the kidney, failure or loss of kidney function, and end-stage kidney disease) criteria, have been subsequently modified by the Acute Kidney Injury Network (AKIN) group, and most recently by the Kidney Disease: Improving Global Outcomes (KDIGO) group (Table 57-5).<sup>157,158</sup>

**Table 57-5** Kidney Disease: Improving Global Outcomes (KDIGO) Classification of Acute Kidney Injury

Stage	Serum Creatinine	Urine Output	In-hospital Mortality Odds Ratio
1	↑ Serum Cr $\geq 1.5\times$ baseline within 7 days OR ↑ Serum Cr $\geq 0.3$ mg/dl within 48 h	<0.5 mL/kg/h for 6–12 h	2.5
2	↑ Serum Cr $\geq 2\times$ baseline	<0.5 mL/kg/h for >12 h	5.4
3	↑ Serum Cr $\geq 3\times$ baseline OR ↑ Serum Cr $\geq 4$ mg/dL OR renal replacement therapy	<0.3 mL/kg/h for 24 h OR anuria $\times 12$ h	10.1

OR, odds ratio.

Diagnosis, evaluation, and management of acute kidney injury: a KDIGO summary (Part 1). *Crit Care*. 2013;17:204 and Mehta RL, Kellum JA, Shah SV, et al. Acute Kidney Injury Network: report of an initiative to improve outcomes in acute kidney injury. *Crit Care*. 2007;11(2):R31.

Despite the evolving definition of AKI, its incidence appears to be fairly stable over the past 20 years.<sup>159</sup> Moreover, the hospital mortality associated with AKI requiring dialysis has remained approximately 60% for nearly five

decades.<sup>159</sup> This is discouraging when one considers reductions in mortality in association with other organ failures over the same time interval. The reasons for the lack of improvement in outcome are unclear, but likely include insensitive means for identifying patients with incipient renal failure and lack of effective preventive and therapeutic measures.

In the ICU, AKI occurs due to prerenal causes and tubular injury (acute tubular necrosis) in the vast majority of cases.<sup>159</sup> Other potential causes of AKI in the ICU include glomerulonephritis, vasculitis, interstitial nephritis, macro and microvascular disease (e.g., thrombotic thrombocytopenic purpura), toxins (nonsteroidal anti-inflammatory drugs, cisplatin, aminoglycosides, radiologic contrast, myoglobin, and hemoglobin), and urinary tract obstruction. The initial evaluation of AKI should focus on identifying easily correctable causes; thus, assessment of volume status utilizing functional hemodynamic monitoring, identification of nephrotoxic agents through careful history taking and medication review, urinalysis to identify possible glomerulonephritis or interstitial nephritis, and ultrasonography to rule out postrenal or obstructive sources of AKI are all important.

In incipient and established AKI, supportive care is the rule, with the focus on maintenance of euolemia, avoidance of renal toxins, adjustment of medication doses, and monitoring of electrolytes and acid–base status. Pharmacologic approaches to the prevention and treatment of AKI have been uniformly disappointing. Current guidelines recommend against the use of low-dose dopamine, recombinant atrial natriuretic peptide, fenoldopam, colloid solutions, and diuretics for the prevention and treatment of AKI.<sup>155</sup> In the specific setting of contrast-induced nephropathy, the first intervention is avoidance of contrast exposure whenever possible. If contrast must be used, low- or iso-osmolar contrast agents, pre- and postcontrast exposure intravascular volume expansion with saline or sodium bicarbonate solutions, and possibly the use of oral (but not intravenous) *N*-acetyl cysteine may be useful.<sup>155</sup>

Although hemodialysis (i.e., renal replacement therapy [RRT]) is typically considered a supportive measure in AKI, recent interest has focused on the potential for RRT to improve renal recovery and reduce mortality. Research on RRT in the ICU has focused on the type, intensity, and dose of dialysis; the timing of initiation of RRT is also of interest, but has not been rigorously studied in this setting.

The intensity of RRT is determined by both the frequency of treatment and the degree of solute clearance per unit of time. Increased intensity of RRT has failed to improve outcomes in critically ill patients with AKI in two large, randomized clinical trials.<sup>160,161</sup> However, it should be noted that the prescribed intensity of RRT is seldom delivered in clinical practice owing to

therapy interruptions for procedures or when filters require replacement. As such, efforts to ensure maximal delivery of the prescribed RRT dose are important.

Continuous renal replacement therapy (CRRT) (including continuous venovenous hemofiltration and hemodialysis) has long been known as a useful technique when hemodynamic instability is present. In contrast to intermittent hemodialysis, effective solute removal is possible with CRRT in the presence of arterial hypotension. Despite this theoretical advantage to CRRT, several studies, including a relatively large, multicenter randomized controlled trial, found no survival benefit to CRRT compared to intermittent hemodialysis.<sup>162</sup> The two techniques are considered equivalent.

## Endocrine Aspects of Critical Care Medicine

### *Glucose Management in Critical Illness*

Hyperglycemia is commonly encountered in critically ill patients and occurs in both diabetics and nondiabetics. Hyperglycemia results primarily because of increased glucose production and insulin resistance caused by inflammatory and hormonal mediators that are released in response to injury. Hyperglycemia may also be aggravated by various therapeutic and supportive interventions, including the use of corticosteroids and total parenteral nutrition. Although the risks of hyperglycemia for patients with diabetes who are ketosis-prone have long been appreciated, hyperglycemia is also detrimental to critically ill patients in a broader sense. Hyperglycemia is associated with increased risk of postoperative infection (wound and otherwise) and poor outcome in patients with stroke, TBI, and AKI.<sup>155,163</sup> In addition, the blood glucose level is a risk factor for mortality in diabetic patients admitted with acute MI.<sup>164</sup>

Given these considerations, strict glycemic control in critically ill patients has been advocated as leading to multiple outcome benefits. A single randomized controlled trial of surgical patients published in 2001 found that intensive insulin therapy (goal glucose <110 mg/dL) reduced ICU mortality by approximately 50% compared to more conventional therapy (goal glucose <215 mg/dL).<sup>165</sup> Based largely on the results of this one trial there was widespread adoption of protocols to target blood glucose between 80 and 110 mg/dL. Unfortunately, the benefits of the initial trial were not reproduced in multiple subsequent trials, and in fact an increased risk of hypoglycemia and associated harm have been observed.<sup>166</sup> After an additional large, multicenter, multinational randomized controlled trial of intensive insulin therapy (NICE-SUGAR [Normoglycemia in Intensive Care Evaluation–Survival Using Glucose Algorithm Regulation] study) showed increased mortality in the tight glucose

control group, the practice of maintaining blood glucose between 80 and 110 mg/dL was widely abandoned.<sup>167</sup> Current serum glucose targets are somewhat variable, but most agree that 140 to 180 mg/dL is an acceptable goal in most patients.

### **Adrenal Function in Critical Illness**

The stress response to injury includes an increase in serum cortisol levels in most critically ill patients.<sup>168</sup> However, adrenal insufficiency may also occur in critically ill patients for several reasons, including inhibition of adrenal stimulation or corticosteroid synthesis by drugs or cytokines and direct injury to or infection of the pituitary or adrenal glands.<sup>169</sup> Thus, adrenal insufficiency has been reported to occur with increased frequency in critically ill patients with trauma, burns, sepsis, and other conditions in comparison with the general population.

The diagnosis of adrenal insufficiency in critical illness is complicated by limitations of commonly used tests of adrenal function. Cortisol is highly protein bound, and serum proteins, including albumin, are commonly depressed in critically ill patients. Although total serum cortisol levels are low in critically ill patients with hypoproteinemia, free cortisol levels are elevated.<sup>170</sup> This suggests that older reports utilizing total serum cortisol levels in critically ill patients may overestimate the incidence of adrenal insufficiency. However, until free cortisol assays are more widely available, the diagnosis of adrenal insufficiency in critical illness must be based on clinical suspicion and total cortisol levels.

In addition to absolute adrenal insufficiency (low baseline cortisol and poor response to adrenocorticotropic hormone [ACTH] administration/stimulation), a condition of relative adrenal insufficiency (defined as an increase in serum cortisol of  $\leq 9$   $\mu\text{g/dL}$  in response to ACTH administration, independent of the baseline cortisol level) has been described in patients in septic shock and with other illnesses. Low-normal baseline cortisol levels, high baseline cortisol levels, and a poor response to ACTH are all predictors of increased mortality in critical illness.<sup>37</sup>

Although high-dose corticosteroids for the treatment of septic shock are of no benefit, evidence suggests that lower doses (hydrocortisone 200 to 300 mg/day) can reduce dependency on vasopressors and shorten the duration of shock. Evidence for a mortality benefit is unclear, with some trials showing improved mortality and others showing lack of efficacy. A 2015 meta-analysis suggests that there is currently low quality evidence supporting a small mortality benefit with the use of low-dose hydrocortisone (200 to 300 mg/day or equivalent) in sepsis, but that the incidence of metabolic derangements is also increased.<sup>171</sup> Given the lack of clear benefit, current

guidelines suggest a trial of low-dose hydrocortisone only in patients with vasopressor-dependent septic shock.<sup>78</sup> There does not appear to be an increased risk of gastric ulceration, superinfection, or neuromuscular weakness according to this analysis, but hypernatremia and hyperglycemia are more common in patients receiving steroids.

### ***Thyroid Function in Critical Illness***

Measures of thyroid function, including levels of thyrotropin (TSH), T<sub>3</sub>, and T<sub>4</sub>, are deranged in the majority of critically ill patients. Depression of T<sub>3</sub> occurs within hours of injury or illness and can persist for weeks. TSH levels may be normal initially, but fall to inappropriately low levels as illness progresses. T<sub>4</sub> levels are also often low, but can be normal or high. Low hormone levels may occur for a variety of reasons, including altered binding and metabolism early in the course of illness, and depressed neuroendocrine function with more prolonged courses. In addition, certain drugs (e.g., dopamine) can depress thyroid function through central mechanisms.<sup>172</sup> Low thyroid hormone levels, particularly T<sub>3</sub>, correlate with the severity of illness and are associated with an increased risk of death.<sup>168</sup>

It is controversial whether the observed abnormalities in thyroid hormones represent an appropriate response to illness or true hypothyroidism; thus, the terms “euthyroid sick syndrome” and “nonthyroidal illness” have been coined to describe thyroid function abnormalities in critical illness. Furthermore, it is not clear whether replacement of thyroid hormones is indicated or beneficial in critical illness. T<sub>3</sub> administration to brain-dead organ donors appears to improve hemodynamic stability, although randomized trials have found minimal or no benefit to T<sub>3</sub> or T<sub>4</sub> administration in patients undergoing cardiopulmonary bypass and cardiac surgery.<sup>173</sup> In addition, several small studies have found no benefit to T<sub>3</sub> or T<sub>4</sub> administration to patients with a variety of critical illnesses. Larger, randomized prospective trials are necessary to define the role of routine thyroid hormone supplementation in nonthyroidal illness.

Importantly, true hypothyroidism may be present in the critically ill, particularly in the geriatric population, and should be considered in the face of refractory shock, adrenal insufficiency, unexplained coma, and prolonged, unexplained respiratory failure. True hypothyroidism is marked by an elevation of TSH (usually >25 mU/L) in the face of a low T<sub>4</sub> level.

### ***Somatotropic Function in Critical Illness***

Growth hormone (GH) levels are low in prolonged critical illness, and it has been conjectured that deficiencies of GH and insulin-like growth factor-1

(IGF-1) contribute to the muscle wasting seen in acute illness.<sup>168</sup> However, although small trials have found that GH administration can attenuate muscle catabolism in critical illness, a large, randomized trial found that administration of high-dose GH to critically ill patients resulted in increased mortality.<sup>174</sup> Thus, GH administration during critical illness cannot be advocated at this time, although further exploration of the benefits of smaller doses of GH may be warranted.

## Anemia and Transfusion Therapy in Critical Illness

Anemia is a frequent if not obligate accompaniment of critical illness. The vast majority of patients admitted to the ICU are anemic at some point in their hospital stay, and approximately 40% of them will receive transfused blood.<sup>175</sup> Importantly, both anemia (hemoglobin [Hb] <9 g/dl) and the amount of transfused blood are independently associated with mortality.<sup>176,177</sup> However, this association does not denote cause and effect, particularly for anemia, which may just be a marker of the severity of illness.

The cause of anemia in critical illness is multifactorial, and related to blood loss from the primary injury or illness, iatrogenic blood loss due to daily blood sampling, nutritional deficiencies, and marrow suppression.<sup>178</sup> Given that approximately 13% of ICU patients may have iron, folate or vitamin B<sub>12</sub> deficiencies, these parameters should be checked when consideration is given to blood transfusion.

Treatment of anemia in critical illness is the source of considerable debate. In unstressed subjects, severe anemia (Hb of 5 g/dL or less) is amazingly well tolerated due to physiologic compensations that maintain oxygen delivery and extraction. However, it has long been assumed that critically ill patients have less efficient compensatory mechanisms and reduced physiologic reserve, and thereby require a higher Hb concentration than unstressed individuals. Historically, this has translated to a red blood cell (RBC) transfusion threshold at an Hb concentration of approximately 10 g/dL. This is reflected in **10** data from multiple studies supporting the prevalence of RBC transfusion in the ICU; approximately 40% of ICU patients receive an RBC transfusion at an average transfusion threshold of 8.5 g/dL.<sup>175</sup>

Transfusion of RBCs is not without risks including infection, transfusion-related acute lung injury (TRALI), transfusion-associated circulatory overload (TACO), transfusion-related immunomodulation (TRIM), microchimerism and more (see [Chapter 17](#) for a more complete discussion of transfusion risks).<sup>175</sup> These negative effects of transfusion may help explain why a large, **11** randomized, controlled trial of transfusion requirements in critical illness (the TRICC [transfusion requirements in critical care] study) found that 30-day mortality was not affected when a restrictive transfusion threshold (Hb

<7 g/dL) was used, compared to a more conventional threshold of less than 10 g/dL.<sup>179</sup> Furthermore, a trend in mortality reduction favored the restrictive group, and various subgroups of patients (less than 55 years of age and less severely ill by APACHE [acute physiology and chronic health evaluation] scoring) had a significantly lower mortality when they were transfused using the restrictive strategy. A similar trial in pediatric patients found no mortality difference between restrictive and liberal transfusion strategies, suggesting that a restrictive strategy is safe in critically ill children.<sup>180</sup> More recent studies in patients with TBI<sup>181</sup> and acute upper gastrointestinal hemorrhage<sup>182</sup> confirm that restricting RBC transfusion to an Hb concentration of less than 7 g/dL reduces exposure to blood products, reduces complications, and in the case of upper gastrointestinal hemorrhage improves survival. Likewise, liberal RBC transfusion as part of goal-directed therapy that has been incorporated into the protocol for septic shock did not favorably affect outcomes.<sup>183</sup> These studies support clinical practice guidelines that recommend a restrictive transfusion practice in the ICU, with the possible exception of patients with active myocardial ischemia.<sup>175</sup>

Alternatives to the transfusion of RBCs for treatment of anemia are not currently available for widespread use. Several hemoglobin-based oxygen carriers (HBOCs) have been studied in clinical trials involving trauma and surgery, but results have been mixed, and none are currently FDA approved for use. Compassionate use of HBOCs in patients who have refused blood transfusion for religious reasons has been reported.

Prevention of anemia in critical illness is an appealing alternative to transfusion. One simple and potentially cost-saving approach is to reduce the volume and frequency of blood draws in the ICU. As noted earlier, iatrogenic blood loss is a major factor in the development of anemia of critical illness. Another potential approach is the administration of recombinant erythropoietin and iron. A large randomized controlled trial found that administration of recombinant erythropoietin to critically ill patients on day 3 of ICU stay and every week thereafter reduced transfusion requirements significantly, without affecting mortality or other outcome variables.<sup>184</sup> However, a subsequent randomized controlled trial with a lower recommended transfusion threshold found no reduction in blood transfusion in association with erythropoietin administration.<sup>185</sup> Although there was a reduction in mortality in trauma patients who received erythropoietin compared to placebo, a subsequent randomized, controlled trial in patients with TBI did not reveal an outcome benefit to the administration of erythropoietin.<sup>181</sup> Given the current high cost of erythropoietin, it is not a cost-effective alternative for general use in critical care at this time, but further investigation of its utility in trauma patients may be warranted.

## Nutrition in the Critically Ill Patient

Critical illness can lead to hypermetabolic states, and if nutritional support is inadequate or delayed, patients are at immediate risk of malnutrition. Poor nutritional status is associated with increased mortality and morbidity among critically ill patients. Therefore, appropriate nutrition is an important aspect of critical care and adequate nutritional support should be considered a standard of care. What constitutes *adequate* nutritional support, however, remains less clear. Although current guidelines recommend providing 80% to 100% of predicted caloric needs as soon as possible during an ICU admission, a growing body of research suggests no harm to intentional underfeeding (providing 20% to 50% of predicted caloric needs).<sup>186,187</sup> Although over 200 formulas have been promoted for predicting daily calorie requirements of the critically ill patient, the American Society for Parenteral and Enteral Nutrition (ASPEN) and SCCM guidelines do not specify any specific formula.<sup>188</sup> It is acceptable to use a simple formula based on the patient's ideal body weight to calculate predicted caloric needs (25 to 30 kcal/kg/day), of which 15% to 20% should be represented by proteins (1.2 to 2 g/kg/day).

Feeding intolerance due to high gastric residual volume can be improved by the administration of gastric prokinetic agents and positioning an enteric tube postpyloric. However, a systematic review comparing gastric versus postpyloric feeding did not suggest a clinical benefit from postpyloric tube feeding with regard to pneumonia, ICU length of stay, and mortality.<sup>189</sup> There is some suggestion that intermittent enteral feeding, as opposed to a continuous feeding regimen, is more likely to allow earlier attainment of the enteral calorie goal.<sup>190</sup>

Most of the trials evaluating parenteral nutrition (PN) do not demonstrate any favorable impact on outcome. In fact, enteral nutrition (EN) is associated with lower infection risk and PN is associated with increased rates of complications and death. Therefore, EN is preferred over PN whenever possible because of its lower cost and less frequent complications.<sup>191</sup> Although not rigorously investigated, PN may be considered in patients unable to tolerate EN. There has been considerable debate regarding the timing of initiation of PN, with Canadian and American guidelines generally recommending delayed initiation, while European guidelines have recommended early initiation.<sup>188,192</sup> A prospective randomized trial comparing initiation of PN at or before ICU day 2 with PN initiation at ICU day 8 showed the delayed initiation group had a decrease in infections, shorter duration of mechanical ventilation, less need for RRT, and a cost savings.<sup>193</sup> However, it is unclear how long of a delay in initiating PN is acceptable, assuming that EN is contraindicated or not tolerated despite vigorous attempts. Overall, strategies to optimize delivery of EN (starting at

the target rate, use of a feeding protocol with a higher threshold of gastric residuals volumes, use of motility agents, and use of small bowel feeding) and minimize the risks of EN (elevation of the head of the bed) should be considered. Studies that demonstrate a benefit from the use of supplemental PN in patients unable to tolerate adequate EN are lacking.<sup>191</sup>

Among special enteral formulations, immunonutrition has been hypothesized to influence infectious morbidity and mortality in critically ill patients via a beneficial effect on gastrointestinal immunologic function. This effect appears more likely in surgical patients, such as those with burns and those who are in trauma. Specific enteral formulations, particularly those with high concentrations of glutamine, have the strongest data to support their use.<sup>194</sup> The beneficial effects in medical ICU patients are less well established, and two recent randomized controlled trials found no benefit to nutritional supplementation with immunomodulatory agents in patients with ALI.<sup>195,196</sup> Trials supporting the administration of supplemental antioxidant micronutrients (selenium, zinc, and vitamins A, C, and E) are of overall low quality with high risk of bias and should be interpreted with caution.<sup>197</sup>

## **Sedation and Analgesia for the Critically Ill Patient**

### **Goals and Assessment**

Most patients in the ICU will experience some form of pain, agitation, or anxiety during their admission, and the indications for sedation and analgesia in the ICU are many. Although individual medications frequently provide multiple pharmacodynamic effects, including sedation, analgesia, and anxiolysis, it is helpful to think about these effects separately when selecting medications for an individual patient. For instance, painful procedures such as the insertion of indwelling catheters, endotracheal tubes, and thoracostomy tubes require analgesia, but often do not require anxiolysis or sedation. Conversely, agitated delirium or acute alcohol withdrawal do not require analgesia and are more appropriately treated with sedatives.

The goal of any sedation and analgesia strategy in the ICU is to provide enough medication to effectively treat patient symptoms, but to avoid adverse effects such as delirium, long-term cognitive deficits, and respiratory depression that are associated with overtreatment. The patient with an ideal level of sedation and analgesia is at reduced risk for dislodging catheters, removing monitoring devices, or falling out of bed. They are more likely to be synchronous with the mechanical ventilator, which improves oxygenation and reduces the risk of lung injury. They are also better able to participate with care, early mobilization, and physical and occupational therapy.

Assessing the adequacy of attempts to achieve these goals can be difficult.

Several factors such as inter-individual variability, evolving severity of disease and organ dysfunction, variably intense pain stimuli and multiple drug interactions influence the analgesic and sedative needs of ICU patients. Therefore, it is important to titrate medications according to established therapeutic goals and reevaluate sedation requirements frequently. Several validated scales are available to assess sedation levels over time. The most commonly used are the Ramsay sedation scale, the Riker sedation–agitation scale (SAS), and the Richmond agitation–sedation scale (RASS). Features common to all of these scales are the ability to grade sedation over different depths and allow for indicators of agitation. There is no evidence that one scale is superior to another at this time, although the RASS has been more rigorously assessed for reliability and validity.<sup>198,199</sup> Similarly, there are a variety of validated pain scales. These scales are discussed in [Chapter 55](#). The important point regarding assessment scales for pain, sedation, and delirium is that an assessment utilizing a validated scoring system should be made before and after every intervention to assess progress in achieving treatment goals.

### *Pharmacologic Management*

Virtually any hypnotic-anxiolytic or opioid used in the operating room can be used in the ICU to provide sedation and analgesia, respectively. However, propofol, midazolam, and dexmedetomidine are the most commonly used hypnotic-anxiolytics. Each of these drugs has its own particular advantages and disadvantages, and detailed discussions of their properties can be found in [Chapters 19](#) and [20](#). Some important considerations of their use in the ICU environment are discussed here.

Dexmedetomidine is unique in that its mechanism of action is profoundly different from that of propofol and benzodiazepines. It provides sedation without inducing unresponsiveness or coma, may have some analgesic effects,<sup>200,201</sup> and has little effect on respiratory drive. Generally speaking, however, dexmedetomidine is effective for patients who do not require deep sedation (e.g., patients with severe ARDS requiring aggressive mechanical ventilation). Because it does not reliably produce amnesia, it is not appropriate as a solo hypnotic-anxiolytic in patients requiring paralysis. Propofol is generally more effective in these settings, but can cause hypertriglyceridemia and lead to the potentially lethal “propofol infusion syndrome.”

Benzodiazepines may be a good choice in patients who require deep sedation or amnesia (e.g., during the co-administration of neuromuscular blockers), but who have hypotension or shock. They are also effective in patients with alcohol withdrawal. Neither randomized nor retrospective data

support dexmedetomidine use in patients with alcohol withdrawal, in terms of meaningful clinical outcome.<sup>202,203</sup> Although dexmedetomidine may reduce short-term benzodiazepine use in this situation, it does not reduce long-term use or improve symptom control.

Although the aforementioned physiologic rationale for the choice of a certain regimen exists, certain regimens may be superior in terms of patient outcomes of untoward neurocognitive effects, time on the ventilator, and length of stay. A large, well-conducted study<sup>204</sup> (two separate arms, no institutional cross-over) comparing dexmedetomidine with either propofol or midazolam demonstrated noninferiority for dexmedetomidine, although patients receiving propofol required less rescue sedation than those receiving dexmedetomidine. When compared to midazolam, dexmedetomidine may also be associated with a small reduction in the duration of mechanical ventilation, and it appears to provide significantly better patient responsiveness and cooperation compared to both drugs. Conversely, patients receiving dexmedetomidine were twice as likely as patients receiving propofol to have had cardiovascular instability. A trend toward higher mortality was observed in the dexmedetomidine group, but disappeared when all dexmedetomidine patients were compared to all propofol and midazolam patients. Interestingly, there was no difference between dexmedetomidine and midazolam on measures of agitation and delirium, whereas the difference between dexmedetomidine and propofol was statistically significant. A meta-analysis including 27 randomized trials comparing propofol versus midazolam suggested that tracheal extubation occurred earlier with the use of propofol for patients who were ventilated for a duration shorter than 36 hours.<sup>205</sup> However, no differences were found with regard to the ICU length of stay or mortality. Greater levels of hypotension and elevated triglyceride levels were observed with the use of propofol. Because the publication of this meta-analysis, an open label randomized trial demonstrated that a continuous infusion of propofol was associated with shorter length of mechanical ventilation and ICU stay compared to intermittent benzodiazepine administration.<sup>206</sup>

Opiates are a very common component of many ICU analgesia and sedation regimens, and are increasingly being used as single agents in certain types of patients<sup>199</sup> (e.g., patients with acute postoperative pain, with uncomplicated respiratory failure requiring modest degrees of mechanical ventilation, or who require sedation but do not tolerate hypnotic-anxiolytic drugs). Like dexmedetomidine, opiates do not reliably produce amnesia, and are not appropriate as single agents in patients who require paralysis. Morphine and fentanyl are the most commonly used opioids to provide analgesia in the ICU. Morphine should be avoided in patients with renal failure due to active metabolites that accumulate in the presence of impaired

renal function.

Neuromuscular blockade may be occasionally indicated in ICU patients with severe ARDS with refractory hypoxemia. A single trial has demonstrated a benefit in mortality and ventilator-free days, but routine use is discouraged until these results are validated. Concerns remain that this practice may predispose to critical illness polyneuropathy and myopathy (see section on ICU-acquired Weakness), and an increased risk of nosocomial pneumonia.<sup>207,208</sup> Together, these studies underscore the fact that there is not likely to be a clearly, consistently superior regimen for all patients on all outcomes of interest, and careful consideration of the relative pros and cons must be undertaken for each individual patient.

### *Delirium and Neurocognitive Complications*

Neurocognitive complications including delirium and prolonged cognitive dysfunction are associated with a number of sedative medications, and may be more common in patients treated with deeper levels of sedation. The distinguishing characteristics of delirium include an acute onset and fluctuating course, inattention, disorganized thinking, and altered level of consciousness. Structured screening instruments such as the Confusion Assessment Method for the ICU (CAM-ICU) are available, and their use in concert with proactive screening regimens are recommended for the diagnosis of delirium in the ICU.<sup>209,210</sup>

Critically ill patients are often deeply sedated, in part due to concerns for patient comfort, but also because of potential benefits afforded by a reduction in the sympathoadrenal response to injury. Although some literature supports the notion that benzodiazepine use may be associated with an increased frequency of delirium, two well-conducted trials failed to show a reduction in delirium in patients randomized to dexmedetomidine compared to benzodiazepine.<sup>211,212</sup> In addition, available evidence from observational and randomized trials suggests that practices favoring light sedation, bolus administration versus continuous infusion of sedatives, and promoting daily trials of awakening in ICU patients result in a variety of benefits, including a shortened duration of mechanical ventilation, decreased time in the ICU, and reduced mortality.<sup>213–221</sup>

Nonpharmacologic techniques including the use of both verbal and written communication, frequent reorientation, maintenance of a day–night cycle and noise reduction strategies can be used to improve comfort and safety and to reduce delirium and confusion. Antipsychotic medications like haloperidol and quetiapine are also being used more commonly in ICU sedation regimens, primarily to treat or prevent delirium or agitation, and to promote sleep or treat insomnia. The data for such use are limited and of poor quality. The

only randomized, controlled trial of such use did show a reduction in periods of delirium with regular quetiapine administration, but the study was small.<sup>222</sup> SCCM guidelines specifically cite the lack of evidence for the use of haloperidol, atypical antipsychotics, or dexmedetomidine for the prevention of delirium.<sup>199</sup> Because those guidelines were issued in 2013, a retrospective study found an association between haloperidol use and an increase in next-day delirium, suggesting it is not effective for prevention.<sup>223</sup> A similar randomized trial<sup>224</sup> found no benefit. A systematic review of a number of pharmacologic prevention or treatment strategies (e.g., dexmedetomidine, various antipsychotics, cholinesterase inhibitors) resulted in a number of subtle findings and a high degree of heterogeneity for some comparisons, but trends generally favored pharmacologic intervention.<sup>225</sup> The relationship between delirium and antipsychotics as cause, prophylaxis, or treatment is not completely understood, and intervention decisions continue to require careful clinical assessment and follow-up.

The depth or use of sedation may also play a role in long-term outcomes after discharge from the ICU and hospital. Increasing evidence suggests that patients admitted to the ICU are at risk of developing symptoms of posttraumatic stress disorder,<sup>226,227</sup> delusional memories, and longer-term cognitive dysfunction. Approximately one-third will have signs and symptoms of cognitive dysfunction 12 months after discharge.<sup>228</sup> Interestingly, in this retrospective analysis, exposure to various sedative medications was not significantly associated with the development of longer-term cognitive dysfunction. Further, long-term follow-up of patients enrolled in sedation trials has not found sedation regimens promoting light sedation or daily awakening to be associated with increased long-term cognitive, psychological, or functional problems.<sup>217,229,230</sup>

## Complications in the ICU: Detection, Prevention, and Therapy

### *Nosocomial Infections*

Nosocomial infections are a major source of morbidity and mortality in the critically ill. At some level, nosocomial infections are unavoidable and occur because of the nature of intensive care—patients are critically ill with altered host defenses, they require invasive devices (endotracheal tubes, intravascular catheters, etc.) that provide portals of entry for infectious organisms, and they receive therapies that increase the risk of infection (e.g., glucocorticoids, PN). On the other hand, many nosocomial infections are preventable with relatively simple interventions.<sup>231</sup> This became more financially relevant in the United States in 2008, when the Center for Medicare and Medicaid

Services (CMS) ceased reimbursing hospitals for treatment of preventable complications such as catheter-associated urinary tract infection (CAUTI) and catheter-related bloodstream infection (CRBSI).

6

Several types and sources of infections are relatively unique to ICU care and should be included in the differential diagnosis when signs suggestive of infection arise. These infections include sinusitis, VAP, CRBSI (also referred to as central line-associated bloodstream infection [CLABSI]), CAUTI, and invasive fungal infection.

## Sinusitis

Radiographic sinusitis is common in critically ill patients with indwelling oral and nasal tubes. Nasotracheal intubation confers a greater risk than does orotracheal intubation of radiographic sinusitis, occurring in approximately 95% and 25% of patients with nasal and oral tubes after 1 week of intubation, respectively.<sup>232</sup> Several reports suggest that approximately 10% of radiographically diagnosed sinusitis is infected, as determined by quantitative cultures, although the incidence may be much higher. One study reported that bacterial sinusitis was responsible for 16% of fevers of unknown origin in a surgical ICU.<sup>233</sup> The organisms cultured from sinuses represent those that are responsible for other nosocomial infections, particularly VAP (staphylococcal species, enteric gram-negative bacteria, and nonlactose-fermenting gram-negative rods such as *Pseudomonas* and *Acinetobacter*). Bacterial sinusitis may predispose to the development of VAP, possibly because of microaspiration of infected secretions.

Prevention of sinusitis should focus on efforts to improve sinus drainage, including semirecumbent positioning and avoidance of nasal tubes. Bacterial sinusitis should be considered in patients with unexplained fever and leukocytosis in the ICU. If radiographic sinusitis is documented, any nasal tubes should be removed, and nasal irrigation and short-term administration of nasal decongestants should be considered. If the patient is severely ill, broad-spectrum antibiotic coverage should be considered. If these maneuvers do not result in resolution of signs and symptoms of sinusitis in 2 to 3 days, otolaryngologic consultation and consideration of sinus drainage procedures may be undertaken.

## Ventilator-associated Pneumonia

Tracheal intubation and mechanical ventilation increase the risk of nosocomial pneumonia, thus the term VAP. The likelihood of developing VAP increases with the duration of mechanical ventilation, but the precise incidence is difficult to define due to substantial variability in how VAP is defined. Because VAP is widely associated with increased morbidity, it is an

obvious target for QI interventions. In an effort to facilitate the study of such interventions the Centers for Disease Control and Prevention (CDC) implemented a standardized ventilator-associated event (VAE) surveillance program through the National Healthcare Safety Network (NHSN) in 2013.<sup>234</sup> Possible and probable VAP are specifically defined within the larger category of VAE. Importantly, in an effort to remove the subjective variability inherent to interpretation of radiographic studies, this definition of VAP does not make use of radiologic data, nor was it intended to be a clinical definition. Recent studies show inconsistent overlap in VAP detection when the NHSN and traditional definitions are simultaneously applied to the same population, with more cases of VAP detected using lower respiratory tract culture-based clinical criteria (that typically include a radiographic component) than with the NHSN criteria.<sup>235</sup> Given this caveat, recent studies utilizing the NHSN definition put the incidence at less than 4% per mechanical ventilation episode.<sup>236,237</sup> This contrasts with an incidence greater than 15% at 1 week of ICU and greater than 20% at 2 weeks described in older studies, and likely reflects increasing adherence to best practices for VAP prevention as well as changing definitions.<sup>238</sup>

Although the mortality in patients with VAP ranges between 30% and 70%, the attributable mortality (the number of patients who die because of VAP rather than with VAP) is more difficult to assess. This may be due to differences in the type of ICU, patient factors, diagnostic techniques across studies, or differences in the virulence of the causative pathogens. Although earlier work suggested an attributable mortality to VAP greater than 40%, more recent and rigorously conducted work suggests that the effect of VAP on mortality is minimal.<sup>239</sup>

VAP can be categorized as “early-onset,” occurring within the first 48 to 72 hours of intubation/ventilation, or “late-onset,” occurring thereafter (note that 4 days of mechanical ventilation is required in order for it to qualify as a VAE per the NHSN definition). Early-onset VAP is generally caused by organisms such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, methicillin-sensitive *Staphylococcus aureus*, and other relatively antibiotic-sensitive oral flora that enter the trachea around the time of intubation. Late-onset VAP is associated with more virulent organisms such as methicillin-resistant *S. aureus*, *Pseudomonas aeruginosa*, and *Acinetobacter*. In general, early-onset organisms are associated with zero or low attributable mortality, whereas late-onset organisms, particularly *Pseudomonas* and *Acinetobacter* species, are associated with higher mortality.<sup>240</sup>

There are a number of interventions that can reduce the incidence of VAP, some of which are relatively simple and inexpensive, and others that are costlier and/or associated with some risk. The simplest and least expensive interventions are strict handwashing between patients, and semirecumbent

positioning of the patient (head-of-bed angle at 30 degrees or greater from horizontal). Considering their negligible risks, these practices should be rigorously applied in all ICUs.

The use of acid suppression therapy to prevent gastrointestinal bleeding is more controversial. Acid-suppression therapies have been associated with increased VAP risk because they allow bacterial overgrowth in the stomach. Further, the risk of significant gastrointestinal bleeding is very low in the ICU, even in high-risk patients (those with coagulopathy or on mechanical ventilation). Thus, gastrointestinal acid suppression therapy may be reserved for high-risk patients, and sucralfate may be considered as an alternative agent to acid-suppressive regimens despite its potentially reduced effectiveness.

Somewhat more expensive interventions to reduce VAP that may be useful include specialized endotracheal tubes with subglottic suctioning ports and silver coatings. Although a meta-analysis supports the use of endotracheal tubes with subglottic suctioning ports to reduce the incidence of VAP and shorten both hospital and ICU length of stay, silver-coated tubes have not been proven beneficial in this regard.<sup>241,242</sup> Lending support to the use of subglottic suctioning tubes is a recent cost-benefit analysis that found the optimal strategy for VAP prevention includes their use.

Given that aspiration of gastric and oropharyngeal organisms appears to be a mechanism for the development of VAP, intervening to “decontaminate” these sites has been investigated. Although selective digestive decontamination (SDD) with nonabsorbable antimicrobial agents remains controversial, a recent meta-analysis suggests that SDD may lower the incidence of VAP and bacteremia, as well as reduce mortality.<sup>243</sup> It is unclear if antibiotic resistance is increased with this practice. Limited oral decontamination with chlorhexidine has become more commonplace in many ICUs, but recent evidence also questions this practice.<sup>244</sup> Further clarification of the role of SDD and limited oral decontamination is expected following completion of two large multicenter randomized trials ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT02389036) identifiers: NCT02389036 and NCT02208154).

An additional and important approach to reduce the overall mortality of VAP involves refinement of the diagnostic process and limitation of antibiotic therapy, to avoid the development and proliferation of antibiotic resistant organisms. As mentioned earlier, an invasive diagnostic strategy is likely more accurate than traditional clinical criteria to diagnose VAP. Invasive strategies typically involve collection of either tracheal aspirate specimens or bronchial–alveolar specimens using lavage or protected brushes, and then quantitating bacterial growth in the laboratory. Thus, VAP is diagnosed only when bacteria are seen within bronchoalveolar cells microscopically or when bacterial growth exceeds specific thresholds ( $\geq 10^4$  colony-forming units/mL

for bronchoalveolar lavage and  $\geq 10^3$  colony-forming units/mL for protected brush specimens). Current Infectious Disease Society of America guidelines specify that tracheal aspirate specimens are equivalent to bronchial–alveolar specimens for VAP diagnosis, although the data supporting this recommendation are conflicting.<sup>245–247</sup> It therefore seems appropriate to favor collection of bronchial-alveolar specimens for VAP diagnosis when possible, while reserving tracheal aspirate specimens for instances when it is not feasible to obtain a bronchial-alveolar specimen.

It is clear that delay in treatment of nosocomial infections (including VAP) is associated with increased mortality. Treatment should not be delayed pending diagnostic evaluation; rather, treatment should be started after culture specimens are sent, if the clinical suspicion of VAP is high. Antibiotics can then be narrowed in spectrum or discontinued altogether depending on the results from quantitative cultures after 48 to 72 hours (Table 57-6). This approach is known as “de-escalating therapy” and is designed to ensure adequate antibiotic treatment up front, but avoid overuse of antibiotics in the long term.<sup>240</sup> Antibiotic selection should be predicated on hospital bacterial growth and resistance patterns. In general, for patients with early-onset VAP, antibiotics can be relatively narrow in spectrum and limited to a single agent. For late-onset VAP, broader spectrum antibiotics should be initiated and include agents from two different classes—resistant gram-negative organisms and methicillin-resistant *S. aureus*.

**Table 57-6** Suggested Empiric Antibiotic Regimens for Common Intensive Care Unit Infections

Ventilator-associated pneumonia	
• Early (<72 hours of intubation and hospital admission)	Ceftriaxone PLUS azithromycin; consider adding vancomycin or linezolid if known history of MRSA
• Late (>72 hours of intubation or hospital admission)	Vancomycin OR linezolid AND cefepime; consider adding ciprofloxacin if high incidence of MDR GNRs
Bloodstream infections	
	Vancomycin OR linezolid AND cefepime
Urinary tract infections	
• Noncatheter-associated	Ceftriaxone
• Catheter-associated	Ceftazidime ADD vancomycin if GPCs on gram stain; CONSIDER meropenem instead of ceftazidime if concerned for MDR GNRs or ESBLs
<i>C. difficile</i> diarrhea	
	Vancomycin (oral dosing); IF shock, megacolon or ileus, then ADD IV metronidazole
Meningitis	
• Nonsurgical	Dexamethasone AND ceftriaxone AND vancomycin AND ampicillin AND acyclovir
• Postsurgical	Cefepime AND metronidazole AND vancomycin
Intra-abdominal infections	
• Community-acquired	Ceftriaxone AND metronidazole
• Hospital-acquired	Vancomycin AND either piperacillin-tazobactam OR meropenem
Sepsis, site unknown	
	Vancomycin AND meropenem Consider adding ciprofloxacin if concern for MDR GNRs or ESBLs

MDR, multi-drug resistant; MRSA, methicillin-resistant *Staphylococcus aureus*; GNR, gram-negative rods; GPC, gram-positive cocci; ESBL, extended spectrum  $\beta$ -lactamase. Initial antibiotic regimen should take into account local antibiograms. Antibiotic regimens should be narrowed once culture results are available.

The optimal duration of antibiotic therapy for VAP is not well defined. An often-cited meta-analysis found that 8 days of antibiotic therapy was effective for treatment of VAP in terms of mortality and recurrent infections, and resulted in more antibiotic-free days.<sup>248</sup> However, patients who had VAP caused by nonlactose-fermenting gram-negative rods (including *Pseudomonas*) had a higher infection recurrence rate if they received only an initial 8-day course of therapy. It is unclear whether intermediate courses of therapy would have avoided infection recurrence. Thus, it is reasonable to choose an 8-day course of therapy for many patients with VAP; however, if there is an inadequate early clinical response or infection with nonlactose-fermenting

gram-negative rods a longer course should be considered.

## **Catheter-related Bloodstream Infections**

As strictly defined by the CDC, CRBSI includes the following criteria: (1) clinical suspicion of catheter-related infection (including low likelihood of infection elsewhere), plus (2) positive culture of blood drawn from the catheter or a segment of catheter, plus (3) matching positive blood culture drawn from another site, preferably by direct venotomy or arterial puncture. Given this strict definition, the incidence of CRBSI is less than 5% in most studies. However, the incidence of bacteremia is affected by several factors, including the conditions and technique of insertion, type and location of catheter, and the duration of catheterization, and can vary widely from study to study. The attributable mortality of CRBSI is approximately 11%, which is much lower than that for primary bacteremia or bacteremia associated with another site of infection.<sup>277</sup> The cost associated with a CRBSI is quite high and estimated between \$22,000 and \$54,000.<sup>22</sup>

CRBSI is more likely when placement occurs under emergency conditions, and is reduced by the use of strict aseptic technique with full barrier precautions. This includes pre-insertion handwashing, full gown and gloves, and the use of a large barrier drape.<sup>22</sup> In addition, skin cleansing with chlorhexidine is more effective than other agents at reducing catheter-related infection. Attention to these practices can dramatically reduce catheter-related infection.<sup>22,249,250</sup> These simple interventions should be considered as standards of care and are recommended by the CDC.

CRBSI and bacteremia increase with the duration of catheterization, particularly for durations of greater than 2 days. However, routine catheter replacement at 3 or 7 days does not reduce the incidence of infection, and results in increased mechanical complications. Thus, routine guide-wire exchange of catheters is not recommended.

Catheters coated with either antiseptics (chlorhexidine and silver sulfadiazine) or antibiotics (rifampin and minocycline) reduce bacterial colonization of catheters as well as bacteremia. This effect becomes manifest only after days 5 to 6 of the catheter being in place; thus, the CDC recommends the use of antimicrobial-coated catheters in patients with an expected duration of catheterization of greater than 5 days, particularly if the local rate of CRBSI is high.<sup>251</sup> However, a large meta-analysis found that although coated catheters reduced the incidence of colonization and CRBSI, they did not reduce the incidence of clinically diagnosed sepsis or mortality.<sup>252</sup> Ultimately, key strategies to reduce CRBSI are to limit the duration of insertion, and the need for continued central venous catheterization should be reviewed daily.<sup>22,249</sup> CRBSI may be insertion site-

dependent, but adoption of these practices seem to be lessening the role that infectious concerns play when choosing a catheter insertion site.<sup>253</sup>

Catheter-related venous thrombosis occurs commonly, and is associated with an increased risk of infection. Routine flushing of catheter ports with heparin reduces both the incidence of thrombosis and infection. However, heparin solutions contain antimicrobial preservatives and it is unclear if the heparin or the preservative is responsible for the beneficial effect. In addition, heparin may induce thrombocytopenia. Therefore, the CDC does not recommend the routine use of heparin flushing.<sup>251</sup>

Organisms commonly responsible for catheter-related bacteremia include *S. epidermidis* and *S. aureus*, enteric gram-negative bacteria, *P. aeruginosa* and *Acinetobacter*, and occasionally *Enterococcal* species. Although coagulase-negative staphylococci are commonly isolated from blood cultures in the ICU, they are rarely responsible for true infection.<sup>254</sup> When catheter-related bacteremia is confirmed, the offending catheter should be removed and appropriate antibiotics continued for a minimum of 7 days. Longer courses should be considered for *S. aureus* bacteremia, given its predilection to cause endocarditis. Suspected CRBSI can be addressed by sending screening cultures drawn through the catheter and from a peripheral site. Guide-wire exchange of the catheter with culture of the intracutaneous segment and tip can also be considered in this situation, but should a CRBSI be confirmed, the catheter should be removed, not exchanged. Depending on the patient's severity of illness, a strong suspicion of catheter-related bacteremia should trigger the institution of broad-spectrum antibiotic coverage, including coverage for methicillin-resistant staphylococcal species and nonlactose-fermenting gram-negative rods, until culture results return, with subsequent de-escalation of therapy. Similar to VAP, early appropriate antibiotic coverage of catheter-related bacteremia will likely reduce mortality, although this has not been systematically studied.

## Urinary Tract Infection

The urinary tract is the second most common source of infection in the ICU, with infections occurring in up to one-third of patients. The incidence of CAUTI increases with the duration of bladder catheterization.<sup>231,255</sup> The responsible organisms are similar to those causing other nosocomial infections and include staphylococcal species, *Enterococcus*, enteric gram-negative bacteria, and nonlactose-fermenting gram-negative bacteria such as *Pseudomonas*. Bacteriuria is associated with bacteremia about 5% of the time. Similar to other ICU-acquired infections, CAUTIs are associated with increased mortality, although the attributable mortality is not clear.

Prevention of ICU-acquired CAUTI includes using careful handwashing and

aseptic technique during catheter insertion and minimization of catheterization duration. The use of antimicrobial catheter coatings may also reduce the incidence of CAUTI, although the evidence is insufficient at this point to recommend general use of coated catheters.<sup>255</sup>

## Invasive Fungal Infections

Invasive fungal infections in nonneutropenic patients are caused by *Candida* species in the vast majority of cases.<sup>256</sup> Risk factors for *Candida* infection include the presence of central venous catheters, recent abdominal surgery, anastomotic leakage and gastrointestinal perforation, dialysis-dependent renal failure, administration of PN, multiple broad-spectrum antibiotics, and steroids.<sup>256</sup> In addition to these factors, invasive *Aspergillus* and *Mucormycosis* are more typically associated with profound immunosuppression and diabetes, respectively.<sup>257</sup>

A significant clinical dilemma involves accurate and timely identification of invasive fungal infections. Positive cultures from sterile fluid remain the gold standard, but may take 72 to 96 hours to turn positive and may be positive in only 50% of autopsy-confirmed infections.<sup>256</sup> To improve accuracy and timeliness of the diagnosis, a number of molecular and serologic techniques have been developed.  $\beta$ -D-glucan is present in the cell wall of *Candida* and *Aspergillus* species, as well as *Pneumocystis jiroveci*, and an assay detecting its presence is approximately 80% sensitive and specific. A number of promising whole blood-based polymerase chain reaction (PCR) tests have also recently become available, with sensitivities above 90% in published trials and results available within hours of sample collection. However, they are expensive and have not yet been proven in clinical practice.<sup>256</sup> For diagnosis of *Aspergillus* and *Mucormycosis*, imaging with CT and magnetic resonance is invaluable, as biopsy and surgical debridement play an important role in management.<sup>257</sup>

*Candida albicans* is responsible for approximately 50% of invasive *Candida* infections in critically ill patients. *C. tropicalis*, *C. paraisopolis*, *C. glabrata*, and *C. krusei* account for the remainder.<sup>256</sup> In addition to simple bloodstream infection, *Candida* species are associated with CAUTI, postoperative peritonitis, and disseminated blood-borne infection. *Candida* is frequently cultured from the urine and sputum, but treatment is usually not necessary, as *Candida* pneumonia is unlikely and candiduria often clears without treatment, mostly with discontinuation of the bladder catheter. In addition, candiduria often recurs after initially successful antifungal therapy. True *Candida* peritonitis is also difficult to separate from contamination of culture specimens, but given that the mortality associated with *Candida* peritonitis is approximately 50%, treatment is warranted if clinical signs suggest infection.

Similarly, candiduria and *Candida* in sputum cultures may be treated if there are systemic signs of infection, as colonization is a risk factor for invasive infection.

Disseminated blood-borne *Candida* infection can result in endophthalmitis, endocarditis, and hepatic and pulmonary abscesses. It is likely to occur when initial treatment of candidemia is delayed, and is associated with a high mortality. Prevention of invasive *Candida* infection involves avoidance of risk factors, including limitation of intravascular catheterization, PN, and antibiotic administration. Prophylactic therapy with fluconazole may be effective at reducing the risk of invasive *Candida* infection in high-risk patients, but this strategy has not been associated with improved mortality in the nonneutropenic population, and may increase the incidence of invasive infection with more resistant species, such as *C. glabrata* and *C. krusei*. Prophylactic therapy should be reserved for only the high-risk patient.<sup>256</sup> Empiric therapy should be considered in patients with a high likelihood of invasive *Candida* infection while awaiting culture results, as delay in treatment is associated with increased mortality. However, care should be taken to de-escalate therapy after several days in the absence of positive cultures or clinical response.

Documented *Candida* bloodstream infection should be treated aggressively, with therapy started promptly and continued for at least 2 weeks after the last positive blood culture. An ophthalmologic examination is warranted in patients with documented or suspected bloodstream infection, as patients with endophthalmitis may require longer courses of therapy. Intravascular catheters that are potential sources of bloodstream infection should be removed. Treatment of *Candida* infections has evolved over time, and current guidelines now recommend echinocandins such as caspofungin, micafungin, and anidulifungin as the first-line treatment in most settings.<sup>258</sup> Liposomal amphotericin B is generally reserved for refractory, life-threatening infections such as fungal endocarditis, invasive *Aspergillosis* and *Mucormycosis*. In addition, surgical debridement plays a key role in management of *Mucormycosis*.<sup>257</sup> Suggested empiric treatment of common ICU infections is outlined in [Table 57-6](#).

### **Stress Ulceration and Gastrointestinal Hemorrhage**

Gastric mucosal breakdown with resulting gastritis and ulceration (stress ulceration) can lead to gastrointestinal (GI) bleeding in the ICU. Clinically significant GI bleeding results in hemodynamic instability and/or a sudden fall in hematocrit that results in blood transfusion. The incidence of clinically significant stress-related GI bleeding is relatively low—less than 5% in high-risk patients and less than 1% for low-risk patients.<sup>259</sup> The major risk factors

for stress-related GI bleeding are mechanical ventilation and coagulopathy. Secondary risk factors among mechanically ventilated patients include renal failure, thermal injury, and possibly head injury, although the latter two factors have not been recently evaluated.<sup>259</sup> EN may protect against significant GI bleeding.<sup>259</sup>

**Table 57-7** Caprini Venous Thromboembolism Risk Assessment Model

1 Point	2 Points	3 Points	5 Points
Age 41–60 years	Age 61–74 years	Age >75 years	Stroke <1 month
Minor surgery	Arthroscopic surgery	Personal history of VTE	Elective lower extremity arthroplasty
Body mass index >25 kg/m <sup>2</sup>	Major open surgery >45 min	Family history of VTE	Hip, pelvis, or leg fracture
Swollen legs	Laparoscopic surgery >45 min	Any thrombophilia	Acute spinal cord injury <1 month
Varicose veins	Bed rest >72 h	Elevated serum homocysteine	Multiple trauma <1 month
Pregnant or postpartum <1 month	Immobilizing plaster cast	Heparin-induced thrombocytopenia	
History of miscarriage	Central venous access		
Oral contraceptives or hormone replacement therapy			
Sepsis <1 month			
Serious lung disease <1 month			
Abnormal pulmonary function			
Acute myocardial infarction			
Congestive heart failure <1 month			
History of inflammatory bowel disease			
Medical patient on bed rest			

**High risk: ≥5 points**  
**Intermediate risk: 3–4 points**  
**Low risk: 1–2 points**  
**Very low risk: 0 points**

VTE, venous thromboembolism.

Adapted with permission from Pollak AW, McBane RD 2nd. Succinct review of the new VTE prevention and management guidelines. *Mayo Clinic Proceedings*. 2014;89:394–408.

Stress ulcer prophylaxis (SUP) strategies include acid suppression agents such as histamine type 2 receptor antagonists, proton pump inhibitors, and cytoprotective agents such as sucralfate. However, the agent of choice and related benefits are controversial for the following reasons: (1) recent meta-analyses suggest significant bias in published trials<sup>261,262</sup>; (2) methodological flaws in many of the studies, as well as significant practice changes that have occurred in other areas of care such as VAP prevention and the provision of nutrition because the original studies were published; (3) acid suppression may favor gastric colonization with enteric flora that may increase the risk of nosocomial pneumonia and *C. difficile* colitis.<sup>261,263</sup> Thus, although SUP is commonly used in critically ill patients, the utility of this intervention is unclear. Current evidence appears to support restricting their use to high-risk patients who are without EN for greater than 48 hours.

## Venous Thromboembolism

VTE encompasses both deep venous thrombosis (DVT) and pulmonary embolism (PE), and occurs frequently in critically ill patients, with incidences of DVT of 10% to 30% and PE of 1.5% to 5%.<sup>264</sup> However, the reported incidence varies widely depending on the study design, DVT detection method, and patient population studied. Virtually all critically ill patients have one or more risk factors for VTE.<sup>265</sup> Determination of VTE risk is important in that it will help in choosing prophylactic therapy and in determining the level of suspicion for VTE in individual patients (Table 57-7).

In addition to classic lower extremity DVT, upper extremity DVT occurs with increased frequency in the ICU population. This is directly associated with the use of central venous catheters in the subclavian and internal jugular sites. Upper extremity DVT can result in PE in up to one-third of cases, with occasional fatalities. Catheter-related thrombosis is also associated with increased risk of CRBSI and bacteremia. Finally, upper extremity DVT is associated with considerable long-term morbidity, particularly related to postthrombotic syndrome.<sup>266</sup>

The literature supporting prophylactic measures to prevent VTE in the ICU population is relatively poor and generally shows differences only in intermediate end points (e.g., asymptomatic DVT), with no differences in the incidence of PE or death. In general, the risks of VTE prophylaxis, including heparin-induced thrombocytopenia and bleeding, must be weighed against the risk of VTE. It is generally agreed that high-risk patients without contraindications should receive pharmacologic prophylaxis, and low-risk patients with contraindications should receive mechanical prophylaxis with intermittent pneumatic compression devices. There are an ever-expanding number of medications that may be used for VTE chemoprophylaxis, but unfractionated heparin and low-molecular-weight heparin remain the most commonly used and most studied, with guidelines from professional societies updated regularly.<sup>267</sup> A number of validated scoring systems have been developed for both surgical and medical populations to assess VTE risk.<sup>265</sup> In patients at high risk for DVT with contraindications to anticoagulation, the preventative placement of a vena cava filter may be considered, although there are few data to support this practice. To reduce central venous catheter-associated thrombosis and infection, catheter tips should be positioned in the superior vena cava and catheters may be flushed with a dilute heparin solution. Heparin bonding of catheters may also reduce local thrombosis. Importantly, it should be recognized that the incidence of VTE in patients receiving pharmacologic prophylaxis remains substantial, ranging between 5% and 30% depending on the therapy and population studied.

Given the high incidence of asymptomatic DVT in critically ill patients, a high index of suspicion for VTE must be maintained. However, despite the high incidence of DVT, routine screening studies for DVT do not appear to

improve clinical outcomes in the ICU. Thus, VTE should be considered in critically ill patients in the face of relatively nonspecific findings, such as unexplained tachycardia, tachypnea, fever, asymmetric extremity edema, and gas exchange abnormalities, including high dead space ventilation. Compression Doppler ultrasonography is the most commonly utilized test for diagnosis of DVT and has good positive and negative predictive value compared to contrast venography.<sup>268</sup> Helical chest CT has supplanted radionuclide ventilation–perfusion scanning as the primary test for the diagnosis of PE.<sup>269</sup> CT scanning can also be extended to include the extremities to diagnose DVT. However, ventilation–perfusion scanning and/or pulmonary angiography may have utility in specific circumstances, including in the presence of renal insufficiency (concerns about contrast-induced nephrotoxicity) or equivocal results on CT scan. In addition, pulmonary angiography may be the test of choice when the likelihood of PE is high and anticoagulation is contraindicated, necessitating immediate placement of a vena cava filter. D-dimer levels are not useful in the ICU population because they are frequently elevated and nonspecific in critically ill patients.

The mainstay of treatment for VTE is either unfractionated or low-molecular-weight heparin, which should be started prior to confirmatory studies if clinical suspicion is high. In situations of hemodynamic compromise, the use of systemic thrombolytic therapy may be life-saving. However, if bleeding risk is elevated, new catheter-directed thrombolysis and clot evacuation techniques, or open surgical thrombectomy, can be considered. The specific interventions are largely dependent on institutional capabilities and clinical circumstances.

For patients who have contraindications to anticoagulation or who have recurrent PE despite anticoagulation, vena cava filters can be placed in the superior or inferior vena cava, depending on DVT location. Ultimately, given the long-term thrombotic complications associated with these devices, patients with vena cava filters should be anticoagulated when no longer contraindicated, and the devices should be removed when they are no longer required.

### ***ICU-acquired Weakness***

The term ICU-acquired weakness (ICUAW) encompasses a wide variety of neuromuscular abnormalities developing as a consequence of critical illness. ICUAW is characterized by weakness that is symmetrical and bilateral, occurs during an ICU stay, and is not attributable to another specific etiology. The spectrum of illness ranges from subjective muscle fatigue to flaccid quadriplegia. Although various studies have attempted to distinguish neuropathic from myopathic syndromes, resulting in a bewildering list of

associated acronyms, it is likely that there is considerable overlap between the two in terms of risk factors, presentation, and prognosis.<sup>270</sup>

ICUAW is associated with prolonged duration of mechanical ventilation, ICU stay, hospital stay, and mortality.<sup>271</sup> Prospective studies have shown that up to 11% of mechanically ventilated patients exhibit evidence of weakness at 24 hours. By 7 days the incidence may increase to 60%, and among those with ARDS and sepsis the number may be even higher.<sup>271</sup> In addition to sepsis, factors strongly associated with the development of ICUAW include duration of illness and hyperglycemia. Although corticosteroid and neuromuscular blocking drug administration have classically been associated with ICUAW, more recent evidence suggests that their use in modern ICUs is not associated with ICUAW. This is likely due to contemporary practice of using shorter-acting agents in lower doses and for much shorter courses than was historically the case.<sup>272</sup> Less specific contributors to the development of ICUAW include a catabolic nutritional state, systemic pro-inflammatory state, and generalized muscle unloading.<sup>273</sup>

Prevention of ICUAW centers on avoidance or minimization of contributory risk factors, including long courses of high-dose steroids, prolonged neuromuscular blockade, and hyperglycemia. High-quality evidence in support of specific interventions to prevent ICUAW exists only for avoidance of hyperglycemia. There is moderate-quality evidence that early mobilization may be beneficial.<sup>274</sup>

The diagnosis of ICUAW should be entertained in all critically ill patients with unexplained weakness. Electrodiagnostic studies can help confirm the diagnosis and rule out other, potentially treatable causes of weakness such as Guillain–Barré syndrome. Muscle biopsy is confirmatory in cases of myopathy, but given its invasive nature, biopsy is not warranted outside of research settings. Unfortunately, no specific, effective treatment for ICUAW has been identified; however, avoidance of potentially contributing agents and aggressive physical therapy is warranted. Discharge planning should include the potential need for long-term nursing and rehabilitative care.

## End-of-Life Care in the ICU

Nearly 20% of patients in the United States die during a hospitalization with an ICU stay.<sup>275</sup> Consequently, the ICU is an important setting for delivering high-quality end-of-life care. Shared decision making and patient- and family-centered care require good communication between medical teams, patients, and their family members to ensure that delivered care is consistent with patient values and preferences. The Institute of Medicine Committee on Approaching Death released its report *Dying in America: Improving Quality and Honoring Individual Preferences Near the End of Life* in

2014. The report emphasizes the need for improved communication about end-of-life preferences between clinicians and patients in order to avoid unwanted treatment.<sup>276</sup> It is becoming more widely recognized that palliative care is one way to achieve this goal. Its implementation is associated with a higher quality of life, so much so that the CCSC Choosing Wisely campaign for critical care has recommended that patients at high risk of death or severely impaired functional recovery be offered care focused primarily on comfort, as an alternative to care focused primarily on a cure.<sup>23</sup> It is important to recognize that palliative care can also be offered in conjunction with curative care, and that intensivists play an important role in delivering palliative care in the ICU, in collaboration with palliative care specialists.

## KEY POINTS

- 1 Brain adenosine triphosphate is depleted after 4 to 6 minutes of no blood flow. It returns nearly to normal within 6 minutes of starting effective cardiopulmonary resuscitation (CPR).
- 2 Through living wills and other instruments, patients have begun placing limitations on medical treatment to include do not resuscitate orders, even while undergoing palliative surgical procedures.
- 3 The major components of resuscitation from cardiac arrest are airway, breathing, circulation, drugs, and electrical therapy (ABCDE).
- 4 Two theories for the mechanism of blood flow during closed-chest compression have been suggested: cardiac pump and thoracic pump.
- 5 During CPR, myocardial perfusion is 20% to 50% of normal, whereas cerebral perfusion is maintained at 50% to 90% of normal.
- 6 CPR has limited success, with only approximately 40% of victims being admitted to the hospital and 10% surviving to discharge.
- 7 End-tidal carbon dioxide has been found to be an excellent noninvasive guide to the adequacy of closed-chest compressions.
- 8 Effective uninterrupted chest compressions and defibrillation, if appropriate, should take precedence over medications.
- 9 Although there is some evidence of improved early restoration of spontaneous circulation in humans, there is no strong evidence that vasopressors improve long-term survival in human cardiac arrest.
- 10 After vasopressors, the drugs most likely to be of benefit during CPR are those that help suppress ectopic ventricular rhythms.
- 11 Ventricular fibrillation is the most common electrocardiogram pattern found during witnessed sudden cardiac arrest in adults.
- 12 Untreated ventricular fibrillation is a time-sensitive model with three phases: electrical, circulatory, and metabolic.
- 13 Arrest is less likely to be a sudden event and more likely related to progressive deterioration of respiratory and circulatory function in the pediatric age group.
- 14 For optimal outcome, successful restoration of spontaneous circulation must be followed by correction of reversible causes of arrest, including immediate coronary reperfusion and aggressive supportive care.

Treatment of cardiac and respiratory arrest is an integral part of anesthesia practice. The American Board of Anesthesiology states in its *Booklet of Information* that the “clinical management and teaching of cardiac, pulmonary, and neurologic resuscitation” are among the activities that define the specialty of anesthesiology. The cardiopulmonary physiology and pharmacology that form the basis of anesthesia practice are applicable to

treating the victim of cardiac arrest. However, there is specialized knowledge relating to blood flow, ventilation, and pharmacology under the conditions of a cardiac arrest that must be understood to maintain leadership of the modern cardiopulmonary resuscitation (CPR) team. This chapter concentrates on those aspects of CPR that are different from the more common circumstances requiring cardiovascular support (e.g., shock, dysrhythmias).

## History

Anesthesiologists have contributed many of the elements of modern CPR and continue to be active investigators and teachers in the field. Discoveries leading to current CPR practice have a long history recorded in many famous works.<sup>1,2</sup> The earliest reference may be the Bible story of Elisha breathing life back into the son of a Shunammite woman (2 Kings 4:34). In 1543, Andreas Vesalius<sup>3</sup> described tracheotomy and artificial ventilation. William Harvey's manual manipulation of the heart is well known. Early teaching of resuscitation was organized by the Society for the Recovery of Persons Apparently Drowned, founded in London in 1774. The combined techniques of modern CPR developed primarily from the fortuitous assemblage of innovative clinicians and researchers in Baltimore in the 1950s and early 1960s. Building on the long history of contributions from around the world, these investigators laid the framework for current CPR practice. In the late 1950s, mouth-to-mouth ventilation was established as the only effective means of artificial ventilation.<sup>4-7</sup> The internal defibrillator was developed in 1933,<sup>8</sup> but it was not applied successfully until 1947.<sup>9</sup> It was another decade before general use was made possible by the development of external cross-chest defibrillation.<sup>10,11</sup> Despite these advances, widespread resuscitation from cardiac arrest was not possible until Kouwenhoven et al.<sup>12</sup> described success with closed-chest cardiac massage in a series of patients. The final major component of modern CPR was added in 1963, when Redding and Pearson<sup>13</sup> described the improved success obtained by administering vasopressor drugs.

## Scope of the Problem

Cardiovascular disease remains the most common cause of death in the industrialized world. Although cardiovascular mortality has been declining in the United States since the mid-1960s, more than 35% of all deaths are due to cardiovascular causes.<sup>14</sup> Of the 860,000 annual cardiovascular deaths, approximately half are related to coronary artery disease, the majority are sudden deaths, and 70% occur outside the hospital or in hospital emergency departments. Thus, CPR teaching and research tend to focus on myocardial

ischemia as the primary cause of cardiac arrest. However, anesthesiologists are more likely than other practitioners to deal with causes other than myocardial infarction. CPR is symptomatic therapy, aimed at sustaining vital organ function until natural cardiac function is restored. The details of effective resuscitation technique are important. However, search for a remediable cause of the arrest must not be lost in excessive attention to mechanics.

**1** Brain adenosine triphosphate (ATP) is depleted after 4 to 6 minutes of no blood flow. It returns nearly to normal within 6 minutes of starting effective CPR. Studies in animals suggest that good neurologic outcome may be possible from 10- to 15-minute periods of normothermic cardiac arrest if good circulation is promptly restored.<sup>15,16</sup> In clinical practice, the severity of the underlying cardiac disease is the major determining factor in the success or failure of resuscitation attempts. Of those factors under control of the rescuers, poor outcomes are associated with long arrest times before CPR is begun, prolonged ventricular fibrillation (VF) without definitive therapy, and inadequate coronary and cerebral perfusion during cardiac massage. CPR begun by bystanders can more than double survival.<sup>17</sup> However, bystanders provide CPR only 25% to 30% of the time in sudden cardiac arrest. Optimal outcome from VF is obtained only if basic life support (BLS) is begun within 4 minutes of arrest and defibrillation applied within 8 minutes.<sup>18</sup> The importance of early defibrillation has been known for decades and is emphasized in CPR practice.<sup>19,20</sup> What is not as well recognized is the tendency to interrupt chest compressions frequently during a resuscitation attempt. Studies of emergency medical systems (EMSs) suggest that chest compressions are performed less than 50% of the time during a typical out-of-hospital resuscitation, being interrupted for pulse checks, intubations, starting intravenous catheters, defibrillation attempts, and moving the victim.<sup>21</sup> Because blood flow falls rapidly with cessation of compressions and resumes slowly with reinstatement of compressions, these interruptions are a major contributor to poor survival rates.

With an effective rapid-response EMS, initial resuscitation rates of 40% and survival to hospital discharge of 10% to 15% are possible after out-of-hospital arrests,<sup>18,20</sup> although the median reported survival to discharge with any first recorded rhythm is 6.4%.<sup>22</sup> Rates for survival to discharge from in-hospital arrest are about 18% in adults and 27% in children.<sup>23</sup> Within the hospital, the operating room is the location where CPR has the highest rate of success. Cardiac arrest occurs approximately seven times for every 10,000 anesthetics.<sup>24</sup> The cause for the arrest is anesthesia related approximately 4.5 times for every 10,000 anesthetics, but mortality from these arrests is only 0.4 per 10,000 anesthetics. Thus, resuscitation is successful approximately 90% of the time in anesthesia-related cardiac arrests.

## Ethical Issues: Do Not Resuscitate Orders in the Operating Room

Although institution of CPR is standard medical care when an individual is found pulseless, terminally ill patients have become increasingly concerned about inappropriate application of life-sustaining procedures, including CPR. Through living wills and other instruments, patients have begun placing limitations on medical treatment to include do not resuscitate (DNR) orders, even while undergoing palliative surgical procedures. Such requests are generally accepted, even welcomed, by health-care workers. However, the operating room is one area of the hospital where DNR orders continue to cause ethical conflicts between medical personnel and patients.<sup>25,26</sup> There are ethically sound arguments on both sides of the issue as to whether DNR orders should be upheld in the operating room.

The patient's right to limit medical treatment, including refusing CPR, is firmly established in modern medical practice based on the ethical principle of respect for patient autonomy. A terminally ill patient can reject heroic measures such as resuscitation and still choose palliative therapy. If a surgical intervention will ameliorate symptoms or improve quality of life, there is no reason to withhold this treatment. Operative intervention increases the risk of cardiac arrest, and the patient may not want the burden of surviving in a worse condition than preoperatively. The possibility of death under anesthesia may be viewed as especially peaceful. Thus, the time that the DNR order provides the greatest protection against unwanted intervention is during surgery.

Despite these rather strong arguments for treating a DNR request in the operating room the same way it is treated elsewhere in the hospital, many operating room personnel are at least a little uneasy caring for these patients. Many surgeons require that DNR orders be suspended during the perioperative period or assume consent to surgery includes such suspension. There are multiple reasons for the reluctance to accept DNR status during surgery and anesthesia. Approximately 75% of cardiac arrests in the operating room are related to a surgical or anesthetic complication, and resuscitative attempts are highly successful.<sup>24</sup> Ethically, surgeons and anesthesiologists feel responsible for what happens to patients in the operating room: *primum non nocere* (first, do no harm). Although the physicians are highly diligent in monitoring and managing changes in the patient's status, complications and arrests do occur. Honoring a DNR order under these circumstances is frequently viewed as failure to treat a reversible process, and hence, tantamount to killing. This is an ethically sound view if the cause of arrest is readily identifiable and easily reversible and if treatment is likely to allow the patient to fulfill the objectives of coming to surgery.<sup>25</sup>

Institutionally, these ethical conflicts should be addressed by adoption of clear policies by hospitals.<sup>27</sup> For the individual patient, conflicts can be resolved by communication among the patient, family, and caregivers. A mutual decision can often be reached to suspend or severely limit a DNR order in the perioperative period if the patient understands the special circumstances of perioperative arrest, that interventions are brief and usually successful, and that the physicians support the patient's goals in coming to surgery and values in desiring not to prolong death. Many interventions commonly used in the operating room (mechanical ventilation, vasopressors, antidysrhythmics, blood products) may be considered forms of resuscitation in other situations. The only modalities that are not routine anesthetic care are cardiac massage and defibrillation. Therefore, the specific interventions included in a DNR status must be clarified with specific allowance made for methods necessary to perform anesthesia and surgery. A full discussion of this topic may be found in "Ethical Guidelines for the Anesthesia Care of Patients with Do-Not-Resuscitate Orders or Other Directives that Limit Treatment" by the American Society of Anesthesiologists (ASA), which is available on the ASA website ([www.asahq.org](http://www.asahq.org)).

## Components of Resuscitation

**3** The major components of resuscitation from cardiac arrest are airway, breathing, circulation, drugs, and electrical therapy (ABCDE). Traditionally, these have been divided into two categories: basic life support (BLS), for those elements that can be performed without additional equipment—basic airway management, rescue breathing, and manual chest compressions (see AHA's basic cardiac arrest algorithm at <http://bit.ly/2bYhiO8>)—and advanced cardiac life support (ACLS), encompassing all the cognitive and technical skills necessary for resuscitation (see Fig. 58-1 and AHA's adult cardiac arrest algorithm at <http://bit.ly/2c7wYJA>). The lines between BLS and ACLS have tended to blur recently with the introduction of public-access automatic external defibrillators (AEDs) and the recognition that careful attention to uninterrupted, effective chest compressions improves outcome more than any advanced therapy. In the following sections, each of the components involved in resuscitation will be reviewed separately, followed by a discussion of combining the elements to achieve the best outcome.

## Airway Management

The problem of airway obstruction caused by the tongue in the unconscious patient is familiar to the anesthesiologist. The techniques used for airway

maintenance during anesthesia are applicable to the cardiac arrest victim. The primary method recommended to the public is the same head tilt–chin lift method commonly employed in the operating room.<sup>28</sup> The head is extended by pressure applied to the brow while the mandible is pulled forward by pressure on the front of the jaw, lifting the tongue away from the posterior pharynx. The jaw thrust maneuver (applying pressure behind the rami of the mandible) is an effective alternative. Properly inserted oropharyngeal or nasopharyngeal airways can be useful before intubation, recognizing the danger of inducing vomiting or laryngospasm in the semiconscious victim. Supraglottic airways (e.g., laryngeal mask airway, laryngeal tube, King airway, Combitube, etc.; see [Chapter 28](#)) have been used successfully in resuscitation attempts.<sup>29</sup> Tracheal intubation provides the best airway control, preventing aspiration and allowing the most effective ventilation. However, it should not be performed until adequate ventilation (preferably with supplemental oxygen) and chest compressions have been established. When other methods of establishing an airway are unsuccessful, translaryngeal ventilation or tracheotomy by cricothyroid puncture may be necessary.

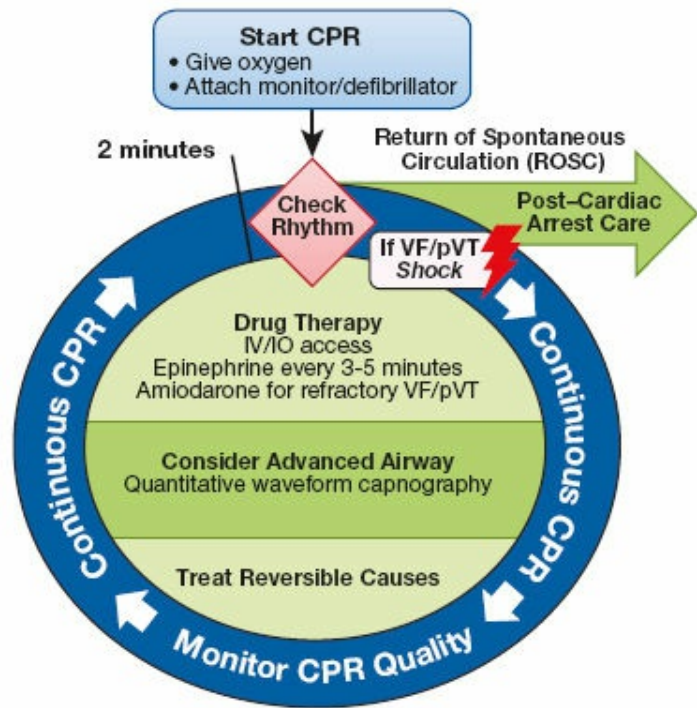

### ***Foreign Body Airway Obstruction***

In 2004, unintentional choking or suffocation accounted for 5,891 deaths in the United States (approximately 0.2% of all deaths) and 725 of the victims were less than 1 year old.<sup>14</sup> Airway occlusion by a foreign object must be considered in any victim who suddenly stops breathing and becomes cyanotic and unconscious. It occurs most commonly during eating and is usually due to food, especially meat, impacting the laryngeal inlet, at the epiglottis or in the vallecula. Sudden death in restaurants from this cause is frequently mistaken for myocardial infarction, leading to the label “café coronary.” Poorly chewed pieces of food, poor dentition or dentures, and elevated blood alcohol levels are the most common factors contributing to choking. The signs of total airway obstruction are the lack of air movement despite respiratory efforts and the inability of the victim to speak or cough. Cyanosis, unconsciousness, and cardiac arrest follow quickly. Partial airway obstruction will result in rasping or wheezing respirations accompanied by coughing. If the victim has good air movement and is able to cough forcefully, no intervention is indicated. However, if the cough weakens or cyanosis develops, the patient must be treated as if there were complete obstruction.

Mothers and friends have been pounding on the backs of choking victims for centuries. In 1974, Heimlich<sup>30</sup> proposed abdominal thrusts as a better method of relieving airway obstruction and, in 1976, Guildner et al.<sup>31</sup> reported that sternal thrusts were just as effective. Subsequently, there were multiple studies of these maneuvers. In clinical practice, Redding<sup>32</sup> observed

that no maneuver was always successful and that each occasionally was successful when another had failed. To minimize confusion from teaching multiple techniques, the AHA has elected to emphasize the abdominal thrust maneuver (with chest thrusts as an alternative for the pregnant and massively obese).<sup>29</sup> This recommendation is made on the twofold premise that the abdominal thrust is at least as effective as other techniques and that teaching one method simplifies education.

**Adult Cardiac Arrest Circular Algorithm—2015 Update**

<b>CPR Quality</b>
<ul style="list-style-type: none"> <li>• Push hard (at least 2 inches [5 cm]) and fast (100-120/min) and allow complete chest recoil.</li> <li>• Minimize interruptions in compressions.</li> <li>• Avoid excessive ventilation.</li> <li>• Rotate compressor every 2 minutes, or sooner if fatigued.</li> <li>• If no advanced airway, 30:2 compression-ventilation ratio.</li> <li>• Quantitative waveform capnography             <ul style="list-style-type: none"> <li>– If PetCO<sub>2</sub> &lt;10 mm Hg, attempt to improve CPR quality</li> </ul> </li> <li>• Intra-arterial pressure.             <ul style="list-style-type: none"> <li>– If relaxation phase (diastolic) pressure &lt;20 mm Hg, attempt to improve CPR quality.</li> </ul> </li> </ul>
<b>Shock Energy for Defibrillation</b>
<ul style="list-style-type: none"> <li>• <b>Biphasic:</b> Manufacturer recommendation (e.g., initial dose of 120-200 J); if unknown, use maximum available. Second and subsequent doses should be equivalent, and higher doses may be considered.</li> <li>• <b>Monophasic:</b> 360 J</li> </ul>
<b>Drug Therapy</b>
<ul style="list-style-type: none"> <li>• <b>Epinephrine IV/IO dose:</b> 1 mg every 3-5 minutes</li> <li>• <b>Amiodarone IV/IO dose:</b> First dose: 300 mg bolus. Second dose: 150 mg.</li> </ul>
<b>Advanced Airway</b>
<ul style="list-style-type: none"> <li>• Endotracheal intubation or supraglottic advanced airway</li> <li>• Waveform capnography or capnometry to confirm and monitor ET tube placement</li> <li>• Once advanced airway in place, give 1 breath every 6 seconds (10 breaths/min) with continuous chest compressions</li> </ul>
<b>Return of Spontaneous Circulation (ROSC)</b>
<ul style="list-style-type: none"> <li>• Pulse and blood pressure</li> <li>• Abrupt sustained increase in PetCO<sub>2</sub> (typically ≥40 mm Hg)</li> <li>• Spontaneous arterial pressure waves with intra-arterial monitoring</li> </ul>
<b>Reversible Causes</b>

For the awake victim, abdominal thrusts are applied in the erect position (sitting or standing). The rescuer reaches around the victim from behind, placing the fist of one hand in the epigastrium between the xiphoid and umbilicus. The fist is grasped with the other hand and pressed into the

epigastrium with a quick upward thrust. In the unconscious, thrusts are applied by kneeling astride the victim, placing the heel of one hand in the epigastrium and the other on top of the first hand. Care must be taken to ensure the xiphoid is not pushed into the abdominal contents and that the thrust is in the midline. Sternal thrusts are valuable in the massively obese or in women in advanced pregnancy. In the erect victim, the chest is encircled from behind, as in the abdominal maneuver, but the fist is placed in the midsternum. For the unconscious, thrusts are applied from the side of the supine victim with a hand position the same as for external cardiac compression. Back blows are applied directly over the thoracic spine between the scapulae. They must be delivered with force. Placing the victim in a head-down position (e.g., leaning over a chair) may help move the obstruction into the pharynx.

Whatever technique is used, each individual maneuver must be delivered as if it will relieve the obstruction. If the first attempt is unsuccessful, repeated attempts should be made because hypoxia-related muscular relaxation may eventually allow success. Complications of thrust maneuvers include laceration of the liver and spleen, gastric rupture, fractured ribs, and regurgitation.

In the unconscious victim, manual dislodgement of the obstruction should be tried only if solid material can be seen obstructing the airway. Grasping the object under direct visualization with a Magill forceps or ordinary instrument (e.g., ice tongs) may be used. Care must be taken not to push the foreign body deeper into the larynx. Blind finger sweeps and blind grasping with instruments are rarely successful and may cause damage to tonsils or other tissue. Finally, if the object cannot be dislodged, a cricothyroidotomy can be lifesaving.

## Ventilation

The standard approach to the unresponsive victim is to follow opening of the airway with ventilation. When ventilation is provided in the rescue setting, mouth-to-mouth or mouth-to-nose ventilation is the most expeditious and effective method immediately available. Although inspired gas with this method will contain approximately 4% carbon dioxide and only approximately 17% oxygen (composition of exhaled air), it is sufficient to maintain viability.

### *Physiology of Ventilation during Cardiopulmonary Resuscitation*

In the absence of an endotracheal tube, the distribution of gas between the lungs and stomach during positive-pressure ventilation will be determined by

the relative impedance to flow into each (i.e., the opening pressure of the esophagus and the lung–thorax compliance). It is likely that esophageal opening pressure during cardiac arrest is no more than that found in anesthetized individuals (approximately 20 cm H<sub>2</sub>O), and lung–thorax compliance is likely reduced. To avoid gastric insufflation, inspiratory airway pressures must be kept low.

Insufflation of air into the stomach during CPR leads to gastric distention, impeding ventilation and increasing the risk of regurgitation and gastric rupture. Avoiding gastric insufflation requires that peak inspiratory airway pressures stay below esophageal opening pressure. Partial airway obstruction by the tongue and pharyngeal tissues is a major cause of increased airway pressure contributing to gastric insufflation during CPR. Meticulous attention to airway management is necessary during rescue breathing. Recommended tidal volumes to cause a noticeable rise in the chest wall in most adults is 0.5 to 0.6 L. Each rescue breath should be given over 1 second during a pause in chest compressions.

### *Techniques of Rescue Breathing*

While maintaining an open airway with the head tilt–jaw lift technique, the hand on the forehead pinches the nose, the rescuer takes a normal breath and seals the victim’s mouth with the lips and exhales, watching for the chest to rise, indicating effective ventilation. For exhalation, the rescuer’s mouth is removed from the victim, and the rescuer listens for escaping air while taking a breath. When both hands are being used in the jaw thrust maneuver of opening the airway, the cheek is used to seal the nose. For mouth-to-nose ventilation, the rescuer’s lips surround the nose and the victim’s lips are held closed. In some patients, the mouth must be allowed to open for exhalation with this technique. Give one breath over 1 second, take a normal breath, and give a second breath over 1 second. During CPR in adults and one-rescuer CPR in children, a pause for two breaths should be made after each 30 chest compressions. When there are two rescuers with a child victim, a pause for two breaths should be made after each 15 compressions.<sup>29</sup>

Several adjuncts to ventilation are available. Perhaps the most useful adjunct is a common mask, such as that used for anesthesia. The mask can be applied to the face and held in place with the thumbs and index fingers while the other fingers are used to apply jaw thrust. Breathing into the connector port of the mask provides ventilation. Mouth-to-mask ventilation may be more aesthetic than mouth-to-mouth ventilation and can be just as effective in trained hands. Masks are also available with one-way valves that direct the victim’s exhaled gas away from the rescuer. Masks with integral nipple adapters are useful for providing supplemental oxygen. An oxygen flow of 10

L/min can raise the inspired concentration to 50%.

The self-inflating resuscitation bag and mask are the most common adjuncts used in rescue vehicles and hospitals. Although these devices have the advantages of noncontact and ability to use supplemental oxygen, they have been shown to be difficult for a single rescuer to apply properly to prevent substantial gas leak while maintaining a patent airway.<sup>33</sup> Tidal volumes with mouth-to-mouth and mouth-to-mask ventilation are often greater than those with the resuscitation bag. It is now recommended that if this device is to be used, two individuals manage the airway: one to hold the mask and maintain head position and one to squeeze the bag, using both hands.<sup>34</sup> The self-inflating resuscitation bag can also be used with supraglottic airways and endotracheal tubes.

Tracheal intubation provides the best control of ventilation without concern for gastric distention. With a supraglottic airway or an endotracheal tube in place, breathing can proceed without synchronizing ventilation with chest compressions. Blood flow during CPR slows rapidly when chest compressions are stopped and recovers slowly when they are resumed. Consequently, advanced airway placement should be accomplished without stopping chest compressions, if possible. Following placement, no pause should be made for ventilation, and one ventilation should be delivered every 6 seconds. Studies have not clearly demonstrated that any type of advanced airway management during resuscitation improves outcome over the self-inflating resuscitation bag and mask.<sup>35</sup>

## Circulation

### *Physiology of Circulation during Closed-chest Compression*

Two theories of the mechanism of blood flow during closed-chest compression have been suggested.<sup>12,36</sup> They are not mutually exclusive, and which mechanism predominates in humans continues to be debated.

4

1

### **Cardiac Pump Mechanism**

The cardiac pump mechanism was originally proposed by Kouwenhoven et al.<sup>12</sup> and Jude et al.<sup>37</sup> According to this theory, pressure on the chest compresses the heart between the sternum and the spine. Compression raises the pressure in the ventricular chambers, closing the atrioventricular valves and ejecting blood into the lungs and aorta. During the relaxation phase of closed-chest compression, expansion of the thoracic cage causes a subatmospheric intrathoracic pressure, facilitating blood return. The mitral and tricuspid valves open, allowing blood to fill the ventricles. Pressure in the

aorta causes aortic valve closure and coronary artery perfusion.

## **Thoracic Pump Mechanism**

In 1976, Criley et al.<sup>38</sup> reported a patient undergoing cardiac catheterization who simultaneously developed VF and an episode of cough-hiccups. With every cough-hiccup, a significant arterial pressure was noted. This observation of self-administered “cough CPR” prompted further investigations on the mechanism of blood flow, and these studies produced the theory of a thoracic pump mechanism for blood flow during closed-chest compressions.<sup>36</sup> According to this theory, blood flows into the thorax during the relaxation phase of chest compressions in the same manner as that described for the cardiac pump mechanism. During the compression phase, all intrathoracic structures are compressed equally by the rise in intrathoracic pressure caused by sternal depression, forcing blood out of the chest. Backward flow through the venous system is prevented by valves in the subclavian and internal jugular veins and by dynamic compression of the veins at the thoracic outlet by the increased intrathoracic pressure. Thicker, less compressible vessel walls prevent collapse on the arterial side, although arterial collapse will occur if intrathoracic pressure is raised enough.<sup>39</sup> The heart is a passive conduit with the atrioventricular valves remaining open during chest compression. Because there is a significant pressure difference between the carotid artery and jugular vein, blood flow to the head is favored. The lack of valves in the inferior vena cava results in less resistance to backward flow, and pressures in the arteries and veins below the diaphragm are nearly equal. This is consistent with the fact that there is little blood flow to organs below the diaphragm.<sup>40,41</sup>

It seems clear that fluctuations in intrathoracic pressure play a significant role in blood flow during CPR. It is also likely that compression of the heart occurs under some circumstances. Factors that influence the mechanism probably include the compliance and configuration of the chest wall, size of the heart, force of the sternal compressions, duration of cardiac arrest, and other undiscovered factors. It is likely that the predominant mechanism of blood flow varies from victim to victim and may even change from one mechanism to the the other during the resuscitation of the same victim.

## **Distribution of Blood Flow during Cardiopulmonary Resuscitation**

Whatever the predominant mechanism, total body blood flow (cardiac output) is reduced from 10% to 33% of normal during experimental closed-chest cardiac massage. Similar severe reductions in flow are likely during clinical CPR in humans. Nearly all the blood flow is directed to organs above the diaphragm.<sup>40,41</sup> Myocardial perfusion is 20% to 50% of normal, whereas

**5** cerebral perfusion is maintained at 50% to 90% of normal. Abdominal visceral and lower extremity flow is reduced to 5% of normal. Total flow tends to decrease with time during CPR, but the relative distribution is not altered. Changes in CPR technique and the use of epinephrine may help sustain cardiac output over time.<sup>41</sup> Epinephrine improves flow to the brain and heart, whereas flow to organs below the diaphragm is unchanged or further reduced.

## **Gas Transport during Cardiopulmonary Resuscitation**

During the low flow state of CPR, excretion of carbon dioxide (CO<sub>2</sub>) (milliliters of CO<sub>2</sub> per minute in exhaled gas) is decreased from pre-arrest levels to approximately the same extent that cardiac output is reduced. This reduced CO<sub>2</sub> excretion is due primarily to shunting of blood flow away from the lower half of the body. The exhaled CO<sub>2</sub> reflects only the metabolism of the part of the body that is being perfused. In the nonperfused areas, CO<sub>2</sub> accumulates during CPR. When normal circulation is restored, the accumulated CO<sub>2</sub> is washed out, and a temporary increase in CO<sub>2</sub> excretion is seen.

Although CO<sub>2</sub> excretion is reduced during CPR, measurement of blood gases reveals an arterial respiratory alkalosis and a venous respiratory acidosis with a markedly elevated arteriovenous CO<sub>2</sub> difference.<sup>42</sup> The primary cause of these changes is the severely reduced cardiac output. Two factors account for the elevation of the venous partial pressure of CO<sub>2</sub> (PvCO<sub>2</sub>). Buffering acid causes a reduction in serum bicarbonate, so the same blood CO<sub>2</sub> content results in a higher PvCO<sub>2</sub>. In addition, the mixed venous CO<sub>2</sub> content is elevated. When flow to a tissue is reduced, all the CO<sub>2</sub> produced fails to be removed and CO<sub>2</sub> accumulates, raising the tissue partial pressure of CO<sub>2</sub>. This allows more CO<sub>2</sub> to be carried in each aliquot of blood, and mixed venous CO<sub>2</sub> content increases. If flow remains constant, a new equilibrium is established in which all CO<sub>2</sub> produced in the tissue is removed but at a higher venous CO<sub>2</sub> content and partial pressure. In contrast to the venous blood, arterial CO<sub>2</sub> content and partial pressure (PaCO<sub>2</sub>) are usually reduced during CPR. Although venous blood may have an increased CO<sub>2</sub>, the marked reduction in cardiac output with maintained ventilation results in efficient CO<sub>2</sub> removal.

Decreased pulmonary blood flow during CPR causes a lack of perfusion to many nondependent alveoli. The alveolar gas of these lung units has no CO<sub>2</sub>. Consequently, mixed alveolar CO<sub>2</sub> (i.e., end-tidal CO<sub>2</sub>) will be low and correlate poorly with arterial CO<sub>2</sub>. However, end-tidal CO<sub>2</sub> does correlate well with cardiac output during CPR. As flow increases, more alveoli become perfused, there is less alveolar dead space, and end-tidal CO<sub>2</sub> measurements

rise.

## ***Technique of Closed-chest Compression***

Cardiac arrest should be assumed in an unresponsive individual with abnormal or absent breathing. The community or institution emergency response system should immediately be activated and chest compressions begun. In emergency circumstances, it is difficult to detect a pulse, even in a major artery (carotid, femoral, axillary). No more than 10 seconds should be taken to check for a pulse and, if a pulse is not definitely felt, chest compressions should be started. Witnessed sudden collapse with unresponsiveness in an adult in the absence of seizure activity is nearly always dysrhythmic cardiac arrest, and chest compressions should be started immediately.

Important considerations in performing closed-chest compressions are the position of the rescuer relative to the victim, the position of the rescuer's hands, and the rate and force of compression. The victim must be supine, the head level with the heart, for adequate brain perfusion. The victim must be on a firm surface. The rescuer should stand or kneel next to the victim's side. Compressions are performed most effectively if the rescuer's hips are on the same level, or slightly above the level of, the victim's chest.

Standard technique consists of the rhythmic application of pressure over the lower half of the sternum. The heel of one hand is placed on the lower sternum, and the other hand is placed on top of the first one. Great care must be taken to avoid pressing the xiphoid into the abdomen, which can lacerate the liver. Even with properly performed CPR, costochondral separation and rib fractures are common. Applying pressure on the ribs by improper hand placement increases these complications and risks puncturing the lung. Pressure on the sternum should be applied through the heel of the hand only, keeping the fingers free of the chest wall. The direction of force must be straight down on the sternum, with the arms straight and the elbows locked into position so the entire weight of the upper body is used to apply force. Inadequate chest recoil due to leaning on the chest during the relaxation phase has been demonstrated to be both common and deleterious to effective chest compressions. During relaxation, care must be taken to remove all pressure from the chest wall, but the hands should not lose contact with the chest wall.

The sternum must be depressed at least 2 to 2½ in (5 to 6 cm) in adults and teens. The duration of compression should be equal to that of relaxation, and the compression rate should be 100 to 120 times per minute. Push hard and push fast, minimizing interruptions in chest compressions. Allow a brief pause for two 1-second breaths after every 30 compressions. With an

advanced airway in place, ventilations at a rate of 1 breath every 6 seconds should be interposed between compressions without a pause.

## **Alternative Methods of Circulatory Support**

**6** As currently practiced, CPR has limited success, with only approximately 40% of victims being admitted to the hospital and 10% surviving to discharge. Despite the occasional success of prolonged resuscitation, standard CPR will sustain most patients for only 15 to 30 minutes. If return of spontaneous circulation has not been achieved in that time, the outcome is dismal. Recognition of these limits and improved understanding of circulatory physiology during CPR have led to several proposals for alternatives to the standard techniques of closed-chest compression. The goals of the new methods are to provide better hemodynamics during CPR and thus improve survival and/or to extend the period of time during which CPR can successfully support viability. Unfortunately, none of the alternatives has proved reliably superior to the standard technique. According to the thoracic pump theory, elevation of intrathoracic pressure during chest compression should improve blood flow and pressure.<sup>39</sup> Studies of techniques that raise intrathoracic pressure (abdominal binding, simultaneous ventilation–compression) demonstrate that the elevated aortic pressure is offset by similar elevations in right atrial and intracranial pressures, so no improvement in myocardial or cerebral blood flow is found. These techniques are no longer recommended for use during CPR because survival is not improved when these techniques are compared with standard CPR.<sup>43–45</sup>

### **Interposed Abdominal Compression Cardiopulmonary Resuscitation**

Interposed abdominal compression (IAC) is fundamentally different from abdominal binding. With this technique, an additional rescuer applies abdominal compressions manually during the relaxation phase of chest compression.<sup>46</sup> Abdominal pressure is released when chest compression begins. One large randomized trial of out-of-hospital cardiac arrest with IAC CPR found no improvement in survival compared with standard CPR,<sup>47</sup> but a subsequent in-hospital study demonstrated improved outcome.<sup>48</sup> The safety of IAC CPR has been established, and it may be considered for in-hospital CPR when there are sufficient personnel trained in its use. Further studies will be needed to establish out-of-hospital efficacy.

### **Mechanical Chest Compression Devices**

Following the description of “cough CPR” and the development of the

thoracic pump theory, a pneumatic vest device was developed that would simulate the events of vigorous coughing.<sup>49</sup> The most common modification is the *load-distributing band (LDB)* device, which uses a pneumatically or electronically actuated circumferential constricting band and backboard.<sup>50</sup> A high quality multicenter randomized controlled trial of the LDB versus manual CPR demonstrated equal survival to hospital discharge.<sup>51</sup> Case series also have used a number of piston-type devices to provide chest compressions with variable outcomes. The most commonly used is the *Lund University Cardiac Arrest System (LUCAS)* which is a gas (oxygen or air) or electric-powered piston that produces a consistent chest compression rate of 100/minute and a compression depth of 5 cm and which incorporates a suction cup attached to the sternum to return the sternum to the starting position.<sup>52</sup> These devices can be useful in circumstances where manual compressions are difficult or dangerous to perform (e.g., in a moving ambulance, in the angiography suite, or during prolonged resuscitation attempts). However, it can take considerable time to deploy and remove the device, prolonging the time chest compressions are not being performed and worsening outcome. Their use requires a well-trained team that can minimize hands-off time while applying and removing the device.

### **Active Compression–Decompression Cardiopulmonary Resuscitation**

The active compression–decompression (ACD) technique developed from the anecdotal report of CPR performed with a plumber's helper applied to the anterior chest wall.<sup>53</sup> This suggested that active decompression of the chest wall might reduce intrathoracic pressure during the relaxation phase of chest compressions, leading to improved venous return, increased stroke volume with compression, and better blood flow. A suction device that can be applied to the chest wall to enable ACD was developed.<sup>54</sup> Hemodynamic studies of this technique in animals and humans have shown that coronary and cerebral perfusion may be somewhat improved with this method compared with standard CPR, although when epinephrine is used there is no difference between techniques.<sup>54,55</sup> Clinical trials of this technique have had mixed results, with four studies showing improved outcome and five showing no positive or negative effects. No survival benefit of ACD CPR over standard CPR was found in a meta-analysis of 10 trials involving 4,162 patients in the out-of-hospital setting and in a meta-analysis of two trials involving 826 patients in the in-hospital setting.<sup>56</sup>

### **Impedance Threshold Device**

The impedance threshold device (ITD) is a valve that impedes air entry into the lungs during chest recoil of the relaxation phase of chest compressions,

thus reducing intrathoracic pressure and increasing venous return to the thorax. Originally designed to be used with a cuffed endotracheal tube and ACD CPR (during which it would act to further increase the venous return of active decompression),<sup>57</sup> it can also be used with conventional CPR and a tight-fitting face mask or supraglottic airway.<sup>58</sup> Two randomized trials of out-of-hospital cardiac arrest comparing conventional CPR and the ITD with ACD CPR have shown improvement in short-term resuscitation.<sup>57,59</sup> One randomized trial of 8,718 out-of-hospital cardiac arrest victims undergoing standard CPR with an active versus sham ITD found no difference in short-term or long-term outcomes.<sup>60</sup> Although improved long-term survival has not been demonstrated, the ITD may be a useful adjunct for professionals trained in its use.

## **Invasive Techniques**

In contrast to the closed-chest techniques, two invasive methods have been able to maintain cardiac and cerebral viability during long periods of cardiac arrest. In animal models, open-chest cardiac massage and extracorporeal CPR (ECPR) (cardiopulmonary bypass through the femoral artery and vein using a membrane oxygenator) can provide better hemodynamics, as well as better myocardial and cerebral perfusion, than closed-chest techniques.<sup>61</sup> Prompt restoration of blood flow and perfusion pressure with cardiopulmonary bypass can provide resuscitation with minimal neurologic deficit after 20 minutes of fibrillatory cardiac arrest in canines.<sup>15</sup> However, these techniques must be instituted relatively early (probably within 20 to 30 minutes of arrest) to be effective.<sup>16,62</sup> If open-chest massage is begun after 30 minutes of ineffective closed-chest compressions, survival is no better, although hemodynamics are improved.<sup>63</sup> The need to apply these maneuvers early in an arrest obviously limits the application. Early observational studies of ECPR have usually included a small number of subjects, younger patients with witnessed arrest, and potentially reversible conditions. Recent studies in Japan suggest ECPR applied rapidly after unsuccessful standard CPR combined with postresuscitation therapeutic hypothermia can significantly improve neurologically favorable survival. Before invasive procedures play a greater role in modern CPR, a method must be developed to predict, early in resuscitation, which patients will and will not respond to closed-chest compressions.

## ***Assessing the Adequacy of Circulation during Cardiopulmonary Resuscitation***

The adequacy of closed-chest compression is frequently judged by palpation

of a pulse in the carotid or femoral vessels. The palpable pulse primarily reflects systolic pressure. Cardiac output correlates better with mean pressure and coronary perfusion with diastolic pressure. In the femoral area, the palpable pulse is as likely to be venous as arterial. Whenever possible, more accurate means of monitoring the efficacy of chest compressions should be used. The importance of monitoring CPR quality is stressed in the AHA ACLS circular algorithm (Fig. 58-1).

Return of spontaneous circulation with an arrested heart greatly depends on restoring oxygenated blood flow to the myocardium. In experimental models, a minimum blood flow of 15 to 20 mL/min/100 g of myocardium has been shown to be necessary for successful resuscitation.<sup>64</sup> Obtaining such flow depends on closed-chest compressions developing adequate cardiac output and coronary perfusion pressure. Similar to the beating heart, coronary perfusion during CPR occurs primarily in the relaxation phase (diastole) of chest compressions. In 1906, Crile and Dolley<sup>65</sup> suggested that a critical coronary perfusion pressure was necessary for successful resuscitation. This concept has been confirmed in numerous other reports.<sup>41,64-74</sup> During standard CPR, critical myocardial blood flow is associated with aortic diastolic pressure exceeding 40 mmHg. Because right atrial pressure can be elevated with some techniques, the aortic diastolic pressure minus the right atrial diastolic pressure is a more accurate reflection of coronary perfusion pressure. The critical coronary perfusion pressure is 15 to 25 mmHg. When invasive monitoring is available during CPR, adjustments in chest compression technique and epinephrine should be used to ensure critical perfusion pressures are exceeded. Damage to the myocardium from underlying disease may preclude survival no matter how effective the CPR efforts. However, vascular pressures below critical levels are associated with poor results even in patients who may be salvageable (Table 58-1).

**7** Although invasive pressure monitoring may be ideal, it is rarely available during CPR. End-tidal CO<sub>2</sub> also has been found to be an excellent noninvasive guide to the adequacy of closed-chest compressions.<sup>75</sup> CO<sub>2</sub> excretion during CPR with an endotracheal tube in place is flow dependent rather than ventilation dependent. Because alveolar dead space is large in low-flow states, end-tidal CO<sub>2</sub> is very low (frequently <10 mmHg). If blood flow improves with better CPR technique, more alveoli are perfused and end-tidal CO<sub>2</sub> rises (usually to >20 mmHg with successful CPR). The earliest sign of return of spontaneous circulation is frequently a sudden increase in end-tidal CO<sub>2</sub> to over 40 mmHg. Within a wide range of cardiac outputs during CPR, end-tidal CO<sub>2</sub> correlates well with cardiac output,<sup>76</sup> coronary perfusion pressure,<sup>77</sup> and initial resuscitation.<sup>78</sup> End-tidal CO<sub>2</sub> correlates with survival in human CPR and can predict a poor outcome.<sup>79,80</sup> Patients with end-tidal CO<sub>2</sub> below 10 mmHg will not be resuscitated successfully. In the absence of

invasive monitoring, end-tidal CO<sub>2</sub> using quantitative waveform capnography should be used to judge the effectiveness of chest compressions, whenever possible.<sup>81</sup> Attempts should be made to maximize the measured end-tidal CO<sub>2</sub> by alterations in technique or drug therapy. It should be remembered that sodium bicarbonate administration liberates CO<sub>2</sub> into the blood and causes a temporary increase in end-tidal CO<sub>2</sub>. The elevation returns to baseline within 3 to 5 minutes of drug administration and end-tidal CO<sub>2</sub> monitoring can again be used for monitoring effectiveness of closed-chest compressions.

**Table 58-1** Critical Variables Associated with Successful Resuscitation

Variable	Amount
Myocardial blood flow (mL/min/100 g)	>15–20
Aortic diastolic pressure (mmHg)	>40
Coronary perfusion pressure (mmHg)	>15–25
End-tidal carbon dioxide (mmHg)	>10

## Pharmacologic Therapy

This discussion of drug therapy is confined to the use of drugs during CPR attempts to restore spontaneous circulation. The use of drugs to support the circulation when there is mechanical cardiac function is discussed 8 elsewhere (see [Chapters 13](#) and [14](#)). During cardiac arrest, drug therapy is secondary to other interventions. Effective uninterrupted chest compressions and defibrillation, if appropriate, should take precedence over medications. Establishing intravenous access and pharmacologic therapy should come as soon as possible but after these critical interventions are established. Although vasopressors are firmly established as improving 9 survival in animal models and there is some evidence of improved early restoration of spontaneous circulation in humans, there is no strong evidence that they improve long-term survival in human cardiac arrest.<sup>82,83</sup> The most common drugs and the appropriate adult doses are shown in [Table 58-2](#). In addition, pharmacologic and other therapeutic approaches for the 1 treatment of bradycardia and tachycardia are shown in [Figures 2](#) 2 and [58-3](#).

### Routes of Administration

The preferred route of administration of all drugs during CPR is intravenous. The most rapid and highest drug levels occur with administration into a central vein. However, peripheral intravenous administration is also effective. The antecubital and external jugular veins are the sites of first choice for

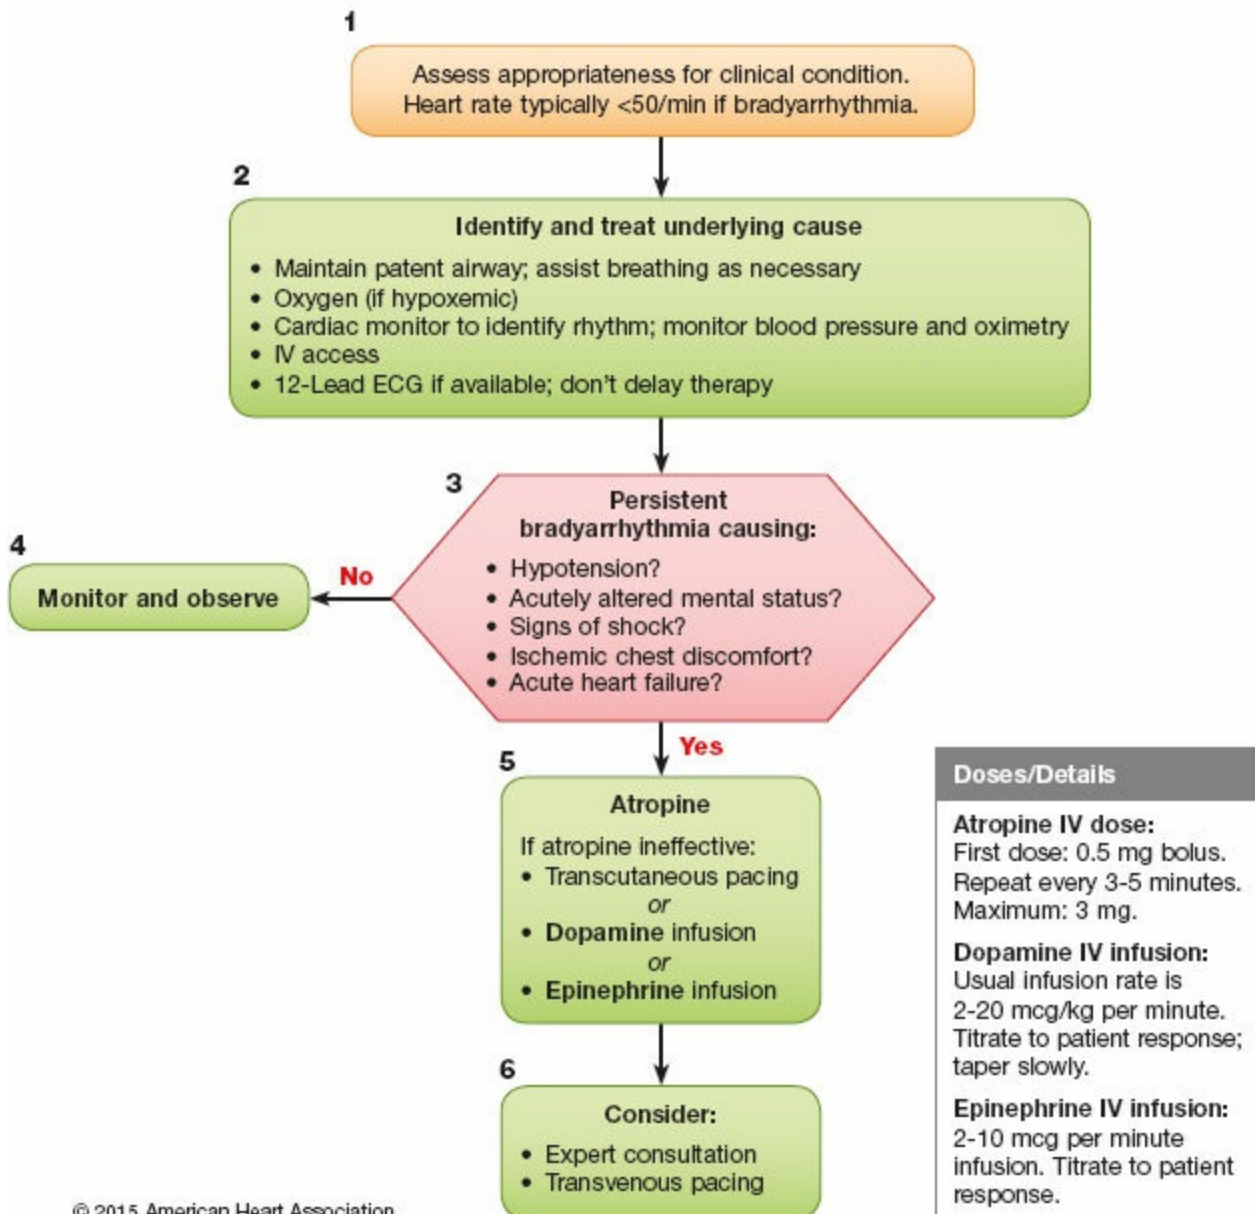

starting an infusion during resuscitation because inserting a central catheter usually necessitates stopping CPR. Because of poor blood flow below the diaphragm during CPR, drugs administered in the lower extremity may be extremely delayed or may not reach the sites of action. Even in the upper extremity, drugs may require 1 to 2 minutes to reach the central circulation. Onset of action may be accelerated if the drug bolus is followed by a 20- to 30-mL bolus of intravenous fluid. Intraosseous administration of fluids and medications is a good alternative to intravenous cannulation, allowing drug delivery similar to that of central venous administration. Commercial kits are available to facilitate intraosseous placement.

**Table 58-2** Adult Advanced Cardiac Life Support Drugs and Doses (Intravenous)

	Dose	Interval	Maximum
Epinephrine	1 mg	Every 3–5 min	None
If dose fails, consider new dose	3–7 mg	Every 3–5 min	None
Vasopressin	40 U	Alternative to epinephrine	—
Amiodarone	300 mg	Repeat 150 mg in 5 min	2 g
Lidocaine	1–1.5 mg/kg	Repeat 0.5–0.75 mg/kg in 5 min	3.0 mg/kg
Sodium bicarbonate	1 mEq/kg	As needed	Check pH

If intravenous or intraosseous access cannot be established, the endotracheal tube is an alternative route for administration of epinephrine, vasopressin, lidocaine, and atropine. Sodium bicarbonate should not be given endotracheally. There are no data on endotracheal administration of amiodarone. The time to effect and drug levels achieved are inconsistent with endotracheal drug administration during CPR, so the optimal dose of drug is unknown using this route. In general, doses 2 to 2.5 times higher than the intravenous dose are recommended when this route is used. Better results may be obtained by administering 5- to 10-mL volumes. It is unclear whether deep injection is better than simple instillation into the endotracheal tube.

## Catecholamines and Vasopressors

### Mechanism of Action

Epinephrine has been used in resuscitation since the 1890s and has been the vasopressor of choice in modern CPR since the studies of Redding and Pearson<sup>13,84</sup> in the 1960s. The efficacy of epinephrine lies entirely in its  $\alpha$ -adrenergic properties<sup>71</sup> (see [Chapter 13](#)). Peripheral vasoconstriction leads to an increase in aortic diastolic pressure, causing an increase in coronary perfusion pressure and myocardial blood flow.<sup>41,85,86</sup> All strong  $\alpha$ -adrenergic drugs (epinephrine, phenylephrine, methoxamine, dopamine, norepinephrine), regardless of  $\beta$ -adrenergic potency, are equally successful in aiding resuscitation, as are strong nonadrenergic vasopressors

(vasopressin).<sup>13,84,87,88</sup>  $\beta$ -Adrenergic agonists without  $\alpha$  activity (isoproterenol, dobutamine) are no better than placebo.  $\alpha$ -Adrenergic blockade precludes resuscitation, whereas  $\beta$ -adrenergic blockade has no effect on the ability to restore spontaneous circulation.<sup>68,69</sup>

The  $\beta$ -adrenergic effects of epinephrine are potentially deleterious during cardiac arrest. In the fibrillating heart, epinephrine increases oxygen consumption and decreases the endocardial-to-epicardial blood flow ratio. Myocardial lactate production in the fibrillating heart is unchanged after epinephrine administration during CPR, suggesting that the increased coronary blood flow does not improve the oxygen supply-to-demand ratio. Large doses of epinephrine increase deaths in swine early after resuscitation because of tachyarrhythmias and hypertension, an effect partially offset by metoprolol treatment. Despite these theoretical considerations, survival and neurologic outcome studies have shown no difference when epinephrine is compared with a pure  $\alpha$ -agonist (methoxamine or phenylephrine) during CPR in animals<sup>84,89</sup> or humans.<sup>83,90</sup>

## Epinephrine

When added to chest compressions, epinephrine helps develop the critical coronary perfusion pressure necessary to provide enough myocardial blood flow for restoration of spontaneous circulation. With invasive monitoring present during CPR, an arterial diastolic pressure of 40 mmHg or coronary perfusion pressure of 20 mmHg must be obtained with good chest-compression technique and/or epinephrine therapy (Table 58-1). In the absence of such monitoring, the dose of epinephrine must be chosen empirically. Since the studies of Redding and Pearson<sup>13,84</sup> in the 1960s, the standard intravenous dose used has been 0.5 to 1.0 mg. In the 1980s, animal studies suggested that higher doses of epinephrine in human CPR might improve myocardial and cerebral perfusion and improve success of resuscitation. Reports were published, including case reports and a series of children with historic controls, of return of spontaneous circulation when large doses (0.1 to 0.2 mg/kg) of epinephrine were given to patients who had failed resuscitation with standard doses.

Subsequent outcome studies did not demonstrate conclusively that higher doses of epinephrine improve survival. Eight adult prospective randomized clinical trials involving more than 9,000 cardiac arrest patients found no improvement in survival to hospital discharge or neurologic outcome, even in subgroups, when initial high-dose epinephrine (5 to 18 mg) is compared with standard doses (1 to 2 mg).<sup>91–98</sup> Some of the studies (and the cumulative data) suggest that there may be an improvement in immediate resuscitation with high-dose epinephrine. High doses apparently are not needed early in

most cardiac arrests and could be deleterious under some circumstances. The use of high-dose epinephrine as rescue therapy when standard doses have failed has not been rigorously studied.

There is only one double-blind randomized control trial of epinephrine versus placebo reported from a single ambulance service in Australia.<sup>99</sup> Of the 534 patients, those receiving epinephrine had a 3.4 times greater chance of return of spontaneous circulation than those receiving placebo and a 2.3 times greater chance of hospital admission. Although more than twice as many patients receiving epinephrine survived to hospital discharge, this was not statistically significant because of the low numbers of survivors.

Current recommendations are to give 1 mg intravenously every 3 to 5 minutes in the adult. If this dose seems ineffective or to treat  $\beta$ -blocker or calcium channel blocker overdose, higher doses (3 to 7 mg) may be considered.

## Vasopressin

Arginine vasopressin has been used as an alternative to epinephrine in a dose of 40 U intravenous/intraosseous (see [Chapter 13](#)). Vasopressin is a naturally occurring hormone (antidiuretic hormone) that, when administered in high doses, is a potent nonadrenergic vasoconstrictor, acting by stimulation of smooth muscle V<sub>1</sub> receptors. It is usually not recommended for conscious patients with coronary artery disease because the increased peripheral vascular resistance may provoke angina. The half-life in the intact circulation is 10 to 20 minutes and longer than epinephrine during CPR. Animal studies have demonstrated that vasopressin is as effective as or more effective than epinephrine in maintaining vital organ blood flow during CPR. Repeated doses during prolonged CPR in swine were associated with significantly improved rates of neurologically intact survival compared with epinephrine and placebo. Postresuscitation myocardial depression and splanchnic blood flow reduction are more marked with vasopressin than epinephrine, but they are transient and can be treated with low doses of dopamine.<sup>100</sup> Clinical studies indicate that vasopressin is as effective as epinephrine but have not definitively shown it to be superior. A small randomized, blinded study comparing vasopressin and standard-dose epinephrine in 40 patients with out-of-hospital VF found improved 24-hour survival with vasopressin but no difference in return of spontaneous circulation or survival to hospital discharge.<sup>101</sup> A larger, clinical trial of 200 inpatients found no difference between the drugs in survival for 1 hour or to hospital discharge.<sup>102</sup> In this study, response times were short, indicating that CPR outcome achieved with both vasopressin and epinephrine in short-term cardiac arrest may be comparable. The hemodynamic effects of vasopressin, compared with

epinephrine, are especially impressive during long cardiac arrests. Thus, vasopressin may find most use in CPR during prolonged duration resuscitation. A multicenter, randomized study of 1,186 patients comparing vasopressin 40 U and epinephrine 1 mg for the first two doses of vasopressor during resuscitation from out-of-hospital cardiac arrest found no overall difference in survival to hospital admission (36% vs. 31%) or discharge (10% vs. 10%).<sup>103</sup> Overall, evidence currently suggests that, like other potent vasopressors, vasopressin is equivalent to but not better than epinephrine for use during CPR.

### *Amiodarone and Lidocaine*

After vasopressors, the drugs most likely to be of benefit during CPR are **10** those that help suppress ectopic ventricular rhythms. Amiodarone and lidocaine are used during cardiac arrest to aid defibrillation when VF is refractory to electrical countershock therapy or when fibrillation recurs following successful conversion. Lidocaine, primarily an antiectopic agent with few hemodynamic effects, tends to reverse the reduction in VF threshold caused by ischemia or infarction. It depresses automaticity by reducing the slope of phase 4 depolarization and reducing the heterogeneity of ventricular refractoriness.

Amiodarone is a pharmacologically complex drug with sodium, potassium, calcium, and  $\alpha$ -adrenergic and  $\beta$ -adrenergic blocking properties that is useful for treatment of atrial and ventricular dysrhythmias. Amiodarone can cause hypotension and bradycardia when infused too rapidly in patients with an intact circulation.<sup>104</sup> This can usually be prevented by slowing the rate of drug infusion, or it can be treated with fluids, vasopressors, chronotropic agents, or temporary pacing. There are two randomized, blinded, placebo-controlled clinical trials in shock-resistant cardiac arrest victims demonstrating improved survival to hospital with amiodarone treatment, although there was no difference in survival to discharge.<sup>105,106</sup> Although weak, this is more evidence of efficacy than exists for lidocaine.

When VF or pulseless ventricular tachycardia is recognized, defibrillation should be attempted (see [Fig. 58-1](#) and <http://bit.ly/2c7wYJA>). No antiarrhythmic agent has been shown to be superior to electrical defibrillation or more effective than placebo in the treatment of VF. Consequently, defibrillation should not be withheld or delayed to establish intravenous access or to administer drugs. When ventricular tachycardia or VF has not responded to or recurred following BLS, epinephrine, and defibrillation, amiodarone should be administered. In cardiac arrest, amiodarone is initially administered as a 300-mg rapid infusion. Supplemental infusions of 150 mg can be repeated as necessary for recurrent or resistant dysrhythmias to a

maximum total daily dose of 2 g. (For dysrhythmias with an intact circulation, amiodarone is usually administered as 150 mg intravenously over 10 minutes, followed by 1 mg/min infusion for 6 hours and 0.5 mg/min thereafter.) Although lidocaine has no proven efficacy in cardiac arrest, it has few side effects. It is an alternative therapy in refractory fibrillation if amiodarone is not available. An initial bolus of 1 to 1.5 mg/kg should be given, and additional boluses of 0.5 to 0.75 mg/kg can be given every 5 to 10 minutes during CPR up to a total dose of 3 mg/kg.

## **Drugs Not Routinely Given during CPR**

### **Atropine**

Atropine sulfate enhances sinus node automaticity and atrioventricular conduction by its vagolytic effects. Although atropine has been given frequently during cardiac arrest associated with an electrocardiogram (ECG) pattern of asystole or slow pulseless electrical activity (PEA), neither animal nor human studies provide evidence that it actually improves outcome from asystolic or bradysystolic arrest.<sup>107,108</sup> The predominant cause of asystole and PEA is severe myocardial ischemia. Excessive parasympathetic tone probably contributes little to these rhythms during cardiac arrest in adults. Even in children, it is doubtful that parasympathetic tone plays a significant role during most arrests. Therefore, the most important treatment for asystole and PEA is effective chest compressions, ventilation, and epinephrine to improve coronary perfusion and myocardial oxygenation. There is no evidence that atropine is detrimental during cardiac arrest. However, *routine* use of atropine during cardiac arrest with these rhythms is unlikely to have benefit and is no longer recommended.

### **Sodium Bicarbonate**

Although sodium bicarbonate was used commonly during CPR in the past, little evidence supports its efficacy. Use of sodium bicarbonate during resuscitation has been based on the theoretical considerations that acidosis lowers fibrillation threshold and impairs the physiologic response to catecholamines. But most studies have failed to demonstrate improved success of defibrillation or resuscitation with the use of bicarbonate.<sup>109,110</sup> The lack of effect of buffer therapy may be partially explained by the slow onset of metabolic acidosis during cardiac arrest. As measured by blood lactate or base deficit, acidosis does not become severe for 15 or 20 minutes of the cardiac arrest.<sup>42,111</sup>

In contrast to the lack of evidence that buffer therapy during CPR improves survival, the adverse effects of excessive sodium bicarbonate

administration are well documented. In the past, metabolic alkalosis, hypernatremia, and hyperosmolarity were common after administration of bicarbonate during resuscitation attempts.<sup>111,112</sup> These abnormalities are associated with low resuscitation rates and poor outcomes.

Intravenous sodium bicarbonate combines with a hydrogen ion to produce carbonic acid that dissociates into CO<sub>2</sub> and water. The partial pressure of CO<sub>2</sub> in blood is temporarily elevated until the excess CO<sub>2</sub> is eliminated through the lungs. Tissue acidosis during CPR is caused primarily by the low blood flow and accumulation of CO<sub>2</sub> in the tissues.<sup>42</sup> Therefore, concern has been expressed that the liberation of CO<sub>2</sub> by bicarbonate administration would only worsen the existing problem. This is of particular concern within myocardial cells and the brain. CO<sub>2</sub> readily diffuses across cell membranes and the blood–brain barrier, whereas bicarbonate diffuses much more slowly. Thus, it is possible that sodium bicarbonate administration could result in a paradoxical worsening of intracellular and cerebral acidosis by further raising intracellular and cerebral CO<sub>2</sub> without a balancing increase in bicarbonate. Direct evidence for this effect has not been found. Use of clinically relevant doses causes no change in spinal fluid acid–base status or myocardial intracellular pH during bicarbonate administration.<sup>113,114</sup> Therefore, paradoxical acidosis from sodium bicarbonate therapy remains a concern primarily on theoretical grounds.

Routine use of sodium bicarbonate is not recommended for patients in cardiac arrest. Current practice restricts its use to arrests associated with hyperkalemia, severe pre-existing metabolic acidosis, and tricyclic or phenobarbital overdose. It may be considered for use in protracted resuscitation attempts after other modalities have been instituted and failed. When bicarbonate is used in these circumstances, the usual dose is 1 mEq/kg. However, dosing of sodium bicarbonate should be guided by blood–gas determination of acid–base status, whenever possible.

## Calcium

With normal cardiovascular physiology, calcium increases myocardial contractility and enhances ventricular automaticity (see [Chapter 12](#)). Consequently, it has been advocated as a treatment for asystole and PEA. Early animal studies showed moderate success with calcium chloride in asphyxial arrest, although vasopressors were better.<sup>13</sup> In 1981, Dembo<sup>115</sup> reported dangerously high serum calcium levels (up to 18.2 mg/dL) during CPR and questioned the efficacy of calcium in cardiac arrest. Subsequently, several retrospective studies and prospective clinical trials during out-of-hospital cardiac arrest showed that calcium was no better than placebo in promoting resuscitation and survival from asystole or PEA.<sup>116–119</sup> Consequently, because of potentially deleterious effects, *routine* use of

calcium is not recommended during CPR unless specific indications exist. Calcium may prove useful if hyperkalemia, hypocalcemia, or calcium channel blocker toxicity is present. There are no other indications for its use during CPR. When calcium is administered, the chloride salt is recommended because it produces higher and more consistent levels of ionized calcium than other salts. The usual dose is 2 to 4 mg/kg of the 10% solution administered slowly intravenously. Calcium gluconate contains one-third as much molecular calcium as does calcium chloride and requires metabolism of gluconate in the liver.

## Electrical Therapy

### *Electrical Pattern and Duration of Ventricular Fibrillation*

Ventricular fibrillation is the most common ECG pattern found during witnessed sudden cardiac arrest in adults. The only consistently effective treatment is electrical defibrillation. The most important controllable determinant of failure to resuscitate a patient with VF is the duration of fibrillation.<sup>120</sup> Other important factors, such as underlying disease and metabolic status, are largely beyond the control of rescuers. The fibrillating heart has high oxygen consumption, increasing myocardial ischemia and decreasing the time to irreversible cell damage. The longer VF continues, the more difficult it is to defibrillate and the less likely is successful resuscitation.<sup>62,121</sup> If defibrillation occurs within 1 minute of fibrillation, CPR is unnecessary for resuscitation. Initial resuscitation success following out-of-hospital fibrillation and survival to hospital discharge are improved the earlier that defibrillation is accomplished.<sup>19,122</sup>

The coarseness of the fibrillatory waves on the ECG may reflect the severity and duration of the myocardial insult and thus have prognostic significance.<sup>123</sup> However, the fibrillation amplitude seen on any one ECG lead varies with the orientation of that lead to the vector of the fibrillatory wave.<sup>124</sup> If the lead is oriented at right angles to the fibrillatory wave, a flat line can be seen. For this reason, the trace from a second lead or from a different position of paddle electrodes should always be inspected before a decision is made not to defibrillate. Low-*amplitude* fibrillatory waveforms are less likely to be associated with successful resuscitation and more likely to convert to asystole following defibrillation.<sup>123</sup> Similarly, low-*frequency* fibrillatory waveforms are associated with poor outcome, and the median frequency of the waveform correlates with myocardial perfusion during CPR and with success of defibrillation.<sup>125,126</sup> Multiple studies in animals and humans have shown that analysis of the VF waveform can predict, with varying reliability, the success of defibrillation attempts.<sup>123,126–129</sup> It is not yet

clear whether such waveform analysis can predict success of resuscitation or direct modification of therapy prospectively. Catecholamines with  $\beta$ -adrenergic activity increase the vigor of fibrillation and the amplitude of the electrical activity, leading to the practice of administering epinephrine to make it “easier” to defibrillate. However, experimental work has shown that manipulation of the electrical pattern with epinephrine does not influence the success of defibrillation or reduce the energy needed for defibrillation.<sup>121,130</sup> Consequently, defibrillation should not be delayed for drug administration.

### ***Defibrillators: Energy, Current, and Voltage***

Defibrillators derive power from a line source of alternating current or an integral battery. The typical defibrillator consists of a variable transformer that stores direct current in a capacitor, a switch to charge the capacitor, and discharge switches to complete the circuit from capacitor to electrodes. Defibrillators are classified by the current waveform delivered: monophasic (current flows in one direction between electrodes) or biphasic (current reverses direction between electrodes during the shock). Older defibrillators used a monophasic damped half-sinusoid or a monophasic truncated exponential waveform. Many of these monophasic defibrillators may still be in use. All defibrillators currently on the market, including AEDs, deliver current in a truncated exponential (BTE), rectilinear (RLB), or pulsed biphasic waveform.

The AED is a device that monitors the ECG, recognizes VF, charges automatically, and gives a defibrillatory shock.<sup>131</sup> It has allowed the introduction of defibrillation into first-responder EMS networks and public access defibrillation because minimally trained individuals can incorporate defibrillation into BLS skills, improving survival in out-of-hospital arrest by reducing time to delivery of the first shock.<sup>18–20,132</sup> The algorithms these devices use to detect VF are accurate with nearly perfect specificity. They will not defibrillate a nonfibrillatory rhythm. Sensitivity rates are somewhat lower. They sometimes have trouble recognizing low-amplitude VF and can misinterpret pacemaker spikes as QRS complexes. Unfortunately, rhythm analysis can require up to 90 seconds, during which chest compressions are not being given. This may adversely influence the outcome in some circumstances.

Some defibrillators measure transthoracic impedance prior to the shock by passing a low-voltage current through the chest during the charge cycle.<sup>133,134</sup> This technology allows current-based defibrillation by adjusting the delivered energy for the measured resistance, permitting the use of low-energy shocks in appropriate patients and identification of victims needing higher energy.<sup>135</sup>

Defibrillation is accomplished by current passing through a critical mass of

myocardium, causing simultaneous depolarization of the myofibrils. However, the output of defibrillators is indicated in energy units (joules or watt-seconds), not current (amperes). The relationships among energy, current, and impedance (resistance) are given by the following equations (standard units are indicated):

$$\text{Energy (joules)} = \text{Power (watts)} \times \text{Duration (seconds)} \quad (58-1)$$

$$\text{Power (watts)} = \text{Potential (volts)} \times \text{Current (amperes)} \quad (58-2)$$

$$\text{Current (amperes)} = \text{Potential (volts)} / \text{Resistance (ohms)} \quad (58-3)$$

$$\text{Current (amperes)} = \{ \text{Energy (joules)} / [ \text{Resistance (ohms)} \times \text{Duration (seconds)} ] \}^{1/2} \quad (58-4)$$

From these equations, it can be determined that as the impedance between the paddle electrodes increases, the delivered energy will be reduced. Because internal resistance is low, the primary determinant of delivered energy will be transthoracic impedance. When transthoracic impedance is high, actual delivered energy will be lower. Even at a constant delivered energy, equation 58-4 indicates that the delivered current (the critical determinant of defibrillation) will be reduced as impedance increases. At high impedance and relatively low energy levels, current could be too low for defibrillation. Optimal results are obtained by keeping impedance as low as possible.

### ***Transthoracic Impedance***

Transthoracic impedance has been measured between 15 and 143 ohms in human defibrillation<sup>136</sup> (see [Chapter 12](#)). The average transthoracic impedance in human defibrillation is 70 to 80 ohms. Many of the important factors in minimizing transthoracic impedance are under the control of the rescuers. Resistance decreases with increasing electrode size, and studies suggest that optimal paddle size may be 13 cm in diameter.<sup>137,138</sup> For adults, handheld paddle electrodes and self-adhesive pad electrodes are most commonly 8 to 12 cm in diameter and work well in practice. Gel pads, electrode paste, or self-adhesive defibrillation or monitor pads specifically designed to conduct electricity in the defibrillation setting must be used.<sup>137,138</sup> When paste is used, it should be applied liberally to the paddle surface, especially the edges, to prevent burns and to obtain the maximum reduction in impedance. Transthoracic impedance is slightly, but significantly, higher during inspiration than during exhalation.<sup>139</sup> Air is a poor electrical conductor. Firm paddle pressure of at least 11 kg reduces resistance by improving paddle-to-skin contact and by expelling air from the lungs.<sup>136</sup> Resistance is probably of little clinical significance when reasonably proper technique and high-energy shocks are used. For lower energy shocks, great

care should be taken to minimize resistance.

### **Adverse Effects and Energy Requirements**

Repeated defibrillation with high energy in animals can be associated with dysrhythmias, ECG changes suggesting myocardial damage, and morphologic evidence of myocardial necrosis.<sup>140,141</sup> Whether similar injuries occur in humans is less certain. Slight elevations in creatine kinase–MB fractions have been measured in patients following cardioversion with high energies.<sup>142</sup> A higher incidence of atrioventricular block has been observed in patients receiving high-energy shocks than in patients receiving low-energy shock.<sup>143</sup> It seems likely that high-energy shocks, especially if repeated at close intervals, may result in myocardial damage. However, if energy is too low, the delivered current may be insufficient for defibrillation, especially when transthoracic impedance is high. There appears to be little risk of significant myocardial injury with currently recommended energy levels.

Older studies using monophasic waveform defibrillators found a general relationship between body size and energy requirements for defibrillation. Geddes et al.<sup>144</sup> observed that the current that is necessary for defibrillation in animals increased with increasing body mass. Children need less energy than adults, perhaps as low as 0.5 J/kg,<sup>145</sup> although the recommended dose is 2.0 to 4.0 J/kg, similar to that for adults.<sup>29</sup> Clinically, over the size range of adults, weight variability is not clinically significant and other factors are more important.<sup>120</sup> Studies of out-of-hospital and in-hospital arrests have demonstrated equal success when using monophasic shocks of 200 J or less initial energy compared with administering all shocks at energies 300 J or more.<sup>143,146</sup> Both monophasic and biphasic waveforms are successful in terminating VF. Neither waveform has been associated with better return of spontaneous circulation or survival.

Prior to 2005, the AHA recommendation for defibrillation with monophasic waveform devices was to use a stacked shock approach with an initial shock of 200 J followed immediately by a second shock at 200 to 300 J if the first was unsuccessful, followed, if both failed, by a third shock at 300 to 360 J.<sup>147</sup> However, the second and third shocks add limited incremental benefit and caused significant interruptions in chest compressions with reduced survival. With monophasic defibrillators, a single shock of 360 J should be given with immediate resumption of chest compressions (see [Fig. 58-1](#) and <http://bit.ly/2c7wYJA>).

Biphasic shocks terminate VF at lower energies than any of the monophasic waveforms<sup>148</sup> and have an 85% to 98% first-shock success.<sup>149</sup> Selected energies from 150 to 200 J are generally effective with biphasic truncated exponential waveforms, and a selected energy of 120 J is effective

with a rectilinear biphasic waveform. AEDs have the energy dose preselected. Most manual biphasic devices display the effective dose range and the user should select that dose. If the effective dose for a manual biphasic device is unknown, a dose of 200 J may be selected. This dose may not be optimal but falls within the effective dose range of nearly all biphasic devices. As with the monophasic devices, a single shock should be delivered with immediate resumption of chest compressions. If additional shocks are necessary, they may be given at the same or higher dose.

## Putting It All Together

Since the mid-1970s, CPR has become widely practiced, facilitated by the efforts of the AHA, the International Red Cross, the European Resuscitation Council, and many other organizations around the world. The International Liaison Committee on Resuscitation, in conjunction with the AHA, periodically conducts an international review of the published science regarding CPR and emergency cardiac care. The resulting Consensus on Science and Treatment Recommendations<sup>150</sup> comprises the most complete evidence-based compilation of scientific data related to CPR practice. Individual organizations, including the AHA, use these data to develop guidelines for CPR practice. However, no common infrastructure exists that allows adoption of true international guidelines for CPR.

Following each consensus conference, the AHA refines and publishes specific guidelines for the teaching and practice of CPR in the United States.<sup>29,147</sup> These guidelines are developed because numerous individuals with varying levels of expertise (laypersons, emergency personnel, nurses, and physicians) need to be trained if CPR is to be effective in saving lives. For training to be effective, a standardized approach is needed. The AHA and other organizations also develop and sponsor courses at different levels of complexity for teaching CPR. The two levels of CPR care are referred to as *BLS* for ventilation and chest compressions without additional equipment, and *ACLS* for using all modalities available for resuscitation. Medical personnel need to be well versed in both levels of care. BLS is also appropriate for laypersons. The algorithms for approaching the patient with cardiac arrest published in the guidelines are familiar to all physicians and are reproduced in this chapter.

The AHA guidelines and algorithms are carefully researched using the best evidence and experts available. Until very recently, survival rates were dismal and remained stagnant for decades in spite of multiple updates to guidelines for CPR practice and many courses for lay public and health-care providers.<sup>151</sup> What has become clear in the past decade is that improvements in the standard clinical process of CPR may be more important to increase survival

than any new intervention.<sup>152</sup> Standardized quality control of CPR practice is mandatory during any clinical trial if meaningful results are to be achieved. A continuous quality improvement model may be more relevant to improved outcomes than the randomized control trial. In addition, there is increasing awareness that the single approach to two pathophysiologically distinct entities (respiratory arrest and cardiac arrest) may not be optimal care for either. In the former, arrest occurs because of hypoxemia, and reoxygenating the blood by effective ventilation is mandatory for successful resuscitation. In the latter, arrest occurs because of cardiac dysrhythmia, usually with normal oxygenation, and attempts at ventilation during resuscitation, in fact, may be harmful. Recognizing these issues, the most recent refinement of the AHA guidelines emphasizes the importance of assessing the quality of CPR efforts and stresses the necessity of minimal interruptions in chest compressions throughout the resuscitation effort (see Fig. 58-1 and <http://bit.ly/2c7wYJA>).

### **Time-Sensitive Model of Ventricular Fibrillation**

Weisfeldt and Becker<sup>153</sup> have described untreated VF as a time-sensitive model with three phases: electrical, circulatory, and metabolic. The *electrical phase* occurs during the first 4 to 5 minutes of the arrest, and early defibrillation is critical for success during this time. The *hemodynamic phase* follows for the next 10 to 15 minutes, when perfusing the myocardium and brain with oxygenated blood is critical. This is followed by what has been called the *metabolic phase*, when the ischemic injury to the heart is so great that it is not clear what interventions will be successful. 12

Prompt defibrillation during the electrical phase is when CPR has had the most dramatic effect and why public-access AED has proven beneficial. The longer VF continues, the more difficult it is to defibrillate and the less likely is successful resuscitation. AEDs have been employed successfully in many settings, including airplanes, airports, casinos, and in the community. The success of public access defibrillation was dramatically demonstrated by the results of installing AEDs in Chicago airports where, over the first 2 years, there was a 55% 1-year neurologically intact survival rate.<sup>154</sup> Similarly, when AEDs were installed in Las Vegas casinos and security personnel were instructed in their use, there was a 53% survival to discharge (74% in patients who received the shock within 3 minutes of collapse).<sup>155</sup> If an arrest is witnessed and a defibrillator or AED is immediately available, then defibrillation should be the first priority in resuscitation. However, in the usual out-of-hospital rescue with emergency medical technicians or paramedics doing the defibrillation, a rapid response is to apply the first shock in 6 to 7 minutes, and the time to first shock frequently is more than 10 minutes. Similar delays occur during in-hospital cardiac arrests.

With the onset of VF and cessation of coronary perfusion, the high oxygen consumption of the fibrillating heart causes the rapid depletion of myocardial high-energy phosphates, reducing the time to irreversible cell damage. Myocardial ATP levels during VF correlate with the success of defibrillation and postdefibrillation contractile function.<sup>156</sup> By about 4 minutes, the ATP levels in the heart have fallen to levels that make restoration of normal contractile function problematic. Effective chest compressions help replete or delay reductions in ATP by generating an adequate coronary perfusion pressure to restore myocardial blood flow. Therefore, the most important intervention during the hemodynamic phase of cardiac arrest is producing coronary perfusion with chest compressions before any attempt to defibrillate. In the absence of prompt defibrillation, the most important intervention for neurologically normal survival from cardiac arrest is restoration and maintenance of cerebral and myocardial blood flow. Because perfusion pressures generated by chest compressions are quite low compared with the intact circulation, any interruption of chest compressions markedly reduces the chances for neurologically normal survival. Therefore, any intervention that interrupts chest compressions is strongly discouraged.

### ***Bystander CPR and Basic Life Support***

Restoration of cerebral and myocardial blood flow must begin at the scene of the cardiac arrest. There are many studies documenting improved survival if bystanders provide CPR to the victim while awaiting arrival of EMS. Unfortunately, the incidence of bystander CPR has been falling for three decades. The reasons for a bystander's reluctance to intervene are multiple but seem to be primarily lack of training, the complexity of the task, and fear of harm. Many of these concerns focus on the mouth-to-mouth ventilation part of the CPR intervention.<sup>157–159</sup> One survey indicated that only 15% of laypersons would perform CPR with mouth-to-mouth ventilation on a stranger. When given the option of doing chest compressions only, 68% indicated they would perform CPR on a stranger.<sup>159</sup>

If the airway remains patent during CPR, chest compressions cause substantial air exchange. Early studies in anesthetized, paralyzed humans suggested that the airway would not remain open in the unconscious,<sup>6,7</sup> leading to the teaching that airway control and artificial ventilation must accompany chest compressions. However, there are considerable data to suggest that eliminating mouth-to-mouth ventilation early in the resuscitation of witnessed fibrillatory cardiac arrest is not detrimental to outcome and may improve survival. Data from the Belgian Cardiopulmonary Resuscitation (CPCR) Registry has demonstrated that 14-day survival and neurologic outcome are the same if bystanders initiate full BLS or perform chest

compressions only. Both are significantly better than if the bystanders only do mouth-to-mouth ventilation or attempt no CPR.<sup>160,161</sup> A recent Japanese study found better survival in victims who received bystander chest compression-only CPR than in those who received both chest compressions and mouth-to-mouth ventilation from bystanders.<sup>162</sup>

The necessity for ventilation during BLS has been studied in animal models. Since 1993, there have been six studies containing data from 169 swine demonstrating that in prolonged fibrillatory cardiac arrest, neurologically intact survival is the same with chest compression-only resuscitation as with idealized standard CPR (as recommended by the 2000 AHA guidelines<sup>147</sup>), with a 15:2 compression-to-ventilation ratio when compressions are interrupted for only 4 seconds to provide ventilation.<sup>163-166</sup> However, it has been demonstrated that a single lay rescuer interrupts chest compressions for an average of 16 seconds to deliver the two recommended mouth-to-mouth ventilations.<sup>167</sup> When the 15:2 compression-to-ventilation ratio with 16-second pauses for ventilation was tested in the swine model of prolonged fibrillatory arrest, standard CPR resulted in just 13% 24-hour survival compared with 73% in animals receiving chest compressions only.<sup>168</sup>

Recognizing the deleterious effects of prolonged pauses in chest compressions for ventilation, the 2005 AHA guidelines changed the compression-to-ventilation ratio from 15:2 to 30:2, recommending that ventilation be done in 2 to 4 seconds. When the 30:2 ratio with a more realistic 16-second pause for ventilations is compared with continuous chest compressions without ventilation in the animal model, the 24-hour neurologically normal survival is only 42% in the 30:2 group compared with 70% in the continuous compressions group.<sup>169</sup>

Based on these studies, the Save Hearts in Arizona Registry and Education (SHARE) program began a public education program stressing immediate call to 911 and continuous chest compressions without ventilation in the case of witnessed unexpected sudden collapse in adults. The major advantage of this program is that lay individuals can be taught chest-compression-only CPR in a very short period with excellent retention. In Arizona between 2005 and 2009, the rate of bystander CPR increased from 28% to 40%, the rate of chest compression only CPR among bystanders increased from 20% to 76%, and rate of survival to hospital discharge during those years was 7.8% for those receiving standard CPR and 13.3% for those receiving chest compression-only CPR.<sup>170</sup> The importance of minimizing interruptions in chest compressions was emphasized in a science advisory by the AHA recommending “hands-only CPR” for the lay public.<sup>171</sup> For well-trained health-care providers operating within an organized EMS system, a randomized controlled trial of continuous chest compressions at 100/min with asynchronous ventilations at 10/min versus 30 compressions followed by a 5-second pause for two ventilations

found no difference in survival or favorable neurologic function between the groups.<sup>172</sup>

## **Advanced Life Support**

Recognizing that dysrhythmic arrest is most common in adults and the importance of establishing blood flow, the most recent AHA guidelines have recommended that CPR be initiated in the unresponsive individual with chest compressions before any attempt at ventilation when a single rescuer is present.<sup>29</sup> The principle of not interrupting chest compressions in order to maintain cerebral and myocardial perfusion applies to resuscitation attempts by health-care providers as well as lay bystanders. The adverse hemodynamic consequences of interrupting chest compressions have been well documented.<sup>173</sup> Blood flow stops almost immediately with cessation of chest compressions and returns slowly when they are resumed. Several compressions are necessary before perfusion pressures return to the levels obtained before compressions were stopped. This is particularly true for prolonged, repeated pauses for ventilation. But it is also relevant for the many other interruptions that occur during resuscitation: pulse checks, rhythm analysis, charging the defibrillator, stacked shocks, intubation, patient assessment, and intravenous line placement. Recent reports have documented that paramedics spend only about half the time during a resuscitation doing chest compressions, mostly because they are following the standard guidelines.<sup>21,174</sup>

Consequently it must be emphasized that chest compressions are to be paused only when absolutely necessary, and then for the shortest time possible. Intravenous line placement should not require cessation of chest compressions. Pulse checks occur only during pauses for rhythm analysis. Initial airway management may consist of insertion of an oropharyngeal airway and providing oxygen by mask with rescue breaths, assisted ventilation or intubation delayed until return of spontaneous circulation or until at least three cycles of compressions–rhythm analysis–shock are complete. A second rescuer's priorities should be obtaining intravenous access, delivering drugs, and relieving the individual giving chest compressions. If there are time and resources for airway management, ventilation and intubation are encouraged to take place while chest compressions continue.

Once ventilation begins, rescuers must be aware of the potentially deleterious effects of positive-pressure ventilation.<sup>175,176</sup> Positive-pressure ventilation increases intrathoracic pressure, reducing venous return, cardiac output, and coronary perfusion pressure and adversely affecting survival. These effects are amplified by the fact that physicians and paramedics often

ventilate at rates that are many times the recommended 10 breaths per minute, even after extensive retraining.<sup>174-177</sup>

## ***Rhythm Analysis and Defibrillation***

As mentioned previously, after 4 to 5 minutes of VF, the myocardium is so depleted of high-energy phosphates that development of a normal contractile state is difficult, if not impossible. Therefore, immediate defibrillation during the circulatory phase is counterproductive, usually producing either asystole or PEA. In Seattle, it was noted that patients who had CPR prior to defibrillation had a better survival, and the improvement was accounted for by better results in the group of patients in whom the response time was greater than 4 minutes.<sup>178</sup> In a randomized trial of 200 out-of-hospital cardiac arrests in Oslo, there was a highly significant improvement in outcome if CPR was provided before defibrillation when the response time was greater than 5 minutes.<sup>179</sup> Consequently, resuscitation should be initiated with 200 continuous chest compressions at a rate of 100 per minute unless bystanders are already providing good chest compressions. Rhythm analysis and defibrillation, if indicated, follow. Pulse checks are done only during the period of rhythm analysis.

The interruption caused by stacked defibrillatory shocks was discussed previously. When combined with time for rhythm analysis and postshock pulse checks, this interruption may be unacceptably long or even fatal when an AED is in use instead of an experienced clinician interpreting the rhythm with a manual defibrillator.<sup>180,181</sup> The success rate of a single shock is between 70% and 85% with most monophasic waveform defibrillators and more than 90% with the newer biphasic waveform units. Despite this success, the postshock pulse check detects a pulse in only 2.5% of the victims. Recognizing these concerns, the current AHA guidelines recommend a single shock at 360 J for monophasic defibrillators and at the manufacturer's recommended power for biphasic units, with immediate resumption of 200 chest compressions before the next pulse/rhythm check.

In prolonged VF arrest, successful defibrillation almost always results in asystole or PEA, as indicated by the extremely small number of victims with a pulse following shocks. In fact, the standard laboratory model for PEA is prolonged VF followed by defibrillation, all without chest compressions. Immediately restarting chest compressions after defibrillation to provide coronary perfusion nearly always results in reversion to a perfusing rhythm. This certainly suggests that the best chance for restoration of spontaneous circulation following defibrillation will be by immediately resuming chest compressions without waiting to check a pulse or reanalyze the ECG rhythm.

Attention to the quality of CPR and minimizing interruptions in chest

compressions has led to significant improvements in survival from cardiac arrest over the past decade. In rural Rock and Walworth counties in Wisconsin, in the 3 years preceding a change, there were 92 witnessed out-of-hospital adult cardiac arrests with an initially shockable rhythm; 18 of these victims survived and 14 (15%) were neurologically intact. In the first 3 years of applying a minimal-interruption approach in these counties, there were 89 witnessed out-of-hospital cardiac arrests; 42 (47%) of these patients survived and 35 (39%) were neurologically intact.<sup>182</sup> In two large metropolitan Arizona cities after institution of minimally interrupted cardiac resuscitation by the EMS, the rate of survival nearly tripled.<sup>183</sup> Among the 886 patients, survival to hospital discharge increased from 1.8% to 5.4%, and in the subgroup of 174 patients with witnessed cardiac arrest with VF, survival increased from 4.7% to 17.6%. These highly statistically significant results are encouraging in that they indicate a significant improvement in outcome from sudden cardiac death is possible.

## Pediatric Cardiopulmonary Resuscitation

The principles of CPR discussed previously also apply to the child<sup>13</sup> in cardiac arrest. Arrest is less likely to be a sudden event and more likely related to progressive deterioration of respiratory and circulatory function in the pediatric age group. Airway and ventilation problems lead to asystole and PEA as the most common presenting rhythms. However, the consequences of myocardial and cerebral ischemia are the same as for the adult, and the basic approach to the unresponsive victim is similar. Although the higher incidence of respiratory arrest has led to emphasis on providing rescue breathing in children, the delay in providing ventilation is minimal when starting CPR with chest compressions and this approach is recommended in an unresponsive pulseless child (see AHA's Pediatric cardiac arrest algorithm for the single rescuer at <http://bit.ly/2bYpScU> and for two or more rescuers at <http://bit.ly/2cMLpVH>). The specific anatomic and physiologic considerations necessary for the child will be familiar to anesthesiologists. The special circumstance of neonatal resuscitation is discussed in [Chapters 41](#) and [42](#).

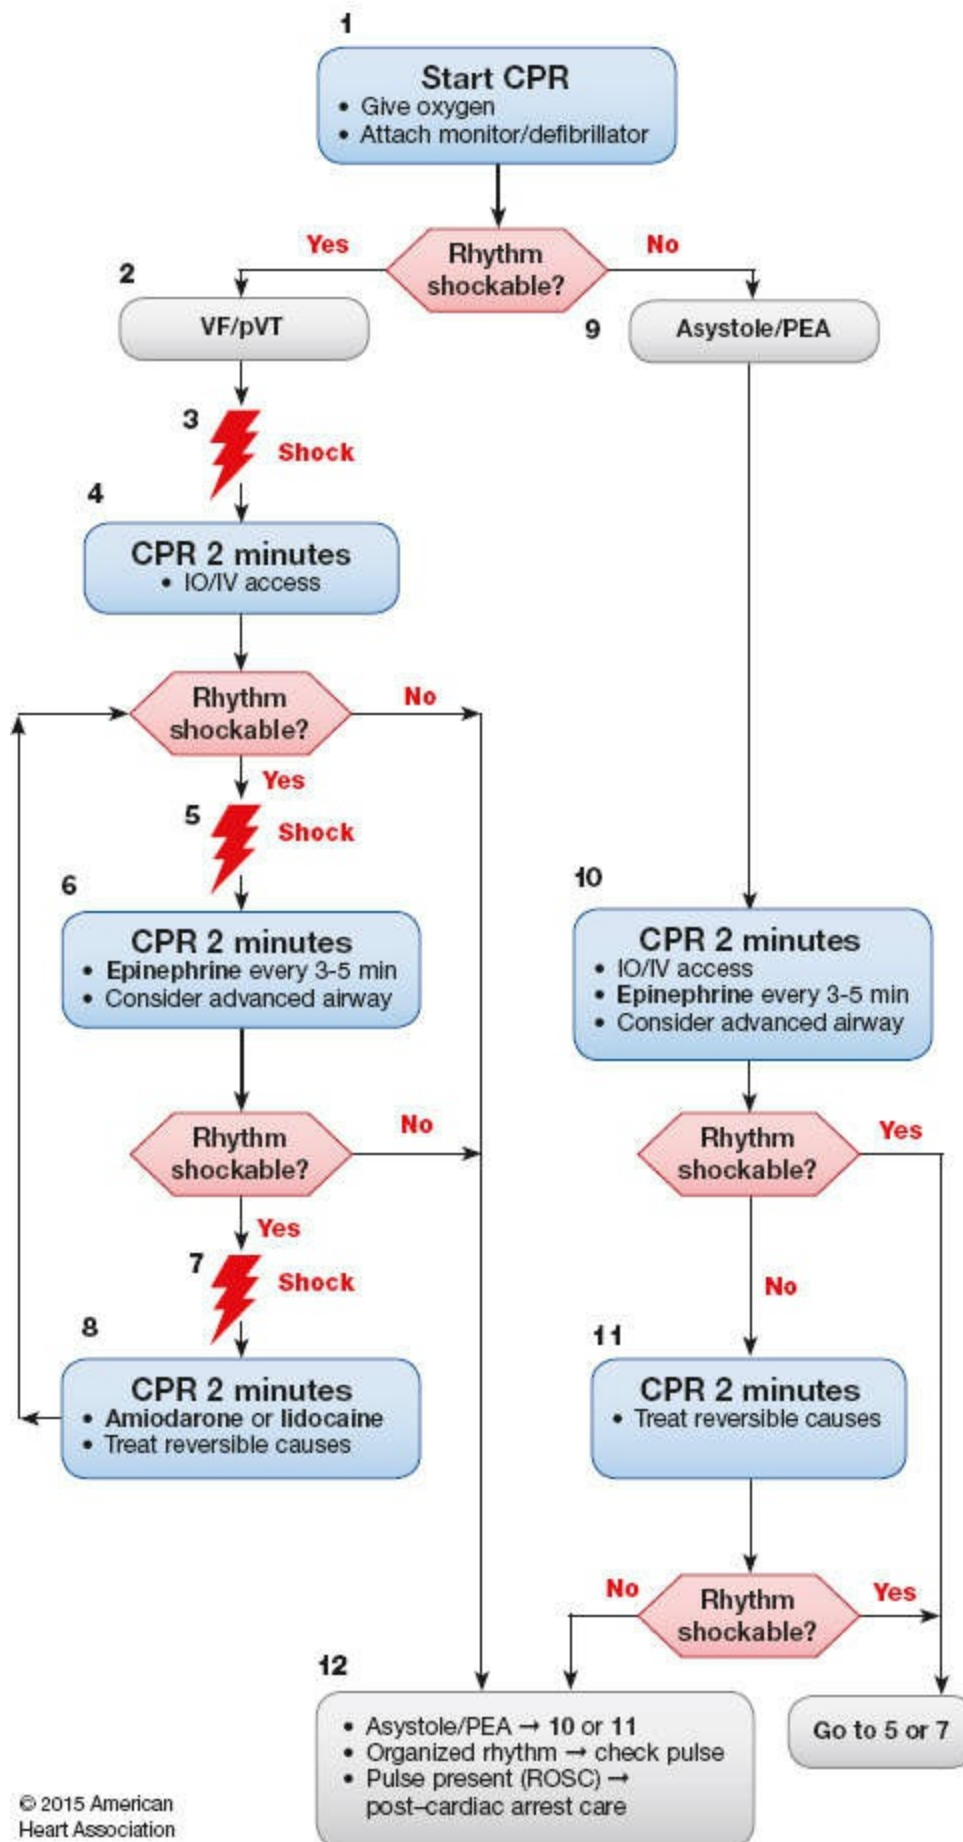

The problem of airway management in the infant is well known to the anesthesiologist. Effective ventilation is especially critical because respiratory problems are frequently the cause for arrest. Mouth-to-mouth or mouth-to-nose and mouth (for infants) can be used as well as bag-valve-mask devices until intubation is possible. Cardiac compression in the infant is provided with two fingers on the midsternum or by encircling the chest with the hands and using the thumbs to provide compression. For the small child, compression can be provided with one hand on the midsternum. For both infants and

children, compressions should be at least one-third the depth of the chest at a rate of 100 to 120/min. For a single rescuer, a 30:2 compression-to-ventilation ratio should be used and with two or more rescuers a 15:2 ratio is recommended.

The algorithm for pulseless arrest in the child is shown in [Figure 58-4](#). Although defibrillation is less frequently necessary in children, the same principles apply as in the adult. However, the recommended starting energy is 2 J/kg (monophasic or biphasic), which is doubled if defibrillation is unsuccessful. Considerations for drug administration are the same as for the adult, except that the interosseous route in the anterior tibia is a particularly attractive option in small children. Drug therapy is similar to that of the adult but plays a larger role because electrical therapy is less often needed ([Table 58-3](#)). The pediatric algorithms for bradycardia and tachycardia are shown in [Figures 58-5](#) and [58-6](#).

**Table 58-3** Medications for Pediatric Resuscitation

Drug	Dose	Remarks
Adenosine	0.1 mg/kg (maximum 6 mg) Second dose: 0.2 mg/kg (maximum 12 mg)	Monitor ECG Rapid IV/IO bolus with flush
Amiodarone	5 mg/kg IV/IO; may repeat twice up to 15 mg/kg Maximum single dose 300 mg	Monitor ECG and blood pressure; adjust administration rate to urgency (IV push during cardiac arrest, more slowly over 20–60 minutes with perfusing rhythm). Expert consultation strongly recommended prior to use when patient has a perfusing rhythm. Use caution when administering with other drugs that prolong QT (obtain expert consultation).
Atropine	0.02 mg/kg IV/IO 0.04–0.06 mg/kg ET <sup>a</sup> Repeat once if needed Maximum single dose 0.5 mg	Higher doses may be given with organophosphate poisoning
Calcium chloride (10%)	20 mg/kg IV/IO (0.2 mL/kg) Maximum single dose 2 g	Administer slowly
Epinephrine	0.01 mg/kg (0.1 mL/kg 1:10,000) IV/IO 0.01 mg/kg (0.1 mL/kg 1:1,000) ET <sup>a</sup> Maximum dose 1 mg IV/IO; 2.5 mg ET	May repeat every 3–5 min
Glucose	0.5–1.0 g/kg IV/IO	Newborn: 5–10 mL/kg D <sub>10</sub> W Children: 2–4 mL/kg D <sub>25</sub> W Adolescents: 1–2 mL/kg D <sub>50</sub> W
Lidocaine	Bolus: 1 mg/kg IV/IO Infusion: 20–50 µg/kg/min	—
Magnesium sulfate	25–50 mg/kg IV/IO over 10–20 min; faster in torsades de pointes Maximum dose 2 g	—
Naloxone	Full reversal: ≤5 yr or ≤20 kg: 0.1 mg/kg IV/IO/ET <sup>a</sup> ≥5 yr or >20 kg: 2 mg IV/IO/ET <sup>a</sup>	Use lower doses to reverse respiratory depression associated with therapeutic opioid use (1–5 µg/kg titrate to effect)
Procainamide	15 mg/kg IV/IO over 30 to 60 min Adult dose: 20 mg/min IV infusion up to total maximum dose of 17 mg/kg	Monitor ECG and blood pressure Give slowly over 30–60 min Use caution when administering with other drugs that prolong QT
Sodium bicarbonate	1 mEq/kg IV/IO slowly	After adequate ventilation

ECG, electrocardiogram; IV, intravenous; IO, intraosseous; ET, endotracheal.

<sup>a</sup>Flush with 5 mL of normal saline and follow with five ventilations.

## Postresuscitation Care

The major factors contributing to mortality following successful resuscitation are progression of the primary disease and cerebral damage suffered as a result of the arrest. There is growing awareness that many potentially useful interventions during active CPR may not result in improved survival because of the lack of uniform supportive postresuscitation care, allowing progression to multisystem organ dysfunction and death. For optimal outcome, successful restoration of spontaneous circulation must be followed

by correction of reversible causes of arrest, including immediate coronary reperfusion and aggressive supportive care (Fig. 58-7). Patients with successful restoration of spontaneous circulation should be transported to a facility with the capability of aggressive postarrest care, including percutaneous coronary intervention, targeted temperature management (TTM), and neurologic critical care.

Any cardiac arrest, even of brief duration, causes a generalized decrease in myocardial function similar to the regional hypokinesis seen following periods of regional ischemia. This is usually referred to as *global myocardial stunning* and can be mitigated with inotropic agents, if necessary. Active management following resuscitation appears to mitigate postischemic brain damage and improve neurologic outcomes. Although a significant number of patients have severe neurologic deficits following resuscitation, aggressive brain-oriented support does not seem to increase the proportion surviving in vegetative states.<sup>184</sup> Most severely damaged victims die of multisystem failure within 1 to 2 weeks.

## Pediatric Bradycardia With a Pulse and Poor Perfusion Algorithm

© 2015 American Heart Association

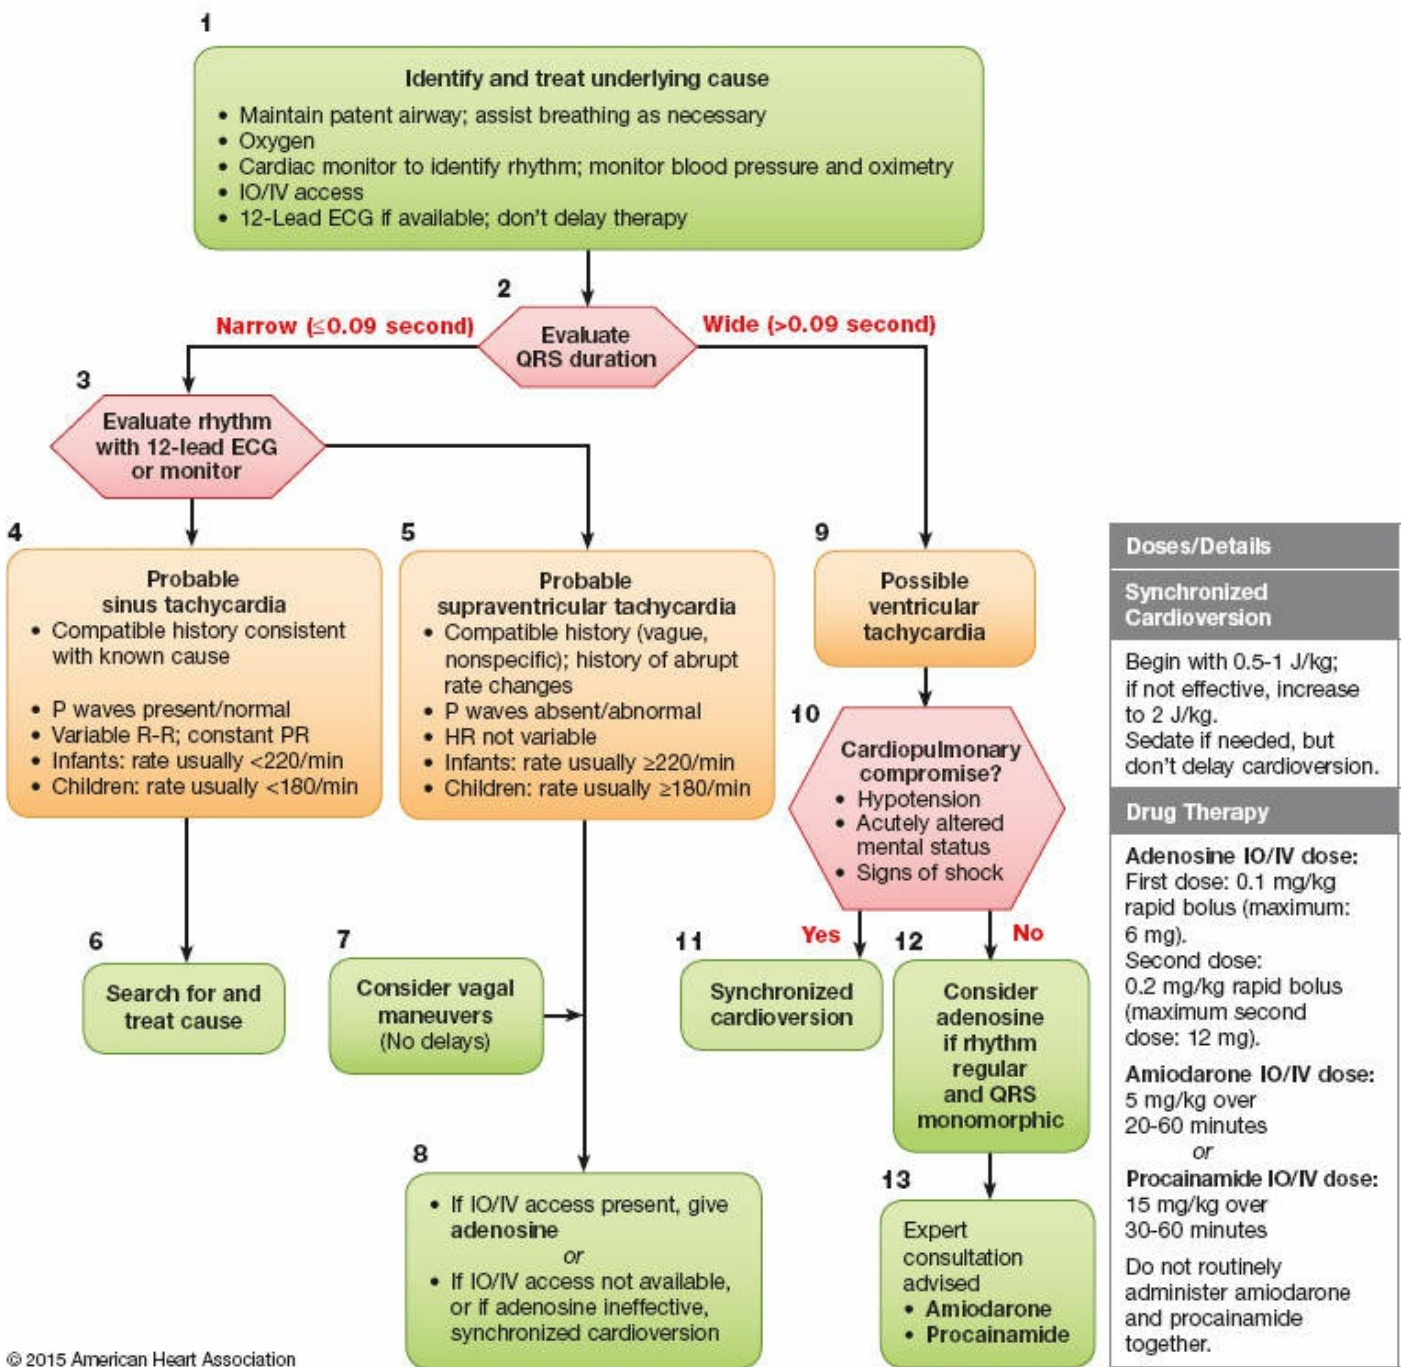

**Figure 58-5** Pediatric advanced life support bradycardia (with pulse and poor perfusion) algorithm. ABCs, airway, breathing, and circulation; ECG, electrocardiogram; CPR, cardiopulmonary resuscitation; HR, heart rate; IV, intravenous(ly); IO, intraosseous(ly); AV, atrioventricular. Reprinted with permission. 2015 American Heart Association Guidelines for CPR & ECC—Part 12: Pediatric Advanced Life Support. ©2015 American Heart Association, Inc.

When flow is restored following a period of global brain ischemia, three stages of cerebral reperfusion are seen in the ensuing 12 hours. Immediately following resuscitation, there are multifocal areas of the brain with no reflow. Within 1 hour, there is global hyperemia followed quickly by prolonged global hypoperfusion. Elevation of intracranial pressure is unusual following

resuscitation from cardiac arrest. However, severe ischemic injury can lead to cerebral edema and increased intracranial pressure in the ensuing days. Nonconvulsive seizures are common postresuscitation with or without therapeutic hypothermia.<sup>185</sup> Continuous or frequent electroencephalography (EEG) for diagnosis of seizure should be performed on comatose patients and treatment instituted if indicated.

Postresuscitation support is focused on providing stable oxygenation and hemodynamics to minimize any further cerebral insult. A comatose patient should be maintained on mechanical ventilation for several hours to ensure adequate oxygenation and ventilation. Restlessness, coughing, or seizure activity should be aggressively treated with appropriate medications, including neuromuscular blockers, if necessary. Oxygen free radicals are a major cause of reperfusion injury and postresuscitation hyperoxia may contribute to poor neurologic outcome.<sup>186–188</sup> Following return of spontaneous circulation, inspired oxygen should be titrated to maintain oxygen saturation by pulse oximetry of at least 94% or an arterial PaO<sub>2</sub> above 100 mmHg as soon as possible. Hypocapnia (PaCO<sub>2</sub> <30 mmHg) should be avoided. Because cerebral autoregulation of blood flow is severely attenuated after cardiac arrest, both prolonged hypertension and hypotension are associated with a worsened outcome. Therefore, mean arterial pressure should be maintained at 90 to 110 mmHg. Hyperglycemia during cerebral ischemia is known to result in increased neurologic damage. Although it is unknown if high serum glucose in the postresuscitation period influences outcome, it seems prudent to control glucose in the 100 to 150 mg/dL range. Specific pharmacologic therapy directed at brain preservation has not been shown to have further benefit. Some animal trials of barbiturates were promising, but a large multicenter trial of thiopental found no improvement in neurologic status when this drug was given following cardiac arrest.<sup>184</sup> Similar results were found with calcium channel blockers. Animal studies were encouraging, but a clinical trial found no improvement in outcome.<sup>189</sup>

In contrast to pharmacologic therapy, three more recent studies have demonstrated improved neurologic outcome with TTM ( $32^\circ$  to  $36^\circ C$ ) for 12 to 24 hours in cardiac arrest survivors who remained comatose after admission to the hospital.<sup>190-192</sup> The earlier trials used hypothermia and studied only patients whose initial rhythm was VF. A subsequent study found no difference in survival or neurologic outcome with TTM at  $33^\circ$  versus  $36^\circ C$ . These are the first studies to document improved neurologic outcome with a specific postarrest intervention. The International Liaison Committee on Resuscitation

now recommends targeted temperature management for unconscious adult patients with return of spontaneous circulation after cardiac arrest at a constant temperature between 32° and 36°C for at least 24 hours.<sup>193</sup>

## Prognosis

For the comatose survivor of CPR, the question of ultimate prognosis is important. Most patients who completely recover show rapid improvement in the first 48 hours. Predicting poor neurologic outcome (death or vegetative state) is difficult. It is generally agreed that poor outcome should not be predicted prior to 72 hours after return of spontaneous circulation in patients not undergoing hypothermia and that time should be extended for those receiving hypothermia.<sup>194</sup> At this time point, most comatose patients with a poor outcome have either no response or only extensor posturing to painful stimuli. But the false positive rate (a good outcome when a poor outcome is predicted) for this sign is high. So, decisions should not be made on this basis alone. Confirmatory signs that have nearly a 0% false positive rate are the absence of a pupillary light reflex at 72 hours and absence of the N20 wave on somatosensory evoked potentials at 24 to 72 hours. Less reliable confirmatory signs include unreactive burst suppression or status epilepticus on EEG, status myoclonus (lasting > 30 minutes) during first 72 hours after return of spontaneous circulation, diffuse anoxic injury on computed tomography or magnetic resonance imaging of the brain, and markedly and persistently elevated neuron-specific endolase.<sup>195</sup>

---

The current guidelines for cardiopulmonary resuscitation (2015 International Consensus on Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science with Treatment Recommendations) are an update to the 2010 guidelines (2010 American Heart Association [AHA] Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care) rather than a complete revision.<sup>29,149</sup> Thus, a number of figures remain the same between both editions. To assist the reader, the AHA has published web-based integrated guidelines, which are available at <https://eccguidelines.heart.org/index.php/circulation/cpr-ecc-guidelines-2>. In addition, the AHA limits the number of algorithms that can be reproduced outside their publications. Thus, we have included URLs to help you quickly locate algorithms online that were not able to be included within the chapter.

## Conclusion

## KEY POINTS

- 1 There are certain principles that are common to all disaster events, independent of their etiology. As a group, anesthesiologists are well prepared to assist their communities in planning for and in caring for patients who sustain injury or harm from such events.

- 2 Often overlooked during emergency preparedness and disaster management training is the development of a family plan and a personal preparedness plan. The former is important whether one lives alone; has a pet, family, or friends living with him or her, or has legal responsibility for a loved one (elderly parents, disabled person). A plan should be in place that provides care for and information to loved ones.
- 3 Anesthesiologists' basic understanding of physiology and pharmacology, airway skills, fluid resuscitation expertise, ability to manage ventilators, and provide anesthesia both in and out of the operating rooms, is invaluable.
- 4 If assigned to triage patients, the anesthesiologist will be expected to classify patients into four groups: Those requiring immediate care, delayed care, minimal care (first aid), and expectant (no care).
- 5 If a patient presents with life-threatening injury, the patient is treated first and decontaminated afterward; otherwise all other patients are decontaminated in the triage area before they are evaluated and treated.
- 6 During a disaster, the anesthesiologist in charge of the schedule for the day should become the operating room medical director, co-locate with the operating room nurse in charge, and determine the status of ongoing cases. Surgeons in the midst of a procedure should be contacted and urged to finish as soon as possible. Elective cases should be postponed or cancelled.
- 7 In many disasters, infrastructure degradation plays a large part in reducing surgical capabilities at a time when demand is increased. Surgeons and anesthesiologists must consider what types of procedures can safely be undertaken and must prioritize care based on urgency and practicality.
- 8 There are three categories of biologic weapons. Category A are those weapons that are highly contagious, are associated with a high mortality rate, and have all the characteristics of a relatively ideal weapon of mass destruction.
- 9 The principle of disaster management following the release of ionizing radiation always involves containment (avoidance of bringing patients with material emitting ionizing radiation to the hospital). Therefore, as part of the containment process, to the extent possible, patients should be decontaminated at the site. Removal of clothing is critically important.  $\beta$  and  $\gamma$  rays and neutrons will no longer be present unless there is still material emitting this radiation on a person's clothing. Rather than guess whether radiation is still present it is best to disrobe patients and wash them with warm soapy water.
- 10 Orally administered potassium iodide can attenuate most radiation-induced thyroid effects, but must be given as quickly as possible because

after 24 hours, there is little protective effect.

- 11 Because of the possibility of blast, thermal, and crush injuries that may occur along with radiation injury, the care of the injured may require the care of patients who have multiple combined injuries.
- 12 Patients who have sustained traumatic injury from an improvised explosive device but do not have third-degree burns should receive minimal amounts of intravenous crystalloid and should undergo “damage control resuscitation/surgery” as soon as possible.
- 13 Infrastructure degradation worsens the consequences of mass casualty events. Preparing to deliver care under austere circumstances, developing creative responses, and practicing (conducting simulations) regularly will mitigate the effects of a disaster and increase resilience for individuals, teams, and institutions.

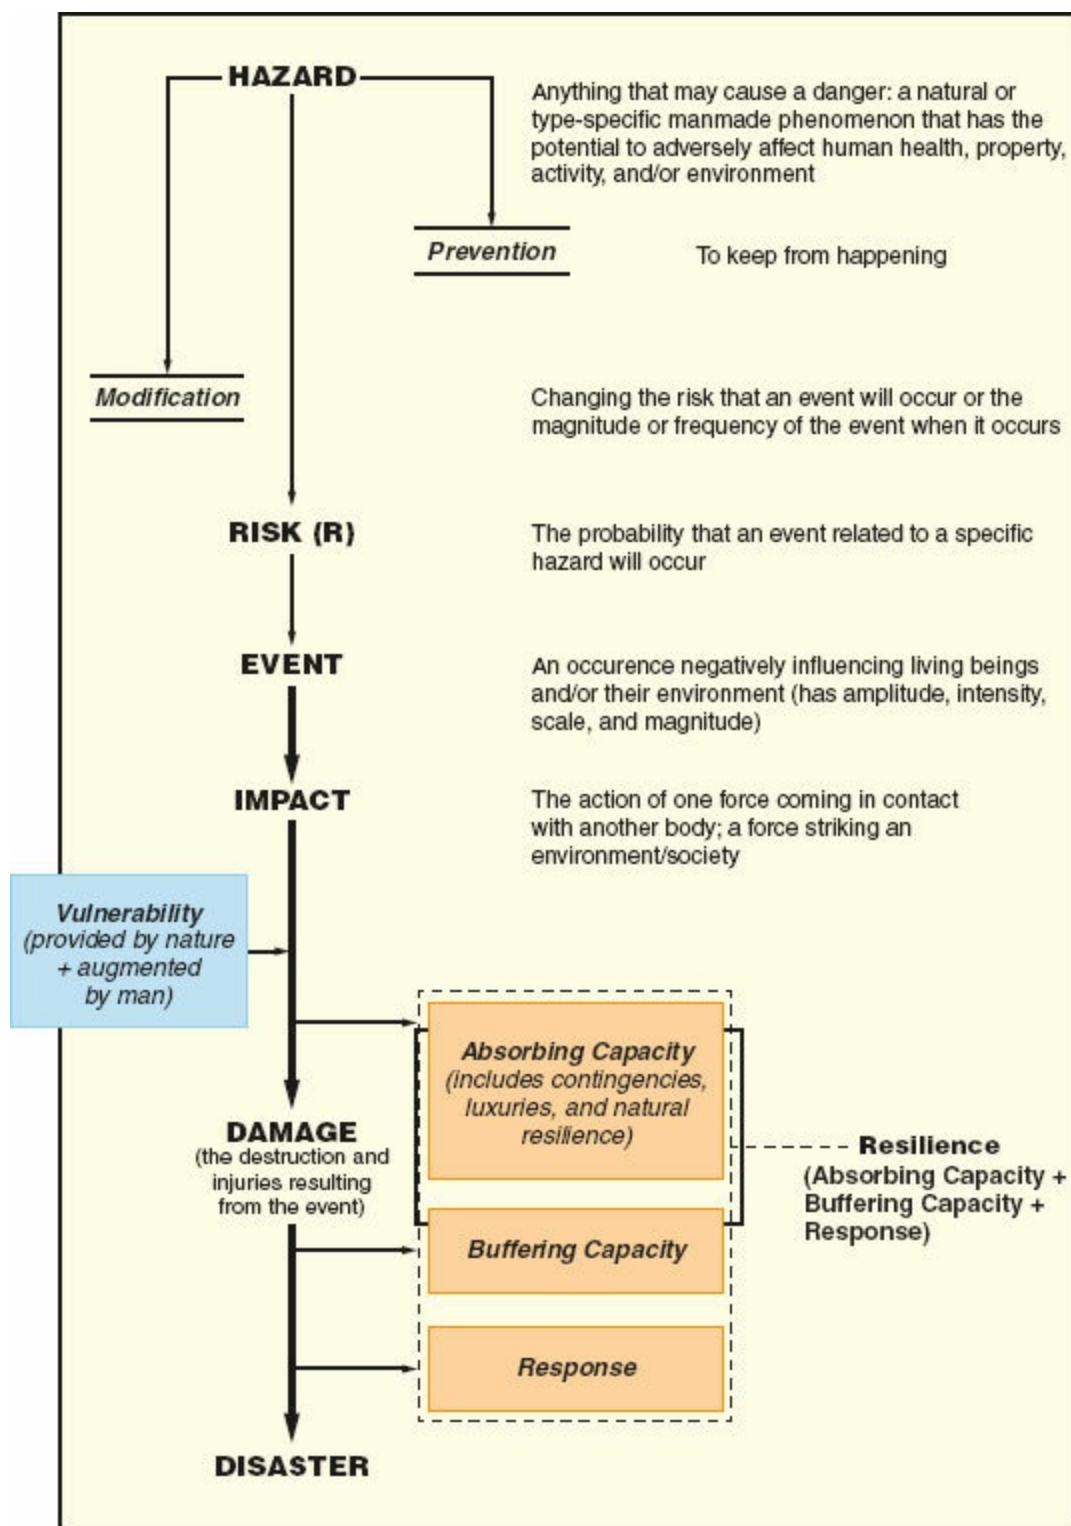

## Introduction

Hurricane Sandy, the Boston Marathon bombing, the Asiana plane crash, the pandemics caused by Ebola and Zika viruses are all events that entered our national consciousness, connoting vivid images of unfortunate circumstances. Although we cannot control, or even predict, the source of the next major disaster in the United States, it is far more likely to be Mother Nature and not an international terrorist who will be the force behind the destruction, but the latter scenario cannot be ignored. We can, however, control our preparedness and, therefore, our response to situations that result in mass casualties. As anesthesiologists, we have a responsibility not only to know our institution’s disaster plan and our role therein but also to prepare our family members and ourselves so that we do not become unintended victims of the next disaster, which in turn would result in our unavailability to provide care during a disaster and in our becoming an additional burden to the health-care system.

The World Association for Disaster and Emergency Medicine (WADEM) provides a useful diagram for defining disaster nomenclature (Fig. 59-1).<sup>1</sup> A *mass casualty incident* ( $\leq 10$  casualties arriving at a hospital simultaneously) typically refers to a situation that creates havoc within the hospital, but in these situations the hospital usually has the resources to manage the number of casualties arriving at its emergency department (ED). A *mass casualty event* ( $> 10$  casualties arriving at the ED) is one that has the potential to overwhelm a hospital’s ability to respond effectively. Certainly, the size of the hospital has bearing on how one defines a given situation, as larger hospitals have more resources to manage a larger number of casualties without being overwhelmed. Nonetheless, environmental factors also play a role in how effectively a hospital can respond to a situation. For example, a hospital’s physical structure may be so damaged by an earthquake or a tornado that it is

rendered inoperable, making it unsafe to provide care to its current patients, much less any new patients. As another example, flooding may result in the facility losing its external and its emergency back-up electrical power supply—making it, for all practical purposes, inoperable.

**Figure 59-1** Diagrammatic descriptions of definitions. (Adapted from Task Force on Quality Control of Disaster Management, World Association for Disaster and Emergency Medicine, Nordic Society for Disaster Medicine. Health disaster management: guidelines for evaluation and research in the Utstein style. Volume I. Conceptual framework of disasters. *Prehosp Disaster Med.* 2003;17(Suppl). World

Association for Disaster and Emergency Medicine website. <https://wadem.org/wp-content/uploads/2016/03/intro.pdf>.)

Mass-casualty incidents and events may result from any number of disasters, most commonly from naturally occurring events, but they may also result from human activity, both intentional and unintentional. The Joint Commission (TJC) lists the most likely disasters for which a hospital should be prepared:

- Air disaster
- Violence/security/active shooter
- Hurricane
- Tornado
- Water crisis
- Winter storm

Chemical, biologic, radiologic, nuclear, and explosive (CBRNE) attacks comprise the most likely intentional events, whereas industrial accidents, vehicle collisions, collapse of stadiums or other public structures, and fires make up the most commonly encountered unintentional events (Table 59-1).

**Table 59-1** Types of Disasters According to the Joint Commission on Accreditation of Health-care Organizations

------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

The first step in any disaster response plan is to mitigate or reduce the risk. The 2015 Sendai Framework lays out a path for international collaboration on disaster risk reduction.<sup>2</sup> The United States is also cognizant of the benefits to its foreign policy by assisting in humanitarian missions. The US Agency for International Development (USAID) spends a significant portion of its budget each year to provide humanitarian assistance in the wake of natural disasters such as floods, volcanic eruptions, and earthquakes. Of significance is that it spends just as much to mitigate the effects of future catastrophes.

The American Society of Anesthesiologists (ASA) recognized the importance of emergency preparedness and in the past decade established a Committee on Trauma and Emergency Preparedness (COTEP) and a Committee on Global Humanitarian Outreach (CGHO). The ASA has an extensive online set of resources to aid its members in emergency preparedness and disaster management.<sup>3</sup> As a member-driven organization, the ASA's development of these resources, for the most part, stems from members' requests to provide assistance during disasters (e.g., the 9-11 terrorist attack, numerous hurricanes and tornados, the 2010 Haitian earthquake, the Fukushima disaster, and most recently the 2015 Nepal earthquake). ASA members who have been involved in relief efforts, including former or current military members and international members who have experienced terrorism on a more frequent basis, have created a cacophony of voices calling for more education and training on how to prepare for a disaster and how to manage the victims of such disasters. Most residency program directors and anesthesiology residents would agree that although anesthesiologists are well prepared to manage individual patients, they lack the knowledge and education to manage the numbers of patients that might arise from a mass casualty event. There are entire books devoted to the topic and governments created large bureaucracies to address such events—so it would be naïve to think that a single book chapter could provide adequate knowledge to cope with all contingencies.

However, there are certain principles that are common to all such events, independent of their etiology, and as a group anesthesiologists **1** are as well prepared, if not better prepared, to assist their communities in planning for and in caring for patients affected by a disaster. We must expend the energy to be better educated, as the initial response to any disaster always occurs at the local level; therefore, as anesthesiologists we must be prepared to provide assistance during such emergencies. Other physicians, hospital administrators, and nongovernment organizations (NGOs) all place anesthesia providers at the top of the list of health-care workers who are needed to manage the sequelae of natural disasters and mass casualty events. In fact, anesthesiologists are in such demand that the NGO Doctors Without Borders

(*Medecins san Frontieres*) waives its policy that clinicians commit for 9- to 18-month assignments; there is an option for anesthesia providers of 1- to 3-month assignments.<sup>4</sup>

Anesthesiologists have the requisite skills to assist in many types of disasters. We might be asked to provide anesthesia for an amputation to facilitate extrication from rubble, to start an intravenous infusion in someone debilitated by diarrhea or Ebola virus disease (EVD), or to provide ventilatory support to an anthrax victim. Although the clinical situations are not customary, these are services we provide on a daily basis to individual patients.

However, disasters and mass casualty events are not something in which we participate on a daily basis; thus, education and training for these situations is critically important, beginning with preparation to respond to the most likely disasters that may occur in our respective geographic location. Even though natural and industrial disasters have occurred for millennia, the recent increasing use of CBRNE weapons by terrorists emphasizes the need for increased preparedness.

However, time and time again history demonstrates that enthusiasm for education is high after an event and then tapers off; maintaining that enthusiasm is difficult and therefore most, if not all, health-care facilities are not prepared to deal with mass casualty incidents, much less a mass casualty event, the exception being those facilities staffed by physicians with prior military training.<sup>4-7</sup> The majority of physicians most likely have not received adequate education to provide appropriate patient care in such situations. Rössler et al.<sup>8</sup> demonstrated that 24% of anesthesiologists who were deployed during humanitarian crises did not feel sufficiently prepared. Especially important for anesthesiologists who were deployed was the knowledge to repair and maintain anesthesia equipment, to perform peripheral nerve blocks using anatomic landmark techniques, to perform triage of mass casualties, and to treat patients with coexisting tropical disease.

In dealing with acts of terrorism, geography is not helpful in anticipating what might occur, but that is not to say that one cannot anticipate what to expect. One can learn from experience; terrorists have been successful, in their minds' eyes, with improvised explosive devices (IEDs), and even in those situations in which IEDs were not used, terrorists have chosen to use certain weapons of mass destruction (WMDs) more often than others. For example, a nerve agent, such as sarin, is most likely to be chosen as a chemical agent. Similarly, among biologic agents, anthrax, which was used in 2001, or smallpox would be the most likely choice because of the high lethality and infectivity associated with those two agents.<sup>9,10</sup> Twice in the past 20 years "dirty" bombs have either been planned or planted (and fortunately not used), so such devices would be the most likely source of

radiation used by terrorists. However, to underscore what was stated here based on past experience, a natural or industrial event is more likely than a terrorist event.

One must also be cognizant that although he or she might never plan to participate in a humanitarian mission overseas and therefore thinks that there is no need to train to work in an austere environment, the environment may become very austere depending on the circumstances of the disaster in which one finds oneself. Any time a situation arises in which medical capability is significantly below standards to which we are accustomed in the United States (US), the anesthesiologist is practicing in an austere environment. This austerity might occur in a:

- Mass casualty event in which the number of cases overwhelms capacity
- Natural disaster in which the hospital is damaged or loses electricity or water
- Disaster (natural/industrial/terrorist) in which care is provided on site.

As described above, graduates of anesthesiology training programs in North America have the potential to cope well in such situations, provided that they understand the basic requisites of disaster management, the focus of this chapter.

## Preparation

### *Family Plan*

To manage the numbers of casualties that would be expected during a mass **2** casualty, one must be prepared.<sup>11,12</sup> Often overlooked during emergency preparedness and disaster management training is the development of a family plan and a personal preparedness plan. A family plan is important whether one lives alone; has a pet, family, or friends living with him or her; or has legal responsibility for a loved one (elderly parents, disabled person). There are a number of websites that guide one through the creation of such a plan (Appendix A).<sup>3</sup> During hurricane Katrina, about 35% of policemen and firemen did not show up for work, which should not be surprising.<sup>13</sup> These individuals may have had to evacuate a parent in an assisted living facility or children in a day care center. Just as the military requires service members to have a family care plan (a Will and Last Testament as well!), as critically important health-care providers, we should also have family care plans. However, if you know that you will be unavailable during a disaster, then you have a responsibility to inform your employer or group of your personal situation. All family plans should include periodic family drills and updates. Plans might include situations such as what to do if there is a fire, what to do if parents do not make it home, the location of second copies of all-important

documents, where to meet if the house or neighborhood is destroyed or not accessible. Many assume that they will be able to communicate with loved ones during a disaster but often cell phone towers are damaged or so many people are trying to use the system that the network is overwhelmed. Plan in advance so that you are prepared for these contingencies.

Just as service members have a duffel bag or sea bag packed with toiletries, bedding, change of clothes, money, flashlights, and battery-operated radio, those with such important roles as ours ideally should have a packed “bag” as well. In a hurricane, earthquake, flood, tornado, or huge solar flare, loss of electric power is very likely. ATMs, gas pumps, toll booths, and so on do not function without electricity—hence the need for some cash, flashlights, a battery-operated radio (to stay abreast of the news)—and a vehicle that has a fuel tank that is not empty!

## Government Plan

In September 2011, the United States Department of Homeland Security published its first edition of a 111-page document, the National Preparedness Goal.<sup>14</sup> [Table 59-2](#) lists the multiple issues for which the Federal Emergency Management Agency (FEMA) must prepare, and with which agencies it must coordinate: the US Departments of Justice, of Health and Human Services, of Agriculture, of Commerce, and of Defense. Of note is that within the “Response” section of the document, medical response is one of eleven types of responses for which the government has planned—a response which is under the auspices of the Department of Health and Human Services (DHHS). DHHS created and maintains a National Disaster Medical System (NDMS). Unfortunately, the system has not been adequately established and maintained. As highlighted by the US response to the earthquake in Haiti in 2010, the DHHS maintains only three International Medical Surgical Response Teams (IMSuRT), teams that were established with the idea that they would provide care to US citizens injured in areas of conflict. Unfortunately, only one is funded and equipped; and, prior to the earthquake in Haiti, it had been activated and used only once—namely, for the earthquake that occurred in 2003 in Bam, Iran. Other teams that DHHS maintains in its NDMS are:

- Disaster Medical Assistance Team (DMAT) is a team that can rapidly mobilize a staff of physicians, nurses, and other support personnel and set up emergency facilities and pharmaceutical dispensaries geographically as close as possible to a disaster. The teams are self-sustaining for at least 72 hours before they require outside logistics. Just as the reserve military forces do, a DMAT is supposed to train one weekend per month. Not many surgeons and anesthesiologists have joined a DMAT, as the team does not have the capacity to perform

surgical procedures!

- Disaster Mortuary Team (DMORT), as the name implies, is a team that manages large numbers of dead bodies following a mass casualty event and that has the capacity to conduct forensic examinations.
- National Veterinary Response Team (NVRT) is a team established to provide veterinary services, as well as zoonotic disease surveillance.

**Table 59-2** Issues for Which FEMA Must Prepare and Agencies with Which It Must Coordinate

Prevention	Protection	Mitigation	Response	Recovery
Forensics and attribution	Access control and identity verification	Community resilience	Critical transportation	Economic recovery
Intelligence and information sharing	Cybersecurity	Long-term vulnerability reduction	Environmental response/health and safety	Health and social services
Interdiction and disruption	Intelligence and information sharing	Risk and disaster resilience assessment	Fatality management services	Housing
Screening, search, and detection	Interdiction and disruption	Threats and hazard identification	Infrastructure systems	Infrastructure systems
	Physical protective measures		Mass care services	Natural and cultural resources
	Risk management for protection programs and activities		Mass search and rescue operations	
	Screening, search, and detection		On-scene security and protection	
	Supply chain integrity and security		Operational communications	
			Public and private services and resources	
			Public health and medical services	
			Situational assessment	

Most recently, the DHHS through its NDMS created an experimental Medical Specialty Enhancement Team (MSET). The MSET consists of a group of precredentialed anesthesiologists and surgeons (30 of each), along with a few pediatricians. The concept is that there would be a pool of specialists who would be activated during a crisis, whether domestic or international, and would have sufficient logistic support to ensure that the team could deploy to either a fixed facility or a field site. Once activated, MSET members would be federal employees during their deployments for a minimum of 2 weeks and would be protected by workers' compensation laws, the federal tort claims act, and the Uniformed Services Employment and Reemployment Rights Act (USERRA). DHHS knows that many anesthesia providers do not have time for monthly drills or frequent call ups that the DMATs have. Although MSET members would be encouraged to train with DMATs, participation in an MSET will require far less of an investment in time. However, if activated, members of the teams would be expected to deploy or risk being dropped from the team and program. The MSET is a work in progress and many of the details of logistics and training are unanswered, the hope being that once successfully established, the size and number of teams could be expanded and

the teams better developed. The plan would be for any initial response to be local as such teams might take 2 or 3 days or longer to mobilize and deploy.

### *Health-care Agency Plans*

In recent years, the US has endured several notable events: the anthrax attacks of 2000 and 2001, the destruction of the World Trade Center Towers on September 11, 2001, the SARS epidemic of 2004, and the continued devastation caused by nature (hurricanes, earthquakes, tornadoes, floods, and fires) and terrorists. Subsequently, TJC, the Centers for Medicare and Medicaid Services (CMS), and the American Hospital Association (AHA) have more closely monitored and evaluated hospitals' and communities' emergency preparedness. In 2003, TJC published "Health Care at the Crossroads: Strategies for Creating and Maintaining Community-Wide Emergency Preparedness Systems."<sup>15</sup> The white paper has not been updated, but emergency preparedness is one of the standards TJC uses to certify hospitals. Since 2003, TJC has hosted annual conferences and disseminates information to health-care systems to help them be better prepared. One of TJC's most recent publications, "Requirements for Emergency Management Oversight," attempts to provide a clear description of leadership-level oversight of emergency management in general and critical access hospitals.<sup>16</sup> To ensure that Medicare and Medicaid patients receive appropriate care during a disaster, the CMS has published a checklist that is meant to serve as a guide for health-care facilities to prepare for and to plan for disasters and emergencies.<sup>17</sup> Similarly, the AHA sends advisories to its member hospitals to provide them information on current scourges (e.g., management of patients with EVD or those infected with Zika virus).

Despite the best efforts of law enforcement, fire and rescue teams, and emergency medical agencies, hospitals will continue to play a vital role in helping communities respond to catastrophic events, whether natural, unintentional, or terrorist-initiated. TJC was proactive in recognizing that, "It is no longer sufficient to develop disaster plans and dust them off if a threat appears imminent. Rather a system of preparedness across communities must be in place every day."<sup>15</sup> Such a system is one that is best prepared to handle a surge in casualties or degradation of a facility's ability to handle any new patients following a disaster. The TJC acknowledged this need, despite decreasing health-care resources, for what it describes as "surge capacity" within health-care systems to handle potentially hundreds, if not thousands or more, of patients who might be victims of catastrophic events. By planning and drilling, the TJC hopes to reduce the appeal to terrorists of using WMD as an effective means of terrorism, and to help communities better respond to natural disasters. The white paper TJC published focused on three major

areas:

- Enlisting the community to develop the local response.
- Focusing on the key aspects of the system that prepare the community to mobilize to care for patients, protect its staff, and serve the public.
- Establishing the accountabilities, oversight, leadership, and sustainment of a community-preparedness system.<sup>15</sup>

Although the guidelines are not mandatory or required by law, all hospitals aspire to have TJC accreditation and from that perspective, the white paper was important in that hospitals do have biannual drills of their emergency preparedness and disaster management plans, sometimes coordinating with local law enforcement agencies and health departments and emergency medical response teams, to create as realistic scenarios as possible. Unfortunately, the participation of anesthesiology departments in these drills is often minimal. Drills are usually held on weekdays during working hours, times during which it is often difficult to spare anesthesia providers. Because anesthesiology departments are fully staffed and completely operational during those hours, hospital administrators certify that they can handle the number of casualties coming through their ED. Unfortunately, the drills are not very realistic—for financial reasons, surgical procedures are never delayed or canceled and the system is never tested at night or on weekends. At night, when there are minimal telecommunications personnel in place, how would a hospital mobilize its staff? Many have telephone “trees,” but again, because they are not tested, many anesthesia providers have long since misplaced their contact information. Even if tested, how operational would the plan be during a major disaster when communication systems are overwhelmed? Short text messaging would be the best manner for departments to alert personnel to the disaster.

Other advantages to having anesthesiology departments actually participate in drills would be the establishment of trust with liaisons in the emergency response community and with local law enforcement agencies. How much better the outcome would have been if that had been the case in Moscow during the 2002 Nord-Ost siege when the Spetsnaz forces most likely used carfentanil against Chechen rebels without informing emergency response or hospital personnel, resulting in 170 deaths.<sup>18</sup>

Impediments to the establishment of effective response plans are not only financial but also based on a lack of awareness of what occurs during a disaster. As Israelis know from their years of dealing with suicide bombers, and as the Japanese found out during the release of sarin by an Aum Shinrikyo terrorist group in the Tokyo subway system in 1996, victims do NOT go to level I trauma centers, nor do they wait to be transported by emergency medical teams—they fan out in all directions to whatever health-care facility they can find, and they do so on foot, by private vehicles, or by

whatever means available.<sup>19</sup>

St. Luke's Hospital in Tokyo found itself inundated with close to 900 patients within 90 minutes after the subway sarin attacks. The ED lobby entrance (almost the entire first floor of the hospital) was crammed with patients, none of whom had been decontaminated. The ensuing chaos was difficult to manage and delayed treatment for those who needed it most. The affected patients required treatment best understood by anesthesiologists who use cholinesterase inhibitors daily and best administered by intravenous lines inserted by these same providers.

Depending on available staff, including how many of the providers will actually respond to a mass casualty event or disaster, there may be insufficient personnel available to cover all rooms in the facility's operating suites. In addition, other areas of the hospital will continue to require coverage, such as the obstetric ward, intensive care, radiology, and endoscopy suites for both disaster-related care and routine emergencies. Creative staffing at higher ratios of coverage may be required to manage patient surges.

Other places anesthesia providers can assist in delivery of health care during a disaster include:

- Triage outside the hospital (who better to manage the pain or labored respiration of the expectant patient?)
- Decontamination (who better to evaluate for the presence of anticholinesterase [nerve] agents or cyanide toxicity?)
- Vascular access or airway management (made more difficult if wearing a hazard material, or HAZMAT, suit and even more difficult if one has never worn such a suit)
- Ventilator management in the intensive care unit (ICU) or in overflow areas of the hospital such as the post-anesthesia care unit (PACU) of patients with respiratory failure caused by a nerve agent or biologic agent

## **Role of Anesthesiologist in Managing Mass Casualties**

It is difficult to anticipate every situation in which anesthesiologists could be requested to assist in managing mass casualty situations. For example, on October 26, 2002, terrorists held 750 hostages at the Nord-Ost Theater in Moscow. Many believe that the authorities instilled nebulized or volatile carfentanil into the air ducts of the opera house, thereby immobilizing the terrorists. Unfortunately, because of the incapacitating effect of the carfentanil, the hostages became victims too. Patients were transported from the theater to hospitals without any treatment prior to arrival. Ideally, anesthesiologists or other health-care providers with an opioid antagonist such as naloxone should have been readily available and present at the site to

manage both casualties. Unfortunately, this was not the case.

Anesthesiologists' basic understanding of physiology and pharmacology, airway skills, fluid resuscitation expertise, and ability to manage ventilators and provide anesthesia, both in and out of the operating rooms, is invaluable. In these mass casualty situations, many patients suffer burns, fractures, lacerations, soft tissue trauma, and amputations that will require triage, stabilization in the emergency room or in another facility near the emergency room, and possibly more definitive treatment in the operating room or in the ICU. 3

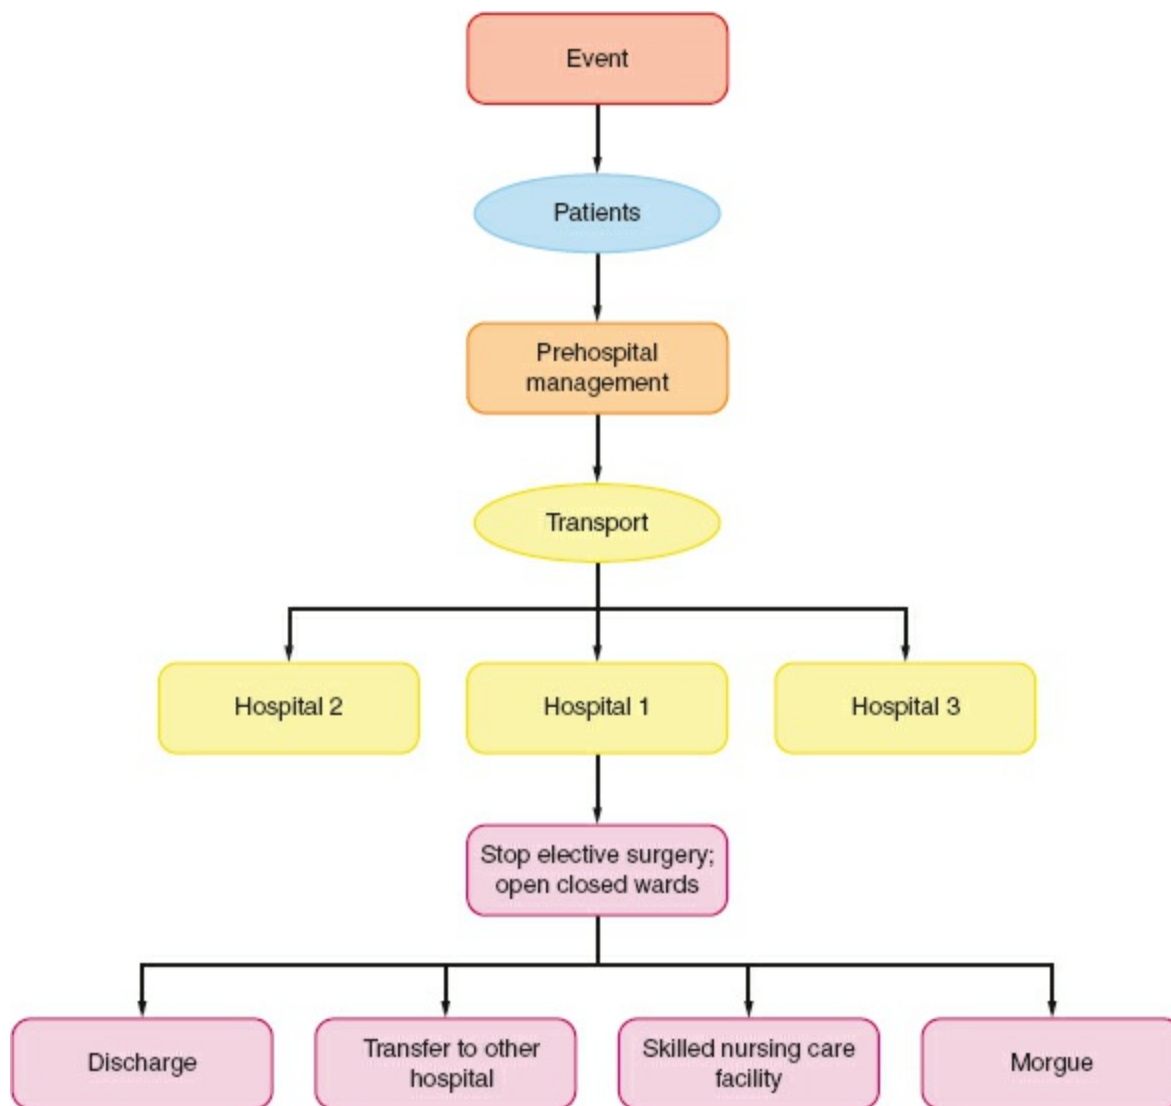

During a mass casualty event, an anesthesiologist may well be requested to provide anesthetic services in an area other than the operating room or ICU. He or she will not know where they will be working until they report to the hospital and the command and control center has developed a plan to manage the event.<sup>20</sup> The site of the command and control center is pre-established and outlined in the hospital's emergency preparedness plan, but typically it is within the hospital's ED or in close proximity. Other entrances to the hospital are typically closed during a mass casualty event for the purposes of maintaining control of the numbers of patients that might present and to allow for decontamination of patients, if necessary, avoiding exposure of hospital personnel to contagious agents or transferrable substances, such as nerve agents. The lack of such control and decontamination of the Tokyo subway sarin attack victims in 1995 resulted in a number of health-care workers becoming ill by absorbing sarin from patients who had not been properly decontaminated.<sup>19</sup> Not only were they unable to work but they also became patients themselves, increasing the number of patients requiring care and consuming resources.

## Triage

4 If assigned to triage patients, the anesthesiologist will be expected to classify patients into four groups—those requiring immediate care, delayed care, minimal care (first aid only), and expectant (no care, or comfort care only). The latter group includes those expected not to survive, or, because of the number of patients arriving, those for whom there are not adequate personnel or resources to adequately resuscitate without jeopardizing the lives of other patients who would not receive the care they require and for whom the prognosis is more favorable (Fig. 59-2). Experience has taught that initially triage officers are conservative; they try to save as many patients as possible, but over days, if not hours, they gain experience and become better at identifying patients for whom resources exist to improve outcome. In the future, biotechnology may play a role,<sup>21</sup> but at present hospitals must rely on physicians' experience and, again, because of

their knowledge of the hospital's resources in both the operating room (OR) and the ICU, they may well be the ideal triage officer. He or she will have to assess and decide if patients fall into one of the four groups. "Expectant" patients are usually transported to an area separate from the ED, where they receive comfort care. Such a site must be situated so that newly arriving patients are not exposed to the sight of dying patients. Anesthesiologists may well be assigned to provide such care because of expertise in managing airways, in establishing intravenous access for the administration of medications, and our familiarity with the available anxiolytic and analgesic medications. As emotionally difficult as the process of identifying or managing patients not expected to survive is the assessment of patients who may have been injured or affected during a disaster but who do not appear to require treatment, yet might require delayed care. Various symptoms may be exhibited, depending on the type of agent, which will direct the appropriate therapy:

- Chemical (nerve) agents: If only headache, miosis, rhinorrhea, and lacrimation after exposure, patients can be decontaminated (see later) and dismissed. Patients with dyspnea, bronchospasm, or arrhythmias will require treatment with atropine.
- Biologic agents: Fever, rash, dyspnea, cough. Antibiotics, antitoxins, antiviral agents, and supportive care.
- Radiation/nuclear: Nausea within 6 hours of exposure; because of the prevalence for those with this symptom, check leukocyte count, dismiss, and have the patient return in 48 hours for repeat check—if no change in count, no therapy is indicated. There are several new therapies in development for mitigation of the effects of radiation exposure.
- Explosive: If tympanic membranes are intact and SpO<sub>2</sub> is within normal limits, other injuries are unlikely.

**Figure 59-2** Surge capacity: How hospitals can deal with increased number of patients arriving at their emergency departments following a mass casualty event.

## Decontamination

In most situations, those with proper training decontaminate people in contact with chemical agents or radioactive materials—the decontamination is normally performed first and then patients are evaluated and triaged. The principle is to limit the exposure of the patient to the agent and prevent contamination of caregivers. Off-gassing of some chemical agents can be problematic, especially with large numbers of exposed patients awaiting decontamination. Consideration should be given to providing lightweight “escape hoods” (available from multiple vendors) to reduce respiratory exposure before decontamination can be performed. The decontamination process is usually fairly straightforward; clothes are removed and individuals are washed with copious amounts of water (the contaminated water and apparel can present quite a challenge!); if individuals have been exposed to a chemical agent, a dilute solution of sodium hypochlorite 0.5% (household bleach) can be used.

However, if a patient presents with life-threatening injury, the patient is treated first and decontaminated afterward. Patients with severe chemical agent poisoning may present with acute respiratory failure requiring emergency tracheal intubation. In this scenario, an anesthesiologist would be assigned to the decontamination station. For obvious reasons, the intubation would have to be performed with the anesthesiologist wearing a HAZMAT or a biohazard suit with multiple-layered gloves and a gas mask. The suits are not insulated or cooled and if the decontamination is performed outside the hospital, the extremes of temperature can significantly hinder performance, as does the decreased manual dexterity, because of the gloves and the impairment in vision from the face hoods. Ideally, individuals with prior training would manage the airway intubation, but depending on circumstances, that may not happen. As many have learned from past experience, it is best to anticipate the unexpected, and to be flexible if the maximum numbers of patients are to be saved. Preparation of equipment and drugs before the arrival of contaminated patients decreases the difficulties with manual dexterity that are encountered while wearing the multiple-layered or rubber gloves. Consider securing the airway with a laryngeal mask airway, when indicated, rather than with a tracheal tube. Intraosseous cannulas are often easier to insert than intravenous cannulas when wearing HAZMAT personal protective equipment (PPE).

### *Emergency Department*

Another place where an anesthesiologist might be assigned is the ED. While some level I trauma centers have an anesthesia team assigned to support the ED, many do not. Depending on the types of casualties, but especially for casualties from a violent explosion, anesthesiologists might be assigned to manage the airway and secure central venous access. Anesthesiologists should position themselves at the head of the bed and assume responsibility for the airway and venous access. For the former, it would be ideal to have two or three assistants (one providing in-line C-spine stabilization, another individual applying cricoid pressure, and a third individual administering medications.) Sometimes it is necessary to remind ED physicians and trauma surgeons that “A” (airway) and “B” (breathing) come before “C” (circulation); certainly, the primary and secondary surveys can be conducted during this critical time point but ventilation and oxygenation must be assured. Often, all three can be conducted simultaneously.

In previous industrial accidents and fires, appropriate management of the airway has been critical. Patients with large-area burns will require intravenous access for provision of intravascular volume resuscitation. Depending on the event (burn versus crush injury—protocols for fluid

resuscitation vary), in patients with extensive soft tissue and skeletal muscle damage, alkalization of the urine with volume resuscitation and diuresis may be organ and life saving.

## *Operating Room Management*

COTEP developed and published a checklist to assist the anesthesiologist in charge of the operative suite in prioritizing tasks for the management of a mass casualty event (Table 59-3).<sup>3</sup> The first task is to open the facility's operating manual (Environment of Care Manual in TDJ parlance) to the appropriate annex for the disaster, which hopefully will be hospital specific. Next, the disaster call-in tree is activated. Experience has shown that a branching tree of phone numbers is far better than a linear list. The anesthesiologist in charge should become the operating room medical **6** director, co-locate with the operating room nurse in charge, and determine the status of on-going cases. Surgeons in the midst of procedures should be contacted and urged to finish as soon as possible. Elective cases should be postponed or cancelled. A list of available rooms and staff should be rapidly assembled and transmitted to the hospital emergency operations center (HEOC). Determine realistic staffing for the next 0 to 2, 2 to 12, and 12 to 24 hours. Free staff should be directed to set up open rooms to receive trauma patients. Support staff can be directed to resupply (oversupply) locations in anticipation of heavy use. Coordination with the PACU, blood bank, and ICUs will improve patient movement and space availability. It is advisable to send a senior anesthesiologist, especially one with critical care experience, to the ED to act as a liaison between the ED and the OR. This physician should have his or her own dedicated communications link with the operating rooms to transmit timely intelligence on the nature and number of surgical cases anticipated. The liaison can also act as an advisor to the ED. Some larger institutions can consider sending teams to the ED to help with triage and initial management of casualties. If HAZMATS are involved, consideration should be given to appropriate secondary decontamination, isolation techniques, PPE, and antidotes needed.

In many types of disasters, infrastructure degradation plays a large **7** part in reducing surgical capabilities at a time when demand is increased. Surgeons and anesthesiologists must consider what types of procedures can safely be undertaken and must prioritize care based on urgency and practicality. Closed reduction of fractures or external fixation may be the most suitable options, other than amputation, for the orthopedic surgeon. General surgeons may lose the ability to do robotic or laparoscopic intra-abdominal surgery, and many intrathoracic and intracranial procedures will be impractical. Wong et al.<sup>22</sup> showed that burn dressing changes and

extensive wound debridements were the most frequent planned surgical procedures after acute trauma. Although early in a mass casualty event, elective procedures are cancelled or delayed, there will be a backlog of patients requiring surgery. Falls, burns, motor vehicle accidents, and childbirth will continue to occur, possibly with increased frequency, depending on the disaster. As the community's infrastructure degrades over time, hygiene and sanitation becomes a problem. Increased respiratory infections, gastrointestinal (GI) disease, and wound infections are likely to increase. Loss of electrical power, which can result in loss of heating, air conditioning, and water may make it difficult to maintain normal operative and postoperative conditions. Patients may present dehydrated and some authors suggest liberalization of fasting guidelines to reduce intraoperative fluid needs and improve postoperative wound healing.<sup>23</sup>

**Table 59-3** Operating Room Procedures for Mass Casualty: Management Step by Step

**Objective:** To be able to manage the flow of patient care in operating rooms (ORs) during a mass casualty situation.

Steps: Indicate date and time for each item.

- Refer to facility's operations manual.  
Open up appropriate annex.
- Activate call-in tree.  
Assign an individual to activate. Use clerical personnel or automatic paging system, if available.
- Assess status of operating rooms.  
Determine staffing of ORs 0–2, 2–12, and 12–24 hours.  
Hold elective cases.
- Alert current ORs.  
Finish current surgical procedures as soon as possible and prepare to receive trauma.
- Assign staff.  
Set up for trauma/emergency cases.
- Anesthesia coordinator should become OR medical director.  
Work with OR nursing manager to facilitate communication and coordination of staff and facilities.
- Report OR status to hospital command center (HCC).  
Enter telephone, email address of HCC.
- Ensure adequate supplies.  
Coordinate with anesthesia techs/supply personnel to ensure adequate supplies of fluids, medications, disposables, etc.

- Contact the postanesthesia care unit.  
Accelerate transfer of patients to floors/ICUs in preparation for high volume of cases.
- Anesthesiologist should act as liaison in emergency department (ED).  
Send an experienced practitioner to the ED to act as a liaison (your eyes and ears) and keep communications open to anesthesia coordinator.
- Consider assembly of stat teams.  
Combination of anesthesia, surgical, nursing, respiratory personnel to triage, as needed.
- Hazardous material/weapons of mass destruction event.  
Review special personal protective procedures, such as decontamination and isolation techniques. Consider if part of the OR hallways should be considered "hot" or should have ventilation altered. Good resources include Chemical Hazards Emergency Medical Management and Radiation Emergency Medical Management websites.
- Coordinate with blood bank.  
Verify blood availability.
- Coordinate with other patient care areas.  
Intensive care units, obstetrics, pediatrics, etc. to ensure continuity of care for new and existing patients.

ICU, intensive care unit.

Developed by the Committee on Trauma and Emergency Preparedness.

## Chemical

### *Nerve Agents*

Prior to the last century, it was unthinkable that rogue states or terrorists would use chemical agents. During the First World War, more than one

million soldiers and civilians were exposed to chemical gas injuries, with over 100,000 of them dying. In 1935, Italy invaded Abyssinia (Ethiopia) and during that invasion, sprayed mustard gas from aircrafts. When Japan invaded China in 1937, mustard, phosgene, and hydrogen cyanide were used. In that same year, German chemical laboratories produced the first nerve agent, tabun. During 1963 to 1967, Egypt used phosgene and mustard agents in support of South Yemen during the civil war in that country. When Iraq attacked Iran in the 1980s, mustard and nerve agents were used. In all these examples, chemical agents were used by the military during armed conflict. The governments mentioned have all signed the Chemical Weapons Convention. January 2012 marked the end of an era as, in compliance with the Chemical Weapons Convention ratified by the Senate in 1997, the US Army Chemical Materials Agency completed destruction of 27,000 tons of chemical weapons that it had manufactured and stored over the years.<sup>24</sup>

However, as one era ended another one had already begun. In 1994 and 1995, the use of the nerve agent sarin by the Japanese cult Aum Shinrikyo was a major turning point, because it was the first time that a terrorist group had used a nerve agent in a terrorist attack. More than 5,000 persons were evaluated at hospitals, approximately 1,000 of whom had been exposed to the nerve agent, and 18 died. Both sides in the ongoing Syrian Civil War that started in 2013 have used chemical agents, including chlorine, mustard agent, and sarin. The nerve agents are so named because of their mechanism of action. The G series agents (GA, GB, GD, GF) were developed but never used by Germany during 1930s. They are considered nonpersistent, lasting in the environment a few minutes to a few days. The Novichok or V series agents (VE, VG, VM, VR, and VX) were manufactured by the USSR in 1980s. They persist in the environment and are 10 times more toxic than the G agents. VX is the only one ever fielded by the United States.

Similar to organophosphate insecticides and to the anticholinesterase (AChE) drugs that anesthesiologists use daily, nerve agents inhibit AChE. This inhibition results in excessive amounts of acetylcholine (the reason why a cholinergic agent such as atropine or glycopyrrolate is administered anytime we inject an AChE, such as neostigmine) at preganglionic muscarinic and postganglionic muscarinic and nicotinic receptors, leading to copious secretions, meiosis, arrhythmias, bronchospasm, tonic muscle contractions, respiratory paralysis, seizures, and death. A cholinergic agent and competitive muscarinic blocker (i.e., atropine or glycopyrrolate) is administered to attenuate and block the muscarinic side effects of the agents.

When anticipating a nerve agent attack, US military personnel pretreat themselves with low-dose pyridostigmine and don PPE; the latter prevents the agent from contacting and wetting skin from which it is readily absorbed, and low-dose pyridostigmine binds to AChE, preventing any nerve agent that is

absorbed from binding to the enzyme. Pyridostigmine is a reversible drug that will be metabolized over time, whereas the nerve agents bind to AChE irreversibly.

US military personnel carry syringes of atropine and of pralidoxime chloride (2-PAM-CL), an oxime that reactivates AChE by removing the nerve agent from its binding site on the enzyme. Spontaneous reactivation of enzyme complex is variable, which partly accounts for differences in acute toxicity between the nerve agents. 2-PAM-CL is administered to reactivate the dialkylphosphonyl AChE enzyme more quickly.<sup>25</sup> The most optimistic estimates are that after exposure 30 minutes will elapse before casualties are transported to EDs, the diagnosis of nerve agent attack is made, and the oxime can be administered. Thirty minutes is optimistic, given that there have been deaths at chemical weapons manufacturing facilities within 2 minutes of accidental exposure. Toxicity of the nerve agents is not just related to which agent, but also to the dose of agent to which one is exposed, and also the duration of exposure. However, if numbers of casualties arrive at a triage site outside a hospital ED, the sooner one administers an oxime, such as 2-PAM-CL, obidoxime, or HI-6, the better. Most of the nerve agents can be reversed with the exception of soman. With soman, aging of AChE occurs so fast that an oxime will have no effect. Even though aging occurs more slowly and reactivation occurs relatively rapidly in the case of nerve agents other than soman, early oxime administration is still clinically important in patients poisoned with these agents. Experimental studies on the treatment of nerve agent poisoning have to be interpreted with caution. Some studies have used prophylactic protocols, whereas the drugs concerned (atropine, oxime) would be given only to a civilian population after exposure. The experimental use of pyridostigmine before nerve agent exposure, although rational, is not of relevance in the civilian context. With the possible exception of the treatment of cyclosarin (GF) and soman poisoning, a review of available experimental evidence suggests that there are no clinically important differences between the different oximes in the treatment of nerve agent poisoning, if studies employing pretreatment with pyridostigmine are excluded.<sup>25</sup>

## Diagnosis

Patients exposed to a nerve agent, either ingested, inhaled, or via the transdermal route, present with evidence of muscarinic site stimulation: airway, pupillary, and GI tract constriction; bradycardia; and activation of the glands within the eyes, nose, mouth, and sweat glands manifested by intense lacrimation, rhinorrhea, salivation, and sweating. The degree of exposure correlates with the amount of secretions produced. Nicotinic stimulation at preganglionic sites leads to tachycardia and hypertension, and at the nicotinic

acetylcholine receptor on the neuromuscular junction, fasciculation, twitching, fatigue, and flaccid paralysis. The excessive parasympathetic activity leads to miosis and loss of accommodation so that patients complain of blurred vision. Within the respiratory system, the increased parasympathetic activity leads to bronchorrhea and bronchoconstriction, which together with the respiratory muscle fatigue initially manifests as coughing, wheezing, and shortness of breath. The agent on the skin will produce localized sweating and fasciculation obvious to the naked eye. Within the cardiovascular system, activity within the muscarinic system leads to bradycardia, but depending on the degree of nicotinic activity in the preganglionic nodes, a patient's heart rate may be low, normal, or high. Within the GI tract, the increased parasympathetic activity leads to nausea, vomiting, diarrhea, and incontinence. This overall unopposed parasympathetic activity leads to a mnemonic of "DUMBBELS" (*diarrhea, urination, miosis, bronchorrhea and bronchoconstriction, emesis, lacrimation, and salivation*).

## Treatment

The toxicity of the nerve agents depends on the compound delivered, the dose that is delivered (LC), and the time (t) that an individual is exposed to that dose. For example, a patient exposed to 10 mg/m<sup>3</sup> of an agent for 10 minutes would have an LCt of 100 mg/min/m<sup>3</sup>. The same could be achieved by being exposed to a concentration of 100 mg/m<sup>3</sup> for only 1 minute. The treatment for nerve agent poisoning is one with which every anesthesiologist is familiar. Atropine is a competitive muscarinic blocker. Pralidoxime chloride is the better long-term treatment as it reactivates AChE by removing the organophosphate compound. Atropine is administered at a dose of 2 to 6 mg or more and repeated every 5 to 10 minutes until secretions begin to decrease (i.e., until the patient is no longer salivating) and ventilation is improved. In severe casualties, 15 to 20 mg would not be unusual and some casualties have required gram amounts of atropine. The US military travels with automatic injectors containing 2 mg of atropine and 600 mg of 2-PAM-CL.

Depending on the extent of exposure, treatment differs. For minimal exposure, often seen with brief exposure to nerve agent vapor, patients may complain of headache and tightness in the chest and manifest miosis, rhinorrhea, and salivation. Individuals must be removed from further exposure, clothing removed, topical atropine applied to the eye if pain is significant, and wet decontamination must be performed if there was any liquid exposure. With moderate exposure, the same signs are present, but the patient demonstrates more severe rhinorrhea, complains of dyspnea, and on examination, there is evidence of bronchospasm and muscle fasciculation. Patients with moderate (and severe) poisoning require treatment with

atropine and 2-PAM-CL intramuscularly. Casualties again must have their clothing removed and if they were exposed to liquid nerve agent, they need to go through a wet decontamination process. With severe exposure, the same symptoms as mentioned above are present, but now the patient manifests severe respiratory compromise, flaccid paralysis, incontinence, arrhythmias, and convulsions. After decontamination the patient will require repetitive doses of intravenous atropine, along with intramuscular 2-PAM-CL, intravenous (IV) benzodiazepines to treat the seizures (caused by the muscarinic effects of the nerve agents within the central nervous system [CNS]<sup>26</sup>), and intubation and mechanical ventilation, depending on the degree of respiratory compromise.

With nerve injury casualties, decontamination is critical. It needs to be done as quickly as possible, first by leaving the area of exposure. As commented at the beginning of this chapter, health care and emergency workers in Japan became victims themselves by standing unprotected in the subway cars in which there was sarin.<sup>19</sup> Patients are decontaminated by removing their clothing and washing with copious amounts of water and 0.5% hypochlorite (dilute household bleach). The bleach is not as critical as washing with copious amounts of water. Depending on the number of casualties, EDs may coordinate with the fire department. For example, they might arrange fire trucks side-by-side with a “chamber” established between the two trucks in which individuals can disrobe and be sprayed with water as they walk through the chamber. From there, depending upon the severity of the symptoms, they would receive atropine, 2-PAM-CL, and further treatment.

## *Pulmonary Agents*

The so-called pulmonary agents are, by nature, gases at room temperature, and almost any gas could be considered a pulmonary agent if released in sufficient quantity in a closed environment to displace oxygen, thereby causing exposed subjects to die by asphyxiation. Chlorine and phosgene are considered the classic pulmonary agents and the two most likely to be used by terrorists. If quantities are released that are sufficient to displace oxygen, then death results from asphyxia. In addition, these two gases are extremely toxic to the lungs; individuals who survive the acute exposure if they have inhaled even small amounts often develop acute lung injury or acute respiratory distress syndrome (ARDS). However, the treatment is no different from what a critical care anesthesiologist would provide in managing a patient with Silo Filler’s Disease or Farmer’s Lung, which develops after exposure to nitrogen dioxide when a farm worker opens or enters a silo that has inadequate ventilation. The treatment of the resulting noncardiogenic pulmonary edema

from NO<sub>2</sub> or the pulmonary agents is supportive: mechanical ventilation using small tidal volumes (6 to 8 mL/kg), peak airway pressures (<30 cm H<sub>2</sub>O), positive end expiratory pressure, and inspired oxygen concentrations of 50% to 60% or less.

## **Blood Agents**

The third and final class of chemical toxins includes the blood agents—hydrogen cyanide and cyanogen chloride. Because of the instability of the latter, hydrogen cyanide is more likely to be used by terrorists in a closed environment as an aerosol. Again, anesthesiologists are familiar with this class of substances because of our clinical use of sodium nitroprusside as an intravascular vasodilator, which has cyanide as a metabolite. Cyanide inhibits cellular respiration by interrupting the oxidative electron transfer process in mitochondria. The treatment for cyanide toxicity is similar to what anesthesiologists would do for a patient who had an accidental overdose of sodium nitroprusside: Intravenous thiosulfate and supportive care, including tracheal intubation, ventilation with 100% oxygen, and inotropes and vasopressors to stabilize the cardiovascular system.

## **Biologic**

### **History**

This section includes a discussion that considers the naturally occurring infectious agents, as well as those agents most likely to be used by terrorists. Many of the latter caused plagues in the past or were used as weapons. Infectious organisms have been used as biologic weapons since the dawn of history. Ghengis Khan is reported to have used cats infected with fleas bearing the plague to destroy towns in his conquest of Asia. In the 1770s, British forces distributed blankets that harbored smallpox virus to American Indians, killing more than 50% of the infected tribes. In World War II, Unit 731, a Japanese military unit, is reported to have dropped plague-infected fleas over populated areas of China, causing outbreaks of plague and killing several hundred thousand people.<sup>27</sup>

The ideal biologic agent is one that has the greatest potential for adverse public health consequences, generating mass casualties, and with potential for easy large-scale dissemination that could cause mass hysteria and civil disruption. Such a weapon should be relatively easy to produce, inexpensive, highly infectious, and contagious, resulting in widespread morbidity and mortality. To be effective, there should be little or no natural immunity, which is currently the case with diseases such as smallpox for which we no

longer routinely vaccinate individuals, except in the military and in high-risk public health areas. There are three categories of biologic weapons (Table 59-4). Category A includes weapons that are highly contagious, that are associated with a high mortality rate, and that have all the characteristics of a relatively ideal weapon of mass destruction.

**Table 59-4** Biologic Agents Used for Warfare

<b>Category A:</b> Highly contagious and fit all the characteristics of a relatively ideal biologic agent
<i>Bacillus anthracis</i> (anthrax)
<i>Variola major</i> (smallpox)
<i>Yersinia pestis</i> (plague)
<i>Clostridium botulinum</i> (botulism)
<i>Francisella tularensis</i> (tularemia)
Viral hemorrhagic fever (Ebola, Lassa, Marburg, Argentine)
<b>Category B:</b> Relatively easy to disseminate but have low mortality rates
<i>Coxiella burnetii</i> (Q fever)
<i>Vibrio cholerae</i> (cholera)
<i>Burkholderia mallei</i> (glanders)
Enteric pathogens ( <i>E. coli</i> 0157:H7, <i>Salmonella</i> , <i>Shigella</i> )
Cholera, cryptosporidium
Various encephalitic viruses
Various biologic toxins
<b>Category C:</b> Emerging pathogens that might be engineered for biologic warfare
Various equine encephalitic viruses

## Smallpox

The last case of naturally occurring smallpox in the world was reported in 1977 in Somalia.<sup>28</sup> In 1978, two laboratory workers were infected with the disease in the United Kingdom.<sup>28</sup> In 1980, the World Health Organization (WHO) announced that the world was free of this scourge. Terrorists might consider using smallpox as a weapon because an increasing number of people no longer carry immunity. Routine vaccination for smallpox is no longer performed, except in the military and for some public health-care workers considered at high risk of contracting the disease (individuals whom the government would rely on to staff vaccination stations if there were a breakout).<sup>28</sup> Forty to eighty percent of patients exposed to the smallpox virus will become infected with the disease. Smallpox is highly infective, requiring only 10 to 100 organisms to infect an individual. The mortality rate is approximately 30% in unvaccinated patients and as high as 50% if smallpox occurs in communities that have no native immunity against smallpox. The protective effect of the smallpox vaccine decreases with time, but even at 20

years, the vaccine would provide some protection.

When an unvaccinated person is initially infected, she or he develops a prodrome of malaise, headache, and backache, with the onset of fever to as high as 40°C. The fever decreases over the next 3 or 4 days, at which time a rash develops. This progression is in contradistinction to chickenpox, in which the rash develops at the same time as the fever. Unlike chickenpox, smallpox has a predilection for the distal extremities and face, though no part of the body is spared. Also, all lesions in a patient with smallpox are at the same stage, whereas with chickenpox, lesions are at multiple different stages: papules, vesicles, pustules, and scabs. Most cases of smallpox are transmitted through aerosolized droplets that are inhaled, but clothes and blankets that have come in contact with pustules, until the scab falls off, are infectious; the organism can be transmitted in these linens.

Smallpox has probably been present in humans since 10,000 BC. It is transmitted human to human, and if used as a bioterrorism agent, would likely be dispersed by aerosols in the environment with the hope that multiple humans would be infected and would transmit the virus to other humans. There is evidence that the former Soviet Union developed transgenic smallpox viruses that are very infectious and for which the US vaccine may not be completely protective. The time of onset after exposure to such a virus might be very short. Currently there are only two WHO- approved depositories of smallpox, at the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia, and at the Institute of Virus Preparations in Russia. With the collapse of the Soviet Union, there was a concern that some stores of smallpox made it into rogue countries that may have developed their own biologic weapons.

A look at how the WHO eradicated smallpox might be helpful in understanding how the United States has prepared to respond to smallpox as a biologic weapon. In the eighteenth century, 400,000 Europeans a year were dying from smallpox. Though only 1% of patients who survive smallpox become blind, it accounted for one-third of all cases of blindness in Europe. The WHO eradicated smallpox by identifying patients with smallpox and placing them in strict quarantine. Such patients are readily identified because of the presence of smallpox lesions on the face. Patients were quarantined and all their contacts were vaccinated, because there was a 3- to 7-day window with the naturally occurring virus before the patient developed symptoms and signs of smallpox.<sup>29</sup>

Vaccination against smallpox is controversial. The vaccine is made from a live vaccinia virus developed in calf lymph, but is not an attenuated smallpox virus itself. Smallpox is a member of the Orthopox genus of the poxviridae family of double-stranded deoxyribonucleic acid (DNA) viruses that also contain cowpox, monkey pox, and vaccinia. In the event of a documented case of smallpox, the CDC plans to quarantine the patient and immediate patient

contacts within a certain geographic area would be vaccinated. There are stockpiles of vaccines placed strategically throughout the United States just for such an event. A bifurcated needle is dipped into the reconstituted vaccine and then 10 to 15 points of entry are made into the dermis of the upper deltoid. Because of the side effects of smallpox vaccinations, people with immunologic disorders, eczema (active or with a history of severe eczema), and pregnant or nursing women should not receive the vaccine. The CDC monitors for adverse side effects of vaccination; most are not serious, such as fever, rash, and malaise, although two cases of cardiomyopathy have been reported.<sup>30</sup> There is no plan to vaccinate the entire US population following an isolated case.

Many obstacles have been overcome to develop second- and third-generation smallpox vaccines. Before 2001, the vaccine that was used, Dryvax (similar to what Jenner used in the 18th century), contained live attenuated virus and was the reason that immunocompromised individuals developed adverse events when vaccinated. From 2001 to the present, Acambis Modified Vaccinia Ankara (ACAM) has been used to vaccinate against smallpox. Dryvax and ACAM are fairly similar, though the latter may be a little safer to use than Dryvax, but not so much safer than when immunocompromised individuals are offered the vaccine. To avoid the dangers of a live vaccine, an inactive vaccine (modified vaccinia Ankara [MVA; Imvamune]) was developed<sup>31</sup>; the United States has a contract to purchase 20 million doses. The available evidence is that even immunocompromised individuals, such as those with HIV infection, might tolerate immunization. The CDC and the states' departments of health will implement their quarantine and vaccination plans should an index case or cluster cases occur.

## Anthrax

*Bacillus anthracis* (anthrax) was probably used as a biologic weapon in the Middle Ages, when troops laying siege to a town would catapult infected animal carcasses over the ramparts into the inhabited areas. For reasons discussed later, this method was not a particularly effective method of infecting the native population. During the twentieth century, several countries, including the United States, Great Britain, Russia, and Iraq, studied ways to “weaponize” anthrax. Normally, if anthrax spores are inhaled, they clump in the nasal pharynx. To be weaponized, *B. anthracis* must be finely ground so that it readily aerosolizes and can get to and deposit in the terminal bronchioles and alveoli.<sup>32</sup> Inhalation anthrax, which was relatively uncommon in the past, has an 80% fatality rate. One of the letters that was mailed in the anthrax attacks of 2001 contained 2 g of weapons-grade anthrax. With a median lethal dose (LD<sub>50</sub>) of 1,000 spores, under optimal conditions, this was

enough material to infect 50 million individuals. In a terrorist attack, for maximum effect, anthrax could be aerosolized and sprayed from airplanes or delivered through a dispersion device mounted on top of a missile. The attacks on North America in 2001 and the accidental release of spores at a biologic facility in the city of Sverdlovsk in the former Soviet Union in 1979 are illustrative of the potential of anthrax as a weapon. In the United States, 5 of 11 cases resulted in death (45% mortality rate); in the former Soviet Union, 66 of 77 died (86% mortality rate).<sup>33</sup> The Aum Shinrikyo also released anthrax spores in Tokyo in 1993. Fortunately, they used a nonpathogenic strain of anthrax and so there were no casualties.<sup>32</sup> As demonstrated in 2001 in the United States, terrorists are sophisticated enough that they might be successful in obtaining and releasing weapons-grade anthrax. Such attacks, even if detected early,<sup>34</sup> would create mass hysteria and greatly affect the entire country and world.<sup>35</sup>

Anthrax is a gram-positive, spore-forming bacillus that is transmitted to humans from contaminated animals, their byproducts, or carcasses. Spores may persist in soil for years. The disease is all but gone from North America, but is still prevalent in many developing countries, and herbivores, especially cattle, usually die within 24 to 48 hours of contracting the disease. The carcass has such a large number of organisms, that humans, who are relatively resistant to infection, can be exposed and contract the disease.<sup>36</sup>

There are three primary types of anthrax infection: Cutaneous, inhalation, and GI. Ninety-five percent of cases are cutaneous. From a public health perspective, inhalation anthrax is most concerning, as it usually affects 2,000 to 20,000 people worldwide per annum. People can be exposed through contact with animals in an agricultural or industrial setting (i.e., a rendering plant or tanning facility, or, as mentioned previously, in the production of biologic weapons).<sup>37</sup>

Anthrax has additional appeal to bioterrorists because inhalation anthrax is difficult to detect. It manifests as an influenza-like disease with fever, myalgias, malaise, and a nonproductive cough with or without chest pain.<sup>38</sup> After a few days, the patient appears to get better, but then a couple of days later the patient becomes much more ill with dyspnea, cyanosis, hemoptysis, stridor, and chest pain. The most notable finding on physical examination and laboratory testing is a widened mediastinum. Usually when a patient develops profound dyspnea, death ensues within 1 to 2 days. In the past, penicillin G was the treatment of choice, but since weaponized anthrax has been engineered to be resistant to penicillin G, ciprofloxacin or doxycycline is more commonly used. In the outbreaks in Florida, Washington DC, and New Jersey, contacts of infected patients or people exposed to the spores were treated with ciprofloxacin or doxycycline. A more recent study concluded that this drug regimen is the best strategy for managing a small-scale attack, as

occurred in 2001.<sup>39</sup>

## Plague

The oldest cases of *Yersinia pestis* (bubonic plague) were documented in China in the third century. *Y. pestis* has been thought to be the etiologic agent in multiple epidemics and three pandemics, the first of which was during the Roman emperor Justinian's reign; the second pandemic was during the 14th century—the Black Death—and killed one-third of the population of Europe; and the last was at the end of the 19th century and killed millions in China and India.<sup>40</sup> The first documented use of plague as a biologic weapon was in 1346 when the Tartars in their siege of the fortress at Kaffa catapulted infected corpses into the city.<sup>27</sup> The plague was used by Unit 731 to infect large areas of China, and as many as 200,000 Chinese may have died. More recently, the United States and Russia have studied *Y. pestis* as a bioagent, examining ways to aerosolize and ways to distribute the bacillus. Surprisingly, the organism is only viable for approximately 60 minutes after being distributed; if dispersed by an airplane, its viability would limit its infectivity for only 10 km from the dispersion site.

*Y. pestis* is a nonmotile, gram-positive bacillus. Rodents and fleas are its natural hosts, and they re-infect each other by fleas biting infected rodents. Soil can be contaminated and therefore rodents can acquire the disease simply by digging in an infected area. Humans are an accidental host and they usually acquire the disease from a fleabite, though rarely there can be direct inoculation of infected material into a person. Direct person-to-person transmission occurs with pneumonic plague.

There are two types of plague: Bubonic and pneumonic. With bubonic plague, after a fleabite, there is a 2- to 6-day incubation period, at which time there is the sudden onset of fever, chills, weakness, and headache. Intense painful swelling occurs in the lymph nodes, usually in the groin, axilla, or neck. These swellings or buboes are typically oval in nature, 1 to 10 cm in diameter, and extremely tender. Up to 25% of patients will have pustules, papules, or skin lesions near these buboes. Without treatment, patients become septic, develop septic shock with cyanosis and gangrene in peripheral tissues, leading to the “black death” descriptor that was used during the pandemics in Europe. As mentioned, material from these buboes is infective only if inoculated into human tissue. However, patients who have bubonic plague can seed their lungs, in which case they develop pneumonic plague. During coughing, they aerosolize *Y. pestis*, which is highly contagious. Mortality for either form of the disease is above 50%. Diagnosis is made with a Gram stain or culture of organisms from blood, sputum, or buboes. The treatment of choice is streptomycin, but chloramphenicol and tetracycline are

acceptable alternatives. Patients with pneumonic plague should be managed as one would manage a patient with drug resistance to tuberculosis, because the respiratory secretions are highly infectious. There is currently no vaccine against *Y. pestis*.

## Tularemia

*Francisella tularensis* (tularemia) has some similarities to anthrax and plague, but is not nearly as dangerous. It was studied as a biologic weapon in the twentieth century because it is highly infectious, requiring an inoculum of perhaps as small as only ten organisms.<sup>41</sup> During World War II, tularemia developed in soldiers along the German-Russian front and was thought secondary to the use of *F. tularensis* as a biologic weapon. The fact that both armies were infected underscores one of the dangers of using infectious agents as biologic weapons. Often these are dispersed with aerosols, and despite the best predictions of air currents, they are notoriously unpredictable; with the shifting air currents, one's own troops could become infected. Unit 731 of the Japanese army also studied the use of *F. tularensis* as a biologic weapon, and the United States and Russia were known to have grown large quantities of *F. tularensis*.

*F. tularensis* is a gram-negative, pleomorphic rod. There are several animal hosts, with the cotton-tailed rabbit being one of the most susceptible. Normally, humans acquire *tularensis* through direct contact of an infected animal or from the bite of an infected tick or deerfly.<sup>41</sup> Occasionally, the ingestion of infected food or inhalation of a small amount of aerosol will initiate the disease. There are two strains of *F. tularensis*, Jellison A and B, with the B strain being relatively innocuous; in North America the A strain is quite virulent. Normally, a patient will develop a cutaneous ulcer at the site of entry after contact with an animal. As few as 10 or 50 organisms can invade the body through either hair follicles or mini abrasions. The incubation period is 2 to 6 days, at which time there is swelling and ulceration at the site of entry. As the swelling continues, the skin eventually breaks, creating an ulcer, which develops a necrotic base that becomes black as it scars. It is likely that *F. tularensis* would be delivered as an aerosol from an airplane, in which case, following inhalation, there is a 3- to 5-day incubation period, and then the onset of disease is marked with fever, pharyngitis, bronchitis, pneumonia, pleuritis, and hilar lymphadenopathy. Mortality rate for pneumonic tularemia is 5% to 15%.

The treatment of choice for tularemia is streptomycin, though gentamicin, tetracycline, and chloramphenicol have been used. There is concern that the former Soviet Union, perhaps the United States, and perhaps terrorists have engineered *F. tularensis* to be resistant to a number of agents. Prophylaxis

with streptomycin, ciprofloxacin, or doxycycline has been recommended in the past for individuals exposed to the organism. There was a vaccine comprised of an attenuated whole organism strain, but it is no longer available.

## Botulism

The first known work with *Clostridium botulinum* (botulism) as a biologic weapon was in World War II. Both the Germans and Japanese military and scientific communities experimented with *C. botulinum*. Unit 731 fed pure cultures of *C. botulinum* to Chinese captives with devastating effects. Both the United States and former Soviet Union are known to have produced large quantities of *C. botulinum* toxin, as have Iraq, Iran, Syria, and North Korea. In fact, after the first Gulf War, Iraq admitted to having over 19,000 L of concentrated botulism toxin, of which almost half was loaded on military weapons.<sup>42</sup> Nineteen thousand liters of botulinum toxin is enough to kill the world's population three times over! More recently, Aum Shinrikyo, the cult in Japan, dispersed aerosols of botulinum toxin on three different occasions in Japan. Fortunately, their dispersal methods were associated with multiple problems and no one was injured. Of concern is that a terrorist organization working with a rogue state could acquire and use botulinum as a bioterrorist weapon.

Botulism manifests as neuroparalysis caused by the toxin from *C. botulinum*. Unlike all the other biologic weapons mentioned previously, it is not caused by a live organism and, therefore, is not contagious. The organism from which botulinum toxin is derived is a gram-positive spore, which is an obligatory anaerobe, widely distributed in soil and in marine and agricultural products. Humans ingest *C. botulinum* without apparent effects until the organism begins to release toxins, of which there are several. Toxins are distributed from the GI tract, or from the lungs if inhaled, in the bloodstream to cholinergic nerve endings, where they block the release of acetylcholine at muscarinic and nicotinic receptors by inhibiting the intracellular fusion of the vesicles containing acetylcholine to nerve terminal membrane for release into the synaptic cleft. This mechanism is the exact opposite of the chemical nerve agents such as sarin, which result in an increase in the amount of acetylcholine at the cholinergic receptors, but the end result is the same. Patients develop a progressive weakness and a flaccid paralysis that begins in the extremities and progress until the respiratory muscles cease to contract. Of note, *C. botulinum* toxin is the most potent poison known to humans; the LD<sub>100</sub> dose is only 1 pg.<sup>43</sup>

Shortly after ingestion or inhalation of the toxin, the incubation period is between 2 hours and 8 days, but most commonly between 12 and 36 hours.<sup>44</sup>

As muscles become weak, patients develop diplopia, dysphonia, dysarthria, dysphagia, and eventually dyspnea and finally paralysis. Along with the effects noted within the skeletal muscle system caused by the lack of acetylcholine at the nicotinic receptor, muscarinic blockade results in decreased salivation, ileus, and urinary retention, again the opposite of what is seen with nerve agent poisoning.

Toxins can be removed through gastric lavage, use of cathartics, and with enemas. The treatment of patients includes the use of a trivalent antitoxin. Patients with profound respiratory embarrassment should have their airways protected and mechanical ventilation initiated. Without the use of antitoxin, it takes the patient 2 to 8 weeks to recover. The mortality rate is quoted as 5% to 10%.

## *Hemorrhagic Fevers*

There are a number of viral hemorrhagic fevers that are listed as category A agents, including the arena viruses (Lassa fever and others), bunya viruses (hanta), flaviviruses (Dengue), and filoviruses (Ebola and Marburg). There are at least 18 viruses that cause human hemorrhagic fevers, which form a special group of viruses characterized by viral replication in lymphoid cells, after which patients develop fever and myalgia with an incubation of anywhere from 2 to 18 days, depending on the agent itself and the amount that is inhaled or inoculated across the dermis. They encompass syndromes that vary from febrile hemorrhagic fever with edema to septic shock, which rapidly leads to death. Both the United States and the former Soviet Union have experimented and have weaponized several of these viruses. Studies in nonhuman primates suggest that the agents are highly infectious, requiring only a few virions to produce illness.<sup>44</sup> The Aum Shinrikyo cult in Japan went to Africa in the 1990s to try to obtain an Ebola virus, which they planned to weaponize but fortunately, they were unsuccessful. There is no known incident where these agents have been used as a biologic weapon, but the natural outbreak of EVD during 2014–2015 spurred considerable investment in research and development into diagnostic tests and treatment with antivirals of the filoviruses (Ebola viruses and Marburg viruses).<sup>45</sup>

The viruses are single-stranded, ribonucleic acid (RNA) viruses that have a rodent or insect reservoir (bats are the natural reservoirs of Ebola virus)<sup>46</sup> and are communicated to humans by inhalation of an aerosol, through contact with an infected animal, or the bite of an infected insect. Humans are not a reservoir for the virus. The hemorrhagic fevers are contagious, and significant person-to-person transmission has occurred. The incubation period is within several days of contact or inhalation of the agent, at which time patients present with fever, myalgia, and evidence of a

capillary leak (systemic leak or pulmonary edema), thrombocytopenia, and disseminated intravascular coagulation (DIC). The fatality rate, depending on the specific virus used, is anywhere from 2% to 60%. However, in the 2014–2015 EVD pandemic, as of March 3, 2016, the CDC and WHO reported that there had been 15,250 confirmed cases and that there were 11,316 deaths, for a fatality rate of about 75%.<sup>47</sup> There are no specific antiviral therapies for this class of viruses. Ribavirin, interferon- $\alpha$ , and hyperimmune globulin are often administered, with ribavirin being more protective against some of the viruses than others, but unfortunately one does not initially know what the etiologic agent is when the patient first presents.

Administration of convalescent serum and ZMapp (Mapp Biopharmaceutical, San Diego, CA, USA), a mixture of monoclonal antibodies, has been shown to be effective if treatment is begun early enough. An experimental vaccine is being tested. The 2014–2015 outbreak demonstrated that Ebola presents a significant risk to health-care workers, especially during the late stages of the disease. High-level PPE is required to be worn by health-care workers whenever aerosols are generated, such as during suctioning, intubation, and bronchoscopy. Even flushing a toilet to dispose of bodily secretions has been shown to aerosolize viral particles. PPE is donned under observation prior to entering a patient's negative pressure isolation room. Proper doffing after patient contact is equally critical to avoid infection. The ASA website has an extensive protocol along with videos.<sup>48</sup> PPE can take as long as 30 minutes to put on and remove. Emergency intubation thus becomes impractical. All airway management should therefore be anticipatory. Elective surgery should be avoided. Every effort should be made to perform emergency procedures in the patient's isolation room. Equipment can be brought to the bedside and left afterward. If it is necessary to transport patients, staff must wear appropriate PPE and the patient, ideally, should be transported in an isopod. Intraoperative procedures should be established and practiced to avoid staff exposure.

Dengue fever, Chikungunya, and Zika virus disease have become increasingly prevalent across the tropics and subtropics. Dengue, Chikungunya, and Zika are viruses transmitted through *Aedes aegypti* and *Aedes albopictus* mosquitoes. In 2016, there was an outbreak of Zika in the Americas. Most infected patients were asymptomatic or had minor disease consisting of fever and rash. However, Zika virus infection has been associated with an increased incidence of microcephaly in babies born to infected mothers and an increase in Guillain–Barré disease. All three diseases can be transmitted through blood contamination and Zika virus has also been transmitted sexually. Current guidance suggests higher levels of PPE when participating in aerosol-generating procedures. Pregnant caregivers should consider higher levels of protection due to the apparent increased risk to the

fetus from Zika infection.<sup>49</sup> At present, there is no vaccine for Zika virus infection and care of infected patients is supportive.

## Radiation—Nuclear

The greatest likelihood for dealing with patients who are exposed to ionizing radiation would come from a nuclear power plant or reactor accident, then from a terrorist action, and lastly from a detonation of a nuclear bomb. With respect to nuclear power plants, the US Nuclear Regulatory Commission has not found that people living adjacent to the plants have increased rates of cancer; however, the commission continues to study the issue.<sup>50</sup> Unfortunately, that was not the case when there was release of radioactive material as has occurred in the past at Chernobyl, and most recently at the Fukushima Daiichi nuclear power plant in Japan following the earthquake and tsunami on March 11, 2011. Because the details of the disaster in Japan are still not completely clear, this discussion will focus on Chernobyl; it is claimed that the meltdown that occurred in Japan released only 10% as much radiation as occurred at Chernobyl.<sup>51</sup>

On April 26, 1986, workers at the Chernobyl nuclear power plant did not recognize or respond to evidence that one of the reactors was malfunctioning, with loss of cooling capacity and an explosion of the nuclear reactor.<sup>52</sup> Two workers died as a direct effect of the explosion, while those who remained in shielded areas survived unless they went to fight the fire, in which case they eventually died of radiation injury. Short-term  $\gamma$  and  $\beta$  emissions from the explosion and subsequent  $\gamma$  and  $\beta$  radiation from the reactor core debris killed many more, with long-term health effects to the entire community. Because of a lack of protective clothing and respirators, the radioactive material that exploded into the atmosphere rained down for several days, affecting many more workers and thousands of civilians. Primary sources of radiation were iodine-131, strontium-90, and cesium-137. During the subsequent 24 hours, 140,000 people were evacuated and potassium iodide tablets were distributed to as many people in the area as possible. Two hundred and thirty patients were subsequently hospitalized, with many patients succumbing to infections because of bone marrow suppression, and in those patients in whom bone marrow transplantation was attempted, 17 of 19 died because of associated radiation burns. All told, radiation burns caused 21 deaths. Oropharyngeal burns occurred in 28 patients. Over the next several years, the average radiation exposure around Chernobyl was four times normal due to residual ground contamination. Almost two decades later, the effects of Chernobyl continue to be felt in the immediate vicinity and in the area down-wind from the reactor site.<sup>52</sup> The experience from Chernobyl reveals the kind of injuries that anesthesiologists can anticipate from nuclear accidents, including

radiation burns, bone marrow suppression, the destruction of the lining of the GI tract, GI bleeding with translocation of bacteria, infection, sepsis, septic shock, and death. As evidenced by the experiences in Chernobyl, potassium iodide is indicated to protect the thyroid gland from taking up iodine-131, and other drugs are being considered, such as 5-androstenediol.

There have been other situations from which we can learn during which people have been exposed to ionizing radiation. On March 28, 1979, at the Three Mile Island nuclear power plant, the number 2 nuclear reactor overheated, and because the pressure relief valve failed to close, radioactive coolant was released into the containment facility.<sup>53</sup> As is often the case, there were numerous communication missteps, which resulted in the release of inconsistent information, generating genuine fear among individuals living nearby the nuclear power plant. There were no biologic effects of the event, but severe psychological sequelae did result.

On September 13, 1987, in Goiania, Brazil, a lead canister containing between 1,400 and 1,600 curies of cesium-137 contaminated 250 people; four of them died, and many others had short- and long-term health sequelae.<sup>54</sup> Mitigation efforts required the removal of 6,000 tons of clothing, furniture, dirt, trees, and other materials. The cesium had been left in a building in a lead canister when it was abandoned by its occupants; the canister was taken, opened by looters, and children played with the material.

### *Potential Sources of Ionizing Radiation Exposure*

We are exposed to radiation on an annual basis from cosmic radiation, radon, medical devices, and in multiple stores and factories. In essence, half of our exposure comes from natural sources, with most of the remaining exposure originating from medical imaging and devices.<sup>50</sup> A chest radiograph leads to 5 to 10 millirem (mrem) of exposure, whereas a computed tomographic scan can result in 5,000 mrem of exposure.

Obviously, the greatest concern is the exposure to ionizing radiation that is unintentional—as occurred at the Chernobyl nuclear power plants. Intentional exposure threats are the result of military conflict or terrorism. With respect to the former, the two situations in which this occurred were in Hiroshima and Nagasaki in 1945. In Hiroshima, the bomb (“Little Boy”) was only a 12.5-kiloton bomb, which killed an estimated 66,000 people and injured 69,000 more. The bomb that fell at Nagasaki (“Fat Boy”) was a 22-kiloton plutonium implosion bomb, which killed between 39,000 and 74,000 people, with 75,000 people sustaining severe injuries. We learned from that experience that the majority of casualties are from the initial blast, fire, and the collapse of buildings. Radiation exposure subsequently killed many more. With any nuclear explosion, many individuals will be injured or die from the

primary effect of the blast. Patients could have burn, crush, or radiation injury, or any combination thereof.

More recently, we have come to recognize that exposure to ionizing radiation may be as a result of terrorism. The most likely event will be the use of a dispersion device such as a conventional weapon or bomb surrounded with radionuclides such as cesium or strontium. In fact, in 1987, Iraq tested a 1-ton “dirty” bomb, and in 1996, Islamic terrorists in Chechnya placed a bomb packed with cesium-137 in a Moscow park that did not explode. While a radiation dispersion device remains the most likely event, terrorists could also target a nuclear power plant using a commercial jet, munitions, or internal sabotage.

While a blast, crush, or thermal injury is readily apparent, the effects of ionizing radiation are usually not apparent. Anesthesiologists should be familiar with types of ionizing radiation, which include  $\alpha$  particles,  $\beta$  particles,  $\gamma$  rays, x-rays, and neutrons. One also needs to understand how radiation is measured (Table 59-5). There are several methods, which take into account not only the decay rate of a radioactive isotope (becquerel [Bq] or a curie [Ci]) but also the dose absorbed, usually quantified as the amount absorbed by any type of tissue or material. The radiation-absorbed dose (rad or Gray [Gy]) is the international system of units (SI) method for denoting the amount of energy deposited in joules per kilogram. One Gy equals 100 rad. A sievert is the SI unit for measurement of *human* exposure to radiation in joules per kilogram, with  $1 \text{ Sv} = 100 \text{ rem}$  (roentgen equivalent for man).

In a nuclear accident or catastrophe, patients could have several types of radiation exposure. They may receive external radiation from an x-ray-emitting device or from  $\gamma$  rays or  $\beta$  particles, they may be contaminated with debris emitting ionized radiation, or they might inhale gaseous radioactive material.<sup>55</sup> Some of this material can become incorporated into tissue as radioactive iodine isotopes would. In order to protect individuals, the distance from the source or explosion is important, as are the amount of shielding, the time one is exposed, and the amount of radioactive material to which one is exposed. Human tissue will block  $\alpha$  particles (though if inhaled,  $\alpha$  particles can penetrate up to 50  $\mu\text{m}$  into the pulmonary epithelium material, leading to the development of lung cancer), but will not stop  $\beta$  particles or  $\gamma$  rays. Aluminum shields stop  $\beta$  particles, but  $\gamma$  rays can penetrate even concrete walls and lead is required to shield for both  $\gamma$  and x-rays.

**Table 59-5** Radiation Exposure Terms

Term	Definition	Equivalence
Becquerel (Bq)	SI unit for measurement of radioactivity, defined as decay events per second 1 Bq = 1 disintegration per second	
Curie (Ci)	Traditional measure of radioactivity, as measured by radioactivity decay	1 Ci = $0.7 \times 10^{10}$ disintegrations per second
Radiation-absorbed dose (rad)	Dose deposited by any type of radiation, in any type of tissue or material	1 rad = 0.01 Gy
Gray (Gy)	SI unit for the energy deposited by any type of radiation, in joules per kilogram	1 Gy = 100 rad
Roentgen equivalent man (rem)	Unit of human exposure to radiation	1 rem = 0.01 Sv
Sievert (Sv)	SI unit for measurement of human exposure to radiation, in joules per kilogram	1 Sv = 100 rem

SI, International System of units.

The most likely injury from ionizing radiation is to those tissues that have the greatest turnover rate, that is, the sensitivity of tissues to radiation (from greatest to least) is for lymphoid, GI, reproductive, dermal, bone marrow, and nervous system tissue. In reality, the response of lymphoid and bone marrow to ionizing radiation cause the greatest problems. The thrombocytopenia, granulocytopenia, and the GI injury lead to bleeding and bacterial translocation across the GI epithelium, the net result of which is sepsis and bleeding—the hallmarks of acute radiation syndrome, which lead to death.

Because ionizing radiation is invisible, affected individuals may appear normal. Patients who present with nausea, vomiting, diarrhea, and fever are likely to have severe acute radiation syndrome. Hypotension, erythema, and CNS dysfunction will manifest later. “Short-term” effects such as these, however, may not appear until days to weeks after the exposure, depending on the amount of exposure (as little as 0.75 to 1 Gy), whereas hematopoietic syndrome (severe lymphoid and bone marrow suppression) results from exposure to 3 to 6 Gy and may lead to death within 8 to 50 days. Long-term effects include thyroid cancer and psychological injury, as has been documented many times in the past.

## Management

Should a radiation disaster occur, it would be followed by a huge coordinated local, state, and federal response, which at the federal level would include the US Department of Homeland Security, the Department of Energy, the Department of Justice, FEMA, the Environmental Protection Agency, and the Nuclear Regulatory Commission. Of most importance, depending on the type of catastrophe, would be the immediate evacuation of the area. If evacuation, is impossible, a safe place should be sought within the home or building. The **9** principles of disaster management always involve containment (avoid

bringing patients with material emitting ionizing radiation to the hospital). Therefore, as part of the containment process, to the extent possible, patients should be decontaminated at the site. Removal of clothing is critically important.  $\beta$  and  $\gamma$  rays and neutrons will no longer be present on the patient unless there is still material emitting this radiation on a person's clothing. Rather than guess whether radiation is still present, it is best to disrobe patients. In previous mass casualty situations, maintenance of casualties' privacy has been a concern, but not one with an easy solution. Afterward, patients' skin should be washed with warm soapy water. Depending on the number of casualties, decontamination areas may have to be set up outside of hospitals, especially because individuals will arrive by private vehicles or on foot. Take care to isolate patients' personal belongings, giving the same consideration to biologic fluids—including saliva, blood, urine, and stool (all of which may be contaminated with radioisotopes and may therefore require special precautions when being handled)—as for clothing.

Potassium iodide can attenuate most of the radiation-induced thyroid effects, but must be given as quickly as possible because there is little protective effect if it is given more than 24 hours after exposure. Treatment is largely supportive, as these patients will develop acute radiation syndrome manifested by bleeding and sepsis. Treatment guidelines for management of postirradiation sepsis have been developed and advocated by the military.<sup>56</sup> The use of granulocyte colony-stimulating factor may be of benefit. Other treatments would include oral and GI decontamination using nasopharyngeal lavage, oral lavage and brushing, early stomach lavage, or administration of emetic and osmotic laxatives. Blocking agents include potassium iodide and strontium lactate. Mobilizing agents include ammonium chloride, calcium gluconate, and diuretics, which may enhance renal excretion. Chelation therapy that has been recommended includes calcium diethylenetriamine pentaacetic acid (DTPA) as an initial dose and then zinc DTPA.<sup>57</sup> Granulocyte macrophage colony-stimulating factor and thrombopoietin or interleukin-11, though postulated, have not been proven to be of benefit. For individuals with a contaminated GI tract, selective decontamination may be helpful, though this again has not been demonstrated to be of benefit in this situation.<sup>58</sup>

Unfortunately, because of the possibility of blast, thermal, and crush injuries, along with the radiation injury, the care of the injured may require the care of patients who have multiple combined injuries. The initial response should be as per the advanced trauma life support (ATLS) guidelines, which include an assessment of the airway, breathing, and circulation, and extent of trauma and then decontamination of the patient, after which the patient is stabilized and further evaluated. Wounds must be considered contaminated. "Dirty wounds" should not be closed but cleaned and debrided,

excised, and observed. Unfortunately, in this situation, there is also the possibility that there may be the combined effects of a radiation-releasing event and the use of either chemical or biologic agents.<sup>58</sup> Because of the variety of types of terrorism, some of it reportedly government sponsored, communities and the US government have had to plan for the detonation of a nuclear device on US soil.<sup>59,60</sup>

## Explosives

Management of traumatic injury is covered in [Chapter 53](#), but a chapter on disaster management would not be complete without mentioning the use of explosive devices by terrorists. As the media reports daily, particularly in Afghanistan, the use of IEDs is the terrorist's favorite weapon. Patients have burns, fractures, lacerations, multiple shrapnel injuries, soft tissue trauma, and traumatic amputations. As the weapons have become more sophisticated and powerful, the extent of injuries has increased significantly. In 2012, US military personnel experienced more multiple-than single-traumatic extremity amputations.<sup>61</sup>

Patients with any evidence of burns to the face or airway will require appropriate airway management. Patients should be intubated, awake if possible, because a significant number of these patients will have mild-to-moderate glottic edema at the time of intubation. Those patients with burns must be managed aggressively with respect to fluid resuscitation. With **12** isolated total body surface injury, fluid resuscitation is aggressive. With polytrauma and no third-degree burns, “damage control resuscitation/surgery” is the norm.<sup>62</sup> The patient's body temperature is maintained and surgery is performed as soon as possible to stop the bleeding, thereby decreasing the need for blood products and the chances of developing a dilutional coagulopathy. Patients who do develop a coagulopathy appear to benefit from a ratio of packed red blood cells to fresh frozen plasma to platelets of 1:1:1.<sup>63,64</sup> One study has demonstrated that tranexamic acid decreases the need for additional blood products. In patients with crush injury and markedly elevated creatine phosphokinase, alkalization of the urine-forced diuresis may attenuate renal failure from myoglobinuria.

## Conclusion

Although it is unlikely that an anesthesiologist will be at the initial site of a natural or intentional disaster, it could happen. Most likely, anesthesiologists will become involved if the hospital at which they work provides care for a number of these patients. Anesthesiologists could find themselves involved in triage, in the ED, OR, or ICU.<sup>65</sup> As suggested for several of these situations,

airway management and ventilator management may be critical, as would the establishment of intravascular access and volume resuscitation.

Obviously, it is critical to have a high index of suspicion if you are managing the index case, or two or more patients, with presenting signs and symptoms that are suggestive of the use of a biologic weapon. The individual who is the point of contact for the index case should notify the hospital infectious disease specialist and the local and state health departments. Factors that might indicate the intentional release of a biologic agent would include unusual temporal or geographic clustering of cases, an uncommon age distribution, or a significant number of cases (more than one) of acute flaccid paralysis that might suggest use of botulinum toxin.

If called to the hospital to be involved in managing such a catastrophe, the anesthesiologist must review basic decontamination and isolation techniques and, as mentioned previously, must follow those guidelines scrupulously. It is clear that anesthesiologists have the requisite training and experience to be of vital importance in managing such casualties. However, based on their training, they may not be emotionally prepared to manage these patients. They must remember that unlike their normal practice, they may have to triage patients, accept the fact that the standard of care may be different, and focus their efforts on interventions that will carry the greatest benefit for the greatest number of casualties.

This process begins when the anesthesiologist gets the call at home or in the hospital regarding an impending mass casualty event. She or he must first report to the command and control center and, though most likely they may work in the operating room, they could also be used in the triage area in the ED or in the ICU. Of utmost importance is familiarity with the hospital's disaster plan. One must also develop one's own family care plan in anticipation of absence from the home for extended periods of time. Ensuring one's own safety through the appropriate use of protective devices to serve as barriers against radiologic, biologic, and chemical weapons is also of vital importance. Infrastructure degradation worsens the consequences of mass casualty events. Preparing to deliver care under austere circumstances, developing creative responses, and practicing (simulations) regularly will mitigate the effects of a disaster and increase resilience for individuals, teams, and institutions. 13

# Appendix A. Disaster Preparedness Planning Guide for Families (from FEMA)

Prepare. Plan. Stay Informed.

## Family Emergency Plan

Make sure your family has a plan in case of an emergency. Before an emergency happens, sit down together and decide how you will get in contact with each other, where you will go, and what you will do in an emergency. Keep a copy of this plan in your emergency supply kit or another safe place where you can access it in the event of a disaster.

## Formulas

### Hemodynamic Formulas

Hemodynamic Variables: Calculations and Normal Values		
Variable	Calculation	Normal Values
Cardiac index (CI)	$CO/BSA$	2.5–4.0 L/min/m <sup>2</sup>
Stroke volume (SV)	$CO \times 1000/HR$	60–90 mL/beat
Stroke index (SI)	$SV/BSA$	40–60 mL/beat/m <sup>2</sup>
Mean arterial pressure (MAP)	Diastolic pressure + $\frac{1}{3}$ pulse pressure	80–120 mmHg
Systemic vascular resistance (SVR)	$\frac{MAP - \overline{CVP}}{CO} \times 79.9$	1,200–1,500 dyne-cm-sec <sup>-5</sup>
Pulmonary vascular resistance (PVR)	$\frac{\overline{PAP} - \overline{PCWP}}{CO} \times 79.9$	100–300 dyne-cm-sec <sup>-5</sup>
Right ventricular stroke work index (RVSWI)	$0.0136 (PAP - CVP) \times SI$	5–9 g-m/beat/m <sup>2</sup>
Left ventricular stroke work index (LWSWI)	$0.0136 (MAP - PCWP) \times SI$	45–60 g-m/beat/m <sup>2</sup>

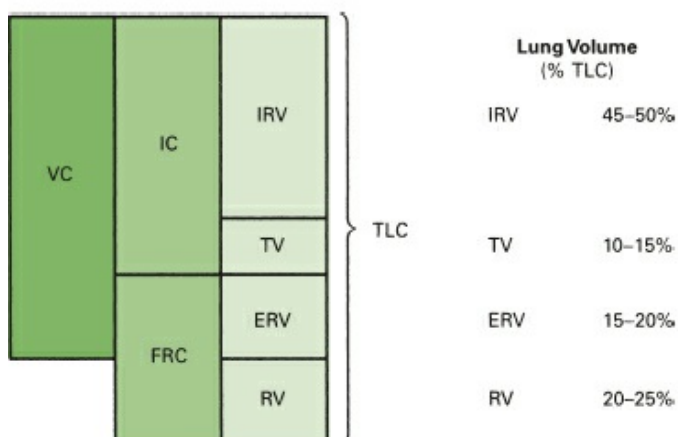

HR, heart rate; CVP, mean central venous pressure; PAP, mean pulmonary artery pressure; BSA, body surface area; CO, cardiac output; PCWP, pulmonary capillary wedge pressure; MAP, mean arterial blood pressure.

## Respiratory Formulas

	Normal Values (70 kg)
Alveolar oxygen tension $PAO_2 = (P_B - 47) FiO_2 - PaCO_2$	110 mmHg ( $FiO_2 = 0.21$ )
Alveolar-arterial oxygen gradient $AaO_2 = PAO_2 - PaO_2$	<10 mmHg ( $FiO_2 = 0.21$ )
Arterial-to-alveolar oxygen ratio, a/A ratio	>0.75
Arterial oxygen content $CaO_2 = (SaO_2) (Hb \times 1.34) + PaO_2 (0.0031)$	21 mL/100 mL
Mixed venous oxygen content $C\bar{V}O_2 = (S\bar{V}O_2) (Hb \times 1.34) + P\bar{V}O_2 (0.0031)$	15 mL/100 mL
Arterial-venous oxygen content difference $a\bar{V}O_2 = CaO_2 - C\bar{V}O_2$	4–6 mL/100 mL
Intrapulmonary shunt $Q_s/Q_T = (CCO_2 - CaO_2) / (CCO_2 - C\bar{V}O_2)$ $CCO_2 = (Hb \times 1.34) + (PAO_2 \times 0.0031)$	<5%
Physiologic dead space $\bar{V}_D/\bar{V}_T = (PaCO_2 - P_eCO_2) / PaCO_2$	0.33
Oxygen consumption $\dot{V}O_2 = CO(CaO_2 - C\bar{V}O_2)$	240 mL/min
Oxygen transport $O_2T = CO (CaO_2)$	1,000 mL/min

$CaO_2$ , arterial oxygen content;  $C\bar{V}O_2$ , mixed venous oxygen content;  $CCO_2$ , pulmonary capillary oxygen content; CO, cardiac output;  $FiO_2$ , fraction inspired oxygen;  $O_2T$ , oxygen transport;  $P_B$ , barometric pressure;  $Q_s/Q_T$ , intrapulmonary shunt;  $PaCO_2$ , alveolar carbon dioxide tension;  $PaCO_2$ , arterial carbon dioxide tension;  $PAO_2$ , alveolar oxygen tension;  $PaO_2$ , arterial oxygen tension;  $P_eCO_2$ , expired carbon dioxide tension;  $V_D$ , dead space gas volume;  $V_T$ , tidal volume;  $\dot{V}O_2$ , oxygen consumption (minute).

## Lung Volumes and Capacities

		Normal Values (70 kg)
Vital capacity	VC	4,800 mL
Inspiratory capacity	IC	3,800 mL
Functional residual capacity	FRC	2,400 mL
Inspiratory reserve volume	IRV	3,500 mL
Tidal volume	TV	1,500 mL
Expiratory reserve volume	ERV	1,200 mL
Residual volume	RV	1,200 mL
Total lung capacity	TLC	6,000 mL

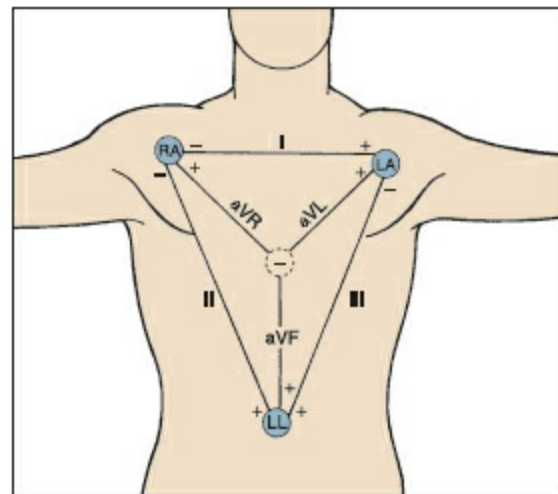

# APPENDIX 2

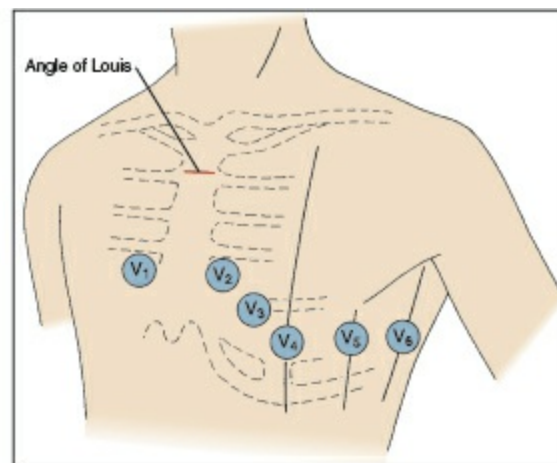

## Atlas of Electrocardiography

GINA C. BADESCU • BENJAMIN M. SHERMAN • JAMES R. ZAIDAN • PAUL G. BARASH

Lead Placement		
	Electrode	
	Positive	Negative
<b>Bipolar Leads</b>		
I	LA	RA
II	LL	RA
III	LL	LA
<b>Augmented Unipolar</b>		
aVR	RA	LA, LL
aVL	LA	RA, LL
aVF	LL	RA, LA
<b>Precordial</b>		
V <sub>1</sub>	4 ICS–RSB	
V <sub>2</sub>	4 ICS–LSB	
V <sub>3</sub>	Midway between V <sub>2</sub> and V <sub>4</sub>	
V <sub>4</sub>	5 ICS–MCL	
V <sub>5</sub>	5 ICS–AAL	
V <sub>6</sub>	5 ICS–MAL	

Abbrev.	Meaning
LA	Left arm
RA	Right arm
LL	Left leg
ICS	Intercostal space
RSB	Right sternal border
LSB	Left sternal border
MCL	Midclavicular line
AAL	Anterior axillary line
MAL	Midaxillary line

### The Normal Electrocardiogram—Cardiac Cycle

The normal electrocardiogram is composed of waves (P, QRS, T, and U) and intervals (PR, QRS, ST, and QT).

## **Atrial Fibrillation**

**Rate:** Variable (~ 150–200 beats/min)

**Rhythm:** Irregular

**PR interval:** No P wave; PR interval not discernible

**QT interval:** QRS normal

*Note:* Must be differentiated from atrial flutter: (1) absence of flutter waves and presence of fibrillatory line; (2) flutter usually associated with higher ventricular rates (> 150 beats/min). Loss of atrial contraction reduces cardiac output (10%–20%). Mural atrial thrombi may develop. Considered controlled if ventricular rate is < 100 beats/min.

## Atrial Flutter

2

**Rate:** Rapid, atrial usually regular (250–350 beats/min); ventricular usually regular (<100 beats/min)

**Rhythm:** Atrial and ventricular regular

**PR interval:** Flutter (F) waves are saw-toothed. PR interval cannot be measured.

**QT interval:** QRS usually normal; ST segment and T waves are not identifiable.

*Note:* Vagal maneuvers will slow ventricular response, simplifying recognition of the F waves.

## Atrioventricular Block (First Degree)

3

**Rate:** 60–100 beats/min

**Rhythm:** Regular

**PR interval:** Prolonged (>0.20 sec) and constant

**QT interval:** Normal

*Note:* Usually clinically insignificant; may be early harbinger of drug toxicity.

## Atrioventricular Block (Second Degree), Mobitz Type I/Wenckebach Block

4

**Rate:** 60–100 beats/min

**Rhythm:** Atrial regular; ventricular irregular

**PR interval:** P wave normal; PR interval progressively lengthens with each cycle until QRS complex is dropped (dropped beat). PR interval following dropped beat is shorter than normal.

**QT interval:** QRS complex normal but dropped periodically.

*Note:* Commonly seen in trained athletes and with drug toxicity.

### **5** *Atrioventricular Block (Second Degree), Mobitz Type II*

**Rate:** <100 beats/min

**Rhythm:** Atrial regular; ventricular regular or irregular

**PR interval:** P waves normal, but some are not followed by QRS complex.

**QT interval:** Normal but may have widened QRS complex if block is at level of bundle branch. ST segment and T wave may be abnormal, depending on location of block.

*Note:* In contrast to Mobitz type I block, the PR and RR intervals are constant and the dropped QRS occurs without warning. The wider the QRS complex (block lower in the conduction system), the greater the amount of myocardial damage.

### **6** *Atrioventricular Block (Third Degree), Complete Heart Block*

**Rate:** <45 beats/min

**Rhythm:** Atrial regular; ventricular regular; no relationship between P wave and QRS complex.

**PR interval:** Variable because atria and ventricles beat independently.

**QT interval:** QRS morphology variable, depending on the origin of the ventricular beat in the intrinsic pacemaker system (atrioventricular junctional vs. ventricular pacemaker). ST segment and T wave normal.

*Note:* AV block represents complete failure of conduction from atria to ventricles (no P wave is conducted to the ventricle). The atrial rate is faster than ventricular rate. P waves have no relationship to QRS complexes (e.g., they are electrically disconnected). In contrast, with AV dissociation, the P wave is conducted through the AV node and the atrial and ventricular rate are

similar. Immediate treatment with atropine or isoproterenol is required if cardiac output is reduced. Consideration should be given to insertion of a pacemaker. Seen as a complication of mitral valve replacement.

### **Bundle-Branch Block—Left (LBBB)**

**Rate:** <100 beats/min

**Rhythm:** Regular

**PR interval:** Normal

**QT interval:** Complete LBBB (QRS >0.12 sec); incomplete LBBB (QRS = 0.10–0.12 sec); lead V<sub>1</sub> negative RS complex; I, aVL, V<sub>6</sub> wide R wave without Q or S component. ST segment and T-wave direction opposite direction of the R wave.

**Note:** LBBB does not occur in healthy patients and usually indicates serious heart disease with a poor prognosis. In patients with LBBB, insertion of a pulmonary artery catheter may lead to complete heart block.

### **Bundle Branch Block—Right (RBBB)**

**Rate:** <100 beats/min

**Rhythm:** Regular

**PR interval:** Normal

**QT interval:** Complete RBBB (QRS > 0.12 sec); incomplete RBBB (QRS = 0.10–0.12 sec). Varying patterns of QRS complex; rSR (V<sub>1</sub>); RS, wide R with M pattern. ST segment and T wave opposite direction of the R wave.

**Note:** In the presence of RBBB, Q waves may be seen with a myocardial infarction.

## Coronary Artery Disease

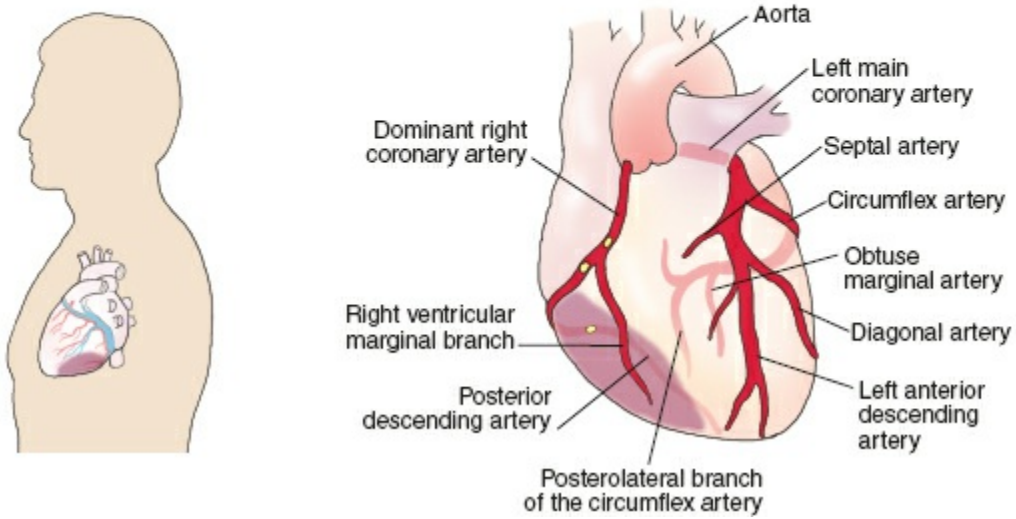

### *Transmural Myocardial Infarction (TMI)*

Q waves seen on ECG, useful in confirming diagnosis, are associated with poorer prognosis and more significant hemodynamic impairment. Arrhythmias frequently complicate course. Small Q waves may be normal variant. For myocardial infarction (MI), Q waves > 0.04 seconds or depth exceeds one-third of R wave. For inferior wall MI, differentiate from RVH by axis deviation.

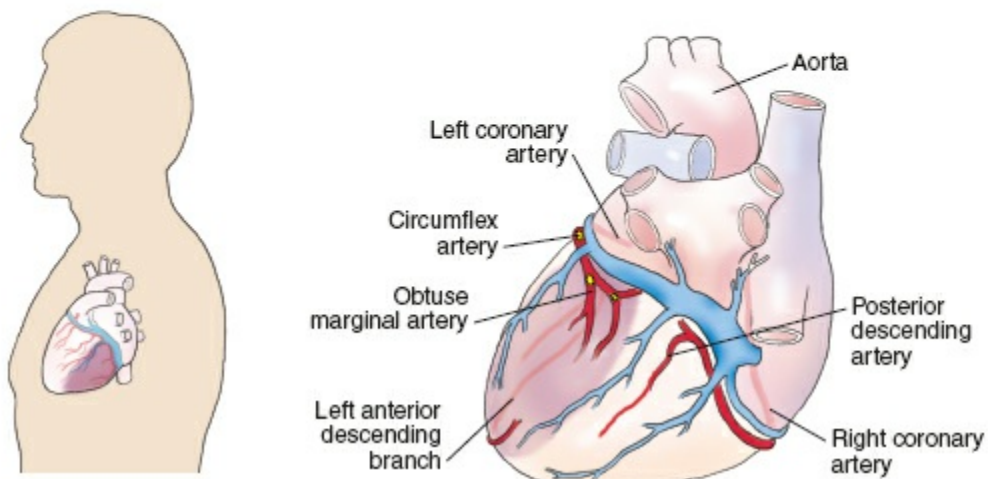

## Myocardial Infarction

Anatomic Site	Leads	ECG Changes	Coronary Artery
Inferior	II, III, AVF	Q, $\uparrow$ ST, $\uparrow$ T	Right

## Myocardial Infarction

Anatomic Site	Leads	ECG Changes	Coronary Artery
Posterior	V <sub>1</sub> -V <sub>2</sub>	$\uparrow$ R, $\downarrow$ ST, $\downarrow$ T	Posterior descending

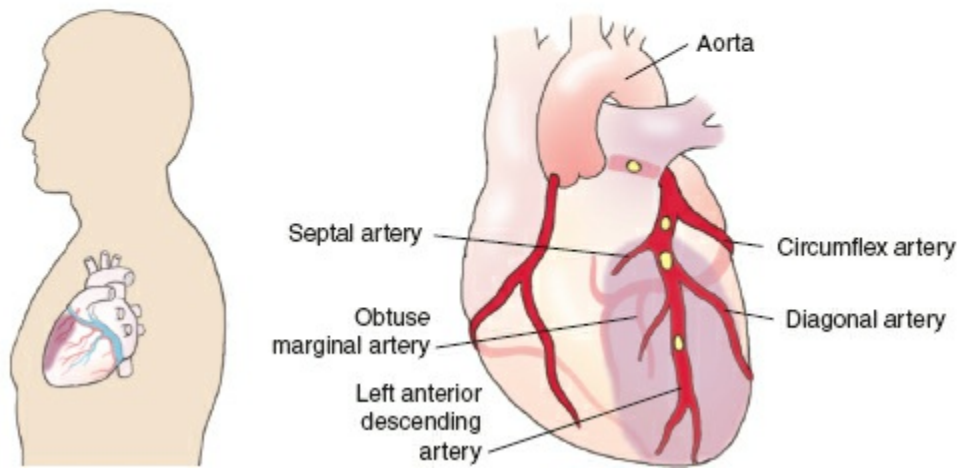

Myocardial Infarction			
Anatomic Site	Leads	ECG Changes	Coronary Artery
Lateral	I, aVL, V <sub>5</sub> -V <sub>6</sub>	Q, ↑ST, ↑T	Left circumflex

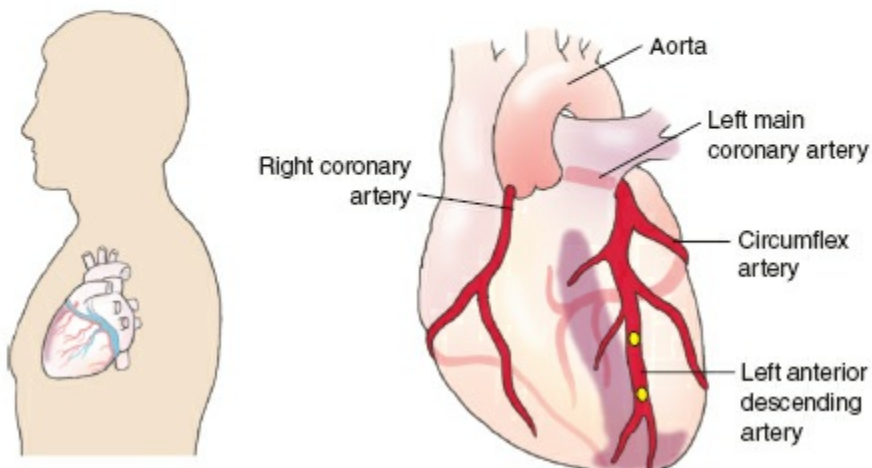

## Myocardial Infarction

Anatomic Site	Leads	ECG Changes	Coronary Artery
Anterior	I, aVL, V <sub>1</sub> -V <sub>4</sub>	Q, ↑ST, ↑T	Left anterior descending

## Myocardial Infarction

Anatomic Site	Leads	ECG Changes	Coronary Artery
Anteroseptal	V <sub>1</sub> -V <sub>4</sub>	Q, ↑ST, ↑T	Left anterior descending

10

### Subendocardial Myocardial Infarction (SEMI)

Persistent ST-segment depression and/or T-wave inversion in the absence of Q wave. Usually requires additional laboratory data (e.g., isoenzymes) to confirm diagnosis. Anatomic site of coronary lesion is similar to that of TMI electrocardiographically.

11

### Myocardial Ischemia

12

**Rate:** Variable

**Rhythm:** Usually regular but may show atrial and/or ventricular arrhythmias.

**PR interval:** Normal

**QT interval:** ST segment depressed; J-point depression; T-wave inversion; conduction disturbances. (A) TP and PR intervals are baseline for ST-segment deviation. (B) ST-segment elevation. (C) ST-segment depression.

*Note:* Intraoperative ischemia usually is seen in the presence of “normal” vital signs (e.g.,  $\pm$  20% of preinduction values).

## Digitalis Effect

13

**Rate:** < 100 beats/min

**Rhythm:** Regular

**PR interval:** Normal or prolonged

**QT interval:** ST-segment sloping (“digitalis effect”)

*Note:* Digitalis toxicity can be the cause of many common arrhythmias (e.g., premature ventricular contractions, second-degree heart block). Verapamil, quinidine, and amiodarone cause an increase in serum digitalis concentration.

Electrolyte Disturbances				
	↓Ca <sup>2+</sup>	↑Ca <sup>2+</sup>	↓K <sup>+</sup>	↑K <sup>+</sup>
Rate	<100 beats/ min	<100 beats/ min	<100 beats/ min	<100 beats/ min
Rhythm	Regular	Regular	Regular	Regular
PR interval	Normal	Normal/ increased	Normal	Normal
QT interval	Increased	Decreased	Normal	Increased
Other			T wave flat U wave	T wave peaked

*Note:* ECG changes usually do not correlate with serum calcium. Hypocalcemia rarely causes arrhythmias in the absence of hypokalemia. In contrast, abnormalities in serum potassium concentration can be diagnosed by ECG. Similarly, in the clinical range, magnesium concentrations are rarely associated with unique ECG patterns. The presence of a U wave (>1.5 mm in height) can also be seen in left main coronary artery disease, with certain medications and long QT syndrome.

## Calcium

14

## Potassium

Hypokalemia ( $K^+ = 1.9$  mEq/L)

Hyperkalemia ( $K^+ = 7.9$  mEq/L)

## Hypothermia

**Rate:** < 60 beats/min

**Rhythm:** Sinus

**PR interval:** Prolonged

**QT interval:** Prolonged

*Note:* Seen at temperatures below 33°C with ST-segment elevation (J point or Osborn wave). Tremor due to shivering or Parkinson disease may interfere with ECG interpretation and may be confused with atrial flutter. May represent normal variant of early ventricular repolarization. (Arrow indicates J point or Osborn waves.)

## Multifocal Atrial Tachycardia

**Rate:** 100–200 beats/min

**Rhythm:** Irregular

**PR interval:** Consecutive P waves are of varying shape.

**QT interval:** Normal

*Note:* Seen in patients with severe lung disease. Vagal maneuvers have no effect. At heart rates <100 beats/min, it may appear as wandering atrial pacemaker. May be mistaken for atrial fibrillation. Treatment is of the causative disease process.

## Paroxysmal Atrial Tachycardia (PAT)

15

**Rate:** 150–250 beats/min

**Rhythm:** Regular

**PR interval:** Difficult to distinguish because of tachycardia obscuring P wave. P wave may precede, be included in, or follow QRS complex.

**QT interval:** Normal, but ST segment and T wave may be difficult to distinguish.

*Note:* Therapy depends on the degree of hemodynamic compromise. Carotid sinus massage, or other vagal maneuvers, may terminate rhythm or decrease heart rate. In contrast to management of PAT in awake patients, synchronized cardioversion, rather than pharmacologic treatment, is preferred in hemodynamically unstable anesthetized patients.

## Pericarditis

16

**Rate:** Variable

**Rhythm:** Variable

**PR interval:** Normal

**QT interval:** Diffuse ST and T-wave changes with no Q wave and seen in more leads than a myocardial infarction.

## Pericardial Tamponade

**Rate:** Variable

**Rhythm:** Variable

**PR interval:** Low-voltage P wave

**QT interval:** Seen as electrical alternans with low-voltage complexes and varying amplitude of P, QRS, and T waves with each heart beat.

## Pneumothorax

**Rate:** Variable

**Rhythm:** Variable

**PR interval:** Normal

**QT interval:** Normal

*Note:* Common ECG abnormalities include right-axis deviation, decreased QRS amplitude, and inverted T waves V<sub>1</sub>–V<sub>6</sub>. Differentiate from pulmonary embolus. May present as electrical alternans; thus, pericardial effusion should be ruled out.

**Rate:** <100 beats/min

**Rhythm:** Irregular

**PR interval:** P waves may be lost in preceding T waves. PR interval is variable.

**QT interval:** QRS normal configuration; ST segment and T wave normal.

*Note:* Nonconducted PAC appearance similar to that of sinus arrest; T waves with PAC may be distorted by inclusion of P wave in the T wave.

### Premature Ventricular Contraction (PVC)

**Rate:** Usually <100 beats/min

**Rhythm:** Irregular

**PR interval:** P wave and PR interval absent; retrograde conduction of P wave can be seen.

**QT interval:** Wide QRS (>0.12 sec); ST segment cannot be evaluated (e.g., ischemia); T wave opposite direction of QRS with compensatory pause. Fourth and eighth beats are PVCs.

### Pulmonary Embolus

**Rate:** >100 beats/min

**Rhythm:** Sinus

**PR interval:** P-pulmonale waveform

**QT interval:** Q waves in leads III and aVF

*Note:* Classic ECG signs S1Q3T3 with T-wave inversion also seen in V<sub>1</sub>-V<sub>4</sub> and RV strain (ST depression V<sub>1</sub>-V<sub>4</sub>). May present with atrial fibrillation or flutter.

### 23 *Sinus Bradycardia*

24 **Rate:** < 60 beats/min

**Rhythm:** Sinus

25 **PR interval:** Normal

**QT interval:** Normal

*Note:* Seen in trained athletes as normal variant.

### 26 *Sinus Arrhythmia*

**Rate:** 60–100 beats/min

**Rhythm:** Sinus

**PR interval:** Normal

**QT interval:** R-R interval variable

*Note:* Heart rate increases with inhalation and decreases with exhalation + 10%–20% (respiratory). Nonrespiratory sinus arrhythmia seen in elderly with heart disease. Also seen with increased intracranial pressure.

## Sinus Arrest

**Rate:** < 60 beats/min

**Rhythm:** Varies

**PR interval:** Variable

**QT interval:** Variable

*Note:* Rhythm depends on the cardiac pacemaker firing in the absence of sinoatrial stimulus (atrial pacemaker 60–75 beats/min; junctional 40–60 beats/min; ventricular 30–45 beats/min). Junctional rhythm most common. Occasional P waves may be seen (retrograde P wave).

## Sinus Tachycardia

27

**Rate:** 100–160 beats/min

**Rhythm:** Regular

**PR interval:** Normal; P wave may be difficult to see.

**QT interval:** Normal

*Note:* Should be differentiated from paroxysmal atrial tachycardia (PAT). With PAT, carotid massage terminates arrhythmia. Sinus tachycardia may respond to vagal maneuvers but reappears as soon as vagal stimulus is removed.

## Subarachnoid Hemorrhage

**Rate:** < 60 beats/min

**Rhythm:** Sinus

**PR interval:** Normal

**QT interval:** T-wave inversion is deep and wide. Prominent U waves are seen. Sinus arrhythmias are observed. Q waves may be seen and may mimick acute coronary syndrome.

### **Torsades de Pointes**

28

**Rate:** 150–250 beats/min

**Rhythm:** No atrial component seen; ventricular rhythm regular or irregular.

**PR interval:** P wave buried in QRS complex.

**QT interval:** QRS complexes usually wide and with phasic variation twisting around a central axis (a few complexes point upward, then a few point downward). ST segments and T waves difficult to discern.

*Note:* Type of ventricular tachycardia associated with prolonged QT interval. Seen with electrolyte disturbances (e.g., hypokalemia, hypocalcemia, and hypomagnesemia) and bradycardia. Administering standard antiarrhythmics (lidocaine, procainamide, etc.) may worsen torsades de pointes. Prevention includes treatment of the electrolyte disturbance. Treatment includes shortening of the QT interval, pharmacologically or by pacing; unstable polymorphic VT is treated with immediate defibrillation.

Torsades de Pointes: Sustained

29

### **Ventricular Fibrillation**

**Rate:** Absent

**Rhythm:** None

**PR interval:** Absent

**QT interval:** Absent

*Note:* “Pseudoventricular fibrillation” may be the result of a monitor malfunction (e.g., ECG lead disconnect). Always check for carotid pulse before instituting therapy.

Coarse Ventricular Fibrillation

Fine Ventricular Fibrillation

30

## Ventricular Tachycardia

**Rate:** 100–250 beats/min

**Rhythm:** No atrial component seen; ventricular rhythm irregular or regular.

**PR interval:** Absent; retrograde P wave may be seen in QRS complex.

**QT interval:** Wide, bizarre QRS complex. ST segment and T wave difficult to determine.

*Note:* In the presence of hemodynamic compromise, VT with a pulse is treated with immediate synchronized cardioversion, whereas VT without a pulse is treated with immediate defibrillation. If the patient is stable, with short bursts of ventricular tachycardia, pharmacologic management is preferred. Should be differentiated from supraventricular tachycardia with aberrancy (SVT-A). Compensatory pause and atrioventricular dissociation suggest a PVC. P waves and SR' (V<sub>1</sub>) and slowing to vagal stimulus also suggest SVT-A.

## Wolff-Parkinson-White Syndrome (WPW)

**Rate:** <100 beats/min

▶ 31

**Rhythm:** Regular

**PR interval:** P wave normal; PR interval short (<0.12 sec)

**QT interval:** Duration (>0.10 sec) with slurred QRS complex (delta wave).  
Type A has delta wave, RBBB, with upright QRS complex V<sub>1</sub>. Type B has delta wave and downward QRS-V<sub>1</sub>. ST segment and T wave usually normal.

*Note:* Digoxin should be avoided in the presence of WPW because it increases conduction through the accessory bypass tract (bundle of Kent) and decreases AV node conduction; consequently, ventricular fibrillation can occur.

## Atrial Pacing

▶ 32

### Pacemaker Tracings

Atrial pacing as demonstrated in this figure is used when the atrial impulse can proceed through the AV node. Examples are sinus bradycardia and junctional rhythms associated with clinically significant decreases in blood pressure. (*Arrows are pacemaker spikes.*)

## ▶ 33 Ventricular Pacing

In this tracing, ventricular pacing is evident by absence of atrial wave (P wave) and pacemaker spike preceding QRS complex. Ventricular pacing is employed in the presence of bradycardia secondary to AV block or atrial fibrillation. (*Arrows are pacemaker spikes.*)

DDD pacing, one of the most commonly used pacing modes, paces and senses both the right atrium and right ventricle (A-V sequential pacing). Each atrial and the right ventricular complex are preceded by a pacemaker spike.

## Pacemaker and Implantable Cardiac Defibrillator Protocols

GINA C. BADESCU • BENJAMIN M. SHERMAN • JAMES R. ZAIDAN • PAUL G. BARASH

### Pacemakers

Pacemakers are devices that deliver electrical energy and control the patient's cardiac conduction system when necessary ([Table 3-2](#)).

#### *Indications for Permanent Pacemaker Implantation*

1. Sinus node dysfunction<sup>1</sup>
  - Patients with documented symptomatic bradycardia or chronotropic incompetence
  - Patients with bradycardia induced by essential medical regimen
  - Patients with syncopal episodes and induced sinus bradycardia or pauses on electrophysiologic studies
  - Patients with symptoms and heart rate less than 40 bpm
2. Atrioventricular node dysfunction
  - Third-degree or high-grade second-degree atrioventricular block (AVB) with symptomatic bradycardia or ventricular arrhythmias
  - Third-degree AVB or high-grade second-degree AVB with medication-induced bradycardia
  - Asymptomatic third-degree AVB with documented asystole longer than 3 seconds or longer than 5 seconds if atrial fibrillation is present
  - Third-degree AVB s/p AV node ablation, or postoperative third-degree AVB that is not expected to recover
  - Neuromuscular disorders with third-degree AVB: Erb dystrophy, Kearns–Sayre syndrome, myotonic muscular dystrophy
  - Second-degree AVB with symptomatic bradycardia, or exercise-induced AVB

3. Bifascicular block and:
  - Type II second- or third-degree AVB
  - Alternating bundle branch block
  - Syncope
4. Second- or third-degree AVB after an ST elevation myocardial infarction (STEMI)
5. Hypersensitive carotid sinus syndrome and neurocardiogenic syncope
6. Cardiac transplantation patients who develop persistent inappropriate bradycardia
7. Other conditions:
  - Neuromuscular disease
  - Cardiac sarcoidosis with development of AVB
  - Central obstructive sleep apnea
8. Prevention and termination of certain arrhythmias (e.g., supraventricular tachycardia)
9. Hemodynamic indications:
  - Cardiac resynchronization therapy (CRT) in patients with ejection fraction (EF) below 35% and QRS greater than 120 msec
  - Hypertrophic cardiomyopathy and sinus node dysfunction (SND) or AV node dysfunction
10. Congenital heart diseases

**Table 3-1** Abbreviation Table

Abbrev	Meaning	Abbrev	Meaning
3D	three dimensional	ICD	implantable cardiac defibrillators
ASA	American Society of Anesthesiologists	ILR	implantable loop recorder
ATP	antitachycardia pacing	LV	left ventricle
AV	atrioventricular	LVOT	left ventricular outflow tract
AVB	atrioventricular block	MRI	magnetic resonance imaging
BPEG	British Pacing and Electrophysiology Group	NASPE	North American Society of Pacing and Electrophysiology
bpm	beats per minute	NBG	N (NASPE), B (BPEG), G (GENERIC)
CAD	coronary artery disease	PG	pulse generator
CIED	cardiac implantable electronic devices	PP	external cardioversion–defibrillation pads or paddles
CPB	cardiopulmonary bypass	RA	right atrium
CRP	current return pad	R&R	rate and rhythm
CRT-D	cardiac resynchronization therapy—defibrillation	RF	radio frequency
CT	cautery tool	RT	radiation therapy
DCM	dilated cardiomyopathy	RV	right ventricle
ECG	electrocardiogram	SCD	sudden cardiac death
ECT	electroconvulsive therapy	SND	sinus node dysfunction
EF	ejection fraction	STEMI	ST-segment elevation myocardial infarction
EMI	electromagnetic interference	TUNA	transurethral needle ablation
HCM	hypertrophic cardiomyopathy	TURP	transurethral resection of prostate
HR	heart rate	VT	ventricular tachycardia
HRS	Heart Rhythm Society	VF	ventricular fibrillation
HV	HV interval		

## Implantable Cardiac Defibrillators

Implantable cardiac defibrillators (ICDs) are rhythm management devices, which consist of a generator and a lead system.<sup>2</sup> One lead is usually placed in the right atrium and the second lead in the right ventricular apex (Table 3-3). A specific type of ICD is the biventricular pacemaker, used for CRT. This device will have a third lead placed in the coronary sinus to pace the left ventricular (LV) lateral wall in synchrony with the right ventricle (RV), in the patient with EF below 35% and a QRS duration longer than 120 msec.<sup>1</sup>

### Indications for ICD Implantation

1. Secondary prevention of sudden cardiac death (SCD) patients with a previous ventricular tachycardia/fibrillation (VT/VF) cardiac arrest
  - Patients with coronary artery disease (CAD) who survived one cardiac arrest (if > 48 h after an acute MI)
  - Patients with nonischemic dilated cardiomyopathy and
  - Hypertrophic cardiomyopathy
  - Arrhythmogenic right ventricular (RV) dysplasia
  - Genetic proarrhythmic syndromes with one prior episode of VT/VF; include long and short QT syndrome, Brugada syndrome, catecholaminergic polymorphic VT, idiopathic VF
  - Syncope with inducible sustained VT: when the arrhythmia is assumed to be the reason the syncope
2. Primary prevention of SCD
  - Includes all the subgroups from the secondary prevention that are considered high risk but did not yet have an episode of VT/VF.

### Potential Intraoperative Problems with CIEDs

Electromagnetic interference (EMI) with the device is more likely when electrocautery is used above the umbilicus in a patient with a CIED implanted in subclavicular region. For generators placed elsewhere (e.g., abdominal site), expert opinion also points to the 15-cm rule, which is a distance of 15 cm around the generator or cardiac leads with the highest risk of interference.<sup>3</sup>

EMI leads to:

1. Inhibition of pacemaker by EMI
2. Inappropriate delivery of antitachycardia therapy by ICD
3. Changes in lead parameters:
  - Atrial mode switching
  - Inappropriate ventricular sensing

- Electrical reset
  - Increase in ventricular thresholds
4. “Runaway” pacemaker<sup>4</sup>
  5. Pacemaker failure after direct contact with electrocautery and cardioversion
  6. Conversion from VOO (Table 3-2) back to backup mode (reprogramming)
  7. Transient or permanent loss of capture
  8. Dislodgement of leads during atrial fibrillation ablation procedures<sup>5</sup>
  9. Rate adaptive pacing (interaction of minute ventilation sensor with ECG/plethysmography)
  10. Oversensing and inhibition with use of lithotripsy
  11. Noise reversal mode
  12. Myocardial burns
  13. Radiofrequency ablation and therapeutic radiation are associated with a high risk of interference similar to EMI, due to long exposure to current. Grant et al. reported in a recent study that the most notable risk factor for malfunction of CIED in patients undergoing radiation therapy was neutron producing radiotherapy (RT). The incident CIED dose up to 5.4 Gy did not correlate with CIED malfunction, leading to the conclusion that it is possible that surgical relocation of the CIED may be minimized if nonneutron-producing RT is to be delivered.<sup>6</sup>
  14. Scanning wand. A case report recently published by Plakke et al. documented a case of asystole induced by interference of the scanning wand with the temporary pacemaker with epicardial pacing wires placed routinely at separation from cardiopulmonary bypass.<sup>7</sup> Publication of this case report gave rise to a controversy, the manufacturer stating the scanning wand was used off-label, without properly following the instruction manual and placing most of the blame for the incident on the anesthesiologist.<sup>8</sup> This resulted in the provider’s response of how responsibility is assigned with the use of this device.<sup>9</sup> This clearly begs the more important question of how do we get the health-care providers appropriately educated on use of such devices.

**Table 3-2** Generic Pacemaker Code: NASPE/BPEG Revised (2002)

Position I, Pacing Chamber(s)	Position II, Sensing Chamber(s)	Position III, Response(s) to Sensing	Position IV, Programmability	Position V, Multisite Pacing
O = none	O = none	O = none	O = none	O = none
A = atrium	A = atrium	I = inhibited	R = rate modulation	A = atrium
V = ventricle	V = ventricle	T = triggered		V = ventricle
D = dual (A + V)	D = dual (A + V)	D = dual (T + I)		D = dual (A + V)

NBG: N refers to North American Society of Pacing and Electrophysiology (NASPE), now called the Heart Rhythm Society (HRS); B refers to British Pacing and Electrophysiology Group (BPEG); and G refers to generic.

Reproduced with permission from Practice advisory for perioperative management of patients with cardiac rhythm management devices: pacemakers and implantable cardioverter-defibrillators. A report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Rhythm Management Devices. *Anesthesiology*. 2011;114:247–261.

**Table 3-3** Generic Defibrillator Code (NBG): NASPE/BPEG

Position I, Shock Chamber(s)	Position II, Antitachycardia Pacing Chamber(s)	Position III, Tachycardia Detection	Position IV, <sup>a</sup> Antibradycardia Pacing Chamber(s)
O = none	O = none	E = electrogram	O = none
A = atrium	A = atrium	H = hemodynamic	A = atrium
V = ventricle	V = ventricle		V = ventricle
D = dual (A + V)	D = dual (A + V)		D = dual (A + V)

<sup>a</sup>For robust identification, position IV is expanded into its complete NBG code. For example, a biventricular pacing defibrillator with ventricular shock and antitachycardia pacing functionality would be identified as VVE-DDDRV, assuming that the pacing section was programmed DDRV. Currently, no hemodynamic sensors have been approved for tachycardia detection (position III).

Reproduced with permission from Practice advisory for perioperative management of patients with cardiac rhythm management devices: pacemakers and implantable cardioverter-defibrillators. A report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Rhythm Management Devices. *Anesthesiology*. 2011;114:247–261.

## General Principles of Perioperative Management of Patients with CIEDs

- The perioperative management of the patient with a CIED is via an individualized recommendation, made by the CIED team (electrophysiologist, cardiologist), in collaboration with members of the surgical/anesthesia team (perioperative team).<sup>3</sup> The recommendations should not be made by the industry representative without supervision by a physician who is qualified to manage these devices.
  - The perioperative team should provide information to the CIED team regarding the upcoming procedure (Table 3-4).
  - The CIED team should, in turn, provide information about the device and a recommendation for perioperative management of the device (Table 3-5).
  - The patient with a pacemaker should have had an interrogation of the device in the 12 months prior to the surgical procedure, whereas the patient with an ICD should have had the device interrogated within 6 months prior to the scheduled procedure.
  - The inactivation of the ICD or programming of a pacemaker to asynchronous mode is recommended when EMI is likely to occur.

- In patients in whom the ICD antiarrhythmia detection is turned off, the external defibrillator, with the pads positioned on the patient, is immediately available and ready to deliver therapy.
- In cases in which EMI is likely, the function of the CIED can be altered either by ferrous magnet or by reprogramming. See below for magnet response for ICD.
- Magnet response: Placing a magnet over a pacemaker generator will turn the pacemaker to asynchronous mode in most models. Placing a magnet over an ICD will suspend the arrhythmia detection. It will *not* switch the pacemaker function to asynchronous mode; therefore, in patients who are pacemaker dependent, the team must be aware of the risk of inhibition of the pacemaker by the EMI. If EMI is likely to occur, the recommendation is to reprogram the CIED prior to the case, by turning the arrhythmia detection function to off and program the pacemaker to asynchronous mode. Because a minority of models do not respond to magnet application in the fashion described above, it is always recommended to contact the manufacturer and confirm the response to magnet for the specific model one is dealing with.
- Complications related to application of magnet are rare. However, recent publication of a case report of three patients with intraoperative complications related to inadequate preoperative evaluation of the CIED and knowledge about response to magnet application underline the importance of following the ASA and HRS guidelines and gain knowledge about these issues preoperatively, as the complications are most of the time acute and severe.<sup>10</sup>

**Table 3-4** Essential Elements of the Information Given to the CIED Physician

- Type of procedure
- Anatomic location of surgical procedure
- Patient position during the procedure
- Will monopolar electrosurgery be used? (If so, anatomic location of EMI delivery.)
- Will other sources of EMI likely be present?
- Will cardioversion or defibrillation be used?
- Surgical venue (operating room, procedure suite, etc.)
- Anticipated postprocedural arrangements (anticipated discharge to home <23 hours, inpatient admission to critical care bed, telemetry bed)
- Unusual circumstances: Cardiothoracic or chest wall surgical procedure that could impair/damage or encroach upon the CIED leads, anticipated large blood loss, operation in close proximity to CIED

Reprinted with permission from Crossley GH, Poole JE, Rozner MA, et al. The Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) Expert Consensus Statement on the Perioperative Management of Patients with Implantable Defibrillators, Pacemakers, and Arrhythmia Monitors: Facilities and Patient Management. This document was developed as a joint project with the American Society of Anesthesiologists (ASA), and in collaboration with the American Heart Association (AHA), and the Society of Thoracic Surgeons (STS). *Heart Rhythm*. 2011;8(7):1114–1154.

**Table 3-5** Essential Elements of the Preoperative CIED Evaluation to Be Provided to the Operative Team

- Date of last device interrogation
- Type of device: Pacemaker ICD, CRT-D, CRT-P, ILR, implantable hemodynamic monitor
- Manufacturer and model
- Indication for device
  - Pacemaker: Sick sinus syndrome, AV block, syncope
  - ICD: Primary or secondary prevention
  - Cardiac resynchronization therapy
- Battery longevity documented as >3 months
- Are any of the leads <3 months old?
- Programming
  - Pacing mode and programmed lower rate
  - ICD therapy
    - Lowest heart rate for shock delivery
    - Lowest heart rate for ATP delivery
  - Rate-responsive sensor type, if programmed on
- Is the patient pacemaker dependent, and what is the underlying rhythm and heart rate if it can be determined?
- What is the response of this device to magnet placement
  - Magnet pacing rate for a pacemaker
  - Pacing amplitude response to magnet function
  - Will ICD detections resume automatically with removal of the magnet? Does this device allow for magnet application function to be disabled? If so, document programming of patient's device for this feature.
- Any alert status on CIED generator or lead
- Last pacing threshold: Document adequate safety margin with the date of that threshold

Reprinted with permission from Crossley GH, Poole JE, Rozner MA, et al. The Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) Expert Consensus Statement on the Perioperative Management of Patients with Implantable Defibrillators, Pacemakers, and Arrhythmia Monitors: Facilities and Patient Management. This document was developed as a joint project with the American Society of Anesthesiologists (ASA), and in collaboration with the American Heart Association (AHA), and the Society of Thoracic Surgeons (STS). *Heart Rhythm*. 2011;8(7):1114–1154.

## Risk Mitigation Strategies

- Use bipolar cautery where possible.<sup>3</sup>
- Use short bursts of monopolar cautery, 5 seconds or less.
- Place the return current pad in such a way to avoid crossing the generator.
- Have rescue equipment, including external pacemaker/defibrillator, immediately available for all patients with CIED.
- Activating the electrocautery in the area of the generator, even if the active electrode is not touching the patient, will cause interference.

## Anesthesia Device Services

In the last few years, perioperative management of rhythm devices has

become a more active focus of the Surgery and Anesthesia Departments in different institutions across the country. This is due to the increasing number of patients that present for surgery with one of these devices in place, posing real scheduling and management challenges, with the most concerning issue being scheduling delay. The Anesthesiology Department at the University of Washington evaluated management of CIED in the perioperative period by an Anesthesia Device Service (ADS) versus the Electrophysiology/Cardiology Service (EPCS) over a period of 4 years (2009–2013).<sup>11</sup>

The ADS was developed with help and training from the EPCS and managed 548 patients during this time, with no major complications or safety concerns and at the end of the 4 years obtained a slight reduction in the scheduling delays. Most errors made by the ADS were with restoration of the demand features postoperatively in the patients where the asynchronous mode was used during surgery, whereas the EPCS failed mostly at following the recommendations of the perioperative management of CIEDs by the HRS, published in 2011.<sup>12</sup>

The creation of such a service is a serious undertaking, necessitating training of anesthesiologists and a very close collaboration between the Anesthesiology and Cardiology Departments. However, it is conceivable that in the future this type of service will become an integral part of the perioperative surgical home, particularly in high volume centers where the scheduling delays have a serious impact.

Table 3-6 and Figure 3-1 are examples of approaches to perioperative management of patients with CIEDs.<sup>13</sup>

## Recommendations for Postoperative Follow-Up of Patients with CIEDs (Tables 3-7, 3-8 and 3-9)

### *Optimization of Pacing after Cardiopulmonary Bypass*

Separation from CPB is usually associated with a conduction abnormality, from first-degree AV block, sinus bradycardia, to third-degree AV block, or interventricular delays.<sup>14</sup>

1. **Lead placement:** Right atrial (RA) lead: place at the cephalic atrial wall, between the atrial appendages. Right ventricular lead: place at the level of the right ventricle outflow tract (RVOT). For the patient with obstructive cardiomyopathy, the RV lead is better placed in the RV apex, for less dynamic obstruction of the LVOT. Biventricular pacing is initiated for patients with intraventricular conduction lesions and dyssynchrony of contraction. Place the LV lead at the basal posterolateral wall, and hook the two ventricular leads through a y piece to the ventricular output of the temporary pacemaker box.

**Table 3-6** Example of a Stepwise Approach to the Perioperative Management of the Patient with a CIED

Perioperative Period	Patient/CIED Condition	Intervention
Preoperative evaluation	Patient has CIED	Focused history
	Determine CIED type (PM, ICD, CRT)	Focused physical examination Manufacturer's CIED identification card Chest x-ray (no data available) Supplemental resources <sup>a</sup>
	Determine if patient is CIED-dependent for pacing function	Verbal history Bradyarrhythmia symptoms Atrioventricular node ablation No spontaneous ventricular activity <sup>b</sup>
	Determine CIED function	Comprehensive CIED evaluation <sup>c</sup> Determine if pacing pulses are present and create paced beats
Preoperative preparation	EMI unlikely during procedure	If EMI is unlikely, then special precautions are not needed
	EMI likely; CIED is PM	Reprogram to asynchronous mode when indicated Suspend rate adaptive functions <sup>d</sup>
	EMI likely; CIED is ICD	Suspend antitachyarrhythmia functions. If patient is dependent on pacing function, then alter pacing function as above
Intraoperative management	EMI likely; All CIED	Use bipolar cautery; ultrasonic scalpel
	Intraoperative physiologic changes likely (e.g., bradycardia, ischemia)	Temporary pacing and cardioversion–defibrillation available Plan for possible adverse CIED-patient interaction
	Monitoring	Electrocardiographic monitoring per ASA standard Peripheral pulse monitoring
	Electrocautery interference	CT/CRP no current through PG/leads Avoid proximity of CT to PG/leads Short bursts at lowest possible energy
	RF catheter ablation	Use bipolar cautery; ultrasonic scalpel Avoid contact of RF catheter with PG/leads RF current path far away from PG/leads
	Lithotripsy	Discuss these concerns with operator Do not focus lithotripsy beam near PG R-wave triggers lithotripsy? Disable atrial pacing
	MRI	Generally contraindicated If required, consult ordering physician, cardiologist, radiologist, and manufacturer
	Radiation therapy	PG/leads must be outside of RT field Possible surgical relocation of PG Verify PG function during/after RT course
	ECT	Consult with ordering physician, patient's cardiologist, a CIED service, or CIED manufacturer
Emergency defibrillation-cardioversion	ICD: magnet-disabled	Terminate all EMI sources Remove magnet to re-enable therapies
	ICD: programming disabled	Observe for appropriate therapies Programming to re-enable therapies or proceed directly with external cardioversion/defibrillation
	ICD: either of above	Minimize current flow through PG/leads PP as far as possible from PG PP perpendicular to major axis PG/leads To extent possible, PP in anterior–posterior location
Postoperative management	Regardless of CIED type	Use clinically appropriate cardioversion/defibrillation energy
	Immediate postoperative period Postoperative interrogation and restoration of CIED function	Monitor cardiac R&R continuously Back-up pacing and cardioversion/defibrillation capability Interrogation to assess function Settings appropriate? <sup>e</sup> Is CIED an ICD? <sup>f</sup> Use cardiology/PM-ICD service if needed

<sup>a</sup>Manufacturer's databases, pacemaker clinic records, cardiology consultation

<sup>b</sup>With cardiac rhythm management device (CRMD) programmed VVI at lowest programmable rate.

<sup>c</sup>Ideally, CIED function assessed by interrogation, with function altered by reprogramming if required.

<sup>d</sup>Most times this will be necessary; when in doubt, assume so.

<sup>e</sup>If necessary, reprogram appropriate setting.

<sup>f</sup>Restore all antitachycardia therapies.

Reprinted with permission from Practice advisory for perioperative management of patients with cardiac rhythm management devices: pacemakers and implantable cardioverter-defibrillators. A report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Cardiac Rhythm Management Devices. *Anesthesiology*. 2011;114:247–261.

**Table 3-7** Specific Procedures and Writing Committee Recommendations on Postoperative CIED Evaluation

Procedure	Recommendation
Monopolar electrosurgery	CIED evaluated <sup>a</sup> within 1 month from procedure unless Table 3-8 criteria are fulfilled
External cardioversion	CIED evaluated <sup>a</sup> prior to discharge or transfer from cardiac telemetry
Radiofrequency ablation	CIED evaluated <sup>a</sup> prior to discharge or transfer from cardiac telemetry
Electroconvulsive therapy	CIED evaluated <sup>a</sup> within 1 month from procedure unless fulfilling Table 3-8 criteria
Nerve conduction studies (ENG)	No additional CIED evaluation beyond routine
Ocular procedures	No additional CIED evaluation beyond routine
Therapeutic radiation	CIED evaluated prior to discharge or transfer from cardiac telemetry; remote monitoring optimal; some instances may indicate interrogation after each treatment (see text)
TUNA/TURP	No additional CIED evaluation beyond routine
Hysteroscopic ablation	No additional CIED evaluation beyond routine
Lithotripsy	CIED evaluated <sup>a</sup> within 1 month from procedure unless fulfilling Table 3-8 criteria
Endoscopy	No additional CIED evaluation beyond routine
Iontophoresis	No additional CIED evaluation beyond routine
Photodynamic therapy	No additional CIED evaluation beyond routine
X-ray/CT scans/mammography	No additional CIED evaluation beyond routine

<sup>a</sup>This evaluation is intended to reveal electrical reset. Therefore, an interrogation alone is needed. This can be accomplished in person or by remote telemetry.

CIED, cardiac implantable electronic device; CT, computed tomography; TUNA, transurethral needle ablation; TURP, transurethral resection of prostate. Reprinted with permission from Crossley GH, Poole JE, Rozner MA, et al. The Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) Expert Consensus Statement on the Perioperative Management of Patients with Implantable Defibrillators, Pacemakers, and Arrhythmia Monitors: Facilities and Patient Management. This document was developed as a joint project with the American Society of Anesthesiologists (ASA), and in collaboration with the American Heart Association (AHA), and the Society of Thoracic Surgeons (STS). *Heart Rhythm*. 2011;8(7):1114–1154.

**Table 3-8** Indications for the Interrogation of CIEDs prior to Patient Discharge or Transfer from a Cardiac Telemetry Environment

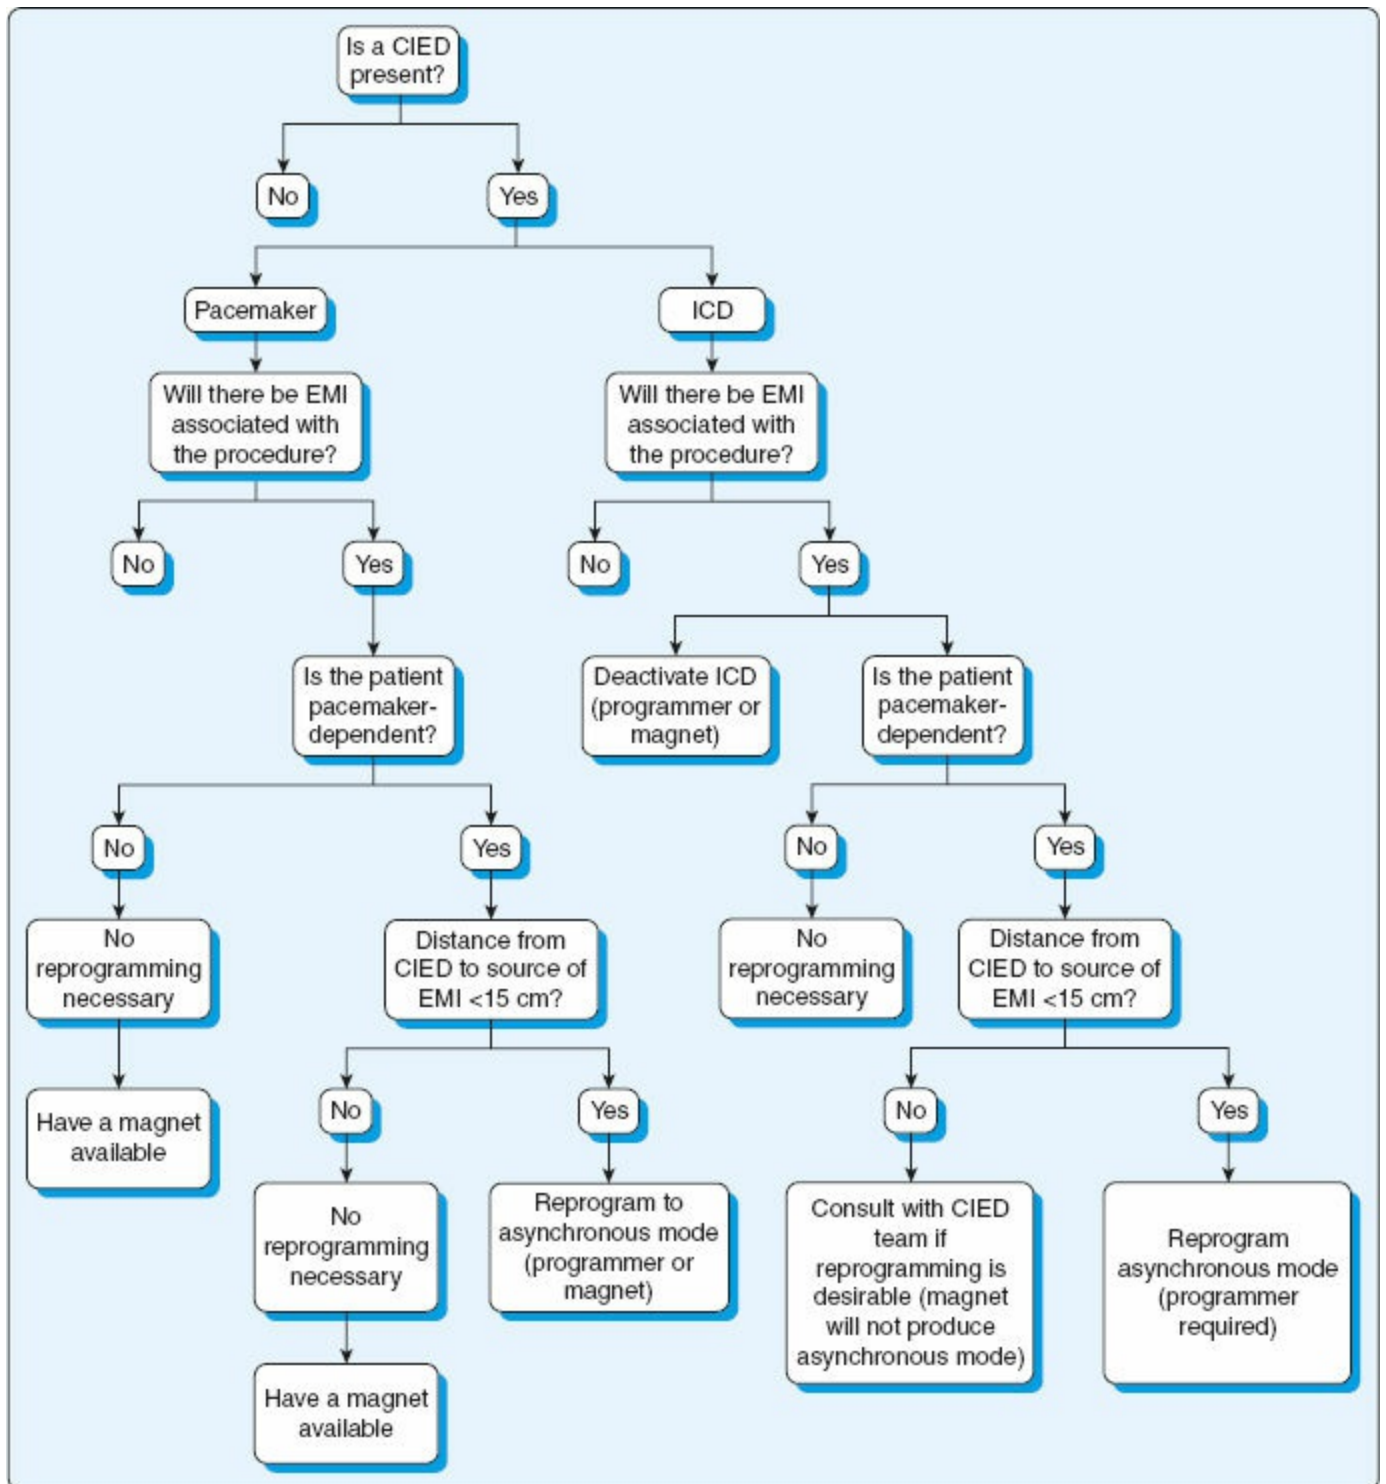

- Patients with CIEDs reprogrammed prior to the procedure that left the device nonfunctional such as disabling tachycardia detection in an ICD.
- Patients with CIEDs who underwent hemodynamically challenging surgeries such as cardiac surgery or significant vascular surgery (e.g., abdominal aortic aneurysmal repair).<sup>a</sup>
- Patients with CIEDs who experienced significant intraoperative events including cardiac arrest requiring temporary pacing or cardiopulmonary resuscitation and those who required external electrical cardioversion.
- Emergent surgery where the site of EMI exposure was above the umbilicus
- Cardiothoracic surgery
- Patients with CIEDs who underwent certain types of procedures (Table 3-7) that emit EMI with a greater probability of affecting device function.
- Patients with CIEDs who have logistical limitations that would prevent reliable device evaluation within 1 month from their procedure

<sup>a</sup>The general purpose of this interrogation is to assure that reset did not occur. In these cases, a full evaluation including threshold evaluations is suggested.

CIED, cardiac implantable electrical device; EMI, electromagnetic interference; ICD, implantable cardiac defibrillator.

**Table 3-9** Treatment of Pacemaker Failure

Rate	Possible Response
Adequate to maintain blood pressure	1. Oxygen, airway control 2. Place magnet over pacemaker 3. Atropine if sinus bradycardia
Severe bradycardia and hypotension	1. Oxygen, airway control 2. Place magnet over pacemaker 3. Other types of pacing if magnet does not activate the pacemaker (transcutaneous, esophageal, or transvenous) 4. Atropine if sinus bradycardia 5. Isoproterenol to increase ventricular rate
No escape rhythm	1. Cardiopulmonary resuscitation 2. Place magnet over pacemaker 3. Other types of pacing if magnet does not activate the pacemaker (transcutaneous, esophageal, or transvenous) 4. Isoproterenol to increase ventricular rate

Reprinted with permission from Zaidan JR, Youngberg JA, Lake CL, et al., eds., *Cardiac, Vascular and Thoracic Anesthesia*. New York, NY: Churchill Livingstone; 2000.

2. **Rate:** program to obtain the best improvement in cardiac output and improvement in mixed venous saturation and arterial blood pressure.
3. **AV delay:** In patients with LV dysfunction, we can maximize the contribution of the atria to the preload. Use pulse wave Doppler through the mitral valve inflow, and modify the AV delay to obtain a clear E and A waveforms, and to ensure that the A wave finishes before the onset of the QRS; the closure of the mitral valve should happen at the end of the A wave, but before any diastolic mitral regurgitation.
4. **Pacing mode:** Three modes are explained here. In the patient with normal AV conduction, AAI mode allows for increase in HR and a physiologic depolarization of the ventricles. If inhibition by electrocautery is a concern, use asynchronous pacing in AOO mode (Table 3-2). For the patient with AV conduction delay, DOO or DDI should be used. DDI mode also avoids tracking of rapid atrial rates in case of post bypass atrial fibrillation.
5. **Biventricular pacing**<sup>14,15</sup> in patients with EF below 35% and QRS longer than 120 msec acute biventricular pacing improves torsion and mechanics of contraction, particularly in patients with mitral regurgitation due to papillary muscle dyssynchrony. Speckle-tracking, 3D echocardiography, M-mode definition of septal to wall motion delay, color Doppler tissue imaging, and analysis of segmental velocity are used to characterize ventricular dyssynchrony. Currently, available

temporary pacemakers only allow biventricular pacing through a Y connection of the two ventricular epicardial wires to the ventricular output of the box. Acute CRT leads to an increase in myocardial performance with a slight decrease in myocardial oxygen consumption.

# APPENDIX 4

## American Society of Anesthesiologists Standards, Guidelines, and Statements

### Committee of Origin: Standards and Practice Parameters

*(Approved by the ASA House of Delegates on October 21, 1986, and last amended on October 20, 2010, with an effective date of July 1, 2011)*

These standards apply to all anesthesia care although, in emergency circumstances, appropriate life support measures take precedence. These standards may be exceeded at any time based on the judgment of the responsible anesthesiologist. They are intended to encourage quality patient care, but observing them cannot guarantee any specific patient outcome. They are subject to revision from time to time, as warranted by the evolution of technology and practice. They apply to all general anesthetics, regional anesthetics, and monitored anesthesia care. This set of standards addresses only the issue of basic anesthetic monitoring, which is one component of anesthesia care. In certain rare or unusual circumstances, (1) some of these methods of monitoring may be clinically impractical, and (2) appropriate use of the described monitoring methods may fail to detect untoward clinical developments. Brief interruptions of continual\* monitoring may be unavoidable. These standards are not intended for application to the care of the obstetrical patient in labor or in the conduct of pain management.

### Standard I

Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics, and monitored anesthesia care.

#### Objective

Because of the rapid changes in patient status during anesthesia, qualified

anesthesia personnel shall be continuously present to monitor the patient and provide anesthesia care. In the event there is a direct known hazard, for example, radiation, to the anesthesia personnel which might require intermittent remote observation of the patient, some provision for monitoring the patient must be made. In the event that an emergency requires the temporary absence of the person primarily responsible for the anesthetic, the best judgment of the anesthesiologist will be exercised in comparing the emergency with the anesthetized patient's condition and in the selection of the person left responsible for the anesthetic during the temporary absence.

## Standard II

During all anesthetics, the patient's oxygenation, ventilation, circulation, and temperature shall be continually evaluated.

### Oxygenation

#### Objective

To ensure adequate oxygen concentration in the inspired gas and the blood during all anesthetics.

#### Methods

1. Inspired gas: During every administration of general anesthesia using an anesthesia machine, the concentration of oxygen in the patient breathing system shall be measured by an oxygen analyzer with a low oxygen concentration limit alarm in use.†
2. Blood oxygenation: During all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed.† When the pulse oximeter is utilized, the variable pitch pulse tone and the low threshold alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.† Adequate illumination and exposure of the patient are necessary to assess color.†

### Ventilation

#### Objective

To ensure adequate ventilation of the patient during all anesthetics.

#### Methods

1. Every patient receiving general anesthesia shall have the adequacy of ventilation continually evaluated. Qualitative clinical signs such as chest excursion, observation of the reservoir breathing bag, and auscultation of breath sounds are useful. Continual monitoring for the presence of expired carbon dioxide shall be performed unless invalidated by the nature of the patient, procedure, or equipment. Quantitative monitoring of the volume of expired gas is strongly encouraged.†
2. When an endotracheal tube or laryngeal mask is inserted, its correct positioning must be verified by clinical assessment and by identification of carbon dioxide in the expired gas. Continual end-tidal carbon dioxide analysis, in use from the time of endotracheal tube/laryngeal mask placement, until extubation/removal or initiating transfer to a postoperative care location, shall be performed using a quantitative method such as capnography, capnometry, or mass spectroscopy.† When capnography or capnometry is utilized, the end-tidal CO<sub>2</sub> alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.†
3. When ventilation is controlled by a mechanical ventilator, there shall be in continuous use a device that is capable of detecting disconnection of components of the breathing system. The device must give an audible signal when its alarm threshold is exceeded.
4. During regional anesthesia (with no sedation) or local anesthesia (with no sedation), the adequacy of ventilation shall be evaluated by continual observation of qualitative clinical signs. During moderate or deep sedation the adequacy of ventilation shall be evaluated by continual observation of qualitative clinical signs and monitoring for the presence of exhaled carbon dioxide unless precluded or invalidated by the nature of the patient, procedure, or equipment.

## **Circulation**

### **Objective**

To ensure the adequacy of the patient's circulatory function during all anesthetics.

### **Methods**

1. Every patient receiving anesthesia shall have the electrocardiogram continuously displayed from the beginning of anesthesia until preparing to leave the anesthetizing location.†
2. Every patient receiving anesthesia shall have arterial blood pressure

and heart rate determined and evaluated at least every 5 minutes.†

3. Every patient receiving general anesthesia shall have, in addition to the above, circulatory function continually evaluated by at least one of the following: palpation of a pulse, auscultation of heart sounds, monitoring of a tracing of intra-arterial pressure, ultrasound peripheral pulse monitoring, or pulse plethysmography or oximetry.

## Body Temperature

### Objective

To aid in the maintenance of appropriate body temperature during all anesthetics.

### Methods

Every patient receiving anesthesia shall have temperature monitored when clinically significant changes in body temperature are intended, anticipated, or suspected.

## Continuum of Depth of Sedation: Definition of General Anesthesia and Levels of Sedation/Analgesia\*

**Committee of Origin: Quality Management and Departmental Administration**

*(Approved by the ASA House of Delegates on October 13, 1999, and last amended on October 15, 2014)*

	Minimal Sedation (Anxiolysis)	Moderate Sedation/Analgesia (Conscious Sedation)	Deep Sedation/Analgesia	General Anesthesia
<i>Responsiveness</i>	Normal response to verbal stimulation	Purposeful† response to verbal or tactile stimulation	Purposeful† response following repeated or painful stimulation	Unarousable even with painful stimulus
<i>Airway</i>	Unaffected	No intervention required	Intervention may be required	Intervention often required
<i>Spontaneous Ventilation</i>	Unaffected	Adequate	May be inadequate	Frequently inadequate
<i>Cardiovascular Function</i>	Unaffected	Usually maintained	Usually maintained	May be impaired

**Minimal Sedation (Anxiolysis)** is a drug-induced state during which patients respond normally to verbal commands. Although cognitive function and physical coordination may be impaired, airway reflexes, and ventilatory and cardiovascular functions are unaffected.

**Moderate Sedation/Analgesia (Conscious Sedation)** is a drug-induced depression of consciousness during which patients respond purposefully<sup>†</sup> to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.

**Deep Sedation/Analgesia** is a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully<sup>†</sup> following repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

**General Anesthesia** is a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

Because sedation is a continuum, it is not always possible to predict how an individual patient will respond. Hence, practitioners intending to produce a given level of sedation should be able to rescue<sup>‡</sup> patients whose level of sedation becomes deeper than initially intended. Individuals administering Moderate Sedation/Analgesia (Conscious Sedation) should be able to rescue<sup>‡</sup> patients who enter a state of Deep Sedation/Analgesia, while those administering Deep Sedation/Analgesia should be able to rescue<sup>‡</sup> patients who enter a state of General Anesthesia.

## **Basic Standards for Preanesthesia Care**

### **Committee of Origin: Standards and Practice Parameters**

*(Approved by the ASA House of Delegates on October 14, 1987, and last affirmed on October 28, 2015)*

These standards apply to all patients who receive anesthesia care. Under exceptional circumstances, these standards may be modified. When this is the case, the circumstances shall be documented in the patient's record.

An anesthesiologist shall be responsible for determining the medical status of the patient and developing a plan of anesthesia care.

The anesthesiologist, before the delivery of anesthesia care, is responsible for:

1. Reviewing the available medical record.
2. Interviewing and performing a focused examination of the patient to:
  - a. Discuss the medical history, including previous anesthetic experiences and medical therapy.
  - b. Assess those aspects of the patient's physical condition that might affect decisions regarding perioperative risk and management.
3. Ordering and reviewing pertinent available tests and consultations as necessary for the delivery of anesthesia care.
4. Ordering appropriate preoperative medications.
5. Ensuring that consent has been obtained for the anesthesia care.
6. Documenting in the chart that the above has been performed.

## Standards for Postanesthesia Care

### Committee of Origin: Standards and Practice Parameters

*(Approved by the ASA House of Delegates on October 27, 2004, and last amended on October 15, 2014)*

These standards apply to postanesthesia care in all locations. These standards may be exceeded based on the judgment of the responsible anesthesiologist. They are intended to encourage quality patient care, but cannot guarantee any specific patient outcome. They are subject to revision from time to time as warranted by the evolution of technology and practice.

### Standard I

All patients who have received general anesthesia, regional anesthesia or monitored anesthesia care shall receive appropriate postanesthesia management.\*\*

1. A Postanesthesia Care Unit (PACU) or an area which provides equivalent postanesthesia care (for example, a Surgical Intensive Care Unit) shall be available to receive patients after anesthesia care. All patients who receive anesthesia care shall be admitted to the PACU or its equivalent **except** by specific order of the anesthesiologist responsible for the patient's care.
2. The medical aspects of care in the PACU (or equivalent area) shall be governed by policies and procedures which have been reviewed and approved by the Department of Anesthesiology.
3. The design, equipment, and staffing of the PACU shall meet requirements of the facility's accrediting and licensing bodies.

### Standard II

A patient transported to the PACU shall be accompanied by a member of the anesthesia care team who is knowledgeable about the patient's condition. The patient shall be continually evaluated and treated during transport with monitoring and support appropriate to the patient's condition.

### **Standard III**

Upon arrival in the PACU, the patient shall be re-evaluated and a verbal report provided to the responsible PACU nurse by the member of the anesthesia care team who accompanies the patient.

1. The patient's status on arrival in the PACU shall be documented.
2. Information concerning the preoperative condition and the surgical/anesthetic course shall be transmitted to the PACU nurse.
3. The member of the Anesthesia Care Team shall remain in the PACU until the PACU nurse accepts responsibility for the nursing care of the patient.

### **Standard IV**

The patient's condition shall be evaluated continually in the PACU.

1. The patient shall be observed and monitored by methods appropriate to the patient's medical condition. Particular attention should be given to monitoring oxygenation, ventilation, circulation, level of consciousness, and temperature. During recovery from all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed in the initial phase of recovery.<sup>§</sup> This is not intended for application during the recovery of the obstetrical patient in whom regional anesthesia was used for labor and vaginal delivery.
2. An accurate written report of the PACU period shall be maintained. Use of an appropriate PACU scoring system is encouraged for each patient on admission, at appropriate intervals prior to discharge and at the time of discharge.
3. General medical supervision and coordination of patient care in the PACU should be the responsibility of an anesthesiologist.
4. There shall be a policy to assure the availability in the facility of a physician capable of managing complications and providing cardiopulmonary resuscitation for patients in the PACU.

### **Standard V**

A physician is responsible for the discharge of the patient from the postanesthesia care unit.

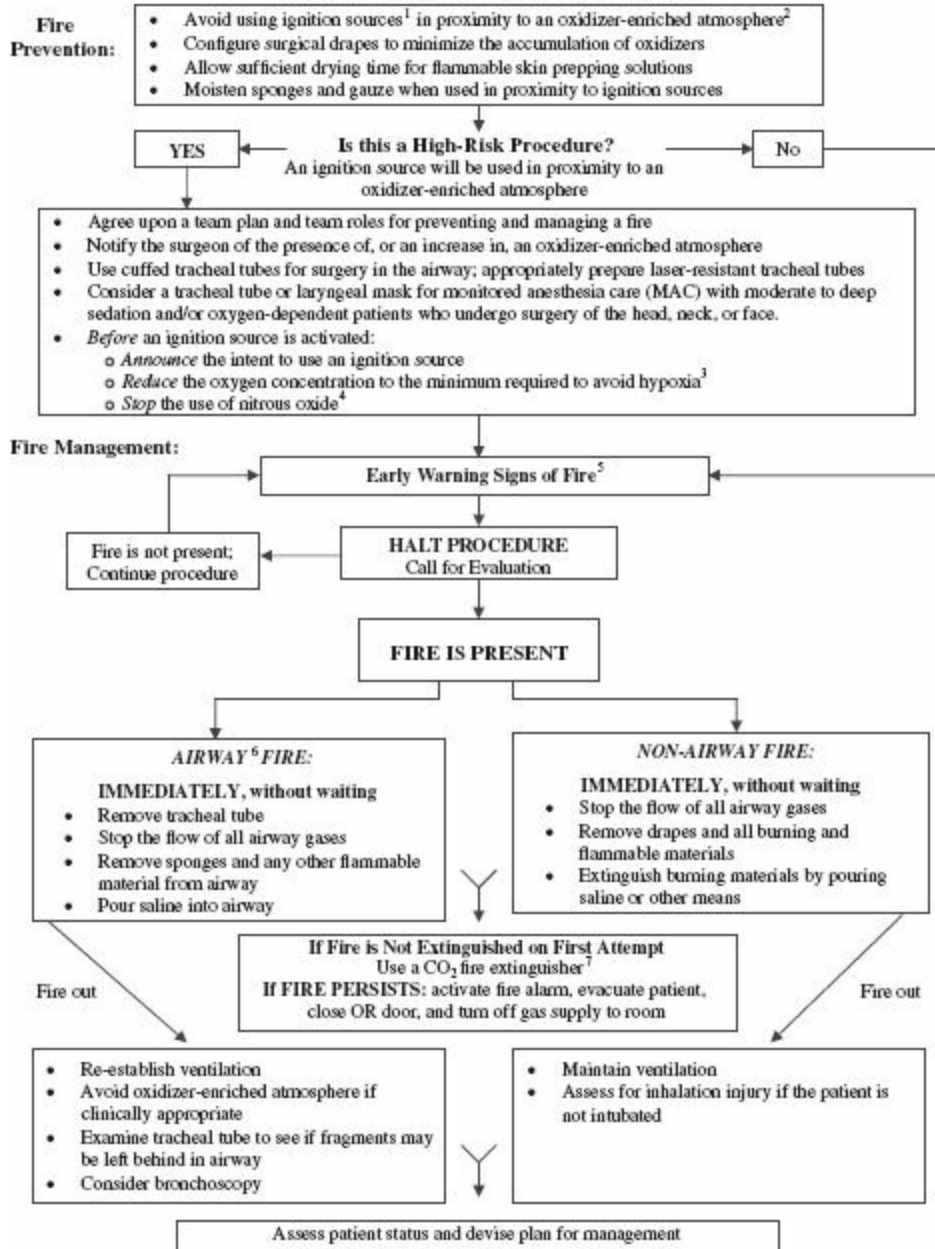

1. When discharge criteria are used, they must be approved by the

Department of Anesthesiology and the medical staff. They may vary depending upon whether the patient is discharged to a hospital room, to the Intensive Care Unit, to a short stay unit or home.

2. In the absence of the physician responsible for the discharge, the PACU nurse shall determine that the patient meets the discharge criteria. The name of the physician accepting responsibility for discharge shall be noted on the record.

## **Practice Advisory for the Prevention and Management of Operating Room Fires**

OPERATING ROOM FIRES ALGORITHM

<sup>1</sup> Ignition sources include but are not limited to electrosurgery or electrocautery units and lasers.  
<sup>2</sup> An oxidizer-enriched atmosphere occurs when there is any increase in oxygen concentration above room air level, and/or the presence of any concentration of nitrous oxide.  
<sup>3</sup> After minimizing delivered oxygen, wait a period of time (e.g., 1-3 min) before using an ignition source. For oxygen dependent patients, reduce supplemental oxygen delivery to the minimum required to avoid hypoxia. Monitor oxygenation with pulse oximetry, and if feasible, inspired, exhaled, and/or delivered oxygen concentration.  
<sup>4</sup> After stopping the delivery of nitrous oxide, wait a period of time (e.g., 1-3 min) before using an ignition source.  
<sup>5</sup> Unexpected flash, flame, smoke or heat, unusual sounds (e.g., a "pop," snap or "foomp") or odors, unexpected movement of drapes, discoloration of drapes or breathing circuit, unexpected patient movement or complaint.  
<sup>6</sup> In this algorithm, airway fire refers to a fire in the airway or breathing circuit.  
<sup>7</sup> A CO<sub>2</sub> fire extinguisher may be used on the patient if necessary.

**Figure 1** Operating room fires algorithm. CO<sub>2</sub>, carbon dioxide; OR, operating room. (From Caplan RA, Barker SJ, Connis RT, et al; American Society of Anesthesiologists Task Force on Operating Room Fires. Practice advisory for the Prevention and Management of Operating Room Fires: a report by the American Society of Anesthesiologists Task Force on Operating Room Fires. *Anesthesiology*. 2008;108:786–801, with permission.)

# OR Fire Prevention Algorithm\*

Start Here

**Is patient at risk for surgical fire?**

Procedures involving the head, neck and upper chest (above T5) *and* use of an ignition source in proximity to an oxidizer.

NO

**Proceed, but frequently reassess for changes in fire risk.**

Nurses and surgeons avoid pooling of alcohol-based skin preparations and allow adequate drying time. Prior to initial use of electrocautery, communication occurs between surgeon and anesthesia professional.

YES

**Does patient require oxygen supplementation?**

NO

**Use room air sedation.**

YES

**Is >30% oxygen concentration required to maintain oxygen saturation?**

NO

**Use delivery device such as a blender or common gas outlet to maintain oxygen below 30%.**

YES

**Secure airway with endotracheal tube or supraglottic device.**

Although securing the airway is preferred, for cases where using an airway device is undesirable or not feasible, oxygen accumulation may be minimized by air insufflation over the face and open draping to provide wide exposure of the surgical site to the atmosphere.

Provided as an educational resource by the **Anesthesia Patient Safety Foundation**

## Position on Monitored Anesthesia Care

Committee of Origin: Economics

*(Approved by the House of Delegates on October 25, 2005, and last amended on October 16, 2013)*

Monitored anesthesia care is a specific anesthesia service for a diagnostic or therapeutic procedure. Indications for monitored anesthesia care include the nature of the procedure, the patient's clinical condition and/or the potential need to convert to a general or regional anesthetic.

Monitored anesthesia care includes all aspects of anesthesia care—a preprocedure visit, intraprocedure care, and postprocedure anesthesia management. During monitored anesthesia care, the anesthesiologist provides or medically directs a number of specific services, including but not limited to:

- Diagnosis and treatment of clinical problems that occur during the procedure
- Support of vital functions
- Administration of sedatives, analgesics, hypnotics, anesthetic agents, or other medications as necessary for patient safety
- Psychological support and physical comfort
- Provision of other medical services as needed to complete the procedure safely.

Monitored anesthesia care may include varying levels of sedation, analgesia, and anxiolysis as necessary. The provider of monitored anesthesia care must be prepared and qualified to convert to general anesthesia when necessary. If the patient loses consciousness and the ability to respond purposefully, the anesthesia care is a general anesthetic, irrespective of whether airway instrumentation is required.

Monitored anesthesia care is a physician service provided to an individual patient. It should be subject to the same level of payment as general or regional anesthesia. Accordingly, the ASA Relative Value Guide provides for the use of proper base units, time and any appropriate modifier units as the basis for determining payment.

## **Distinguishing Monitored Anesthesia Care (“MAC”) from Moderate Sedation/Analgesia (Conscious Sedation)**

### **Committee of Origin: Economics**

*(Approved by the ASA House of Delegates on October 27, 2004, last amended on October 21, 2009, and reaffirmed on October 16, 2013)*

Moderate Sedation/Analgesia (Conscious Sedation; hereinafter known as Moderate Sedation) is a physician service recognized in the CPT procedural coding system. During Moderate Sedation, a physician supervises or personally administers sedative and/or analgesic medications that can allay patient anxiety and control pain during a diagnostic or therapeutic procedure.

Such drug-induced depression of a patient's level of consciousness to a "moderate" level of sedation, as defined in The Joint Commission (TJC) standards, is intended to facilitate the successful performance of the diagnostic or therapeutic procedure while providing patient comfort and cooperation. Physicians providing moderate sedation must be qualified to recognize "deep" sedation, manage its consequences and adjust the level of sedation to a "moderate" or lesser level. The continual assessment of the effects of sedative or analgesic medications on the level of consciousness and on cardiac and respiratory function is an integral element of this service.

The American Society of Anesthesiologists has defined Monitored Anesthesia Care (*see Position on Monitored Anesthesia Care, updated on October 16, 2013*). This physician service can be distinguished from Moderate Sedation in several ways. An essential component of MAC is the anesthesia assessment and management of a patient's actual or anticipated physiological derangements or medical problems that may occur during a diagnostic or therapeutic procedure. While Monitored Anesthesia Care may include the administration of sedatives and/or analgesics often used for Moderate Sedation, the provider of MAC must be prepared and qualified to convert to general anesthesia when necessary. Additionally, a provider's ability to intervene to rescue a patient's airway from any sedation-induced compromise is a prerequisite to the qualifications to provide Monitored Anesthesia Care. By contrast, Moderate Sedation is not expected to induce depths of sedation that would impair the patient's own ability to maintain the integrity of his or her airway. These components of Monitored Anesthesia Care are unique aspects of an anesthesia service that are not part of Moderate Sedation.

The administration of sedatives, hypnotics, analgesics, as well as anesthetic drugs commonly used for the induction and maintenance of general anesthesia is often, but not always, a part of Monitored Anesthesia Care. In some patients who may require only minimal sedation, MAC is often indicated because even small doses of these medications could precipitate adverse physiologic responses that would necessitate acute clinical interventions and resuscitation. If a patient's condition and/or a procedural requirement is likely to require sedation to a "deep" level or even to a transient period of general anesthesia, only a practitioner privileged to provide anesthesia services should be allowed to manage the sedation. Due to the strong likelihood that "deep" sedation may, with or without intention, transition to general anesthesia, the skills of an anesthesia provider are necessary to manage the effects of general anesthesia on the patient as well as to return the patient quickly to a state of "deep" or lesser sedation.

Like all anesthesia services, Monitored Anesthesia Care includes an array of postprocedure responsibilities beyond the expectations of practitioners providing Moderate Sedation, including assuring a return to full

consciousness, relief of pain, management of adverse physiological responses or side effects from medications administered during the procedure, as well as the diagnosis and treatment of co-existing medical problems.

Monitored Anesthesia Care allows for the safe administration of a maximal depth of sedation in excess of that provided during Moderate Sedation. The ability to adjust the sedation level from full consciousness to general anesthesia during the course of a procedure provides maximal flexibility in matching sedation level to patient needs and procedural requirements. In situations where the procedure is more invasive or when the patient is especially fragile, optimizing sedation level is necessary to achieve ideal procedural conditions.

In summary, Monitored Anesthesia Care is a physician service that is clearly distinct from Moderate Sedation due to the expectations and qualifications of the provider who must be able to utilize all anesthesia resources to support life and to provide patient comfort and safety during a diagnostic or therapeutic procedure.

## **Ethical Guidelines for the Anesthesia Care of Patients with Do-Not-Resuscitate Orders or Other Directives That Limit Treatment**

### **Committee of Origin: Ethics**

*(Approved by the ASA House of Delegates on October 17, 2001, and last amended on October 16, 2013)*

*These guidelines apply both to patients with decision-making capacity and also to patients without decision-making capacity who have previously expressed their preferences.*

- I. Given the diversity of published opinions and cultures within our society, an essential element of preoperative preparation and perioperative care for patients with Do-Not-Resuscitate (DNR) orders or other directives that limit treatment is communication among involved parties. It is necessary to document relevant aspects of this communication.
- II. Policies automatically suspending DNR orders or other directives that limit treatment prior to procedures involving anesthetic care may not sufficiently address a patient's rights to self-determination in a responsible and ethical manner. Such policies, if they exist, should be reviewed and revised, as necessary, to reflect the content of these guidelines.
- III. The administration of anesthesia necessarily involves some practices

and procedures that might be viewed as “resuscitation” in other settings. Prior to procedures requiring anesthetic care, any existing directives to limit the use of resuscitation procedures (that is, do-not-resuscitate orders and/or advance directives) should, when possible, be reviewed with the patient or designated surrogate. As a result of this review, the status of these directives should be clarified or modified based on the preferences of the patient. One of the three following alternatives may provide for a satisfactory outcome in many cases.

- A. Full Attempt at Resuscitation: The patient or designated surrogate may request the full suspension of existing directives during the anesthetic and immediate postoperative period, thereby consenting to the use of any resuscitation procedures that may be appropriate to treat clinical events that occur during this time.
  - B. Limited Attempt at Resuscitation Defined With Regard to Specific Procedures: The patient or designated surrogate may elect to continue to refuse certain specific resuscitation procedures (e.g., chest compressions, defibrillation, or tracheal intubation). The anesthesiologist should inform the patient or designated surrogate about which procedures are (1) essential to the success of the anesthesia and the proposed procedure, and (2) which procedures are not essential and may be refused.
  - C. Limited Attempt at Resuscitation Defined With Regard to the Patient’s Goals and Values: The patient or designated surrogate may allow the anesthesiologist and surgical/procedural team to use clinical judgment in determining which resuscitation procedures are appropriate in the context of the situation and the patient’s stated goals and values. For example, some patients may want full resuscitation procedures to be used to manage adverse clinical events that are believed to be quickly and easily reversible, but to refrain from treatment for conditions that are likely to result in permanent sequelae, such as neurologic impairment or unwanted dependence upon life-sustaining technology.
- IV. Any clarifications or modifications made to the patient’s directive should be documented in the medical record. In cases where the patient or designated surrogate requests that the anesthesiologist use clinical judgment in determining which resuscitation procedures are appropriate, the anesthesiologist should document the discussion with particular attention to the stated goals and values of the patient.
  - V. Plans for postoperative/postprocedural care should indicate if or

when the original, pre-existent directive to limit the use of resuscitation procedures will be reinstated. This occurs when the patient leaves the postanesthesia care unit or when the patient has recovered from the acute effects of anesthesia and surgery/procedure. Consideration should be given to whether continuing to provide the patient with a time-limited or event-limited postoperative/postprocedure trial of therapy would help the patient or surrogate better evaluate whether continued therapy would be consistent with the patient's goals.

- VI. It is important to discuss and document whether there are to be any exceptions to the injunction(s) against intervention should there occur a specific recognized complication of the surgery/procedure or anesthesia.
- VII. Concurrence on these issues by the primary physician (if not the surgeon/proceduralist of record), the surgeon/proceduralist and the anesthesiologist is desirable. If possible, these physicians should meet together with the patient (or the patient's legal representative) when these issues are discussed. This duty of the patient's physicians is deemed to be of such importance that it should not be delegated. Other members of the health-care team who are (or will be) directly involved with the patient's care during the planned procedure should, if feasible, be included in this process.
- VIII. Should conflicts arise, the following resolution processes are recommended:
  - A. When an anesthesiologist finds the patient's or surgeon's/proceduralist's limitations of intervention decisions to be irreconcilable with one's own moral views, then the anesthesiologist should withdraw in a nonjudgmental fashion, providing an alternative for care in a timely fashion.
  - B. When an anesthesiologist finds the patient's or surgeon's/proceduralist's limitation of intervention decisions to be in conflict with generally accepted standards of care, ethical practice or institutional policies, then the anesthesiologist should voice such concerns and present the situation to the appropriate institutional body.
  - C. If these alternatives are not feasible within the time frame necessary to prevent further morbidity or suffering, then in accordance with the American Medical Association's Principles of Medical Ethics, care should proceed with reasonable adherence to the patient's directives, being mindful of the patient's goals and values.
- IX. A representative from the hospital's anesthesiology service should

establish a liaison with surgical, procedural, and nursing services for presentation, discussion and procedural application of these guidelines. Hospital staff should be made aware of the proceedings of these discussions and the motivations for them.

- X. Modification of these guidelines may be appropriate when they conflict with local standards or policies, and in those emergency situations involving patients lacking decision-making capacity whose intentions have not been previously expressed.

## Practice Guidelines for Preoperative Fasting and Use of Pharmacologic Agents to Reduce Risk of Pulmonary Aspiration: Application to Healthy Patients Undergoing Elective Procedures

**Committee of Origin: Standards and Practice Parameters**

*(Approved by the ASA House of Delegates on October 17, 2001, and last amended on October 26, 2016)*

### Summary of Fasting Recommendations

Ingested Material	Minimum Fasting Period <sup>†</sup>
• Clear liquids <sup>‡</sup>	2h
• Breast milk	4h
• Infant formula	6h
• Nonhuman milk <sup>§</sup>	6h
• Light meal <sup>**</sup>	6h
• Fried foods, fatty foods, or meat	Additional fasting time (e.g., 8 or more hours) may be needed

<sup>†</sup>These recommendations apply to healthy patients who are undergoing elective procedures. They are not intended for women in labor. Following the guidelines does not guarantee complete gastric emptying.

<sup>‡</sup>The fasting periods noted above apply to all ages.

<sup>§</sup>Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.

<sup>§</sup>Since nonhuman milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining an appropriate fasting period.

<sup>\*\*</sup>A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Additional fasting time (e.g., 8 or more hours) may be needed in these cases. Both the amount and type of foods ingested must be considered when determining an appropriate fasting period.

These recommendations apply to healthy patients who are undergoing elective procedures. They are not intended for women in labor. Following the Guidelines does not guarantee complete gastric emptying. The fasting periods noted above apply to patients of all ages.

Examples of clear liquids include water, fruit juices without pulp,

carbonated beverages, clear tea, and black coffee. Because nonhuman milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining an appropriate fasting period.

A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Additional fasting time (e.g., 8 h or more) may be needed in these cases. Both the amount and type of food ingested must be considered when determining an appropriate fasting period.

## Summary of Pharmacologic Recommendations

Medication Type and Common Examples	Recommendation
<i>Gastrointestinal stimulants:</i>	
• Metoclopramide	May be used/no routine use
<i>Gastric acid secretion blockers:</i>	
• Cimetidine	May be used/no routine use
• Famotidine	May be used/no routine use
• Ranitidine	May be used/no routine use
• Omeprazole	May be used/no routine use
• Lansoprazole	May be used/no routine use
<i>Antacids:</i>	
• Sodium citrate	May be used/no routine use
• Sodium bicarbonate	May be used/no routine use
• Magnesium trisilicate	May be used/no routine use
<i>Antiemetics:</i>	
• Ondansetron	May be used/no routine use
<i>Anticholinergics:</i>	
• Atropine	No use
• Scopolamine	No use
• Glycopyrrolate	No use
<i>Combinations of the medications above:</i>	No routine use

---

\*Note that “continual” is defined as “repeated regularly and frequently in steady rapid succession” whereas “continuous” means “prolonged without any interruption at any time.”

†Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with a dagger (†); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient’s medical record.

\*Monitored Anesthesia Care (“MAC”) does not describe the continuum of depth of sedation, rather it describes “a specific anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure.”

‡Rescue of a patient from a deeper level of sedation than intended is an intervention by

a practitioner proficient in airway management and advanced life support. The qualified practitioner corrects adverse physiologic consequences of the deeper-than-intended level of sedation (such as hypoventilation, hypoxia and hypotension) and returns the patient to the originally intended level of sedation. It is not appropriate to continue the procedure at an unintended level of sedation.

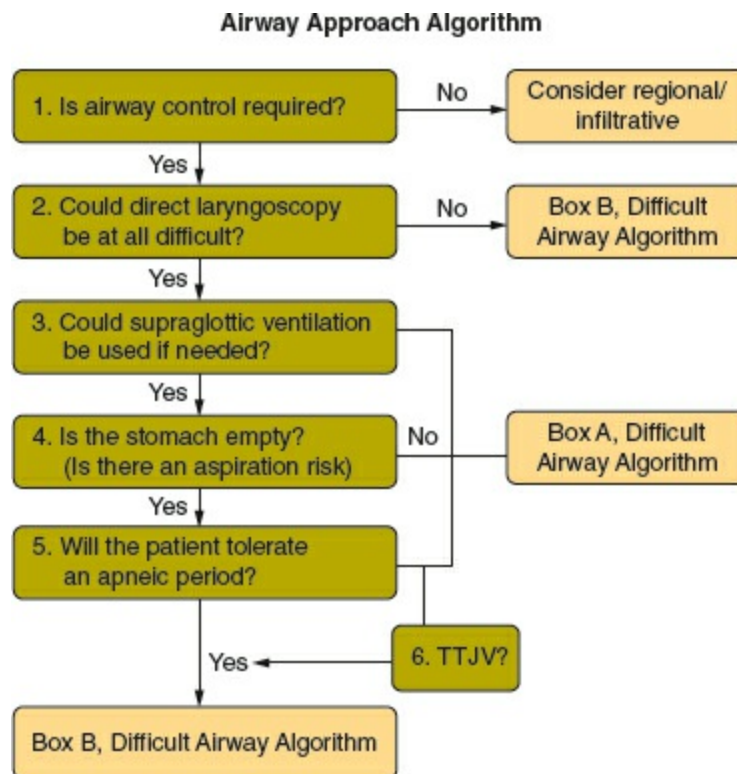

*\*\** Refer to *Perianesthesia Nursing Standards, Practice Recommendations and Interpretive Statements*, published by ASPAN, for issues of nursing care.

*§* Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk (\*); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record.

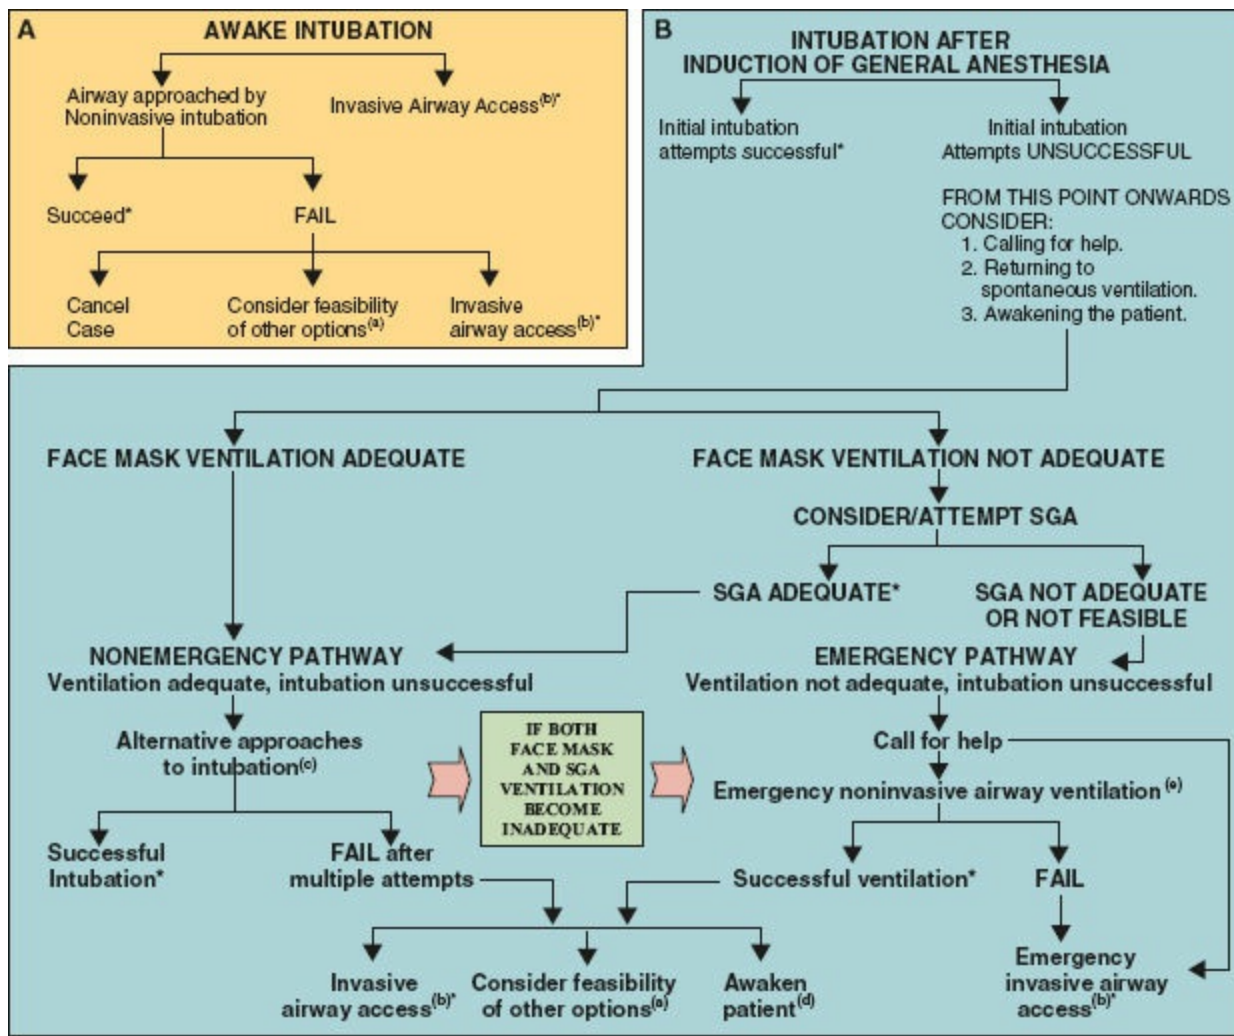

*\** This is not an ASA document but is included because of its relevance to fire safety. (<http://www.apsf.org/newsletters/html/Handouts/ORFireAlgorithmPoster8.5x11.pdf>)

# APPENDIX 5

## The Airway Approach Algorithm and Difficult Airway Algorithm

**Figure 1** The airway approach algorithm: A decision tree approach to entry into the American Society of Anesthesiologists difficult airway algorithm. TTJV, transtracheal jet ventilation. (From Rosenblatt WH, Sukhupragarn W. Airway management. In: Barash PG, Cullen BF, Stoelting RK, et al., eds. Clinical Anesthesia. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2013:788, with permission.)

\*Confirm ventilation, tracheal intubation, or SGA placement with exhaled CO<sub>2</sub>.

a. Other options include (but are not limited to): surgery utilizing face mask or supraglottic airway (SGA) anesthesia (e.g., LMA, ILMA, laryngeal tube), local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous airway, jet ventilation, and retrograde intubation.

c. Alternative difficult intubation approaches include (but are not limited to): video-assisted laryngoscopy, alternative laryngoscope blades, SGA (e.g., LMA or ILMA) as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery.

e. Emergency non-invasive airway ventilation consists of a SGA.

**Figure 2** The American Society of Anesthesiologists difficult airway algorithm. **A:** Awake intubation. **B:** Intubation after induction of general anesthesia. (Reprinted with permission from Apfelbaum JL, Hagberg CA, Caplan RA, et al; American Society of Anesthesiologists Task Force on Management of the Difficult Airway. Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology*. 2013;118(2):251–270.)

# APPENDIX **6**

## **Malignant Hyperthermia Protocol**

This content is made available to Dr. Paul Barash of the Yale School of Medicine, for use as a reference in the book: *Clinical Anesthesia*, until the next edition. Unauthorized copying without express written permission of MHAUS is strictly prohibited.

**MH Hotline: 1-800-644-9737 • Outside the US: 001-209-417-3722**

# Emergency Therapy for MALIGNANT HYPERTHERMIA

CAUTION! This protocol may not apply to all patients; alter for specific needs. Effective February 2015

## DIAGNOSIS

### Signs of MH:

- Increasing ETCO<sub>2</sub> (despite hyperventilation)
- Trunk or total body rigidity
- Masseter spasm or trismus
- Tachycardia/tachypnea
- Mixed respiratory and metabolic acidosis (MH can occur without significant metabolic acidosis)
- Increased temperature (may be an early or a late sign)
- Myoglobinuria

### Sudden/Unexpected Cardiac Arrest in Young Male Patients:

- Presume hyperkalemia and initiate treatment (see #6)
- Measure blood gases and electrolytes
- Measure CK, myoglobin, ABGs, until normalized
- Usually secondary to occult myopathy (e.g., muscular dystrophy)
- Resuscitation may be difficult and prolonged
- Myoglobinuria is common

### Trismus or Masseter Spasm with Succinylcholine:

- Early sign of MH in many patients
- If limb muscle rigidity, begin treatment with dantrolene.
- For emergency procedures, continue with non-triggering agents, evaluate and monitor the patient, and consider dantrolene treatment
- Check CK immediately and at 6-8 hr intervals until returning to normal. Observe for dark or cola-colored urine. If present, liberalize fluid intake and test for serum and urine myoglobin. (see D below)
- Observe in PACU or ICU for at least 24 hours if metabolic signs of MH were present.

## ACUTE PHASE TREATMENT

- 1 GET HELP. GET DANTROLENE. Notify Surgeon. Call MH Hotline.**
  - Discontinue volatile agents and succinylcholine.
  - Hyperventilate with 100% oxygen at flows of 10 L/min, to flush volatile anesthetics and lower ETCO<sub>2</sub>. If available insert activated charcoal filters into the inspiratory and expiratory limbs of the breathing circuit. The Vapor-Clean filter may become saturated after 1 hour; therefore, a replacement set of filters should be substituted after each hour of use.
  - Halt the procedure as soon as possible; if it is not possible to stop surgery, continue with non-triggering anesthetic technique.
  - Don't waste time changing the circle system and CO<sub>2</sub> absorbent.
- 2 Dantrium®/Revonto®/Ryanodex®**  
 2.5 mg/kg rapidly IV, if possible through large-bore IV
 

To convert kg to lbs for amount of dantrolene, give patients 1 mg/lb (2.5 mg/kg approximates 1 mg/lb).

  - Dantrium/Revonto – Each 20 mg vial should be reconstituted with at least 60 mL sterile water for injection, USP (without a bacteriostatic agent). There are 3 grams of mannitol in each 20 mg vial of Dantrium and Revonto.
  - Ryanodex – Each 250 mg vial should be reconstituted with 5 mL sterile water for injection, USP (without a bacteriostatic agent) and shaken to ensure an orange-colored uniform, opaque suspension. There are 125 mg of mannitol in each 250 mg vial of Ryanodex.
  - Repeat until signs of MH are reversed.
  - Somatom as one than 10 mg/kg (up to 30 mg/kg) of dantrolene is necessary.
- 3 Bicarbonate for metabolic acidosis**
  - 1-2 mEq/kg if blood gas values are not yet available
- 4 Cool the patient**
  - If core temperature > 39°C
  - Apply ice to surface.
  - Infuse cold saline intravenously.
  - Lavage open body cavities.
  - Other cooling techniques may be applied at clinician's discretion.
  - Stop cooling if temperature < 38°C and falling to prevent hypothermia.
- 5 Dysrhythmias**  
 Usually responds to treatment of acidosis and hyperkalemia.
  - Use standard drug therapy EXCEPT avoid calcium channel blockers—(may cause hyperkalemia or cardiac arrest in the presence of dantrolene).
- 6 Hyperkalemia**  
 Treat with hyperventilation, bicarbonate, glucose/insulin, calcium.
  - Bicarbonate 1-2 mEq/kg IV
  - For pediatric, 0.1 units regular insulin/kg and 2 mL/kg 25% dextrose or for adult, 10 units regular insulin IV and 50 mL 50% dextrose
  - Calcium chloride 10 mg/kg IV or calcium gluconate 10-50 mg/kg IV for life-threatening hyperkalemia
  - Check glucose levels hourly.
- 7 Follow...**  
 ETCO<sub>2</sub>, minute ventilation electrolytes, blood gases, CK, core temperature, urine output and color, coagulation studies. If CK and/or K<sup>+</sup> rise more than transiently or urine output falls to less than 0.5 mL/kg/hr, induce diuresis to > 1 mL/kg/hr and give bicarbonate to alkalinize urine and prevent myoglobinuria-induced renal failure (see D below).
  - Venous blood gas (e.g., femoral vein) values may document hypometabolism earlier than arterial values.
  - Central venous or RA monitoring as needed.
  - Place Foley catheter and monitor urine output.

## POST ACUTE PHASE

- Watch for MH relapse by continuously monitoring the patient for at least 24 hours following cessation of signs of MH. 25% of MH events relapse, which can be fatal. Treat immediately if relapse occurs. Signs of MH relapse include:
  - Increasing muscle rigidity in the absence of shivering
  - Inappropriate hypoxia with respiratory alkalosis
  - Metabolic acidosis without other cause
  - Inappropriate temperature rise
- Give dantrolene, 1 mg/kg IV q 4-6 hr (2.5 mg/kg/hr by infusion) and continue for at least 24 hr and consider longer or indefinite treatment.
- Determine when to stop, on the interval between doses:
  - Metabolic stability for 24 hours
  - Core temp is less than 39°C
  - CK is decreasing
  - No evidence of myoglobinuria
  - Urine is no longer pigmented
  - Follow vital signs and lab as above (see #7)
  - Transport blood gases as per clinical signs
- CK every 6 hours. Stop when on the downward trend.
- Follow urine myoglobin and initiate therapy to prevent myoglobin and the subsequent development of acute renal failure. CK levels above 10,000 IU/L in a postoperative state of rhabdomyolysis and myoglobinuria. Follow standard intensive care therapy for acute renal failure and myoglobinuria by hydration and diuresis (urine output > 1 mL/kg/hr along with 4-6 mEq/kg of urine with bicarbonate infusion and avoid attention to both urine and serum pH values).
- Counsel the patient and family regarding MH and further procedures, after them to MHAUS. If not and send to the Advanced Medical Reaction to Anesthesia (AMRA) form (www.mhaus.org/registry) and send a letter to the patient and his/her physician. Refer patient to the North American MH Registry and the nearest Registry Center for MH events.

# APPENDIX 7

## Herbal Medications

The authors and publisher have exerted every effort to ensure that the herbal medication selection in this appendix is in accord with current recommendations and practice at the time of publication.

The editors wish to acknowledge the contribution of Stella A. Haddadin, BSc, PharmD, Yale–New Haven Hospital, Department of Pharmacy Services, in the preparation of this appendix.

### Alfalfa

**Uses:** Diuretic, kidney, bladder and prostate conditions, hyperglycemia, asthma, arthritis, indigestion

**Interaction/toxicity:** Excessive use may interfere with anticoagulant therapy, potentiate drug-induced photosensitivity, and interfere with hormone therapy.

### Angelica Root

**Uses:** Gastrointestinal spasm, loss of appetite, feeling of fullness, and flatulence

**Interaction/toxicity:** Can cause photodermatitis, claims to increase stomach acid, therefore interferes with antacids, sucralfate, H<sub>2</sub> antagonists, and proton pump inhibitors. Potentiates the effects and adverse effects of anticoagulants and antiplatelet drugs.

### Anise

**Uses:** Dyspepsia and as a pediatric antifatulent and expectorant

**Interaction/toxicity:** Excessive doses can prolong coagulation, increasing PT/INR because of coumarin contained in anise. An interaction exists with anticoagulant therapy, monoamine oxidase inhibitors (MAOIs), and hormone therapy. Catecholamine activity might increase blood pressure readings and increase heart rate.

### Arnica Flower

**Uses:** Antiphlogistic, antiseptic, anti-inflammatory, analgesic

**Interaction/toxicity:** Potentiates anticoagulant and antiplatelet effect of drugs and possibly increases risk of bleeding.

## Asafoetida

**Uses:** Chronic bronchitis, asthma, pertussis, hoarseness, hysteria, flatulent colic, chronic gastric, dyspepsia, irritable colon, and convulsions

**Interaction/toxicity:** Might increase the risk of bleeding, and excessive doses might interfere with blood pressure control. Can irritate GI tract and is contraindicated in patients with infectious or inflammatory GI conditions.

## Bilberry

**Uses:** Peripheral vascular disease, diabetes, ophthalmologic diseases, peptic ulcer disease and scleroderma

**Interaction/toxicity:** Excessive use may interfere with coagulation and inhibit platelet aggregation; alters glucose regulation.

## Bogbean

**Uses:** Rheumatism, loss of appetite, dyspepsia

**Interaction/toxicity:** Potentiates anticoagulant and antiplatelet drugs and possibly increases risk of bleeding.

## Bromelain

**Uses:** Acute postoperative and posttraumatic conditions of swelling, especially of the nasal and paranasal sinuses, osteoarthritis

**Interaction/toxicity:** Potentiates anticoagulant and antiplatelet drugs and possibly increases risk of bleeding. Increases plasma and urine tetracycline level.

## Cayenne

**Uses:** Muscle spasms, chronic pain

**Interaction/toxicity:** Overdose may cause hypothermia. May cause skin blisters.

## Celery

**Uses:** Rheumatism, gout, hysteria, nervousness, weight loss as a result of

malnutrition, loss of appetite, exhaustion, sedative, mild diuretic, urinary antiseptic, digestive aid, antiflatulent, blood purification

**Interaction/toxicity:** Potentiates anticoagulant and antiplatelet drugs and possibly increases risk of bleeding. There is an additive effect with drugs with sedative properties and may cause increase in phototoxic response to psoralen plus ultraviolet light A (PUVA) therapy because of its psoralen content.

## Chamomile

**Uses:** Flatulence, nervous diarrhea, restlessness, insomnia, antispasmodic

**Interaction/toxicity:** Concomitant use with benzodiazepines might cause additive effects and side effects. Potentiates anticoagulant and antiplatelet drugs and possibly increases risk of bleeding. Is an inhibitor of the cytochrome P450 3A4 enzyme system.

## Clove

**Uses:** Flatulence, nausea, and vomiting

**Interaction/toxicity:** Potentiates anticoagulant and antiplatelet drugs and possibly increases risk of bleeding.

## Dandelion

**Uses:** Diuretic, GI disorders and anti-inflammatory effect

**Interaction/toxicity:** Excessive use may interfere with coagulation and inhibit platelet aggregation; alters glucose regulation. Do not use in the presence of biliary obstruction. Interactions with digoxin, lithium, insulin, oral hypoglycemics, cytochrome P450, ciprofloxacin, disulfiram and metronidazole.

## Danshen

**Uses:** Circulation problems, cardiovascular diseases, chronic hepatitis, abdominal masses, insomnia because of palpitations and tight chest, acne, psoriasis, eczema, aids in wound healing

**Interaction/toxicity:** Potentiates anticoagulant and antiplatelet drugs and possibly increases risk of bleeding. Increases the cardiovascular effects and side effects of digoxin.

## Devil's Claw

**Uses:** Osteoarthritis, rheumatoid arthritis, gout, myalgia, fibrositis

**Interaction/toxicity:** Can affect heart rate, contractility of heart, and blood pressure. Might decrease blood glucose levels and have additive effects with medications used for diabetes. May cause an increase in gastric acid secretions.

## Dong Quai

**Uses:** Gynecologic ailments, menopausal symptoms

**Interaction/toxicity:** Potentiates anticoagulant and antiplatelet drugs and possibly increases risk of bleeding.

## Echinacea

**Uses:** Common colds, urinary tract infections

**Interaction/toxicity:** May cause hepatotoxicity especially with other concomitant hepatotoxins. Antagonizes steroids and immunosuppressants. May possess immunosuppressive activity after long-term use.

## Ephedra

**Uses:** Diet aid, bacteriostatic, antitussive

**Interaction/toxicity:** May cause arrhythmias with inhalation anesthetics and cardiac glycosides. Life-threatening reaction with MAOIs. May cause depletion of catecholamines and lead to perioperative hemodynamic instability. Can cause death.

## Fenugreek

**Uses:** Lower blood sugar in diabetics

**Interaction/toxicity:** Potentiates anticoagulant and antiplatelet drugs and possibly increases risk of bleeding. Inhibits corticosteroid drug activity, interferes with hormone therapy, can alter blood glucose control, and potentiate effect of MAOIs.

## Feverfew

**Uses:** Migraine prophylaxis, antipyretic

**Interaction/toxicity:** Inhibit platelet activity. Potentiates anticoagulants. Abrupt withdrawal may cause rebound headaches. Uterine stimulant. Associated with serotonin syndrome.

## Fish Oil

**Uses:** Cardiovascular disease, colon cancer, psychiatric disorders, diabetes, inflammatory disease, inflammatory bowel diseases, premenstrual syndrome and scleroderma

**Interaction/toxicity:** Excessive use may interfere with coagulation and inhibit platelet aggregation; alters glucose regulation; potentiates anti-hypertensive drugs.

## Flaxseed Oil

**Uses:** Cardiovascular disease, colon cancer, psychiatric disorders, diabetes, inflammatory disease, inflammatory bowel diseases, breast cancer and depression

**Interaction/toxicity:** Excessive use may interfere with coagulation and inhibit platelet aggregation; alters glucose regulation.

## Garlic (Pertains to Supplement Product)

**Uses:** Lower lipids, antihypertensive, antiplatelet, antioxidant, antithrombolytic

**Interaction/toxicity:** Potentiates anticoagulants, especially in the presence of drugs that inhibit platelet function. Potentiates vasodilator drugs and antihypertensives. May decrease blood glucose levels as a result of increased serum insulin levels.

## Ginger (Pertains to Supplement Product)

**Uses:** Antinauseant, antispasmodic

**Interaction/toxicity:** Inhibits thromboxane synthetase. Potentiates anticoagulants. May alter effects of calcium channel blockers.

## Ginkgo

**Uses:** Circulatory stimulant, inhibit platelets

**Interaction/toxicity:** Potentiates anticoagulants, especially in the presence of aspirin, NSAIDs, heparin, and warfarin.

## Ginseng

**Uses:** Antioxidant

**Interaction/toxicity:** Antagonize anticoagulants. Avoid use of sympathetic stimulants, which may result in tachycardia or hypertension. Possesses hypoglycemic effects. Potentiates digoxin and MAOIs.

## Goldenseal

**Uses:** Diuretic, anti-inflammatory, hemostatic

**Interaction/toxicity:** May worsen edema and hypertension. Oxytocic possesses activity.

## Grape Seed

**Uses:** Anti-oxidant, cardiovascular disorders, peripheral circulatory disorders, multiple sclerosis, Parkinson disease

**Interaction/toxicity:** Excessive use may interfere with coagulation and inhibit platelet aggregation; may inhibit xanthine oxidase.

## Green Tea

**Uses:** Improves cognitive performance, lowers cholesterol and triglycerides, aids in the prevention of breast, bladder, esophageal, and pancreatic cancers. Decreased risk of Parkinson disease, gingivitis, obesity

**Interaction/toxicity:** Concomitant use might inhibit effect of adenosine and antagonize effect of warfarin. Because of the caffeine content, there is an increase in cardiac inotropic effects of beta-adrenergic agonist drugs, an increase in the effects and toxicity of clozapine, and an increased risk of agitation, tremors, and insomnia in combination with ephedrine. It might precipitate hypertensive crisis with MAOIs as well. Might reduce sedative effects of benzodiazepines.

## Horse Chestnut

**Uses:** Scleroderma, peripheral vascular disorders, varicose veins and relieving pain, tiredness, tension, swelling in legs, itching, and edema

**Interaction/toxicity:** Excessive use may interfere with coagulation and inhibit platelet aggregation; phosphodiesterase inhibitor and alters glucose regulation. Potentiates anticoagulant and antiplatelet drugs and possibly increases risk of bleeding, hypoglycemic effects, might interfere with binding of protein binding drugs.

## Kava-Kava

**Uses:** Anxiolytic, analgesic

**Interaction/toxicity:** Potentiates barbiturates, opioids, and benzodiazepines.

## Licorice

**Uses:** Heal gastric and duodenal ulcers

**Interaction/toxicity:** May cause hypertension, hypokalemia, and edema.

## Lovage Root

**Uses:** Used for inflammation of the lower urinary tract and prevention of kidney gravel; in “irrigation therapy,” it is used as a mild diuretic

**Interaction/toxicity:** Might increase sodium retention and interfere with diuretic therapy.

## Meadowsweet

**Uses:** Supportive therapy for colds

**Interaction/toxicity:** Can potentiate narcotic effects. Contains a salicylate constituent.

## Onions

**Uses:** Loss of appetite, preventing atherosclerosis, dyspepsia, fever, colds, cough, tendency toward infection, and inflammation of the mouth and pharynx

**Interaction/toxicity:** May enhance antidiabetic drug effects and alter blood sugar control. Might enhance antiplatelet drug activity and increase bleeding risk.

## Papain

**Uses:** Inflammation and swelling in patient with pharyngitis

**Interaction/toxicity:** Concomitant use with anticoagulant and antiplatelet drugs may increase risk of bleeding.

## Parsley

**Uses:** Breath freshener, urinary tract infections, and kidney or bladder stones

**Interaction/toxicity:** Might interfere with oral anticoagulant therapy because of the vitamin K contained in parsley. May interfere with diuretic therapy by enhancing sodium retention. Might potentiate MAOI drug therapy.

## Passion Flower

**Uses:** Generalized anxiety disorder

**Interaction/toxicity:** Concomitant use with barbiturates can increase drug-

induced sleep time; can potentiate the effects of sedatives and tranquilizers, including sedative effects of antihistamines.

## Quassia

**Uses:** Anorexia, indigestion, fever, mouthwash, as an anthelmintic for thread worms, nematodes, and ascaris

**Interaction/toxicity:** Stimulates gastric acid and might oppose effect of antacids and H<sub>2</sub> antagonists. Excessive doses might have additive effects with anticoagulant therapy with Coumadin. Concomitant use of potassium-depleting diuretics or stimulant laxative abuse might increase risk of cardiac glycoside toxicity as a result of potassium loss.

## Red Clover

**Uses:** Hot flashes

**Interaction/toxicity:** Can increase the anticoagulant effects and bleeding risk because of its Coumarin content. May interfere with hormone replacement therapy or oral contraceptives, and may interfere with tamoxifen because of its potential estrogenic effects. Can inhibit cytochrome P450 (cyp450) 3A4.

## Saw Palmetto

**Uses:** Benign prostatic hypertrophy, antiandrogenic

**Interaction/toxicity:** Potentiates birth control pills and estrogens. May cause hypertension.

## St. John's Wort

**Uses:** Depression, anxiety

**Interaction/toxicity:** Possible interaction/toxicity with MAOIs and meperidine. May prolong anesthetic effects. Potentiates digoxin. May decrease effects of warfarin, steroids, and possibly benzodiazepines and calcium channel blockers.

## Sweet Clover

**Uses:** Chronic venous insufficiency, including leg pain and heaviness, nighttime leg cramps, itching and swelling, for supportive treatment of thrombophlebitis, lymphatic congestion, postthrombotic syndromes, and hemorrhoids

**Interaction/toxicity:** Use with hepatotoxic drugs might increase risk of hepatotoxicity. Concomitant use with anticoagulant and antiplatelet drugs may increase risk of bleeding.

## Turmeric

**Uses:** Dyspepsia, jaundice, hepatitis, flatulence, abdominal bloating

**Interaction/toxicity:** Concomitant use with anticoagulant and antiplatelet drugs may increase risk of bleeding.

## Valerian

**Uses:** Sedative, anxiolytic

**Interaction/toxicity:** Potentiates barbiturates and anesthetics. May blunt symptoms of benzodiazepine withdrawal.

## Vitamin E

**Uses:** Vitamin E deficiency, heart disease

**Interaction/toxicity:** Concomitant use with anticoagulant and antiplatelet drugs may increase risk of bleeding. Might prevent tolerance to nitrates.

## Willow Bark

**Uses:** Lower back pain, fever, rheumatic ailments, headache

**Interaction/toxicity:** Enough salicylate is present in willow bark to cause drug interactions common to salicylates or aspirin. Can impair effectiveness of beta-adrenergic blockers, probenecid, and sulfinpyrazone. Can increase effects, side effects, or toxicity of alcohol, anticoagulants, carbonic anhydrase inhibitors, heparin, methotrexate, NSAIDs, sulfonyleureas, and valproic acid.

# Table of Contents

Title Page	2
Copyright	4
Dedication	6
Contributing Authors	7
Preface	31
Contents	34
Multimedia Contents	40
Section 1: Introduction and Overview	52
1 The History of Anesthesia	52
2 Scope of Practice	116
3 Occupational Health	218
4 Anesthetic Risk, Quality Improvement, and Liability	284
5 Electrical and Fire Safety	325
Section 2: Basic Science and Fundamentals	398
6 Genomic Basis of Perioperative Medicine	398
7 Experimental Design and Statistics	457
8 Inflammation, Wound Healing, and Infection	501
9 The Allergic Response	552
10 Mechanisms of Anesthesia and Consciousness	591
11 Basic Principles of Clinical Pharmacology	650
Section 3: Core care Principles	740
12 Cardiac Anatomy and Physiology	740
13 Cardiovascular Pharmacology	800
14 Autonomic Nervous System Anatomy and Physiology	875
15 Respiratory Function in Anesthesia	938
16 Fluids, Electrolytes, and Acid–Base Physiology	997
17 Hemostasis and Transfusion Medicine	1084
Section 4: Anesthetic Drugs and Adjuvants	1182
18 Inhaled Anesthetics	1182
19 Intravenous Anesthetics	1252
20 Opioids	1299
21 Neuromuscular Blocking Agents	1353
22 Local Anesthetics	1432

<b>Section 5: Preoperative Assessment and Perioperative Monitoring</b>	<b>1479</b>
23 Preoperative Patient Assessment and Management	1479
24 Rare Coexisting Diseases	1545
25 The Anesthesia Workstation and Delivery Systems for Inhaled Anesthetics	1618
26 Commonly Used Monitoring Techniques	1758
27 Echocardiography	1823
<b>Section 6: Basic Anesthetic Management</b>	<b>1901</b>
28 Airway Management	1901
29 Patient Positioning and Potential Injuries	2005
30 Monitored Anesthesia Care	2044
31 Ambulatory Anesthesia	2100
32 Office-based Anesthesia	2139
33 Nonoperating Room Anesthesia	2184
34 Anesthesia for the Older Patient	2227
35 Neuraxial Anesthesia	2273
36 Peripheral Nerve Blockade	2344
<b>Section 7: Anesthesia Subspecialty Care</b>	<b>2484</b>
37 Anesthesia for Neurosurgery	2484
38 Anesthesia for Thoracic Surgery	2551
39 Anesthesia for Cardiac Surgery	2674
40 Anesthesia for Vascular and Endovascular Surgery	2762
41 Obstetric Anesthesia	2841
42 Neonatal Anesthesia	2926
43 Pediatric Anesthesia	3033
<b>Section 8: Anesthesia for Selected Surgical Services</b>	<b>3142</b>
44 Anesthesia for Laparoscopic and Robotic Surgeries	3142
45 Anesthesia and Obesity	3183
46 The Liver: Surgery and Anesthesia	3236
47 Endocrine Function	3316
48 Anesthesia for Otolaryngologic Surgery	3392
49 Anesthesia for Ophthalmologic Surgery	3433
50 The Renal System and Anesthesia for Urologic Surgery	3505
51 Anesthesia for Orthopedic Surgery	3609
52 Transplant Anesthesia	3650
53 Trauma and Burns	3724
<b>Section 9: Postanesthetic Management, Critical Care, and Pain Management</b>	<b>3854</b>

54 Postanesthesia Recovery	3854
55 Acute Pain Management	3919
56 Chronic Pain Management	4022
57 Critical Care Medicine	4083
58 Cardiopulmonary Resuscitation	4163
59 Disaster Preparedness	4222
<b>Section 10: Appendices</b>	<b>4270</b>
Appendix 1: Formulas	4271
Appendix 2: Atlas of Electrocardiography	4273
Appendix 3: Pacemaker and Implantable Cardiac Defibrillator Protocols	4295
Appendix 4: American Society of Anesthesiologists Standards, Guidelines, and Statements	4309
Appendix 5: The Airway Approach Algorithm and Difficult Airway Algorithm	4327
Appendix 6: Malignant Hyperthermia Protocol	4329
Appendix 7: Herbal Medications	4331
<b>Index</b>	<b>4340</b>
