- **Local anesthetic spread:** The aim is to spread approximately 5 mL of local anesthetic around the nerve in a circular fashion in order to obtain a complete block while avoiding nerve contact. The local anesthetic injection will appear as an expansion of hypoechogenicity surrounding the nerve, which may separate the nerve from the artery.

## Clinical Pearls

- When performing regional anesthesia in the elbow, direct injection after eliciting a paresthesia or direct injection into the groove under pressure is not advised because of the risk of damage to the nerve. Small volumes (3 to 5 mL) of local anesthetic should be used.
- During nerve block in the forearm, blood withdrawal into the tubing suggests ulnar artery puncture, and the needle should be reinserted after holding pressure. Contact with the ulna indicates that the needle is too deep.
- US imaging facilitates the unique approach of blocking the ulnar nerve in the forearm. This technique may reduce complications such as ulnar nerve neuritis or neurapraxia compared to blocks at the cubital tunnel behind the medial epicondyle.
- A linear or curved array US probe with a small footprint (26 mm; e.g., a “hockey stick” probe) may be used. This size of probe is helpful for easy manipulation on the forearm and for good alignment of the needle using IP technique.

- At the wrist, the ulnar nerve lies between the ulnar artery and the tendon of the flexor carpi ulnaris muscle. A skin wheal is raised at the level of the styloid process on the palmar side of the forearm between these two landmarks, a small-gauge needle is inserted, and 3 mL of solution is injected into the area, with or without paresthesias.

## **Intravenous Regional Anesthesia (Bier Block)**

Without using NS or US, arm anesthesia can be provided by the injection of local anesthetic into the venous system distal to an occluding tourniquet.

### *Procedure*

- A small-gauge (20 or 22) intravenous catheter is inserted and taped on the dorsum of the hand in the arm to be blocked. A heparin lock or small syringe is attached, and saline is injected to maintain patency. A pneumatic tourniquet is applied over the upper arm. The tourniquet pressure should be set to 2.5 times the systolic blood pressure. The tourniquet should be inflated to confirm that the pressure is sufficient to occlude distal arterial blood flow and should be deflated before starting the block.
- The arm is elevated to promote venous drainage. An Esmarch bandage is then wrapped tightly around the limb from distal to proximal to produce further exsanguination. After exsanguination, the tourniquet is inflated to 300 mmHg or 2.5 times the patient's systolic blood pressure and is again tested for adequate occlusion of the distal radial pulse.
- The arm is returned to the horizontal position, a 50-mL syringe with 0.5% lidocaine (without preservative) is attached to the previously inserted cannula, and the contents are injected slowly. The forearm discolors, and the patient perceives a transient "pins and needles" sensation and warmth as anesthesia ensues over the following 5 minutes. Epinephrine should not be added to the local anesthetic solution.
- For short procedures, the cannula can be removed at this point. If surgery extends beyond 1 hour, the cannula can be left in place and used for reinjection after 90 minutes.
- Beyond 45 minutes of surgery, many patients experience discomfort at the level of the tourniquet. Special "double-cuff" tourniquets are available for this block to alleviate this problem. The distal cuff is inflated first followed by the proximal cuff. The distal cuff is then deflated, allowing anesthesia to be induced in the area under the distal cuff. If discomfort ensues, the distal cuff is inflated over the

anesthetized area of skin, and the uncomfortable proximal cuff is released. This step is critical because the major risk of this procedure is premature release of the local anesthetic solution into the circulation. If a double cuff is used, both cuffs should be tested before starting, and the proper sequence for inflation and deflation followed meticulously. The potential for leakage of anesthetic into the circulation is greater with the narrower cuffs used in the double setup. Because the shifting process also increases the potential for unintentional release of anesthetic, the use of a single, wider cuff may be better for short procedures.

- If surgery is completed in less than 20 minutes, the tourniquet is left inflated for at least that total period of time. If 40 minutes has elapsed, the tourniquet can be deflated as a single maneuver. Between 20 and 40 minutes, the cuff can be deflated, reinflated immediately, and finally deflated after 1 minute to delay the sudden absorption of anesthetic into the systemic circulation, although this may not truly lower the eventual peak plasma local anesthetic levels achieved.
- Duration of anesthesia is minimal beyond the time of tourniquet release. The cardiotoxicity of systemic levels of bupivacaine makes this drug contraindicated for Bier block.

### *Clinical Pearls*

- The simplicity of this technique is offset by the potentially significant risk of systemic local anesthetic toxicity if the tourniquet fails or is released prematurely. Complications related to systemic toxicity include seizures, cardiac arrest, and death; other noted complications include nerve damage, compartment syndrome, and thrombophlebitis.<sup>137</sup> Careful testing of the tourniquet and slow injection of solution into a peripheral (not antecubital) vein will reduce the chance of leakage under the tourniquet. Systemic blood levels are time-dependent, and careful attention should be paid to the sequence of tourniquet release and to patient monitoring during this period. A separate intravenous site for injection of resuscitation drugs is needed, as is ready availability of all appropriate resuscitative equipment. With careful attention to these details, this is one of the most effective and reliable techniques available to the anesthesiologist.

## Trunk Nerve Blocks

Anesthesia of the abdomen and chest is often obtained most simply with spinal and epidural injections of local anesthetics, but peripheral block of the spinal nerves in the paravertebral space or the intercostal or inguinal nerves is suitable for many uses. This is particularly relevant when either a narrow band of anesthesia (intercostal or paravertebral) or reduced motor block is preferable. In addition, epidural injection may be hazardous because of infection or coagulopathy. Epidural anesthesia also carries concerns of systemic hypotension and epidural hematoma, which can limit its use for some patients.<sup>138</sup> In many clinical situations, it may be desirable to use intercostal blocks to overcome the combined anesthesia of the somatic and sympathetic fibers that occurs with neuraxial blocks. The sympathetic nerves separate from their somatic counterparts early in their course, which makes independent somatic and sympathetic blockade a practical consideration. Likewise, although paravertebral blocks may result in both somatic and sympathetic blocks, hemodynamic responses are often less than those encountered during epidural block. Sympathetic blocks are performed commonly at the major ganglia, particularly the stellate, celiac, and lumbar plexus. These blocks may require multiple injections and are technically more difficult than axial anesthesia, but they offer advantages in certain clinical situations. The reader is referred to [Chapter 56](#) for discussion of these blocks.

Ilioinguinal and iliohypogastric nerve blocks are used for procedures in the inguinal area, including hernia repair and orchidopexy. A lumbar plexus block is not optimal in these cases since these nerves exit the plexus more cranially (L1–L2) than those nerves targeted by the lumbar plexus block (L3–L5). Transversus abdominis plane (TAP) block<sup>139,140</sup> and rectus sheath blocks<sup>141,142</sup> can be performed for abdominal, umbilical, or other midline surgical procedures and are often performed bilaterally. Approaches to the rectus sheath block target the terminal branches of the 9th, 10th, and 11th intercostal nerves within the rectus sheath; ideally, injection is between the posterior rectus sheath and the rectus abdominis muscle. The TAP block aims to impede innervation of the abdominal wall up to the level of T8 by injecting local anesthetic between the transversus abdominis and internal oblique muscles. The initial technique of multiple injections of local anesthetic in the abdominal wall was modified to a single injection using the landmark technique by locating the “lumbar triangle of Petit.”<sup>143</sup> US-guided regional techniques allow the layers of musculature to be identified, and needle insertion and local anesthetic deposition between the fascial layers can be visualized in real time. Thus, the approach to the TAP block has evolved yet again and has become more common.

## Intercostal Nerve Block

Anesthesia of the intercostal nerves provides both motor and sensory anesthesia of the abdominal wall from the xiphoid to the pubis. Intercostal nerve blockade is used for various conditions of acute and chronic pain affecting the thorax and upper abdomen (e.g., postoperative analgesia after thoracotomies, various cardiac surgeries, and both open and laparoscopic cholecystectomies). It can be performed through several means, including continuous infusions into the subpleural space, through interpleural catheters, and by direct intercostal nerve block. The surgical site (i.e., intraoperative anatomic access) determines the available options.

These nerve blocks involve injections along the easily palpated sharp posterior angulation of the ribs, which occurs between 5 and 7 cm from the midline in the back. The blocks may be performed more laterally (8 to 10 cm from the midline)<sup>144</sup> or more medially (immediately beyond the transverse processes). The levels of T1–T5 may be most amenable to paravertebral block due to the overlying scapula and bulky paraspinal musculature at this region. Establishing blockade of five or six levels of intercostal nerves is a useful anesthetic procedure for providing analgesia and motor relaxation for upper abdominal procedures such as cholecystectomy and gastric surgery. Unilateral blockade of these nerves is a useful treatment for the pain of rib fracture and also serves to reduce postoperative analgesia requirements in patients with subcostal incisions. Several segments must be blocked in each of these applications because of the overlap in supply of the intercostal nerves. This technique is also useful in reducing the pain associated with the insertion of chest tubes or percutaneous biliary drainage procedures.

For intercostal blocks, the patient may be in the lateral, sitting, or prone position. For operative anesthesia, the prone position is most practical. A pillow is placed under the abdomen to provide slight flexion of the thoracic spine. The arms are draped over the edge of the stretcher or operating table so that the scapula falls away laterally from the midline. The anesthesiologist stands at the patient's side. Most anesthesiologists prefer to stand on the side that allows their dominant hand to hold the syringe at the caudad end of the patient.

### *Procedure Using Landmark-based Technique*

**Landmarks.** The reader is referred to the Clinical Anatomy section (see earlier) for descriptions of the locations of the relevant landmarks. The spinous processes in the midline from T6 to T12 are marked. The ribs are then identified along the line of their most extreme posterior angulation. The 6th and 12th ribs are marked first at their inferior borders, and a line is drawn between these two points. The rest of the ribs between them are identified,

and a mark is placed on the inferior border of each rib along the angled parasagittal plane identified by the first line between the 6th and 12th ribs.

**Needling.** After aseptic preparation, light sedation is provided for the patient, and a skin wheal is raised at each mark on the inferior border of each respective rib. Starting with the lowest rib, the index finger of the cephalad hand retracts the skin above the identifying mark in a cephalad direction. Using the other hand, the anesthesiologist inserts a needle (22 gauge, 3.75 cm) directly onto the rib, maintaining a constant 10 degree cephalad angulation. After contact is made with the rib, the cephalad traction is slowly released, the cephalad hand takes over the needle and syringe, and the needle is allowed to “walk” down to below the rib at the same angle. The needle is then advanced approximately 4 mm under the rib.

Age influences the point of needle insertion in children. The needle is inserted at the intersection of the lower border of the rib and the mid-axillary line or posterior axillary line in children below 10 years old and above 10 years old, respectively. Anterior approaches are used rarely and will not be described here.

**Injection.** Once in the groove, aspiration is performed, and 3 to 5 mL of local anesthetic solution (lower volumes for children <3 years old) is injected. The needling and injection procedure is repeated for each segmental level and for both sides if applicable. Since the intercostal space is highly vascularized, local anesthetics are absorbed rapidly, and toxic levels of local anesthetic may be encountered when using large volumes, which can quickly lead to neurologic or cardiovascular sequelae. Maximum doses should be calculated and followed carefully for these blocks.

### *Procedure Using Ultrasound Imaging*

The ribs can be visualized easily with the use of US. A high-frequency (5 to 15 MHz) probe is placed in a longitudinal axis. The rib will appear as a hyperechoic line casting a hypoechoic bony shadow underneath (Fig. 36-26). The pleurae can also be seen to “glitter” as they slide with respiration. The remainder of the procedure will be similar to that of the blind technique. If a more medial (proximal) intercostal nerve block is desired, such as to relieve the pain of herpes zoster or of proximal rib fractures, US imaging of the costotransverse joint and ribs may be helpful. The section on paravertebral block describes and illustrates this imaging.

### *Clinical Pearls*

- Intercostal nerve blocks can be supplemented by a number of somatic paravertebral nerve blocks or sympathetic block of the celiac plexus. Care should be taken to adjust the total dose of drug in these combined

techniques so that the maximal recommended amounts are not exceeded.

- The advantages of intercostal block over sole intravenous opioid use include superior analgesia, opioid sparing, improved pulmonary mechanics (including earlier extubation), and reduced central nervous system depression.<sup>144</sup> Intercostal blocks are often used in addition to systemic analgesia (e.g., intravenous, patient-controlled analgesia).
- Despite frequent concern about the incidence of pneumothorax with intercostal blocks, this complication is rare, especially when US is used in experienced hands. This depends primarily on maintaining strict safety features of the described technique. Emphasis should be placed on absolute control of the syringe and needle at all times, particularly during injection.
- A common complication is related to the sedation required to perform this block in the prone position. Overdose can lead to airway obstruction and respiratory depression in the prone position. Attention must be paid to the patient's mental status because this block produces the highest blood levels of local anesthetics compared to any other regional anesthetic technique. When the block is performed for postoperative pain relief, the dose should be reduced to 0.25% bupivacaine or ropivacaine to minimize the risk of toxicity.
- It is possible to produce partial spinal or epidural anesthesia if the injection is made close to the midline and the local anesthetic tracks along a dural sleeve to the epidural or subarachnoid space. Respiratory insufficiency can also be seen if the intercostal muscles are blocked in a patient who depends on them for ventilation. Patients with chronic obstructive disease with ineffective diaphragm motion are not good candidates for this technique.

**Figure 36-26** Arrangement of relevant anatomy for ultrasound-guided intercostal nerve block. The ultrasound image shows the hyperechoic lines of the ribs casting a

hypoechoic bony shadow. The pleura is the hyperechoic line deep to that of the ribs and has a glittery appearance, especially on respiration.

## **Paravertebral Block**

### *Techniques*

Paravertebral block is useful for segmental anesthesia, particularly of the upper thoracic segments. It is also useful if blockade more proximal (central) than that of the intercostal nerves is needed, such as to relieve the pain of herpes zoster or a proximal rib fracture. Thoracic paravertebral block is used for breast surgery and perioperatively for thoracic surgery. Thoracolumbar paravertebral anesthesia is used commonly for inguinal herniorrhaphy and postoperative analgesia following hip surgery. Lumbar paravertebral blockade has been used successfully for outpatient hernia operations, providing significant postoperative analgesia.

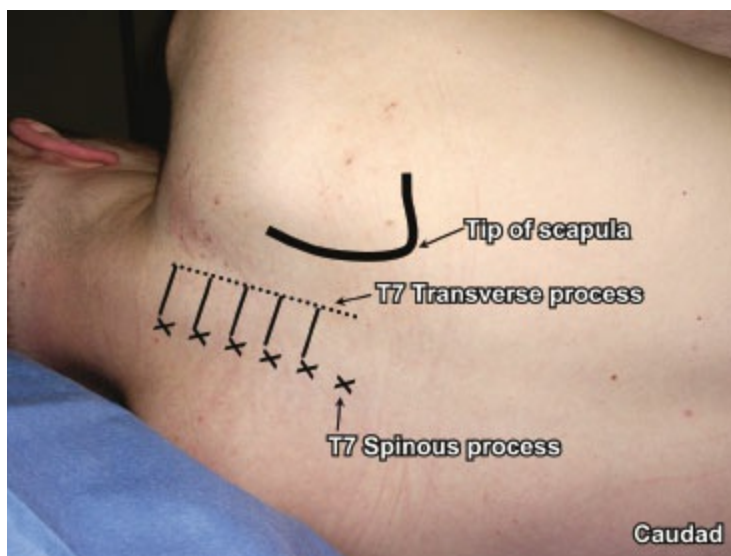

Single-injection paravertebral block used for surgical anesthesia has been shown to surpass general anesthesia with respect to postoperative pain relief, incidence of vomiting, and pain upon mobilization.<sup>145</sup> Paravertebral blocks are considered “unilateral epidurals” since they block spinal nerves selectively on the side of anesthetic application, although they also have the potential for epidural spread (i.e., they can be bilateral if desired). The anesthesia includes both somatic and sympathetic effects, with a reduced hemodynamic response (e.g., hypotension) compared to epidural anesthesia. This nerve block requires excellent knowledge of paravertebral anatomy but can be performed easily with experience.

The upper five ribs are more difficult to palpate laterally, and blockade of their associated intercostal nerves is best performed with a paravertebral injection. This approach is technically more difficult and has slightly greater potential for complications because of the proximity of the lung and intervertebral foramina. The paravertebral block can be used at any level. At the lumbar spine, some prefer to perform lumbar plexus block to reduce the number of injections and avoid sympathetic block. The injection is made into the triangular paravertebral space where the spinal nerve has just left the intervertebral foramen. The nerve may be difficult to localize using bony landmarks in a blind fashion, and larger volumes of local anesthetic are often required. NS has been used to locate the nerve. US can be performed prior to the block to improve bony landmark identification, particularly for obese patients or those with a spinal deformity. However, real-time US guidance can be challenging and may offer limited additional value from preprocedural landmark identification since the overriding bone tissue reflects the US beam and provides dorsal shadowing, which obscures imaging (especially of the needle) to the depth of the paravertebral space.

Paravertebral block is performed with the patient in the lateral, sitting, or prone position, the latter using a pillow placed under the patient's abdomen to produce flexion of the thoracic and lumbar spine.

### *Procedure Using Nerve Stimulation or Loss-of-Resistance Technique*

**Landmarks.** The paravertebral approach varies depending on the spinal level and the respective orientation of the vertebral spinous and transverse processes (see Clinical Anatomy section). Thus, paravertebral blocks in the upper thoracic region are performed at each level by identifying the spinous process of the vertebra above the level to be blocked; in the lumbar region, the spinous process of the level to be blocked is used to locate the transverse process. The appropriate spinous processes for the region to be blocked are marked, and transverse lines are drawn across the cephalad border and extended laterally to overlie the transverse process (approximately 2.5 cm) (Fig. 36-27). Finally, the transverse processes are marked individually or by drawing a vertical line parallel to the spine joining the ends of the transverse lines. For a diagnostic block, a single nerve may need to be anesthetized. For pain control, several levels must be identified. The injection of at least three segments (as in intercostal blockade) is required to produce reliable segmental block because of sensory overlap from multiple nerves.

**Figure 36-27** Landmarks for paravertebral block at the thoracic spine. The spinous process of the level below the block (e.g., spinous process of T7 for block at T6) is identified, and a line is drawn horizontally from the cranial aspect of the spinous process to mark the transverse process. The needle is inserted at appropriate spinal levels at the lateral line marking the transverse processes.

**Needling.** After aseptic skin preparation and patient sedation, skin wheals are raised at the marked transverse processes. A 22-gauge, 70-mm insulated

needle is introduced through the skin wheal in the sagittal plane and directed slightly cephalad to contact the transverse process (usually at a depth of 2 to 4 cm in the thoracic region and 5 to 8 cm in the lumbar region) or—oftentimes likely—the costotransverse ligament. Gentle cephalad or caudad exploration may be required to identify the bone. The depth of the transverse process should be noted on the needle shaft. The needle is then withdrawn from the transverse process to the skin level and reinserted 10 degrees superiorly (to target the spinal nerve corresponding to the spinous process) or inferiorly (corresponding to the vertebral level below the spinous process) and 1 cm deeper than the point of bone contact. The needle should be angled slightly medially to avoid causing pneumothorax. There will be a subtle “give” at the midpoint between these landmarks (spinous and transverse processes), indicating entrance into the paravertebral space.

**Nerve Localization.** For NS, an initial current of 2.5 to 5 mA is used, and the needle is advanced until contractions of the appropriate muscles (e.g., abdominal muscles with lumbar paravertebral block) are observed, after which the current intensity is reduced to localize the nerves at 0.5 to 0.6 mA. A test dose of local anesthetic will confirm nerve localization upon elimination of the nerve response, resulting from the current dissipation at the needle tip from the conducting solution.<sup>26</sup> For loss of resistance, a 22-gauge Tuohy needle is used. After walking off the transverse processes, a “pop” or loss of resistance may be felt when entering the paravertebral space.

**Injection.** When the needle has entered the paravertebral space, 3 to 7 mL of local anesthetic, depending on the number of sites and patient size, is injected at each site following careful aspiration. Attention must be paid to the total milligram dose injected; the volume required to block each level limits the concentration that can be used and the total number of levels that can be blocked. If lumbar paravertebral injections are combined with intercostal blocks, the concentration and total volume for both blocks may have to be reduced.

### *Procedure Using Ultrasound Imaging*

Imaging for these blocks is often used before block performance (i.e., “preprocedural,” “supported,” or “off-line” imaging) rather than during (i.e., “real-time” or “on-line” imaging) to identify the deep bony landmarks, including the articular and transverse processes. Real-time US-guided paravertebral block is an advanced block and should only be performed by experienced personnel.

**Scanning.** Placing the probe transversely at the midline will provide an

overview of the vertebral lamina and processes, as well as costal structures if viewing the thoracic spine (Fig. 36-28, top). A medial-to-lateral scan using a longitudinally placed probe can then be used to locate and mark important bony landmarks (Fig. 36-28, bottom). For this, a 5 to 7 MHz curved-array US probe (lower frequency for obese patients and higher frequency linear probes for thin adult or pediatric patients) is positioned in the sagittal plane on top of the spinous processes of the target thoracic or lumbar region. Subsequent lateral scanning will allow consecutive identification of the lamina, articular, and transverse processes, and, in the thoracic spine, the ribs.

**Appearance.** The initial transverse scan will show a hyperechoic outline of the vertebral spinous and transverse processes, the lamina, and (in the thoracic spine) the associated rib. During the lateral scan with the probe placed longitudinally to the spine, the laminae will appear first as largely overlapping linear structures. The articular processes in long axis appear as “multiple lumps,” just lateral to the spinous processes and are short rectangular structures with hyperechoic lines and underlying hypoechoic bony shadowing. Moving laterally, the transverse processes appear and will look similar to the articular processes; they will disappear from view when the probe is moved beyond their tips, which can help distinguish them from the articular processes and mark the lateral block location. Beyond the transverse processes, the rib heads appear as long shadows within hyperechoic borders, deep to the linear hyperechoic muscle fibers of the paravertebral muscles. The paravertebral space lies deep to the transverse processes, and the pleura can often be identified between and deep to the transverse process, as well as deep to the ribs.

**Needling.** Since multiple injections are generally needed to completely cover all the dermatomes of the surgical area in clinical practice, US imaging is more suitable for a preblock assessment (“supported” US) to visualize and measure the depth of needle penetration required for the needle to contact the transverse processes. Needling will be identical to that for the blind technique, with the exception that the depth to the transverse process will be known more accurately. It is possible to perform real-time US guidance, using either IP or OOP needle alignment. The reader is referred to the Clinical Pearls for advice related to important precautions when using US guidance.

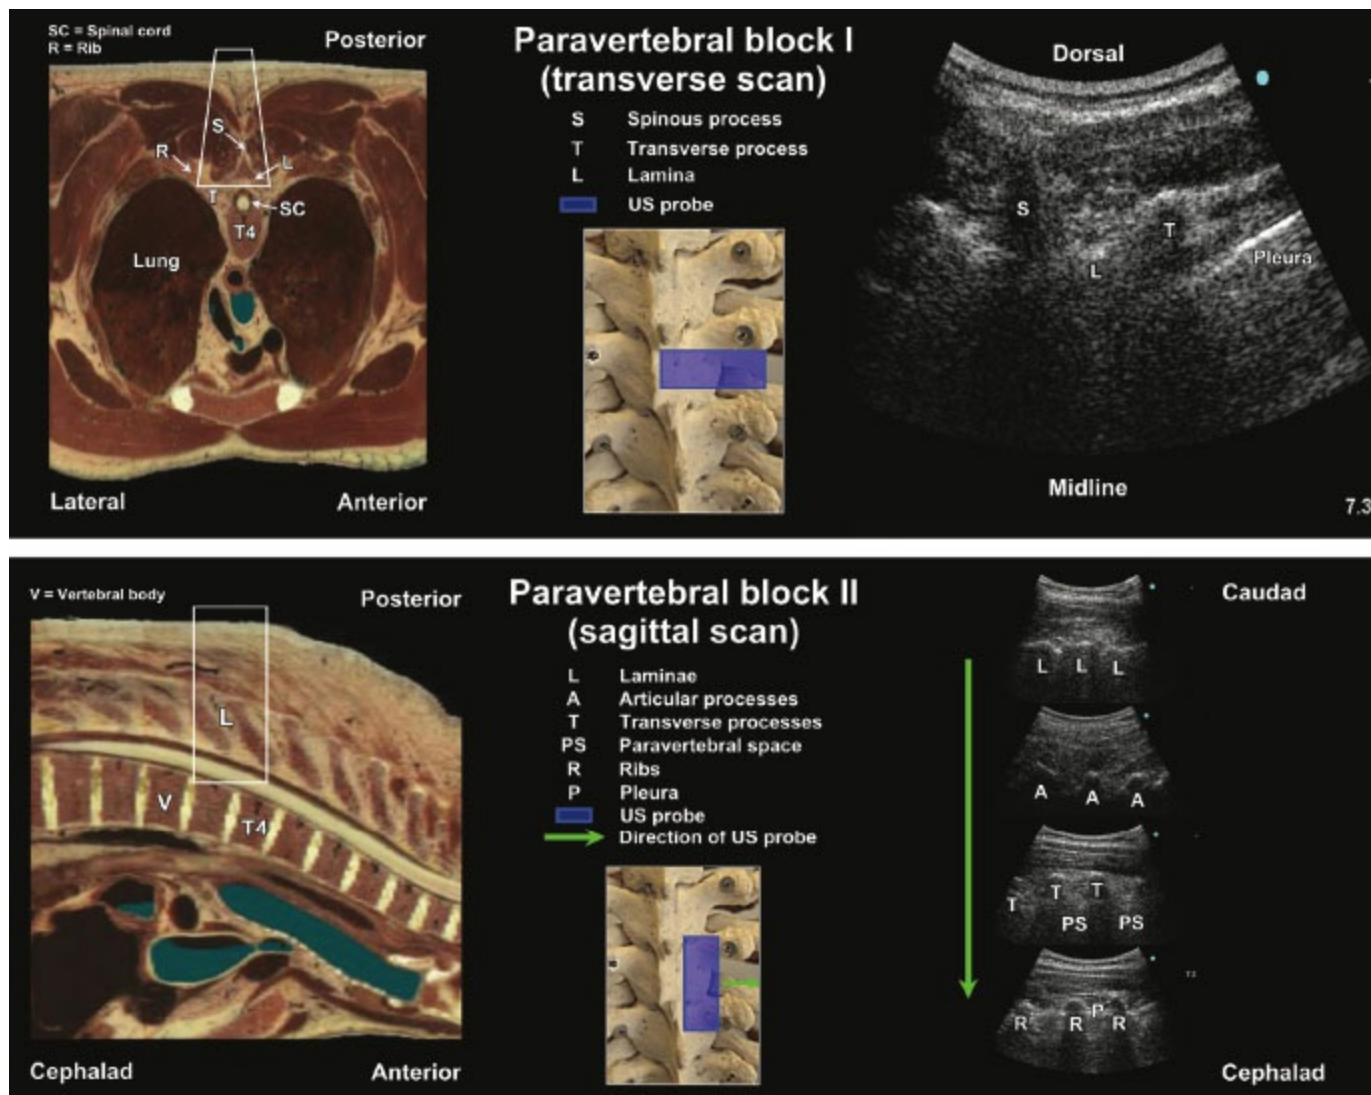

**Local Anesthetic Spread.** In adults, visualization of local anesthetic spread will be difficult if using real-time US guidance. The overlying bones largely reflect the US beam and obstruct visibility beyond into the paravertebral space. However, local anesthetic spread may be seen with US in young children (<2 to 3 years old) since fusion of the neural arches and vertebral

bodies has not yet occurred, allowing good visibility into the paravertebral space.

### *Clinical Pearls*

- Since the paravertebral space is well vascularized, inadvertent vascular puncture will often occur, highlighting the need for frequent aspiration and injection in small aliquots.<sup>146</sup>
- Pneumothorax is more likely with a paravertebral technique than with intercostal block. The needle should be directed medially as it passes below the transverse process and never more than 2 cm beyond the transverse process. If cough or chest pain occurs, a chest radiograph should be performed to rule out pneumothorax.
- Subarachnoid injection is also more likely in the thoracic area because of the extension of the dural sleeves to the level of the intervertebral foramina. Careful aspiration is important but may not prevent unintentional injection of local anesthetic into the subdural space. Total spinal anesthesia can result with a 5- to 10-mL injection. Systemic toxicity is also a possibility because of the need for relatively large volumes of local anesthetic.
- If attempting real-time US guidance of paravertebral block, it is important to observe the angulation of the needle, and use of IP needle alignment with respect to a longitudinal probe position may be most prudent. The needle should not be inserted with a significant medial direction as there is a risk of spinal cord injury from intraforaminal insertion and injection. Likewise, a lateral direction increases the risk of pneumothorax. If choosing to use real-time US guidance during block procedure, note that: (1) with the probe placed in the sagittal/longitudinal plane, OOP needling may be more risky, as it often requires the medial or lateral angulations described earlier, and (2) an IP needling approach can be more risky when the probe is placed in the coronal/transverse plane.
- Traditionally, paravertebral blocks and other trunk blocks are performed blindly, with either sole use of landmarks, including a loss of resistance to needle penetration of the costotransverse ligament for paravertebral block, or combined landmark and NS technique. US imaging may be beneficial for these blocks, particularly paravertebral block, in order to facilitate landmark localization. For example, preprocedural scanning can identify the tips of the transverse processes, which will help to identify correct needle insertion site. US may be particularly useful for performing blocks in obese patients (where the depth of needle insertion will be modified) or those with anatomic variation (e.g., scoliosis). This section provides a detailed

description of the technique using NS guidance but will also provide illustrations in the sections on paravertebral and inguinal blocks of US imaging prior to block performance.

**Figure 36-28** Arrangement of relevant anatomy and transverse probe placement for thoracic paravertebral block. **Top:** The probe is first placed in the midline of the spine to capture a transverse view of the vertebral and costal (if thoracic spine) elements. **Bottom:** The probe is then rotated longitudinally and moved laterally to view the laminae, articular processes, and transverse processes; the paravertebral space can be found deep to and between the latter.

## Transversus Abdominis Plane Block

### *Procedure Using Landmark Technique*

- The patient is positioned supine, and the “Triangle of Petit” is identified with the inferior margin the iliac crest, the posterior margin the latissimus dorsi muscle, and the external oblique muscle lying anterior.
- A blunted 22-gauge, 50- to 100-mm needle (depending on body

habitus) is inserted perpendicularly, immediately posterior to the mid-axillary line and above the iliac crest.

- The first and second “pops” will be felt as the needle traverses through the fascial layer of the external and internal oblique muscles, respectively. The needle tip should be within the plane between the internal oblique and the transversus abdominis.

### *Procedure Using Ultrasound Imaging*

- **Scanning:** A high-frequency (10 to 15 MHz) linear probe is often used for this block. With the patient lying supine, the probe is placed transversely in the midline to identify the rectus muscles. The probe is then moved laterally, and the three layers of muscles—the external oblique, the internal oblique, and the transversus abdominis—can be identified (Fig. 36-29). The probe should then be positioned above the iliac crest in the anterior axillary line.
- **Appearance:** The intercostal nerves can be too small and scattered to be identified under US imaging; therefore, the TAP block is predominantly a muscular plane block. The three layers of the abdominal muscles can be identified clearly since they are separated by the hyperechoic fascia. Beneath the abdominal muscles is the peritoneum, which is the hyperechoic line seen on US underneath the transversus abdominis. Below this lies the peritoneal cavity, in which bowel peristalsis can be seen in real time.
- **Needling:** During IP needling, the image should be adjusted so that the three layers of the abdominal muscles and a small portion of the peritoneal cavity are in view. A 22-gauge, 100-mm needle can be used in a medial-to-lateral direction to reduce the risk of peritoneal puncture, and it should aim toward the muscle plane between the internal oblique and transversus abdominis muscles.
- **Local anesthetic spread:** The aim is to spread 20 to 30 mL of local anesthetic, without exceeding the toxic dose (e.g., 2 mg/kg of bupivacaine or 3 mg/kg of ropivacaine; one-tenth of these volumes for children), on either side of the abdomen for transverse incision across  the midline. The local anesthetic injection will appear as an expansion of hypoechoogenicity deep to the fascial plane of the internal oblique and above that of the transversus abdominis muscle.

**Figure 36-29** Arrangement of relevant anatomy for ultrasound-guided TAP block. A high frequency linear probe is placed transversely above the iliac crest on the anterior axillary line, revealing the three layers of abdominal muscles, the peritoneum, and the peritoneal cavity. The needle is at an IP alignment to the probe, inserted in a medial-to-lateral direction.

### Clinical Pearls

- It is important to ensure local anesthetic spread in the correct fascial plane, rather than injecting local anesthetic intramuscularly.
- Color Doppler should be employed to ensure the needle trajectory is clear of blood vessels within the abdominal muscles.
- For midline incisions of the abdomen, rectus sheath block (described later) can be performed by targeting the local anesthetic injection between the rectus abdominis muscle and the posterior rectus sheath, which is formed by the aponeurosis of the three layers of abdominal muscles.
- TAP blocks have been demonstrated to provide effective analgesia in the obstetric and general surgery populations.<sup>147-149</sup>
- TAP catheters can be placed under direct vision by the surgeon to provide effective continuous postoperative analgesia. Following closure of the abdominal muscle layers, a catheter is inserted percutaneously above the incision, with the tip located at the most lateral point of the incision.
- TAP blocks can be modified into transversalis fascial plane (TFP) block by targeting the local anesthetic injection into the layer between the transversus abdominis muscle aponeurosis and the transversalis fascia. Local anesthetic will spread proximally over the inner surface of the quadratus lumborum muscle to anesthetize the proximal portions of the T12 and L1 nerves. The TFP block has been demonstrated to provide analgesia for anterior iliac bone graft harvesting.<sup>150,151</sup>

Other variations of abdominal field blocks have been described. Each

block differs in the location where the injection is made (Fig. 36-30), but all use the transversus abdominis muscle as the primary landmark. The most well-studied of these blocks, including the rectus sheath block and ilioinguinal/iliohypogastric nerve block are described next.

## **Rectus Sheath Block**

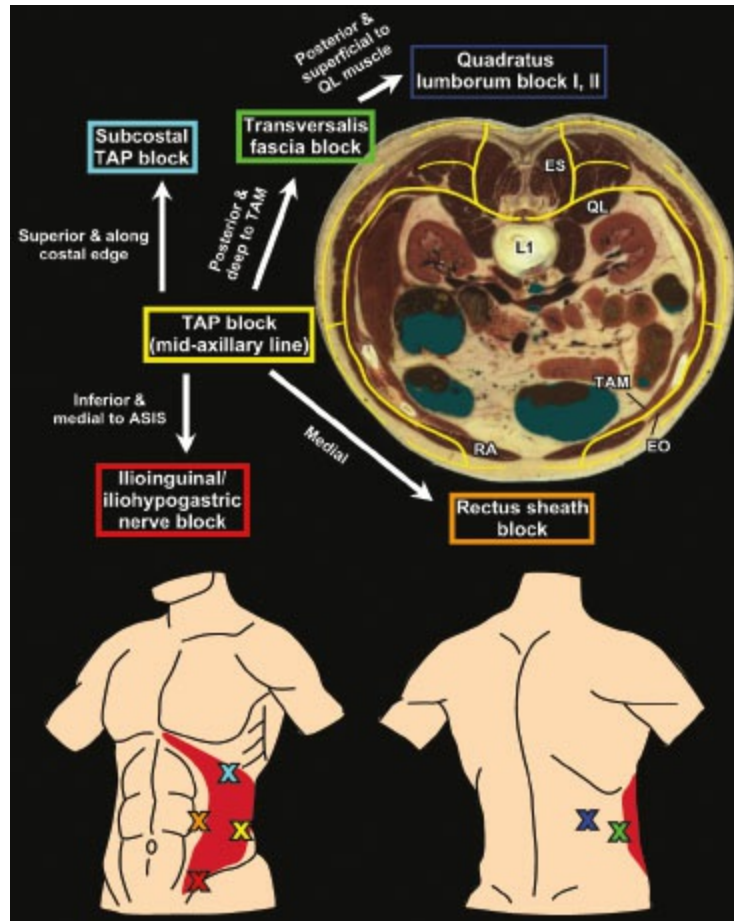

### *Procedure Using Landmark Technique*

- The patient is positioned supine, and the umbilicus and linea semilunaris are identified. The external layer of the rectus sheath is marked on both sides, and a short-beveled needle is inserted at a point where the border of the rectus sheath intersects an imaginary horizontal line at the level of the umbilicus.
- The needle is advanced 60 degrees to the skin toward the umbilicus until a “pop” is felt as the needle penetrates the anterior rectus sheath. Local anesthetic is injected, and the same steps are repeated for the other side.

### *Procedure Using Ultrasound Imaging*

- **Scanning:** A linear probe (6 to 15 MHz) is placed transversely on the anterior abdominal wall lateral to the intended site of incision. Penetration depth varies with the thickness of the subcutaneous layer.
- **Appearance:** At the midline, the linea alba can be seen between the bellies of the rectus muscle, whereas the peritoneum can be visualized behind the posterior rectus sheath (Fig. 36-31). The external oblique, internal oblique, and transversus abdominis muscles can be seen lateral to the rectus muscle; the internal oblique muscle is on the same plane as the rectus muscle. Target nerves, which are not visible with US, are located between the internal oblique and transversus abdominis muscles before piercing the posterior rectus sheath and traversing the belly of the rectus muscle. The intended position of injection is the lateral space between the posterior rectus sheath and the rectus muscle. Color Doppler may be used to identify and avoid the inferior epigastric vessels that run through the rectus muscle.
- **Needling:** A 22-gauge, 50 to 100 mm needle (depending on subcutaneous fat depth) is inserted IP in a lateral-to-medial direction. A lateral insertion point will help to avoid inferior epigastric vessels. The needle is aimed through the external and internal oblique muscles toward the lateral gutter of the rectus muscle directly superior to the posterior rectus sheath. With this approach, the needle does not penetrate the belly of the rectus muscle and avoids the inferior epigastric vessels.

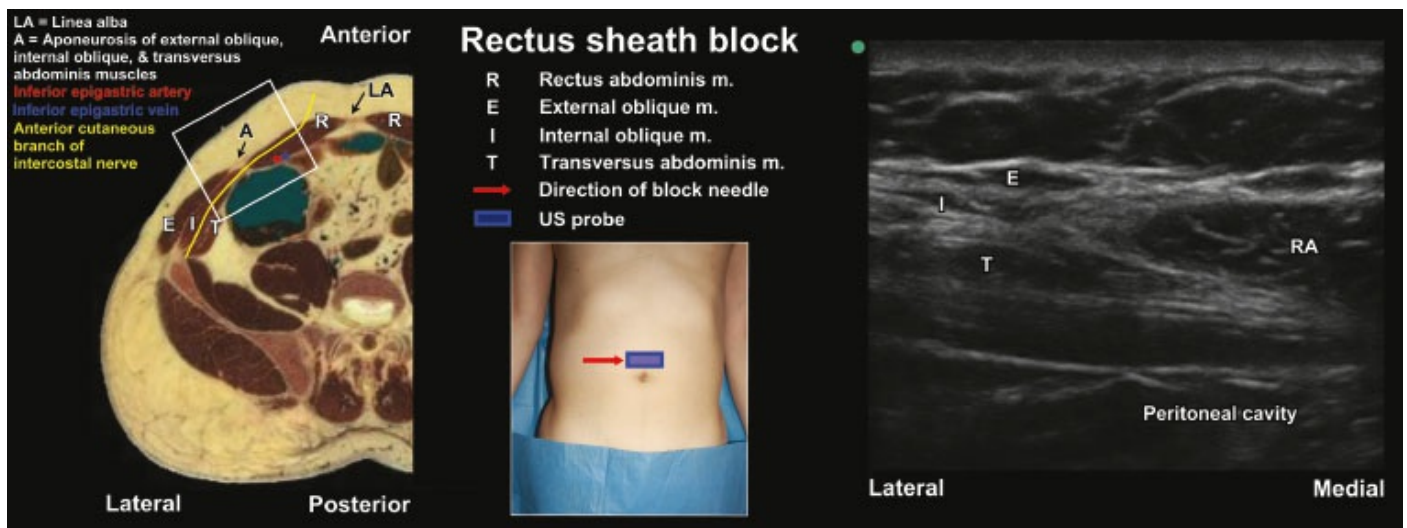

- Local anesthetic spread: Injection of 1 to 2 mL D5W can confirm needle tip position. A volume of 10 mL (0.2 mL/kg for children) local anesthetic (e.g., 0.5% ropivacaine) is injected on each side. The hypoechoic spread will be seen between the posterior rectus sheath and the rectus muscle.

**Figure 36-30** Variations of abdominal field blocks. **Top:** The TAP block is performed at the mid-axillary line; moving the block site medially allows rectus sheath block, while moving the block site posteriorly allows transversalis fascia and quadratus lumborum block. Moving the insertion site superiorly or inferiorly from the TAP insertion site allows subcostal TAP and ilioinguinal/iliohypogastric block, respectively. **Bottom:** Needle insertion sites (X) for abdominal field blocks, color-coded according to the top figure. The approximate location of the transversus abdominis muscle is indicated in *red*.

### Ilioinguinal and Iliohypogastric Nerve Blocks

These blocks are performed easily with a blind technique, although US imaging may be used to help improve the success rate of nerve localization and deposition of local anesthetic in the correct fascial plane proximal to the nerves.

**Figure 36-31** Arrangement of relevant anatomy for ultrasound-guided rectus sheath block. Placement of a transverse probe over the midline reveals the rectus abdominis and layers of the abdominal wall. Below these can be seen the peritoneum and peritoneal cavity. The needle is advanced in an IP alignment to the probe.

### *Procedure Using Blind Technique (Single-injection Fascial Click)*

**Landmarks.** The injection site is located at about 1 to 2 cm medial and 1 to 2 cm inferior to the anterior superior iliac spine.

**Needling and Injection.** A 25-gauge, 36- to 50-mm blunted hypodermic needle can be used. The needle is inserted from the anterior abdomen (vertically) until a fascial click is detected, presumably at the junction of the internal oblique and transversus abdominis muscles. About 10- to 15-mL (0.3 to 0.5 mL/kg for children) local anesthetic can be injected. An additional 0.5 to 1 mL local anesthetic can be injected subcutaneously to block the iliohypogastric nerve.

### *Procedure Using Ultrasound Imaging*

**Scanning.** Two different approaches have been used for US scanning of the ilioinguinal and iliohypogastric nerves.<sup>61,152</sup> In their clinical study, Willschke et al.<sup>61</sup> used a small footprint (“hockey stick”), 5 to 10 MHz probe, placed in transverse axis, just medial and superior to the anterior superior iliac spine. The cross-sectional view of the ilioinguinal nerve can be captured lying between the internal oblique and transversus abdominis muscles. In their cadaveric study, Eichenberger et al.<sup>152</sup> found that a 7.5 MHz probe was superior to one with a 10 MHz frequency. They used a position about 5 cm cranial and slightly posterior to the anterior superior iliac spine, where both nerves have been shown to be present between the above-mentioned muscles with a 90% probability. These authors visualized both nerves as distinct entities.

**Appearance.** The nerves appear hypoechoic with many hyperechoic dots and a distinct hyperechoic rim (Fig. 36-32). They have an oval, somewhat “boomerang” shape and appear embedded between the fascicular hypoechoic-appearing muscles. In the more cranial position, the iliac bone, with its hyperechoic border and dorsal shadowing, may be captured on the medial aspect of the screen. The thin external oblique muscle lies superficial at the cranial position, but it may not be visible more inferiorly.

**Needling.** An OOP alignment, with the needle placed caudad to the probe in its center, is preferred, although an IP approach is also feasible.

**Local Anesthetic Spread.** Either one or two injections can be made, depending on the number of distinct nerves localized. The dose of local anesthetic may be lower when using US imaging since the nerves are well localized. In children, 0.075 mL/kg has been shown to be effective for a single injection.<sup>153</sup> A hypoechoic area of solution should be visualized adjacent to the nerve(s).

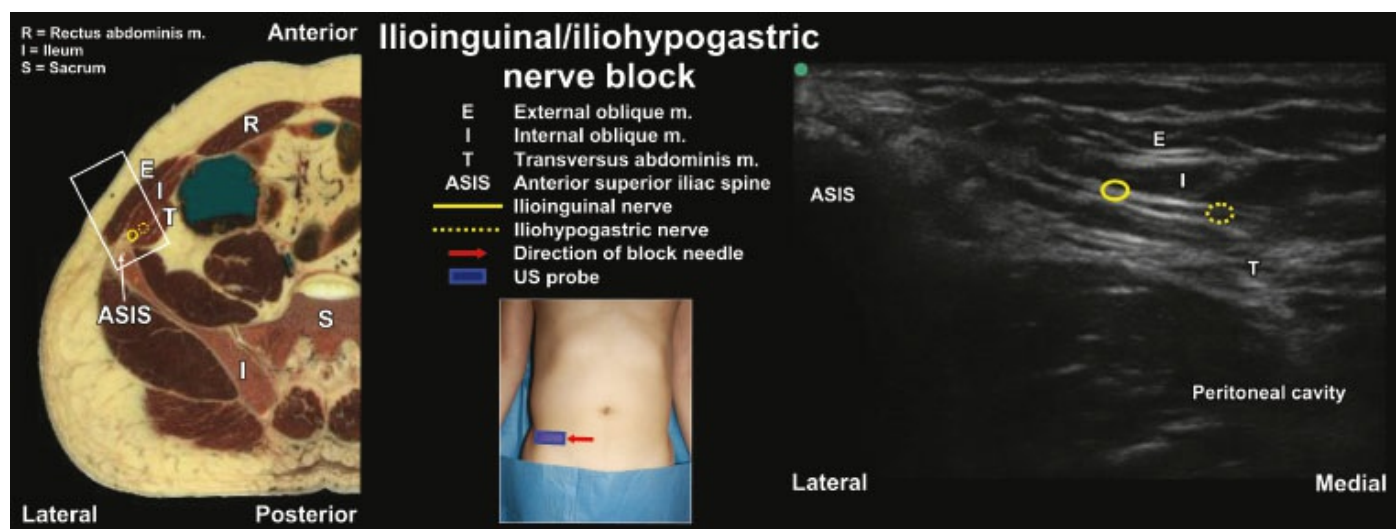

### Clinical Pearls

- The ilioinguinal and iliohypogastric nerves may exist as a common trunk at the level of the anterior superior iliac spine, which further supports the use of US guidance for localizing the individual nerve.<sup>152</sup>
- Since there is high variability in skin innervation from these nerves, it is impossible to confirm with clinical tests which nerve is blocked. Injecting lateral to the most laterally positioned ilioinguinal nerve, or medial to the iliohypogastric nerve, has been reported as one method to block these nerves individually.<sup>152</sup>
- Complications of this block are generally volume-related and include systemic toxicity and transient femoral nerve palsy. A recent assessment of the accuracy of the blind technique using US demonstrated that, even in experienced hands, needles were inserted deep to the transverses abdominis muscle over 40% of the time,<sup>154</sup> reinforcing the value of US in helping to prevent inaccurate needle placement or inappropriate anesthetic spread.

### Penile Block

Penile block is used in children and adults for surgical procedures of the glans and shaft of the penis. The dorsal nerves (terminal branches of pudendal nerve; S2–S4) lie bilaterally on the outer aspect of the dorsal arteries of the penis. From the base of the penis, the nerves divide several times and encircle the shaft of the penis before reaching the glans. This block is often performed as a circumferential infiltration of the root of the penis

(ring block). Two skin wheals are raised at the dorsal base of the penis, one on each side just below and medial to the pubic spine. A 25-gauge, 37.5-mm needle is introduced on each side, and 5 mL of anesthetic (0.5 to 1 mL for infants) is injected superficially and deep along the lower border of the pubic ramus to anesthetize the dorsal nerve. For a complete ring of infiltration, an additional 5 mL (adults) is infiltrated in the subcutaneous tissue around the underside of the shaft. A larger needle or a second injection site may be needed to complete the ring. Twenty to twenty-five milliliters of 0.75% lidocaine or 0.25% bupivacaine usually suffices in adults. Epinephrine-containing solutions should not be used to avoid compromising penile circulation. US can be used to improve the efficacy of penile blocks and, in one study, was found to decrease postoperative pain and delay the administration of postoperative analgesics,<sup>155</sup> although procedures using US were, on average, 10 minutes longer in duration compared to those performed blindly.

**Figure 36-32** Arrangement of relevant anatomy for ultrasound-guided ilioinguinal/iliohypogastric nerve block. Transverse scanning on the abdomen just medial to the anterior superior iliac spine (ASIS) shows the nerves lying between the internal oblique and transversus abdominis muscles, just medial to the ASIS. These nerves can be blocked using an IP alignment and medial-to-lateral needle insertion to avoid puncturing through the peritoneum.

## Lower Extremity

Combined blocks of the lumbar and sacral plexuses provide effective surgical anesthesia to the entire lower extremity. Prior to the 1990's, an "anterior lumbar block" approach (also referred to as the "femoral three-in-one" approach), which was first described by Winnie et al in 1973, had been commonly performed. This block was based on the assumption that a large volume local anesthetic injection into the femoral nerve sheath would

produce spread of the solution proximally to anesthetize the obturator and lateral femoral cutaneous nerves as well. Later reports of failures to obtain obturator nerve block with this approach<sup>157,158</sup> led to the femoral block being considered as an individual nerve block and advocated the posterior lumbar block approach for accessing the whole lumbar plexus.

PNB is indicated when spinal or epidural techniques are contraindicated or when selective anesthesia of one leg or foot is needed. Because the anatomic landmarks identifying the fascial sheaths or compartments of the plexuses are not as clearly defined as those in the upper extremity, lower extremity blocks are often performed more distally, where the nerves have already separated into terminal branches. Thus, in addition to the fascial compartment approach (psoas block), there are peripheral approaches described at the anterior and posterior hip, knee, and ankle.

## **Techniques**

### **Lumbar Plexus Block (Psoas Compartment Block)**

Several techniques for blocking the lumbar plexus using a posterior approach have been described; however, the one at the psoas compartment, described first by Chayen et al.<sup>159</sup> in 1976, remains popular. This block is often performed with a single injection at a point some distance lateral to the spinous process of L4 since the nerves of the lumbar plexus are in proximity between the transverse processes of L4 and L5. Continuous psoas compartment blocks have also been shown to be effective for anesthesia (with sciatic nerve block) and perioperative analgesia in patients with hip fractures<sup>160</sup> and after hip arthroplasty.<sup>161</sup> A more cephalad approach, near L3, as described by Parkinson et al.,<sup>158</sup> may be used, although there have been reports of renal subcapsular hematomas with blocks performed at this level.<sup>162</sup> This block has the advantage of anesthetizing the entire lumbar plexus and therefore provides anesthesia/analgesia of the anterolateral and medial thigh, the knee, and the cutaneous distribution of the saphenous nerve below the knee. Although the sacral nerve roots may be anesthetized, this block will likely not provide complete anesthesia/analgesia for the entire upper leg, and sciatic nerve block will usually need to be performed as well. The patient is placed in the lateral position, with the operative side up. Adequate sedation should be provided since the plexus lies deep and the needle must penetrate several muscles.

**Figure 36-33** Surface landmarking for the lumbar plexus (psoas compartment) block. The needle insertion site (X) is one-third the distance along a horizontal line extending from the L4 transverse process to where it crosses a vertical line dissecting the posterior superior iliac spine.

### *Procedure Using Nerve Stimulation Technique*

**Landmarks.** The landmarks developed by Capdevila et al.<sup>161</sup> using computed tomography are illustrated in [Figure 36-33](#). Compared to the depth of the lumbar plexus or transverse processes, the distance between the L4 spinous process and the lumbar plexus is not affected by body mass index. The spinous process of L4 is estimated to lie approximately 1 cm cephalad to a line between the tops of the iliac crests (intercrystal line); a horizontal line is drawn laterally from the L4 spinous processes to the far side of the body. A vertical line, running parallel to the spine, is then drawn at the point of the posterior superior iliac spine to intersect the horizontal line. The lumbar plexus is then located with an “X,” below a point on the horizontal line and at the junction between the lateral third and medial two-thirds between the spine and posterior superior iliac spine. The mean skin-to-lumbar plexus depth at the level of L4 is 8.4 cm in adult men and 7.1 cm in adult women based on computed tomography assessment. The distance between the posterior edges of the transverse processes of the lumbar vertebrae and the lumbar plexus is about 1.8 cm. A strong correlation exists between weight and plexus depth in children; in one study, plexus depth ranged from 1.24 to 1.74 mm/kg in children aged 3 to 12.<sup>163</sup>

**Needling.** A skin wheal is raised at the marked block site. An insulated needle (17 to 20 gauge [22 to 25 gauge for children], 110 to 150 mm long, depending on body habitus) is inserted perpendicular to all planes at the “X” until contact with the L4 transverse process is made (approximately 5 to 6 cm deep). After contact, the needle is withdrawn and redirected caudad below

the process to a maximum depth of 2 cm to the transverse process.

**Nerve Localization.** With the nerve stimulator set to deliver an output current of 1 to 1.5 mA, contraction of the quadriceps muscle (patellar twitch) is sought. The plexus is localized when the motor response is maintained at 0.3 to 0.5 mA. If a motor response is not obtained at first, moving the needle cautiously in a slight medial direction, without aiming toward the spinal cord, or in a direction 15 degree-caudad or cephalad, may help.

**Injection.** After the plexus is localized, 30 to 40 mL of local anesthetic is injected, using careful aspiration and administration of a test dose to rule out intravascular, epidural, or subarachnoid placement. Fifteen to twenty minutes may be required for spread of the anesthetic to all the roots of the lumbar plexus. It will take longer to produce anesthesia of the caudad branches (the lower sacral fibers that form the tibial nerve), and they may not become anesthetized at all.

#### *Procedure Using Ultrasound Imaging*

The lumbar plexus is difficult to view adequately since the target structures are deep. Similar to paravertebral block, US imaging may be best for identifying the exact location and depth of the transverse processes prior to the block procedure. If there is desire to perform the block at L3–L4, viewing the kidneys prior to and/or during the block may help prevent renal injury and hematoma. This is especially important in young children since the lower pole of the kidney can reach as low as L4–L5. The combined use of NS technique with US is still recommended to confirm correct needle placement.

**Scanning.** A curved array probe (5 to 8 MHz) is placed in the transverse plane in the midline at the level of the L4 spinous process to provide an overview of the L4 vertebra. The probe should be rotated to the longitudinal axis, parallel to the spine, which will allow a lateral scan to be performed to identify the tips of the transverse processes. The absence of associated ribs means that the tips of the transverse processes are fairly easily delineated. A 6 to 13 MHz “hockey stick” transducer may be used for young children and infants.

**Appearance.** For adults and older children, the deep location of this block precludes clear visibility of the lumbar plexus. Indeed, the transverse processes (which are the primary landmarks) are often only vaguely delineated. Therefore, it is important to switch between transverse and longitudinal scanning between the spinous processes and the tip of the transverse processes to survey the area. In the transverse scan, the spinous

processes appear hypoechoic (likely due to dorsal shadowing effect) and extend superficially, whereas the transverse processes are hyperechoic masses/lines at the lateral edge of the vertebra. The fascicular-appearing musculature is evident surrounding the vertebra yet poorly delineated by most compact US machines. In the longitudinal scan, the lateral tips of the transverse processes will be identified at the most lateral point where a hyperechoic nodule is viewed.

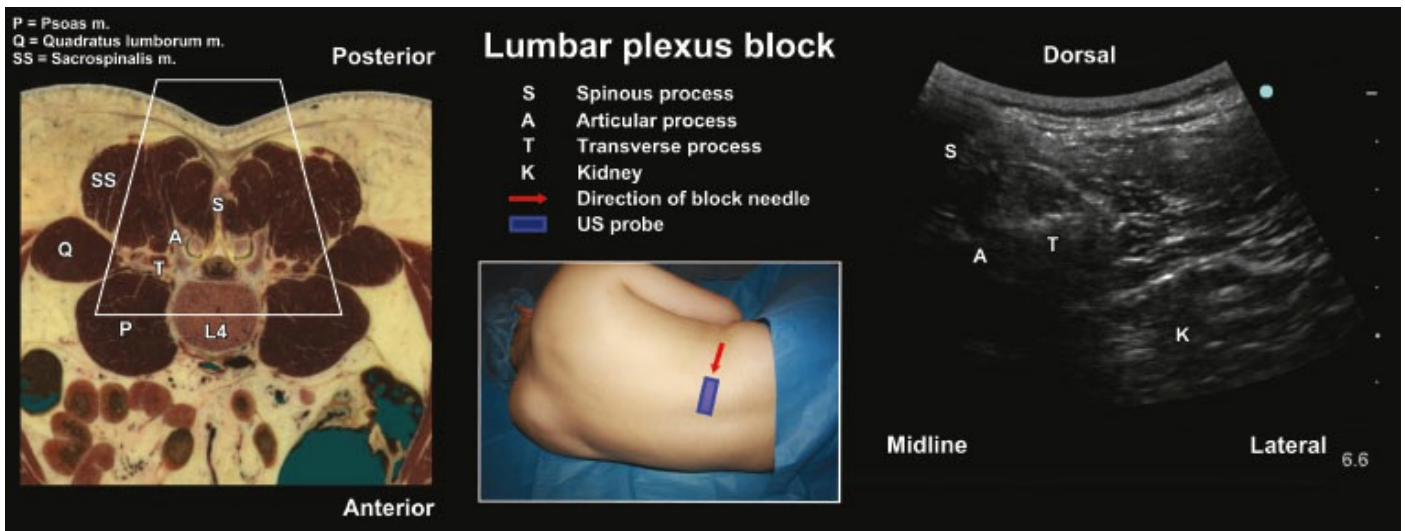

**Needling.** Needling will be identical to that for the blind technique, with the exception that the depth to the transverse process will be more accurately known. If choosing to perform a more cephalad approach above L4, real-time imaging may be helpful to view the kidneys (especially during inspiration when they fall toward L3–L4) (Fig. 36-34). An IP needle alignment to a longitudinal probe may be most suitable to avoid excessive medial or lateral needle angulation (see Paravertebral Blockade Clinical Pearls).

**Local Anesthetic Spread.** In all patients except young children, it will be difficult to view local anesthetic spread when using US guidance. If seen, a hypoechoic mass will spread within the muscle mass lateral and deep to the transverse process.

### *Clinical Pearls*

- The psoas compartment block can be beneficial for placing a catheter to provide long-lasting analgesia; the catheter is held securely by the psoas muscles and kept away from any active joint region. After obtaining good localization with the stimulating needle (bevel facing caudad and lateral), a stimulating catheter is advanced 3 to 5 cm. In some cases, injecting a nonconducting solution such as D5W to expand the perineural space, while maintaining the electrical characteristics, is helpful.<sup>27</sup> Quadriceps muscle contraction should be maintained during catheter advancement with a stimulating catheter.
- Prepuncture US may be beneficial prior to needle insertion and catheter placement. Using a higher frequency (6 to 13 MHz) linear array transducer, Ilfeld et al.<sup>164</sup> showed that the depth and location of each transverse process could be estimated accurately, allowing the user to minimize risks associated with needle/catheter insertion into the lumbar plexus.
- Complications of this technique include hematoma in the muscle sheath, retroperitoneal space, or kidney (hence, this block is contraindicated in patients with coagulopathy or bleeding diathesis); infection; and catheter placement within the peritoneum. Neuropathy is possible, and unintended spread to the epidural or even subarachnoid

space has also been reported.

**Figure 36-34** Arrangement of relevant anatomy for ultrasound-assisted lumbar plexus block. A curved array probe can be placed transversely to capture an overview of the spinous, articular, and transverse processes, with the psoas muscle just deep and lateral to the latter. Puncture of the kidney can be a potential complication of lumbar plexus block; if attempting real-time needle insertion, the safest needle alignment will be IP to a longitudinally placed probe over the L3–L5 transverse processes since the kidney may come to view at a more cephalad position.

### Separate Blocks of the Terminal Nerves of the Lumbar Plexus

Anesthesia can be performed for four terminal nerves of the lumbar plexus (lateral femoral cutaneous, femoral, obturator, and saphenous), although a psoas compartment block (described earlier) is preferable if anesthesia of all these nerves are required. Anesthesia of the lateral femoral cutaneous nerve is used occasionally to provide sensory anesthesia for obtaining a skin graft from the lateral thigh. It can also be blocked as a diagnostic/therapeutic tool to identify cases of meralgia paresthetica (a neurologic disorder of the lateral femoral cutaneous nerve). It has been shown that the obturator nerve provides variable sensory supply to the medial aspect of the thigh and knee joint and also gives off branches to the hip joint.<sup>165</sup> Obturator nerve block can be effective to prevent obturator reflex during transurethral bladder tumor resections, for treatment of pain in the hip area, for adductor spasm (as seen in multiple sclerosis patients), or as a diagnostic tool when studying hip mobility.<sup>166</sup> Saphenous nerve block often complements sciatic nerve block when anesthesia of the medial aspect of the ankle and foot are required. Procedures on the knee require anesthesia of the femoral and the obturator nerves, although postoperative analgesia of the knee can usually be provided by femoral nerve block alone. Single-injection femoral nerve block provides suitable postoperative analgesia after total knee arthroplasty while sparing

the side effects of intrathecal morphine.<sup>167</sup> The use of a continuous technique can also reduce side effects as compared to continuous epidurals<sup>168</sup> and can facilitate rehabilitation.<sup>169</sup> A US-guided infrapatellar nerve block has been described for use for postoperative analgesia after outpatient arthroscopic surgery<sup>170</sup> but will not be discussed further here. Separate femoral nerve block is used extensively for analgesia, and US guidance has been described for this block; therefore, this chapter will provide a comprehensive description of this block. US guidance for obturator nerve block has been described and will be examined here. The other two nerve blocks will only be discussed briefly. The block sites for the femoral, lateral femoral cutaneous, and obturator nerves are illustrated in [Figure 36-15](#).

### *Femoral Nerve/Fascia Iliaca Block*

#### **Procedure Using Nerve Stimulation**

- **Landmarks:** The patient is placed in the supine position, with slight external rotation of the femur. A pillow can be placed under the patient's hip to facilitate palpation of the femoral pulse and accentuate other pertinent landmarks for ease of palpation. Vloka et al.<sup>171</sup> studied cadavers using four common needle insertion sites for femoral nerve block and found that the point where the nerve lies beneath the inguinal crease, immediately lateral to the femoral artery, was optimal for localizing the nerve. The femoral artery descends at the "mid-inguinal point," at the junction between the medial third and lateral two-thirds of the inguinal ligament, although it is most superficial at the femoral crease. It lies approximately 1 to 1.5 cm medial to the nerve. The inguinal crease is the skin fold located approximately 2.5 cm caudad and parallel to the inguinal ligament (Clinical Anatomy of lower extremity).
- **Needling:** A skin wheal is raised lateral to the area where the femoral artery pulsation is felt, and a 50-mm, 22-gauge insulated needle is inserted perpendicular to the skin or using a cephalad angle of approximately 30 degrees. Aspiration is performed frequently since the femoral artery is situated close to the nerve.
- **Nerve localization:** Using NS, a quadriceps muscle response (patellar twitch preferably) is sought, with an end point of 0.5 mA used for accurate localization. Branches to the sartorius muscle arise just inferior to the inguinal ligament and leave the femoral nerve proximal to the main block location site; a response of this muscle to stimulation often indicates that the needle is too superficial and medial to the main femoral nerve. For a fascia iliaca block, loss-of-resistance technique is used instead of NS. The needle is placed vertically 5 cm lateral to the

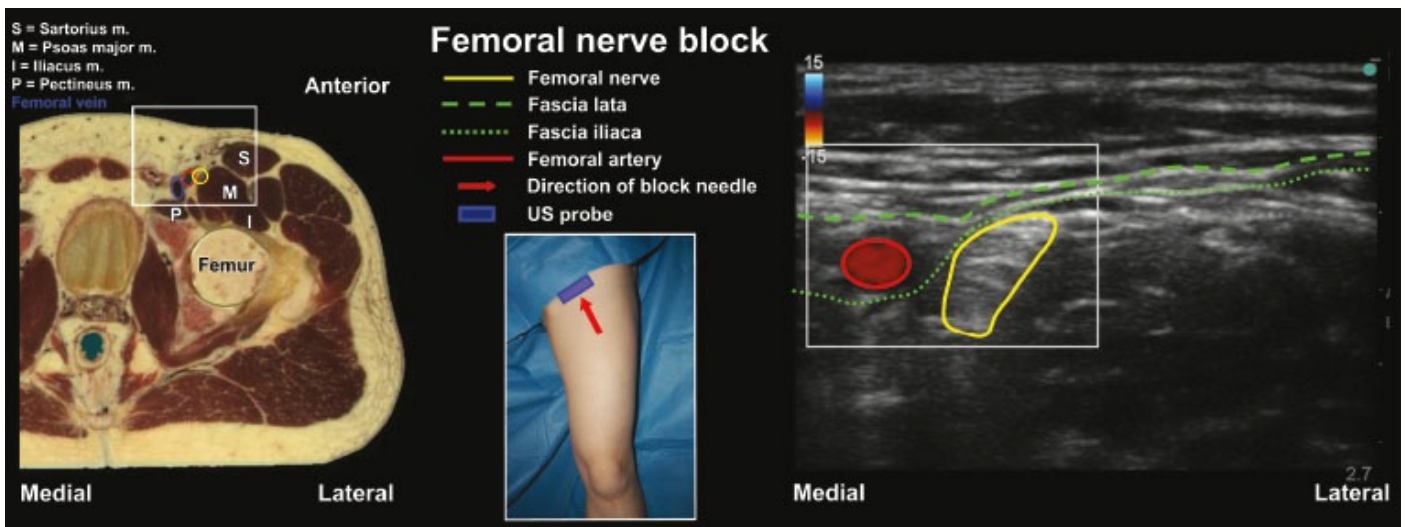

artery at the inguinal crease. Two pops are felt when the needle traverses the fascia lata and fascia iliaca and enters the iliopsoas muscle.

- **Injection:** Injection of 20 mL (or less) of local anesthetic should suffice for sole femoral nerve anesthesia. Twenty to thirty milliliters of local anesthetic may be required for the fascia iliaca block. Intermittent injection with interval aspiration should be performed.

### **Procedure Using Ultrasound Imaging (Fig. 36-35)**

- **Scanning:** A 10 MHz or higher transducer can be used for both blocks if the neurovascular structures are not located too deep (i.e., thin individuals), as this will show good distinction between the nerve and the surrounding structures (vessels and muscles). A midrange 5- to 8-MHz linear transducer is recommended if the nerve and artery are deep (> 4 cm). Position the probe transverse to the nerve axis at the level of the inguinal crease. The nerve should appear approximately 1 cm deep and 1.5 cm lateral to the femoral artery, depending on body habitus (color Doppler may be used to identify the femoral artery and vein). A 5 to 10 MHz “hockey stick” transducer can be used for most children.
- **Appearance:** The nerve lies about 1 cm lateral and deep to the large, circular, anechoic, and pulsatile femoral artery. The nerve often appears triangular in shape and of variable size due to its irregular course; early branching above the inguinal ligament can increase the transverse diameter of the nerve. The fascia lata (most superficial) and fascia iliaca (immediately adjacent to the nerve and in fact separating the nerve from the artery) may be seen superficial to the femoral nerve and often appear bright and longitudinally angled.
- **Needling:** Place the nerve at the medial edge of the screen, with the probe capturing a transverse view of the neurovascular structures. A 50-mm, 22-gauge needle (for single-injection) can be inserted using either IP or OOP (Fig. 36-35) needle alignment. The needle should be inserted using an acute (30 to 45 degrees) angle to maximize viewing. IP blocks may be made easier by angling the needle tip slightly away from the nerve, whereas accuracy of catheter placement may be improved by tilting the needle hub in a caudad direction once the needle tip is positioned appropriately.<sup>172</sup> Inserting the catheter perpendicular or parallel to the nerve does not affect quality of analgesia, although the former technique may facilitate faster catheter insertion.<sup>173</sup>
- For fascia iliaca block, the needle is generally placed more laterally than with conventional femoral nerve block.
- Local anesthetic spread: Performing a test dose with D5W is

recommended prior to local anesthetic application to visualize the spread and confirm nerve localization. Local anesthetic spread should occur within the fascial space surrounding the nerve. The solution may displace the nerve medially toward or laterally away from the artery.

**Figure 36-35** Arrangement of relevant anatomy for ultrasound-guided femoral nerve block. The probe is placed in a slightly oblique plane (at the level of and parallel to the inguinal crease) to capture the nerve in short axis lateral to the femoral artery. The needle (not shown) can be visualized as it transects the fascia lata and fascia iliaca. If IP needling is used, it should occur in a lateral-to-medial direction.

## Clinical Pearls

- When inserting a catheter, it is debatable whether a stimulating catheter improves placement,<sup>174,175</sup> but using a solution to expand the perineural space has been shown to be beneficial in some cases.<sup>176,177</sup> If a stimulating catheter is used, injection of D5W for tissue expansion will maintain motor responses to NS.<sup>26,27</sup>
- With an IP needle alignment, lateral-to-medial needle insertion will ensure that the nerve is reached before encountering the femoral vessels.
- It is important to ensure that the US beam is perpendicular to the nerve's transverse axis to minimize the chance of anisotropic effects changing the echogenic properties of the structure. It has been shown that an approximate 10 degree cephalad or caudad tilt of the transducer can make the nerve isoechoic (similar-appearing) to the underlying iliopsoas muscle.<sup>178</sup>

### *Lateral Femoral Cutaneous Nerve*

Using NS technique, Shannon et al.<sup>179</sup> found that the lateral femoral cutaneous nerve can be localized at the inguinal crease, approximately 0 to 1 cm medial

to the anterior superior iliac spine (Fig. 36-15), although this mark may be highly variable<sup>180</sup> and should be confirmed with NS. An insulated needle (22 gauge, 50 mm; 35 mm for children) is inserted using a perpendicular approach if the puncture is close to the anterior superior iliac spine or in a lateral direction if it is at a distance. A “pop” may be felt as the needle penetrates the fascia lata. The primary end point for NS with this nerve is paresthesia over the lateral thigh (Fig. 36-14) with a current of approximately 0.5 to 0.6 mA. The sensory distribution may not extend proximal to the greater trochanter. Five to ten milliliters of a local anesthetic is usually sufficient to obtain a block. A recent study demonstrated that nerve targeting may not be necessary in some cases; in patients undergoing knee surgery, injection of local anesthetic immediately under the inguinal ligament provided sufficient blockade without having to inject directly around the nerve.<sup>181</sup>

### *Obturator Nerve*

Since the obturator nerve branches early after its descent from the obturator foramen, blocking the nerve within the foramen near the superior pubic ramus (i.e., before it branches) is often described for blind techniques. The patient is placed supine with their hip slightly externally rotated; the hip may also be slightly flexed and abducted. If using US imaging, a straight leg has been shown to be the best position. The public tubercle is located, and a mark is placed 1.5 cm both inferior and lateral to it (this mark should resemble that in Fig. 36-15). An inguinal approach is another option and may result in higher block success rates and fewer needle attempts in certain circumstances.<sup>182</sup>

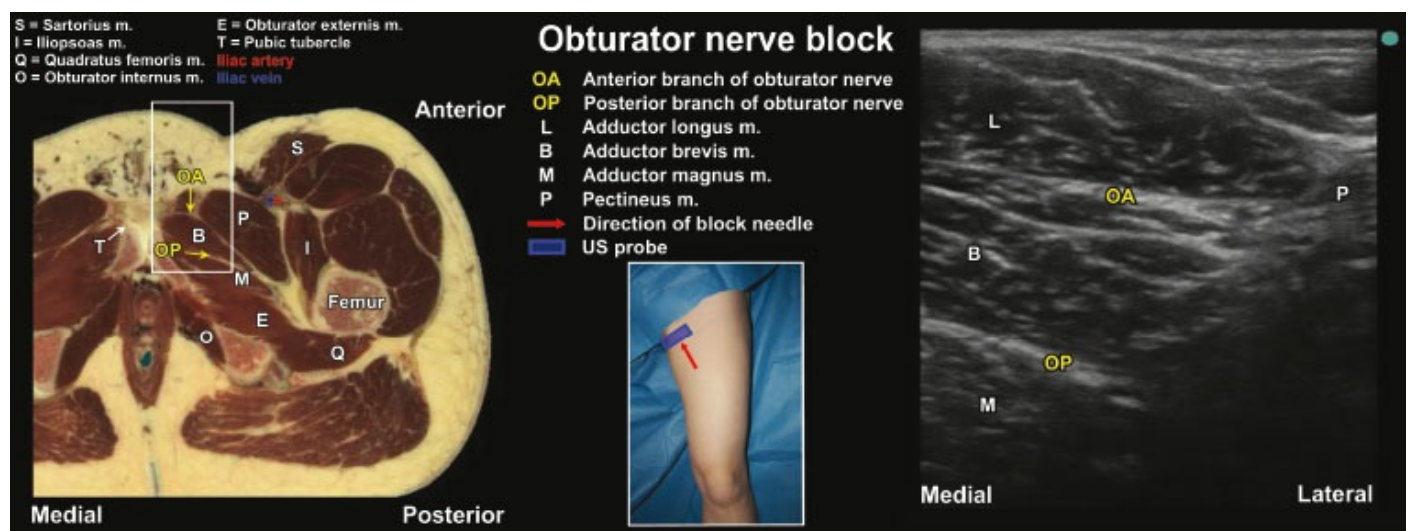

### **Procedure Using Nerve Stimulation Technique**

- An insulated needle (18 to 22 gauge, 90 to 100 mm for adults; 22 to 25 gauge, 35 to 50 mm for children) is inserted perpendicularly until contact with the inferior pubic ramus is obtained. The needle is then redirected laterally and caudally to enter the obturator foramen and is advanced 2 to 3 cm. NS using 0.5 mA for a current end point, with adductor muscle contraction, has been shown to greatly improve nerve localization.<sup>166</sup>

**Procedure Using Ultrasound Imaging (Fig. 36-36).** Scanning: The use of US-guided obturator block at the proximal thigh is based predominantly on the identification of three muscle layers, namely, the adductor longus, adductor brevis, and adductor magnus muscles (from superficial to deep). The anterior branch of the obturator nerve usually lies on the lateral edge between the adductor longus and brevis muscles, whereas the posterior

branch of the obturator nerve lies between the adductor brevis and magnus muscles; however, the obturator nerve shows a considerable degree of variability at this level.<sup>183,184</sup> Soong et al.<sup>185</sup> found that the anterior and posterior branches may be most easily visualized with the probe placed 2 cm laterally and distally to the pubic tubercle. The branches may be localized on either side of the adductor brevis muscle if the fascial planes of the muscles are highly visible (hyperechoic). The depths of the anterior and posterior branches as measured during US guidance were 15.5 and 29.3 mm, respectively; tissue compression by the probe may influence this depth. The main (common) obturator nerve may be hard to view with US imaging. An IP needling technique and color Doppler can be used to help avoid adjacent blood vessels.

**Figure 36-36** Arrangement of relevant anatomy for ultrasound-guided obturator nerve block (anterior and posterior branches) in the proximal thigh using an OOP approach. It is important to identify the three adductor muscles—the adductor longus, adductor brevis, and adductor magnus (from superficial to deep). The pectineus muscle should also be in view on the lateral side since the anterior branch of the obturator nerve is sandwiched between the adductor longus and adductor brevis deep to the pectineus muscle.

- **Appearance:** Using a high frequency probe, US visualization of the three layers of muscle—adductor longus, adductor brevis, and adductor magus—should be seen. The anterior branches of the nerve usually appear as hypoechoic circles in between a hyperechoic layer formed by the adductor longus and brevis, whereas the posterior branches are located between the layers of the adductor brevis and magnus muscles at this level. The nerve can also be blocked more distally at the knee.
- **Needling:** To anesthetize the anterior branch of the obturator nerve, a 22-gauge needle is inserted in either an IP or OOP fashion deep to the adductor longus muscle to deposit local anesthetic immediately

beneath the muscle. Similarly, the needle can be inserted deeper to adductor brevis to reach the posterior branch. Five to ten milliliters of local anesthetic should suffice.

- Local anesthetic spread: A homogeneous, hypoechoic spread pattern between the muscle layers should appear during injection. It is important to avoid intramuscular injection.

### **Clinical Pearls**

- Using cadavers and live subjects, Akkaya et al.<sup>186</sup> demonstrated that a hyperechoic triangle bordered by the superior pubic ramus, posterior edge of the pectineus muscle, and anterior aspect of the external obturator muscle is an ideal landmark to locate the obturator nerve, which lies just medial to the obturator vein.
- A report using US guidance suggested that a single injection of local anesthetic into the interfascial space (i.e., between the adductor longus and adductor brevis muscles) containing the anterior branch of the obturator nerve results in upward (cranial) spreading of anesthetic to block the posterior branch<sup>187</sup>; further spreading was encouraged by applying pressure distal to the needle insertion site.
- Aspiration is essential when injecting near the unbranched obturator nerve since the obturator artery lies adjacent to the nerve, and hemorrhage involving this artery can be life-threatening.<sup>188</sup>

### *Saphenous Nerve*

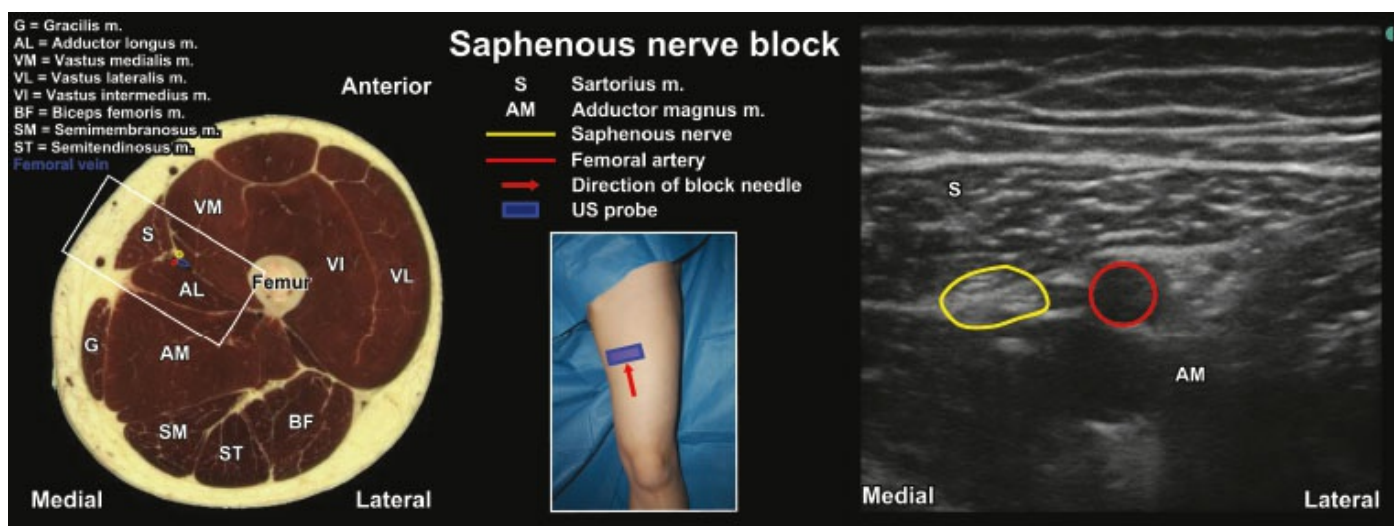

Many approaches to saphenous nerve blockade have been described, with needle placement at various locations, including the mid-thigh, surrounding the knee, or at the ankle (as discussed in Ankle Block). A transsartorial block using a blind technique, first described by van der Wal et al.,<sup>189</sup> has been shown to be more effective compared to blockade at the medial femoral condyle (paracondylar block) or tibial tuberosity (below-knee field block) for producing anesthesia to the medial aspect of the foot.<sup>190</sup> US guidance has been used successfully with a transsartorius perifemoral,<sup>191</sup> subsartorial,<sup>192</sup> or perivenous (saphenous vein)<sup>193,194</sup> approach; the perifemoral approach will be discussed later. An effective approach using the sartorius and gracilis tendons as landmarks has also been described.<sup>195</sup> Using the more proximally located larger femoral artery (rather than the more distal saphenous branch of the descending genicular artery) as a highly visible landmark seems to help to identify the sartorius muscle and nerve.

### **Procedure Using Nerve Stimulation Technique (Transsartorial)**

- Landmarks: The sartorius muscle is palpated at the medial aspect of the knee joint by asking the patient to raise their extended leg 5 to 10 cm

off the table. The block location is marked by the end of a 4 cm vertical line drawn from this point in a proximal direction (Benzon et al.<sup>190</sup> used a slightly more cephalad point 3 to 4 cm superior and 6 to 8 cm posterior to the superomedial border of the patella).

- **Needling:** An insulated 22-gauge needle is inserted caudally using an angle of 45 degrees with a slight posterior angle advanced from the medial aspect of the knee, in a slight posterior and caudad angle, to penetrate the sartorius muscle at a depth of approximately 2 to 3 cm.
- **Nerve localization:** Since the saphenous nerve is purely sensory, paresthesia at the medial malleolus should be felt with the nerve stimulator at 0.6 mA or less at a depth of 3 to 5 cm. Elicitation of paresthesia is not usually performed in children, as it can be uncomfortable or painful.
- **Injection:** Following careful aspiration, 10 mL of local anesthetic (e.g., 1.5% to 2% lidocaine) is injected.

**Figure 36-37** Arrangement of relevant anatomy for ultrasound-guided saphenous nerve block using a transsartorius perifemoral approach. The probe is placed in the coronal plane at the location where the femoral artery has yet to become the popliteal artery, approximately 10 to 12 cm proximal and 3 to 4 cm medial to the midpoint of the patella. Using the large femoral artery as a landmark may be beneficial to more distal approaches where the nerve lies adjacent to the smaller saphenous branch of the descending genicular artery (see text).

### Procedure Using Ultrasound Imaging (Fig. 36-37)

- Using US, the sartorius muscle can be identified easily as being a superficial roof to the relatively large landmark of the femoral artery before the artery travels deep and becomes the popliteal artery via the adductor hiatus.<sup>191</sup> The nerve is located between the sartorius muscle and the artery in the thigh.

- **Scanning:** A high-frequency linear US transducer (e.g., L38, MicroMaxx, Sonosite, Bothell, WA, USA) is placed transversely to the longitudinal axis of the extremity at the mid-thigh, approximately 10 to 12 cm proximal and 3 to 4 cm medial to the midpoint of the patella. The femoral artery can be identified here with certainty by power Doppler, which in turn confirms the identity of the overlying sartorius muscle. The probe is then used to scan distally until it captures the point just prior to where the femoral artery becomes the popliteal artery.
- **Appearance:** Using color Doppler is important to visualize the femoral artery as a large hypoechoic (beneath the color) structure at a depth of approximately 2 to 3 cm in average-sized individuals. The sartorius muscle can then be identified as a highly delineated, lip-shaped muscle with hyperechoic borders immediately superficial to the artery. The nerve can be blocked as it lies sandwiched between the artery and the muscle at this level, or it can be blocked more distally at the knee.
- **Needling:** A 22-gauge needle is inserted in either an IP or OOP fashion to penetrate the sartorius muscle to deposit local anesthetic immediately beneath the muscle and medial to the artery. Five to ten milliliters of local anesthetic should suffice.
- **Local anesthetic spread:** A small hypoechoic mass on the medial surface of the femoral artery should appear during injection.

## **Sciatic Nerve Block Using Gluteal, Subgluteal, Posterior Popliteal, and Anterior Approaches**

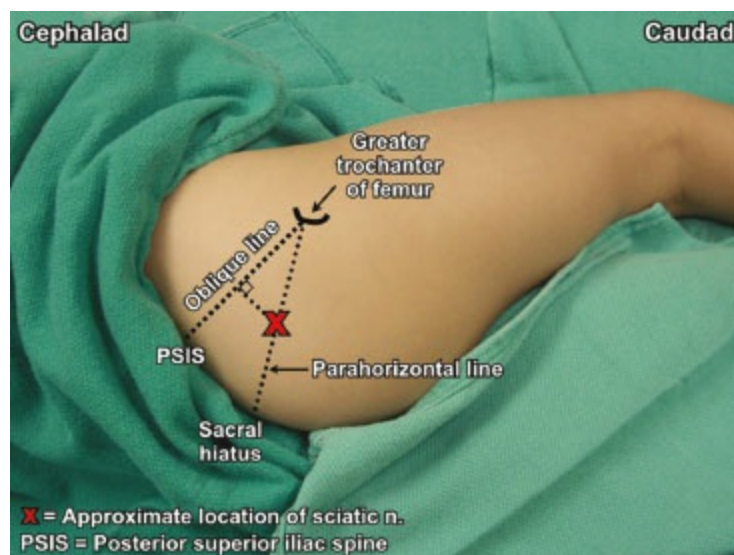

A sciatic nerve block can be used with lumbar plexus block for anesthesia of the lower extremity. Together with saphenous nerve block, the block produces adequate anesthesia of the sole of the foot and the lower leg. The large sciatic nerve is deep within the gluteal region and may be difficult to locate blindly or with US. Of benefit during US-guided blockade of the sciatic nerve and its terminal branches (tibial and common peroneal nerves) are the numerous bony and vascular landmarks that can be used for ease of identification. Knowledge of anatomy is paramount with these blocks, and the block location and approach will ultimately depend on the surgical requirement.

### *Posterior Sciatic Nerve Block: Classical Gluteal (Labat) Approach*

Position the patient semiprone (Sims' position) with the hip and knee flexed and the operative side uppermost.

### **Procedure Using Nerve Stimulation**

- Landmarks (Fig. 36-38): An oblique line is drawn joining the posterior superior iliac spine to the midpoint of the greater trochanter (on its medial aspect). Next, a horizontal line is drawn joining the greater trochanter (at above location) to the sacral hiatus. A perpendicular line drawn at the midpoint of the oblique line and reaching the parahorizontal line is the traditional puncture site (this intersection should be approximately 5 cm caudad along the perpendicular line).
- Needling: Raise a local anesthetic skin wheal after aseptic preparation. A 100-mm (shorter for pediatric patients), 22-gauge needle (insulated if NS is desired) is inserted perpendicular to the skin. For children, the depth to the nerve can be approximated as  $\sim 1$  mm/kg weight, with less and more depth for younger and older individuals, respectively.
- Nerve localization: Nerve responses of the lower leg and foot are sought. If they are not obtained at the full depth of the needle, the needle is withdrawn to the skin and reintroduced at a location perpendicular to the course of the nerve. Bone contact typically requires lateral needle adjustment.
- Injection: Injection of 20 to 30 mL of local anesthetic (e.g., 0.75% ropivacaine, 1% mepivacaine, 0.5% bupivacaine) is performed. If several blocks are required (i.e., lumbar plexus and/or saphenous nerve), a reduced concentration of local anesthetic may be necessary to prevent exceeding the toxic dose.

**Figure 36-38** Landmarks for sciatic nerve block using a posterior gluteal (Labat) approach when using nerve stimulation procedure. This location will also serve as a reference point when applying ultrasound imaging.

### Procedure Using Ultrasound Imaging (Fig. 36-39)

- Scanning: A curved, lower frequency 2 to 5 MHz probe (higher frequency for young children) is generally used for scanning the gluteal

region. Moving the probe cephalad and caudad in the gluteal region will help examine the ischial bone (a hyperechoic line with bony shadowing underneath); the widest portion of this bone, with the ischial spine medial, should be located. The bulky gluteus maximus muscle will be seen superficial and posterior to the sciatic nerve. The internal pudendal vessels (artery and vein), which may be identified using color Doppler, are adjacent to the ischial spine, which is medial to the sciatic nerve and adjacent inferior gluteal artery. Alternatively, the nerve can be first located at the subgluteal region, at about the midpoint between the greater trochanter and the ischial tuberosity, and traced proximally. Bony landmarks (e.g., medial aspect of greater trochanter, femoral condyles) are less visible in children, especially those under 7 years old.

- **Appearance:** The sciatic nerve in the gluteal region is found lateral to the ischial spine and superficial to the ischial bone. The nerve appears predominantly hyperechoic (bright) and is often wide and flat in short axis on US. Overlying the sciatic nerve is the large gluteus maximus, which is quite distinct with the usual “starry night” appearance. The inner muscle layers (superior and inferior gemellus muscles, obturator internus muscle, and quadratus femoris muscle) are often indistinct.
- **Needling:** Both IP and OOP approaches are appropriate for US-guided sciatic nerve block in the gluteal region. For an OOP approach, the needle is inserted inferior to the probe in a cephaloanterior direction. A fairly steep angle of insertion will be required, but placing the needle slightly inferior to the probe will reduce the angle somewhat for better visibility of the needle. With the IP approach, the needle may be moved in a lateral-to-medial direction to penetrate the gluteus maximus muscle before reaching the sciatic nerve above the ischial bone ([Fig. 36-39](#)).
- **Local anesthetic spread:** Performing a test dose with D5W is recommended prior to local anesthetic application to visualize the spread and confirm nerve localization. It is generally recommended to deposit the local anesthetic solution so that it spreads completely around the sciatic nerve.

**Figure 36-39** Arrangement of relevant anatomy for ultrasound-guided sciatic nerve block using a posterior gluteal (Labat) approach. An IP needle alignment to a curved low frequency probe is used. A lateral-to-medial needle direction may help avoid puncture of the inferior gluteal or internal pudendal vessels.

### Clinical Pearls

- For both IP and OOP needling approaches, scanning before needling will determine the angle, distance, and depth of needle penetration.
- The OOP approach is often used for catheter insertion, and it is important to line up the site of needle insertion with the target nerve.

### Posterior Sciatic Nerve Block: Subgluteal Approach

The patient is positioned semiprone (Sims position) with the hip and knee flexed and the foot resting on the dependent knee. In some patients, the supine position with the hip flexed and knee bent is either most comfortable or necessitated due to fracture or pain at the hip. The latter position requires an assistant to support the bent leg.

### Procedure Using Nerve Stimulation Technique

- Landmarks: A horizontal line is drawn joining the medial aspect of the greater trochanter to the ischial tuberosity. The traditional puncture site is located on this line just medial to its midpoint.
- Needling: An insulated needle, 100 to 150 mm, depending on patient habitus, is used. The needle is inserted perpendicular to the skin. Shorter needles are recommended for use in children.
- Nerve localization: Confirming sciatic nerve localization with NS is important prior to local anesthetic application. Similar responses as those for the classic gluteal approach are sought, with ankle responses preferable. It is important to distinguish the tibial (inversion or plantar flexion) and common peroneal (eversion or dorsiflexion) components

of the nerve and obtain both responses or, at minimum, the tibial response.

- **Injection:** Injection of 20 to 30 mL of local anesthetic is sufficient. If additional blocks of the lower extremity are performed, a solution with lower concentration should be considered to prevent exceeding the toxic dose of local anesthetic.

### **Procedure Using Ultrasound Imaging (Fig. 36-40)**

- **Scanning:** A curved, lower frequency 2 to 5 MHz probe or linear 4 to 7 MHz probe is suitable for scanning the subgluteal region; high frequency probes are recommended for scanning young children. The center of the probe should be aligned with the midpoint of a line between the ischial tuberosity and the greater trochanter. If the sciatic nerve is hard to localize at the subgluteal region, it can be traced proximally from the bifurcation point at or near the apex of the popliteal fossa.
- **Appearance:** On the lateral side of the screen, the medial aspect of the greater trochanter appears almost pear-shaped and hypoechoic when using a curved array probe. The sciatic nerve in the subgluteal region appears predominantly hyperechoic (bright) and is often elliptical in a short-axis view using US.
- **Needling:** Similar to the classic gluteal approach, both IP and OOP plane needling can be performed, with the needle directed from lateral to medial for the IP technique. Using an angle of insertion of approximately 45 degrees to the skin will provide the best view of the needle and will reach the nerve, although 60 to 70 degrees may be required in certain obese individuals.
- **Local anesthetic spread:** The goal is to deposit local anesthetic (20 to 30 mL) next to, but not directly within, the sciatic nerve structure in the subgluteal region. A hypoechoic local anesthetic fluid collection is often seen around the hyperechoic nerve within the sheath compartment during injection.

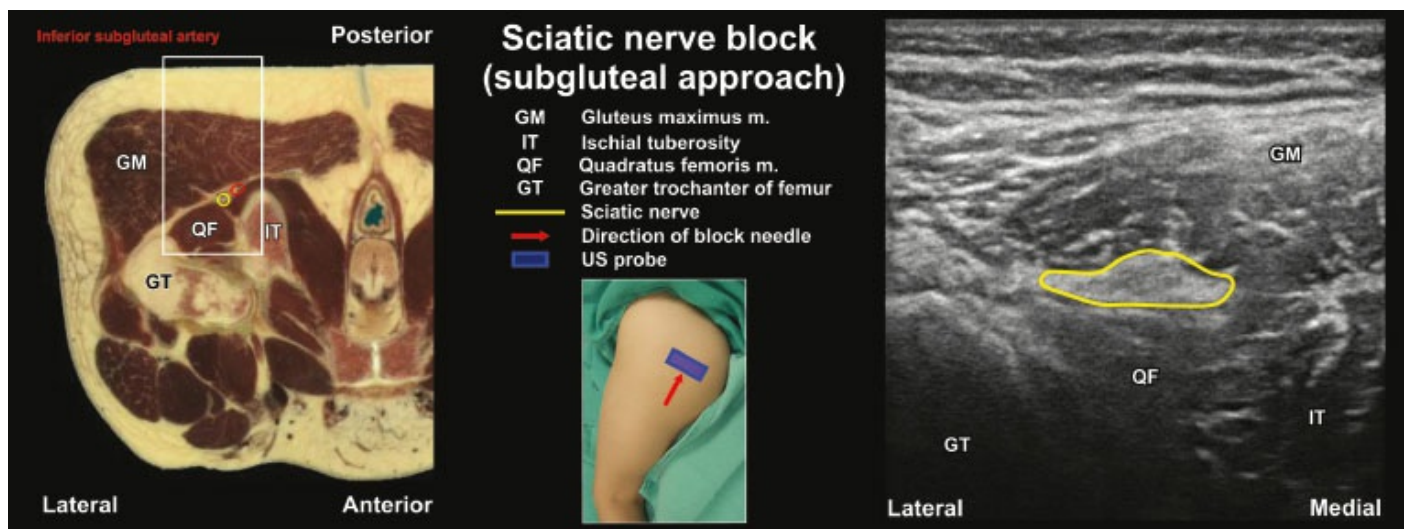

### **Clinical Pearls**

- Since a low frequency curved array probe is necessary in many cases, the needle tip as viewed with an OOP approach will be even harder to identify than when using higher resolution linear probes. Nevertheless, this approach is used often since indwelling catheters are commonly placed in the subgluteal area. It will be important to use NS in addition to US-guided technique to confirm placement of the needle and local anesthetic.

### *Posterior Popliteal Sciatic Block*

The sciatic nerve can be blocked below the hip at the lateral mid-femoral or lateral popliteal locations in addition to the posterior popliteal location,<sup>196,197</sup> but when using US guidance, the posterior approach allows the needle to be placed closely to the probe and thus may improve needle tracking and visibility. Furthermore, the posterior popliteal approach is most amenable to inserting indwelling catheters. The patient is positioned laterally or prone with the operative leg slightly flexed. Ideally, the ankles should be positioned beyond the end of the table so that motor responses to NS can be readily observed in the prone position. The landmarks become more visible when the knee is flexed against resistance.

**Figure 36-40** Arrangement of relevant anatomy for ultrasound-guided sciatic nerve block with a subgluteal approach. Out-of-plane approaches are preferred since this approach is used often for indwelling catheter placement, especially in children. The medially positioned ischial tuberosity is not captured in this image but will serve as a good bony landmark in most circumstances.

### Procedure Using Nerve Stimulation Technique

- Landmarks: The puncture site is often located at the tip of a triangle formed by the popliteal crease at the base, the biceps femoris tendon laterally, and the semimembranosus tendon medially (which generally lies medial to the tendon of the semitendinosus at this location). Alternatively, drawing lines 8 cm long in a cephalad direction from the insertion site of the medial and lateral tendons (above), the puncture point is at the midpoint of a line attaching the two (almost parallel) lines. It may be best to insert the needle at approximately 10 cm above the popliteal fossa in order to ensure that the sciatic nerve is blocked before its bifurcation. For children, the distance between the popliteal fold and the needle insertion point can be calculated based on patient weight: less than 10 kg = 1 cm, 10 to 20 kg = 2 cm, 20 to 30 kg = 3

cm, and so forth.

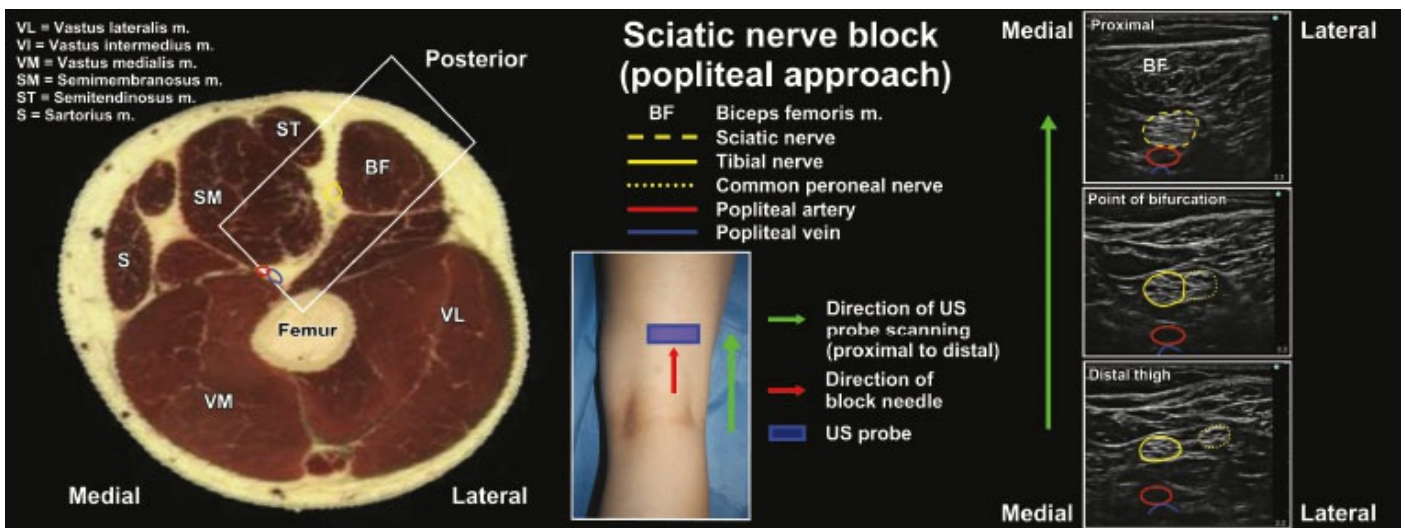

- **Needling:** Depending on the patient, a 50-mm insulated 22-gauge needle can be inserted using an angle of 45 degrees cephalad to the skin. A fan-wise search is conducted perpendicular to this line until the nerve is contacted. If the femur is contacted by the needle, the depth is noted; the nerve should lie midway between the skin and the femur.
- **Nerve localization:** NS is used to elicit motor responses at the ankle or foot. The aim should be to localize the sciatic nerve before its bifurcation into its tibial and common peroneal nerve components. If only ankle inversion and/or plantar flexion (tibial nerve) or eversion and/or dorsiflexion (common peroneal) is seen, adjust the needle insertion site a few centimeters cephalad to obtain complete ankle and foot movements. Otherwise, injecting after obtaining a sole tibial nerve response has been shown to provide similar success to that after both tibial and common peroneal responses (with two injections).<sup>198</sup> Maintaining a motor response with currents less than 0.5 mA will help ensure the nerve–needle distance is appropriate for a successful block.<sup>199</sup>
- **Injection:** Twenty to thirty milliliters of local anesthetic should be deposited at the final needle location.

### **Procedure Using Ultrasound Guidance (Fig. 36-41)**

- **Scanning:** A linear, higher frequency 10 to 15 MHz probe is commonly used for scanning the sciatic nerve transversely in the popliteal fossa. A “hockey stick” probe is suitable for most children. A distal-to-proximal scan can effectively locate the sciatic nerve in the posterior popliteal fossa prior to its bifurcation (Fig. 36-41). At the popliteal crease, the transverse probe captures the tibial and common peroneal nerves, with the former being adjacent and lateral to the popliteal vessels (Doppler is valuable here). During a proximal scan, the tibial and common peroneal nerves approach each other and join to form the sciatic nerve.
- **Appearance:** At the level of the popliteal crease, the tibial and common peroneal nerves lie superficial and lateral to the popliteal vessels (the common peroneal nerve is the most lateral). Both nerves appear round-to-oval and hyperechoic compared to the surrounding musculature. The hyperechoic border of the femur (condyles) may be apparent. During the proximal scan, the tibial nerve moves away from the vessels and approaches the common peroneal nerve. More cephalad in the posterior thigh, the biceps femoris muscle lies superficial to the joining nerves and appears as a larger, oval-shaped structure with less internal punctate areas (hypoechoic spots) than the nerves. The sciatic nerve appears as a large, oval hyperechoic structure. The high fat and muscle

content of the area may impair visualization of the nerve itself. Furthermore, the probe often needs to be tilted for optimal imaging since the nerve becomes more superficial as it descends distally.

- **Needling:** An OOP approach is performed commonly, especially if placing indwelling catheters. The probe is positioned directly above the sciatic nerve at or slightly cephalad to its bifurcation point and so that the nerve is in the center of the image. The needle should be inserted at the caudal surface of probe (especially if a catheter is to be inserted), with the needle tip contacting the skin approximately 3 to 4 cm caudal to the probe surface.
- **Local anesthetic spread:** For local anesthetic injection at the bifurcation, hypoechoic injectate will be seen to expand within the common epineural sheath. For injections above or below the bifurcation, a circumferential spread producing a “donut” shape surrounding the hyperechoic nerve structure is preferable. Several separate injections (medial and lateral) may be required for complete circumferential spread.

**Figure 36-41** Arrangement of relevant anatomy for ultrasound-guided sciatic nerve block with a popliteal approach. The probe is placed initially at the popliteal crease and is used to scan proximally to capture the sciatic nerve just proximal to its bifurcation (i.e., the ideal block site), approximately 6 to 10 cm above the crease.

### Clinical Pearls

- The ideal needle insertion point for sciatic nerve block using the popliteal approach remains debatable. The tibial and common peroneal branches may be blocked separately<sup>200</sup> or injection may occur between these nerves at the bifurcation.<sup>201</sup>
- Several groups have provided evidence that injection distal (caudad), rather than proximal, to the bifurcation point results in faster block

onset and improved sensory block.<sup>200–203</sup> Recently, a randomized comparison between a single subepineural injection at the neural bifurcation and separate injections around the tibial and peroneal divisions demonstrated a higher success rate and shorter performance, onset, and total anesthesia-related times with the former approach.<sup>204</sup>

- Compared to NS guidance alone, US guidance, either alone or in conjunction with NS, was shown to improve the success of both single-injection and catheter-delivered local anesthetic as well as patient outcome with respect to postoperative pain.<sup>205–207</sup>
- The US probe may be rotated 90 degrees to show the sciatic nerve in the long axis. This is helpful to differentiate the sciatic nerve from other nonneural structures.
- During needle insertion using an OOP approach, it may be helpful to use incremental needle angulations. The needle may be best tracked within the tissue if an initial shallow angle is used to identify the needle tip clearly as a hyperechoic dot, which can then be followed with subsequent steeper needle angulations (see the description of the “walk-down” technique under Practical Approaches for US guidance).

### *Anterior Sciatic Nerve Block*

This block is most suitable for patients who cannot be positioned laterally. The block is indicated for surgery below the knee, with the only sensory deficiency being the medial strip of skin supplied by the saphenous nerve. The anterior block is performed on a short portion of the sciatic nerve close to the lesser trochanter of the femur. This block may cause more discomfort since the needle traverses through more muscle layers than other approaches of sciatic nerve block. The patient is positioned supine, with the leg to be blocked externally rotated slightly.

### **Procedure Using Nerve Stimulation Technique**

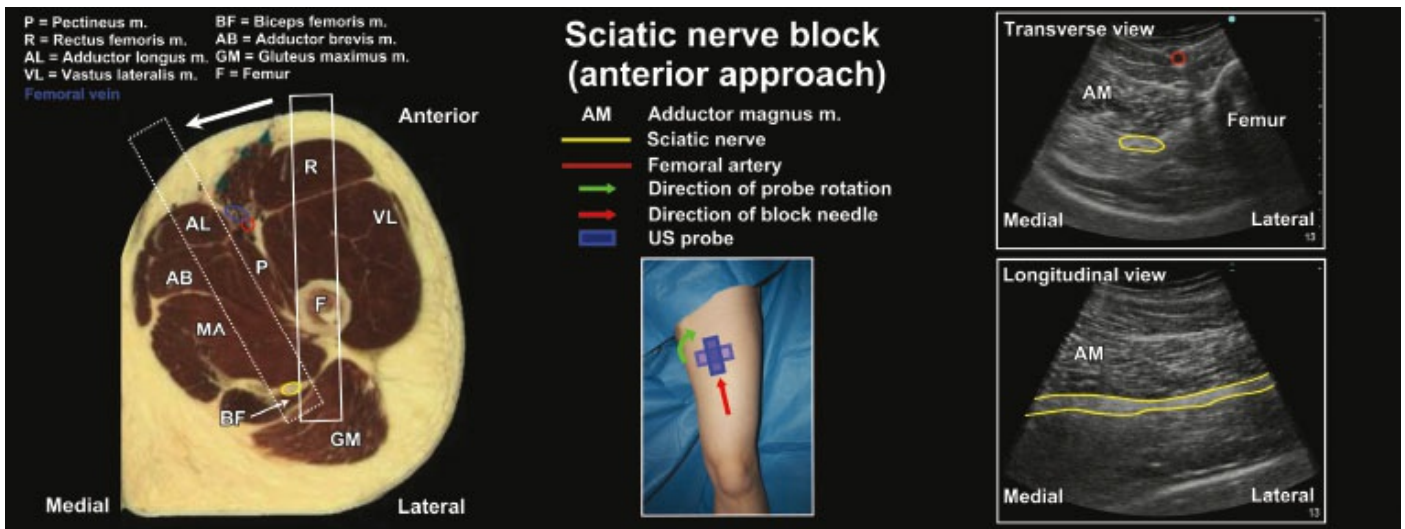

- Landmarks: A line is drawn connecting the anterior superior iliac spine with the pubic tubercle (inguinal ligament). A second line, parallel to the first, is drawn across the thigh from the greater trochanter. A line is then drawn downward from a point at the medial third of the upper line; the nerve is usually located at the intersection of the perpendicular line and the lower of the two parallel lines. Alternatively, the nerve is located lateral to the femoral artery pulse at the level of the inguinal crease.
- Needling: A 22-gauge, 100- to 150-mm insulated needle will be required for this deep block.
- The needle is inserted perpendicular to the skin and advanced until contact with the femur occurs. The needle is then withdrawn slightly,

angulated slightly medial and cephalad, and introduced 5 cm further.

- Nerve localization: Motor responses of the ankle joint or foot are sought.
- Injection: Twenty to thirty milliliters of local anesthetic are injected after careful aspiration and administration of a test dose.

### **Procedure Using Ultrasound Imaging (Fig. 36-42)**

- Scanning: It is most common to use a curved, lower frequency 2 to 5 MHz probe to scan the sciatic nerve in the proximal thigh. Place the probe over the proximal thigh approximately 8 cm distal to the femoral crease. A transversely placed probe is commonly used, although the nerve may be best visualized by placing the probe axis longitudinally along the course of the nerve, since capturing a longitudinal axis of the nerve may improve its identification since it has a distinctive cable-like appearance. Moving in a medial-to-lateral direction may be helpful to capture an image of the nerve.
- Appearance: In transverse axis, the sciatic nerve often appears oval or round, predominantly hyperechoic, medial, and posterior to the lesser trochanter, and deep to the adductor magus muscle. If using Doppler, the femoral neurovascular structures are seen superficial below the hyperechoic fascial tissue and lateral to the sciatic nerve in this projection when the leg is externally rotated. A longitudinal view captures a broad, linear, and hyperechoic cable of fibers and may allow easier identification of the nerve.<sup>208</sup>
- Needling: When using a probe positioned in transverse axis to the nerve, an IP approach involves advancing the needle in a medial-to-lateral and anterior-to-posterior direction, whereas an OOP approach involves inserting the needle along the midline of the probe at a location 2 to 3 cm inferior and perpendicular to the probe. If the probe is placed longitudinally, the needle direction for OOP alignment will be similar to that for the IP approach described earlier. Using an IP approach with the probe placed longitudinally, the needle will be placed in a cephalad-to-caudad direction, allowing it to be aimed easily toward a relatively larger target (i.e., the cable-like sciatic nerve). It is highly recommended to use combined US and NS guidance for this procedure.
- Local anesthetic spread: After careful aspiration and injection of a small amount of D5W to visualize the anesthetic spread, inject the local anesthetic while ensuring that it spreads circumferentially around the nerve.

**Figure 36-42** Arrangement of relevant anatomy for ultrasound-guided sciatic block using an anterior approach. Transverse probe positioning allows a short-axis view of the nerve (upper US image). A longitudinally placed probe captures the long axis of the nerve (lower US image), which may be beneficial if the transverse view is difficult to capture due to bony shadowing from the lesser trochanter.

### Clinical Pearls

- Although depositing the local anesthetic around the nerve is desirable, it is technically challenging to reposition the needle on both sides of the nerve because of the nerve's depth within the muscle layers.
- As with other sciatic nerve blocks, if this block is being combined with others, the local anesthetic may need to be diluted to reduce the risk of toxicity.
- Complications are rare but can include intravascular injection (e.g., femoral artery), infection in the injection area, hematoma formation, nerve injury, and potential CNS toxicity.

### Other Approaches to Sciatic Block

- A supine approach developed by Raj et al.,<sup>209</sup> in which the patient's leg is maximally flexed, stretches the nerve within the space between the greater trochanter and the ischial tuberosity; needle insertion occurs at the midpoint between these two structures. In this approach, landmarks are easy to find, and the position offers an alternative to patients who cannot accommodate prone or lateral positioning. This approach has also been shown to be amenable to catheter-delivered continuous anesthesia of the sciatic nerve.<sup>210</sup>
- Several novel approaches to sciatic nerve blockade have been described that may be useful when the patient cannot be positioned for traditional approaches:
  - a. Le Corroller et al.<sup>211</sup> have described a lateral approach in which

the patient is positioned supine, and injection occurs on the midpoint of a vertical line drawn cephalad from the greater trochanter to the anterior superior iliac spine.

- b. Osaka et al.<sup>212</sup> have described a medial approach at the mid-thigh, where the patient is positioned supine and the hip and knee flexed and externally rotated. The sciatic nerve is beneath the adductor magnus muscle, 1.5 to 2 cm posterior to the femur at the upper mid-thigh.

## **Ankle Block**

All five nerves of the foot can be blocked at the level of the ankle. The superficial nerves—sural, superficial peroneal, and saphenous nerves—can be blocked by simple infiltration techniques. US guidance can be useful for blocking the posterior tibial and deep peroneal (fibular) nerves, as their locations can be easily identified next to reliable landmarks (i.e., bones and vessels) that are clearly visible with US.

### *Posterior Tibial Nerve*

#### **Procedure Using Landmark Technique**

- **Landmarks:** The posterior tibial nerve is the major nerve to the sole of the foot. It can be approached with the patient either in the prone position or lying supine with the hip and knee flexed so that the foot rests on the bed. The medial malleolus is identified, along with the pulsation of the posterior tibial artery behind it. The nerve is located posterior to the artery.
- **Needling:** A needle is introduced through the skin just behind the posterior tibial artery and directed 45 degrees anteriorly, seeking a paresthesia in the sole of the foot. Motor responses that may be seen with NS include twitches of the first (medial plantar branch) and fifth (lateral plantar branch) toes.
- **Injection:** Five milliliters of local anesthetic produces anesthesia if a paresthesia is identified. If not, a fan-shaped injection of 10 mL can be performed in the triangle formed by the artery, the Achilles tendon, and the tibia itself.

#### **Procedure Using Ultrasound Imaging (Fig. 36-43)**

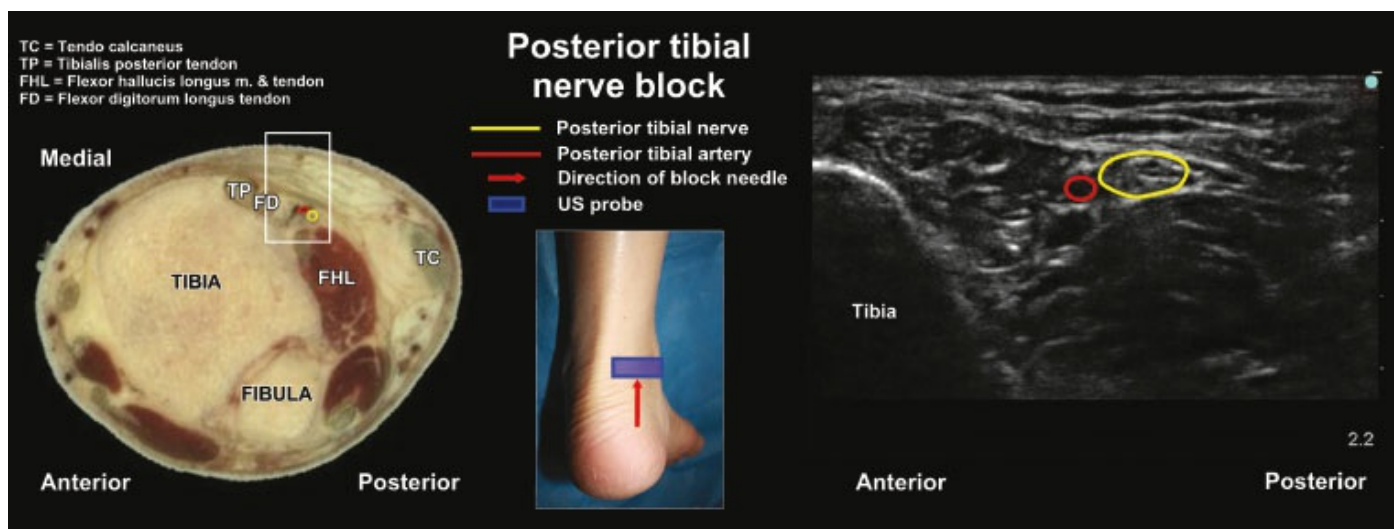

- **Scanning:** A linear (“hockey stick”), 10 MHz probe with a small footprint is positioned in transverse (short) axis to the nerve just posterior and inferior to the medial malleolus. Alternatively, the nerve can be identified 3 to 5 cm above the malleolus. The use of color Doppler may be helpful, since the nerve lies posterior and deep to the

posterior tibial artery at both of these locations. The nerve should be localized before it branches into the medial and lateral plantar nerves.

- **Appearance:** Immediately anterior to the artery lies the hypoechoic circular posterior tibial vein, although it may be compressed and not apparent on the screen. Posterior to the artery, the nerve appears slightly more hyperechoic than the surrounding tissues and has a condensed, honeycomb-like structure.
- **Needling:** A 36- to 50-mm needle is inserted using an OOP approach with the needle caudal or an IP approach with the needle anterior to the transversely positioned probe.

### *Sural Nerve*

The patient is placed either in the prone position or supine with the hip and knee flexed so that the foot rests on the bed. The posteriorly located sural nerve can be blocked by injection on the lateral side. Subcutaneous injection of 5 mL of local anesthetic behind the lateral malleolus, filling the groove between it and the calcaneus, produces anesthesia of the sural nerve. The effectiveness of a sural nerve block was found to be improved using a perivascular approach (i.e., identifying the lesser saphenous vein 1 cm proximal to the lateral malleolus), rather than a traditional, surface landmark-based approach, under US guidance.<sup>213</sup>

**Figure 36-43** Arrangement of relevant anatomy for ultrasound-guided posterior tibial nerve block at the ankle using an IP approach. The nerve is imaged adjacent to the posterior tibial artery before the nerve divides into the medial and lateral plantar nerves.

### *Deep Peroneal Nerve*

#### **Procedure Using Landmark Technique**

- **Landmarks:** This is the major nerve to the dorsum of the foot and lies in the deep plane of the anterior tibial artery. The patient is positioned

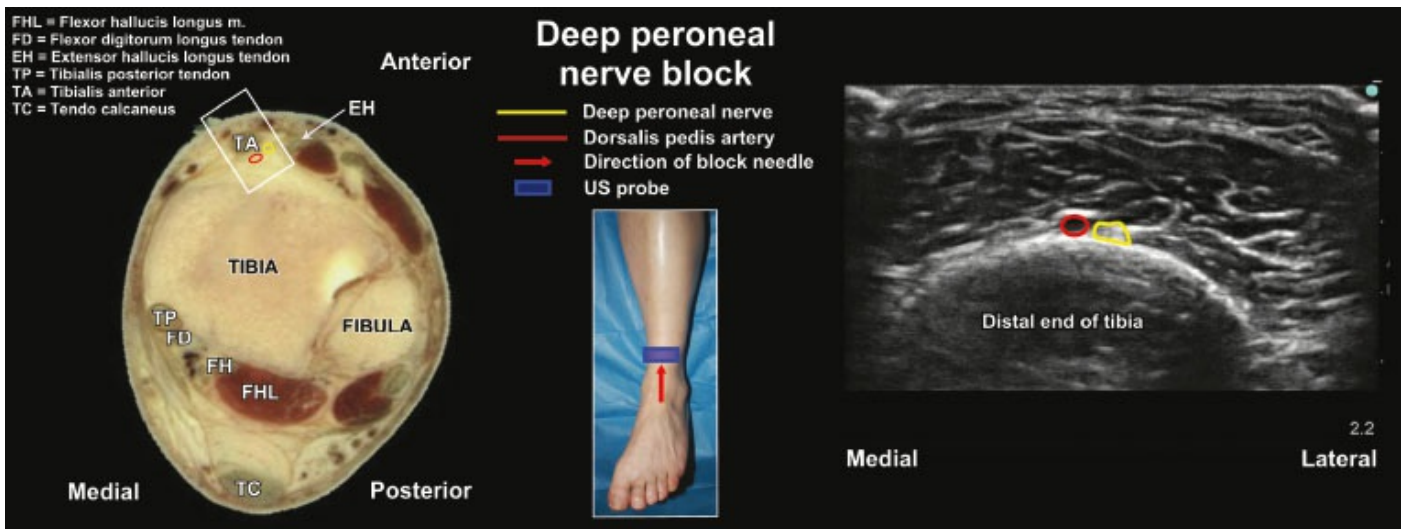

supine, generally with the leg extended. Pulsation of the artery is sought at the level of the skin crease on the anterior midline surface of the ankle. If the artery is not palpable, the tendon of the extensor hallucis longus can be identified (the nerve lies immediately lateral to this) by asking the patient to extend the big toe.

- **Needling and Injection:** If the artery pulse can be felt, 5 mL of local anesthetic is injected just lateral to it. If the artery is not palpable, the tendon of the extensor hallucis longus can be identified (see earlier). If using NS, toe extension is sought for this nerve. Injection can be made into the deep planes below the fascia using either one of these landmarks.

### **Procedure Using Ultrasound Imaging (Fig. 36-44)**

- **Scanning:** A small footprint linear (“hockey stick”) 10 MHz probe is placed in transverse (short) axis to the nerve at the anterior surface of the ankle joint. Alternatively, the nerve can also be found 3 to 5 cm above the ankle joint. However, the nerve itself can be difficult to see, and only the artery can be located consistently. Color Doppler can be used at both locations to identify the anterior tibial artery lying medial to the nerve.
- **Appearance:** If seen, the nerve appears as a small cluster of hyperechoic, fascicular-appearing fibers immediately lateral to the artery, with both the nerve and the artery adjacent to the well-demarcated distal end of the tibia.
- **Needling:** An OOP approach will be most suitable here since the tendons lie on either side of the nerve. A 36- to 50-mm needle is inserted OOP and caudal to the transversely positioned small footprint probe.
- **Local anesthetic spread:** Injection of 4 to 5 mL of local anesthetic lateral to the nerve will help to avoid the anterior tibial artery, which lies medial to the nerve. It is important to perform aspiration prior to injection.

**Figure 36-44** Arrangement of relevant anatomy for ultrasound-guided deep peroneal nerve block at the anterior ankle. If possible, the medially located anterior tibial artery should be localized with Doppler to differentiate between the nerve and surrounding tendons.

### *Saphenous Nerve*

The patient is placed supine with the leg extended. The saphenous nerve is anesthetized by infiltrating 5 mL of local anesthetic around the saphenous vein at the level where it passes anterior to the medial malleolus. A wall of anesthesia between the skin and the bone itself suffices to block the nerve. Alternatively, this nerve can be blocked at a more proximal site in the thigh. See the section on Separate Blocks of the Terminal Nerves of the Lumbar Plexus for blockade of this nerve more proximally in the thigh.

### *Superficial Peroneal Branches*

A subcutaneous ridge of local anesthetic solution is injected along the skin crease between the anterior tibial artery and the lateral malleolus. This subcutaneous ridge overlies the subfascial injection used for the deep peroneal nerve. Another 5 to 10 mL of local anesthetic may be required to cover this area. The superficial peroneal nerve may be visualized using US, which may aid in more accurate injection of local anesthetic.<sup>214</sup>

### *Clinical Pearls*

- Anesthesia of the foot usually ensues within 15 minutes of these five injections.
- Complications of ankle block are rare, although neuropathy can be produced. Care should be taken not to pin any of the deep nerves against the bone at the time of injection, and intraneural injection should be avoided. Epinephrine should not be added to local anesthetics used for this block in order to avoid compromising the

distal circulation.

- US imaging for the deep nerves may help to avoid bone contact and multiple injections with the infiltration technique.

## *Continuous Catheter Technique*

Continuous catheter regional anesthesia has been well documented to provide effective pain relief with reduced incidence of side effects and an improved quality of life.<sup>215,216</sup> Traditionally, catheters have been introduced blindly once neural structures are identified using a peripheral nerve stimulator and often after the initial local anesthetic dose has been injected via the needle. Although continuous delivery of local anesthetic has been used successfully at a number of block sites following blind catheter insertion,<sup>217</sup> the method is associated with at least 10% to 40% secondary block failure due to the catheters being in a suboptimal location.<sup>218,219</sup> This high failure rate resulted in the development of stimulating catheters to aid in their positioning close to the nerve,<sup>220</sup> which improved success rates. However, insertion and precise positioning of stimulating catheters requires technical expertise and can be a time-consuming process. Moreover, needle insertion with stimulating catheters remains a blind procedure since neurostimulation and anatomic landmarks are still required to locate the nerve.

In recent years, ultrasonography has been used extensively to initiate regional blocks,<sup>221,222</sup> and several large-scale studies have shown its efficacy in guiding the placement of perineural catheters.<sup>223,224</sup> However, catheter insertion for continuous regional anesthesia, whether guided by NS or US, suffers from several fundamental problems owing to the design of current needle-catheter assemblies, including dislodgement or movement of the catheter, leakage at the insertion site, and imprecise catheter placement.<sup>217</sup> The increasing popularity of US technology in regional anesthesia has facilitated increased use of catheter-over-needle approaches to continuous catheter placement. Several commercially available catheter-over-needle kits are marketed throughout the world. The primary benefit of this approach is that the catheter is held tightly by the surrounding skin since the needle—which enables initial skin puncture—is housed within the catheter and is removed once the needle tip is located appropriately. This overcomes the common problems described earlier for the traditional catheter-through-needle approach.<sup>225,226</sup> Another benefit over traditional catheter assemblies is that the catheter tip can be positioned with a high degree of accuracy proximal to the intended target nerve. Indeed, a catheter-over-needle approach has been used successfully for supraclavicular,<sup>225</sup> infraclavicular,<sup>227</sup> interscalene,<sup>228</sup> femoral nerve,<sup>229</sup> TAP,<sup>230</sup> and rectus sheath block.<sup>231</sup> Moreover, the stable indwelling catheter provides a means to deliver intermittent boluses<sup>122,232</sup>

and, if desired, to reverse a nerve block with saline injection through the catheter.<sup>233</sup> A drawback of the catheter-over-needle approach is that needle/catheter assemblies are fixed length, limiting their use for neuraxial anesthesia and targeting of deeper nerves unless one is able to estimate accurately the length required prior to placement.

Continuous peripheral nerve catheter techniques, provided by the catheter-over-needle approach, are a reliable and practical option to facilitate intermittent bolusing of local anesthetic as a means of delivering continuous analgesia. Since the catheter tip can be targeted next to the nerve with relative accuracy and is stable once placed, multiple boluses can be injected through the catheter, avoiding the need for an infusion pump. This method potentially reduces the total dose delivered, minimizing the associated risk of local anesthetic toxicity.<sup>232,234,235</sup> Recently, remote control of local anesthetic infusion was described,<sup>236</sup> enabling pain management according to patient need and allowing the anesthesiologist to access pump information remotely. The main advantage of this technology is that there is no need for a nurse or physician to be physically present to manage the pump.

## Acknowledgments

The authors thank Drs. Gareth Corry and Saadat Ali and the Department of Anesthesiology and Pain Medicine, University of Alberta, for their contributions to the text. The authors acknowledge the Ecole Polytechnique Federale de Lausanne, Switzerland, Visible Human Web Server (<http://visiblehuman.epfl.ch>) as the data source for the anatomic sections used in some of the figures. Most of the material was adapted from one of the author's (B.T.) textbooks, *Atlas of Ultrasound and Nerve Stimulation-Guided Regional Anesthesia*, 2<sup>nd</sup> edition (in press)<sup>237</sup> and *Pediatric Atlas of Ultrasound and Nerve Stimulation-Guided Regional Anesthesia*.<sup>86</sup> B.T. also has a patent licensing agreement with Pajunk.

## ANESTHESIA SUBSPECIALITY CARE

### 37 Anesthesia for Neurosurgery

JOHN F. BEBAWY • JEFFREY J. PASTERNAK

#### Introduction

#### Neuroanatomy

#### Neurophysiology

#### Pathophysiology

#### Monitoring

- Central Nervous System Function

- Influence of Anesthetic Technique on Evoked Potentials

#### Cerebral Perfusion

- Transcranial Doppler Ultrasonography

- Laser Doppler Flowmetry

- Intracranial Pressure Monitoring

- Cerebral Oxygenation and Metabolism Monitors

#### Cerebral Protection

- Ischemic and Reperfusion

- Hypothermia

- Pharmacologic Therapy for Cerebral Protection

- Glucose and Cerebral Ischemia

- A Practical Approach

#### Anesthetic Management

- Preoperative Evaluation

- Induction of Anesthesia and Airway Management

- Maintenance of Anesthesia

- Ventilation Management

- Fluids and Electrolytes

- Transfusion Therapy

- Glucose Management

- Emergence

#### Common Surgical Procedures

Surgery for Tumors

Pituitary Surgery

Cerebral Aneurysm Surgery and Endovascular Treatment

Arteriovenous Malformations

Carotid Surgery

Epilepsy Surgery

Awake Craniotomy

## **Anesthesia and Traumatic Brain Injury**

Anesthetic Management

## **Anesthesia for Spine Trauma and Complex Spine Surgery**

Spinal Cord Injury

Comorbid Injuries

Initial Management

Intraoperative Management

Complications of Anesthesia for Spine Surgery

## **Conclusion**

## **KEY POINTS**

- 1 The brain receives approximately 70% of its blood supply from two internal carotid arteries anteriorly and 30% from two vertebral arteries posteriorly forming the basilar artery, that subsequently converge to form the Circle of Willis, an anastomotic ring at the base of the skull.
- 2 The spinal cord receives its blood supply from one anterior spinal artery and two posterior spinal arteries. The anterior spinal artery originates from 6 to 8 major radicular arteries derived from the aorta, with the largest one being the artery of Adamkiewicz (usually occurring at T11 or T12 and generally supplying T8 to the conus medullaris terminus).
- 3 Cerebral blood flow (CBF) is regulated by “flow-metabolism coupling,” whereby increases in regional neuronal electrical activity require corresponding increases in regional blood flow. Such coupling occurs on the order of seconds, with very little variation in the amount of oxygen extraction by the brain tissue (i.e., CBF matches cerebral metabolic rate of oxygen consumption very quickly and efficiently in the healthy brain).
- 4 Moderate changes in mean arterial pressure (MAP) (or cerebral perfusion pressure) will yield a consistent CBF of 50 mL/100 g/min, due to the normal brain’s ability to autoregulate its blood flow. Cerebral autoregulation of blood flow is thought to remain intact between a MAP of approximately 60 and 160 mmHg and functions by altering cerebrovascular resistance (CVR) on the order of 5 to 60 seconds. The alteration in CVR is accomplished in both a rapid phase (“dynamic

- autoregulation”) and a slow phase (“static autoregulation”).
- 5 CBF is linearly associated with arterial carbon dioxide tension between 20 and 80 mmHg. Hyper- and hypoventilation, both patient-determined and iatrogenic, play critical roles in decreasing or increasing CBF, respectively. A change in arterial carbon dioxide tension of 1 mmHg roughly correlates to a similar change in CBF of 1 to 2 mL/100 g/min. Below the lower limit of this linear effect (i.e., with arterial carbon dioxide tension below 20 mmHg), maximal cerebral vasoconstriction leads to tissue hypoxia and a reflex vasodilation.
  - 6 Intravenous drugs, such as propofol, etomidate, benzodiazepines, and thiopental, decrease CBF by virtue of a drug-induced decrease in cerebral metabolic rate of oxygen consumption and subsequent flow-metabolism coupling. Autoregulation and arterial carbon dioxide tension responsiveness remain intact with these agents.
  - 7 Potent volatile anesthetics, such as isoflurane, sevoflurane, and desflurane, are direct cerebral vasodilators. However, this direct vasodilation is offset by a drug-induced decrease in cerebral metabolic rate of oxygen consumption, and via flow-metabolism coupling, an attenuation of the direct effect on CBF. This leads to minimal, if any, increase in CBF at lower doses. However, at high doses where maximal suppression of cerebral metabolic rate of oxygen consumption has occurred are direct vasodilatory effects observed leading to a dose-dependent increase in CBF. Furthermore, autoregulation is inhibited with potent volatile anesthetic drugs in a dose-dependent fashion, although the cerebral vasculature remains responsive to changes in arterial carbon dioxide tension.
  - 8 The Monro–Kellie doctrine states that “an increase in the volume of one intracranial compartment will lead to a rise in intracranial pressure unless it is matched by an equal reduction in the volume of another compartment.” Since the brain parenchyma is relatively incompressible, cerebrospinal fluid and cerebral blood volume play an integral role in accommodating increases in intracranial pressure (ICP).
  - 9 The most commonly used modalities of evoked potential monitoring are somatosensory evoked potentials, motor evoked potentials, and electromyography, with brainstem auditory evoked potentials and visual evoked potentials being less commonly used. Anesthetic drugs play a major role in facilitating the success of intraoperative evoked potential monitoring.
  - 10 Reliable pharmacologic and nonpharmacologic therapies to prevent neuronal ischemic injury are currently not readily available for use in the perioperative period. At the present time, one can only hope to attenuate injury by preventing secondary insults to surrounding neuronal tissue

(e.g., ensuring adequate oxygen and substrate delivery).

- 11 The preoperative evaluation of the neurosurgical patient is of paramount importance to ensure a safe and successful anesthetic. Specific problems must be identified so as to formulate appropriate plans for intraoperative and postoperative management. For patients with intracranial mass lesions, the most important fact to ascertain is the presence and extent of intracranial hypertension and this should be assumed until information proves otherwise. Choice of drugs for maintenance of general anesthesia depends to a great extent on the ICP and whether neuromonitoring is being employed.

## Introduction

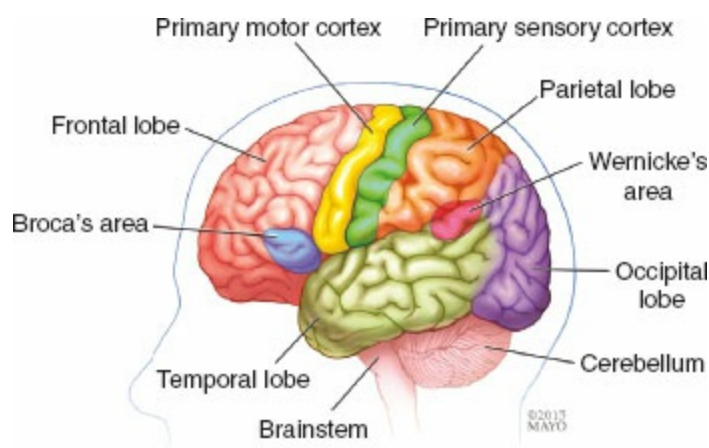

Neuroanesthesia is the practice of perioperative medicine related to the treatment of diseases or injury to the central nervous system (CNS) or peripheral nervous system (PNS). The CNS encompasses the brain and spinal cord, whereas the PNS includes all of the peripheral nerves of the body emanating from the brain and spinal cord. As such, neuroanesthesia is the provision of anesthesia and analgesia for a multitude of procedures, including invasive, minimally invasive, neurodiagnostic, and neurointerventional procedures, and involving the brain, spinal cord, and peripheral nerves.

## Neuroanatomy

The CNS is composed of the brain and the spinal cord. The brain is enclosed by the cranium, a fixed bony cavity, and is physically and functionally divided into two compartments: the supratentorium and the infratentorium (Fig. 37-1). The supratentorium contains the paired cerebral hemispheres and the diencephalon that is composed of the thalamus and hypothalamus. Each cerebral hemisphere is divided into four lobes (frontal, temporal, parietal, and occipital). Eloquent cortical areas are generally considered to be regions responsible for gross motor function and language. The primary somatosensory and motor cortex strips lie adjacent to the central sulcus in the parietal and frontal lobes, respectively, and extend inferiorly to the Sylvian fissure. Cortical regions that are responsible for language are located in the left hemisphere in almost all right-handed people as well as in the majority of left-handed people. The two primary regions responsible for language are Broca area, located in the premotor frontal cortex and responsible for language formation,<sup>1</sup> and Wernicke area, located in the posterior superior temporal cortex and responsible for language acquisition. Lesions in Broca area lead to expressive aphasia whereas those in Wernicke area cause receptive aphasia.

The extrapyramidal system consists of a group of brain structures that modify motor function but are not components of the corticospinal tract and primary motor cortex. These structures include the basal ganglia (comprised of the caudate nucleus, globus pallidus, putamen, substantia nigra, and red nucleus), cerebellum, and components of the auditory and vestibular pathways. Dysfunction of structures in the extrapyramidal system results in difficulty with motor control without frank weakness. This includes Parkinson disease, essential tremor, and ataxia.

The diencephalon lies cephalad to the midbrain and is composed of the thalamus and hypothalamus. The thalamus acts as a sensory and motor “relay station,” functionally and physically connecting the cortex with the rest of the nervous system. The hypothalamus, lying below the thalamus, has autonomic and endocrine functions and is connected to the pituitary gland via the infundibulum.

**Figure 37-1** Gross anatomy of the brain. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

The limbic system consists of a group of structures that play a role in cognitive function, memory consolidation, and emotional responses. Components of the limbic system include, but are not limited to, the hippocampus, amygdala, part of the hypothalamus, and some regions of the cortex (e.g., insular region). The hypothalamus, although generally considered a component of the diencephalon, also functions in the limbic system due to its role in the regulation of autonomic and endocrine function in addition to modulation of behavior and sexual function.

The infratentorium encompasses the brainstem and the cerebellum. The brainstem is comprised of the midbrain, pons, and medulla and is responsible for consciousness *via* the reticular activating system, a variety of autonomic functions including respiratory and cardiovascular control, and many reflexes (e.g., cough/gag, pupillary reflexes). The brainstem contains nuclei for cranial nerves III to XII. The cerebellum, among the most rudimentary parts of the

brain, lies in the posterior fossa and is responsible for such actions as processing proprioceptive input and establishing axial posture and gait.<sup>2</sup>

**1** The brain receives approximately 70% of its blood supply from two internal carotid arteries anteriorly and 30% from two vertebral arteries posteriorly forming the basilar artery, that subsequently converge to form the Circle of Willis, an anastomotic ring at the base of the skull (Fig. 37-2). The common carotid artery, originating from the aortic arch, divides at the level of the thyroid cartilage into the internal and external carotid arteries. The internal carotid artery traverses the skull base through the foramen lacerum and subsequently travels through the cavernous sinus and into the carotid groove. Thereafter, the artery divides into the posterior communicating artery (PCOM), the anterior cerebral artery (ACA), and the middle cerebral artery (MCA).

**Figure 37-2** The circle of Willis, demonstrating the anterior and posterior blood supply to the brain.

The bilateral vertebral arteries originate from the subclavian arteries and converge to form the basilar artery at the pontomedullary junction. When reaching the midbrain (along the ventral surface of the brainstem), the basilar artery divides into the posterior cerebral arteries (PCAs) and also

anastomoses with the PCOMs, thus completing the circle of Willis. Interestingly, less than 50% of people demonstrate a “complete” circle of Willis.<sup>3</sup>

The venous system of the brain consists of both deep and superficial veins that ultimately drain into the dural venous sinuses (Fig. 37-3). These sinuses are valveless endothelialized channels lying between the dura mater and skull periosteum. All of the sinuses eventually drain into the sigmoid sinus and thereafter into the internal jugular veins.

The entire CNS is insulated from its bony encasement by cerebrospinal fluid (CSF) that is produced mostly by the choroid plexus of the lateral and third ventricles (Fig. 37-4). The average volume of CSF in an adult is approximately 150 mL. CSF is created at a rate of 15 to 20 mL/hr and moves from these ventricles via the aqueduct of Sylvius to the fourth ventricle. From there, CSF flows out of the fourth ventricle via the foramen of Magendie and the lateral foramina of Luschka to the subarachnoid space in the cranium. It does so via a series of interconnected cisterns at the base of the brain, to be subsequently reabsorbed into the dural venous sinuses, primarily the superior sagittal sinus, *via* arachnoid villi and granulations.<sup>4</sup> Some CSF traverses the foramen magnum, entering the subarachnoid space within the spinal column. This movement of CSF is important for acute and chronic compensation in elevated ICP states.

**Figure 37-3** Gross anatomy of the venous drainage system of the brain, including the major venous sinuses. (Used with permission of Mayo Foundation for Medical

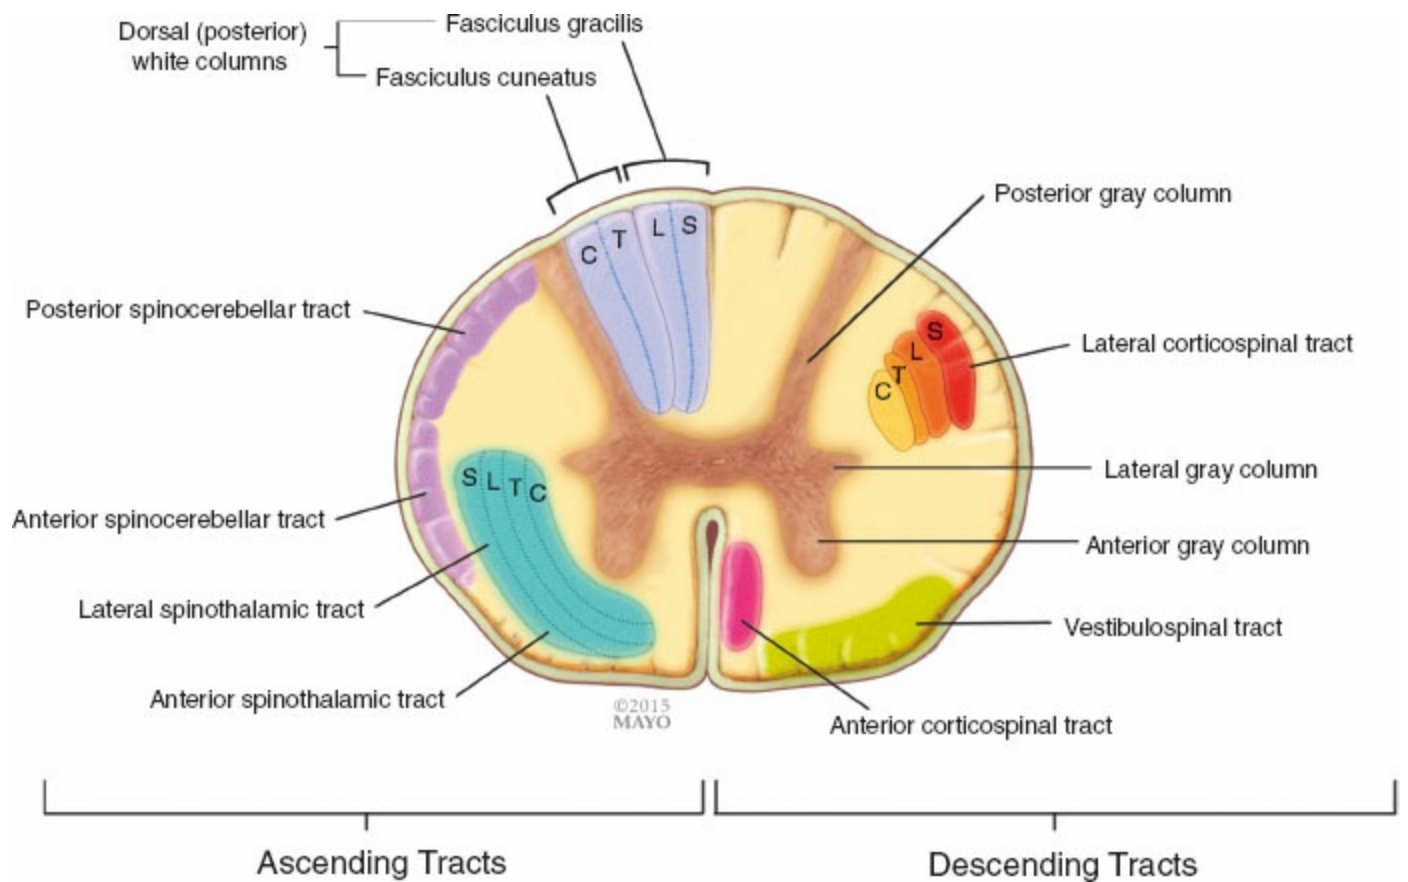

**Figure 37-4** Cerebrospinal fluid compartments within and around the brain. This includes the ventricular system and gross cerebral spinal fluid flow patterns. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

The spinal column is composed of 33 vertebrae (7 cervical, 12 thoracic, 5 lumbar, and 9 fused sacral and coccygeal), with nerve roots leaving the enclosed spinal cord and exiting through corresponding intervertebral foramina. The spinal cord itself is composed of central gray matter, the dorsal columns containing tracts responsible for proprioception and light touch, lateral spinothalamic tracts responsible for pain and temperature, and outer white matter containing the lateral corticospinal tracts (Fig. 37-5). The lateral gray columns contain the cell bodies of the preganglionic neurons that eventually enter the sympathetic chain (running on either side of the vertebral bodies), arising from T1 to L2 or L3. The spinal cord itself terminates at L1 or L2 in adults, ending in structures known as the conus medullaris terminus and filum terminale.

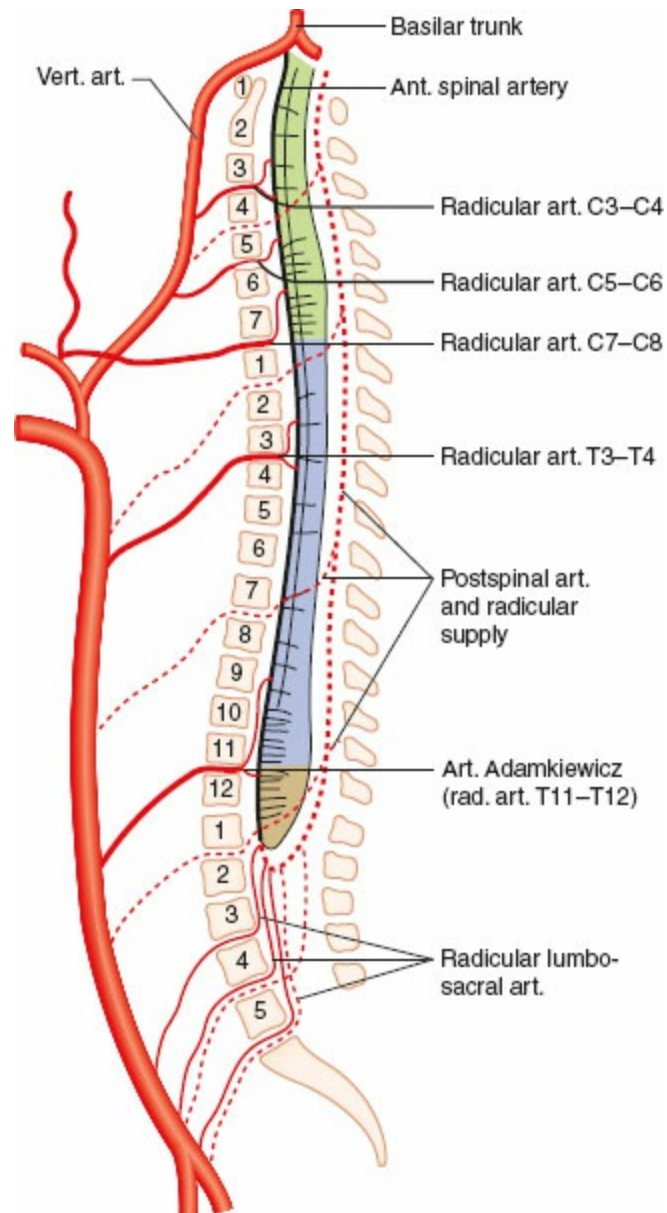

**2** The spinal cord receives its blood supply from one anterior spinal artery and two posterior spinal arteries (Fig. 37-6). The anterior spinal artery originates from six to eight major radicular arteries derived from the aorta, with the largest one being the artery of Adamkiewicz (usually occurring at T11 or T12 and generally supplying T8 to the conus medullaris terminus). Thus, the artery of Adamkiewicz is responsible for supplying arterial blood to the anterior two-thirds of the spinal cord. The posterior

spinal arteries originate from the posterior cerebral circulation and supply the dorsal horns and white matter (posterior third of the spinal cord).<sup>5</sup>

Various regions of the brain and spinal cord responsible for distinct functions are shown in [Table 37-1](#).

## Neurophysiology

Although the adult brain accounts for only 2% of total body weight, it is responsible for 20% of total body oxygen consumption and 25% of total body glucose consumption. The cerebral metabolic rate of oxygen consumption (CMRO<sub>2</sub>) is normally 3 to 3.8 mL/100 g/min and brain glucose consumption is approximately 5 mg/100 g/min. Normal cerebral blood flow (CBF) is 50 mL/100 g/min or 750 mL/min. Therefore, the brain receives about 15% of the cardiac output to meet these high metabolic requirements. The brain depends on a continuous supply of oxygen and glucose, with irreversible injury potentially occurring after only 4 to 5 minutes of global ischemia.<sup>6</sup>

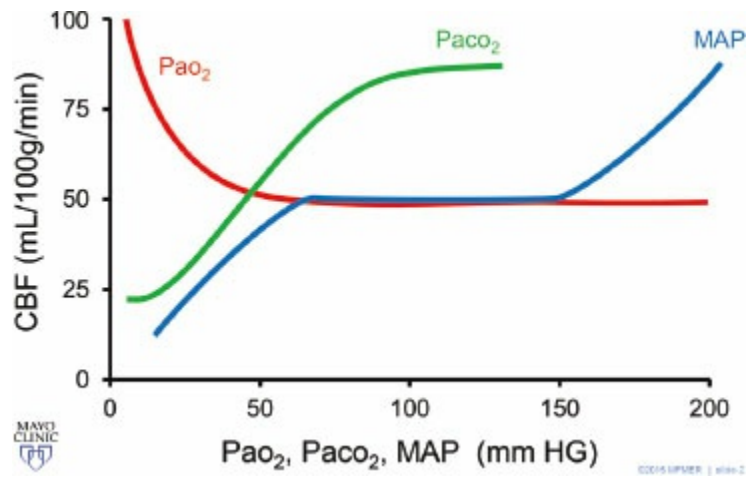

CBF is regulated by “flow-metabolism coupling,” whereby increases in regional neuronal electrical activity require corresponding increases in regional blood flow. Such coupling occurs on the order of seconds, with very

little variation in the amount of oxygen extraction by the brain tissue (i.e., CBF matches CMRO<sub>2</sub> very quickly and efficiently in the healthy brain).<sup>7,8</sup>

CPP is the difference between mean arterial pressure (MAP) and either intracranial pressure (ICP) or central venous pressure (CVP), depending on which is higher. CBF itself is equal to CPP/cerebrovascular resistance (CVR). Fortunately, even moderate changes in MAP (or CPP) will yield a consistent CBF of 50 mL/100 g/min, due to the normal brain's ability to autoregulate its blood flow. Cerebral autoregulation of blood flow is thought to remain intact between a MAP of approximately 60 to 160 mmHg and functions by altering CVR on the order of 5 to 60 seconds (Fig. 37-7). However, the lower limit of autoregulation (LLA) is likely to be not only higher than an MAP of 60 mmHg but also dynamic throughout the day and differs among individuals. In those with otherwise healthy brains, the LLA may be as high as a MAP of 80 mmHg in some individuals.<sup>9</sup> The alteration in CVR is accomplished in both a rapid phase ("dynamic autoregulation") and a slow phase ("static autoregulation").<sup>10</sup> Dynamic autoregulation is thought to respond to pulsatility changes more closely linked to the systolic systemic blood pressure,<sup>11</sup> whereas static autoregulation is a phenomenon that accommodates to changes in MAP over longer time intervals.<sup>12</sup> Above the upper limit of autoregulation and below the LLA, CBF is pressure-dependent. Below the LLA maximal cerebral vasodilation occurs and cerebral ischemia can result. Above the upper limit of autoregulation, cerebral vessels are maximally vasoconstricted and increases in perfusion pressure may lead to disruption of the blood-brain barrier (BBB), cerebral edema, or cerebral hemorrhage.<sup>13</sup>

**Table 37-1** Functionality of CNS Structures

Anatomic Location	Structure	Function
Postcentral gyrus	Primary somatosensory cortex	Sensation
Precentral gyrus	Primary motor cortex	Movement
Occipital lobe	Primary visual cortex	Vision
Temporal lobe	Primary auditory cortex	Hearing
Wernicke area (angular gyrus of dominant hemisphere)	Primary language association cortex	Language
Broca area (frontal lobe of dominant hemisphere)	Primary language expression cortex	Language
Frontal lobe	Primary personality cortex	Personality/Intellect
Temporal lobe	Limbic cortex	Emotion
Temporal lobe	Hippocampus	Memory
Diencephalon	Hypothalamus	Vegetative regulation
Brain stem	Reticular activating system	Consciousness
Brain stem	Vasomotor center	Circulatory/respiratory control
Spinal cord	Dorsal horn (sensory)/ventral horn (motor)	Movement/sensation/reflexes

**Figure 37-7** Autoregulation in the central nervous system: cerebral blood flow (CBF) remains constant between mean arterial pressures (MAP) of approximately 60 to 160 mmHg (*blue*). CBF varies linearly between arterial carbon dioxide partial pressures ( $\text{PaCO}_2$ ) of 20 to 80 mmHg (*green*). Cerebral blood flow remains constant above an arterial oxygen partial pressure ( $\text{PaO}_2$ ) of 50 mmHg (*red*). (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

CVR changes responsible for autoregulation are the result of both myogenic responses in cerebral resistance vessels and neurogenic forces (e.g., sympathetic activation due to chronic hypertension). The autoregulatory curve is shifted rightward in cases of chronic hypertension. Anesthetics, especially the potent volatile anesthetics, have a dose-dependent effect of decreasing the extent of autoregulation.<sup>14</sup>

Besides MAP, other physiologic parameters play an important role in regulating CBF. Arterial carbon dioxide tension ( $\text{PaCO}_2$ ) is the most important of these variables. CBF is linearly associated with  $\text{PaCO}_2$  between 20 and 80 mmHg (Fig. 37-7). Hyper- and hypoventilation, both patient-determined and iatrogenic, play critical roles in decreasing or increasing CBF, respectively. A change in  $\text{PaCO}_2$  of 1 mmHg roughly correlates to a similar change in CBF of 1 to 2 mL/100 g/min. Below the lower limit of this linear effect (i.e., with  $\text{PaCO}_2$  below 20 mmHg), maximal cerebral vasoconstriction leads to tissue hypoxia and a reflex vasodilation. This phenomenon is the basis for spontaneous hyperventilation that develops in response to acutely elevated ICP.<sup>15</sup> This beneficial reflex, however, can be detrimental as low regional CBF and ischemia can occur.<sup>16</sup> Furthermore, the effect of hyperventilation on CBF and ICP is only sustainable for approximately 6 hours, as the pH of the CSF will renormalize.

Oxygen tension in the arterial blood ( $\text{PaO}_2$ ) has minimal effect on CBF unless marked hypoxemia ( $\text{PaO}_2 < 50$  mmHg) occurs, below which CBF increases dramatically (Fig. 37-7). When  $\text{PaO}_2$  is greater than 350 mmHg, slight cerebral vasoconstriction can occur. It is unclear why this reflex occurs, but it may be a method by which the brain protects itself from “oxygen

toxicity” (i.e., oxygen free radical formation).<sup>17</sup> Temperature is also an important determinant of CBF, with a 6% to 7% decrease in CBF per 1°C decrease in core temperature.

Regional CBF is more complex than global CBF (as described earlier) and is governed by both humoral and neurogenic factors. Certain circulating catecholamines and other mediators such as  $\alpha_1$ -adrenergic agonists, ionic calcium, endothelin, and thromboxane A<sub>2</sub> may have cerebral vasoconstrictive effects, whereas other factors such as  $\beta_2$ -adrenergic agonists, nitric oxide, adenosine, and prostaglandins play a role in regional cerebral vasodilation.<sup>18</sup> Neurogenic influences over local regulation of CBF include effects mediated by the release of acetylcholine, dopamine, serotonin, and substance P.<sup>19</sup>

Anesthetics can have profound effects on CBF. Intravenous drugs, **6** such as propofol, etomidate, benzodiazepines, and thiopental, decrease CBF by virtue of a drug-induced decrease in CMRO<sub>2</sub> and subsequent flow-metabolism coupling. Autoregulation and PaCO<sub>2</sub> responsiveness remain intact with these agents.<sup>20</sup> Opioids have very little effect on CMRO<sub>2</sub>, CBF, autoregulation, or PaCO<sub>2</sub> responsiveness. Ketamine is unique in that it increases CBF and CMRO<sub>2</sub>, with little effect on autoregulation or PaCO<sub>2</sub> responsiveness.<sup>21</sup>

Potent volatile anesthetics, such as isoflurane, sevoflurane, and **7** desflurane are direct cerebral vasodilators. However, this direct vasodilation is offset by a drug-induced decrease in CMRO<sub>2</sub>, and via flow-metabolism coupling, an attenuation of the direct effect on CBF. These effects lead to minimal, if any, increase in CBF at lower doses. However, at high doses where maximal suppression of CMRO<sub>2</sub> has occurred are direct vasodilatory effects observed leading to a dose-dependent increase in CBF.<sup>22</sup> Furthermore, autoregulation is inhibited with potent volatile anesthetic drugs in a dose-dependent fashion, although the cerebral vasculature remains responsive to changes in PaCO<sub>2</sub>. Nitrous oxide is a direct cerebral vasodilator and causes minimal effect on CMRO<sub>2</sub>.<sup>23,24</sup> Nitrous oxide may have a variable effect on cerebral autoregulatory capacity leading to preserved autoregulation during propofol anesthesia but further impairment of autoregulation during sevoflurane anesthesia.<sup>25,26</sup>

Spinal cord physiology is very similar to brain physiology in that autoregulation is maintained and spinal cord perfusion pressure (SCPP) = MAP – SSSP (spinal subarachnoid space pressure). The specific effects of different anesthetic drugs on spinal cord physiology are not as well characterized as the effects of these drugs on the brain.

## Pathophysiology

ICP is the pressure within the intracranial cavity, which is a closed vault

containing the brain parenchyma (1,400 mL), CSF (150 mL), and the cerebral blood volume (CBV) (150 mL). The Monro–Kellie doctrine states that “an increase in the volume of one intracranial compartment will lead to a rise in ICP unless it is matched by an equal reduction in the volume of another compartment.”<sup>27</sup> Since the brain parenchyma is relatively incompressible, CSF and CBV play an integral role in accommodating increases in ICP. CSF will tend to egress out of the cranial cavity and into the spinal subarachnoid space, whereas CBV will be decreased by both a reflex arterial vasoconstriction and increased venous efflux from the brain and venous sinuses. Since these compartments are relatively low in volume, their ability to compensate for large increases in ICP is greatly limited. When these compensatory effects are exhausted, a small increase in volume can lead to a dramatic increase in the pressure within the cranium (Fig. 37-8). The results can be neurologically devastating with impaired perfusion and possible herniation of the brain. This can cause irreversible brain injury or even death. Hence, meticulous care in those patients in whom elevated ICP is suspected is critical. This includes avoiding hypoventilation, maintaining adequate CPP, implementing techniques to reduce intracranial volume (i.e., mannitol, CSF diversion, cerebral vasoconstricting anesthetics), and considering decompressive craniectomy.

**Figure 37-8** Intracranial elastance curve. The intracranial elastance curve is composed of three sections. Intracranial pressure (ICP) remains low and relatively constant at low volumes until the “elbow” of the curve is reached. At this point, small changes in volume lead to moderate changes in pressure. When a critical intracranial volume is reached, the pressure increases precipitously. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Normal ICP is 7 to 15 mmHg. Poor neurologic outcome is associated with prolonged ICP above 20 to 25 mmHg.<sup>28</sup> Normal ICP is subject to fluctuation with such activities as the Valsalva maneuver or patient position. Kety and Schmidt demonstrated in 1948 that increases in ICP can lead to CBF

reduction, which led many investigators to question the safe management of elevated ICP in terms of its effects on cerebral ischemia.<sup>29</sup>

 The intracranial elastance curve is quite useful in visualizing the ICP–volume relationship. The initial “flat part of the curve,” where intracranial elastance is low, demonstrates that in nonpathologic brain states, changes in intracranial volume are compensated for quite easily by CSF and CBV buffering. When this compensation is exhausted (“elbow of the curve”) and elastance increases, small increases in volume lead to rapid rises in ICP. Cerebral elastance ( $E = dP/dV$ ) can be estimated with invasive cerebral and spinal monitoring devices (e.g., lumbar drain, extraventricular drain).

Elevated ICP may be caused by a variety of pathophysiologic mechanisms. The most common contributing factor to increased ICP is cerebral edema. Edema in the brain is generally classified into three major types: cytotoxic, vasogenic, and interstitial.<sup>30,31</sup> Cytotoxic edema is characterized by increased *intracellular* water. This commonly occurs in the setting of cerebral ischemia, where failure of membrane ionic pumps leads to accumulation of ions, and thus water, within cells. Vasogenic edema occurs when there is loss of integrity of the BBB, leading to accumulation of extracellular water. Vasogenic edema commonly occurs in regions of brain surrounding tumors, abscesses, or contusions. Dexamethasone is effective at decreasing only vasogenic edema, due in part to its effect at upregulating expression of proteins responsible for the integrity of the tight junctions between endothelial cells in the brain.<sup>32</sup> Interstitial edema is characterized by increased extracellular fluid in the setting of an intact BBB. Interstitial edema occurs in patients with hydrocephalus due to permeation of CSF into the interstitial space and in those with a significant osmotic difference between the brain interstitial space and the intravascular space as occurs in acute hyponatremia. In many circumstances, cerebral edema may be due to a combination of cytotoxic, vasogenic, and interstitial edema.

In addition to edema, there are a variety of other causes that can contribute to intracranial hypertension. Increased CBV, because of either increased arterial inflow or decreased venous efflux, can lead to increases in ICP. Increased arterial inflow is due to cerebral arterial vasodilation from factors such as use of vasodilatory drugs, hypercapnia, severe hypoxemia, or acidosis and decreased venous efflux can be caused by jugular venous obstruction, or elevated pressures within the airways. Likewise, inadequate CSF absorption, due to diminished absorption at the arachnoid villi as may occur with subarachnoid hemorrhage (SAH) or obstructive hydrocephalus as may occur with tumor, can cause hydrocephalus and elevated ICP. Lastly, mass effect from tumors, hematomas, or abscesses can elevate ICP by a direct space-occupying effect.

Clinical symptoms of intracranial hypertension include headache, nausea,

vomiting, and papilledema. As ICP continues to increase, Cushing triad, consisting of hypertension, bradycardia, irregular respiration, may appear. Patients risk brain herniation and death with very severe intracranial hypertension. The signs of herniation will depend on the structures that are herniating and may include pupillary dilation, oculomotor weakness, absent pupillary light reflex, and cardiorespiratory arrest. Radiologically, computed tomography (CT) is most commonly used, and ICP elevation may manifest itself as effacement of sulci, compression of the ventricles, midline shift, or even ventriculomegaly, depending on the etiology.

Acute spinal cord injury is distinctly different from chronic spinal cord injury. Although both may involve loss of sensory, motor, and possibly autonomic function below the level of injury, flaccid paralysis and hypotension are evident in the acute phase whereas spastic paralysis, pain, and possible risk for autonomic hyperreflexia are observed in the chronic phase. Acute spinal cord compression, due to trauma or tumor, is usually a surgical emergency, as time to decompression has been correlated with functional outcome in some populations.<sup>33</sup> The role of steroids in preventing secondary injury is much more controversial.<sup>34</sup> Cervical injuries necessitate extremely careful management of the airway, and these injuries are associated with more physiologic perturbations than lower injuries, including diaphragmatic paralysis, cardiac disturbances, and death.

## Monitoring

### *Central Nervous System Function*

The most important monitor of CNS function is the neurologic examination of an awake and responsive patient. Although some neurosurgical procedures are specifically performed with mild sedation, most are performed in patients who receive general anesthesia. In this latter circumstance, other modes to monitor the integrity of the nervous system may be necessary. Electrophysiologic monitoring techniques are commonly used in the operating room to assess the functional integrity of the nervous system during surgeries that might put neurologic structures at risk. There is some consensus that these monitoring techniques can detect reversible changes in neurologic function in the patient during general anesthesia, allowing a surgical or physiologic change of plan that may avert permanent neurologic injury. However, there is a paucity of definitive data proving that such monitoring will prevent neurologic injury and improve outcomes.

The most commonly used modalities of evoked potential monitoring are somatosensory evoked potentials (SSEPs), motor evoked potentials (MEPs), and electromyography (EMG), with brainstem auditory evoked

potentials (BAEPs) and visual evoked potentials (VEPs) being less commonly used (Fig. 37-9). The peaks and troughs of evoked potential waveforms can be characterized by two parameters: amplitude and latency. Amplitude, measured in microvolts (for SSEPs and BAEPs) or millivolts (for MEPs), refers to the measured signal voltage of a peak relative to a baseline voltage or an adjacent peak. Latency, usually measured in milliseconds, refers to the delay in peak signal following stimulation and reflects transit time along the neural pathway.

**Figure 37-9** Representative brainstem auditory evoked potential (BAEP), somatosensory evoked potential (SSEP), and motor evoked potential (MEP) tracings. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

SSEPs are elicited in a cyclical, repetitive manner from a peripheral nerve (e.g., median, ulnar, posterior tibial) and usually measured at the level of the subcortex (upper cervical spine, inion) and cortex (scalp). Stimuli predominantly travel via the posterior column/medial lemniscus pathway in the CNS. This modality is especially useful for monitoring the integrity of the peripheral nerves, dorsal columns of the spinal cord, the brainstem, the subcortex, and the sensory cortex of the brain. Any insult to this pathway may alter the SSEP response. Since sensory tracts decussate at the brainstem before proceeding through the thalamus and up to the sensory cortex, stimuli are recorded on the contralateral scalp. Notably, SSEPs are inherently small in amplitude, requiring a prolonged stimulation time, signal averaging,

conversion from analog to digital format, and signal filtration to achieve a stable waveform. Therefore, it may take minutes to obtain a waveform. Muscle relaxants may be helpful as they tend to remove artifact caused by spontaneous EMG activity. SSEPs are commonly used during spine surgery, especially when posterolateral sensory elements are at risk of ischemia from surgical distraction.<sup>35</sup> They may also be useful during neurovascular brain surgery to ensure sufficient perfusion to the somatosensory cortex during procedures that may put this cortex at risk, such as cerebral aneurysm clipping.<sup>36</sup> Lower extremity SSEPs tend to correlate with the integrity of cortex supplied by the ACA whereas upper extremity SSEPs tend to correlate with the cortex supplied by the MCA distribution. The commonly used definitions of “significant changes” to the SSEP waveform include a decrease in the amplitude by 50% or an increase in the latency by 10%.<sup>37</sup>

MEPs are produced at the level of the cortex by direct stimulation of the cerebral cortex or by indirect stimulation of the scalp. MEP signals are usually measured as compound muscle action potentials (CMAPs) at the muscular level. MEPs are useful for assessing the motor cortex and the anterolateral spinal cord (containing the corticospinal tracts) during surgeries that may put these structures at risk. Stimulation may be performed magnetically or electrically, with the latter being the more common method. Indirect electrical stimulation of the motor cortex, via scalp electrodes, is performed, usually in a single pulse or train of pulses that travels caudad and depolarizes the upper motor neurons in the spinal cord, summing in the ventral horn. From here, the signal travels to the  $\alpha$ -motor neurons via the internuncial pathways, descending to the motor endplates, where muscle movement related to an action potential can be measured.<sup>38</sup> Unlike SSEPs, MEPs do not require signal averaging or filtration and are produced by a single pulse or train of a few pulses requiring only seconds. Measurement of a response in muscles is severely inhibited by muscle relaxants. MEPs are useful during spine surgery, especially when anterior elements are at risk, and during intracranial surgery during procedures where the motor cortex or descending motor pathway are at risk for injury or ischemia. Although there is no formal definition of “significant changes” that warrant concern for altered neural pathway function, a decrease in amplitude of 50% is considered “significant” as is a need to increase the stimulation intensity required to maintain a reproducible signal. Latency of MEPs has much less of a role in defining a worrisome change than with SSEPs.<sup>39</sup>

EMG is a monitoring modality that is used to continually assess the integrity of distinct peripheral or cranial nerves or nerve roots. Spontaneous neural electrical activity can be monitored or, in stimulated EMG, electrical current can be induced in a nerve and then that signal can be detected as a means to monitor nerve integrity or identify a nerve.<sup>40</sup> EMG is sensitive to

both mechanical and thermal injury. EMG, unlike SSEPs and MEPs, is not a monitor of ischemia. Needle electrodes are placed in a muscle known to be innervated by a particular nerve root, and if that nerve root is disturbed, EMG activity is recorded from that muscle. For example, EMG can be monitored in muscles innervated by spinal nerves during spine surgery or in muscles innervated by cranial nerves during various intracranial procedures that may put cranial nerves at risk, such as during acoustic neuroma resection. In addition, a surgeon may use stimulated EMG to identify cranial nerves during surgery.<sup>41</sup> “Triggered EMG,” as is commonly performed with pedicle screw testing during spine surgery, relies on direct stimulation of the screws being placed within the bony pedicle. If there is disruption of the bony pedicle, and hence contact or near-contact between the screw and neural elements, the amount of current necessary to stimulate the corresponding nerve root will be much less than if the pedicle were intact.<sup>42</sup> Like MEPs, EMG is particularly sensitive to the effects of muscle relaxants.<sup>43</sup>

BAEPs are used to assess the integrity of the auditory canal, tympanic membrane, hair cells, spiral ganglion, vestibulocochlear nerve (cranial nerve VIII), cochlear nuclei, superior olivary complex, lateral lemniscus, inferior colliculus, and medial geniculate thalamic nuclei. A device that produces auditory stimuli (i.e., clicking sounds) is placed in the external auditory canal and responses are recorded from the scalp. Thousands of signals are averaged, yielding a typical waveform consisting of six waves. In general, any injury to CN VIII will affect all of the waves after wave I, decreasing their amplitude and prolonging their latency.<sup>44</sup> Retraction on the cerebellum may prolong the latency of the tracing between waves I and V. BAEPs are often performed during surgery at or near the brainstem such as microvascular decompression of cranial nerves V or VII or for acoustic neuroma resection. Fortunately, BAEPs are extremely robust with little effect from any anesthetic regimen.<sup>45</sup>

VEPs are used to assess the integrity of the visual pathway, including the eye, optic nerve, optic chiasm, and visual cortex in the occipital lobe. A bright stimulus is applied to the eyes using special goggles or contact lenses, and responses are recorded from scalp electrodes. VEPs may be useful during surgery at or near the optic chiasm or the occipital cortex. Unfortunately, VEPs are exquisitely sensitive to almost any anesthetic regimen and the difficulty in the ability to obtain and interpret the signals make them very infrequently used.<sup>46</sup>

### *Influence of Anesthetic Technique on Evoked Potentials*

Anesthetic drugs play a major role in facilitating the success of intraoperative evoked potential monitoring. With regard to cortical SSEPs, potent volatile anesthetics and nitrous oxide have the greatest inhibitory effect causing a

decrease in amplitude and an increase in wave latency. These drugs may limit the acquisition of robust SSEP signals, doing so in a nearly linear dose-dependent fashion. Robust signals can, however, usually be obtained in neurologically intact patients with up to 0.5 MAC of inhaled agent.<sup>47</sup> In neurologically impaired patients, such as those with peripheral neuropathy, total intravenous anesthesia (TIVA) might be required and is commonly performed with a hypnotic (e.g., propofol) and an opioid infusion. Nitrous oxide has more of a depressant effect on signal amplitude rather than latency. Intravenous anesthetics such as propofol tend to have a very limited effect on SSEPs, unless administered in very high doses. Likewise, opioids tend to have a very minimal effect on SSEPs, except with bolus administration, which may decrease amplitudes transiently. Etomidate and ketamine are exceptions in that they actually can increase cortical amplitudes at clinical doses and have been used to enhance SSEP waveforms. Muscle relaxants are generally beneficial for SSEP monitoring as they eliminate myogenic interference. Lastly, it is important to note that these anesthetic effects are much less prominent with regard to subcortical, cervical, and peripheral signal acquisition, as these areas are much more resistant to the inhibitory effects of anesthesia.

MEPs elicited from the scalp are exquisitely sensitive to the effects of anesthesia. Potent volatile anesthetics are greatly inhibitory to the acquisition of MEPs, though doses of 0.5 MAC can still be used. Above this concentration, a nonlinear and greatly accelerated suppression of MEP amplitudes occurs. As with SSEPs, nitrous oxide depresses MEP amplitudes. Intravenous anesthetics are generally conducive to MEP acquisition, except at very high doses. As such, TIVA is commonly employed when MEPs are being monitored. Like SSEPs, ketamine and etomidate may improve MEP amplitudes and lower the electrical threshold required to obtain a response.<sup>48,49</sup> Muscle relaxants must be given very judiciously or avoided completely so as not to abolish the MEP response or prohibitively increase its variability, rendering it difficult to follow over time.<sup>50</sup>

Muscle relaxants can impair or, with deep neuromuscular blockade, abolish, EMG signals. Inhaled and intravenous anesthetics have very little effect on the acquisition of spontaneous or “triggered” EMG. Hence, it is wise to avoid muscle relaxation or reverse the effects of muscle relaxants prior to pedicle screw testing or cranial nerve identification.

BAEPs, as mentioned earlier, are quite robust regardless of the anesthetic regimen being used. Small increases in latency can be seen with deep inhalational or intravenous anesthesia. Notably, cold irrigation fluids at the brainstem will also cause some increases in interwave latencies.

VEPs are the most sensitive neuromonitoring modality with regards to anesthesia. Inhalational-based anesthetics, with and without nitrous oxide, are

more inhibitory to VEPs than TIVA techniques in general. One proposed anesthetic technique for facilitating VEP monitoring might involve an opioid-based TIVA with muscle relaxants and BIS monitoring, although other techniques may be used.<sup>51</sup>

## Cerebral Perfusion

### *Transcranial Doppler Ultrasonography*

Transcranial Doppler Ultrasonography (TCD) is a tool used in neurology, neurosurgery, and neurocritical care. An ultrasound probe is placed over a “window” that is a thinner region of the cranium, such as the temporal bone above the zygomatic arch, to measure blood flow velocities in major cerebral vessels, including the MCA, PCA, and ACA and the basilar artery. The ultrasound probe emits a high-frequency sound wave that reflects off red blood cells and returns to the probe at a different frequency determined by the Doppler Effect. Specifically, the velocity of blood cells relative to the ultrasound probe will cause a change in the frequency of ultrasound waves that are reflected back to the probe. This “Doppler shift” is proportional to the velocity of blood and the sign (positive or negative) of the Doppler shift is determined by direction of blood flow. Positive (increase in frequency) occurs when blood is moving toward the probe and negative (decrease in frequency) occurs when blood is moving away from the probe. Flow velocity that is greater than expected can indicate stenosis, emboli, or vasospasm. It is important to note that TCD cannot determine actual CBF (reported as flow; that is unit volume per unit time). Rather, TCD measure blood flow velocity (in units of m/s). This distinction is significant as decreased arterial diameter will lead to an increased blood flow velocity but a decrease in blood flow volume. However, in other circumstances, such as cerebral autoregulatory failure, increases in CBF velocity occur with increases in CBF. Therefore, thoughtful interpretation of TCD data is required.<sup>52,53</sup> Also, other parameters that can influence CBF and blood flow velocity must be held constant to minimize their effect on the data. These variables include PaCO<sub>2</sub>, systemic blood pressure, angle of insonation, and doses of drugs that can impact cerebral hemodynamics including anesthetics. Most TCD monitors are capable of deriving a variety of parameters in addition to mean flow velocity, including pulsatility of the waveform, which reflects distal CVR—commonly called the *pulsatility index*. TCD is also useful in quantifying the status of both static and dynamic autoregulation, using parameters known as the *index of autoregulation* and the *rate of restoration of flow velocity*, respectively.<sup>54</sup>

### *Laser Doppler Flowmetry*

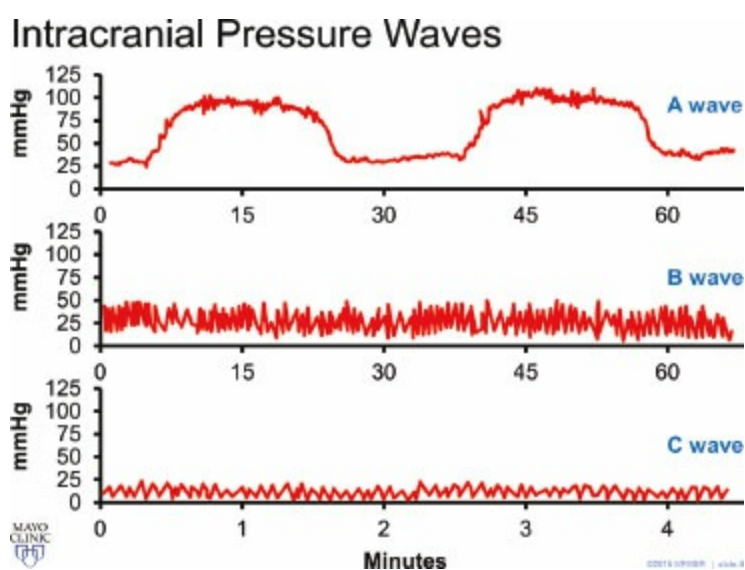

Laser Doppler Flowmetry (LDF) is a relatively new monitoring technology used to quantify blood flow in human tissue such as the brain. LDF employs a very small fiberoptic laser that is 0.5 to 1 mm in diameter and is implanted into the brain. LDF measures the Doppler shift caused by passing red blood cells in microscopic vessels in real-time. Unlike ultrasound that uses sound waves, LDF is based on the Doppler shift in the frequency of light. This signal is then processed to yield the regional CBF. Such measurements are useful in detecting the effects of various physiologic changes, such as anemia and hyperventilation, on CBF. LDF yields measurements of CBF similar to the Xenon ( $^{133}\text{Xe}$ ) washout technique, one of the established gold standard techniques used to determine CBF.<sup>55</sup>

### *Intracranial Pressure Monitoring*

ICP monitoring is a useful tool for patients suffering from any cause of elevated ICP. ICP monitoring is probably most studied in patients with traumatic brain injury (TBI) at risk for intracranial hemorrhage, worsening cerebral edema, and diminished CPP. Normal ICP is 7 to 15 mmHg, and monitoring is generally initiated when ICP is thought to be above 20 mmHg or one is unable to assess for increased ICP by clinical means. ICP greater than 40 mmHg represents severe, life-threatening intracranial hypertension. Knowledge of the ICP alone can be useful but further information about cerebral well-being can be obtained from observing changes in ICP over time. Specifically, the presence of characteristic Lundberg waves can provide valuable information about the state of the brain. There are three, classically described Lundberg waves: A, B, and C (Fig. 37-10). “A waves,” also called plateau waves, occur in the setting of severely exhausted compensatory mechanisms for elevated ICP. ICP increases to 50 to 100 mmHg and remains elevated for minutes. “A waves” occur due to intense vasodilation in response to decreased cerebral perfusion and are always pathologic. “B waves” are elevations in ICP of 20 to 30 mmHg above baseline, occurring once or twice a minute and reflecting changes in vascular tone when CPP is at the LLA. “C waves” are small oscillations occurring four to eight times per minute, where ICP is in the normal range, and reflect systemic changes in vasomotor tone, with little pathologic significance.<sup>56</sup>

Monitoring can be accomplished using a variety of devices, most of which are invasive at this time, with a few notable exceptions (e.g., CT scan, optic nerve sheath diameter).<sup>57</sup> Although invasive modalities allow for actual pressure measurement, they have associated risks (described later). Noninvasive modalities, although associated with fewer risks, rely on surrogate variables to estimate ICP and therefore are prone to inaccuracy. The most commonly used device is a ventriculostomy or external ventricular

drain (EVD) that measures ICP by way of a transducer (zeroed at the external auditory meatus) connected via tubing placed in the lateral ventricle. Currently, this is the gold standard of ICP monitoring. In addition to pressure transduction, a ventriculostomy also allows for drainage of CSF to attenuate elevated ICP and to provide CSF samples for laboratory diagnostic purposes. Also, a ventriculostomy can be used to deliver drugs, such as antibiotics and thrombolytic agents. There are certain disadvantages with EVD monitoring, including difficulty in placement, fluid leaks, clots, and air bubbles, all of which can lead to inaccurate recording. Most notably, infection is a great risk, since the intraventricular drain pierces the meninges and brain parenchyma. CSF sepsis can lead to increased morbidity and mortality in these patients, and aseptic technique in placement of EVDs is of prime importance.<sup>58</sup>

**Figure 37-10** Lundberg A, B, and C wave morphologies. (Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Intraparenchymal devices are also used to measure ICP, though much less frequently. Two such systems currently exist. The first is a microtransducer system attached to a flexible wire, and the second is a fiberoptic system with a pressure transducer at its tip. Both systems require a hollow screw to be inserted in the skull, whereby the wire or fiberoptic cables can traverse the brain parenchyma. These systems are highly accurate (second only to EVDs), are more easily placed than a ventriculostomy, and are associated with fewer infectious and hemorrhagic risks. Unfortunately, these devices are incapable of removing CSF or allowing drugs to be administered into the CSF.

Subarachnoid “bolts” are not commonly used anymore, but remain an alternative to EVDs. These systems rely on a small bolt that is threaded through a burr hole in the skull, with the tip placed 1 mm beneath the dura. The bolt is then attached to a stopcock assembly and transducer. Subarachnoid bolts are capable of diverting CSF, with lower infectious and hemorrhagic

risks than EVDs, but are notoriously inaccurate in measuring ICP; therefore, they are rarely used.<sup>59</sup> Epidural sensor/transducer systems have lower infectious and hemorrhagic risks than EVDs. They are unacceptably inaccurate, however, reflecting only the epidural space and not the entire intracranial compartment.

### *Cerebral Oxygenation and Metabolism Monitors*

Other devices used to monitor the homeostasis of the brain, including its oxygenation and metabolism, are available but may not be commonly employed in the clinical setting. Jugular bulb venous oximetry is the most common of these techniques and involves a fiberoptic catheter placed in a retrograde fashion into the internal jugular vein. The catheter is advanced cephalad beyond the common facial vein and into the jugular bulb that lies at the skull base. Proper placement entails x-ray confirmation of the catheter tip at the level of the mastoid process. This catheter is capable of measuring the mixed cerebral venous oxygen tension ( $SjVO_2$ ) that is indicative of the brain's global oxygen consumption/extraction. Other metabolites that can be measured from this source include lactate and glucose concentrations. Measurement can be accomplished by serial sampling but this method only gives information about the status of the brain at single points in time. Furthermore, extracranial blood may contaminate the sample. More useful perhaps is the continuous fiberoptic measurement of  $SjVO_2$ . High  $SjVO_2$  (80% to 85%) may reflect high oxygen delivery or low  $CMRO_2$  whereas low  $SjVO_2$  usually indicates low oxygen delivery (e.g., low CBF or hypoxemia) or high  $CMRO_2$ .  $SjVO_2$  below 55%, commonly used to define critical jugular bulb desaturation, may be caused by cerebral ischemia in the setting of systemic hypotension or markedly elevated ICP.<sup>60</sup>  $SjVO_2$  may be useful in guiding hyperventilation that results in a reduction in  $SjVO_2$  due to vasoconstriction, with the goal of maintaining the saturation above 55%.<sup>61</sup>

Other monitors used to measure cerebral metabolism include brain tissue oxygen monitors and microdialysis catheters. Brain tissue oxygen monitors measure the partial pressure of oxygen ( $PbtO_2$ ) in a portion of brain interstitium 15 to 20 mm wide, directly and invasively, via a Clark-type electrode.  $PbtO_2$  is normally 25 to 48 mmHg.  $PbtO_2$  values reflect the balance between oxygen supply and demand in the region of brain surrounding the electrode. Factors that affect  $PbtO_2$  include local oxygen delivery, predicted by the fraction of inspired oxygen, cardiac output, hemoglobin concentration, local oxygen extraction,  $PaO_2$ , and CBF. Generally, values below 20 mmHg in pathologic brain states are considered significant and may portend secondary injury to otherwise healthy brain tissue.<sup>62</sup> Indications for brain tissue oxygen monitoring are most commonly TBI and SAH, and experience is growing with

this type of monitoring.

Cerebral microdialysis is becoming more popular in neurocritical care units. A filamentous catheter is placed into the brain parenchyma, consisting of outer and inner tubes and a semipermeable membrane at its tip. A pump is used to perfuse the inner catheter with a crystalloid solution that is iso-osmolar with CSF. At the tip of the catheter, metabolites in the extracellular fluid are driven by a concentration gradient into the outer tubing and are eventually collected into a microvial. This solution is then analyzed for its metabolite contents and their concentrations, including glucose, pyruvate, lactate, glutamate, and glycerol. Clinical correlation, with attention to the location of the catheter tip and comparison of values over time, is required. Although glucose, pyruvate, and lactate concentrations are measures of adequate aerobic metabolism, glutamate and glycerol levels represent ischemic neuronal stress and cell membrane degradation, respectively.<sup>63</sup> Indeed, one of the major limitations of cerebral microdialysis as well as brain tissue oxygen monitors is that findings will depend on the location of measurement. For example, measurement of values obtained from regions of brain remote from the site of brain injury might indicate minimal, if any, abnormality. Therefore, microdialysis and measurement of oxygen partial pressure is best obtained from locations where “at risk” brain exists.

Lastly, cerebral oximetry has become more prevalent in the clinical setting recently. This technology involves a noninvasive, transcutaneous, measurement of regional cerebral blood oxygenation (rSO<sub>2</sub>) over the frontal cortices bilaterally. Oxygenation is given as a percentage of maximum hemoglobin saturation. This reflects the contribution of both arterial and venous blood. A decrease of at least 20% from baseline values is considered significant hypoxia, though definitive data in this regard do not exist.<sup>64</sup> Mechanistically, light from the probe placed on the forehead is transmitted through the skull. Hemoglobin oxygen saturation is determined by the ratio of the absorbances of two or more different wavelengths of light allowing for the determination of oxyhemoglobin and deoxyhemoglobin. This technology differs from pulse oximetry in that it uses two photodetectors, thereby allowing for subtraction of the absorbance from hemoglobin in the scalp and skull. Specifically, near-field photodetection is subtracted from far-field photodetection, yielding a value of brain tissue oxygenation. Cerebral oximetry also differs from pulse oximetry in that it does not rely on pulsatile blood flow. Regional estimates of cerebral oxygenation in the frontal cerebral cortices provide a sensitive method of detecting changes in oxygen delivery due to the very limited oxygen reserve of this highly metabolic area. Factors that may play a role in averting long-term injury based on low cerebral oximetry values include increasing systemic blood pressure, increasing cardiac output, increasing oxygen delivery (FiO<sub>2</sub>), increasing PaCO<sub>2</sub> to ameliorate

cerebral vasoconstriction, or red blood cell transfusion to increase oxygen-carrying capacity and delivery.<sup>65</sup>

## Cerebral Protection

### *Ischemic and Reperfusion*

Because of its high rate of oxygen and glucose consumption, inability to store substrate, and inability to dispose of toxic metabolites quickly, the brain is especially susceptible to rapid ischemic injury. With the accumulation of intracellular calcium ( $\text{Ca}^{2+}$ ) under ischemic conditions, neuronal damage quickly occurs and is compounded by the accumulation of lactic acid.<sup>66</sup> Global ischemia, as can occur during severe hypotension and severe anemia, may be responsive to interventions that restore total cerebral perfusion and oxygen-carrying capacity, such as cardiopulmonary resuscitation (CPR) or red blood cell transfusion. Focal ischemia occurs due to a regional insult such as an embolus or arterial disruption. Treatment of focal ischemia must be focused on restoring perfusion to the region in question. In cases of focal ischemia, a penumbra of salvageable tissue usually surrounds a necrotic core of dead parenchyma. Efforts must also be directed at restoring oxygen and substrate delivery to the ischemic penumbra that is being supplied by some collateral circulation. Much of the research being performed in cerebral protection today deals with this concept of “saving the penumbra,” and practical methods include augmentation of CPP and reducing brain edema in the acute setting (see later).<sup>67</sup> Another area under study is that of reperfusion and “reperfusion injury.” Specifically, reperfusion of previously ischemic brain tissue can actually worsen neurologic outcome largely due to the production of free radicals derived from oxygen and mediators of inflammation and exacerbation of injury of the microvasculature upon restoration of flow.<sup>68,69</sup>

### *Hypothermia*

Induced systemic hypothermia has been regarded as a potentially beneficial intervention in certain subgroups of the neurologically injured population, though definitive human studies regarding its consistent efficacy have been lacking. Theoretically, hypothermia should be extremely protective to the brain and spinal cord from a metabolic standpoint, as it lowers the  $\text{CMRO}_2$  of the CNS to a much greater extent than anesthetics are capable of doing. Although anesthetics can cause an isoelectric EEG, reducing the brain’s metabolic activity by up to 60%, hypothermia can do far more by reducing even the brain’s homeostatic need for oxygen, required for basic neuronal survival. Animal models have shown that cerebral protection is possible with

even a decrease of 1°C in core temperature, demonstrating that the possible protective effects of hypothermia on the CNS are not simply a result of decreased metabolism, but rather may involve other mechanisms as well.<sup>70</sup>

The use of hypothermia in patients with global ischemia may be promising. Profound hypothermia in humans (27°C), as is currently used for cold-cardiopulmonary bypass, and deep hypothermia (12°C to 18°C) used during circulatory arrest, have been shown to provide cerebral protection.<sup>71</sup> When adults who have sustained an out-of-hospital cardiac arrest and return of spontaneous circulation, are cooled to 32°C to 34°C for 12 to 24 hours, neurologic outcome may be improved.<sup>72</sup> Clinical improvement has also been seen in neonates with hypoxic-ischemic encephalopathy treated with mild hypothermia within 6 hours of delivery.<sup>73</sup>

The use of hypothermia in those with focal ischemia is less promising. The Intraoperative Hypothermia for Aneurysm Surgery Trial (IHAST) demonstrated no improvement in neurologic outcome but higher rates of infectious complications in patients who had cerebral aneurysm clipping with mild total-body hypothermia compared to those that had normothermic management.<sup>74</sup> Data involving TBI patients and mild hypothermia have yielded mixed results, with “short-term” cooling (24 to 48 hours) showing little benefit, whereas “long-term” cooling for up to 5 days showing some promise.<sup>75</sup>

What is clearly known in both humans and animals is that cerebral hyperthermia is detrimental, with focal cerebral ischemic infarct size in animals tripling for each 1°C rise in core temperature.<sup>76</sup> Hyperthermia must be avoided in the setting of cerebral ischemia.

### *Pharmacologic Therapy for Cerebral Protection*

As with induced hypothermia, there is promise for cerebral protection in the setting of neuronal ischemia by both anesthetic and nonanesthetic drugs. However, most of this data comes from animal stroke models and not definitive human studies. Anesthetics may mitigate the effects of CNS ischemia both by their reduction on CMRO<sub>2</sub> as well as by other molecular mechanisms. Volatile anesthetics may reduce ischemia-induced glutamate release, increase the availability of antiapoptotic mediators, activate ATP-dependent potassium channels, reduce excitotoxic stressors, and augment CBF.<sup>77,78</sup> Likewise, barbiturates (of proven benefit in focal ischemia in animal studies),<sup>79</sup> nitrous oxide, propofol, etomidate, ketamine, and lidocaine have been associated with beneficial effects on cerebral ischemia in animal and preclinical studies.<sup>80,81</sup>

Nonanesthetic agents, too, have been the focus of many studies for their possible neuroprotective effects. Calcium-channel blockers, by inhibiting the

effects of voltage-gated calcium channels, have been investigated, although they do not seem clinically useful for this indication.<sup>82</sup> Likewise, magnesium has been investigated as a possible neuroprotective agent, by virtue of its antagonistic effect on various voltage-gated and transmitter-activated channels, though so far human clinical studies are disappointing.<sup>83</sup>

Other agents, such as free radical scavengers (e.g., tirilazad,  $\alpha$ -tocopherol, NXY-059),<sup>84</sup> amino acid modulators (e.g., gavestinel),<sup>85</sup> erythropoietin (activates antiapoptotic pathways and decreases inflammation),<sup>86</sup> and most recently statins for their upregulation of nitric oxide synthase and both anti-inflammatory and antioxidative effects are currently under investigation. Interestingly, patients treated with statins for 1 to 6 months, without cardiac disease, showed a 16% reduction in stroke risk in a recent human study, though other human data demonstrate no protective effect, or even a deleterious effect, on patients having already suffered a hemorrhagic stroke.<sup>87</sup> Despite ongoing, and often promising, work in this field, it is important to note that a single and definitive neuroprotective agent in human clinical studies has never been identified.

### *Glucose and Cerebral Ischemia*

As mentioned earlier, ischemia is rapidly detrimental to the nervous system not only because of oxygen starvation but also because glucose is the only substrate that can be aerobically metabolized by the brain under normal conditions. Glucose is not stored in the nervous system, so when glucose is reduced or absent due to limited cerebral circulation, adenosine triphosphate (ATP) is no longer produced at a rate that supplies the energy requirement of neurons and cellular injury quickly ensues. Cerebral glucose consumption (5 mg/100 g/min) parallels CMRO<sub>2</sub>, so hypoxemia and hypoglycemia are roughly equally detrimental to the brain. With cerebral ischemia and hypoglycemia, lactate is metabolized to some extent in the brain, but with much less efficacy than glucose.<sup>88</sup> Hyperglycemia (serum blood glucose over 180 mg/dL) in the setting of cerebral ischemia has also been shown to worsen neurologic outcomes, presumably by worsening cerebral acidosis in an anaerobic setting, in which glucose is converted to lactic acid.<sup>89,90</sup>

### *A Practical Approach*

Reliable pharmacologic and nonpharmacologic therapies to prevent neuronal ischemic injury are currently not readily available for use in the perioperative period. One can only hope to attenuate injury. With some exceptions, inhaled and intravenous anesthetics may protect the brain from ischemic injury. For surgeries in which there is planned regional ischemia,

such as temporary clipping of cerebral vessels during aneurysm surgery, propofol given in a large bolus (1 to 2 mg/kg) followed by a high-dose infusion (150 µg/kg/min) is often used and titrated to induce burst-suppression *prior* to the planned ischemia. In cardiac or neurologic surgeries in which circulatory and pulmonary arrest is planned, such as aortic arch repair or giant basilar aneurysm clipping, deep hypothermia (12°C to 18°C) can be instituted to protect the nervous system. Another example of practical neurologic protection involves the placement of a lumbar CSF drain prior to thoracoabdominal aortic aneurysm repair. This technique is used to lower CSF pressure and ostensibly maintain spinal cord perfusion when radicular arteries originating from the aorta are at surgical risk.

## Anesthetic Management

### *Preoperative Evaluation*

The preoperative evaluation of the neurosurgical patient is of paramount **11** importance to ensure a safe and successful anesthetic. Specific problems must be identified so as to formulate appropriate plans for intraoperative and postoperative management. For patients with intracranial mass lesions, the most important fact to ascertain is the presence and extent of intracranial hypertension and this should be assumed until information proves otherwise. This information can be obtained most readily from the history and physical examination, CT and magnetic resonance imaging (MRI) scans, and ICP measurements, if available. Patients with elevated ICP may complain of headaches, dizziness, visual or gait disturbances, nausea or vomiting, and seizures. On physical examination, such patients may exhibit abnormalities such as altered level of consciousness, confusion, papilledema, loss of strength or sensation, and cranial nerve dysfunction. Radiologic studies are generally most helpful in quantifying the degree of ICP derangement with “slit ventricles,” or a shift of midline brain structure of more than 5 mm indicating advanced pathology.<sup>91</sup> As part of a preoperative evaluation of the neurosurgical patient, findings on routine blood tests can also prove useful. A careful evaluation of laboratory values may demonstrate electrolyte disturbances, which can be due to pituitary pathology (e.g., syndrome of inappropriate antidiuretic hormone secretion [SIADH]), diuretics, steroids, or anticonvulsants being taken by the patient.

In patients with elevated ICP, premedication must be carefully titrated, or avoided completely. Benzodiazepines and opioids, even in small doses, can depress respiration, leading to elevated PaCO<sub>2</sub> and subsequent exacerbation of intracranial hypertension. Corticosteroids, such as dexamethasone, and anticonvulsants should be continued preoperatively.<sup>92</sup>

Preoperative evaluation of patients presenting for spine surgery, especially in the acute setting, should focus on the airway examination, current hemodynamic conditions, the level of injury, the degree of injury (complete versus incomplete), the timing of injury (i.e., less than 8 hours or 8 hours or more), and the complete neurologic examination. Carefully planning for endotracheal intubation and subsequent hemodynamic management of these patients is vital, as advanced airway techniques and critical fluid management with concomitant vasopressor use may be required.

### ***Induction of Anesthesia and Airway Management***

Induction of general anesthesia and airway management are critically important periods, especially in those patients who have elevated ICP, an unsecured aneurysm, or cervical spinal cord injury. Constant attention to hemodynamics is critical in patients with elevated ICP in order to maintain CPP. To that end, the induction of general anesthesia in patients with elevated ICP should be “slow and controlled,” with constant attention to the blood pressure throughout the process.<sup>93</sup> In many cases, preinduction arterial catheterization, osmotic diuresis, or CSF drainage may be helpful. Hypotension must be avoided. Patients with elevated ICP may receive a short-acting opioid and lidocaine (1.5 mg/kg) intravenously to blunt the sympathetic response to laryngoscopy. Also, hypoventilation and hypercapnia should be avoided. Following induction of anesthesia, a muscle relaxant should be administered. Succinylcholine should be used with caution in patients with pre-existing motor deficits as upregulation of nicotinic receptors at the neuromuscular junction can lead to increased risk of hyperkalemia. Also, succinylcholine can increase ICP but this effect is of short duration.<sup>94</sup> During intubation, strict control of blood pressure is important, as a rapid increase in arterial blood pressure will worsen ICP, especially in patients with autoregulatory failure, or put an unsecured aneurysm at risk of rupture. Hypotension and decreased CPP can also be detrimental. In the case of a cervical spinal cord injury, maintenance of MAP is very important during induction of anesthesia, whereas the actual performance of intubation may require more complex techniques (e.g., awake fiberoptic intubation, midline and sagittal stabilization) to ensure that the spinal cord is not further compromised.

### ***Maintenance of Anesthesia***

The maintenance of general anesthesia in neurosurgical patients requires regimens that vary depending on the hemodynamic and monitoring goals for that procedure. For intracranial surgeries, ICP control is paramount until the

**2** dura mater is opened. To this end, once Mayfield fixation of the head and positioning are safely completed, mannitol (0.5 to 1.5 g/kg) may be administered if ICP control is needed, as are steroids (e.g., dexamethasone 10 mg) and, in some cases, a prophylactic anticonvulsant. Choice of drugs for maintenance of general anesthesia depends to a great extent on the ICP and whether neuromonitoring is being employed. For patients with elevated ICP, volatile anesthetics are often limited to 0.5 MAC, if used at all, to minimize the degree of cerebral vasodilation and inhibition of autoregulation that can result. Anesthesia is either maintained or supplemented with intravenous drug infusions such as propofol with or without a short-acting opioid such as remifentanyl or sufentanyl. This regimen works well in neuromonitoring cases as well, where more than 0.5 MAC of volatile agent may interfere with SSEP and MEP monitoring. Muscle relaxants are generally used, unless limited by MEP or EMG monitoring, and nitrous oxide may be considered in select neurosurgical cases. Because of its mild vasodilating effects, potential for expanding pneumocephalus, and unfavorable effects on neuromonitoring, N<sub>2</sub>O should be avoided in cases where the patient has significantly increased ICP, the potential for intradural air, or where it will interfere with monitoring modalities. In the absence of muscle relaxant, immobility can be achieved with remifentanyl infusions approaching 0.2 µg/kg/min.<sup>95</sup> Throughout the procedure, CPP must be maintained, possibly requiring a vasopressor. If autoregulation is greatly inhibited due to the disease process or the anesthetic drugs, CBF will be directly dependent on MAP, thus hypertension should be avoided. In cases of acute spinal cord injury, many of the same principles apply in regards to maintenance of anesthesia, as spinal cord perfusion (especially in cervical spine surgery) and the ability to perform neuromonitoring are of great concern.

### **Ventilation Management**

Ventilatory management of patients undergoing neurosurgery is also a key consideration. For patients undergoing an intracranial procedure, tidal volume should be maintained at 6 to 8 mL/kg to minimize potential inflammatory injury to the lungs, with peak pressures kept at less than 40 cmH<sub>2</sub>O.<sup>96</sup> These principles hold especially true for patients with SAH or TBI, who may already exhibit acute lung injury (ALI) or adult respiratory distress syndrome (ARDS). Positive end-expiratory pressure (PEEP) should be avoided unless needed to improve oxygenation, as it increases intrathoracic pressure and may impede cerebral venous drainage.<sup>97</sup> Positive pressure ventilation (PPV) is generally used for neurosurgical procedures, as it allows direct control of PaCO<sub>2</sub>, and is especially beneficial during sitting craniotomies, where negative intrathoracic pressure may contribute to the development of venous air embolism (VAE).

## Fluids and Electrolytes

For many years, the teaching of fluid maintenance during craniotomy was to keep the patient “dry,” so as to minimize the amount of reactive cerebral edema both during the surgery and postoperatively. This strategy is generally not considered optimal, as the primary goal of fluid management in neurosurgical cases should be to maintain cerebral perfusion, which is a more important consideration and will actually lessen the amount of cerebral edema produced.<sup>98</sup> Hence, the goal of fluid management should be to keep the patient euvolemic. Isotonic or slightly hypertonic solutions (e.g., 0.9% sodium chloride) should be used if large amounts of fluid are to be administered. Hypotonic solutions, such as Ringer lactate, when administered in large amounts, can contribute to cerebral edema. Glucose-containing solutions are avoided, as hyperglycemia is detrimental to cerebral metabolism (see section Glucose and Cerebral Ischemia), and because glucose is quickly metabolized and not osmotically active, leaving free water that can worsen brain edema.

Depending on patient comorbidities and length of the surgery, electrolyte derangements may be common and require close monitoring. Certainly, patients with SIADH, diabetes insipidus (DI), or cerebral salt wasting syndrome, will require careful monitoring of electrolytes. Hypertonic saline (3%) supplementation (given slowly at a rate of 50 to 100 mL/hr, and with the serum sodium level checked hourly) may be required in moderate to severe hyponatremic states.<sup>99</sup> Rapid rises in serum sodium (more than 3 to 4 mEq/L/hr) must be avoided as this poses a risk for central pontine myelinolysis.<sup>100</sup> In patients with DI, hypotonic solutions such as Ringer lactate or 0.45% sodium chloride might be required and their administration should be carefully titrated based on volume status and serum electrolyte concentrations. Mannitol, especially at large doses, can cause mild electrolyte derangements which are generally short-lived (e.g., hyponatremia, hyperkalemia), and these should be monitored and possibly corrected. Also, diuresis from mannitol can result in dehydration that can impair cerebral perfusion.<sup>101</sup> Sodium chloride solution (0.9%), given in large amounts, can cause hyperchloremic metabolic acidosis and subsequent acute kidney injury due to renal tubular acidosis.<sup>102</sup>

## Transfusion Therapy

The transfusion of blood products may be required perioperatively in patients having neurosurgical procedures. Preoperatively, coagulation studies, if available, should be carefully noted and are required in patients receiving anticoagulants.<sup>103</sup> Preoperative coagulopathies should be corrected as

intraoperative or postoperative bleeding can have a significantly adverse impact on outcome. Neurosurgical patients having nonurgent surgery should have a platelet count over 100,000/mm<sup>3</sup>. For patients having craniotomy for indications that would be at low risk for intraoperative bleeding, a “type and screen” with a negative antibody screen may be adequate. Red blood cells that are “typed and crossed” should be available for procedures with high risk for bleeding such as neurovascular procedures (e.g., aneurysm clipping, arteriovenous malformation [AVM] resection) or tumor craniotomies that invade the cranial sinuses. For coagulopathies that may develop with the release of brain tissue thromboplastin, fresh frozen plasma, platelets, and cryoprecipitate may be needed. Complex spine surgery (especially with planned osteotomies or due to tumor) is usually associated with more profound blood loss, volume shifts, and the need for transfusion therapy. In these cases, multiple units of blood products should be immediately available and close, repetitive monitoring of the complete blood count (CBC) and coagulation studies should be performed.<sup>104</sup>

### *Glucose Management*

As discussed earlier, glucose management is very important in neurosurgical cases for the prevention of both hypo- and hyperglycemia. In 2001, van den Berghe et al.<sup>105</sup> showed that strict glycemic control (i.e., target serum glucose concentration of 80 to 110 mg/dL) in critically ill surgical patients was associated with improved outcome. In recent years, however, strict glycemic control has been associated with increased risk for hypoglycemia that can be detrimental to the brain.<sup>106,107</sup> To reduce the risk of both hypoglycemia and excessive hyperglycemia, most authors agree that serum glucose during neurosurgical procedures should be maintained in the 90- to 180-mg/dL range. For hyperglycemia exceeding this range, short-acting insulin should be readily available and can be given intravenously as a bolus with or without an infusion. In these cases, monitoring of serum glucose must be frequent enough to capture episodes of hypoglycemia.<sup>108</sup> In cases of hypoglycemia, 50% dextrose should be available, and 20 to 50 mL of this solution is administered with further titration based on continued close monitoring of serum glucose concentration.

### *Emergence*

Emergence from general anesthesia following neurosurgical procedures requires meticulous attention to hemodynamic and ventilatory parameters, while also ensuring a prompt neurologic examination. Postcraniotomy hypertension is a well-described, albeit poorly understood, phenomenon, but

can certainly be detrimental as it may increase bleeding from the surgical site and worsen cerebral edema.<sup>109,110</sup> Careful analgesia (so as not to obtund the patient postoperatively) is helpful to minimize risk for hypertension, but usually antihypertensive medications are required. These can include labetalol, esmolol, nicardipine, or clevidipine. Control of hypertension is especially important for patients emerging from cerebral AVM resection, as bleeding from the resection bed may be very significant. In patients having undergone posterior fossa surgery, and those in whom a pre-existing ventilatory disturbance was present due to brainstem compromise, emergence may be much slower and the time to safe extubation much more prolonged.<sup>111</sup> Coughing on emergence for all patients should be avoided due to the risk of bleeding and elevation in ICP, and a low-dose remifentanyl infusion or either intravenous or intratracheal lidocaine may be helpful in this regard. Likewise, postoperative nausea and vomiting should be prophylactically treated in these cases for the same reasons.<sup>112</sup> Dexamethasone used for this indication should be avoided in patients in whom the diagnosis of lymphoma is being considered (or at least delayed until an adequate pathology specimen is obtained), as steroids can cause tumor lysis of lymphoma and potentially interfere with diagnosis. Also, dexamethasone should also be avoided following pituitary surgery as it can suppress the hypothalamic–pituitary–adrenal axis and significantly increase the false positive rate for diagnosis of postoperative hypopituitarism.<sup>113</sup>

## Common Surgical Procedures

### *Surgery for Tumors*

One of the most common indications for neurosurgery is the removal of  both benign and malignant tumors that emanate from or spread to the CNS or PNS. In adults, supratentorial lesions are more common and include tumors derived from support cells in the CNS (e.g., gliomas, astrocytomas, oligodendrogliomas), meningiomas, or metastases. The most common metastatic tumors to the brain include melanoma or those that originate in the lung, breast, or kidney. Infratentorial tumors in the posterior fossa are more common in children and include medulloblastoma, pilocytic astrocytoma, ependymoma, and brainstem glioma.<sup>114</sup>

Independent of their histology, the morbidity of brain tumors is associated with their size, rate of growth, and proximity to and invasion of nearby structures. Furthermore, glial disruption of the BBB may cause significant vasogenic edema, which may persist even after tumor resection, and autoregulation is usually impaired in parenchyma surrounding tumors.<sup>115</sup> Fortunately, most brain tumors grow slowly, allowing adaptive and

compensatory mechanisms to accommodate increases in ICP due to edema or mass effect. Unfortunately, this same fact often leads to delayed diagnosis.

The anesthetic management of these patients must take all of these factors into account, as patients with dangerously elevated ICP preoperatively must be treated with great caution, sometimes requiring preoperative CSF diversion and dexamethasone. Surgery for intracranial tumors can be safely accomplished with a careful preoperative evaluation and a smooth induction, maintenance, and emergence regimen. Preoperative assessment should include an understanding of the lesion site and dimensions, plan for surgical approach, neurologic symptomatology, ICP concerns, and medical comorbidities. Anxiolysis with benzodiazepines must be carefully considered, as even small increases in PaCO<sub>2</sub> in otherwise asymptomatic patients can quickly lead to dangerously elevated ICP due to increased intracranial elastance. Steroids and anticonvulsants should be continued, and in many cases supplemented, prior to and during craniotomy. Hemodynamic instability during any part of the anesthetic should be minimized due to the possibility of impaired autoregulation in peritumoral brain parenchyma. Hypertension can increase the risk of bleeding and exacerbate brain edema. Generally, propofol is administered for induction of general anesthesia. Lidocaine (1 to 1.5 mg/kg) and fentanyl (1 to 2 µg/kg) may be given intravenously to blunt the hemodynamic and ICP response to laryngoscopy. Adequate vascular access (usually two large-bore peripheral intravenous catheters, and arterial catheter, and possibly a central venous catheter) is mandatory for brain tumor resection. ICP and CPP are of great concern throughout these procedures, and an arterial catheter is very helpful to monitor CPP closely while also allowing the titration of PaCO<sub>2</sub> by revealing its gradient with end-expired CO<sub>2</sub> via arterial blood gas measurement.<sup>116</sup> After vascular access is established and any neuromonitoring modalities are applied, the Mayfield pins are usually applied to the skull. The hemodynamic response is similar to laryngoscopy, and optimal control of blood pressure must again be sought, often by using propofol, opioids, or short-acting β-adrenergic antagonists such as esmolol.

Excessive flexion, extension, or rotation of the neck may impair cerebral venous drainage via compression of the internal jugular veins. A head-up position is also favorable to promote venous drainage. PEEP should be avoided, or used cautiously, as this may also impair venous drainage, although if oxygenation is impaired, a PEEP up to 10 cm H<sub>2</sub>O can be considered. In patients with large tumors or known significant intracranial hypertension, efforts should be made to decrease brain volume for optimal surgical exposure and to minimize retractor-related edema. This can include mild hyperventilation and use of mannitol (0.5 to 1.5 g/kg) or hypertonic saline (3% starting at 50 to 100 mL/hr with hourly sodium surveillance).<sup>117</sup> Mannitol should be given as a bolus to achieve its full effect, although great

care should be taken in patients with congestive heart failure, pulmonary edema, or renal failure as the initial elevation in central circulatory volume may be detrimental in these patients prior to the diuretic phase.<sup>118</sup> For maintenance of general anesthesia, the choice of anesthetics is heavily dictated by avoiding increases in ICP (at least until the dura is open), maintaining CPP, neuromonitoring requirements, and ensuring a rapid emergence. Short-acting and easily titratable drugs are generally preferred. These include propofol, remifentanyl, sevoflurane, desflurane, and possibly nitrous oxide unless otherwise contraindicated. Muscle relaxants are beneficial if not precluded by neuromonitoring. Fluid maintenance should be accomplished with dextrose-free iso-osmolar crystalloids or colloids, with the goal of euvolemia (see earlier).

Patients who demonstrated a normal level of consciousness (Glasgow Coma Score [GCS] of 13 to 15) preoperatively are generally extubated at the conclusion of the case, and as with induction, hemodynamic stability is paramount during this period. Aberrations in blood pressure, usually systemic hypertension, can lead to worsening cerebral edema or tumor resection bed bleeding postoperatively, and short-acting and easily titratable drugs, such as labetalol, nicardipine, or esmolol should be immediately available. Coughing at extubation, and vomiting after extubation, which may both worsen ICP, can be minimized with careful opioid titration and a prophylactic antiemetic. Adequate analgesia must be ensured as well, as craniotomy is painful and inadequate analgesia can worsen systemic hypertension. At the same time, avoiding analgesic doses which may obtund the patient and preclude a careful neurologic assessment is vitally important. In this regard, the use of short-acting opioids (i.e., remifentanyl, fentanyl), local anesthetic infiltration, intravenous acetaminophen, or dexmedetomidine can be considered.<sup>119-122</sup>

Infratentorial tumors and tumors of the posterior fossa, due to their proximity to the brainstem, may be associated with more hemodynamic perturbations intraoperatively and postoperatively, as well as changes in respiratory control and arousal levels postoperatively. These patients may more frequently require postoperative intubation and mechanical ventilation, due to altered levels of consciousness and delayed emergence.

In adults, tumors of the posterior fossa include acoustic neuromas, metastases, meningiomas, and hemangioblastomas. These tumors, because of their proximity to the brainstem and cranial nerves, can cause altered respiratory patterns, cardiac dysrhythmias, or cranial nerve dysfunction. Surgery for these tumors can be performed in the prone, lateral, or sitting positions, and may require specific cranial nerve monitoring, such as EMG or BAERs of cranial nerves. The sitting position requires special attention, as the risk of VAE is increased. VAE occurs when the operative site is above the level of the right atrium in the presence of open, noncollapsible venous

channels. VAE occurs in 30% to 75% of all sitting posterior fossa surgery, but is usually hemodynamically insignificant. It is estimated that 8% to 15% of episodes of VAE cause significant hemodynamic change.<sup>123,124</sup> When air is entrained into the heart and pulmonary circulation, it can lead to impaired gas exchange, intrapulmonary shunting, hypoxemia, and a concomitant decrease in end-expired CO<sub>2</sub>. If air entrainment becomes severe, arrhythmias, decreased cardiac output, severe pulmonary hypertension, and hemodynamic collapse can result. Monitoring for VAE in the sitting position may include precordial Doppler ultrasonography, which can detect 0.25 mL of air in the heart. A more sensitive monitor is transesophageal echocardiography, which is much more cumbersome, invasive, and requires an observer familiar with this technique. Also, transesophageal echocardiography may not allow for continuous monitoring for air as the device will cease working when probe temperature rises from normal use to a preset value. However, transesophageal echocardiography allows for a quantitative assessment of intracardiac air whereas precordial Doppler sonography is a qualitative monitor for VAE (i.e., indicates only if air is present in the heart).

Prevention of VAE entails decreasing the height difference between the operative site and the heart as much as possible, maintaining euvolemia, and the use of bone wax by the surgeon to occlude visibly open dural venous sinuses or larger veins. Treatment of VAE includes notifying the surgeon to flood the surgical field, administering 100% oxygen, aspirating air through a multiorifice central venous catheter positioned at the junction of the superior vena cava and right atrium, and supportive hemodynamic care. Depending on the degree of hemodynamic perturbation, treatment may include vasopressors, fluids, inotropes, and adjusting the OR table position so that the head is at the level of the heart. This final maneuver is saved for severe or unremitting manifestations of VAE as it likely will disrupt the surgical field. If nitrous oxide was being used, it should be stopped not only to deliver 100% oxygen but also because nitrous oxide may increase air bubble volume, potentially exacerbating the clinical effects of VAE. The application of PEEP, although theoretically favorable, is generally not helpful.<sup>125</sup>

## **Pituitary Surgery**

Pituitary surgery is usually performed endoscopically and transnasally. Anesthetic concerns for pituitary surgery include systemic manifestations of any associated endocrinopathy, electrolyte and fluid disturbances caused by endocrine disease, SIADH, or DI, and inadvertent surgical trespass into the cavernous sinus or internal carotid artery. Patients with a sellar mass may exhibit visual field defects, and a careful history and physical examination preoperatively is important to differentiate between organic and anesthetic

causes of visual problems after surgery.

Growth hormone (GH) secreting tumors cause acromegaly. A large mandible and hypertrophy of tissue leads to decreased airway aperture and predisposes to obstructive sleep apnea and difficulty with mask ventilation and intubation. Also, a smaller sized endotracheal tube and additional tools and strategies to secure the airway, such as awake fiberoptic intubation or a video laryngoscope-based intubation may be considered. Furthermore, longstanding acromegalics are prone to cardiac rhythm disturbances and hypertrophic cardiomyopathy, and caution with cardiac depressant medications is warranted.

Adrenocorticotrophic hormone (ACTH) secreting tumors cause Cushing syndrome by causing hypercortisolism. Cushing syndrome is associated with glucose intolerance or diabetes mellitus, increased skin fragility (potentially making peripheral intravenous access difficult), impaired wound healing, and secondary hypertension. There is some data to suggest, however, that Cushing syndrome are not significantly associated with airway difficulty.<sup>126</sup>

Patients with thyroid-stimulating hormone (TSH) secreting pituitary adenomas should be rendered euthyroid before surgery unless vision is threatened. Such patients may have inadvertently been treated for Grave disease preoperatively, thereby decreasing the production of free T4 and T3 hormones and reducing the amount of negative feedback to the pituitary adenoma, which may predispose to rapid tumor growth.<sup>127</sup>

SIADH is common with sellar tumors, due to compression of the posterior pituitary and an excess of circulating antidiuretic hormone (ADH), which may lead to intravascular volume overload and hyponatremia. Extracellular body water is usually normal, and edema or hypertension is usually not characteristic. Treatment of perioperative SIADH involves water restriction (to the extent that it is safe to do so), treating the underlying cause, and demeclocycline which is a tetracycline antibiotic that inhibits ADH action in the renal tubules. The hallmark of DI is polyuria with dilute urine output. Fluid replacement is required and desmopressin may be needed for persistent or severe cases.<sup>128</sup>

Because accidental surgical entry into the cavernous sinus or internal carotid artery is a known, albeit infrequent, complication of pituitary surgery, adequate vascular access and an arterial catheter are recommended. A lumbar subarachnoid catheter is sometimes placed before or after pituitary surgery. Intraoperatively, injection of air or sterile saline or withdrawal of CSF can facilitate exposure of the tumor as increases or decreases in intracranial volume can serve to move the sellar structures inferiorly or superiorly, respectively. Postoperatively, a lumbar CSF drainage catheter can be used to drain CSF that will decrease CSF volume where a dural sealant or fat graft has been used and reduce the risk for chronic CSF leakage.<sup>129</sup>

## Cerebral Aneurysm Surgery and Endovascular Treatment

The development of cerebral aneurysms, and their likeliness to rupture causing SAH, is associated with age over 40 years, female sex, cigarette smoking, systemic hypertension, or connective tissue disorders.<sup>130</sup> Ruptured aneurysms are the most common cause of spontaneous SAH, accounting for 80% of nontraumatic SAH. Aneurysms are thought to arise from turbulent blood flow at arterial branching points, causing “sac-like” or “fusiform” dilatations to occur. Cerebral aneurysms most commonly occur at the anterior communicating arteries (40%), PCOMs (25%), and MCA (25%), with only 10% arising from the vertebrobasilar system.<sup>131</sup>

Following SAH, an acute increase in ICP is accompanied by a decrease in CPP. These changes result in an increase in systemic blood pressure to maintain CBF. Patients may present with severe headache (classically, the “worst headache of my life”), nausea and vomiting, photophobia, seizures, focal neurologic deficits, and altered consciousness. A noncontrast head CT scan is usually sufficient to diagnose SAH, but more sophisticated imaging, such as digital-subtraction angiography, CT angiography, or MRI angiography, is required to identify the location and morphology of the aneurysm.

Cerebral aneurysms, and their neurologic sequelae, are categorized by a variety of ways for both treatment and prognostication. The Hunt and Hess Grading Scale (based on clinical symptoms) (Table 37-2),<sup>132</sup> the World Federation of Neurological Surgeons Grading Scale (based on GCS and motor deficits) (Table 37-3),<sup>133</sup> and the Fisher Grade System (based on radiologic bleeding) (Table 37-4)<sup>134</sup> are commonly used. Aneurysm size is an important factor when considering management. “Small” aneurysms are less than 10 mm in diameter, “large” aneurysms are 10 to 24 mm in diameter, and “giant” aneurysms are more than 24 mm in diameter. Rupture risk increases with aneurysm diameter, with those larger than 6 mm generally requiring treatment.<sup>135</sup>

Preoperative assessment must include knowledge of the aneurysm size and location and whether it is intact or ruptured. Caring for patients with ruptured aneurysms must take into account the presence and possibility of rebleeding, vasospasm of cerebral arteries, hydrocephalus, cardiac dysfunction, neurogenic pulmonary edema, and seizures. Cerebral vasospasm rarely occurs within 72 hours of rupture. Surgical or endovascular treatment of ruptured aneurysms is generally undertaken within the first 48 hours after presentation of SAH, to minimize the risk of rebleeding but prior to increased risk for cerebral vasospasm. Cardiac and pulmonary conditions should be optimized to the greatest extent possible, which may require inotropes, antiarrhythmics, hypertonic saline supplementation if SIADH or cerebral salt

wasting syndrome are present, maintenance of euvolemia, and maintenance of tissue oxygenation, all without delay of surgical treatment. Furthermore, enteral nimodipine and a statin drug should be administered per ICU protocol. Nimodipine is the only intervention that decreases risk for cerebral vasospasm. Statins, via their pleotropic effects, may also decrease risk of vasospasm.

**Table 37-2** Hunt and Hess Grading System

Hunt and Hess Grade	Clinical Symptoms
0	Unruptured aneurysm/asymptomatic
1	Minimal headache, slight nuchal rigidity
2	Moderate to severe headache, nuchal rigidity, cranial nerve palsy
3	Mildly obtunded, confused, focal deficits
4	Severely obtunded, hemiparesis, early decerebrate posturing
5	Coma, decerebrate posturing

**Table 37-3** World Federation of Neurological Surgeons (WFNS) Grading Scale

WFNS Grade	Glasgow Coma Scale Score	Motor Deficit
1	15	No
2	14–13	No
3	14–13	Yes
4	12–7	Yes or no
5	6–3	Yes or no

Aneurysms amenable to surgical clipping are usually saccular as opposed to fusiform in morphology. Great caution must be taken to minimize risk for rupture by avoiding hypertension during intubation, Mayfield head fixation, and during the surgical procedure. Also, in patients with prior rupture, adequate CPP must be maintained as ICP may be elevated. If the rupture was more than 3 days prior, patients may have cerebral arterial vasospasm. In any case, a plan must be in place in the event of intraoperative aneurysm rupture. Anesthetic induction is controlled with the above-mentioned ICP considerations in mind. In those with prior rupture, CPP is maintained, sometimes requiring careful vasopressor use in an effort to also prevent hypertension that can increase risk for rerupture.

In patients without prior rupture and a normal ICP, excessive hypertension should be avoided. A maintenance anesthetic technique similar to the one described earlier for brain tumors is used, not necessarily because of ICP concerns, but because neuromonitoring may be employed to detect regional

ischemia. During exposure of the aneurysm, burst-suppression on the EEG may be desired to decrease the impending ischemic burden on the brain from temporary occlusion of large cerebral vessels. Burst-suppression can be accomplished with propofol administered as a 1- to 2-mg/kg bolus followed by infusion of 100 to 150 µg/kg/min. Additional vasopressor may be required during this time to maintain CPP.

**Table 37-4** Fisher Grade System

Fisher Grade	Blood on Computed Tomography Scan
1	No subarachnoid blood seen
2	Diffuse vertical layers of blood <1 mm thick
3	Localized clot and/or vertical layer of blood ≥1 mm thick
4	Intracerebral or intraventricular clot with diffuse or absent subarachnoid hemorrhage

Prior to direct clipping of the aneurysmal neck, the surgeon may place one or more temporary clips on parent or feeding arteries to “soften” the neck and make it more amenable to direct clipping while minimizing the chances of rupture. Alternatively, when temporary clips are anatomically difficult to place, adenosine 0.3 to 0.4 mg/kg may be safely given as a bolus to cause a transient circulatory arrest and profound hypotension, allowing safe permanent clip application.<sup>136,137</sup> Other techniques, such as deep hypothermic circulatory arrest (DHCA), retrograde suction decompression, or rapid ventricular pacing achieve the same end point but are logistically more difficult to perform. During temporary and permanent clipping, SSEP and MEP monitoring may be performed as this is the period of time during which the brain is at greatest ischemic risk.

Inadvertent rupture is possible during dissection around the aneurysm. A plan must be in place to contend with this potentially devastating complication, including the availability of blood products and adenosine (0.3 to 0.4 mg/kg), or another rapidly acting antihypertensive medication (e.g., sodium nitroprusside), for rescue. In this regard, large-bore intravenous access is required, especially for large aneurysms over 10 mm and ruptured aneurysms; and, central venous access is recommended. Arterial catheters are routinely used for aneurysm surgery.

Endovascular treatment of aneurysms involves groin arterial access and the deployment of coils into the aneurysmal sac or another means to occlude blood flow into the sac. An example of the latter technique is the pipeline treatment or the deployment of a stent into the parent artery to prevent blood from entering the aneurysmal sac. The International Subarachnoid Aneurysm Trial (ISAT) demonstrated that, despite a greater occurrence of rebleeding,

there was a 25% decrease in poor neurologic outcomes at 1 year in patients undergoing coiling versus surgical clipping of aneurysms.<sup>138</sup> Other data, however, do not suggest a significant benefit of coiling *versus* clipping of aneurysms. Furthermore, certain aneurysms may not be amenable to coiling, due to their morphology. The major disadvantage of coiling is incomplete obliteration of the aneurysm, requiring recoiling that may be necessary in up to 30% of cases. General anesthesia is used, with adequate muscle relaxation, as movement should be prevented. An arterial catheter is needed to monitor the blood pressure closely and to obtain blood samples for coagulation measurements at repeated intervals, as heparin is given periodically. The anesthesiologist should communicate very closely with the interventionalist throughout the procedure, as any extravasation of dye into the brain parenchyma may be indicative of aneurysmal or feeding vessel rupture. In this circumstance, protamine must be immediately available; to reverse the effects of heparin, and hyperventilation, mannitol, burst-suppression, and placement of an EVD should be available on an emergency basis, with the possibility of emergency craniotomy as a strong possibility. Embolism of coils to unintended locations in the brain is also possible throughout the procedure; thus, a prompt neurologic examination at the conclusion of the procedure is very important.

### **Arteriovenous Malformations**

Cerebral AVMs are congenital abnormalities in which a plexus of arteries and “arterialized” veins form a nidus that may lead to cerebral hemorrhage, headaches, seizures, or signs of cerebral ischemia due to a “steal” effect. AVMs are usually detected between the ages of 10 and 40 years, with approximately 70% being supratentorial.<sup>139</sup> Morphologically, these structures have a nidus of dysplastic vessels of varying size, and are drained by one or more superficial or deep veins. Characteristically, there is no capillary bed between arteries and veins within AVMs. These lesions can be diagnosed by MRI or cerebral angiography, and treatment modalities include embolization in the interventional radiology suite preoperatively to minimize intraoperative burden or improve curativity. In addition, stereotactic radiosurgery or surgical removal can be considered. The Spetzler–Martin Grading System is used to predict surgical outcome, and is based on size, eloquence of adjacent brain, and pattern of venous drainage (i.e., superficial versus deep) of the AVM (Table 37-5).<sup>140</sup> Notably, about 7% of cerebral AVMs include a flow-related cerebral aneurysm as well, and this information should be sought and accounted for in the anesthetic plan.<sup>141</sup>

**Table 37-5** Spetzler–Martin Grading System

Feature of Arteriovenous Malformation	Score
<b>Size</b>	
Small (<3 cm)	1
Medium (3–6 cm)	2
Large (>6 cm)	3
<b>Adjacent brain</b>	
Noneloquent	0
Eloquent	1
<b>Venous drainage pattern</b>	
Superficial	0
Deep	1

Vascular access, more than in any other intracranial neurosurgical procedure, is of great importance, and a central venous catheter is highly recommended. The greatest risk of AVM resection is bleeding, both intraoperatively as surgical hemostasis can be challenging due to poor visualization of arterial and especially venous vessels and postoperatively. Strict control of blood pressure is required to maintain CPP without worsening blood loss from the resection bed due to ongoing systemic hypertension. At the same time, avoidance of hypotension is crucial as these patients often present with seizures or focal neurologic deficits due to an ischemic “steal” phenomenon. Because most AVMs are high-flow and low-resistance shunts, the incidence of sudden rupture with *acute* rises in systemic blood pressure (as with direct laryngoscopy) is low unless there is an accompanying aneurysm. Blood products should be immediately available, and antihypertensives are very often needed, especially during emergence from anesthesia. The phenomenon of “normal perfusion pressure breakthrough,” or NPPB, is controversial in terms of its mechanism, but very much clinically relevant to the anesthesiologist. NPPB is thought to be a type of autoregulatory inhibition caused by the AVM and affecting the surrounding “normal” brain, in which previously normal cerebral vessels are maximally vasodilated due to longstanding “steal” caused by the AVM. When the AVM has been resected, these “vasoparalyzed” vessels are unable to vasoconstrict, leading to cerebral hyperemia, cerebral edema, headache, and possibly increased risk for postoperative bleeding.<sup>142,143</sup> Another phenomenon that may lead to perioperative hyperemia and postoperative morbidity is “occlusive hyperemia.”<sup>144</sup> This phenomenon is primarily related to arterial and venous obstruction occurring in normal brain tissue that surrounded the AVM due to surgical disruption of these vessels. This obstruction can impact flow in brain parenchyma that surrounded the AVM leading to ischemia from poor arterial flow and edema and increased risk for hemorrhage from impaired venous outflow.<sup>145</sup> Postoperatively, up to 50% of patients may

experience seizures, thus prophylactic anticonvulsants are typically administered.<sup>146</sup> Neuromonitoring is increasingly being used to facilitate cerebral AVM resections, and a maintenance anesthetic regimen that allows neuromonitoring may be required. Arterial catheterization and careful induction and intubation, as described with cerebral aneurysms, are standard.

## Carotid Surgery

Surgery to remove carotid plaque that may be causing symptomatic cerebral ischemia is generally indicated when the plaque burden is over 70% occlusive in the ipsilateral ICA. Up to 20% of strokes may be due to cerebral ischemia caused by intimal narrowing of the ICA, either unilaterally or bilaterally. Carotid revascularization has proven to be a useful procedure for reducing the risk of stroke in cases of severe occlusion of the ICA (i.e., 70% to 99% occlusion) in the presence of symptoms of ischemia. However, benefit in less severe occlusive states or in asymptomatic patients may not outweigh risks and medical management may be preferred.<sup>147</sup> Currently, procedural treatments of carotid artery stenosis include carotid endarterectomy or carotid artery stenting. The most significant advantage of carotid endarterectomy over stenting is that it has an overall lower incidence of postoperative stroke and restenosis, whereas potential disadvantages of this surgery include the need for a general or regional anesthetic technique, a possible increased risk for cardiac events, and a higher incidence of cranial nerve dysfunction.<sup>148</sup> However, carotid artery stenting may be accomplished with very minimal sedation and carries a lower incidence of cranial nerve injury, although it has been associated with a higher risk of restenosis and stroke in the postprocedural period.<sup>149</sup>

Carotid endarterectomy is performed either “awake” with regional anesthesia or “asleep” with general anesthesia. Neither technique has been found to be superior at improving neurologic outcome.<sup>150</sup> “Awake” carotid surgery usually involves a superficial and sometimes deep cervical plexus block to provide anesthesia within the C2 to C4 dermatomes.<sup>151</sup> Low-dose analgesia and sedation with remifentanyl or propofol may be considered. It is important to ensure that the patient is responsive to commands and able to perform manual tasks on the contralateral side. This technique requires a cooperative patient who is able to tolerate lying flat for a prolonged period of time, and patients with chronic obstructive pulmonary disease or uncompensated congestive heart failure may be unsuitable candidates. Advantages of an “awake” technique include a direct monitor of the patient’s neurologic status, better hemodynamic stability, shorter hospital length of stay, and decreased bleeding complications. If the patient becomes agitated, confused, or unresponsive following carotid occlusion, the anesthesiologist

should assume that cerebral ischemia has ensued and assure adequate perfusion and oxygenation by increasing systemic blood pressure to up to 20% greater than preoperative values.

“Asleep” carotid surgery employs general endotracheal anesthesia, and frequently some form of monitoring for cerebral ischemia is used. EEG is probably the most common and ischemia presents as ipsilateral slowing of oscillations. SSEPs and MEPs can also be used with ischemia appearing as a decrease in waveform amplitude or an increase in waveform latency. Carotid stump pressure is the pressure measured in the internal carotid artery distal to the cross-clamp and is thought to reflect adequate collateral blood flow via the circle of Willis. A stump pressure greater than 50 mmHg is desirable. Cerebral oximetry or TCD are other, less commonly employed techniques used to monitor for cerebral ischemia. To date, no modality of neuromonitoring has been shown to ensure adequate collateral blood flow or definitively decrease the incidence of neurologic complications perioperatively.

General anesthesia provides the advantages of a motionless patient, the ability to ensure eucapnia, and control of the airway at all times. Eucapnia is preferred, as hyperventilation will cause cerebral vasoconstriction and decreased CBF, whereas hypoventilation and hypercapnia may lead to a “steal” phenomenon from watershed areas of cerebral perfusion.

Regardless of the type of anesthesia performed, invasive arterial blood pressure monitoring is preferred as operative morbidity is generally due to neurologic complications whereas mortality is usually due to cardiac complications. Therefore, blood pressure control is critical. Patients are generally chronically hypertensive preoperatively and may have cardiovascular disease and other significant comorbidities. Blood pressure should be maintained at baseline levels prior to cross-clamping. Patients having regional anesthesia often maintain baseline blood pressure but those having general anesthesia may require pharmacologic manipulation of blood pressure. Cross-clamping occurs above and below the area of plaque, usually at the levels of the common carotid artery below and the ICA above and heparinization is commonly performed prior to cross-clamping. Upon cross-clamp occlusion of the common carotid artery, blood pressure should be augmented to improve collateral flow from the contralateral side, often requiring a vasopressor. During manipulation of the carotid baroreceptor, bradycardia and possibly hypotension are not uncommon, and the surgeon may infiltrate the carotid sinus with lidocaine to prevent this response. Following restoration of flow in the carotid artery, hypertension may persist, probably due to surgical denervation of the carotid baroreceptor.<sup>152</sup> Since cerebral vessels distal to the stenotic carotid artery have been maximally vasodilated, autoregulation may not be intact. Hypertension with cerebral

vasomotor paralysis can lead to cerebral edema and increased risk for cerebral hemorrhage. Any neurologic compromise postoperatively may also be indicative of cerebral emboli or ICA thrombosis, and patients must be monitored extremely closely in the recovery room or intensive care unit for these complications. Lastly, the anesthesiologist must be keenly aware of the potential for a postoperative neck hematoma, which may quickly compromise the airway. Immediate intubation, which may be more difficult and surgical exploration of the wound is required.<sup>153</sup>

Other modalities of treating ICA stenosis, including carotid angioplasty, have gained popularity in the last few years, with some evidence supporting their safety and efficacy over traditional endarterectomy.

## **Epilepsy Surgery**

Epilepsy affects about 1% of the general population and is characterized by recurrent seizure activity of both the generalized and partial varieties. Complex partial seizures, including temporal lobe epilepsy, are most common, involving an initial focus of abnormal neuronal discharge that spreads with a subsequent loss of consciousness. Epilepsy may occur idiopathically, or as part of a constellation of symptoms related to head injury, tumors, neurovascular disease, metabolic derangement, or infection. Approximately 30% of patients with drug resistant epilepsy undergo surgical treatment for their disease.<sup>154</sup> Perioperative management of patients having surgery for epilepsy requires a keen understanding of the pharmacologic effects of both anesthetics and antiepileptic drugs. Surgery for epilepsy is generally indicated when there is a discrete epileptic focus, most often identified in the temporal lobe. Thus, temporal lobectomy with amygdalohippocampectomy is a very common surgical procedure performed for the treatment of epilepsy.

Preoperative evaluation is critical, with particular attention paid to the patient's preoperative antiepileptic regimen, their known side effects, and in some cases plasma concentrations of drugs with known therapeutic windows. Antiepileptic drugs are generally continued throughout the perioperative period unless seizure focus mapping is intended. Antiepileptics taken by the patient can induce liver enzymes and increase the metabolism of muscle relaxants, opioids, and dexmedetomidine, leading to a need for higher dosages.<sup>155</sup> Anesthetics have mixed and variable excitatory and inhibitory effects on seizure activity. Thus, if used improperly, can be detrimental to seizure focus mapping, which is often necessary to perform this surgery. Benzodiazepines should be avoided when electrocorticography (ECoG) is planned. Induction of anesthesia with propofol, a muscle relaxant, and an opioid is acceptable. During maintenance of anesthesia and prior to ECoG, any anesthetic regimen conducive for craniotomy can be used, but 30 minutes

prior to ECoG initiation, propofol infusion should be stopped and potent volatile anesthetic held to a minimum (0.5 MAC) or stopped as well. To prevent awareness, scopolamine, nitrous oxide, and high-dose opioid infusion can be used with very little adverse effect on ECoG. Dexmedetomidine is also thought to be useful in this regard. In any case, the patient should be counseled about the possibility of intraoperative awareness during the procedure. In some cases, methohexital, etomidate, or alfentanil (50 µg/kg) can be used to enhance epileptiform activity and assist in mapping.<sup>156</sup> Once ECoG is complete, the general anesthetic technique used prior to ECoG can be resumed during the resection. Postoperatively, patients should be monitored closely for seizure activity, and any seizures, which might signify postoperative bleeding, metabolic derangements, hypercapnia, or hypoxemia, should be treated aggressively so as to avoid cerebral damage or status epilepticus.

### *Awake Craniotomy*

Craniotomy performed with monitored anesthesia care, also known as “awake craniotomy,” has gained popularity in some institutions and is used in cases in which a lesion lies adjacent to primary cortex that controls motor function, speech, or sensory function. Awake craniotomy allows for speech, motor, or sensory cortical mapping in real-time, hence facilitating a more aggressive resection of the tumor and minimizing risk to motor, sensory, or speech function. A motivated patient is critical to the success of the procedure, and the preoperative assessment should include a detailed explanation of the anesthetic so as to ensure cooperation and allay anxiety. Awake craniotomy can be performed with the patient sedated for the duration of the procedure, or with an “asleep–awake–asleep” technique employing a supraglottic airway device or nasopharyngeal tubes for general anesthesia prior to and following the awake mapping.<sup>157,158</sup> During awake mapping, the airway device is removed so that the patient can communicate and then replaced following mapping (or alternately the patient kept sedated for surgical closure). For a fully “awake” craniotomy, an arterial catheter is placed and sedation prior to and following awake mapping may be facilitated with propofol, remifentanyl, or dexmedetomidine infusions. A selective scalp nerve block may be performed preoperatively, either unilaterally or bilaterally, blocking the six nerves on each side which innervate the scalp and dura mater. These include the supratrochlear, supraorbital, zygomaticotemporal, auriculotemporal, lesser occipital, and great occipital nerves.<sup>159</sup> Otherwise, the surgeon may choose to perform a field block. Care must be taken to avoid local anesthetic toxicity, particularly as the surgeon infiltrates the dura mater with additional local anesthetic. During cortical mapping, electrical stimulation is used by the

surgeon *via* a probe stimulator, in conjunction with neuropsychologic testing, to map critical cortical regions. This allows the surgeon to determine safe resection margins and is of particular significance if the tumor is located near major language areas in cortex (usually located in the left hemisphere).

Regardless of the anesthetic technique used, close attention to the airway is critical, as hypoventilation and hypercapnia are detrimental to surgical exposure and apnea requiring emergent intubation may be very difficult in a patient in whom the head is turned and fixed in a Mayfield head-holder. In this regard, the surgical drape should be positioned in a manner allowing direct and constant access to the patient's face. Patient positioning is very important, and careful padding and positioning should be accomplished before any sedation is administered. Lastly, and often overlooked in these cases, is the importance of constant communication with the patient, not only to facilitate speech or motor testing but also to comfort the patient who may be very anxious.

Complications of awake craniotomy intraoperatively may include a disinhibited or uncooperative patient, oversedation prohibitive to neuropsychologic testing, respiratory depression, airway obstruction, intractable brain edema, seizures, or uncontrollable pain. Emergency airway equipment allowing for mask ventilation, placement of a supraglottic airway device, or fiberoptic intubation must be immediately available. Seizures should be treated with cold saline applied to the brain surface by the surgeon and a small bolus of propofol (20 mg) intravenously. Postoperatively, patients may be observed in the PACU or the ICU with similar considerations as for general anesthesia craniotomies, including adequate analgesia.

## **Anesthesia and Traumatic Brain Injury**

TBI is a significant public health problem in the developed and underdeveloped world, accounting for 15% to 20% of mortality in people 5 to 35 years old.<sup>160</sup> TBI is often associated with other trauma such as thoracic, abdominal, and orthopedic injuries. It is important to note that the primary insult to the brain is often irreversible. Death following TBI is often associated with secondary insults from hypotension, hypoxemia, and malignantly increased ICP due to hematoma or edema.<sup>161</sup> Emergency and anesthetic management of patients with TBI should focus on minimizing these secondary insults to optimize perfusion of the injured brain. Patients presenting with TBI are stratified according to the GCS on presentation (3 to 15). GCS 13 to 15 corresponds to mild head injury, GCS 9 to 12 corresponds to moderate head injury, and GCS below 9 represents severe head injury. Patients with TBI are often intubated when GCS is 8 or less owing to high risk for impaired airway protection. A GCS of 8 or less also corresponds to 35%

mortality.<sup>162</sup> Noncontrast CT scan that shows midline shift of more than 5 mm or absent ventricles should also lead to immediate intubation, as ICP may be significantly elevated potentially impairing ventilation. ICP monitoring is frequently used in patients with acute TBI, and can be instituted in the emergency department by an EVD, where mannitol, hyperventilation, and propofol can be used to control elevated ICP. Operative management, such as decompressive craniectomy, is normally indicated for depressed skull fractures, dural breach, midline shift more than 5 mm, basal cistern compression, refractory ICP elevation, and acutely expanding intracranial hemorrhage, including subdural and epidural hematomas.<sup>163,164</sup>

## **Anesthetic Management**

Patients presenting with TBI are assumed to have concomitant cervical spine injury, and intubation, if not already performed, must take this into account. Furthermore, 40% of patients will have an associated life-threatening injury.<sup>165,166</sup> A detailed but rapid primary survey, along with a focused neurologic examination is critical. Hypoxemia is common, which may be further exacerbated by pulmonary injury. Doses of anesthetic drugs must be tailored so as to avoid worsening systemic hypotension as patients may have hypovolemia from an associated injury. Succinylcholine is controversial following an acute closed head injury, as it may raise ICP very transiently but can be considered if there is a need to rapidly secure an airway and no other contraindications to its use exist. Nasal intubation is contraindicated if a basilar skull fracture is present or presumed. Once the airway is secured, attention must be paid to hemodynamics, as systolic blood pressure less than 80 mmHg is associated with a worse neurologic outcome. Fluid resuscitation and vasopressors are often needed to assure an adequate systemic and cerebral perfusion pressure. There is some evidence that achieving euvolemia with hypertonic saline may be beneficial in TBI patients, especially pediatric patients, as intravascular volume is repleted and CPP is maintained with less cerebral edema.<sup>167</sup> Euglycemia should be maintained. Intravascular access should include an arterial catheter and large-bore intravenous cannulae, and possibly a central venous line. Cross-matched red blood cells and other blood products should be available, and any available results relating to red blood cell counts and clotting function should be reviewed.

Choice of an anesthetic maintenance technique depends on an understanding of ICP management (see earlier), with inhalational drugs in higher doses used with caution to avoid excessive cerebral vasodilation. Additional mannitol or hypertonic saline may be required to control edema. Hyperventilation should not continue beyond 2 to 6 hours, as its effect to decrease ICP may not be durable after this time.<sup>168</sup> After this acute phase of

hyperventilation, a PaCO<sub>2</sub> of 30 to 35 mmHg is desirable. Of particular importance for TBI management, CPP should always be kept above 60 mmHg to maintain cerebral perfusion but excessive hypertension should be avoided to reduce risk of exacerbating edema or increasing risk for hemorrhage.<sup>169</sup> The release of brain tissue thromboplastin into the systemic circulation may lead to disseminated intravascular coagulation and coagulopathy must be aggressively sought and treated. Likewise, ARDS or neurogenic pulmonary edema may be present, and a lung-protective ventilation strategy using PEEP and low tidal volumes may be needed to maintain oxygenation.

Complications that may occur during and immediately following operative management of TBI include seizures, intracranial hemorrhage, sudden and profound hypotension following decompression of large hematomas, and cerebral edema. The latter can be treated with propofol, mannitol, or hypertonic saline, temporary hyperventilation, CSF diversion, and possibly avoiding replacement of the bone flap at the conclusion of surgery.

Extubation at the conclusion of surgery depends on the degree of ICP elevation, the severity of injury, and concomitant injuries. Most patients are admitted to the neurointensive care unit after surgery and require continued intubation, mechanical ventilation, and sedation.

## **Anesthesia for Spine Trauma and Complex Spine Surgery**

### **Spinal Cord Injury**

Acute spinal cord injury often necessitates emergency surgery to stabilize the spinal column and prevent secondary injury. Cervical spine injuries are most common, as this is the most mobile part of the spine.<sup>170</sup> Cervical injuries are also the most devastating injuries from a neurologic perspective. Cervical cord injuries cause more functional motor, sensory, and autonomic deficits than lower cord injuries. Also, higher cord injuries can impact respiratory muscle function to a greater extent with intercostal function being impacted by thoracic and cervical injuries and phrenic function being impaired by lesions at C5 or higher. Although voluntary respiratory effort remains with injury at the C4 level, vital capacity may be diminished by up to 25%.<sup>171</sup> Sympathetic nervous system function is usually impaired following higher thoracic and cervical cord injuries and cardiac accelerator nerve function (derived from the T1 to T5 segments), may lead to profound hypotension and bradycardia. Likewise, temperature control is lost with SCI because of a loss of sweating function and cutaneous vasodilation due to loss of sympathetic function. The American Spinal Injury Association (ASIA) score is used to stratify spinal cord injury based on sensory, motor, and reflex function ([Table 37-6](#)).<sup>172</sup>

Following acute spinal cord injury, spinal cord autoregulation is impaired and the phenomena of spinal shock may be present. Spinal shock is characterized by sensory–motor deficits below the level of the injury and flaccid paralysis, usually lasting up to 6 weeks.<sup>173</sup> After this initial period, spasticity of the affected muscles tends to occur. Hypotension can result from autonomic impairment and hypovolemia associated with other injuries (e.g., long bone fractures, intra-abdominal bleeding). During this time, it is critical to prevent secondary injury by providing aggressive hemodynamic support. Although primary injury may be due to stretching, compression, or transection of the spinal cord or its blood supply due to hyperflexion, hyperextension, or impingement of the fractured spinal column, secondary injury is a more complicated biochemical phenomenon involving the release of inflammatory mediators, cytokines, and amino acids leading to cellular edema, apoptosis, and free radical formation.<sup>174</sup> As with TBI, mitigating these secondary insults, by avoiding hypoxemia, hypotension, and worsening cord edema, is of paramount importance in ensuring the best outcome possible.

**Table 37-6** American Spinal Cord Association (ASIA) Impairment Scale

ASIA Impairment Class	Deficit	Deficit Description
A	Complete	No motor or sensory function
B	Incomplete	Sensory but no motor function below neurologic level including S4–5
C	Incomplete	Motor function preserved below neurologic level + $\geq 50\%$ key muscles have severe weakness
D	Incomplete	Motor function preserved below neurologic level + $\geq 50\%$ key muscles have mild weakness
E	None	Normal motor and sensory function

### Comorbid Injuries

Many patients presenting with acute spinal cord injury may also have comorbid injuries. These include TBI, nonvertebral fractures, facial injuries, chest or abdominal injuries (including pneumothorax and pulmonary contusion), and traumatic amputations. Obviously during this time, life-threatening injuries must be addressed, all the while ensuring that spinal alignment is maintained to avoid adding secondary injury to the spinal cord. Comorbid injuries pose a significant problem in the SCI population, as they

may be the cause or contribute to hypotension and hypoxemia. They may also be more difficult to diagnose and treat in a patient for whom manipulation may be difficult or dangerous.

### *Initial Management*

Patients presenting with acute spinal cord injury, depending on the level and extent of injury, may be compromised from a ventilatory and hemodynamic standpoint, and immediate control of these parameters is crucial. A detailed neurologic examination is critical to establish the operative plan and subsequent prognostication. Airway management in cervical spinal injury focuses on maintaining in-line stabilization throughout, and may require the use of fiberoptic intubation or other adjuncts to secure the airway. In a stable patient, radiographic studies are helpful in assessing the degree of cervical injury and options for intubation.<sup>175</sup> However, plain x-ray imaging of the cervical spine is not sensitive for ligamentous injury thus underestimating risk. Succinylcholine is safe in the initial 24 hours following spinal cord injury as new junctional and extrajunctional nicotinic receptors have not yet been fully expressed. In addition to intravenous fluids and blood products, vasopressors and inotropes are often required to support the blood pressure as hypotension and anemia can contribute to secondary injury of the spinal cord. Arterial blood pressure monitoring and large-bore intravenous access (preferably central venous access) are required. MAP should be maintained above 85 mmHg to ensure adequate spinal cord perfusion for at least 7 days from the date of injury.<sup>176</sup>

Other strategies to protect the spinal cord, such as corticosteroids, naloxone, or hypothermia, may be instituted at this time, but convincing human data for these therapies is lacking. Corticosteroids have received particular attention in this regard, both in animal and human studies. The mechanism to account for their potential neuroprotective effect is largely unknown, but thought to include reduction of vasogenic edema, improvement of spinal cord perfusion, anti-inflammatory effects, and free radical scavenging. The most comprehensive human trials were the National Acute Spinal Cord Injury Studies (NASCIS) I to III, which demonstrated that early steroid intervention may improve neurologic outcome in SCI patients. These studies were highly suspect, however, in that their results were not reproducible, their populations were skewed, and survival or quality of life did not improve with the intervention (methylprednisolone).<sup>177</sup> Furthermore, corticosteroids are known to have untoward effects, including the predisposition to infection and glucose dysregulation that must be weighed against their potential benefits. Currently, both the American Association of Neurological Surgeons and Congress of Neurological Surgeons do not

recommend the use of high-dose steroids in patients with acute spinal cord injury.<sup>178</sup>

## *Intraoperative Management*

The choice of technique for maintenance of anesthesia in patients with spinal cord injury should focus on two key considerations: maintaining blood pressure and allowing for intraoperative neuromonitoring. Again, MAP should be maintained above 85 mmHg. Complex spine surgery, which often involves multiple level fusions and osteotomies, should also take into account the real possibility of significant, and sometimes profound, surgical bleeding and the need for postoperative mechanical ventilation following massive transfusion.<sup>179</sup> Depending on the spinal levels requiring intervention and the extent of the planned surgery, the patient may be placed in Mayfield head-fixation. Clearly, adequate intravascular access is vitally important. Measurements of arterial blood gas, coagulation parameters, hemoglobin concentration, and platelet counts should be undertaken very frequently, as coagulopathy and anemia are quite common and need to be corrected rapidly as they can contribute to secondary injury. Close communication with the surgeon is very important, as these large operations often may benefit from early closure and staging of the procedure. Use of antifibrinolytics, such as tranexamic acid or aminocaproic acid, can decrease risk of bleeding with minimal, if any, increased risk for thrombotic complications.<sup>180</sup> In noninfectious, nontumor cases, intraoperative cell salvage can be quite helpful in reducing the total amount of allogeneic blood transfused.<sup>181</sup> Other blood-sparing techniques, such as acute normovolemic hemodilution and deliberate hypotension, have largely fallen out of favor, due to the known harmful effects of anemia and hypotension on the neurologic and cardiovascular systems.

## *Complications of Anesthesia for Spine Surgery*

Fortunately, complications specifically related to anesthesia for spine surgery are rare, but they are often devastating when they occur. Postoperative visual loss is one such complication, with an incidence of 0.088 to 1.2 per 1000 after spine surgery.<sup>182–184</sup> Most cases are due to posterior ischemic optic neuropathy, with central retinal artery occlusion and cortical blindness being much less common. Risk factors include male sex, obesity, use of the Wilson frame, longer surgery and anesthesia duration, and high estimated blood loss, whereas use of colloid may be protective.<sup>185</sup> Ophthalmologic consultation should be immediately undertaken if this complication is suspected.

Another complication of spine surgery is anterior spinal artery syndrome. This syndrome is caused by sustained hypoperfusion of the anterior spinal artery, owing to either surgical distraction or hypotension, and leads to motor weakness.<sup>186,187</sup> MEPs may be helpful in detecting and averting this devastating complication.

Deliberate hypotension, hypothermia, and hypovolemia may predispose spine surgery patients to the formation of deep venous thromboses (DVT) and subsequent pulmonary emboli (PE). Lumbar fusion is associated with an incidence of symptomatic DVT of up to 4%, with a 2% incidence of PE.<sup>188,189</sup> Because prophylaxis with an anticoagulant is often impossible prior to spine surgery for fear of worsening blood loss and formation of epidural hematoma, an inferior vena cava filter is often placed prior to surgery in high risk patients.

Autonomic dysreflexia (AD) is an important physiologic phenomenon that is not a complication of spine surgery, but rather a late complication of complete SCI. AD occurs weeks to months after such injury, in 60% to 80% of such SCI patients, and is characterized by a profound hypertensive response to any stimulus below the level of injury, such as distention of a hollow organ such as the bladder, pain, or surgery.<sup>190</sup> The most common manifestation of AD is profound systemic hypertension, accompanied by headache, profuse sweating, and flushing above the level of injury and oftentimes bradycardia, cardiac arrhythmias, or cardiac dysfunction. The pathophysiology of this phenomenon is thought to be due to a disruption of descending inhibitory tracts with intact sympathetic reflex arcs below the level of injury. The primary goal in patients at risk for AD is prevention. Triggers should be minimized (i.e., appropriate bowel and bladder care) and anesthesia should still be used for painful or stimulating procedures in insensate regions. Treatment of an acute episode of AD involves removing the inciting stimulus and deepening the level of anesthesia along with the administration of potent vasodilators. Recommended vasodilators include calcium-channel blockers, nitrates, or hydralazine.<sup>191</sup> There is some controversy regarding the preferred anesthetic technique for these patients, although general and spinal anesthesia are usually preferred to epidural anesthesia or mild-to-moderate sedation. Spinal anesthesia had the advantage over epidural anesthesia as it is generally a denser block and does not risk sparing of sacral segments that may occur with epidural anesthesia. If general anesthesia is used, succinylcholine should generally be avoided as it may trigger a profound hyperkalemic response. As with all neurosurgical patients, careful monitoring for these patients in the postoperative period is critical, as AD may manifest itself at this time.

## Conclusion

The perioperative care of neurosurgical patients requires a sound understanding of neurophysiologic and neuropharmacologic principles, the timely application of these principles, and vigilance to often rapidly changing clinical conditions. At the core of neuroanesthesia practice are the ideas of maintaining cerebral oxygen and substrate delivery, facilitating intraoperative neuromonitoring, and assuring for a rapid emergence to facilitate neurologic examination in appropriate patients. Expert application of the requisite knowledge to achieve these goals, along with efficient resource utilization, will provide the safest neurologic outcome possible for this vulnerable patient population.

# 38 Anesthesia for Thoracic Surgery

JAMES B. EISENKRAFT • EDMOND COHEN • STEVEN M. NEUSTEIN

## Preoperative Evaluation

History

Physical Examination

Evaluation of the Cardiovascular System

Pulmonary Function Testing and Evaluation for Lung Resectability

## Preoperative Preparation

Smoking

Infection

Hydration and Removal of Bronchial Secretions

Wheezing and Bronchodilation

Pulmonary Rehabilitation

## Intraoperative Monitoring

Direct Arterial Catheterization

Central Venous Pressure Monitoring

Pulmonary Artery Catheterization

Transesophageal Echocardiography

Monitoring of Oxygenation and Ventilation

## One-lung Ventilation

Absolute Indications for One-lung Ventilation

Relative Indications for One-lung Ventilation

Methods of Lung Separation

Lung Separation in the Patient with a Tracheostomy

Lung Separation in the Patient with a Difficult Airway

## Management of One-lung Ventilation

Confirmation of Correct Position of DLT or Endobronchial Blocker

Inspired Oxygen Fraction

Tidal Volume and Respiratory Rate

Positive End-expiratory Pressure to the Dependent Lung

Continuous Positive Airway Pressure to the Nondependent Lung

Clinical Approach to Management of One-lung Ventilation

## Choice of Anesthesia for Thoracic Surgery

### Hypoxic Pulmonary Vasoconstriction

Effects of Anesthetics on Hypoxic Pulmonary Vasoconstriction

Other Determinants of Hypoxic Pulmonary Vasoconstriction

Potentiators of Hypoxic Pulmonary Vasoconstriction

Nitric Oxide and One-lung Ventilation

## **Anesthesia for Diagnostic Procedures**

Bronchoscopy

## **Diagnostic Procedures for Mediastinal Mass**

Mediastinoscopy

Thoracoscopy

Video-assisted (Minimally Invasive) Thoracoscopic Surgery

## **Anesthesia for Special Situations**

High-frequency Ventilation

Bronchopleural Fistula and Empyema

Lung Cysts and Bullae

Anesthesia for Resection of the Trachea

Bronchopulmonary Lavage

Myasthenia Gravis

Myasthenic Syndrome (Eaton–Lambert Syndrome)

## **Postoperative Management and Complications**

Postoperative Pain Control

Complications Following Thoracic Surgery

## **KEY POINTS**

- 1 It is important to determine prior to the onset of anesthesia and surgery whether the patient will be able to tolerate the planned lung resection.
- 2 Preoperative assessment of vital capacity is critical because at least three times the tidal volume ( $V_T$ ) is necessary for an effective cough.
- 3 Smoking increases airway irritability, decreases mucociliary transport, and increases secretions. It also decreases forced vital capacity and forced expiratory flow 25% to 75%, thereby increasing the incidence of postoperative pulmonary complications.
- 4 The absolute indications for lung separation using a double-lumen tube have been for protection against spillage of blood, infectious material, or lavage fluid from one lung, or for ventilation in the case of bronchopleural fistula or bullae. A lobectomy or pneumonectomy is a relative indication.
- 5 The most important advance in checking the proper position of a double-lumen tube is the introduction of the pediatric flexible fiberoptic bronchoscope.
- 6 During one-lung ventilation (OLV), the dependent lung should be ventilated using a  $V_T$  that results in a plateau airway pressure less than 25 cm  $H_2O$  at a rate adjusted to maintain  $PaCO_2$  at  $35 \pm 3$  mmHg.

- 7 The choice of anesthetic technique for OLV must take into consideration the effects on oxygenation and therefore on hypoxic pulmonary vasoconstriction.
- 8 The need for OLV is much greater with video-assisted thoracoscopic surgery than with open thoracotomy because it is not possible to retract the lung during video-assisted thoracoscopic surgery as it is during an open thoracotomy.
- 9 The potential advantages offered by high-frequency positive-pressure ventilation during thoracic anesthesia are that lower  $V_T$  and inspiratory pressures result in a quiet lung field for the surgeon, with minimal movements of airway, lung tissue, and mediastinum.
- 10 Myasthenia gravis is a disorder of the neuromuscular junction, characterized by weakness and fatigability of voluntary muscles with improvement following rest. Surgical thymectomy is a commonly performed therapy.
- 11 In addition to a more comfortable patient, important benefits of adequate pain relief are avoidance of postoperative atelectasis and limited inspiratory thoracic cage expansion.

Lung cancer is the most common cause of cancer mortality in the United States in men, and surpassed breast cancer as the leading cause of cancer deaths in women in 1987 (Fig. 38-1).<sup>1</sup> It is currently estimated to be responsible for 1.59 million deaths annually worldwide. Each year there are more deaths from lung cancer than from colon, breast, and prostate cancers combined. The most recent statistics from the American Cancer Society indicated that approximately 221,200 new cases of lung cancer would be diagnosed in 2015 (115,610 among men and 105,590 among women). The Society also estimated that there would be 158,040 deaths from lung cancer, which represents 27% of all cancer deaths.<sup>2</sup> The increased incidence of lung cancer has led to an increase in the amount of noncardiac thoracic surgery performed in the United States. The overall risk of developing lung cancer is greater in women than in men (1 in 13 vs. 1 in 16). Most lung cancers are found in the older population, the average age at time of diagnosis is about 70 years. Less than 2% of all cases occur in those age 45 years or less.<sup>2</sup>

In this chapter, the physiologic, pharmacologic, and clinical considerations for the patient undergoing pulmonary surgery are reviewed, followed by sections on anesthesia for diagnostic and therapeutic procedures, high-frequency ventilation, and special situations, including bronchopleural fistula (BPF) and tracheal reconstruction. A discussion of myasthenia gravis (MG) is included because of its relationship to the thymus gland and because thymectomy is one of the most commonly performed surgical procedures in these patients. The chapter concludes with a review of the postoperative

management of the patient who has undergone noncardiac thoracic surgery.

## Preoperative Evaluation

**1** The preoperative evaluation of the patient for thoracic surgery should focus on the extent and severity of pulmonary disease and cardiovascular involvement (see [Chapter 22](#)). It is important to determine whether the patient will be able to tolerate the planned lung resection. To discover postoperatively that the patient cannot tolerate the resection would be catastrophic.

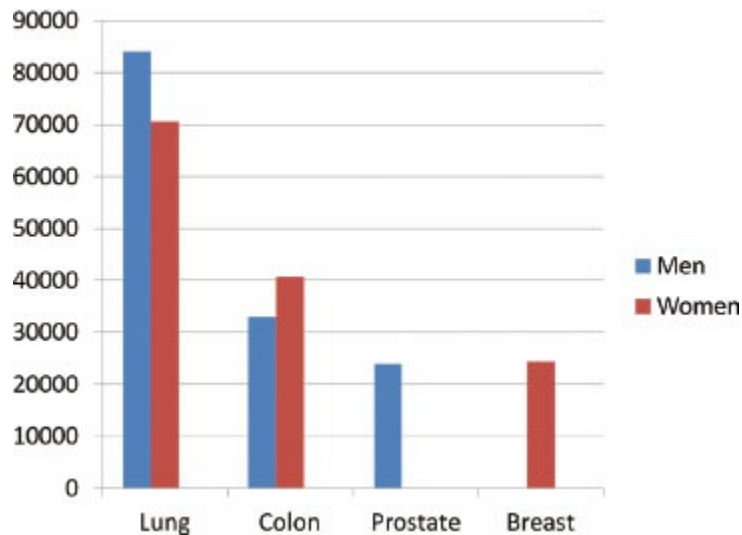

The most common complications following thoracic surgery are pulmonary in nature, the most frequent being pneumonia and atelectasis.<sup>3</sup> It is more difficult to predict postoperative pulmonary complications following elective cardiothoracic, compared with noncardiothoracic surgery.<sup>4</sup> Thoracic surgery is known to be high risk, and patient factors that have been associated with increased risk include advanced age, poor general health status, chronic obstructive pulmonary disease (COPD), body mass index higher than 30 kg/m<sup>2</sup>, low FEV<sub>1</sub> and low predicted postoperative FEV<sub>1</sub>.<sup>5,6</sup>

## History

### Dyspnea

Dyspnea occurs when the requirement for ventilation is greater than the patient's ability to respond appropriately (see [Chapter 11](#)). Dyspnea is quantified by the degree of physical activity required to produce it, the level of activity possible (e.g., ability to walk on level ground or climb stairs), and management of daily activities. Severe exertional dyspnea usually implies a significantly diminished ventilatory reserve and a forced expiratory volume in 1 second (FEV<sub>1</sub>) later 1,500 mL, with possible need for postoperative ventilatory support.

## 2011 Estimated US Cancer Mortality

**Figure 38-1** Estimated 2011 deaths from cancer in the United States. Lung cancer is the leading cause of cancer-related mortality. (Based on data from The American Cancer Society, Cancer Statistics, 2010. A presentation from the American Cancer Society. 2011 Estimated U.S. Cancer Deaths. Available at: <http://www.cancer.org/acs/groups/content/@epidemiologysurveillance/documents/docum029997.pptx>. Accessed November 26, 2012.)

### Cough

Recurrent productive cough for 3 months of the year for two consecutive years is necessary to make the diagnosis of chronic bronchitis. Cough indirectly increases airway irritability. If the cough is productive, the volume, consistency, and color of the sputum should be assessed. Sputum should be cultured to rule out infection and to establish whether there is a need for preoperative antibiotic therapy. Blood-stained sputum or episodes of gross hemoptysis should alert the anesthesiologist to the possibility of a tumor invading the respiratory tract (e.g., the main stem bronchus), which might interfere with endobronchial intubation.

### Cigarette Smoking

Cigarette smoking is the main risk factor for developing lung cancer and in the United States, is linked to about 90% of lung cancers. Using other tobacco products such as cigars or pipes also increases the risk for lung cancer. Tobacco smoke is a toxic mix of more than 7,000 chemicals. Cigarette smokers have a 15 to 30 times greater likelihood of developing and/or dying from lung cancer than nonsmokers. Former smokers have a lower risk of lung cancer than if they had continued to smoke, but their risk is still greater than the risk for people who never smoked. Stopping smoking at any age decreases the risk of lung cancer.<sup>7</sup>

Cigarette smoking increases the risk of chronic lung disease and other malignancies (mouth, nose, throat, voicebox [larynx], esophagus, liver, bladder, kidney, pancreas, colon, rectum, cervix, stomach, blood, and bone marrow [acute myeloid leukemia]), as well as the incidence of postoperative pulmonary complications. The number of pack-years (packs smoked per day multiplied by the number of years) is directly related to measurable changes in respiratory gas flow and closing capacity, making these patients prone to postoperative atelectasis and arterial hypoxemia.

## **Exercise Tolerance**

Patients who can walk up three or more flights of stairs are at reduced risk, and those unable to climb two flights are generally at increased risk.<sup>8</sup> The best evaluation is actually the history of the patient's quality of life. An otherwise healthy patient, with good exercise tolerance, generally does not require additional screening tests. Quality of life measures alone have been shown to correlate poorly with such measures as FEV<sub>1</sub>, diffusion capacity for carbon monoxide (DLCO), and exercise testing, and should not substitute for actual testing.

## **Risk Factors for Acute Lung Injury**

In some cases, thoracic surgery may lead to acute lung injury (ALI) postoperatively. Perioperative risk factors that have been identified include preoperative alcohol abuse and patients undergoing pneumonectomy. Intraoperative risk factors include high ventilatory pressures and administration of excessive amounts of fluid.<sup>9</sup> Poor preoperative pulmonary function and positive fluid balance on postoperative day 1 have been identified as independent risk factors for lung injury in patients undergoing open thoracotomy.<sup>10</sup>

## **Physical Examination**

The physical examination of the patient should address the following aspects.

### **Respiratory Pattern**

The presence of cyanosis and clubbing, the breathing pattern, and the type of breath sounds should be noted.

**Cyanosis.** The presence of peripheral cyanosis (in the fingers, toes, or ears) should be distinguished from causes of poor circulation (acrocyanosis). The presence of central cyanosis (in the buccal mucosa) is usually secondary to arterial hypoxemia. If cyanosis is present, the arterial hemoglobin

saturation with oxygen is 80% or less ( $\text{PaO}_2 < 50$  to  $52$  mmHg), which indicates a limited margin of respiratory reserve.

**Clubbing.** Clubbing of fingers and toes is often seen in patients with chronic lung disease, malignancies, or congenital heart disease associated with right-to-left shunt.

**Respiratory Rate and Pattern.** A patient's inability to complete a normal sentence without pausing for breath is an indication of severe dyspnea. Inspiratory paradox, the abdomen moving in while the chest moves out, suggests diaphragmatic fatigue and respiratory dysfunction. The patient should be assessed for paroxysmal retraction (Hoover sign), limited diaphragmatic movement because of hyperinflation, asymmetry of chest movement secondary to phrenic nerve involvement, hemothorax, pleural effusion, and pneumothorax. The pattern and rate of breathing have important roles in distinguishing between obstructive and restrictive lung diseases. For constant minute ventilation, the work done against airflow resistance decreases when breathing is slow and deep. Work done against elastic resistance decreases when breathing is rapid and shallow (e.g., as in pulmonary infarct or pulmonary fibrosis).

**Breath Sounds.** Wet sounds (crackles) are usually caused by excessive fluid in the airways and indicate sputum retention or edema. Dry sounds (wheezes) are produced by high-velocity gas flow through bronchi and are a sign of airways obstruction. Distant sounds are an indication of emphysema and possibly bullae. The trachea should be in the midline. Displacement of the trachea may be secondary to a number of causes, including mediastinal mass, and should alert the anesthesiologist to a potentially difficult intubation of the trachea or airway obstruction on induction of anesthesia.

## ***Evaluation of the Cardiovascular System***

One of the most important factors in the evaluation of a patient scheduled for thoracic surgery is the presence of an increase in pulmonary vascular resistance secondary to a fixed reduction in the cross-sectional area of the pulmonary vascular bed. The pulmonary circulation is normally a low-pressure, high-compliance system capable of handling an increase in blood flow by recruitment of normally underperfused vessels. This acts as a compensatory mechanism that normally prevents an increase in pulmonary arterial pressure. In COPD, there is distention of the pulmonary capillary bed with decreased ability to tolerate an increase in blood flow (decreased compliance). Such patients demonstrate an increase in pulmonary vascular resistance when cardiac output increases because of a decreased ability to compensate for an increase in pulmonary blood flow. This results in pulmonary hypertension, signs of which include a narrowly split second heart

sound, increased intensity of the pulmonary component of the second heart sound, and right ventricular and atrial hypertrophy. An increase in pulmonary vascular resistance is of significance in the management of the patient during anesthesia because several factors, such as acidosis, sepsis, hypoxia, and application of positive end-expiratory pressure (PEEP), all further increase the pulmonary vascular resistance and increase the likelihood of right ventricular failure.

In patients with ischemic or valvular heart disease, the function of the left side of the heart should also be carefully evaluated.

## **Electrocardiogram**

A patient with COPD may present with electrocardiographic features of right atrial and ventricular hypertrophy and strain. These include a low-voltage QRS complex due to lung hyperinflation and poor R-wave progression across the precordial leads. An enlarged P wave (“P pulmonale”) in standard lead II is diagnostic of right atrial hypertrophy. The electrocardiographic changes of right ventricular hypertrophy are an R/S ratio of greater than 1 in lead V<sub>1</sub> (i.e., R-wave voltage exceeds S-wave voltage).

## **Chest Radiography**

Hyperinflation and increased vascular markings are usually present with COPD. Prominent lung markings often occur in bronchitis, while they are decreased in emphysema, particularly at the bases, where actual bullae may be present in severe cases. Hyperinflation, with an increased anteroposterior chest diameter, may be present, together with an enlarged retrosternal air space of greater than 2 cm in diameter seen in a lateral chest radiograph.

The location of the lung lesion should be assessed by posteroanterior and lateral projections on chest radiography. In addition to tracheal or carinal shift, a mediastinal mass may indicate difficulty with ventilation, a difficult and bloody dissection, difficulty in placing a double-lumen tube (DLT; because of deviation of the main stem bronchus), or a collapsed lobe owing to bronchial obstruction with possible sepsis. Review of a computed tomography (CT) study is also useful, and often provides more information about tumor size and location than the chest radiograph.

## **Arterial Blood Gas Analysis**

A common finding in arterial blood gas analysis of patients with COPD is hypoventilation and CO<sub>2</sub> retention. The “blue bloaters” (chronic bronchitis) are cyanotic, hypercarbic, hypoxemic, and usually overweight. They are in a state of chronic respiratory failure and have a decreased ventilatory response

to CO<sub>2</sub>. In these patients, the high PaCO<sub>2</sub> increases cerebrospinal fluid bicarbonate concentration, the medullary chemoreceptors become reset to a higher level of CO<sub>2</sub>, and sensitivity to CO<sub>2</sub> is decreased. Such patients hypoventilate when given high concentrations of oxygen to breathe because of a decreased hypoxic drive.

The “pink puffers” (patients with emphysema) are typically thin, dyspneic, and pink, with essentially normal arterial blood gas values. They present with an increase in minute ventilation to maintain their normal PaCO<sub>2</sub>, which explains the increase in work of breathing and dyspnea. The preoperative PaO<sub>2</sub> correlates with the intraoperative PaO<sub>2</sub> during one-lung ventilation (OLV), but the intraoperative PaO<sub>2</sub> during two-lung ventilation correlates more closely.<sup>11</sup>

### ***Pulmonary Function Testing and Evaluation for Lung Resectability***

There are three goals in performing pulmonary function tests in a patient scheduled for lung resection. The first goal is to identify the patient at risk of increased postoperative morbidity and mortality. In thoracic surgery for lung cancer, the specific question is: How much lung tissue may be safely removed without making the patient a pulmonary cripple? This should be weighed against the 1-year mean survival rate of the patient with surgically untreated lung carcinoma. The second goal is to identify the patient who will need short-term or long-term postoperative ventilatory support. The third goal is to evaluate the beneficial effect and reversibility of airway obstruction with the use of bronchodilators.

### **Effects of Anesthesia and Surgery on Lung Volumes**

Anesthesia and postoperative medications can cause changes in lung volumes and ventilatory pattern. Total lung capacity (TLC) decreases after abdominal surgery but not after surgery on an extremity. Vital capacity is decreased by 25% to 50% within 1 to 2 days after surgery and generally returns to normal after 1 to 2 weeks. Residual volume (RV) increases by 13%, whereas expiratory reserve volume decreases by 25% after lower abdominal surgery and 60% after upper abdominal and thoracic surgery. Tidal volume (V<sub>T</sub>) decreases by 20% within 24 hours after surgery and gradually returns to normal after 2 weeks. Pulmonary compliance decreases by 33% with similar reductions in functional residual capacity (FRC) secondary to small airway closure. Most of the patients who undergo lung resection are smokers with a certain degree of COPD. They are prone to postoperative complications in direct relation to the amount of lung to be resected (lobectomy or pneumonectomy) and to the severity of the preoperative lung disease.

## Spirometry

**2** Forced vital capacity (FVC), forced expired volume in 1 second ( $FEV_1$ ), maximum voluntary ventilation (MVV), and RV/TLC correlate with outcome following thoracic surgery (see [Chapter 11](#)).<sup>12</sup> An abnormal preoperative vital capacity can be identified in 30% to 40% of postoperative deaths. A patient with an abnormal vital capacity has a 33% likelihood of complications and a 10% risk of postoperative mortality.

$FEV_1$  is a more direct indication of airway obstruction. In the past, an  $FEV_1$  of less than 800 mL in a 70-kg man had been considered an absolute contraindication to lung resection. However, with the advent of thoracoscopic surgery and improved postoperative pain management, patients with smaller lung volumes are now successfully undergoing surgery. It is preferable to indicate the percentage of predicted value, rather than just using the actual results in liters. The percentage of predicted value takes into account the age and size of the patient, and the same number may have a different implication in another patient. The ratio  $FEV_1/FVC$  is useful in differentiating between restrictive and obstructive pulmonary diseases. It is normal in restrictive disease because both  $FEV_1$  and FVC decrease, whereas in obstructive disease the ratio is usually low because the  $FEV_1$  is markedly decreased. MVV is a nonspecific test and is an indicator of both restriction and obstruction. Although MVV has not been systematically evaluated as a predictor of morbidity, it is generally accepted that an MVV less than 50% of predicted value is an indication of high risk. A ratio of RV to TLC (RV/TLC) of greater than 50% is generally indicative of a high-risk patient for pulmonary resection. By multiplying the preoperative  $FEV_1$  by the percentage of lung tissue expected to remain following resection, a predicted postoperative  $FEV_1$  can be calculated. Patients with a predicted postoperative  $FEV_1$  value above 40% are at reduced risk and those with predicted postoperative  $FEV_1$  below 30% are at increased risk.<sup>13</sup> Those patients who fall into the latter category are more likely to need postoperative ventilation.

## Flow–Volume Loops

The flow–volume loop displays essentially the same information as a spirometer but is more convenient for measurement of specific flow rates ([Fig. 38-2](#)). The shape and peak airflow rates during expiration at high lung volumes are effort dependent, but indicate the patency of the larger airways. Effort-independent expiration occurs at low lung volumes and usually reflects small airway resistance, best measured by forced expiratory flow (FEF) during the middle half of the FVC (FEF<sub>25%–75%</sub>).

In general, patients with obstructive airway disease ([Fig. 38-3](#)), such as asthma, bronchitis, and emphysema, have grossly decreased  $FEV_1/FVC$  ratios

because of increased airway resistance and a decrease in FEV<sub>1</sub>. Peak expiratory flow rate and MVV are usually decreased, whereas TLC increases secondary to increases in RV. In these patients, the effort-independent portion of the flow–volume curve is markedly depressed inward, with reduction of the flow rate at 25% to 75% of FVC.

In patients with restrictive disease (Fig. 38-3), such as pulmonary fibrosis and scoliosis, there is a decrease in FVC with a relatively normal FEV<sub>1</sub>. Because the airway resistance is normal, FEV<sub>1</sub>/FVC is also normal. TLC is markedly decreased, whereas MVV and FEF<sub>25%–75%</sub> are usually normal. The flow–volume curves of these patients are normal in shape, but the lung volumes and peak flow rates are decreased.

**Significance of Bronchodilator Therapy.** Pulmonary function tests are usually performed before and after bronchodilator therapy to assess the reversibility of the airway obstruction. This is useful in the assessment of the degree of airway obstruction and the patient’s effort ability. After treatment with bronchodilators, increases in peak expiratory flow compared with a baseline indicate reversibility of airway obstruction (often seen in asthmatic patients). A 15% improvement in pulmonary function tests may be considered a positive response to bronchodilator therapy and indicates that this therapy should be initiated before surgery. The overall prognosis of COPD is better related to the level of spirometric function after bronchodilator therapy than to a baseline function.

**Figure 38-2** Flow–volume loop in a normal subject.  $\dot{V}_{75}$ ,  $\dot{V}_{50}$ , and  $\dot{V}_{25}$  represent flow at 75%, 50%, and 25% of vital capacity, respectively. RV, residual volume. (Adapted from Goudsouzian N, Karamanian A. *Physiology for the Anesthesiologist*. 2nd ed.

## Split-Lung Function Tests

Regional lung function studies serve to predict the function of the lung tissue that would remain after lung resection. A whole (two)-lung test may fail to estimate whether the amount of postresection lung tissue will allow the patient to function at a reasonable level of activity without disabling dyspnea or cor pulmonale.

**Figure 38-3** Flow–volume loops relative to lung volumes in a normal subject, in a patient with COPD, in a patient with fixed obstruction (tracheal stenosis), and in a patient with pulmonary fibrosis (restrictive defect). Note the concave expiratory form in the patient with COPD and the flat inspiratory curve in the patient with a fixed obstruction. (Adapted from Goudsouzian N, Karamanian A. *Physiology for the Anesthesiologist*. 2nd ed. Norwalk, CT: Appleton-Century-Crofts; 1984.)

**Regional Perfusion Test.** This involves the intravenous injection of insoluble radioactive xenon ( $^{133}\text{Xe}$ ). The peak radioactivity of each lung is proportional to the degree of perfusion of each lung.

**Regional Ventilation Test.** Using an inhaled, insoluble radioactive gas, the peak radioactivity over each lung is proportional to the degree of ventilation. Combining radispirometry with whole-lung testing (FEV<sub>1</sub>, FVC, maximal breathing capacity) has resulted in a fair degree of correlation between predicted volumes and pulmonary function tests measured after pneumonectomy.

**Computed Tomography and Positron Emission Tomography Scans.** Patients normally undergo CT scanning. The CT scan provides anatomic sections through the chest and can delineate the size of the tumor. It can also reveal if there is airway or cardiovascular compression.

Positron emission tomography (PET) scans use a glucose analog that is labeled with a radionuclide positron emitter. This scan can detect tumor based

on the metabolic activity. Because malignant tumors are growing at such a fast rate compared with healthy tissue, the tumor cells will use up more of the sugar that has the radionuclide attached to it. There is greater uptake by malignant mediastinal lymph nodes than benign nodes. PET may be more accurate than CT for mediastinal staging.<sup>14</sup> Currently, PET scans can be used to further evaluate lesions that are seen on a CT scan. The PET scan can also be used to follow the results of lung cancer treatments.<sup>15</sup>

The CT and PET scans can be done at the same time to produce a PET–CT scan. A mass that is seen on the CT scan is more likely to be malignant if it also demonstrates enhanced glucose uptake on the PET scan.

### **Diffusing Capacity for Carbon Monoxide**

The ability of the lung to perform gas exchange is reflected by the diffusing capacity for carbon monoxide (DLCO). It is impaired in such disorders as interstitial lung disease, which affects the alveolar-capillary site. A predicted postoperative DLCO below 40% is associated with increased risk. Predicted postoperative diffusing capacity percent is the strongest single predictor of risk of complications and mortality after lung resection. There is little interrelationship of predicted postoperative diffusing capacity percent and predicted postoperative FEV<sub>1</sub>, indicating that these values should be assessed independently when estimating operative risk.<sup>13</sup> In a study of 956 patients, a lower DLCO<sub>PPO</sub> (diffusing capacity for carbon monoxide, predicted postoperative) and the preoperative administration of chemotherapy, were found to be predictive of postoperative complications. In that study, FEV<sub>1</sub> was not found to be predictive of complications.<sup>16</sup> In another study, the DLCO<sub>PPO</sub> was the most predictive factor for postoperative morbidity and mortality.<sup>17</sup> It has been demonstrated that PPO FEV<sub>1</sub> and DLCO are predictive for postoperative pulmonary complications in both minimally invasive and open lobectomies.<sup>18</sup> If the PPO FEV<sub>1</sub> and DLCO are greater than 60%, the patient is at low risk, and no further testing is needed.<sup>19</sup>

**Maximal Oxygen Consumption.** The maximal oxygen consumption (VO<sub>2</sub> max) is a predictor of postoperative complications. Patients with a VO<sub>2</sub> max over 15 to 20 mL/kg/min are at reduced risk.<sup>20</sup> A VO<sub>2</sub> max below 10 mL/kg/min indicates very high risk for lung resection.<sup>21</sup> A simpler test that can be performed is exercise oximetry—a decrease of 4% during exercise is associated with increased risk.<sup>22</sup> A 6-minute walk test of less than 2,000 feet has been correlated both with a VO<sub>2</sub> max below 15 mL/kg/min and with a decrease in oximetry reading during exercise. It has been suggested that the percentage of predicted VO<sub>2</sub> max may be a better indicator for risk, and a threshold of 50% to 60% could be established without an increase in surgical mortality.<sup>23</sup> Brunelli and Fianchini<sup>24</sup> had patients climb the maximum number

of stairs possible. On the basis of the results of this study, these authors recommended that patients who were able to climb more than 14 m can safely undergo surgery, and those who were able to climb less than 12 m, with predicted postoperative function FEV<sub>1</sub> below 35% not be considered for major lung resection. The inability to do a maximal stair climbing has been correlated with an increased mortality following major lung resection.<sup>25</sup> In a recent study, climbing to 20 m with a speed of at least 15 m/min, correlated with meeting qualifying criteria for pneumonectomy. The results for stair climbing correlated with VO<sub>2</sub> consumption during treadmill exercise.<sup>26</sup> Climbing 22 m has been correlated with at least VO<sub>2</sub> of 15 mL/kg/min, although the stair climbing is not standardized.<sup>27</sup> Evaluation of lung function with spirometry and DLCO, and estimating peak oxygen consumption helps to predict risk of postoperative complications.<sup>28</sup> An 11-point scoring scale has been developed for predicting postoperative pulmonary complications.<sup>29</sup> ASA physical status of 3 or higher, emergency or high risk surgery, and history of CHF or chronic lung disease were independent predictors for reintubation following extubation. The preoperative evaluation of the patient for lung resection is summarized in [Figure 38-4](#).

## Preoperative Preparation

The wide spectrum of physiologic changes that occur during thoracic surgery puts patients at great risk of developing postoperative complications. Morbidity and mortality increase when these changes are superimposed on an acutely or chronically compromised patient. Several conditions, including infection, dehydration, electrolyte imbalance, wheezing, obesity, cigarette smoking, cor pulmonale, and malnutrition, show particular correlations with postoperative complications. Proper, vigorous preoperative preparation can improve the patient's ability to face the surgery with a decreased risk of morbidity and mortality. It is important that conditions predisposing to postoperative complications be rigorously treated before surgery.

### Smoking

There is a high prevalence of smoking among patients presenting for surgery, and there is extensive evidence that these patients are at increased risk for development of postoperative respiratory complications.<sup>30</sup> Smoking increases airway irritability, decreases mucociliary transport, decreases FVC and FEF<sub>25%</sub> to 75%, and increases secretions, thereby increasing the incidence of postoperative pulmonary complications. In contrast, cessation of smoking for a period of longer than 4 to 6 weeks before surgery is associated with a decreased incidence of postoperative complications. Furthermore,

cessation of smoking 48 hours before surgery has been shown to decrease the percentage of carboxyhemoglobin, to shift the oxyhemoglobin dissociation curve to the right, and to increase oxygen availability. It should be emphasized, however, that most of the beneficial effects of cessation of smoking, such as improvement in ciliary function, improvement in closing volume, increase in FEF<sub>25%</sub> to 75%, and reduction in sputum production, usually occur 2 to 3 months after smoking has ceased. In one study, there was no evidence of a paradoxical increase in postoperative complications in patients who stopped smoking within 2 months before undergoing thoracic resection for lung tumor.<sup>31</sup> Smoking is associated with increased mortality and pulmonary complications, but these can be decreased by preoperative cessation; the risk decreases with a longer cessation.<sup>32</sup> A recent study indicated that the discontinuation of smoking for more than 8 weeks prior to surgery can help improve postoperative pulmonary function.<sup>33</sup> One meta-analysis indicated that there was no improvement with cessation of smoking for less than 8 weeks<sup>34</sup> but another meta-analysis indicated a progressive improvement with each week of abstinence from smoking.<sup>35</sup>

**Figure 38-4** The order of tests to determine the cardiopulmonary status of the patient and the extent of lung resection that would be tolerated. **A:** The whole-lung function test is a basic screening test. **B:** The split-lung function tests are regional tests to determine the involvement of the diseased lung to be removed. ABG, arterial blood gas; FVC, forced vital capacity; FEV<sub>1</sub>, forced expiratory volume in 1 second; VC, vital capacity; MVV, maximum voluntary ventilation; RV/TLC, residual volume/total lung capacity; DLT, double-lumen tube, D<sub>LCO</sub>, diffusing capacity for carbon monoxide. (Adapted from

Neustein SM, Cohen E. Preoperative evaluation of thoracic surgical patients. In: Cohen E, ed. *The Practice of Thoracic Anesthesia*. Philadelphia: JB Lippincott; 1995:187.)

## **Infection**

Acute or chronic infection should be vigorously treated before surgery. Broad-spectrum antibiotics are commonly used. Treatment of the acutely ill patient depends on the results of the Gram stain of the sputum and blood cultures. Unless there are other modifying circumstances such as allergic history or patients are already receiving antibiotics, cefazolin is routinely administered perioperatively. To be most effective, it needs to be given prior to skin incision.<sup>36</sup> In one prospective study, the incidence of mortality was lower in the group treated with prophylactic antibiotics compared with the untreated group (9% vs. 17%), and a lower incidence of postoperative pulmonary infection was also found.<sup>37</sup> Although not all surgeons routinely administer antibiotics prophylactically to their patients, any infection present before surgery should be vigorously treated.

## **Hydration and Removal of Bronchial Secretions**

Correction of hypovolemia and electrolyte imbalance should be accomplished before surgery because adequate hydration decreases the viscosity of bronchial secretions and facilitates their removal from the bronchial tree. Humidification of inspired gas is extremely useful. The use of mucolytic drugs, such as acetylcysteine (Mucomyst), or oral expectorants (potassium iodide) can be beneficial to patients with viscous secretions. Commonly used methods for removing secretions from the bronchial tree include postural drainage, vigorous coughing, chest percussion, deep breathing, and the use of an incentive spirometer. These modalities often require patient cooperation and frequent verbal encouragement to maximize the benefit.

## **Wheezing and Bronchodilation**

The presence of acute wheezing represents a medical emergency, and elective surgery should be postponed until effective treatment has been instituted. Chronic wheezing is often seen in patients with COPD and is attributable to the presence of gas flow obstruction secondary to smooth muscle contraction, accumulation of secretions, and mucosal edema. Smooth muscle contraction may occur in small airways only (detectable by changes in FEF<sub>25%</sub> to 75%) or may be widespread, with a large reduction of FEV<sub>1</sub> and FVC. The efficacy of bronchodilators in reversing the bronchospastic component is extremely important. A trial of bronchodilators and measurement of their effects on

pulmonary function should be performed in any patient who shows evidence of airflow obstruction. Several classes of bronchodilators are available.

### **Sympathomimetic Drugs**

Sympathomimetic drugs increase the formation of 3',5'-cyclic adenosine monophosphate (cAMP). The balance between cAMP, which produces bronchodilation, and cyclic guanosine monophosphate, which produces bronchoconstriction, determines the state of contraction of the bronchial smooth muscle. Increasing cAMP production therefore causes relaxation of the bronchial tree. Sympathomimetic drugs, such as epinephrine, isoproterenol, isoetharine, and ephedrine, all have mixed  $\beta_1$  and  $\beta_2$  sympathetic agonist effects. The  $\beta_1$  (cardiac effects) of these drugs are often undesirable in patients with COPD. Selective  $\beta_2$  sympathomimetic drugs, such as albuterol, terbutaline, and metaproterenol, given as inhaled aerosols, are the preferred drugs for the treatment of bronchospasm, particularly in patients with cardiac disease.

### **Phosphodiesterase Inhibitors**

Phosphodiesterase inhibitors inhibit the breakdown of cAMP by cytoplasmic phosphodiesterase. The methylxanthines, such as aminophylline, increase the level of cAMP, resulting in bronchodilation. In addition, aminophylline improves diaphragmatic contractility and increases the patient's resistance to fatigue. Therapeutic blood levels of aminophylline are 5 to 20  $\mu\text{g}/\text{mL}$  and can be achieved by infusing a loading dose of 5 to 7  $\text{mg}/\text{kg}$  over 20 minutes, followed by a continuous intravenous infusion of 0.5 to 0.7  $\text{mg}/\text{kg}/\text{hr}$ . Aminophylline may cause ventricular dysrhythmias, and this side effect should be borne in mind when treating patients who have myocardial ischemia. Because newer medications have fewer side effects, aminophylline is now rarely used.

### **Steroids**

Although not true bronchodilators, steroids are traditionally considered to decrease mucosal edema and may prevent the release of bronchoconstricting substances. They are of questionable benefit in acute bronchospasm. Steroids may be administered orally, parenterally, or in aerosol form, such as beclomethasone by inhaler.

### **Cromolyn Sodium**

Cromolyn sodium stabilizes mast cells and inhibits degranulation and

histamine release. It is useful in the prevention of bronchospastic attacks but is of little value in the treatment of the acute situation (see [Chapter 8](#)).

## Parasympatholytic Drugs

Parasympatholytics include atropine and ipratropium (see [Chapter 14](#)). In the past, atropine has been avoided in patients with COPD and bronchitis because of the concern regarding increases in the viscosity of mucus produced by this agent. However, atropine blocks the formation of cyclic guanosine monophosphate and therefore has a bronchodilator effect.

## *Pulmonary Rehabilitation*

Sekine et al. reported that pulmonary rehabilitation led to reduced hospital stay and improved postoperative FEV<sub>1</sub>, compared with a historical control group.<sup>37</sup> The pulmonary rehabilitation included education in a variety of areas such as breathing, exercise, and nutrition. Preoperative physical therapy in patients undergoing surgery for lung cancer led to better oxygenation and shortened hospital stay in the treatment group.<sup>38</sup>

## Intraoperative Monitoring

All patients undergoing anesthesia for thoracic surgical procedures require adherence to the Standards of Basic Anesthetic Monitoring American Society of Anesthesiologists (ASA) (see [Chapter 26](#)). In particular, these include an electrocardiogram (lead II and, if possible, V<sub>5</sub>), chest or esophageal stethoscopes for heart and breath sound auscultation, and a temperature probe. A chest stethoscope may be placed over the dependent hemithorax to assess dependent lung ventilation. Pulse oximetry, which is a standard of care, is especially valuable during thoracic surgery because hypoxemia may occur during OLV.

Dysrhythmias occur commonly both during and after thoracic surgery, making the usual need for continuous electrocardiographic monitoring even more important. Intraoperative supraventricular tachyarrhythmias may be caused by cardiac manipulation. Dysrhythmias that occur during OLV may be a sign of inadequate oxygenation or ventilation. Postoperative dysrhythmias may be related to sympathetic nervous system stimulation from pain or to a decreased pulmonary vascular bed following lung resection. Patients who present for lung resection often have COPD due to cigarette smoking, have right-sided heart strain, and are prone to multifocal atrial tachyarrhythmias.

The axis of electrocardiogram lead II parallels that of the P wave, making this lead useful for dysrhythmia detection. The simultaneous monitoring of

lead V<sub>5</sub> also allows for monitoring of anterolateral wall myocardial ischemia. The use of multiple leads increases the sensitivity for ischemia detection.<sup>39</sup> The following invasive monitors are also indicated and have led to marked improvements in patient care.

### **Direct Arterial Catheterization**

Peripheral arterial catheterization has become an essential tool for the anesthesiologist in the management of patients undergoing major thoracic surgical procedures (see [Chapter 26](#)). It allows for continuous beat-to-beat measurement of blood pressure and frequent sampling for the determination of arterial blood gases. Continuous blood pressure readings are critical during thoracic surgery because surgical manipulations may result in cardiac compression and there may be sudden bleeding. Immediate recognition of these changes allows time for proper identification of the etiology and the institution of appropriate treatment.

Serial arterial blood gas analyses are performed as needed in the management of patients undergoing one-lung anesthesia or during cases in which a part of the lung may be “packed away” for a period. Arterial hypoxemia may occur because of shunting of mixed venous through the collapsed lung and an inadequate hypoxic pulmonary vasoconstriction (HPV) response. Significant changes in acid–base status and hyperventilation or hypoventilation can also be identified.

A radial artery catheter (see [Chapter 26](#)) can be placed in either extremity during thoracic surgery. For a mediastinoscopic examination, one approach is to place the catheter in the right arm and to use it to monitor for possible compression of the innominate artery by the mediastinoscope. This can help avoid central nervous system complications that might result from inadequate cerebral blood flow via the right carotid artery (see “Mediastinoscopy”). The other approach would be to place the arterial catheter in the left radial artery, allowing for continuous blood pressure measurements, uninterrupted by innominate artery compression. If this is done, a pulse oximeter probe should be placed on the right upper extremity to monitor for innominate artery compression. During thoracotomy, placement of the arterial catheter in the dependent arm can be used to monitor for possible axillary artery compression, which may occur if the patient is not properly positioned. For a brief thoracoscopy case in a relatively healthy patient, it would be acceptable to proceed without an arterial catheter, as long as the pulse oximeter is functioning reliably. Such an example might be a healthy patient presenting for bilateral VAT sympathectomy for hyperhidrosis.

The patient undergoing a pulmonary resection, and especially a right pneumonectomy, is at risk for postoperative pulmonary edema. It is

especially important to not fluid overload such a patient, as the likelihood of postoperative edema is greater with increased intraoperative fluid administration. Prior to its administration it would be preferable to be able to identify which patients would be likely to respond favorably to a fluid bolus. The central venous pressure (CVP) may not accurately reflect intravascular volume status, and is no longer recommended as a guide for fluid responsiveness.<sup>40</sup> Systolic pressure variation (SPV) and pulse pressure variation (PPV) have been reported as being able to predict fluid responsiveness.<sup>41</sup> In a recent paper, a PPV greater than 13% predicted fluid responsiveness, less than 9% predicted that the patient would not be responsive, and 9% to 13% reflected a gray zone.<sup>42</sup> Stroke volume variation has been reported to predict fluid responsiveness, specifically in patients undergoing thoracic surgery, during OLV.<sup>43</sup>

### *Central Venous Pressure Monitoring*

The CVP may reflect the patient's blood volume, venous tone, and right ventricular performance; however, it is also affected by central venous obstructions and alterations of intrathoracic pressure such as PEEP (see [Chapter 26](#)). The CVP reflects right-sided heart function, not left ventricular performance. Catheters for measuring CVP may be placed for thoracotomies, and in particular, patients undergoing pneumonectomy. Uses of CVP catheters or large-bore introducers include (1) insertion of a transvenous pacemaker where necessary, (2) infusion of vasoactive drugs, and (3) insertion of a pulmonary artery (PA) catheter, which may subsequently be required during surgery or in the postoperative period. A recent study in healthy subjects indicated that, contrary to common belief, the CVP did not reflect intravascular volume status.<sup>44</sup>

The CVP catheter can be placed centrally from either the external or the internal jugular vein, from the subclavian veins, or from one of the arm veins. The success rate is highest using the right internal jugular vein, and a pacemaker or PA catheter can be inserted most easily from this vein. The major disadvantage of using the external jugular vein during thoracotomy is that the catheter often kinks when the patient is turned to the lateral decubitus position. The subclavian technique leads to a higher incidence of pneumothorax, which can be disastrous if it occurs in the dependent lung during OLV. If necessary and if possible, a subclavian catheter should be placed ipsilateral to the surgery. As discussed earlier, the CVP is no longer considered an accurate guide for fluid responsiveness. However, it is a common practice among thoracic anesthesiologists to place a CVP catheter for certain thoracic cases such as esophagectomy and pneumonectomy.

## *Pulmonary Artery Catheterization*

The PA catheter is most reliably inserted through the right internal jugular vein using a modified Seldinger technique (see [Chapter 26](#)). Insertion of the PA catheter through either the external jugular vein or the subclavian vein often leads to obstruction of the catheter when the patient is placed in the lateral decubitus position. Misinterpretation of data from a PA catheter is a real risk in a patient with cardiac and pulmonary diseases undergoing thoracic surgery with OLV. These errors can be produced by altered ventilatory modes, the location of the PA catheter tip, ventricular compliance changes, or ventricular interdependence.<sup>45</sup> A major limitation of the PA catheter is the assumption that the pulmonary capillary wedge pressure (PCWP) provides a good approximation of left ventricular end-diastolic volume. The use of PCWP directly to assess preload assumes a linear relationship between ventricular end-diastolic volume and ventricular end-diastolic pressure. However, alterations in ventricular compliance affect this pressure–volume relationship during surgery. Decreases in ventricular compliance can occur with myocardial ischemia, shock, right ventricular overload, or pericardial effusion. Numerous investigators have demonstrated a poor correlation between PCWP and left ventricular end-diastolic volume in acutely ill patients.<sup>46</sup> This correlation is further worsened by the application of PEEP. In addition, ventricular interdependence can cause misdiagnosis when the interventricular septum encroaches on the left ventricular cavity, leading to increased values of PCWP. A PCWP associated with a decreased cardiac output can be interpreted as left ventricular failure, when in fact, left ventricular end-diastolic volume may not be increased but decreased because of compression of the left ventricle by a distended right ventricle. This situation can occur with acute respiratory failure and high levels of PEEP. Techniques such as echocardiography, which directly measure ventricular dimensions, may facilitate resolution of this complex situation.

Because most of the pulmonary blood flow is to the right lower lobe, the tip of a flow-directed PA catheter is usually located in the right lower lobe. During a left thoracotomy with OLV, the catheter tip would then be in the dependent lung and should provide accurate hemodynamic measurements. However, during a right thoracotomy with OLV, the catheter tip would most likely be in the nondependent lung, and may not be accurate. The use of intraoperative mean pulmonary artery pressure has been reported to be an indicator of safety for lung resection under thoracotomy.<sup>47</sup> The authors concluded that following occlusion of the main PA, upper safety limits of 33 mmHg for right, and 35 mmHg for left thoracotomy could be used. The authors noted that the difference between sides was minimal, and less than expected. The monitoring of Sv–O<sub>2</sub> has been evaluated in patients

undergoing one-lung anesthesia.<sup>48</sup> Changes in Sv – O<sub>2</sub> were mainly dependent on changes in SaO<sub>2</sub>. Currently, the use of the PA catheter for monitoring during thoracic surgery is generally unnecessary, and may be reserved for patients with pulmonary hypertension.

### *Transesophageal Echocardiography*

Transesophageal echocardiography (TEE) is a useful intraoperative monitor for ventricular function, valvular function, and wall motion changes that might reflect ischemia (see [Chapter 27](#)). Its use in thoracic surgical patients has been limited, but it is widely used in patients undergoing lung transplant. The use of TEE requires special training, and may not be available at all centers. A recent review concluded that although the intraoperative use of TEE is not routinely indicated, it may be useful for diagnosing right ventricular dysfunction, in the setting of hypotension or arrhythmias following lung resection.<sup>49</sup> Right ventricular dysfunction may occur during OLV, clamping of the pulmonary artery for pneumonectomy, or lung transplantation. TEE may be used to help determine if it is necessary to utilize cardiopulmonary bypass during lung transplantation.<sup>50</sup>

TEE may be useful in visualizing hilar lung tumors, and evaluating possible extension into the heart. In one study, central lung tumors were seen with TEE in nine of the nine patients, peripheral lung tumors in one of the three patients, and an anterior mediastinal mass in one of one patient.<sup>51</sup> In this study, TEE revealed PA compression in five patients and PA infiltration in two patients. In another study investigating echocardiographic recognition of mediastinal tumors, TEE revealed that the tumors were often adjacent to the heart and identified those patients in whom there was compression of the innominate vein or PA, or infiltration of the heart.<sup>52</sup>

Intraoperative TEE has also revealed tumor invasion of the heart, indicating that a resection by thoracotomy without cardiopulmonary bypass was not feasible.<sup>53</sup> In one case report, TEE monitoring during an attempted resection of a tumor invading the left atrium showed embolization of the tumor.<sup>54</sup> Fragments of the tumor were seen to pass through the aortic valve. This patient subsequently died of disseminated metastases. In an exploratory thoracotomy for hemothorax, intraoperative TEE revealed the presence of a subacute aortic dissection, which was believed to be the cause of the hemothorax.<sup>55</sup> TEE was used intraoperatively to evaluate a large anterior mediastinal mass, providing data on right ventricular outflow compression, and ventricular contractility and filling status.<sup>56</sup> In another recent report, a mediastinal mass was diagnosed intraoperatively using TEE; in that case, the mass had been misdiagnosed preoperatively with transthoracic echocardiography as a pericardial effusion.<sup>57</sup>

## **Additional Noninvasive Monitoring**

Although data are presently limited, it has been reported that decreased cerebral oximetry values by absolute cerebral oximetry during OLV have been correlated with postoperative complications.<sup>58</sup> In a subsequent study, the larger decreases in cerebral oxygen saturation occurred in patients with better preoperative lung function.<sup>59</sup> At this time, the data are still too limited to recommend cerebral oximetry as a routine monitor during thoracic surgery.

A meta-analysis of the use of noninvasive cardiac output measurements during surgery revealed poor agreement with thermodilution. Noninvasive cardiac output measurements are not commonly utilized during thoracic surgery and thus are recommended at this time.<sup>60</sup>

## ***Monitoring of Oxygenation and Ventilation***

### **Oxygenation**

During the administration of all thoracic surgical anesthetics, the concentration of inspired oxygen in the breathing system must be measured using an oxygen analyzer with a low oxygen concentration limit alarm (see [Chapter 25](#)). Such analyzers vary in sophistication from fuel cells to rapidly responding paramagnetic analyzers that monitor oxygen breath-by-breath and display an oxygram (analogous to, and a mirror image of, the capnogram). Adequacy of blood oxygenation must also be ensured, and adequate illumination and exposure of the patient are helpful to assess the color of shed blood or the presence of cyanosis of the lips, nail beds, or mucous membranes. Most patients undergoing thoracic surgical or diagnostic procedures have an arterial catheter in place for continuous monitoring of blood pressure and sampling of arterial blood for blood gas analyses.

Pulse oximetry is a standard of care for noninvasive assessment of blood oxygenation. The use of pulse oximetry is especially important during OLV, when rapid assessment of oxygenation is critical. A low SpO<sub>2</sub> reading provides the clinician with an indication for blood gas sampling and laboratory analysis of arterial blood. The traditional two-wavelength pulse oximeter may display spurious readings of SpO<sub>2</sub> in the presence of dyshemoglobins, methemoglobin, and carboxyhemoglobin. Multiwavelength (8 or 12 wavelengths) pulse oximeters are available that can measure carboxyhemoglobin, methemoglobin, deoxygenated hemoglobin, and oxygenated hemoglobin (HbO<sub>2</sub>%).<sup>61,62</sup> Continuous noninvasive monitoring of total hemoglobin concentration is also available.<sup>63–65</sup>

### **Ventilation**

All patients must be continually monitored to ensure adequacy of ventilation. Monitoring includes qualitative signs such as chest excursion (visual observation of the lungs when the chest is open) and auscultation of breath sounds. In addition, during OLV, a stethoscope can be placed on the chest wall under the ventilated dependent lung. During controlled ventilation, circuit low-pressure and high-pressure alarms with an audible signal must be used. The respiratory rate,  $V_T$ , minute volume, and inflation pressures should be monitored.

Adequacy of ventilation is confirmed by monitoring arterial blood gas analyses and  $\text{PaCO}_2$ , in particular. This may be estimated continuously and noninvasively by capnography (see [Chapter 26](#)). The end-tidal  $\text{CO}_2$  concentration represents alveolar  $\text{CO}_2$  ( $\text{PACO}_2$ ), which approximates  $\text{PaCO}_2$ . There is normally a small arterial-to-alveolar  $\text{CO}_2$  difference (4 to 6 mmHg), depending on alveolar dead space. The capnogram waveform is also helpful in diagnosing airway obstruction, incomplete relaxation, and even malposition of the DLT.<sup>66,67</sup> During OLV, systemic hypoxemia is usually a greater problem than hypercarbia.<sup>68</sup> This is because  $\text{CO}_2$  is approximately 20 times more diffusible than oxygen and  $\text{PaCO}_2$  is more dependent on ventilation, compared with  $\text{PaO}_2$ , which is more dependent on perfusion.

## Physiology of One-lung Ventilation

**Physiology of the Lateral Decubitus Position.** Ventilation and blood flow in the upright position are discussed in [Chapters 15](#) and [29](#). These variables will now be considered as they pertain to the lateral decubitus position under six circumstances that are encountered during thoracic surgery.

**Lateral Position, Awake, Breathing Spontaneously, Chest Closed.** In the lateral decubitus position, the distribution of blood flow and ventilation is similar to that in the upright position, but turned by 90 degrees ([Fig. 38-5](#)). Blood flow and ventilation to the dependent lung are significantly greater than that to the nondependent lung. Good  $V \cdot /Q \cdot$  matching at the level of the dependent lung results in adequate oxygenation in the awake patient who is breathing spontaneously. There are two important concepts in this situation. First, because perfusion is gravity-dependent, the vertical hydrostatic pressure gradient is smaller in the lateral than in the upright position; therefore, zone 1 is usually less extended. Second, in regard to ventilation, the dependent hemidiaphragm is pushed higher into the chest by the abdominal contents compared with the nondependent lung hemidiaphragm. During spontaneous ventilation, the conserved ability of the dependent diaphragm to contract results in an adequate distribution of  $V_T$  to the dependent lung. Because most of the perfusion is to the dependent lung, the  $V \cdot /Q \cdot$  matching in this position is maintained similar to that in the upright position.

**Lateral Position, Awake, Breathing Spontaneously, Chest Open.** Controlled positive-pressure ventilation is the most common way to provide adequate ventilation and ensure gas exchange in an open-chest situation. Frequently, thoracoscopy is performed using intercostal blocks with the patient breathing spontaneously to allow proper lung examination. The thoracoscope provides an adequate seal of the open chest to prevent a “free” open-chest situation. Two complications can arise from the patient breathing spontaneously with an open chest. The first is mediastinal shift, usually occurring during inspiration (Fig. 38-6). The negative pressure in the intact hemithorax, compared with the less negative pressure of the open hemithorax, can cause the mediastinum to move vertically downward and push into the dependent hemithorax. The mediastinal shift can create circulatory and reflex changes that may result in a clinical picture similar to that of shock and respiratory distress. Sometimes, depending on the severity of the distress, the patient needs to be tracheally intubated immediately, with initiation of positive-pressure ventilation, and the anesthesiologist must be prepared to intubate in this position without disturbing the surgical field.

**Figure 38-5** Schematic representation of the effects of gravity on the distribution of pulmonary blood flow in the lateral decubitus position. Vertical gradients in the lateral decubitus position are similar to those in the upright position and cause the creation of West zones 1, 2, and 3. Consequently, pulmonary blood flow increases with lung dependency, and is largest in the dependent lung and least in the nondependent lung.  $P_a$ , pulmonary artery pressure;  $P_A$ , alveolar pressure;  $P_v$ , pulmonary venous pressure. (Adapted from Benumof JL. Physiology of the open-chest and one lung ventilation. In: *Thoracic Anesthesia*. New York, NY: Churchill Livingstone; 1983:288.)

The second phenomenon is paradoxical breathing (Fig. 38-7). During inspiration, the relatively negative pressure in the intact hemithorax compared with atmospheric pressure in the open hemithorax can cause movement of air from the nondependent lung into the dependent lung. The opposite occurs during expiration. This gas movement reversal from one lung

to the other represents wasted ventilation and can compromise the adequacy of gas exchange. Paradoxical breathing is increased by a large thoracotomy or by an increase in airway resistance in the dependent lung. Positive-pressure ventilation or adequate sealing of the open chest eliminates paradoxical breathing.

**Lateral Position, Anesthetized, Breathing Spontaneously, Chest Closed.** The induction of general anesthesia does not cause significant change in the distribution of blood flow, but it has an important impact on the distribution of ventilation. Most of the  $V_T$  enters the nondependent lung, and this results in a significant  $V/Q$  mismatch. Induction of general anesthesia causes a reduction in the volumes of both lungs secondary to a reduction in FRC. Any reduction in volume in the dependent lung is of a greater magnitude than that in the nondependent lung for several reasons. First, the cephalad displacement of the dependent diaphragm by the abdominal contents is more pronounced and is increased by paralysis. Second, the mediastinal structures pressing on the dependent lung or poor positioning of the dependent side on the operating table prevents the lung from expanding properly. The aforementioned factors will move lungs to a lower volume on the S-shaped volume–pressure curve (Fig. 38-8). The nondependent lung moves to a steeper position on the compliance curve and receives most of the  $V_T$ , whereas the dependent lung is on the flat (noncompliant) part of the curve.

**Figure 38-6** Schematic representation of mediastinal shift in the spontaneously breathing, open-chested patient in the lateral decubitus position. During inspiration, negative pressure in the intact hemithorax causes the mediastinum to move downward. During expiration, relative positive pressure in the intact hemithorax causes the mediastinum to move upward. (Adapted from Tarhan S, Moffitt EA. Principles of thoracic anesthesia. *Surg Clin North Am.* 1973;53:813.)

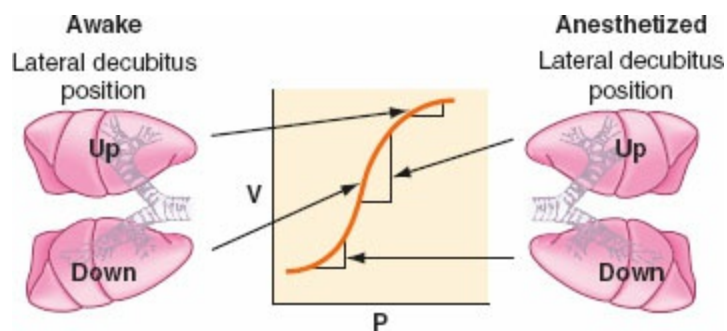

**Lateral Position, Anesthetized, Breathing Spontaneously, Chest Open.** Opening the chest has little impact on the distribution of perfusion. However, the upper lung is now no longer restricted by the chest wall and is free to expand, resulting in a further increase in  $V\cdot/Q\cdot$  mismatch as the nondependent lung is preferentially ventilated, owing to a now increased compliance.

**Lateral Position, Anesthetized, Paralyzed, Chest Open.** During paralysis and positive-pressure ventilation, diaphragmatic displacement is maximal over the nondependent lung, where there is the least amount of resistance to diaphragmatic movement caused by the abdominal contents (Fig. 38-9). This further compromises the ventilation to the dependent lung and increases the  $V\cdot/Q\cdot$  mismatch.

**OLV, Anesthetized, Paralyzed, Chest Open.** During two-lung ventilation in the lateral position, the mean blood flow to the nondependent lung is assumed to be 40% of cardiac output, whereas 60% of cardiac output goes to the dependent lung (Fig. 38-10). Normally, venous admixture (shunt) in the lateral position is 10% of cardiac output and is equally divided as 5% in each lung. Therefore, the average percentage of cardiac output participating in gas exchange is 35% in the nondependent lung and 55% in the dependent lung.

**Figure 38-7** Schematic representation of paradoxical respiration in the spontaneously breathing, open-chested patient in the lateral decubitus position. During inspiration, movement of gas from the exposed lung into the intact lung and movement of air from the environment into the open hemithorax cause collapse of the exposed lung. During expiration, the reverse occurs, and the exposed lung expands. (Adapted from Tarhan S, Moffitt EA. Principles of thoracic anesthesia. *Surg Clin North Am.* 1973;53:813.)

**Figure 38-8** The left side of the schematic shows the distribution of ventilation in the awake patient (closed chest) in the lateral decubitus position, and the right side shows the distribution of ventilation in the anesthetized patient (closed chest) in the lateral decubitus position. The induction of anesthesia has caused a loss in lung volume in both lungs, with the nondependent (up) lung moving from a flat, noncompliant portion to a steep, compliant portion of the pressure–volume curve, and the dependent (down) lung moving from a steep, compliant part to a flat, noncompliant part of the pressure–volume curve. Thus, the anesthetized patient in the lateral decubitus position has most

tidal ventilation in the nondependent lung (where there is the least perfusion) and less tidal ventilation in the dependent lung (where there is the most perfusion). V, volume; P, pressure. (Adapted from Benumof JL. *Anesthesia for Thoracic Surgery*. Philadelphia, PA: WB Saunders; 1987:112.)

**Figure 38-9** This schematic of a patient in the lateral decubitus position compares the closed-chested anesthetized condition with the open-chested anesthetized and paralyzed condition. Opening the chest increases nondependent lung compliance and reinforces or maintains the larger part of the tidal ventilation going to the nondependent lung. Paralysis also reinforces or maintains the larger part of tidal ventilation going to the nondependent lung because the pressure of the abdominal contents ( $P_{AB}$ ) pressing against the upper diaphragm is minimal, and it is therefore easier for positive-pressure ventilation to displace this less resisting dome of the diaphragm. V, volume; P, pressure. (Adapted from Benumof JL. *Anesthesia for Thoracic Surgery*. Philadelphia, PA: WB Saunders; 1987:112.)

OLV creates an obligatory right-to-left transpulmonary shunt through the nonventilated, nondependent lung because the  $V/Q$  ratio of that lung is zero. In theory, an additional 35% should be added to the total shunt during OLV. However, assuming active HPV, blood flow to the nondependent hypoxic lung will be decreased by 50% and therefore is  $(35/2) = 17.5\%$ . To this, 5% must be added, which is the obligatory shunt through the nondependent lung. The shunt through the nondependent lung is therefore 22.5% (Fig. 38-10). Together with the 5% shunt in the dependent lung, total shunt during OLV is  $22.5\% + 5\% = 27.5\%$ . This results in a  $PaO_2$  of approximately 150 mmHg ( $FiO_2 = 1$ ).<sup>69</sup>

Because 72.5% of the perfusion is directed to the dependent lung during OLV, the matching of ventilation in this lung is important for adequate gas exchange. The dependent lung is no longer on the steep (compliant) portion of the volume–pressure curve because of reduced lung volume and FRC. There are several reasons for this reduction in FRC, including general anesthesia, paralysis, pressure from abdominal contents, compression by the weight of mediastinal structures, and suboptimal positioning on the operating table. Other considerations that impair optimal ventilation to the dependent lung include absorption atelectasis, accumulation of secretions, and the formation of a transudate in the dependent lung. All these create a low  $V/Q$ .

ratio and a large  $P(A-a)O_2$  gradient.

## One-lung Ventilation

### Absolute Indications for One-lung Ventilation

Currently, a variety of thoracic surgical procedures such as lobectomy, pneumonectomy, esophagogastrectomy, pleural decortication, bullectomy, and bronchopulmonary lavage are commonly performed. Customarily, the indications are classified either as absolute or as relative (Table 38-1). The absolute indications include life-threatening complications, such as massive bleeding, sepsis, and pus, in which the nondiseased contralateral lung must be protected from contamination. Bronchopleural and bronchocutaneous fistulae are absolute indications because they offer a low-resistance pathway for the delivered  $V_T$  during positive-pressure ventilation. A giant unilateral bulla may rupture under positive pressure, and ventilatory exclusion is mandatory. Finally, during bronchopulmonary lavage for alveolar proteinosis or cystic fibrosis, prevention of drowning the contralateral lung is necessary.

Video-assisted thoracoscopy (VAT) is now widely used in clinical practice. Unlike conventional thoracoscopy, VAT allows for an extensive variety of diagnostic and therapeutic procedures. Improvements in video-endoscopic surgical equipment and a growing enthusiasm for minimally invasive surgical approaches have contributed to its use. In most cases general anesthesia with OLV is required. The lung should be well collapsed to provide the surgeon with an optimal view of the surgical field, and to facilitate palpation of the lesion in the lung parenchyma. In addition, it is difficult to place the stapler on a lung that is not completely collapsed, and there is an increase in incidence of postoperative air leak in these circumstances. The increased use of VAT has significantly increased the number of procedures that require lung separation. In some institutions, 80% to 90% of the procedures are now performed using the thoracoscopic approach. In contemporary anesthesia practice, VAT is an absolute indication for lung separation.

**Figure 38-10** Schematic representation of two-lung ventilation versus one-lung ventilation (OLV). Typical values for fractional blood flow to the nondependent and dependent lungs, as well as  $P_{aO_2}$  and  $Q \cdot S/Q \cdot t$  for the two conditions, are shown. The  $Q \cdot S/Q \cdot t$  during two-lung ventilation is assumed to be distributed equally between the two lungs (5% to each lung). The essential difference between two-lung ventilation and OLV is that, during OLV, the nonventilated lung has some blood flow and therefore an obligatory shunt, which is not present during two-lung ventilation. The 35% of total flow perfusing the nondependent lung, which was not shunt flow, was assumed to be able to reduce its blood flow by 50% by hypoxic pulmonary vasoconstriction. The increase in  $Q \cdot S/Q \cdot t$  from two-lung to OLV is assumed to be due solely to the increase in blood flow through the nonventilated, nondependent lung during OLV. (Adapted from Benumof JL. *Anesthesia for Thoracic Surgery*. Philadelphia, PA: WB Saunders; 1987:112.)

Modified from Benumof JL. Physiology of the open-chest and one lung ventilation. In: Kaplan JA, ed. *Thoracic Anesthesia*. New York, NY: Churchill Livingstone; 1983:299.

### Relative Indications for One-lung Ventilation

In clinical practice, a DLT is commonly used for a lobectomy or pneumonectomy; these represent relative indications for lung separation when performed through an open thoracotomy. Upper lobectomy, pneumonectomy, and thoracic aortic aneurysm repair are high-priority indications. These procedures are technically difficult, and optimal surgical exposure and a quiet operative field are highly desirable. Lower or middle

lobectomy and esophageal resection are of lower priority. There are a number of additional procedures that have not been traditionally included as indications for OLV. Nevertheless, many surgeons are accustomed to operating with the lung collapsed for these cases. OLV minimizes lung trauma from retractors and manipulation, improves visualization of lung anatomy, and facilitates identification and separation of anatomic structures and lung fissures. These procedures include minimally invasive cardiac surgery, lung volume reduction, thoracic aneurysm repair, thoracic spinal procedures, mediastinal mass resection, thymectomies, and mediastinal lymph node dissection.

It is important to distinguish between the need for lung isolation versus lung separation.

**Lung Isolation.** Whenever the nondiseased lung is threatened with contamination by blood or pus from the diseased lung, the lungs must be isolated to prevent potentially life-threatening complications. Other indications are bronchopleural and bronchocutaneous fistulas because they offer a low-resistance pathway for the delivered  $V_T$  during positive-pressure ventilation. Finally, during bronchopulmonary lavage for alveolar proteinosis or cystic fibrosis, protection of the contralateral lung from drowning is necessary. These situations, however, are relatively uncommon and in modern anesthesia practice constitute less than 10% of all thoracic procedures.

**Lung Separation.** All other indications for OLV can be considered as lung separations, in which there is no risk of contamination of the dependent lung. This includes all the relative indications that are primarily for surgical exposure. VAT for diagnostic and therapeutic procedures, which requires a well-collapsed lung, should also be included in this category. The majority of procedures where OLV is used are for lung separation; only a minority require lung isolation.<sup>70,71</sup>

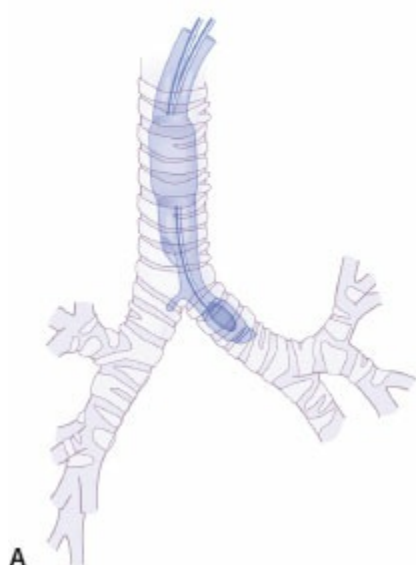

## *Methods of Lung Separation*

### **Double-Lumen Endobronchial Tubes**

Double-lumen endobronchial tubes are currently the most widely used means of achieving lung separation and OLV. There are several different types of DLT, but all are essentially similar in design in that two endotracheal tubes are “bonded” together. One lumen is long enough to reach a main stem bronchus, and the second lumen ends with an opening in the distal trachea. Lung separation is achieved by inflation of two cuffs: A proximal tracheal cuff and a distal bronchial cuff located in the main stem bronchus (see “Positioning Double-lumen Tubes”). The endobronchial cuff of a right-sided tube is slotted or otherwise designed to allow ventilation of the right upper

lobe because the right main stem bronchus is too short to accommodate both the right lumen tip and a right bronchial cuff.

**Robertshaw Tube.** The Carlens tube (which had a carinal hook) was the first clinically available DLT and was used by pulmonologists for split function spirometry testing (Fig. 38-11A). Subsequently, the Robertshaw-design DLT (which lacked a carinal hook) was developed to facilitate thoracic surgery (Fig. 38-11B). This DLT is available in left-sided and right-sided forms. The absence of a carinal hook facilitates insertion. This tube design has the advantages of having D-shaped, large-diameter lumens that allow easy passage of a suction catheter, offer low resistance to gas flow, and have a fixed curvature to facilitate proper positioning and reduce the possibility of kinking. The original red rubber Robertshaw tubes were available in three sizes: small, medium, and large. Red rubber tubes are rarely used now and have been replaced by clear, polyvinyl chloride (PVC) disposable Robertshaw-design DLTs. These are available in both right-sided and left-sided versions and in 35 French (Fr), 37 Fr, 39 Fr, and 41 Fr sizes. A 32-Fr left-sided DLT is available for small adults, and a 28 Fr for use in pediatric cases. The advantages of the disposable tubes include the relative ease of insertion and proper positioning as well as easy recognition of the blue color of the endobronchial cuff when fiberoptic bronchoscopy is used. Other advantages are the confirmation of the position on a chest radiograph using the radiopaque lines in the wall of the tube and the continuous observation of tidal gas exchange and respiratory moisture through the clear plastic. The right-sided endobronchial tube is designed to minimize occlusion of the opening of the right upper lobe bronchus. The right endobronchial cuff is doughnut-shaped and allows the right upper lobe ventilation slot to ride over the opening of the right upper lobe bronchus. The tube is also suitable for use in long-term ventilation in the intensive care unit (ICU) because it has a high-volume, low-pressure cuff. These disposable PVC tubes are generally considered the tubes of choice for achieving lung separation and OLV.

**Figure 38-11 A:** Left main stem endobronchial intubation using a Carlen's tube. Note carinal "hook" used for correct positioning. (Reprinted with permission from Hillard EK, Thompson PW. Instruments used in thoracic anaesthesia. In: Mushin WW, ed. *Thoracic Anaesthesia*. Oxford: Blackwell Scientific; 1963:315.) **B:** A left-sided Robertshaw type double-lumen tube constructed from polyvinyl chloride. (Courtesy of Nellcor Puritan Bennett, Inc., Pleasanton, California.)

A rubber-silicone left-sided DLT, Silbronco (Silbronco DLT, Fuji Systems, Tokyo, Japan), is also available. This tube has a D-shaped wire-reinforced lumen to maintain the tip at a 45-degree angle. The reinforced wall tends to prevent obstruction or kinking of the bronchial lumen, yet at the same time maintains flexibility. It is especially useful if the left main stem bronchus is angled at 90 degrees from the trachea, making it almost impossible to position a PVC DLT. This clinical scenario can be seen in patients who have previously undergone a left upper lobectomy and the expansion of the left lower lobe displaces the left main bronchus upward.<sup>72</sup> As the left main bronchus is considerably longer than the right bronchus, there is a narrow margin of safety on the right main bronchus, with potentially a greater risk of upper lobe obstruction whenever a right-sided DLT is used. A left-sided DLT is preferred for both right- and left-sided procedures. A left-sided DLT was selected for 1,166 of the 1,170 patients in one report, and was used successfully in over 98% of those patients.<sup>73</sup> The authors recommended selecting the largest DLT that will safely fit the bronchus. This will provide less resistance to ventilation and is less likely to dislocate.

Some authors have suggested using the patient height as a basis for

selecting a DLT. However, the correlation between airway size and height is extremely poor. Tracheal and bronchial dimensions can be also directly measured from the chest radiograph or chest CT scan. It is possible to measure the diameter of the left bronchus from the chest radiograph in almost 75% of patients. In patients in whom the left main bronchus cannot be directly measured, the left bronchial diameter can be accurately estimated by measuring tracheal width. The width of the left bronchus is directly proportional to tracheal width. The left bronchial width is estimated by multiplying the tracheal width by 0.68.<sup>74</sup> Typically, most women will need a 37-Fr DLT and most men will be adequately managed with a 39-Fr DLT. In the past it was a more common practice to use the largest size DLT possible to avoid distal migration of the tube, and so that the pressure in the bronchial cuff could be minimized by needing less air for a seal. The common practice of fiberoptic bronchoscopy has decreased the risk of undetected distal placement or migration of the bronchial tip. A study showed that the routine use of a 35-Fr DLT in adults regardless of height was not associated with an increase in hypoxemia or any other adverse clinical outcomes.<sup>75</sup>

The depth required for insertion of the DLT correlates with the height of the patient. For any adult 170 to 180 cm tall, the average depth for a left-sided DLT is 29 cm. For every 10 cm increase or decrease in height, the DLT is advanced or withdrawn 1 cm.<sup>76</sup>

Recently introduced to clinical practice is the VivaSight-DL disposable DLT (ET View Ltd., Misgav, Israel) which consists of a high-resolution camera embedded on the DLT between the tracheal cuff and the bronchial cuff.<sup>77,78</sup> This device allows continuous real-time viewing of the DLT position, which can be important in cases where the patient's head is away from the anesthesiologist, such as during robotic thoracic surgery. The VivaSight tube is also available as a single-lumen tube (VivaSight-SL) through which an independent blocker may be inserted without the need of a FB. A prospective study of 71 adult patients, compared intubation times using either the VivaSight-DL or a conventional DLT.<sup>79</sup> The duration of intubation with visual confirmation of tube position was significantly reduced using the VivaSight-DL compared with the conventional DLT (51 vs. 264 seconds). None of the patients allocated to the VivaSight-DL required fiberoptic bronchoscopy during intubation or surgery. One limitation of the VivaSight compared with a FB is that its position of the camera is set at the distal part of the tracheal lumen of the tube and therefore it cannot be used to inspect either main stem bronchus if this is deemed necessary. The VivaSight DLT will not allow complete elimination of the use of a FB in lung isolation procedures, but may instead lead to a significant reduction.

 **Placement of Double-lumen Tubes.** This section concentrates on the insertion of disposable Robertshaw-design DLTs because they are the

most widely used. Before insertion, the DLT should be prepared and checked. The tracheal cuff (high volume, low pressure) can accommodate up to 20 mL of air, and the bronchial cuff can be checked using a 3-mL syringe. The tube should be coated liberally with water-soluble lubricant and the stylet should be withdrawn, lubricated, and gently placed back into the bronchial lumen without disturbing the tube's preformed curvature. A Macintosh laryngoscope blade is preferred for intubation of the trachea because it provides the largest area through which to pass the tube. The insertion of the tube is performed with the distal concave curvature facing anteriorly. After the tip of the tube is past the vocal cords, the stylet is removed and the tube is rotated through 90 degrees. A left-sided tube is rotated 90 degrees to the left, and a right-sided tube is rotated to the right. Advancement of the tube ceases when moderate resistance to further passage is encountered, indicating that the tube tip has been firmly seated in the main stem bronchus. It is important to remove the stylet before rotating and advancing the tube to avoid tracheal or bronchial laceration. Rotation and advancement of the tube should be performed gently and under continuous direct laryngoscopy to prevent hypopharyngeal structures from interfering with proper positioning. Once the tube is believed to be in the proper position, a sequence of steps should be performed to check its location.

First the tracheal cuff should be inflated, and equal ventilation of both lungs established. If breath sounds are not equal, the tube is probably too far down, and the tracheal lumen opening is in a main stem bronchus or is lying at the carina. Withdrawal of the tube by 2 to 3 cm usually restores equal breath sounds. The second step is to clamp the right side (in the case of the left-sided tube) and remove the right cap from the connector. Then the bronchial cuff is slowly inflated to prevent an air leak from the bronchial lumen around the bronchial cuff into the tracheal lumen. This ensures that excessive pressure is not applied to the bronchus and helps avoid laceration. Inflation of the bronchial cuff rarely requires greater than 2 mL of air. The third step is to remove the clamp and check that both lungs are ventilated with both cuffs inflated. This ensures that the bronchial cuff is not obstructing the contralateral hemithorax, either totally or partially. The final step is to clamp each side selectively and watch for absence of movement and breath sounds on the ipsilateral (clamped) side; the ventilated side should have clear breath sounds, chest movement that feels compliant, respiratory gas moisture with each tidal ventilation, and no gas leak. If peak airway pressure during two-lung ventilation is 20 cm H<sub>2</sub>O, it should not exceed 40 cm H<sub>2</sub>O for the same V<sub>T</sub> during OLV.

Other methods that have been used for ensuring the correct placement of a DLT include fluoroscopy, chest radiography, selective capnography, and use of an underwater seal. Determination of the presence of gas leaks when

positive pressure is applied to one lumen of a DLT is easily done in the operating room (OR). If the bronchial cuff is not inflated and positive pressure is applied to the bronchial lumen of the DLT, gas leaks past the bronchial cuff and returns through the tracheal lumen. If the tracheal lumen is connected to an underwater seal system, gas will be seen to bubble up through the water. The bronchial cuff can then be gradually inflated until no gas bubbles are seen and the desired cuff seal pressure can be attained. This test is of extreme importance when absolute lung separation is needed, such as during bronchopulmonary lavage.

The most important advance in checking for proper position of a DLT is the introduction of the pediatric flexible fiberoptic bronchoscope (Fig. 5 38-12). Smith et al.<sup>80</sup> showed that when the disposable DLT was believed to be in correct position by auscultation and physical examination, subsequent fiberoptic bronchoscopy showed that 48% of tubes were, in fact, malpositioned. Such malpositions, however, are usually of no clinical significance.<sup>81</sup> When using a left-sided DLT, the bronchoscope is usually first introduced through the tracheal lumen. The carina is visualized, but no bronchial cuff herniation should be seen. The upper surface of the blue endobronchial cuff should be just below the tracheal carina. The bronchial cuff of the disposable DLT is easily visualized because of its blue color. The bronchoscope should then be passed through the bronchial lumen, and the left upper lobe bronchial orifice should be identified. When a right-sided DLT is used, the carina should be visualized through the tracheal lumen but, more importantly, the orifice of the right upper lobe bronchus should be identified when the bronchoscope is passed through the right upper lobe ventilating slot of the DLT. Pediatric fiberoptic bronchoscopes are available in several sizes: 5.6, 4.9, and 3.6 mm in external diameter. The 4.9-mm diameter bronchoscope can be passed through DLTs of 37 Fr and larger. The 3.6-mm diameter bronchoscope is easily passed through all sizes of DLT. In general, it is recommended that the largest size that can pass through the lumen of a DLT be used because it provides better visualization and facilitates identification of the bronchial anatomy. Excellent fiberoptic images of the tracheobronchial tree can be seen by accessing the website [thoracicanesthesia.com](http://thoracicanesthesia.com).

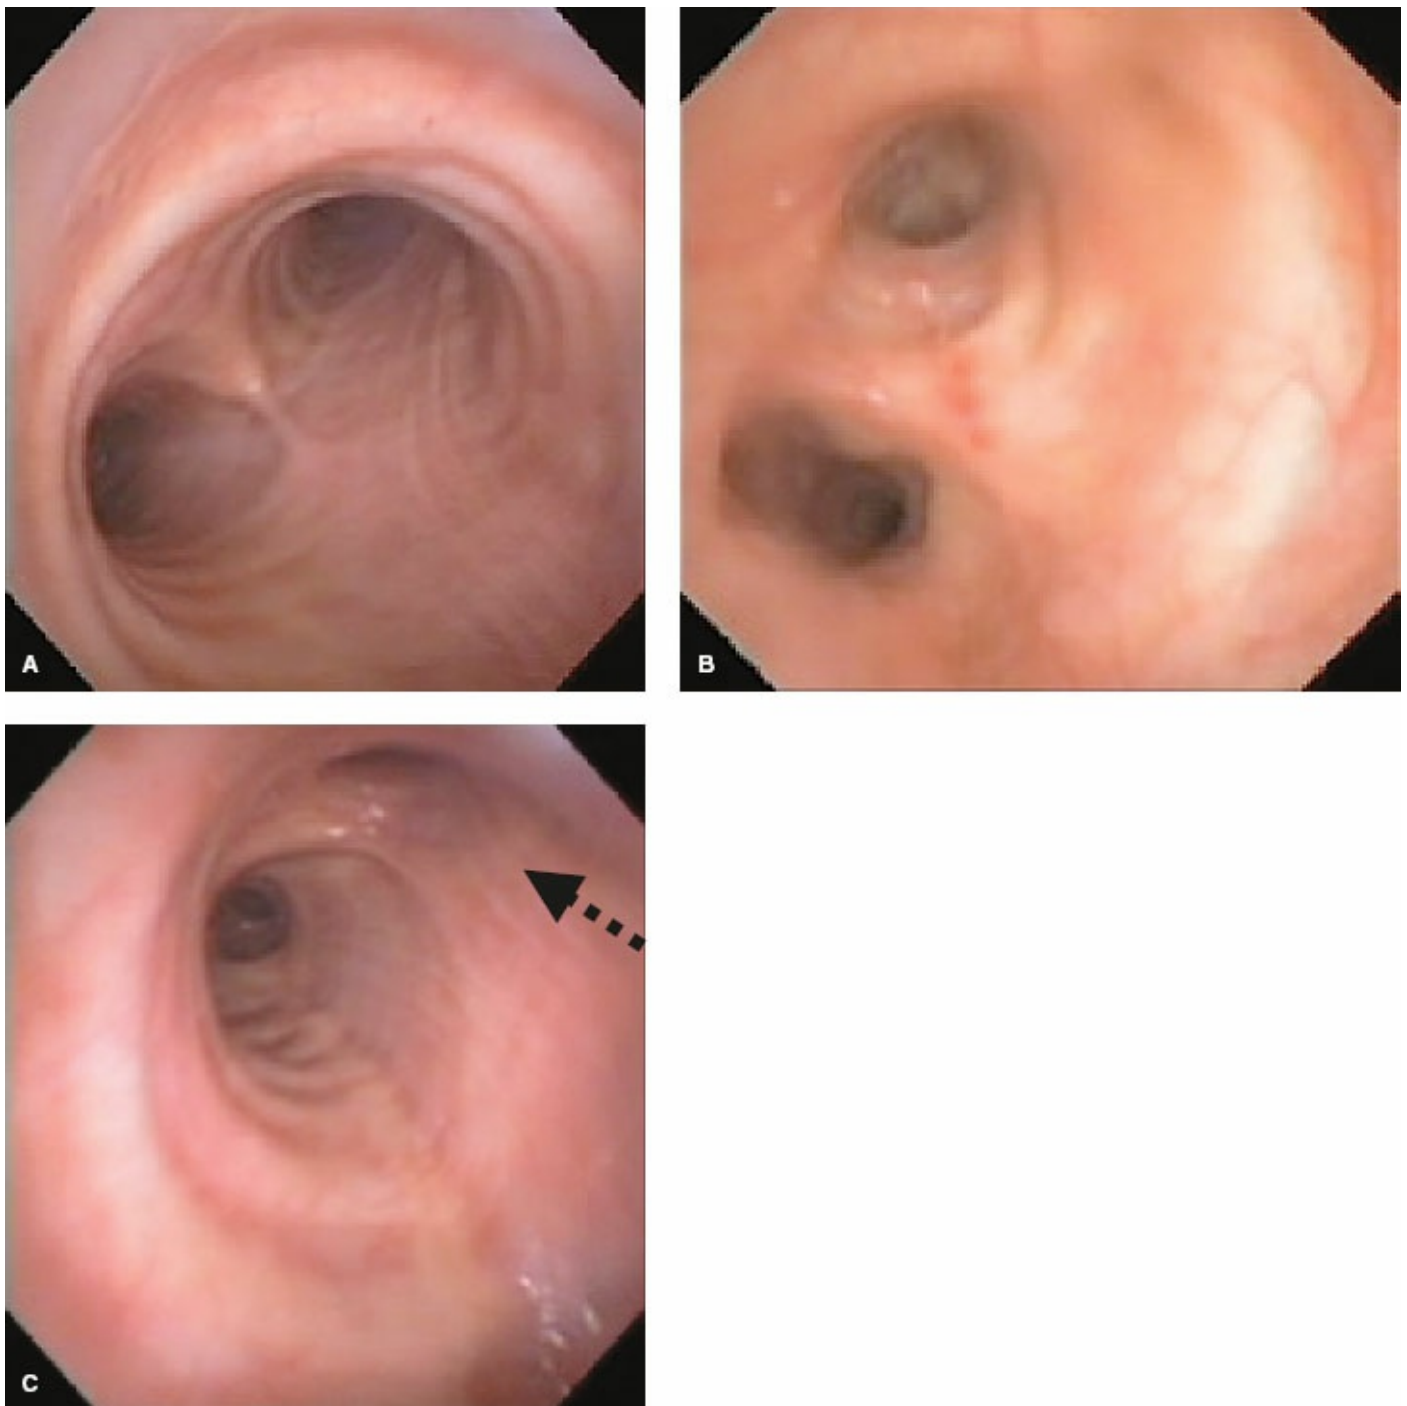

**Problems of Malposition of the Double-Lumen Tube.** The use of a DLT is associated with a number of potential problems, the most important of which is malposition. There are several possibilities for tube malposition. The DLT may be accidentally directed to the side opposite the desired main stem bronchus. In this case, the lung opposite the side of the connector clamp will collapse. Inadequate separation, increased airway pressures, and instability of the DLT usually occur. In addition, because of the morphology of the DLT curvatures, tracheal or bronchial lacerations may result. If a left-sided DLT is

inserted into the right main stem bronchus, it obstructs ventilation to the right upper lobe. It is therefore essential to recognize and correct such a malposition as soon as possible.

Second, the DLT may be passed too far down into either the right or the left main stem bronchus (Fig. 38-13). In this case, breath sounds are very diminished or not audible over the contralateral side. This situation is corrected when the tube is withdrawn and the opening of the tracheal lumen is above the carina.

Third, the DLT may not be inserted far enough, leaving the bronchial lumen opening above the carina. In this position, good breath sounds are heard bilaterally when ventilating through the bronchial lumen. No breath sounds are audible when ventilating through the tracheal lumen because the inflated bronchial cuff obstructs gas flow arising from the tracheal lumen. The cuff should be deflated and the DLT rotated and advanced into the desired main stem bronchus.

Fourth, a right-sided DLT may occlude the right upper lobe orifice. The mean distance from the carina to the right upper lobe orifice is  $2.3 \pm 0.7$  cm in men and  $2.1 \pm 0.7$  cm in women.<sup>82</sup> With right-sided DLTs, the ventilatory slot in the side of the bronchial catheter must overlies the right upper lobe orifice to permit ventilation of this lobe. However, the margin of safety is extremely small, and varies from 1 to 8 mm.<sup>82</sup> It is therefore difficult to ensure proper ventilation to the right upper lobe and avoid dislocation of the DLT during surgical manipulation. When right endobronchial intubation is required, a disposable right-sided DLT is perhaps the best choice because of the slanted doughnut shape of the bronchial cuff, which allows the ventilation slot to ride off the right upper lobe ventilation orifice and increases the margin of safety.

**Figure 38-12** Fiberoptic bronchoscopic view of the main carina (A), the “left bronchial carina” (B), and the right bronchus (C). Note the right upper lobe orifice (arrow).

Fifth, the left upper lobe orifice may be obstructed by a left-sided DLT. Traditionally, it was believed that the take-off of the left upper lobe bronchus was at a safe distance from the carina and that it would not be obstructed by a left-sided DLT. However, the mean distance between the left upper lobe orifice and the carina is  $5.4 \pm 0.7$  cm in men and  $5 \pm 0.7$  cm in women.<sup>82</sup> The average distance between the openings of the right and left lumens on the left-sided disposable tubes is 6.9 cm. Therefore, an obstruction of the left upper lobe bronchus is possible while the tracheal lumen is still above the carina. There is also a 20% variation in the location of the blue endobronchial cuff on the disposable tubes because this cuff is attached to the tube at the

end of the manufacturing process.

Bronchial cuff herniation may occur and obstruct the bronchial lumen if excessive volumes are used to inflate the cuff. The bronchial cuff has also been known to herniate over the tracheal carina, and in the case of a left-sided DLT, to obstruct ventilation to the right main stem bronchus.

Another rare complication with DLTs is tracheal laceration or rupture (Fig. 38-14). Overinflation of the bronchial cuff, inappropriate positioning, and trauma owing to intraoperative dislocation that resulted in bronchial rupture have been described in association with the Robertshaw tube and the disposable DLT.<sup>83,84</sup> Therefore, the pressure in the bronchial cuff should be assessed and decreased if the cuff is found to be overinflated. If absolute separation of the lungs is not needed, the bronchial cuff should be deflated and then reinflated slowly to avoid excessive pressure on the bronchial walls. The bronchial cuff should also be deflated during any repositioning of the patient unless lung separation is absolutely required during this time.

**Figure 38-13** Malposition of the left bronchial limb of the double-lumen tube (DLT). **A:** The limb is too far into the left bronchus because the cuff is not evident. **B:** DLT is withdrawn and the balloon is now in view, indicating appropriate position of the DLT (arrow).

In a prospective trial, 60 patients were randomly assigned to two groups.<sup>85</sup> OLV was achieved with either an endobronchial blocker (blocker group) or a DLT (double-lumen group). Postoperative hoarseness and sore throat were assessed at 24, 48, and 72 hours following surgery. Bronchial injuries and vocal cord lesions were examined by bronchoscopy immediately

after surgery. Postoperative hoarseness occurred significantly more frequently in the double-lumen group compared with the blocker group (44% vs. 17%, respectively). Similar findings were observed for vocal cord lesions (44% vs. 17%). The incidence of bronchial injuries was comparable between groups. Clayton-Smith et al.<sup>86</sup> performed a review and meta-analysis of 39 randomized controlled trials comparing bronchial blockers with DLTs. They concluded that while bronchial blockers are associated with a lower incidence of airway injury, DLTs can be placed more rapidly and reliably.

**Figure 38-14** Bronchoscopic view showing laceration in left mainstem bronchus.

### ***Lung Separation in the Patient with a Tracheostomy***

Occasionally, a patient with a permanent tracheostomy is scheduled for surgery on the lung that requires isolation. Examples of such patients include those who have undergone resection of a tumor in the floor of the mouth or on the base of the tongue, followed by extensive reconstructive surgery with the creation of a permanent tracheal stoma. Routine follow-up may reveal a lung lesion that requires a diagnostic procedure. Conventional double-lumen endobronchial tubes are designed to be inserted through the mouth, not through a tracheal stoma. The standard DLTs are usually too stiff to negotiate the curve required for insertion through a tracheal stoma and are difficult to position.<sup>87</sup> A separately inserted bronchial blocker may permit adequate lung separation.<sup>88</sup>

Saito et al.<sup>89</sup> described a spiral, wire-reinforced, double-lumen

endobronchial tube made of silicone (Koken Medical, Tokyo, Japan) that is designed for placement through a tracheostomy. The middle section of the tube consists of two thin-walled silicone catheters with an internal diameter of 5 mm, glued together and reinforced with a stainless steel spiral wire and covered with a silicone coating with two pilot balloons. The distal section, which contains the bronchial lumen and the bronchial cuff, is made of wire-reinforced silicone to avoid excessive flexibility. The dimensions are based on the Mallinckrodt DLT (Hazelwood, MD). The bronchial cuff is located 1.2 cm from the tip, and the distance between the tip orifice and the tracheal orifice is 4.9 cm. In a clinical trial in patients with permanent tracheal stomas, the tubes functioned well in achieving lung separation, with no sign of kinking or movement, and permitted easy passage of a suction catheter.

### *Lung Separation in the Patient with a Difficult Airway*

An airway may be recognized initially as difficult when conventional laryngoscopy reveals a grade III or IV view (see [Chapter 28](#), Airway Management). When separation of the lungs is required and the patient has a clearly recognized difficult airway, then awake intubation using a flexible fiberoptic bronchoscope can be used to place a DLT, Univent tube, or single-lumen tube (SLT) ([Fig. 38-15](#)). The SLT may then be exchanged for a DLT or Univent tube using a tube exchanger. Furthermore, depending on the extent and duration of the surgical procedure, and the amount of fluid shift, an airway that was not initially classified as difficult may become difficult secondary to facial edema, secretions, and laryngeal trauma from the initial intubation.<sup>90,91</sup>

A logical approach to lung separation is shown in [Figure 38-15](#). The same approach may be used for the patient with an unrecognized difficult airway and a failure to intubate with conventional laryngoscopy. When using a DLT over a fiberoptic bronchoscope, the anesthesiologist should keep in mind that it is a bulky tube with a large external diameter and because of the length of the DLT, only a limited part of the fiberoptic bronchoscope is available for manipulation. In addition, the mismatch between the flexibility of the fiberoptic bronchoscope and the rigidity of the DLT makes it more difficult to advance over the fiberoptic bronchoscope. The Univent tube has the same bulky external diameter and is also often difficult to pass between the vocal cords, particularly in a patient who is awake.

### **Single-Lumen Tube Can Be Successfully Placed**

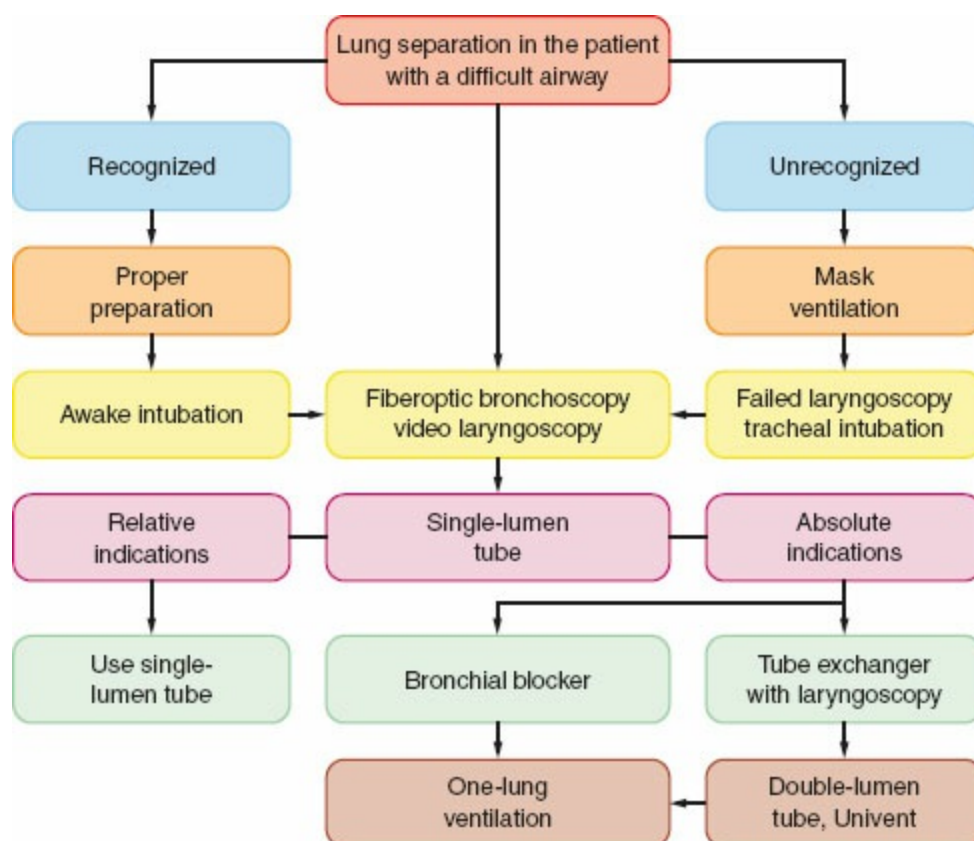

If a failure to provide lung separation could result in a life-threatening situation, there are two possibilities to provide OLV when an SLT is already in

place. First, depending on the indication for lung isolation, a tube exchanger can be used to switch to a DLT or a Univent tube. The second possibility is to direct a bronchial blocker through the SLT into the selected main stem bronchus. These two methods, however, offer limited protection or an inadequate seal in cases such as lung lavage, pulmonary abscess, or hemoptysis, where a DLT would be the tube of choice.

### Use of a Tube Exchanger

Several tube exchangers are commercially available (Cook Critical Care, Bloomington, IN; Sheridan Catheter Corporation, Argyle, NY). On these tube exchangers, the depth is marked in centimeters; they are available in a wide range of external diameters and easily adapted for either oxygen insufflation or jet ventilation. The size of the tube exchanger and the size of the tube to be inserted should be tested before use in a patient. The 11-Fr tube changer will pass through a 35- to 41-Fr DLT, whereas the 14-Fr tube exchanger does not pass through a 35 Fr. To prevent lung laceration, the tube exchanger should never be inserted against resistance. Because the first generation of tube exchangers was very stiff, there was a risk for tracheal or bronchial laceration. Tube exchangers that have a soft flexible tip are now available and should be safer to use and is less likely to cause airway laceration. Finally, when passing any tube over an airway guide, a laryngoscope should be used to facilitate passage of the tube over the airway guide past supraglottic tissues.

**Figure 38-15** Lung separation in the patient with a difficult airway. (Adapted with permission from Cohen E, Benumof JL. Lung separation in the patient with a difficult airway. *Curr Opin Anesthesiol.* 1999;12:29.)

## Use of Modern Bronchial Blockers

 **Bronchial Blocker (BB).** Lung separation can be achieved with a reusable bronchial blocker.<sup>92</sup> Magill described an endobronchial blocker that is placed using a bronchoscope and directed to the nonventilated lung. Inflation of the cuff at the distal end of the blocker serves to block ventilation to that lung. The lumen of the blocker permits suctioning of the airway distal to the catheter tip. Depending on the clinical circumstance, oxygen can be insufflated through the catheter lumen. A conventional tracheal tube is then placed in the trachea. This technique can be useful in achieving selective ventilation in children younger than 12 years of age. However, because the blocker balloon requires a high distending pressure, it may easily slip out of the bronchus into the trachea, obstructing ventilation and losing the seal between the two lungs. This displacement can be secondary to changes in position or to surgical manipulation. The loss of lung separation can be a life-threatening situation if it was performed to prevent spillage of pus, blood, or fluid from bronchopulmonary lavage. For this reason, bronchial blockers are rarely used for these types of cases.

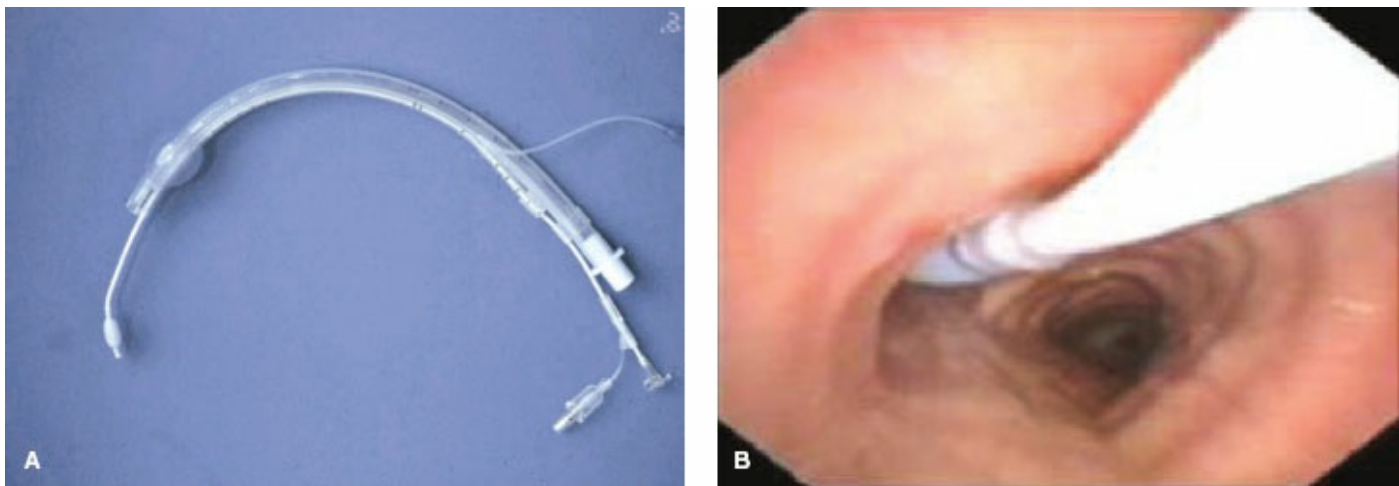

Indications for the use of a bronchial blocker are shown in [Table 38-2](#). An independently passed bronchial blocker may be used with an SLT to obtain lung isolation, thereby avoiding the use of a DLT in a patient with a difficult airway. The use of a bronchial blocker also eliminates the potential risk of needing to change a DLT to an SLT at the conclusion of the procedure. The individual blockers are discussed later, in the chronologic order in which they were developed, and introduced into practice. In the past, Fogarty vascular embolectomy catheters were used for lung separation, but there is no indication for their use in the current practice of thoracic anesthesia. The balloon of the Fogarty is high pressure, low volume, and there is no lumen to allow egress of gas from the lung to facilitate deflation.

**Table 38-2** Indications for the Use of Endobronchial Blockers

ICU, Intensive care unit; OLV, one-lung ventilation; SLT, single-lumen tube; DLT, double-lumen tube; OR, operating room.

**Univent Tube.** The Univent (Fuji Systems Corp., Tokyo, Japan) is a  3 single-lumen tracheal tube with a movable endobronchial blocker (Fig. 38-16). In the Univent tube, the bronchial blocker is housed in a small channel bored in the wall of the tube. The blocker contains a high-volume, low-pressure balloon, and is angled to permit external direction into the desired bronchus under direct fiberoptic bronchoscopic (FB) vision. After intubation of the trachea, the movable blocker is manipulated into the desired main stem bronchus with the aid of a fiberoptic bronchoscope. The Univent tube may be ideal for cases in which a tube change (e.g., from single to double lumen) may be difficult (e.g., mediastinoscopy followed by thoracotomy), or in cases of bilateral lung transplantation. The Univent tube has the advantage common to all bronchial blockers: It is an SLT, and there is no need to change the tube at the end of the procedure if postoperative ventilatory support is required. This is particularly important in cases of difficult intubation, prolonged surgery with airway edema, such as thoracic aortic aneurysm surgery or extensive neurosurgical procedures on the spine with massive fluid replacement, and altered anatomy of the airway. It is also possible to suction through the blocker lumen or to apply continuous positive airway pressure (CPAP) to improve oxygenation in cases of hypoxemia.

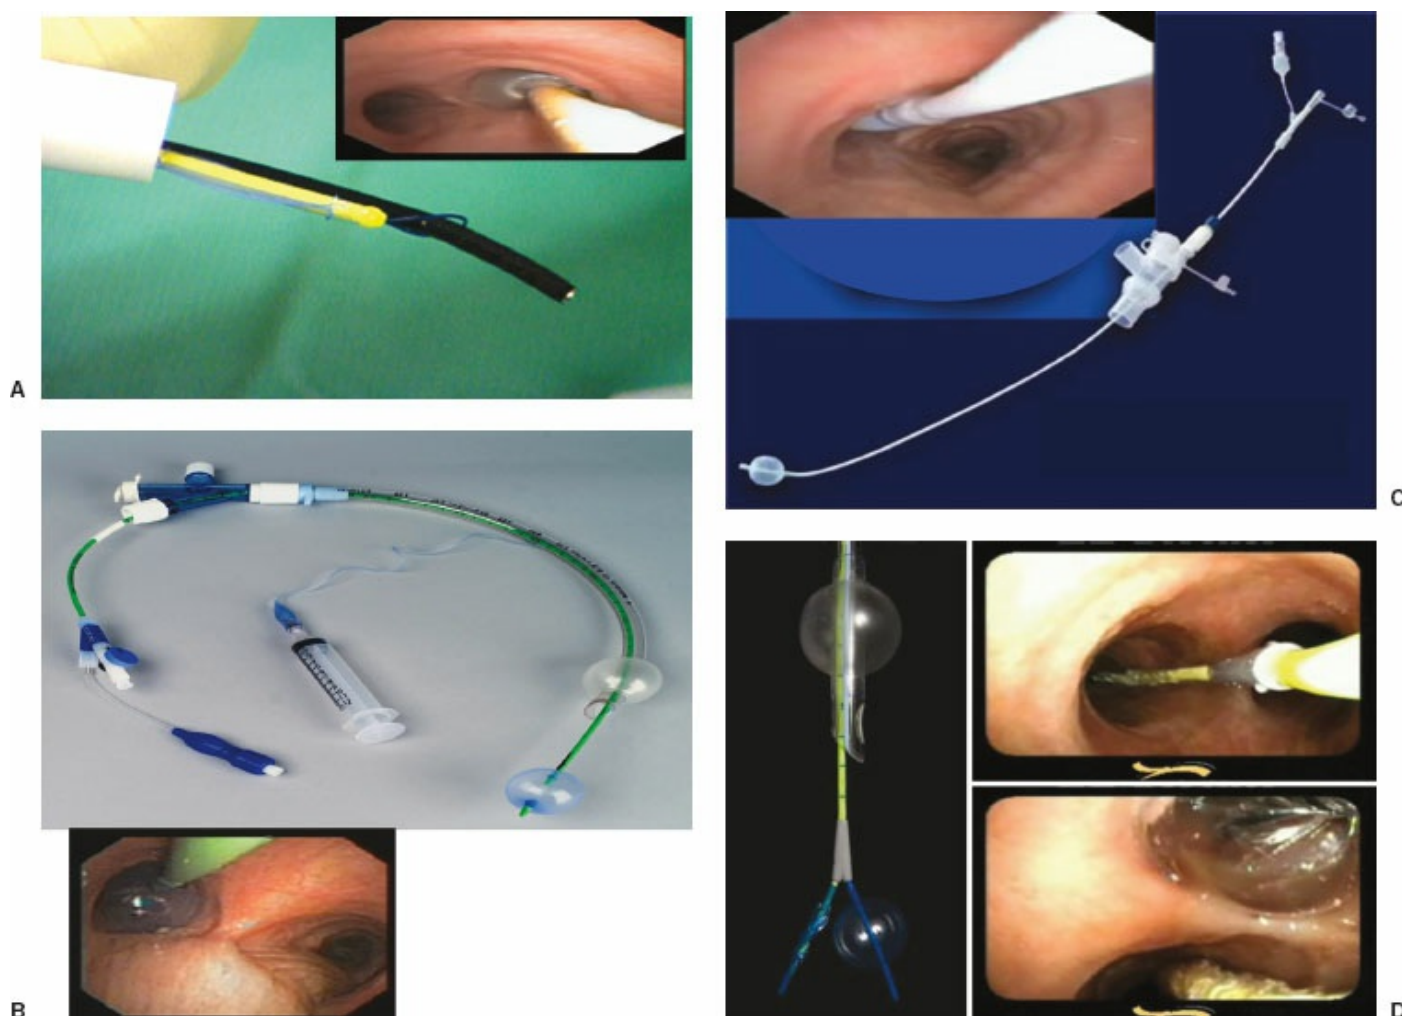

**Figure 38-16 A:** The Univent tube also allows lung separation using a single-lumen endotracheal tube. **B:** The Univent bronchial blocker positioned in left main stem bronchus.

The disadvantages of the Univent tubes are that correct positioning of the blocker may be difficult to achieve or maintain and that the external diameter of the tube is relatively large. Many anesthesiologists prefer to avoid postoperative ventilation with such a large-diameter tube, and in that case, change it to a standard tube at the conclusion of the surgery. The blocker can dislocate during surgical manipulation, and satisfactory bronchial seal and lung separation are sometimes difficult to achieve. The bronchial blocker is somewhat stiff and sometimes will not easily be directed into the main bronchus. This is particularly true for the left side. The bulky external diameter can also make it difficult to pass the tube between the vocal cords.

The first-generation Univent tube's bronchial blocker was difficult to direct into the selected main bronchus. The blocker would spin (torque) on its long axis, which made it difficult to control. The second generation, the Torque Control Blocker Univent, was introduced more recently. It consists of a silicon endotracheal tube that has a high friction coefficient. The Torque Control Blocker provides better control, which facilitates direction of the blocker into the target main stem bronchus.

**Arndt Blocker.** In an attempt to overcome the potential problems described previously, a snare-guided bronchial blocker was introduced (Cook Critical Care) (Fig. 38-17A). It is a wire-guided catheter with a loop snare. A fiberscope is passed through the loop of the bronchial blocker and then guided into the desired bronchus. The blocker is then slid distally over the fiberscope and into the selected bronchus. Bronchoscopic visualization confirms blocker placement and bronchial occlusion. This balloon-tipped catheter has a hollow lumen of 1.6 mm, which allows suction to facilitate the collapse of the lung and insufflation of oxygen to the nondependent lung. The balloon is available in spherical or elliptic shape. The set contains a multiport adapter, which allows uninterrupted ventilation during the positioning of the blocker. The

wire may then be removed, and a 1.6-mm lumen may be used as a suction port or for oxygen insufflation. With the first generation of this device it was not possible to reinsert the string once it had been pulled out, losing the ability to redirect the bronchial blocker if necessary. External reinforcement of the wire now allows for its reintroduction through the lumen. Finally, the external diameter necessitates a large size SLT (at least 8 mm) to be able to accommodate the bronchial blocker. The Arndt blocker is available in a 7-Fr and in a 5-Fr pediatric size. One disadvantage of the Arndt Blocker is that it is advanced blindly over the FB into the desired main bronchus. In some occasions the tip of the blocker may get caught at the main carina or at the Murphy eye of the SLT.

**Figure 38-17** A: Arndt blocker. B: Cohen blocker. C: Uniblocker. D: EZ blocker.

**Cohen Blocker.** The Cohen Flexitip endobronchial blocker (Cook Critical Care) is designed for use as an independent bronchial blocker. It is inserted through a single-lumen endotracheal tube with the aid of a small-diameter (4-mm) fiberoptic bronchoscope (Fig. 38-17B).<sup>93</sup> The blocker has a rotating wheel that deflects the soft tip by more than 90 degrees and easily directs it into the desired bronchus. The blocker cuff is a high-volume, low-pressure balloon inflated via 0.4-mm lumen inside the wall of the blocker. It has a pear

shape that provides adequate seal of the bronchus. Generally, it takes between 6 and 8 mL of air to seal the bronchus with the cuff. The cuff is a distinctive blue color that is easily recognizable by fiberoptic bronchoscopy. It is best to inflate the cuff under “direct vision” via the fiberoptic bronchoscope. The blocker size is 9 Fr. It has a central main lumen (1.6 mm) that allows limited suctioning of secretions and insufflation of oxygen to the collapsed lung in case of hypoxemia. This blocker and the FB do not have to pass through the tracheal tube at the same time for placement; the blocker can be passed ahead of the FB beyond the tracheal tube tip. Therefore, it can be used with a 7-mm tracheal tube.

**Uniblocker.** Fuji Systems introduced a 9-Fr balloon-tipped, angled blocker with a multiple port adapter that is essentially the same design as the Univent tube blocker, but can be used as an independent blocker passed via a special connector through a standard tracheal tube (Fig. 38-17C).

**EZ-Blocker.** The most recent addition to the endobronchial blocker design is the EZ Blocker (Teleflex, Morrisville, NC). This is a 7-Fr, 4-lumen, 75-cm, disposable endobronchial blocker to facilitate selective lung ventilation (Fig. 38-17D). It has a symmetric Y-shaped bifurcation and both branches have an inflatable cuff and a central lumen. The bifurcation resembles the bifurcation of the trachea. During insertion via a standard tracheal tube, each of the two distal ends is placed into a main stem bronchus. The selected lung is isolated by inflating the blocker’s balloon to the least volume necessary to occlude the main stem bronchus under bronchoscopic visualization. This blocker should offer an advantage during bilateral procedures because each lung can be deflated without the need for repositioning the blocker.<sup>94</sup> The characteristics of the various bronchial blockers are summarized in Table 38-3.

The effectiveness of lung isolation among three devices—the left-sided DLT Broncho-Cath, the Torque Control Blocker Univent, and the wire-guided Arndt—has been compared in a prospective randomized trial. There was no significant difference in tube malpositions among the three groups: It took longer to position the Arndt blocker (3 minutes) compared with the left-sided DLT (2 minutes) and the Univent (2 minutes). Excluding the time for tube placement, the Arndt group also took longer for the lung to collapse (26 minutes), compared with the DLT group (17 minutes) or Univent group (19 minutes). Furthermore, unlike the other two groups, the majority of the Arndt patients required suction to achieve lung collapse. Once lung isolation was achieved, overall surgical exposure was rated excellent for the three groups. One minute longer to position a bronchial blocker or 6 minutes longer to collapse the lung with the bronchial blocker is insignificant when considering the duration of the thoracic procedure. The risk benefit and the patient safety of each individual patient should be considered when choosing the methods for lung isolation.<sup>95,96</sup>

A study evaluated the use of the Cohen blocker, the Arndt blocker, the Uniblocker, and DLT in 4 groups of 26 patients in each group. They found no differences among the groups in the time taken to insert these lung isolation devices or in the quality of the lung collapse.<sup>97</sup> The grading was done by the operating surgeons who were blinded as to which device was used. The number of cuff dislocations was higher among the bronchial blocker (BB) groups. Regardless of the type of BB or DLT selected to provide OLV, the decision as to which technique to use depends on the clinical circumstances and the physician's experience and comfort with a particular device. It is important, however, that the clinician does not limit his/her practice to the use of only one device but rather be versatile and comfortable in the use of several.

A recent comprehensive meta-analysis and randomized controlled trials analysis was performed for a comparison of the efficacy and adverse effects of DLTs and EBB in thoracic Surgery.<sup>86</sup> The authors performed a systematic literature search for RCTs comparing BBs and DLTs using databases up to October 2013. The search produced 39 RCTs published between 1996 and 2013. The authors concluded that DLTs were quicker to place and less likely to be incorrectly positioned than EBB. The EBB was associated with fewer patients having a postoperative sore throat, less hoarseness, and fewer airway injuries than DLTs. Most importantly, the time taken for adequate lung collapse as well as the quality of the lung collapse showed no significant difference between the EBB and the DLT.

DLTs have been used to achieve lung separation for more than 50 years and will remain the "gold standard" lung separation. However, there are many clinical situations where DLT may not be the method of choice or may be impossible to use. The anesthesiologist should become familiar with the various devices used to achieve lung separation. Bronchial blockers can be safely and effectively used either for simple procedures such as a brief wedge resections or for more complex extended procedure such as lobectomy or pneumonectomy. The fact that there are several EBBs available for clinical use may be a reflection of the search for the ideal blocker. It is of benefit to the patient if the need to change tubes (DLT to SLT) during the case or at case-end can be avoided because the change may expose the patient to a period during which his/her airway is unprotected.<sup>98</sup>

**Table 38-3** Comparison of Bronchial Blockers (BBs)

	Arndt Blocker	Cohen Blocker	Uniblocker	EZ Blocker
<b>Size</b>	5 Fr, 7 Fr, 9 Fr	9 Fr	9 Fr	7 Fr
<b>Guidance Feature</b>	Wire loop to snare FOB	Deflecting tip	Prefixed bend	Double-lumen bifurcated tip
<b>Recommended Tracheal Tube Size</b>	9 Fr 8 mm 7 Fr 7 mm 5 Fr 4.5 mm	8 mm	8 mm	8 mm
<b>Central Lumen</b>	1.8 mm	1.8 mm	2 mm	
<b>Murphy Eye</b>	Present in 9 Fr	Present	None	None
<b>Disadvantages</b>	BB not visualized during insertion	Expensive	No steering mechanism. Prefixed bend	Lumen too small. Impossible to suction

## Conclusion of the Surgical Procedure

Depending on the extent and the duration of the surgical procedure and the degree of fluid shift, an airway that was initially not classified as difficult may become difficult secondary to facial edema, secretions, and laryngeal trauma from the original intubation. In these cases, when planning to provide lung separation, the postoperative period should be considered and the appropriate tube placed. Many procedures that are not considered to represent absolute indications for lung separation are lengthy and complex. Complex lung resection, with or without chest wall resection, thoracoabdominal esophagogastrectomy, thoracic aortic aneurysm resection with or without total circulatory arrest, or an extensive vertebral tumor resection, may result in facial edema, secretion, and hemoptysis, requiring postoperative ventilatory support. Other indications for postoperative ventilatory support are marginal respiratory reserve, unexpected blood loss or fluid shift, hypothermia, and inadequate reversal of residual neuromuscular blockade.

If a Univent tube was used to provide OLV, the blocker may be fully retracted and the Univent tube can be used as an SLT. If an independent bronchial blocker was used, then the blocker is removed, leaving the SLT in place. The problem arises when a DLT was inserted for lung separation. In a patient with a difficult airway and subsequent facial edema, the DLT may be left in place after surgery.

**Figure 38-18** Conclusion of the surgical procedure. See text for discussion. SLT, single-lumen tube; DLT, double-lumen tube; ICU, intensive care unit.

If the decision to leave the DLT in place is made, it is important to keep in mind that the ICU staff is usually less experienced in managing such a tube, which may easily become dislocated. In addition, it is more difficult to suction through the lumens, and a longer, narrower suction catheter is needed to reach the tip of the endobronchial lumen. Another possibility is to withdraw the DLT to place the 19- to 20-cm mark at the teeth so that the endobronchial lumen is above the carina and both lungs can be ventilated via the bronchial lumen. Tracheal extubation from the DLT should be considered after diuresis and steroid therapy to allow reduction of the facial and airway edema.

If it is necessary to change the DLT to an SLT, a tube exchanger should be used to maintain access to the airway, as previously discussed. The tube exchanger can be passed through the bronchial limb of the DLT. Alternatively, the tube exchange may be performed under direct vision using one of several commercially available video laryngoscopes, such as the GlideScope (Verathon Medical), C-Mac (Karl Storz), or the Mc Grath (Aircraft Medical) (see [Chapter 28](#)). With these video laryngoscopes, the tube exchanger can be placed under direct vision between the vocal cords alongside the existing tube to permit passage of an SLT ([Fig. 38-18](#)). The Airtraq DL (King Systems) is a disposable video blade that is manufactured with a large channel that is large enough to accommodate a DLT.

In summary, the clinician should be able to master different methods of lung separation and make himself/herself familiar with the devices available to provide OLV. In addition, one should always plan in advance for the

postoperative period when selecting the method of lung separation. Finally, in these cases, a close dialog with the surgical team is of vital importance.

## Management of One-lung Ventilation

This section discusses the management of OLV in a paralyzed patient in the lateral decubitus position with an open chest. Inspired oxygen fraction ( $F_{IO_2}$ ),  $V_T$  and respiratory rate, dependent lung, PEEP, and nondependent lung CPAP are reviewed, and an approach to the management of OLV is presented.

### *Confirmation of Correct Position of DLT or Endobronchial Blocker*

Following intubation with a DLT or placement of an endobronchial blocker, the correct position should be checked by clinical assessment, visualization of chest movement, auscultation, and pressure/volume flow profile. In modern anesthesia practice, a standard 4.0-mm fiberscope should be passed down the tracheal lumen to check for correct depth, or alongside the endobronchial blocker that was passed through the single lumen tracheal tube. It is a common practice to visualize the tip of the blue bronchial cuff at the level of the carina to ensure that the left upper lobe orifice is not obstructed. Once the patient is turned into the lateral position, the position of the DLT should be rechecked to exclude dislocation of the tube during positioning.<sup>99</sup>

### *Inspired Oxygen Fraction*

An  $F_{IO_2}$  of 1 is generally recommended during OLV. High oxygen concentration serves to protect against hypoxemia during the procedure and provides a higher margin of safety. A high  $F_{IO_2}$  may, however, cause absorption atelectasis and potentially further increase the amount of shunt because of the collapsed alveoli. The use of an  $F_{IO_2}$  less than 1 during OLV has the potential benefits of decreasing the risk of absorption atelectasis and, if  $N_2O$  is used, may allow potent inhaled anesthetics to be used in lower concentrations. Some clinicians use an  $O_2$  80%/ $N_2O$  20% mixture as long that the  $SpO_2$  is maintained in a safe range. The rate of the lung collapse during OLV was addressed by Ko et al.<sup>100</sup> They compared the effects of three different gas mixtures (air/oxygen,  $F_{IO_2}$  0.4;  $N_2O/O_2$ ,  $F_{IO_2}$  0.4; and oxygen,  $F_{IO_2}$  1) during OLV on lung collapse and oxygenation during subsequent OLV: They found that deflation of the nonventilated lung during thoracic surgery was delayed if air was used as part of the anesthetic gas mixture during the initial period of OLV. For thoracic procedures in which delayed collapse of the nonventilated lung will impede surgical exposure, the optimal anesthetic

technique should include thorough denitrogenation of the lung by using  $\text{FIO}_2$  of 1.

### **Tidal Volume and Respiratory Rate**

It has been recommended that during OLV, the dependent lung be ventilated with a  $V_T$  of 10 to 12 mL/kg. Tidal volumes ( $V_T$ ) ranging between 8 and 15 mL/kg produced no significant effect on transpulmonary shunt or  $\text{PaO}_2$ .<sup>101</sup> A  $V_T$  less than 8 mL/kg can result in a decrease in FRC and increased formation of atelectasis in the dependent lung. A  $V_T$  greater than 15 mL/kg may recruit the atelectatic alveoli in the dependent lung. It will increase the pulmonary vascular resistance of the dependent lung (similar to the application of PEEP) and divert blood flow into the nondependent lung. It has been common practice during OLV to maintain the same  $V_T$  as during two-lung ventilation.

Recently, more attention has been directed toward protection of the ventilated lung with the use of smaller  $V_T$  to avoid acute lung injury (ALI) (see [Chapter 57](#)).<sup>102</sup> This concept stimulated a debate over the optimal  $V_T$  that should be used during OLV. A pro and con editorial argued that a (large)  $V_T$  of 12 mL/kg during OLV may cause overdistention and stretching of the lung parenchyma and therefore would increase the risk of ALI.<sup>103</sup> However, a (small)  $V_T$  of 6 mL/kg could lead to atelectasis in the dependent lung. Furthermore, a small  $V_T$  with PEEP may cause dynamic hyperinflation secondary to the increase in respiratory rate necessary to maintain  $\text{PaCO}_2$ .<sup>104</sup>

Vegh et al.<sup>105</sup> evaluated the effect of low (5 mL/kg) and high (10 mL/kg) tidal volume on arterial oxygenation during OLV. For the first 30 minutes of OLV, 50 patients received a tidal volume of 10 mL/kg at a respiratory rate of 10/min, whereas another 50 patients received a tidal volume of 5 mL/kg with 5 cm  $\text{H}_2\text{O}$  of PEEP at a rate of 20 breaths/min. For the subsequent 30 minutes of OLV each patient received the alternative ventilatory parameters. These authors found that a tidal volume of 5 mL/kg with 5 cm  $\text{H}_2\text{O}$  PEEP resulted in comparable  $\text{PaO}_2$  and shunt fractions during OLV as tidal volumes of 10 mL/kg without PEEP. The smaller TV significantly increased  $\text{PaCO}_2$ .

Mechanical ventilation practice has changed over the past few decades, with  $V_T$  decreasing significantly, especially in patients with ALI. The lungs of patients without ALI are still ventilated with large, and perhaps too large,  $V_T$ . Studies of ventilator-associated lung injury in subjects without ALI demonstrate inconsistent results. Retrospective clinical studies, however, suggest that the use of large  $V_T$  favors the development of lung injury in these patients.<sup>106</sup>

In a multicenter, prospective ARDS Network trial, the results unambiguously confirmed that mechanical ventilation with smaller  $V_T$  (6 mL/kg) rather than traditional  $V_T$  (12 mL/kg) resulted in a significant

increase in the number of ventilator-free days and reduction of inhospital mortality.<sup>107</sup>

Although there is good evidence from studies in the ICU for a detrimental effect of high  $V_T$  and parenchymal overdistension, the data concerning lung injury during OLV is limited. Ventilation strategies during OLV have been compared to ARDS, because both involve ventilation of a decreased lung capacity due to unrecruited alveoli, otherwise known as the concept of “baby lung.”<sup>108</sup> There is no evidence that these findings in patients with acute respiratory distress syndrome are applicable to patients undergoing a thoracic procedure requiring a relatively short period of controlled ventilation.

In one study, patients undergoing elective thoracotomy or laparotomy were randomly assigned to receive either mechanical ventilation with  $V_T$  of 12 or 15 mL/kg, respectively, and without PEEP, or  $V_T$  of 6 mL/kg with PEEP of 10 cm H<sub>2</sub>O. In this study, neither time course nor concentrations of pulmonary or systemic inflammatory mediators (cytokines) differed between the two ventilatory settings within 3 hours.<sup>109</sup>

There are data indicating damaging effects of large  $V_T$  in patients who were ventilated for only several hours. In one study of patients undergoing pneumonectomy, 18% developed postoperative respiratory failure. The patients who developed respiratory failure had been ventilated with larger intraoperative  $V_T$  than those who did not (median, 8.3 vs. 6.7 mL/kg predicted body weight).<sup>110</sup> However, the authors recommended that protective lung ventilation (PV) with low  $V_T$  6 to 7 mL/kg, PEEP to the dependent lung, frequent recruitment maneuvers, and limited administration of fluid be used during OLV.

In patients undergoing general anesthesia, lung recruitment maneuvers proved to be easy to perform and effective in reversing alveolar collapse, hypoxemia, and decreased compliance. The beneficial effect of an alveolar recruitment strategy on arterial oxygenation and respiratory compliance in anesthetized patients undergoing nonthoracic surgery in the supine position has been demonstrated by Tusman et al.,<sup>111</sup> who studied 10 patients undergoing open lobectomy and who received lung recruitment maneuvers. This was done by increasing peak inspiratory pressure to 40 cm H<sub>2</sub>O, together with a PEEP of 20 cm H<sub>2</sub>O for 10 respiratory cycles. They found that alveolar recruitment in the dependent lung augments PaO<sub>2</sub> values during OLV. It is important to apply the maneuvers over several minutes with a pressure of at least 20 cm H<sub>2</sub>O and a peak of 40 cm H<sub>2</sub>O.

Pressure-controlled ventilation (PCV) was also compared with volume-controlled ventilation (VCV) during OLV. The authors suggested that PCV may be preferred for management of OLV because the lower peak airway pressure was associated with greater perfusion of the dependent lung and smaller transpulmonary shunt.<sup>112</sup> A study has investigated whether PCV

results in improved arterial oxygenation compared with VCV during OLV.<sup>113</sup> Fifty-eight patients with good preoperative pulmonary function scheduled for thoracic surgery were prospectively randomized into two groups. Those in group A underwent OLV initially with VCV for 30 minutes followed by PCV for a similar period of time. Those in group B underwent OLV initially with PCV for 30 minutes followed by VCV for a similar duration. Airway pressures and arterial blood gases were obtained during OLV at the end of each ventilatory mode period. The authors found no differences in arterial oxygenation during OLV between VCV ( $\text{PaO}_2$ ,  $206.1 \pm 62.4$  mmHg) and PCV ( $\text{PaO}_2$ ,  $202.1 \pm 56.4$  mmHg;  $p = 0.534$ ).<sup>113</sup>

Cruz Pardons et al.<sup>114</sup> studied 110 patients scheduled for thoracic surgery requiring a minimum of 1 hour of OLV. The patients were randomized into two groups: VCV or PCV, both providing a  $V_T$  of 8 mL/kg. Measurements were taken intraoperatively and up to 24 hours postoperatively. There were no differences in the intra- or early postoperative arterial oxygenation, airway plateau pressure, and mean arterial pressure between groups, except for higher peak airway pressures in the VCV group. The respiratory rate should be adjusted to maintain a  $\text{PaCO}_2$  of  $35 \pm 3$  mmHg. Elimination of  $\text{CO}_2$  is usually not a problem during OLV if the DLT is positioned correctly. The shunt during OLV has little influence on  $\text{PaCO}_2$  values because the arteriovenous  $\text{PCO}_2$  difference is normally only 6 mmHg. Furthermore,  $\text{CO}_2$  is 20 times more diffusible than  $\text{O}_2$  and will be eliminated faster. It is also important not to hyperventilate the patient's lungs because hypocapnia increases vascular resistance in the dependent lung, inhibits nondependent lung HPV, increases shunt, and decreases  $\text{PaO}_2$ . Hypocarbia is believed to inhibit HPV secondary to a vasodilator effect. Because hypocarbia can only be achieved by hyperventilating the dependent lung, it raises the mean intra-alveolar pressure and therefore increases the vascular resistance in that lung.

OLV is known to cause an inflammatory response and ALI.<sup>115</sup> Hypercapnia has been shown to have beneficial effects in patients with lung injuries such as ARDS. Gao et al.<sup>116</sup> therefore studied the effect of deliberate hypercapnia on the inflammatory responses to OLV in patients undergoing lobectomy. Fifty patients having lobectomy under intravenous anesthesia were randomly assigned to ventilation with either air ( $\text{PCO}_2$  35 to 45 mmHg) or  $\text{CO}_2$  (60 to 70 mmHg) from a  $\text{CO}_2$  tank connected to the anesthesia machine.  $\text{FIO}_2$  was maintained at greater than 0.8 during OLV. Duration of OLV was not significantly different between the two groups (means  $\sim 180$  minutes). Alveolar lavage fluid was collected and assayed for inflammatory factors. The authors found that induced hypercapnia during the OLV period inhibited the local inflammatory response, decreased airway pressure as well as increased lung compliance and  $\text{PaO}_2/\text{FIO}_2$  following surgery. No severe adverse effects were reported in relation to the therapeutic hypercarbia. The potential

beneficial effect of inhalation of CO<sub>2</sub> (60 to 70 mmHg) during OLV merits further investigation in patients receiving potent inhaled anesthetics, which have already been shown to inhibit the inflammatory response during lung surgery.

### ***Positive End-expiratory Pressure to the Dependent Lung***

The beneficial effect of selective PEEP 10 cm H<sub>2</sub>O (PEEP<sub>10</sub>) to the dependent lung is caused by an increased lung volume at end expiration (FRC), which improves the ventilation/perfusion ( $V\cdot/Q\cdot$ ) relationship in the dependent lung. The increase in FRC prevents airway and alveolar closure at end-expiration. However, PEEP may lead to an increase in lung volume that could cause compression of the small interalveolar vessels and increase pulmonary vascular resistance. If this increase in resistance is limited to the dependent lung, blood flow can be diverted only to the nondependent (nonventilated) lung, increasing shunt fraction and further decreasing PaO<sub>2</sub>.

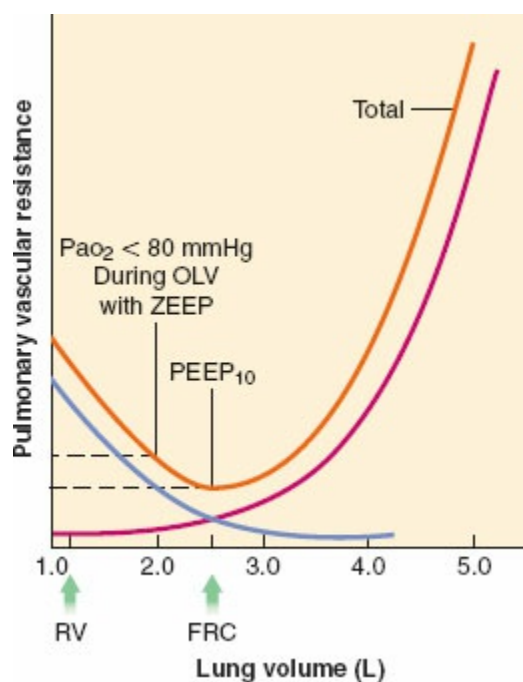

The possibility that the application of PEEP can improve PaO<sub>2</sub> in a diseased dependent lung (low lung volume and low  $V\cdot/Q\cdot$  ratio) with a low PaO<sub>2</sub> (<80 mmHg) during OLV was studied by Cohen et al.<sup>117</sup> They found that the application of PEEP<sub>10</sub> during OLV in patients with a low PaO<sub>2</sub> may increase FRC to normal values, resulting in a lower pulmonary vascular resistance and in an improved  $V\cdot/Q\cdot$  ratio and PaO<sub>2</sub>. Presumably, patients with a higher PaO<sub>2</sub> had a dependent lung with an adequate FRC, and the application of PEEP had the negative effect of redistributing blood flow away from the dependent ventilated lung (Fig. 38-19).

In summary, in most circumstances PEEP alone would not improve arterial oxygenation, unless it could increase FRC to normal values. Since PV with low V<sub>T</sub> is the recommended mode of ventilation during OLV, it most likely would lead to formation of atelectasis. Therefore, combining low V<sub>T</sub> with a small amount of PEEP (5 cm H<sub>2</sub>O) to protect from development of atelectasis is the currently recommended ventilatory strategy.

### ***Continuous Positive Airway Pressure to the Nondependent Lung***

The single most effective maneuver to increase PaO<sub>2</sub> during OLV is the application of CPAP to the nondependent lung.<sup>118,119</sup> A lower level of CPAP (5 to 10 cm H<sub>2</sub>O) maintains the patency of the nondependent lung alveoli, allowing some oxygen uptake to occur in the distended alveoli. CPAP should be applied after delivering an inspiratory V<sub>T</sub> to the nondependent lung to keep it slightly expanded. CPAP, applied by insufflation of oxygen under positive pressure, keeps this lung “quiet” and prevents it from collapsing

completely. Insufflation of oxygen without maintaining a positive pressure failed to improve  $\text{PaO}_2$ . Intermittent reinflation of the collapsed (nondependent) lung with oxygen also resulted in a significant improvement in  $\text{PaO}_2$ .<sup>120</sup>

**Figure 38-19** Effect of 10 cm H<sub>2</sub>O positive end-expiratory pressure (PEEP) on functional residual capacity (FRC). It is postulated that, in patients having  $\text{PaO}_2$  below 80 mmHg with zero end-expiratory pressure (ZEEP), FRC is low. PEEP<sub>10</sub> increases FRC and thereby increases  $\text{PaO}_2$ . OLV, one-lung ventilation; PEEP<sub>10</sub>, positive end-expiratory pressure (10 cm H<sub>2</sub>O); RV, residual volume.

Unfortunately, most thoracic procedures are initiated thoracoscopically, and the application of CPAP to the nondependent lung is generally not acceptable to most surgeons. During VAT, the lung should be well collapsed to allow the surgeon an optimal view of the surgical field and to palpate the lesion in the lung parenchyma. In addition, it is difficult to place the stapler on a lung that is not completely collapsed, and there is an increase in incidence of postoperative air leak.

The beneficial effects of CPAP 10 cm H<sub>2</sub>O (CPAP<sub>10</sub>) are not attributable solely to the effect of positive pressure in diverting blood flow away from the collapsed lung because (in dogs) the hyperinflation of nitrogen into the nondependent lung under 10 cm H<sub>2</sub>O failed to improve  $\text{PaO}_2$ .

The application of high-level CPAP (15 cm H<sub>2</sub>O) is not beneficial. At this pressure, the lung becomes overdistended, which interferes with surgical exposure. Also, this level of CPAP might have hemodynamic consequences, whereas CPAP<sub>10</sub> has been shown to have no significant hemodynamic effects.<sup>121</sup>

CPAP can be applied to the nondependent lung using a number of simple **4** systems, all of which have essentially the same features: an oxygen source, tubing to connect the oxygen source to the nonventilated lung, a pressure relief valve, and a pressure gauge. The catheter to the nondependent lung is usually insufflated with 5 L/min of oxygen using a modified Ayre's T-piece (pediatric) circuit, and the valve on the expiratory limb is adjusted to the desired pressure as read on the attached gauge. Instead of a pressure gauge or manometer inserted into the circuit, a spring-loaded adjustable PEEP valve can be used. The amount of CPAP applied should be titrated to the clinical circumstances. In most cases, even low levels of CPAP may be sufficient to increase the PaO<sub>2</sub> to an accepted safe level. CPAP greater than 10 cm H<sub>2</sub>O, is not beneficial because it creates an overdistention that interferes with surgical exposure and may have undesirable hemodynamic consequences.

High-frequency ventilation with oxygen to the nondependent lung and conventional ventilation (CV) to the dependent lung have also been used to improve PaO<sub>2</sub> during OLV (see "High-frequency Ventilation").

### *Clinical Approach to Management of One-lung Ventilation*

Once the patient is in the lateral decubitus position, the placement of the DLT should be rechecked. Two-lung ventilation should be maintained for as long as possible, and when OLV needs to be instituted, it is generally **6** recommended that an FIO<sub>2</sub> of 1 be used (Table 38-4). The lung should be ventilated using a V<sub>T</sub> that results in a plateau airway pressure greater than 25 cm H<sub>2</sub>O at a rate adjusted to maintain PaCO<sub>2</sub> at 35 ± 3 mmHg. This is usually monitored indirectly with the use of a capnometer or other multigas analyzer. The following measures are recommended during OLV: use of PV with low V<sub>T</sub> 6 to 7 mL/kg, application of PEEP to the dependent lung, frequent recruitment maneuvers, and limiting the volume of fluid administered.

After initiation of OLV, depending on the lung pathology and the intensity of HPV, PaO<sub>2</sub> can continue to decrease for up to 45 minutes. Frequent monitoring of arterial blood gases and use of a pulse oximeter continue throughout the operative period. It is also essential to work closely with the surgeon in case reinsufflation of the lung is necessary. If hypoxemia occurs during OLV, the position of the DLT should be rechecked using a fiberoptic bronchoscope. If the dependent lung is not severely diseased, a satisfactory PaO<sub>2</sub> on two-lung ventilation should not decrease to dangerously hypoxic levels on OLV. If a left thoracotomy is being performed using a right-sided DLT, ventilation to the right upper lobe should be ensured. After the tube

position has been confirmed as correct, CPAP<sub>10</sub> should be applied to the nondependent lung after a  $V_T$  that expands the lung. In most cases, the PaO<sub>2</sub> increases to a safe level. During thoracoscopy, application of CPAP is usually not possible because it impedes the surgeon. This is especially so during video-assisted thoracoscopic surgery (VATS) procedures. In this case, PEEP to the ventilated lung may be tried.

**Table 38-4** Clinical Approach to One-lung Ventilation (OLV) Management

1. Use Fio<sub>2</sub> of 1
2. Ventilate with a  $V_T$  of 6–8 mL/kg with PEEP 5 cm H<sub>2</sub>O
3. Respiratory rate to maintain Paco<sub>2</sub> between 35 and 40 mmHg
4. Check the DLT/endobronchial blocker position subsequent to the lateral decubitus positioning
5. If peak airway pressure exceeds 40 cm H<sub>2</sub>O during OLV, DLT/endobronchial blocker malposition should be excluded
6. For hypoxemia, apply CPAP 10 cm H<sub>2</sub>O to the nondependent lung (not during VAT)
7. If additional correction of hypoxemia is necessary, add PEEP 5–10 cm H<sub>2</sub>O to the ventilated lung
8. Frequent recruiting maneuvers
9. Avoid fluid overload
10. TIVA may be preferable to inhalation anesthetics
11. If necessary, intermittently inflate and deflate the operated lung

$V_T$ , tidal volume; PEEP, positive end-expiratory pressure; DLT, double-lumen tube; CPAP, continuous positive airway pressure; VAT, video-assisted thoracoscopy; TIVA, total intravenous anesthetic.

In the very rare case in which the PaO<sub>2</sub> remains low despite these maneuvers, intermittent two-lung ventilation can be reinstated with the surgeon's cooperation. Also, depending on the stage of surgical dissection, if a pneumonectomy is being performed, ligation of the pulmonary artery eliminates the shunt.

During OLV, the peak airway pressure, the actual  $V_T$  delivered (measured by a spirometer), the shape of the capnogram, and, if available, the pressure–volume loop, should be checked continuously. A sudden increase in peak airway pressure may be secondary to tube dislocation because of surgical manipulation, resulting in impaired ventilation. In addition, the ability to auscultate by a stethoscope over the dependent lung is extremely important.

If there is any doubt about the stability of the patient, or if the patient becomes hypotensive, dusky, or tachycardic, two-lung ventilation should be resumed until the problem has been resolved. Because of pericardial manipulation (during left thoracotomy in particular) and pulling on the great vessels, cardiac dysrhythmias and hypotension are not uncommon. Cardiotonic drugs should be prepared and kept available for use during any thoracic surgical procedure. Most thoracic surgical procedures represent only

relative indications for OLV, and the benefits of OLV should always be weighed against the risks to the patient.

Attention should be directed toward the protection of the ventilated lung. PV should be used with low  $V_T$  and the lowest peak airway pressure, an I:E ratio of 1:1, with high respiratory rate or using pressure control ventilation. Patients with COPD are of particular concern because the application of PEEP may cause dynamic hyperinflation secondary to the increase in respiratory rate to maintain  $PaCO_2$ .

Frequent recruiting maneuvers should be applied to reduce the amount of atelectasis in the dependent lung. They should be applied with a sustained peak pressure of 40 cm H<sub>2</sub>O to be effective. Fluid administration during the procedure must be limited to avoid fluid overload that could increase pulmonary capillary permeability. The risk of ALI and fluid overload increases in proportion to the amount of lung parenchyma resected.<sup>122–124</sup>

A balanced anesthetic technique using inhalational agents with low rates of propofol infusion alone or in combination with remifentanyl is the technique of choice during OLV. It should have the least inhibitory effect on HPV and decrease the transpulmonary shunt through the nonventilated lung. Karzai et al.<sup>125</sup> published an excellent review on the prediction, prevention, and treatment of hypoxemia during OLV.

Yang et al.<sup>126</sup> compared PV with CV in two groups of 50 patients each undergoing OLV. Conventional strategy consisted of  $FIO_2$  1,  $V_T$  10 mL/kg, zero end-expiratory pressure (ZEEP), and VCV; the protective strategy (PV) consisted of  $FIO_2$  0.5,  $V_T$  6 mL/kg, PEEP 5 cm H<sub>2</sub>O, and PCV. During OLV, although 58% of the PV group needed an increased  $FIO_2$  to maintain an  $SpO_2$  greater than 95%, peak airway pressure was significantly lower than in the CV group, whereas the mean  $PaCO_2$  values remained at 35 to 40 mmHg in both groups. Importantly, in the PV group, the incidence of the primary end point of pulmonary dysfunction was significantly lower than in the CV group (incidence of  $PaO_2/FIO_2 < 300$  mmHg, lung infiltration, or atelectasis: 4% vs. 22%). The mechanical ventilation strategies used during OLV are discussed in a recent comprehensive review by Sentürk et al.<sup>127</sup>

## Choice of Anesthesia for Thoracic Surgery

**7** The choice of anesthesia technique for a thoracic surgical procedure must take into account the patient's cardiovascular and respiratory status and the particular effects of anesthetic drugs on these and other organ systems. Thoracic surgical patients are more likely than others to have increased airway reactivity and a propensity to develop bronchoconstriction. This is because many of these patients are cigarette smokers and have chronic bronchitis or COPD. In addition, surgical manipulation of the airways and

bronchial tree by instruments, a DLT, or the surgeon, makes bronchoconstriction more likely to occur. The potent inhaled anesthetic agents have all been shown to decrease airway reactivity and bronchoconstriction provoked by hypocapnia or inhaled or irritant aerosols. Their mechanism of action is probably a direct one on the airway musculature itself, and potent inhaled anesthetic agents are therefore the drugs of choice in patients with reactive airways. For an inhalation induction, halothane or sevoflurane might be preferable because they are the least pungent of the three drugs, although once the patient is asleep, isoflurane may be the preferred drug because it raises the cardiac dysrhythmia threshold and provides greater cardiovascular stability than halothane (see [Chapter 18](#)). Fentanyl does not appear to influence bronchomotor tone, but morphine may increase tone by a central vagotonic effect and by releasing histamine.

In most patients, anesthesia is safely induced with propofol or etomidate (since thiopental is no longer available in the United States). In patients with reactive airways, ketamine may be the drug of choice for induction because it has a bronchodilator effect and has been successfully used in the treatment of asthma. Shimizu et al.<sup>128</sup> compared the effects of isoflurane and sevoflurane on PaO<sub>2</sub> during OLV in 20 patients undergoing thoracotomy and found no significant difference between the groups in PaO<sub>2</sub>, concluding that both agents can be used safely. In an in vitro study, Loer et al.<sup>129</sup> showed that desflurane inhibits HPV, with an ED<sub>50</sub> of 1.6 minimum alveolar concentration (MAC). Propofol infused in doses of 6 to 12 mg/kg/hr does not abolish HPV during OLV in humans.<sup>130</sup> Propofol infusion in combination with remifentanyl is probably the technique of choice for producing a stable OLV with no effect on HPV. Propofol is widely used during OLV and has been investigated in terms of its effect on oxygenation. Kellow et al.<sup>131</sup> compared the effects of propofol and isoflurane anesthesia on right ventricular function and shunt fraction during thoracic surgery and found that isoflurane, but not propofol, was associated with an increase in shunt fraction due to HPV inhibition. However, propofol was associated with a reduction in cardiac index and right ventricular ejection fraction.

In deciding between intravenous versus potent inhaled agent for anesthesia during OLV, consideration should be given to their effects on inflammatory alterations in the deflated lung. Studies have shown that ventilation with increased V<sub>T</sub> and pressures can produce a proinflammatory reaction (e.g., tumor necrosis factor, interleukins) in the nondeflated, ventilated lung.<sup>132</sup> De Conno et al.<sup>133</sup> studied the effect on the pulmonary inflammatory response in the nonventilated lung before and after OLV in 54 adult patients undergoing thoracic surgery, and assessed if there were any immunomodulatory effects of propofol and sevoflurane. The results suggested an immunomodulatory role for sevoflurane. Compared with propofol there

was a significant reduction in inflammatory mediators and a significantly better clinical outcome defined by postoperative adverse events with sevoflurane.<sup>128</sup> A subsequent study compared the effects of desflurane, sevoflurane, and propofol on pulmonary and systemic inflammation in 63 patients undergoing open thoracic surgery. The investigators found that OLV increases the alveolar concentrations of proinflammatory mediators in the ventilated lung and that desflurane and sevoflurane suppress the local alveolar, but not the systemic, inflammatory responses to OLV and thoracic surgery.<sup>134</sup> In murine models isoflurane has also been shown to have a protective effect against acute and ventilator-induced lung injury.<sup>135,136</sup>

The neuromuscular blocking drugs of choice for thoracic procedures are those that lack a histamine-releasing or vagotonic effect and that have some sympathomimetic effect (see [Chapter 21](#)). In this respect, pancuronium, vecuronium, rocuronium, and cisatracurium probably represent the drugs of choice. Succinylcholine is useful to provide rapid profound relaxation for intubation of the trachea and is not associated with an increase in airway reactivity.

Atropine or glycopyrrolate may be used to block the muscarinic effects of acetylcholine and thereby protect against cholinergically induced bronchoconstriction. It may be administered intravenously or in nebulized form (see [Chapter 14](#)).

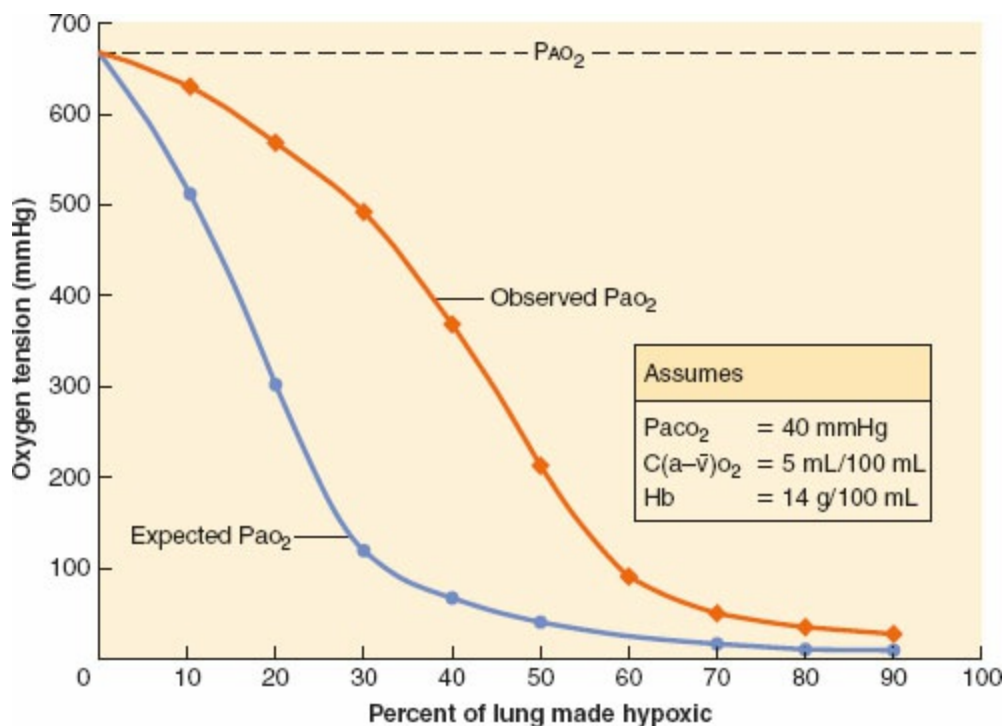

## Hypoxic Pulmonary Vasoconstriction

HPV was first described by Von Euler and Liljestrand in 1946.<sup>137</sup> They were studying changes in the pulmonary circulation of the cat in response to changes in inspired gas mixtures and found that 10.5% inspired O<sub>2</sub> (in N<sub>2</sub>) mixtures caused an increase in pulmonary artery pressure. Breathing 100% O<sub>2</sub> caused a decrease in pulmonary artery pressure. They concluded that the increased pressure during hypoxia was caused by a direct effect on the pulmonary vessels. Whereas they delivered hypoxic gas mixtures to both lungs, others have studied the effects of the size of the hypoxic segment and the size of the hypoxic stimulus on perfusion pressure and on flow diversion.<sup>138</sup> Pulmonary perfusion pressure (in dogs) increased with the size of the hypoxic segment from zero (smallest hypoxic segment) to approximately 2.2 times baseline for the hypoxic whole lung. Flow diversion, as a percentage of flow to the test segment under normoxic conditions, decreased with increasing size of the hypoxic test segment from a maximum of 75% for very small segments to zero when the whole lung was made hypoxic. Flow diversion increased linearly as PaO<sub>2</sub> was decreased over the range of 128 to 28 mmHg. In both flow diversion and changes in perfusion pressure, the response to HPV was predictable, continuous, and maximal at a

predicted  $\text{PaO}_2$  of 30 mmHg (4% oxygen). Thus, HPV causes an increase in both perfusion (pulmonary artery) pressure and flow diversion.

The choice of anesthetic technique for OLV must take into consideration the effects on oxygenation and therefore on HPV. Normally, collapse of the nonventilated, nondependent lung results in activation of reflex HPV in this lung. This causes local increases in pulmonary vascular resistance and diversion of blood flow to other, better oxygenated parts of the pulmonary vascular bed (i.e., the dependent oxygenated and ventilated lung).

The relationship between  $\text{PaO}_2$  and the size of the hypoxic segment (Fig. 38-20) shows that, when not much of the lung is hypoxic, HPV has little effect on  $\text{PaO}_2$  because shunt is small in this situation. When most of the lung is hypoxic, there is no significant normoxic region to which the hypoxic region can divert flow, and then it does not matter, in terms of  $\text{PaO}_2$ , whether the hypoxic region has active HPV. When the amount of lung made hypoxic is 30% to 70%, such as occurs during OLV, there may be a large difference between the  $\text{PaO}_2$  to be expected with normal HPV compared with that expected in its absence. HPV can raise  $\text{PaO}_2$  from potentially dangerous levels to higher and safer ones. Conversely, inhibition of HPV may cause or contribute to hypoxemia during anesthesia.

**Figure 38-20** Role of hypoxic pulmonary vasoconstriction (HPV) in preserving  $\text{PaO}_2$  (in dogs). Assumptions are shown in inset. Lung is ventilated with  $\text{FIO}_2 = 1$ , while increasing portions of lung are subjected to hypoxia or atelectasis. In the absence of HPV, the expected  $\text{PaO}_2$  would follow the *blue line*, whereas in the presence of an active HPV response, observed  $\text{PaO}_2$  is maintained close to the *red line*.  $\text{PAO}_2$ , alveolar  $\text{PO}_2$ ;  $\text{PaO}_2$ , arterial  $\text{PO}_2$ . (Adapted from Marshall BE, Marshall C, Benumof JL, et al. Hypoxic pulmonary vasoconstriction in dogs: Effects of lung segment size and alveolar

oxygen tension. *J Appl Physiol.* 1981;51:1543.)

The response is believed to be accounted for by each smooth muscle cell in the pulmonary arterial wall responding to the oxygen tension in its vicinity. The mechanism of HPV has been the subject of many studies that have been recently summarized in an excellent review.<sup>139</sup>

### ***Effects of Anesthetics on Hypoxic Pulmonary Vasoconstriction***

The inhalation anesthetics and many of the intravenous drugs used in anesthesia have been studied for their effects on HPV. The results have not always been consistent. Benumof<sup>140</sup> classified the preparations used to study these effects as in vitro, in vivo nonintact, in vivo intact, and human studies. On the basis of the results of these three types of preparation, it is generally believed that inhaled agents inhibit HPV, whereas intravenous drugs do not have this effect.<sup>141</sup> The effects of anesthetics and other drugs in HPV in humans is difficult since during a surgical procedure there are many confounding variables, in particular the effects of inhaled agents on hemodynamics, for which to account.<sup>142-144</sup> Clinical studies therefore often fail to show a difference between inhaled and intravenous agents. For example, studies have shown no clinical difference in PaO<sub>2</sub> and shunt between OLV patients anesthetized using propofol or sevoflurane,<sup>145</sup> or propofol versus isoflurane.<sup>146</sup> Another study<sup>131</sup> reported finding a larger shunt with isoflurane. A study comparing sevoflurane with propofol, both titrated to a BIS reading of 40 to 60, found no difference in effect on oxygenation.<sup>147</sup>

Beck et al.<sup>145</sup> studied 40 patients requiring OLV randomized to receive propofol (4 to 6 mg/kg/hr) or sevoflurane (1 MAC) for anesthesia maintenance. During OLV shunt fraction increased in both groups, but there was no significant difference between groups. It was concluded that inhibition of HPV by sevoflurane may only account for small increases in shunt fractions and that much of the overall shunt fraction during OLV has other causes.

Overall, the potent inhaled anesthetics are the drugs of choice during thoracic surgery. However, the technique chosen should always be dictated by the needs of the particular patient, so in the presence of cardiovascular instability or poor oxygenation when depression of HPV is a possibility, a balanced technique may be chosen.

### ***Other Determinants of Hypoxic Pulmonary Vasoconstriction***

Aside from potent inhaled agents, other drugs and maneuvers used during anesthesia may also have an inhibitory effect on regional or whole-lung HPV. Factors associated with an increase in pulmonary artery pressure antagonize

the effect of increased resistance caused by HPV and result in increased flow to the hypoxic region. Such indirect inhibitors of HPV include mitral stenosis, volume overload, thromboembolism, hypothermia, vasoconstrictor drugs, and a large hypoxic lung segment. Direct inhibitors of HPV include infection, vasodilator drugs such as nitroglycerin and nitroprusside, nitric oxide, acetazolamide, phosphodiesterase inhibitors, prostacyclin, angiotensin-converting enzyme inhibitors, hypocarbia, and metabolic alkalemia. All these potential inhibitors should be considered when evaluating a patient for hypoxemia during thoracic surgery.<sup>148</sup>

### *Potentiators of Hypoxic Pulmonary Vasoconstriction*

Almitrine, a respiratory stimulant drug, in low dose has been reported to improve PaO<sub>2</sub> in patients with COPD and to have this effect in the absence of ventilatory stimulation.<sup>149</sup> In large doses it causes vasoconstriction in normoxic lung.<sup>150</sup> Its mechanism of action is not known. Since almitrine potentiates HPV and potent inhaled anesthetics inhibit HPV, Bermejo et al.<sup>151</sup> studied the effect of almitrine versus placebo in patients who were receiving sevoflurane-remifentanyl anesthesia for open chest procedures. The results showed that almitrine failed to improve PaO<sub>2</sub> or shunt fraction during OLV and sevoflurane anesthesia and increased pulmonary artery pressure. The authors concluded that the combination of almitrine and sevoflurane be avoided. This drug is not approved for use in the United States. Long-term use (as a respiratory stimulant) may cause a peripheral neuropathy.

### *Nitric Oxide and One-lung Ventilation*

Nitric oxide is an endothelial-derived relaxing factor that is an important mediator for smooth muscle relaxation. HPV is inhibited by inhaled nitric oxide. Inhibition of nitric oxide synthase improved, but did not completely restore HPV in dogs suffering from sepsis.<sup>152</sup> Frostell et al.<sup>153</sup> showed that inhalation of nitric oxide selectively induced vasodilation and reversed HPV in healthy humans without causing systemic vasodilatation. It was theorized that intravenous administration of almitrine (to increase HPV) causing vasoconstriction throughout the lung, together with inhalation of nitric oxide to inhibit HPV locally and cause increased flow in the ventilated regions, would improve V<sub>·</sub>/Q<sub>·</sub> matching and PaO<sub>2</sub> in patients with V<sub>·</sub>/Q<sub>·</sub> mismatching or during OLV.<sup>154</sup>

Moutafis et al.<sup>155</sup> studied the effects of inhaled nitric oxide in combination with almitrine infusion during OLV in 40 patients undergoing thoracoscopic procedures. They found that inhaled nitric oxide alone did not affect PaO<sub>2</sub>

during OLV, but the additional infusion of almitrine 16 mg/kg/min caused a marked increase in PaO<sub>2</sub>. These authors suggested that this nonventilatory technique should be of value during special thoracic procedures, such as thoracoscopy, where there is a need to manipulate the pulmonary circulation to improve PaO<sub>2</sub> but measures such as PEEP and CPAP cannot be used. Moutafis et al.<sup>155</sup> also reported the use of almitrine infusion/nitric oxide inhalation to improve PaO<sub>2</sub> during OLV for bronchopulmonary lavage.

Although the use of almitrine appears to be attractive, this drug is not without side effects.<sup>156</sup> Also, the manufacturer has not made it available outside France. Phenylephrine could be a possible alternative to almitrine.<sup>157</sup>

## Anesthesia for Diagnostic Procedures

### *Bronchoscopy*

Early bronchoscopes were rigid tubes, but in 1966 the Machida and Olympus Companies introduced the first practical bronchofiberscopes. Since then, they have been improved dramatically and have simplified many otherwise complicated bronchoscopies. The indications for bronchoscopy are shown in [Table 38-5](#) and the instruments of choice in [Table 38-6](#). Operator preferences and experience may play a major role in the choice of instrument.

Before bronchoscopy is performed, the patient must be evaluated for chronic lung disease, respiratory obstruction, bronchospasm, coughing, hemoptysis, and infectivity of secretions. Medications should be reviewed, and the need for a more major procedure should always be anticipated. Thus bronchoscopy may lead to thoracotomy or sternotomy. The planned technique for bronchoscopy should be discussed with the surgeon before the operation, and all equipment and connectors should be checked for compatibility. Monitoring during bronchoscopy should include an electrocardiogram, a blood pressure cuff, a precordial stethoscope, and a pulse oximeter. If thoracotomy is planned, an arterial cannula should also be placed, as well as other monitors (e.g., PA or CVP catheters) that may be indicated by the patient's condition. Many anesthetic techniques are useful for bronchoscopy.

**Table 38-5** Indications for Bronchoscopy

<b>Diagnostic</b>
Cough
Hemoptysis
Wheeze
Atelectasis
Unresolved pneumonia
Diffuse lung disease
Preoperative evaluation
Rule out metastases
Abnormal chest radiograph
Assess local disease recurrence
Recurrent laryngeal nerve palsy
Diaphragm paralysis
Acute inhalation injury
Exclude tracheoesophageal fistula
During mechanical ventilation
Selective bronchography
<b>Therapeutic</b>
Foreign bodies
Accumulated secretions
Atelectasis
Aspiration
Lung abscess
Reposition endotracheal tubes
Placement of endobronchial tubes
Laser surgery of the airway

**Table 38-6** Instruments of Choice for Bronchoscopy

<b>Rigid</b>
Foreign bodies
Massive hemoptysis
Vascular tumors
Small children
Endobronchial resections
<b>Fiberoptic/Flexible</b>
Mechanical problems of neck
Upper lobe and peripheral lesions
Limited hemoptysis
During mechanical ventilation
Pneumonia, for selective cultures
Positioning of double-lumen tubes
Difficult intubation
Checking position of endotracheal tube
Bronchial blockade

Adapted from Landa JF. Indication for bronchoscopy. *Chest*. 1978; 73(suppl):686.

## Local Anesthesia

The patient should first be pretreated with a drying agent such as glycopyrrolate. The local anesthetics most commonly used are lidocaine and tetracaine. In all cases, the total dose of anesthetic must be considered and the

potential for toxicity recognized. A nebulizer can be used to spray the oropharynx and base of the tongue, or the patient may gargle with viscous (2%) lidocaine. Alternatively, the tongue may be held forward, and pledgets soaked in local anesthetic held in each piriform fossa using Krause forceps to achieve block of the internal branch of the superior laryngeal nerve (see [Chapter 28](#)). Tracheal anesthesia is achieved by a transtracheal injection of local anesthetic, or by spraying the vocal cords and trachea under direct vision using a laryngoscope or through the suction channel of the bronchofiberscope. Alternatively, a superior laryngeal nerve block can be performed by an external approach, and a glossopharyngeal block can be used to depress the gag reflex. These blocks cause depression of airway reflexes, so patients must be kept on nothing by mouth status for several hours after the examination. If fiberoptic bronchoscopy is to be performed transnasally, the nasal mucosa should be pretreated topically with 4% cocaine, or viscous lidocaine may be administered through the nares. Local anesthesia for bronchoscopy has the advantages of a patient who is awake, cooperative, and breathing spontaneously. Sedatives may be added to make the patient more comfortable. Disadvantages of local anesthesia include poor tolerance of any bleeding by the patient and the occasional lack of patient cooperation.

## **General Anesthesia**

General anesthesia for bronchoscopy is often combined with topical laryngeal anesthesia so less general anesthesia is needed. A balanced technique uses N<sub>2</sub>O/O<sub>2</sub>, incremental doses of an intravenous drug such as propofol, an opioid, and a neuromuscular blocking drug. A potent inhalational anesthesia technique is also satisfactory. Alternatively, an intravenous-based technique may be used to avoid contamination of the OR atmosphere by potent inhaled agents. If desired, limited scavenging of waste gases may be achieved by placing a suction catheter in the patient's oropharynx. Unless there is some contraindication, ventilation of the lungs is usually controlled. In any patient undergoing a thoracic diagnostic procedure for a suspected malignancy, the possibility of the myasthenic syndrome with sensitivity to nondepolarizing muscle relaxants must always be considered. The doses of neuromuscular blocking drugs should be titrated to effect using a neuromuscular monitoring system.

## **Rigid Bronchoscopy**

A modern rigid ventilating bronchoscope is essentially a hollow tube with a blunted, beveled tip. Various sizes and designs are available; however, in all of them, a side arm is provided for connection to an anesthetic gas source. A number of techniques have been described for maintaining ventilation and

oxygenation during rigid bronchoscopic examination.<sup>158</sup>

**Apneic Oxygenation.** After preoxygenation and induction of general anesthesia, skeletal muscle paralysis and cessation of intermittent positive-pressure ventilation, the PaCO<sub>2</sub> increases. During the first minute, the increase is approximately 6 mmHg. Subsequently, the average rate of increase is 3 mmHg/min.<sup>159</sup> Oxygen is insufflated at 10 to 15 L/min through a small catheter placed above the carina. The apneic period should be kept to the minimum necessary, particularly in high-risk patients, because the technique is limited by buildup of CO<sub>2</sub>, respiratory acidosis, and cardiac dysrhythmias.

**Apnea and Intermittent Ventilation.** Oxygen and anesthesia gases are delivered to the bronchoscope via the anesthesia circuit. Ventilation is possible only when the eyepiece is in place, which limits the period for instrumentation by the surgeon. Intermittent ventilation of the lungs is achieved by squeezing the reservoir bag. In this way, assuming a good bronchoscope fit in the airway, compliance is constantly monitored, the risk of barotrauma is reduced, and V<sub>T</sub> may be estimated. The disadvantage of this technique is that there may be a leak around the bronchoscope, which could lead to hypoventilation and hypercarbia. Packing of the oropharynx can  reduce the leak, and improve ventilation in the case of such a gas leak.

**Sanders Injection System.** Oxygen from a high-pressure source (50 psig) is delivered, using a controllable pressure-reducing valve and toggle switch, to a 2.5- to 3.5-cm 18- or 16-gauge needle inside and parallel to the long axis of the bronchoscope.<sup>160</sup> When the toggle switch is depressed, the jet of oxygen entering the bronchoscope entrains room air, and the air-oxygen mixture resulting at the distal tip of the bronchoscope emerges at a pressure to provide adequate ventilation and oxygenation. The intraluminal tracheal pressure depends on the driving pressure from the reducing valve, the size of the needle jet, the length, internal diameter, and design of the bronchoscope. Increasing the size of the needle jet increases the total gas flow for any given driving pressure. For each combination of gas-driving pressure, jet orifice, and bronchoscope diameter, only one inflation pressure can be attained, regardless of the volume or compliance of the lung. As long as the proximal end of the bronchoscope is open, the system is strictly pressure limited, and the pressure does not increase because of obstruction at the distal end. Pressure varies inversely with the cross-sectional area of the bronchoscope, so insertion of a suction catheter or biopsy forceps into the lumen causes the intratracheal pressure to increase. Provided there is not a tight fit between the bronchoscope and the airway, the risk of barotrauma is low. If the fit is tight, driving pressure should be decreased.

The advantages of the Sanders system are that because continuous ventilation is possible (because the presence of an eyepiece is not necessary for ventilation of the lungs), the duration of the bronchoscopy procedure is

minimized, but the efficiency also permits extended bronchoscopy. A disadvantage is that entrainment of air by the oxygen jet results in a variable  $F_{IO_2}$  at the distal end of the bronchoscope, ventilation of the lungs may be inadequate if compliance is poor, and adequacy of ventilation may be difficult to assess.

**Mechanical Ventilator.** Ventilation of the lungs may be achieved by connecting a mechanical ventilator to an anesthesia circuit that is connected to the bronchoscope side arm. One disadvantage of this ventilation technique is the presence of a leak of anesthesia gases, and consequentially, light anesthesia.

**High-Frequency Positive-Pressure Ventilation.** HFPPV has been used in conjunction with rigid bronchoscopy and has been compared with the Sanders injector in patients with tracheobronchial stenosis. With HFPPV of up to 150 breaths/min, blood gases were identical with both techniques. At a frequency of 500 breaths/min, oxygenation deteriorated and  $CO_2$  was not removed effectively. HFPPV has the advantage that the tracheobronchial wall remains immobilized during ventilation.

## Fiberoptic Bronchoscopy

 New generations of fiberscopes, with their improved optics and smaller diameters, have revolutionized bronchoscopy. The flexibility has also been applied in preoperative assessment of the airway, management of difficult tracheal intubations, endotracheal tube positioning and change, bronchial toilet, correct positioning of DLTs, bronchial blockade, and evaluation of the larynx and trachea. Nasal fiberoptic bronchoscopy under topical anesthesia is well tolerated by most awake patients. The administration of an antisialagogue such as glycopyrrolate is useful in reducing secretions. Oral insertion is also possible in both awake and asleep patients and should be performed with a bite block in place to prevent damage to the bronchoscope.

**Physiologic Changes Associated with Fiberoptic Bronchoscopy.** In all patients, insertion of the fiberoptic bronchoscope is associated with hypoxemia. The average decline in  $PaO_2$  is 20 mmHg and lasts for 1 to 4 hours after the procedure. By 24 hours, the blood gas tensions are usually back to normal. It is therefore recommended that if the initial  $PaO_2$  is 70 mmHg ( $F_{IO_2} = 0.21$ ), bronchoscopy should be performed only with the administration of supplemental oxygen. This can be provided using mouth-held nasal prongs, a special face mask with a diaphragm through which the fiberscope can be passed, or an endotracheal tube with a T-piece diaphragm adapter.

During and after fiberoptic bronchoscopy, patients experience increased

airway obstruction. Thus in 35 patients, insertion of the bronchoscope was associated with an increase in FRC (17% to 30%) and decreases in PaO<sub>2</sub>, vital capacity, FEV<sub>1</sub>, and forced inspiratory flow.<sup>161</sup> All returned to baseline by 24 hours. These changes are believed to be secondary to direct mechanical activation of irritative reflexes in the airway and, possibly, to mucosal edema. They may be avoided if atropine, either intramuscular or aerosolized into the airway, is administered before the procedure.

The standard adult fiberoptic bronchoscope has an external diameter of 5.7 mm and a 2-mm diameter suction channel. If suction at 1 atm is applied to the fiberscope, air is removed at a rate of 14 L/min. If the fiberscope is in the airway, this causes decreases in FIO<sub>2</sub>, PAO<sub>2</sub>, and FRC, leading to decreased PaO<sub>2</sub>. Suctioning should therefore be kept brief. The adult fiberscope can be passed through endotracheal tubes of 7 mm or greater internal diameter. Clearly, passage through an endotracheal tube decreases the cross-sectional area available for ventilating the patient, so if fibroscopy is planned, an endotracheal tube of the largest possible diameter should be used.

Insertion of the bronchoscope also causes a significant PEEP effect that may result in barotrauma in ventilated patients. If PEEP is already being used, it should be discontinued before passage of the fiberscope. A postendoscopy chest radiograph is advisable to exclude the presence of mediastinal emphysema or pneumothorax. In patients whose tracheas are intubated with endotracheal tubes of less than 7 mm internal diameter, use of pediatric fiberscopes, which have smaller diameters, would be more appropriate.

The suction channel of the adult fiberoptic bronchoscope has been used to oxygenate and ventilate the lungs of patients. By attaching a jet ventilation system (similar to that used to drive the Sanders injector for rigid bronchoscopy) to the suction connection at the head of a fiberoptic bronchoscope, successful ventilation of the lungs of patients undergoing gynecologic procedures was achieved.<sup>160</sup> A driving pressure of 50 psig of oxygen was used with a ventilatory rate of 18 to 20 breaths/min. This technique permitted adequate ventilation of patients with normally compliant lungs and chest walls. Ventilation of the lungs should be performed only with the tip of the instrument in the trachea because a more peripheral location may produce barotrauma.

Neodymium-yttrium-aluminum garnet (Nd-YAG) lasers are used for the resection of obstructing and endobronchial lesions (see [Chapter 48](#)). This procedure is performed under general anesthesia. The lasers may be introduced into the bronchial tree through a fiberoptic bundle passed via the suction port of the fiberoptic bronchoscope. During laser resection, FIO<sub>2</sub> should be kept to a minimum and titrated to oxygen saturation (as continuously monitored by pulse oximeter) to make endotracheal fire less

likely (see [Chapter 5](#)). Laser therapy of bronchial tumors is also possible using a rigid bronchoscope. HFPPV through a rigid bronchoscope provides satisfactory operating conditions for laser resection of tracheal tumors and has the advantage of producing airway immobility.

## Complications of Bronchoscopy

Complications of rigid bronchoscopy include mechanical trauma to the teeth, hemorrhage, bronchospasm, loss of a sponge, bronchial or tracheal perforation, subglottic edema, and barotrauma. The incidence of complications is much lower with fiberoptic bronchoscopy. Nevertheless, complications may arise owing to overdose with topical anesthetic, insertion trauma, local trauma, hemorrhage, upper airway obstruction related to passage of the instrument through an area of tracheal stenosis, hypoxemia, and bronchospasm. In most cases, it is best to intubate the trachea with an endotracheal tube after bronchoscopy under general anesthesia. This permits avoidance or treatment of some of these problems, particularly the increased airway irritability. Intubation also facilitates effective suctioning of the trachea and bronchi, and allows the patient to recover more gradually from general anesthesia.

## 8 Diagnostic Procedures for Mediastinal Mass

Patients with an anterior mediastinal mass may present a special problem for the anesthesiologist. Although such masses may cause obvious superior vena cava obstruction, they may also cause obstruction of major airways and cardiac compression, which are less obvious and may become apparent only on induction of anesthesia. Many cases of anesthetic-related airway compression from anterior mediastinal mass have been reported. In one case, total occlusion of the trachea starting 2 to 3 cm above the carina and extending to both main stem bronchi was observed, and a bronchoscope was passed through the obstruction.<sup>162</sup> In the second case of this report, extrinsic compression of the left main stem bronchus occurred on inspiration during recovery from anesthesia. In the third case, flow–volume studies were performed with the patient in the upright and supine positions, with marked reductions in FEV<sub>1</sub> and peak expiratory flow in the latter position. These findings suggested potential obstruction with onset of anesthesia; radiation therapy to the mediastinum was commenced, after which the flow–volume studies showed improved function. The planned surgical procedure was then performed under local anesthesia. In a subsequent series of 105 patients with mediastinal masses, the incidence of intraoperative cardiorespiratory complications was 38%, and the incidence of

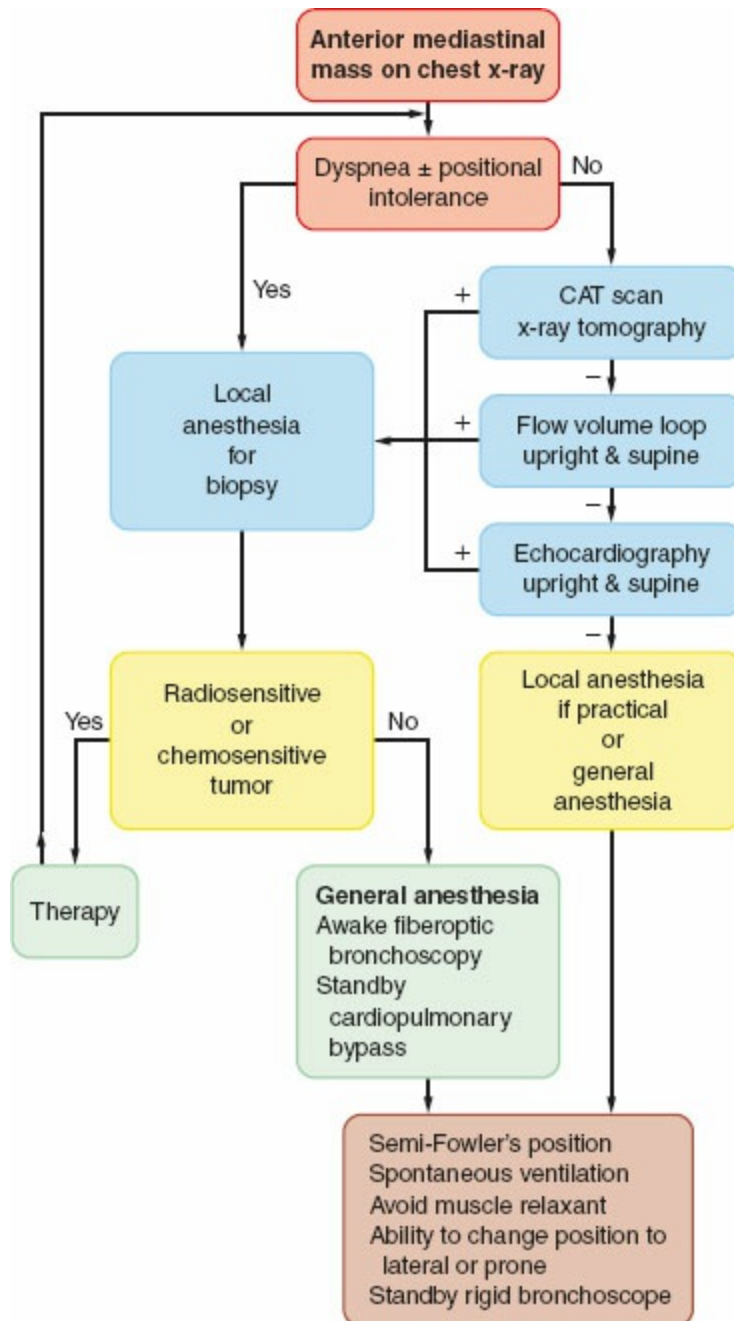

postoperative respiratory complications was 11%.<sup>163</sup> No cases of airway collapse were reported during anesthesia. In this series, patients were at increased risk of complications if there were preoperative cardiorespiratory signs and symptoms, obstructive and restrictive dysfunction on pulmonary function tests, and greater than 50% tracheal compression on CT scan. In another series of patients with mediastinal mass, four patients had abnormal spirometry but underwent general anesthesia without sequelae.<sup>164</sup> In severe cases of airway compression, the femoral vessels should be cannulated prior to induction of anesthesia so that if the airway is lost completely cardiopulmonary bypass can be instituted immediately.<sup>165</sup>

The mass may be sensitive to radiation therapy, which could shrink the tumor and make an induction of general anesthesia less hazardous. However, a serious potential disadvantage of preoperative radiation therapy is that it may affect tissue histologic appearance, thereby preventing an accurate diagnosis. Furthermore, if the patient is a child, it may be difficult to obtain tissue samples under local anesthesia. No fatalities occurred in a series of 44 patients aged 18 years of age or younger with anterior mediastinal masses who underwent general anesthesia before radiation or chemotherapy. However, seven patients did have airway compromise.<sup>166</sup> In another report in a series of children, it was found to be safe to induce general anesthesia if the CT scan revealed that the tracheal cross-sectional area and peak expiratory flow rates were at least 50% of predicted.<sup>167</sup> Airway obstruction caused by an anterior mediastinal mass has been attributed to changes in lung and chest wall mechanics associated with changes in position or to onset of paralysis in muscles that previously maintained airway patency. Preoperative evaluation of a patient with an anterior mediastinal mass to avoid life-threatening total airway obstruction is shown in [Figure 38-21](#). It is important to determine in the history if the patient has dyspnea in the supine position and to examine the CT scan to determine the extent of the tumor and its effect on surrounding structures. If such obstruction occurs, it may be relieved by passage of a rigid bronchoscope or anode tube past the obstruction, by direct laryngoscopy,<sup>168</sup> or by changing the position of the patient.

Airway collapse and inability to ventilate has been reported in a previously asymptomatic patient with a mediastinal mass despite spontaneous ventilation with an inhaled anesthetic and an endotracheal tube.<sup>169</sup> This resulted in sudden cardiopulmonary collapse. Positive-pressure ventilation was impossible, a rigid bronchoscopy was requested and the surgeons began to prepare femoral vessel access for emergent cardiopulmonary bypass. Fortunately, the airway patency was re-established when the patient's spontaneous respiratory efforts improved as he awoke from general anesthesia. The authors emphasize the need for immediate availability of a rigid bronchoscope and that if a patient is at high risk, then serious

consideration should be given to insertion of the femoral cannulas with cardiopulmonary bypass standing by before general anesthesia is induced. Cardiopulmonary bypass is not a suitable rescue modality unless the cannulae have been placed before induction because in the time required to achieve cannulation, severe neurologic damage is likely to occur.<sup>170</sup>

**Figure 38-21** Flow chart describing the preoperative evaluation of the patient with an anterior mediastinal mass. + indicates positive finding; - indicates negative workup. (Reprinted with permission from Neuman GG, Weingarten AE, Abramowitz RM, et al. Anesthetic management of the patient with an anterior mediastinal mass. *Anesthesiology*. 1984;60:144.)

In a situation in which the biopsy procedure cannot be performed under local anesthesia and there is concern that muscle paralysis may result in

airway compression, fiberoptic intubation of the awake patient followed by general anesthesia with spontaneous ventilation has been described. Thus during spontaneous inspiration, the normal transpulmonary pressure gradient distends the airways and helps maintain their patency, even in the presence of extrinsic compression.

## **Mediastinoscopy**

Mediastinoscopy was introduced as a means of assessing spread of bronchial carcinoma. The lymphatics of the lung drain first to the subcarinal and paratracheal areas, and then to the sides of the trachea, the supraclavicular areas, and the thoracic duct. Examination of these nodes has provided a tissue diagnosis and greater selectivity of patients for thoracotomy. It is most useful in right lung tumors because left lung cancers tend to spread to subaortic nodes that are more accessible by an anterior mediastinoscopy in the second or third interspace (Chamberlain procedure). The transcervical approach to the thymus is an adaptation of mediastinoscopy.

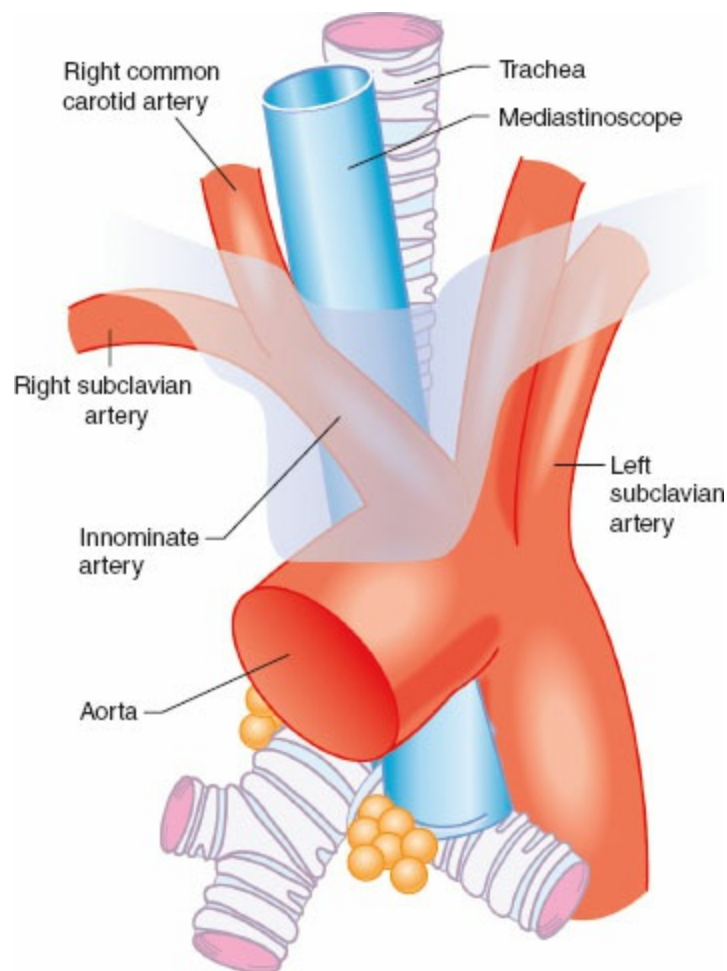

The anesthetic considerations for mediastinoscopy follow naturally from an understanding of the anatomy of this procedure and its potential complications. For cervical mediastinoscopy, the patient is placed in a reverse Trendelenburg (i.e., head-up) position, and the mediastinoscope is inserted into the superior mediastinum through a transverse incision just above the suprasternal notch. The instrument is advanced along the anterior aspect of the trachea and passes behind the innominate vessels and the aortic arch (Fig. 38-22). The left recurrent laryngeal nerve is vulnerable as it loops around the aortic arch, and any of these structures may be traumatized. Because of scarring, previous mediastinoscopy may be considered a contraindication to a repeat examination. Relative contraindications include superior vena cava obstruction, tracheal deviation, and aneurysm of the thoracic aorta.

Preoperative evaluation should include a search for airway obstruction or distortion. Review of a CT scan is very helpful in this regard. Evidence of impaired cerebral circulation, history of stroke, or signs of the Eaton–Lambert syndrome resulting from oat cell carcinoma should be sought. Blood must be available for the procedure because hemorrhage is a real risk and may be life-threatening.

Most surgeons and anesthesiologists prefer general anesthesia using an endotracheal tube and continuous ventilation because this offers a more controlled situation and greater flexibility in terms of surgical manipulation. The anesthetic technique should include a muscle relaxant to prevent the patient from coughing because this may produce venous engorgement in the chest or trauma by the mediastinoscope to surrounding structures.

The incidence of morbidity with mediastinoscopy has been reported as

1.5% to 3.0%, and that of mortality as 0.09%. The most common complication is hemorrhage (0.73%) because of the proximity of major vessels and the vascularity of certain tumors. Tamponade may be the only recourse, and thoracotomy or median sternotomy may be required to achieve hemostasis. Needle aspiration of any structure is essential before any biopsy is taken. If severe bleeding occurs, induced arterial hypotension may be helpful in reducing the size of the tear in a vessel. If bleeding is venous, fluids given via an upper limb vein may enter the mediastinum, in which case a large-bore catheter should be placed in a lower limb vein. A venous laceration may also result in air embolism, particularly if the patient is breathing spontaneously. Some recommend the use of a precordial Doppler probe if the risk of air embolism is likely.

**Figure 38-22** Anatomic relationships during mediastinoscopy. Note the position of the mediastinoscope behind the right innominate artery and aortic arch and anterior to the trachea. (Adapted from Carlens E. Mediastinoscopy: A method for inspection and tissue biopsy in the superior mediastinum. *Dis Chest.* 1959;36:343.)

Pneumothorax is the second most common complication (0.66%). It is usually right-sided, often recognized at the time of the occurrence, and is treated according to the size. A symptomatic pneumothorax should be treated

by chest tube decompression.

Recurrent laryngeal nerve injury occurred in 0.34% of cases and was permanent in 50% of these cases. The nerve may be damaged by the mediastinoscope or be involved in tumor. Such injury is not a problem unless both nerves are damaged, in which case upper airway obstruction may result. Autonomic reflexes may be triggered by manipulation of the trachea or the aorta, the latter having pressor receptors located in the arch. Vagally mediated reflexes may be blocked by atropine.

“Factitious” cardiac arrest has been reported when the right radial pulse was monitored using a plethysmograph, and the tracing suddenly disappeared in the presence of a normal electrocardiogram. A normal pulse returned after the mediastinoscope was removed, and the cause of the apparent arrest was pressure on the innominate artery by the instrument. Decreases in right arm as compared with left arm blood pressure have been reported in cases undergoing mediastinoscopy. Duration was 15 to 360 seconds. This is of particular significance if there is a history of impaired cerebral circulation or transient ischemic attacks, or if a carotid bruit is present, because transient left hemiparesis may occur after mediastinoscopy. It is therefore recommended that blood pressure be monitored in the left arm and that the right radial pulse be monitored continuously during mediastinoscopy. A decrease in the right radial pulse amplitude is an indication for repositioning the mediastinoscope, especially in a patient with a history of cerebrovascular disease.

Other reported complications include acute tracheal collapse, tension pneumomediastinum, mediastinitis, hemothorax, and chylothorax. A chest radiograph taken in the immediate postoperative period is a useful precaution in all patients after mediastinoscopy.

## **Thoracoscopy**

Thoracoscopy (medical thoracoscopy) involves the insertion of an endoscope into the thoracic cavity and pleural space. It is used for the diagnosis of pleural disease, effusions, and infectious disease (especially in immunosuppressed patients and those with acquired immunodeficiency syndrome) and for staging procedures, chemical pleurodesis, and lung biopsy. It is usually performed by the pulmonary physician in the clinic, under local anesthesia. It is also used in therapeutic procedures such as CO<sub>2</sub> laser treatment of spontaneous pneumothorax or bullous emphysema<sup>171</sup> and Nd-YAG laser vaporization of malignant pleural tumors. A small incision is made in the lateral chest wall, and with the insertion of the instrument, fluid and biopsy specimens are easily obtained.

This procedure may be performed using local, regional, or general

anesthesia; the choice depending on the expected duration of the procedure and the physical status of the patient. Pneumothorax is a potential complication of an intercostal block, but it would not have clinical sequelae during a thoracoscopy because it is created as part of the surgical procedure. The collapse of the lung provides the surgeon with a working space, and a chest tube is placed at the conclusion of the surgery. The addition of a stellate ganglion block helps suppress the cough reflex that is sometimes provoked during manipulation of the hilum of the lung.

When air enters the pleural cavity under inspection, a partial pneumothorax occurs, permitting good surgical visualization. Changes in PaO<sub>2</sub>, PaCO<sub>2</sub>, and cardiac rhythm are usually minimal when the procedure is performed using local or regional anesthesia.

With local anesthesia, the spontaneous pneumothorax is usually well tolerated because the skin and chest wall form a seal around the thoracoscope and limit the degree of lung collapse. Occasionally, however, the procedure is poorly tolerated, and general anesthesia must be induced. The insertion of a DLT with the patient in the lateral position may be difficult, in which case the patient may be temporarily placed in the supine position for the intubation.

If general anesthesia is required, a DLT is preferable to an SLT because positive-pressure ventilation via an SLT would interfere with endoscopic visualization. In addition, if pleurodesis is being performed, general anesthesia through a DLT allows for re-expansion of the lung and avoids the pain associated with instillation of talc for recurrent pneumothorax.

### ***Video-assisted (Minimally Invasive) Thoracoscopic Surgery***

VATS entails making small incisions in the chest wall, which allows the introduction of a video camera and surgical instruments into the thoracic cavity.<sup>172</sup> Generally, it is performed by a thoracic surgeon in the operating room under general anesthesia. Although the first thoracoscopy was performed by Jacobeus in 1910, using what was at that time a cystoscope, in more recent years the surgical techniques, instruments, and video technology have been improved to permit a wide variety of procedures to be performed using VATS. These now include diagnostic procedures for evaluation of pleural disease and effusions, staging of lung cancer, and the identification of parenchymal disease, including nodules, mediastinal tumors, and pericardial disease. They also include therapeutic procedures such as operations for pleural disease, including pleurodesis, decortication and drainage of empyema, resection of lung tissue or bullae, pericardial window or stripping, and esophageal surgery. Lung lobectomies are now usually performed by VATS, and an increasing number are being performed robotically.<sup>173–175</sup>

## Anesthesia Considerations

As with a traditional thoracotomy, the patient needs to be in the lateral decubitus position, and lung collapse is needed for adequate surgical exposure. This generally mandates the use of a lung-separation technique. VATS is most commonly performed under general anesthesia with OLV. **8** The need for OLV is much greater in VATS procedures than in open thoracotomy procedures. This is because during VATS, it is not possible to retract the lung, whereas during open thoracotomy lung retraction is possible. Deflation of the non-dependent (operated) lung should begin as soon as possible following tracheal intubation and patient positioning because it can take more than 30 minutes to achieve complete collapse of the lung. Also, the surgeon enters the thoracic cavity much sooner during VATS than with open thoracotomy. Suction applied to the airway can help facilitate a more rapid deflation of the lung. In some cases, carbon dioxide is insufflated into the pleural cavity to facilitate visualization. Insufflation pressures should be maintained as low as possible and the CO<sub>2</sub> inflow rate kept less than 2 L/min. Higher pressures can cause mediastinal shift, hemodynamic compromise, increases in airway pressure, and increases in end-tidal CO<sub>2</sub>. Hemodynamic compromise presents a picture similar to that because of tension pneumothorax. Significant hemodynamic changes can be produced when pressures as little as 5 mmHg are used to insufflate CO<sub>2</sub> into the chest cavity.<sup>176</sup>

CPAP is commonly used for the treatment of hypoxemia during OLV for thoracotomy and is usually very effective. However, during VATS, CPAP interferes with the surgical exposure and is therefore best avoided. It would be preferable to use PEEP to the nonoperated (dependent lung). In addition, a lower PaO<sub>2</sub> may have to be tolerated during VATS compared with a thoracotomy.<sup>177</sup>

## Postoperative Concerns

There is less pain after VATS than open thoracotomy, and an epidural catheter is usually placed before surgery only if there is a likelihood that a thoracotomy may need to be performed. Although a lobectomy can be performed by VAT, sometimes conversion to an open thoracotomy may be required. The patient's respiratory function is better preserved after VATS, and their recovery is faster. However, postoperative dysrhythmias, which commonly occur after thoracotomy, have also been reported after VATS.<sup>178</sup> Other complications that may occur include bleeding, pulmonary edema, and pneumonia.

## Anesthesia for Special Situations

Management of patients with BPF, empyema, cysts, and bullae, as well as those requiring tracheal reconstruction, is considered here. Many of these patients are appropriately managed using high-frequency ventilatory techniques; therefore, these techniques are described first (see [Chapter 28](#)).

### **High-Frequency Ventilation**

With conventional positive-pressure ventilation,  $V_T$  and rates usually exceed or approach those in the normal, spontaneously breathing patient. Gas transport to the alveoli occurs by convection in the larger airways, and then by convection and molecular diffusion in the more distal airways and alveoli. High-frequency ventilation differs from conventional positive-pressure ventilation in that smaller  $V_T$  and more rapid rates are used. Gas transport may depend more on molecular diffusion, high-velocity flow, and coaxial gas flow in the airways, with gas in the center moving distally and that in the periphery moving proximally.

There are several different types of high-frequency ventilation.<sup>179</sup> HFPPV uses small  $V_T$  at rates of 60 to 120 breaths/min (1 to 2 Hz). The ventilator used has a negligible internal compliance so the  $V_T$  generated, which usually approximates the dead space volume, equals the volume set on the ventilator and represents all fresh gas. The high instantaneous gas flows generated facilitate gas exchange and movement in the conducting airways.

HFPPV may be delivered by an open or a closed system. An example of the former is the percutaneous placement of a transtracheal catheter or placement of a catheter through the nose or mouth with its distal end above the carina. Inflow is intraluminal and outflow is extraluminal. This technique has been used during bronchoscopy, tracheal resection, and reconstructive surgery. When open systems are used, the gas outflow pathway is not established mechanically and depends on natural airway patency. It is therefore subject to compromise. Also, aspiration is a potential complication with open systems.

The closed system is superior because it integrates both airway patency and outflow protection. A closed system is represented by a catheter placed in a short segment of an endotracheal tube for delivery of the HFPPV, whereas the remainder of the tube lumen represents the exit pathway for gas. A quadruple-lumen endotracheal tube (Hi-Lo Jet Tracheal Tube, Mallinckrodt, Inc.) has been designed specifically for delivery of HFPPV. One lumen is for the HFPPV delivery, one for gas outflow, one for cuff inflation, and one for measuring airway pressures at the distal end of the tube. The use of a closed system also permits application of PEEP, a situation not possible with an open arrangement.

High-frequency jet ventilation (HFJV) uses a pulse of a small jet of fresh

gas introduced from a high-pressure source (50 psig) into the airway through a small catheter or additional lumen in an endotracheal tube. Rates used are usually 100 to 400 breaths/min. The fresh gas jet entrains gas from an injection cannula side-port reservoir. This system is somewhat analogous to the Sanders injector system described in the “Bronchoscopy” section, and  $FIO_2$  is similarly variable. The jet and entrained gas flows cause forward motion of the mass of gas in the airways. HFJV can be used with an open system or with a closed arrangement, as described earlier. In the latter, PEEP may be added to enhance oxygenation. Also, with use of high fresh gas flows from an anesthesia circuit, inhaled anesthetics may be delivered as an entrained gas mixture.

High-frequency oscillation ventilation uses a mechanism that oscillates gas at rates of 400 to 2,400 breaths/min. It has not been described in association with thoracic surgical procedures. In this system,  $V_T$  is small (50 to 80 mL), and gas exchange occurs through enhanced molecular diffusion and coaxial airway flow.

The potential advantages offered by HFPPV during thoracic anesthesia are that lower  $V_T$  and inspiratory pressures result in a quiet lung field for the surgeon, with minimal movements of airway, lung tissue, and mediastinum. Thus, HFPPV has been used to ventilate both the nondependent and the dependent lung during thoracic surgical procedures, with adequate arterial blood gas measurements obtained throughout. At high frequencies ( $>6$  Hz), however,  $CO_2$  retention may become a problem.

HFJV has been used to ventilate the nondependent lung to improve  $PaO_2$  during one-lung anesthesia, whereas the dependent lung is ventilated with conventional intermittent positive-pressure ventilation.  $PaO_2$  increased compared with that obtained during simple collapse of the nondependent lung. A study comparing HFJV with CPAP to the nondependent lung during conventional intermittent positive-pressure ventilation to the dependent lung found that both improved  $PaO_2$  significantly during closed and open stages of the surgery. When the chest was open, HFJV maintained satisfactory cardiac output, whereas CPAP usually decreased cardiac output; however, there were no significant differences in  $PaCO_2$  between HFJV and CPAP. Because similar increases in  $PaO_2$  may be obtained using selective CPAP to the nondependent lung and much simpler equipment than that necessary to deliver high-frequency ventilation, the use of CPAP would seem preferable to high-frequency ventilation to increase  $PaO_2$  during most one-lung anesthesia situations.

The lower pressures and  $V_T$  associated with high-frequency ventilation result in a small leak through BPFs, and HFJV is now generally considered the conservative treatment of choice in this condition. Another advantage of high-frequency ventilation is that the rapid-rate small  $V_T$  can be delivered through

small tubes or catheters so if an airway has to be divided, the passage of a small tube across the surgical field permits ventilation of the distal airway and lung tissue. This use has been applied during sleeve resection of the lung, tracheal reconstruction, and surgery for tracheal stenosis. In all three situations, the surgeon is able to work easily around the small catheter used to provide the high-frequency ventilation.

### ***Bronchopleural Fistula and Empyema***

A BPF is an abnormal communication between the bronchial tree and the pleural cavity. Occasionally, there is an additional communication to the surface of the chest, a cutaneous BPF. BPF occurs most commonly after pulmonary resection for carcinoma. Other causes include traumatic rupture of a bronchus or bulla (sometimes caused by barotrauma or PEEP), penetrating chest wound, or spontaneous drainage into the bronchial tree of an empyema cavity or lung cyst. The incidence of BPF is higher after pneumonectomy than following other types of lung resection. The problems associated with BPF and empyema are that positive-pressure ventilation may result in contamination of healthy lung, loss of air, decreased alveolar ventilation leading to CO<sub>2</sub> retention, and the development of a tension pneumothorax.

If an empyema is present, it should be drained under local anesthesia before any surgery to close the BPF. Drainage is performed with the patient sitting up and leaning toward the affected side. Empyemas are often loculated, and complete drainage is not always possible. A drain to an underwater seal system is left in the cavity before administration of anesthesia for surgery of the BPF, and after drainage of an empyema, a chest radiograph should be obtained to determine the efficacy of the procedure.

The priorities in the anesthetic management of BPF are the isolation of the affected side in terms of contamination and ventilation. The ideal approach is intubation of the trachea while the patient is awake using a DLT with the patient breathing spontaneously. Supplemental oxygen should be administered, and the patient should be constantly reassured. Neuroleptanalgesia is satisfactory in providing a suitably cooperative patient, and the airway is then pretreated with topical anesthesia. The endobronchial tube selected should be such that the bronchial lumen is on the side opposite the BPF. Selection of the largest possible tube provides a close fit in the trachea, which helps stabilize the tube. Once the tube is adequately positioned in the trachea, there may be a considerable outpouring of pus from the tracheal lumen if an empyema is present; therefore, this lumen should be immediately suctioned using a large-bore suction catheter. The healthy and possibly the affected lung may then be ventilated; adequacy of oxygenation and ventilation is assessed by pulse oximetry and arterial blood gas analysis.

An alternative technique is to insert the DLT under general anesthesia, with the patient breathing spontaneously to avoid a tension pneumothorax. With either technique, the chest drainage tube must be left unclamped to avoid any bouts of coughing and to prevent the buildup of a tension pneumothorax in the event that a predisposing valvular mechanism exists. In patients who do not have an empyema, use of an SLT has been described and may be satisfactory if the BPF and air leak are small. A rapid-sequence induction with ketamine or propofol followed by a relaxant has also been described, but is associated with considerable risk of contamination and tension pneumothorax.

BPF may also be treated conservatively using various ventilatory techniques. Thus, the bronchus of the normal lung may be intubated and ventilated, allowing the BPF to rest and heal. This approach may result in an intolerable shunt, however, and PEEP may be necessary to maintain PaO<sub>2</sub>. Differential lung ventilation using a DLT has also been described, the healthy lung being ventilated with normal V<sub>T</sub>, while the affected lung is exposed to a smaller V<sub>T</sub> or to CPAP with oxygen at pressures just below the critical opening pressure of the fistula. The critical opening pressure of the BPF can be assessed by determining the lowest level of CPAP that must be applied to the bronchus on the affected side to produce continuous bubbling through the underwater seal chest drain.

For a large BPF, HFJV may be the nonsurgical treatment of choice. The use of small V<sub>T</sub> results in minimal gas loss through the fistula, which may heal more quickly. In addition, hemodynamic effects are usually minimal and spontaneous efforts at ventilation are usually abolished, thereby decreasing the work of breathing and eliminating the need for relaxants or excessive sedation.

## *Lung Cysts and Bullae*

Air-filled cysts of the lung are usually bronchogenic, postinfective, infantile, or emphysematous. They may be associated with COPD or be an isolated finding. A bulla is a thin-walled space filled with air that results from the destruction of alveolar tissue. The walls are, therefore, composed of visceral pleura, connective tissue septa, or compressed lung tissue. In general, bullae represent an area of end-stage emphysematous destruction of the lung.

Patients may be considered for surgical bullectomy when dyspnea is incapacitating, when the bullae are expanding, when there are repeated pneumothoraces owing to rupture of bullae, or if the bullae compress a large area of normal lung. Most of these patients have severe COPD and CO<sub>2</sub> retention, and little functional respiratory reserve. The first consideration in management is maintenance of a high FIO<sub>2</sub>. If the bulla or cyst communicates

with the bronchial tree, positive-pressure ventilation may cause it to expand or even to rupture, if it is compliant, producing a situation analogous to tension pneumothorax. If the bulla is very compliant, most of the applied  $V_T$  may be wasted in this additional dead space. Nitrous oxide should be avoided because it causes expansion of any air spaces in the body, including bullae. Once the chest is open, even more of the  $V_T$  may enter the compliant bulla, which is no longer limited by chest wall integrity, and an increase in ventilation is needed until the bulla is controlled.

The anesthetic management of these patients is challenging, particularly if the disease is bilateral. Ideally, a DLT is inserted with the patient awake or under general anesthesia but breathing spontaneously. The avoidance of positive-pressure ventilation (when possible) helps decrease the likelihood of the potential problems described previously, although oxygenation may be precarious with spontaneous ventilation. Once the endotracheal tube is in place, each lung may be controlled separately, and adequate ventilation can be applied to the healthy lung if bilateral disease is not present. Gentle positive-pressure ventilation with rapid, small  $V_T$  and pressures not to exceed 10 cm H<sub>2</sub>O may be used during the induction and maintenance of anesthesia, especially if the bullae have been shown to have no or only poor bronchial communication by preoperative ventilation scanning. While the surgery is being performed, as each bulla is resected, the operated lung can be separately ventilated to check for air leaks and the presence of additional bullae.

If positive-pressure ventilation is to be applied before the chest is opened, the possibility of a tension pneumothorax must be kept in mind, and treatment should be readily available. The diagnosis of pneumothorax may be made by a unilateral decrease in breath sounds (this may be difficult to distinguish in a patient with bullous disease), increase in ventilatory pressure, progressive tracheal deviation, wheezing, or cardiovascular changes. Treatment of a pneumothorax involves the rapid placement of a chest tube. An added risk of chest tube placement is the creation of a cutaneous BPF, which causes problems for ventilation. Alternatively, general anesthesia is induced only after the surgeon has prepared the operative field and draped the patient. In the event of sudden deterioration in the patient's condition during induction, the surgeon may perform an immediate median sternotomy. In any event, the time from induction of anesthesia to sternotomy must be kept to a minimum.

To avoid these problems in a patient with known bullae, HFJV has been used in a patient with a large bulla undergoing coronary artery bypass graft and in another patient undergoing bilateral bullectomy. If bilateral bullectomy is to be performed, a median sternotomy is usually used. Benumof<sup>180</sup> described the use of sequential OLV using a DLT in the

management of a patient needing bilateral bullectomy. The side with the largest bulla and least lung function, as assessed before surgery by ventilation and perfusion scans, should be operated on first. In this way, the lung with the better function should support gas exchange first. If hypoxemia develops during this one-lung situation, application of CPAP to the nonventilated lung during the deflation phase of a tidal breath should increase PaO<sub>2</sub>.

Unlike most cases of pulmonary resection, patients after bullectomy are left with a greater amount of functional lung tissue than was previously available to them, and the mechanics of respiration are improved. At the end of the procedure, the DLT is replaced by an SLT, and the patients generally require several days to be weaned from the ventilator. During this time, the positive airway pressure used should be minimized to avoid causing a pneumothorax owing to rupture of suture or staple lines or of residual bullae.

### *Anesthesia for Resection of the Trachea*

Tracheal resection and reconstruction are technically difficult for the surgeon and challenging for the anesthesiologist. Indications for this type of procedure include congenital lesions (agenesis, stenosis), neoplasia (primary or secondary), injuries (direct or indirect), infections, and postintubation injuries (caused by an endotracheal tube or tracheotomy). For the surgical team, the major problems are maintenance of ventilation to the lungs while the airway is being operated on and postoperative integrity of the anastomoses. In this respect, the presence of lung disease sufficiently severe to require postoperative ventilatory support is a relative contraindication to tracheal resection or reconstruction.

Monitoring of these patients should include placement of an arterial cannula in the left radial artery to permit continuous measurement of blood pressure during periods of innominate artery compression. Steroids should be administered to help reduce any tracheal edema, and a high FIO<sub>2</sub> should be used throughout the procedure to ensure an adequate oxygen reserve at all times in the FRC so that temporary interruptions of ventilation are less likely to produce hypoxemia.

Numerous methods have been reported to provide oxygenation and ventilation of the lungs during these procedures. A small-bore anode tube may be placed through and distal to an upper tracheal lesion so resection may occur around the tube. This technique is useful only in mild stenoses. Alternatively, an endotracheal tube may be passed through the glottis to above the stenosis, and a sterile endotracheal or bronchial tube may later be inserted into the trachea opened distal to the site of stenosis, with the sterile anesthesia tubing being led across the surgical field. After resection of the lesion, the sterile and distally placed endotracheal tube is withdrawn, and the

upper tube (originally passed through the glottis) is advanced across the anastomosis. With low tracheal or bronchial lesions, resection and reconstruction may be performed around an endobronchial or DLT. During these procedures, the patient is kept in a head-down position to minimize aspiration of blood and debris into the alveoli, and ventilation must be carefully monitored throughout the procedure.

Clearly, the presence of a large-bore tube in the airway may make these resections technically difficult, and the use of high-frequency ventilation techniques may improve surgical access. Thus, a small-diameter catheter or catheters may be placed across or through the stenotic lesion or transected airway(s) and ventilation to the distal airways and lungs maintained using HFPPV or HFJV. Potential disadvantages of these high-frequency ventilation techniques are that, by necessity, the system is “open” (see “High-frequency Ventilation”), and egress of gas during exhalation may be compromised if the stenosis is tight. Also, the catheter may become occluded by blood and become displaced, and distal aspiration of debris or blood may occur. With complex resections, two anesthesia teams with two machines and anesthesia circuits or sets of ventilating equipment may be necessary to ensure adequate ventilation of the two distal airway segments. Although during carinal resections, HFPPV to the left lung alone usually provides adequate oxygenation and ventilation.

After tracheal resection or reconstructive surgery, patients should be kept with the neck and head flexed to reduce tension on the anastomotic suture lines. In some cases, this is maintained by using sutures between the chin and the anterior chest wall. Extubation of the trachea is performed as early as possible to minimize tracheal trauma due to the endotracheal tube and cuff.

### ***Bronchopulmonary Lavage***

This procedure involves irrigation of the lung and bronchial tree, and is used as a treatment for alveolar proteinosis, radioactive dust inhalation, cystic fibrosis, bronchiectasis, and asthmatic bronchitis. Lung lavage is performed under general anesthesia using a DLT so one lung may be ventilated while the other is being treated with lavage fluid.<sup>181</sup>

The preoperative assessment of these patients should include ventilation-perfusion scans so lavage can be performed first on the more severely affected lung (i.e., the one with the least ventilation). If involvement is equal, the left lung is generally lavaged first because gas exchange should be better through the larger, right lung. Patients are premedicated and supplied with supplemental oxygen en route to the operating room.

Anesthesia is induced with an intravenous drug and maintained with an inhaled agent in oxygen to maintain the highest possible F<sub>I</sub>O<sub>2</sub>. Muscle

relaxation facilitates placement of the DLT, and the cuff seal should be checked to maintain perfect separation at a pressure of 50 cm H<sub>2</sub>O to prevent leakage of lavage fluid around the cuff. A fiberoptic bronchoscope is useful to check the position of the bronchial cuff of the DLT. Monitoring should include an arterial catheter, and a stethoscope should be placed over the ventilated lung to check for rales, the presence of which may indicate leakage of lavage fluid into this lung.

The patient is maintained on an FIO<sub>2</sub> of 1 throughout the procedure. Before lavage, this serves to denitrogenate the lungs so only oxygen and carbon dioxide remain. Instillation of fluid then allows these gases to be absorbed, resulting in greater access by the fluid to the alveolar spaces than if the more insoluble nitrogen bubbles remained.

Once the trachea is intubated, the patient is turned so the side to be lavaged is lowermost, and the DLT position and seal are checked once again. With the patient in a head-up position, warmed heparinized isotonic saline is infused by gravity from a reservoir 30 cm above the midaxillary line into the catheter to the dependent lung, while the nondependent lung is ventilated. When fluid ceases to flow in (usually after 700 to 1,000 mL in an adult), the patient is placed in a head-down position and fluid is allowed to drain out. The lavage is continued until the effluent is clear (as opposed to the milky fluid that drains initially when lavage is being performed for alveolar proteinosis), at which point the lung is suctioned and ventilation is re-established with large V<sub>T</sub> (and pressures) because compliance is decreased owing to loss of surfactant. With each lavage, inflow and outflow volumes are monitored so the patient is not “drowned” in fluid, and there is no excessive absorption or leakage to the ventilated side. At least 90% of the saline volume should be recovered with each lavage. Two-lung ventilation is re-established and, as compliance improves, an air–oxygen mixture (addition of nitrogen) may be introduced to help maintain alveolar patency. After a further period of ventilation, in most patients, the trachea can be extubated in the operating room. In the posttreatment period, patients are encouraged to cough and engage in breathing exercises to fully re-expand the treated lung. From 3 days to 1 week after lavage of the first lung, the patient may return to the operating room for lavage of the other lung.

Problems sometimes encountered with this procedure include spillage of lavage fluid from the treated to the ventilated lung. This must be managed by stopping the lavage and ensuring functional separation of the lungs before continuing. DLT positioning is critical. Spillage may cause profound decreases in oxygenation, which may necessitate terminating the procedure and maintaining two-lung ventilation with oxygen and PEEP.

During periods when lavage fluid is being instilled into the dependent lung, oxygenation usually improves because the increased intra-alveolar

pressure caused by the fluid produces diversion of the pulmonary blood flow to the nondependent, ventilated lung. Conversely, when the fluid is drained out of the dependent lung, hypoxemia may occur. In some cases in which severe hypoxemia was anticipated during right lung lavage, the risk has been reduced by passing a balloon-tipped catheter into the right main pulmonary artery (checked by radiography) and inflating the balloon during periods of right lung drainage. In this way, blood flow to the dependent, right, nonventilated lung is minimized during periods of drainage. This technique is not without risk (e.g., pulmonary artery rupture) and is reserved for those patients considered to be at greatest risk for hypoxemia during lavage. If the patient has recently had a diagnostic open lung biopsy, a BPF may be present. If this is a possibility, a chest tube should be inserted on the side of the BPF, and this side should be lavaged first. The chest drain is removed several days later.

Limitations in the sizes of available DLTs preclude their use for lavage in patients weighing less than 40 kg. In such cases, cardiopulmonary bypass may be required to provide oxygenation during lavage.

## *Myasthenia Gravis*

**10** The thoracic anesthesiologist will most likely have to manage patients with MG for thymectomy, which is now considered the treatment of choice in most cases of MG. MG is a disorder of the neuromuscular junction, the function of which is altered routinely in the modern practice of anesthesia. The incidence of MG appears to be increasing. The most accurate estimate of incidence of MG was around 30/1,000,000 per year. The incidence in children and adolescents aged 0 to 19 years was found to be between 1 and 5/1,000,000 per year. These rates may well be an underestimate of the true incidence rates, as mild cases will have been missed and cases in the elderly will have been misdiagnosed.<sup>182</sup> People of any age may be affected, but peaks of incidence occur in the third decade for women and the fifth decade for men. MG is a chronic disorder characterized by a clinical course of fluctuating painless weakness and fatigability of voluntary muscles with improvement following rest.<sup>183,184</sup> Onset is usually slow and insidious, any skeletal muscle or group of muscles may be affected, and the condition is associated with relapses and remissions. The most common onset is ocular; if the disease remains localized to the eyes for 2 years, the likelihood of progression to generalized MG is low. In some cases, the disease is generalized and may involve the bulbar musculature, causing problems with breathing and swallowing. Peripheral muscle involvement may cause weakness, clumsiness, and difficulty in holding up the head or in walking. A commonly used clinical classification of MG<sup>185</sup> is shown in [Table 38-7](#).

In MG, there is a decrease in the number of postsynaptic acetylcholine receptors (AChRs) at the endplates of affected muscles. This causes a decrease in the margin of safety of neuromuscular transmission. MG is an autoimmune disorder, and about 80% of the affected patients have detectable circulating antibodies to the nicotinic AChR. These anti-AChR antibodies may cause complement-mediated lysis of the postsynaptic membrane or direct blockade of the receptors, or may modulate the receptor turnover such that the degradation rate exceeds the resynthesis rate. Studies of the endplate area show loss of synaptic folds and a widening of the synaptic cleft. A variable proportion of the patients who do not have anti-AChR antibodies have antibodies to muscle-specific tyrosine kinase (MuSK).<sup>186</sup>

**Table 38-7** Clinical Classification of Myasthenia Gravis (MG)

Class	Description
I	Ocular myasthenia—involvement of ocular muscles only. Mild with ptosis and diplopia. Electrophysiologic testing of other musculature is negative for MG.
IA	Ocular myasthenia with peripheral muscles showing no clinical symptoms but showing a positive electromyogram for MG.
II	Generalized myasthenia
IIA	Mild—slow onset, usually ocular, spreading to skeletal and bulbar muscles. No respiratory involvement. Good response to drug therapy. Low mortality rate.
IIB	Moderate—as IIA but progressing to more severe involvement of skeletal and bulbar muscles. Dysarthria, dysphagia, difficulty chewing. No respiratory involvement. Patient's activities limited. Fair response to drug therapy.
III	Acute fulminating myasthenia—rapid onset of severe bulbar and skeletal weakness with involvement of muscles of respiration. Progression usually within 6 mos. Poor response to therapy. Patient's activities limited. Low mortality rate.
IV	Late severe myasthenia—severe MG developing at least 2 yrs after onset of group I or group II symptoms. Progression of disease may be gradual or rapid. Poor response to therapy and poor prognosis.

Adapted from Osserman KE, Genkins G. Studies in myasthenia gravis: a review of a 20-year experience in over 1200 patients. *Mt Sinai J Med.* 1971;38:497.

The diagnosis of MG is suspected from the patient's history and confirmed by clinical, pharmacologic, electrophysiologic, or immunologic testing. Patients cannot sustain or repeat muscular contraction. The electrical counterpart of this is a decrement in the compound muscle action potentials evoked by repetitive stimulation of a motor nerve. This is the most specific of the nerve tests for MG but it can be performed only on certain muscles, which

may not be the ones affected in an individual patient. Mechanical and electrical (electromyography) decrements improve with 2 to 10 mg of intravenous edrophonium (Tensilon test). MG patients characteristically are sensitive to nondepolarizing muscle relaxants. When the routine electromyographic results are equivocal, a regional nondepolarizing muscle relaxant test may be performed using a tourniquet to isolate the limb and limit the action of the drug. In the regional nondepolarizer muscle relaxant test, electromyograms are performed before and after the administration of 0.2 mg of curare. In equivocal cases, a positive result of a test for anti-AChR antibodies is considered diagnostic.

## Medical Therapy

Anticholinesterases are used to prolong the action of acetylcholine at the postsynaptic membrane and may also exert their own agonist effect at the AChRs. Anticholinesterases are the most commonly used medical therapy in MG (Table 38-8). Interestingly, no randomized controlled trial has been conducted on the use of acetylcholinesterase inhibitors in patients with MG because the response in observational studies is so obvious that a placebo group could not be justified.<sup>187,188</sup> Myasthenic patients learn to regulate their medication and titrate the dose against optimum effect. Overdosage causes the muscarinic effects of acetylcholine and may cause a cholinergic crisis. Underdosage causes weakness or a myasthenic crisis. In a patient with weakness, distinction between the two types of crisis may be made by performing a Tensilon test or by examining pupillary size, which will be large (mydriatic) in a myasthenic crisis but small (miotic) in a cholinergic crisis. Muscarinic side effects are treatable with atropine (see Chapter 14).

**Table 38-8** Anticholinesterase Drugs Used to Treat Myasthenia Gravis

Drug	Dose (mg)			Efficacy
	Oral	IV	IM	
Pyridostigmine (Mestinon)	60	2	2–4	1
Neostigmine (Prostigmine)	15	0.5	0.7–1	1

IV, intravenous; IM, intramuscular.

The immunologic basis of MG has led to the use of short- and long-term immunosuppressive drugs. Steroids are used for short-term immunosuppression, whereas for long-term effect azathioprine, cyclophosphamide, cyclosporine, methotrexate, mycophenolate mofetil, rituximab, and tacrolimus have been used.<sup>184</sup> Steroids often produce initial deterioration before an improvement. The usual regimen is prednisone 1 mg/kg on alternate days. Rapid short-term immunomodulation has been

achieved in acute exacerbations or to improve muscle strength prior to surgery. Plasma exchange or plasmapheresis may produce dramatic but transient improvements in muscle strength with decreases in anti-AChR and anti-MuSK titers, as well as other inflammatory mediators. Usually reserved for severe MG, plasma exchange has been shown to improve respiratory function in both operated and nonoperated patients with MG. Plasmapheresis causes a decrease in plasma cholinesterase levels that may prolong the effect of drugs such as succinylcholine that are normally broken down by this enzyme system.

Long-term immunomodulation is achieved by surgical thymectomy.<sup>189</sup> Abnormalities are found in 75% of thymus glands removed from patients with MG (85% show hyperplasia, 15% show thymoma). After thymectomy, approximately 75% of patients either go into remission or show some improvement. Thymectomy is always indicated in those patients with thymoma, and now considered the treatment of choice in most patients with MG, except for those in Osserman class I (Table 38-7). Response to thymectomy is best if it is performed within the first 3 years following diagnosis. Clinical outcome from thymectomy is equivalent whether performed via a transsternal or video-assisted thoracoscopic approach.<sup>190</sup> A report describing anesthesia concerns in 17 patients who underwent robotic-assisted thoracoscopic thymectomy suggested that refinement of the surgical technique and positioning are required.<sup>191</sup>

## **Management of General Anesthesia**

When possible, patients with MG should be admitted for elective surgery while in remission.<sup>192</sup> On admission, the patient's physical and emotional states should be optimized. Other diseases occasionally associated with MG should be excluded (Table 38-9).<sup>193</sup> The patient's current drug therapy should be reviewed and possible drug interactions considered. Because patients are less active while in the hospital, their anticholinesterase dosage may need to be decreased. If the patient has a history of respiratory disease or bulbar involvement, preoperative evaluation should include respiratory function studies. Breathing exercises and instruction in the use of incentive spirometers may be indicated. Patients should be told of the possible need for postoperative intubation of the trachea and ventilation of the lungs. Ideally, patients with MG should be scheduled to be the first case of the day in the operating room. Patients receiving steroid therapy should receive perioperative coverage. Interactions with other immunosuppressant drugs must be considered and if the patient is in crisis, preoperative plasmaphereses may be necessary.

**Table 38-9** Disorders Associated with Myasthenia Gravis

Thymoma  
Thyroid disease  
Hyperthyroidism  
Hypothyroidism  
Thyroiditis  
Idiopathic thrombocytopenic purpura  
Rheumatoid arthritis  
Systemic lupus erythematosus  
Anemias  
Pernicious  
Hemolytic  
Multiple sclerosis  
Ulcerative colitis  
Leukemia  
Lymphoma  
Convulsive disorders  
Extrathymic neoplasia  
Sjögren syndrome  
Scleroderma

Because the trachea is to be intubated and the lungs ventilated for the planned procedure in the patient with MG, traditional practice is to withhold anticholinesterase therapy on the morning of surgery so that the patient is weak on arrival at the operating room.<sup>194</sup> This avoids interactions with other drugs used in the operating room. Anticholinesterase therapy may be continued if the patient is physically or psychologically dependent on it. Others recommend continuing pyridostigmine, including an oral dose just before induction.<sup>195</sup> Premedication is satisfactorily achieved with a benzodiazepine or barbiturate. Opioids are usually avoided because of the risk of producing respiratory depression.

Monitoring should be dictated by the patient's state and planned surgical procedure, but should include an assessment of neuromuscular transmission (by means of a mechanomyogram/twitch monitor, an integrated electromyographic monitor, a kinemyograph, or an accelograph monitor)<sup>196</sup> if agents affecting neuromuscular transmission are to be used.

Induction of anesthesia is readily achieved with a short-acting barbiturate (if available) or propofol. In elective cases, intubation of the trachea, maintenance, and relaxation are readily achieved using potent inhaled anesthetics. Anesthesia may be deepened using a potent inhaled agent and the trachea intubated under its effect. Myasthenic patients are more sensitive than normal patients to the neuromuscular depressant effects of the potent inhaled agents. In patients with MG, isoflurane at 1.9 MAC end-tidal concentration induced a neuromuscular block of 30% to 50%, whereas halothane at 1.8 MAC induced a block of 10% to 20%. Both agents produced fade in the train-of-four ratio of 41% and 28%, respectively.<sup>197</sup> The less-soluble inhaled agents, sevoflurane and desflurane, are even more easily administered and withdrawn; they are now the most commonly used anesthetic drugs for

patients with MG. Nitahara et al.<sup>198</sup> studied the neuromuscular effects of sevoflurane in 16 myasthenic patients and 12 normal patients. As expected, they found a concentration-dependent decrease in T1 and T4/T1 values. The depressant effects of sevoflurane were more prominent in those myasthenic patients with baseline T4/T1 less than 0.90. Whichever agent is used, at the end of the procedure, the inhaled agent is discontinued and recovery of neuromuscular function begins. Experience with desflurane in MG patients undergoing video-assisted thoracoscopic thymectomy was similar.<sup>199</sup>

**Nondepolarizing Relaxants.** In some cases, patients with MG cannot tolerate the cardiovascular depressant effects of the potent inhaled anesthetics, in which case neuromuscular blocking drugs may be used, titrating dose against monitored effect. Patients with MG are sensitive (i.e., show a decrease in ED<sub>50</sub> and ED<sub>95</sub> when compared with non-MG patients) to the nondepolarizing neuromuscular blocking drugs.<sup>200</sup> All nondepolarizing relaxants have been successfully and uneventfully used with careful monitoring in patients with MG (see [Chapter 21](#)). Since the sensitivity of any individual MG patient is unknown, these drugs should be titrated in 1/10 of the usual dose. Cisatracurium may be preferred because of its short elimination half-life, small volume of distribution, lack of cumulative effect, and high clearance.<sup>201</sup> Sensitivity to nondepolarizing relaxants is increased during the coadministration of a potent inhaled anesthetic.<sup>201</sup>

Other intermediate-duration nondepolarizing agents such as vecuronium and rocuronium may be used; long-acting relaxants are best avoided in patients with MG. If necessary, the residual relaxation produced by nondepolarizers may be reversed by increments of anticholinesterase drugs, whereas neuromuscular transmission is carefully monitored to obtain maximum antagonism yet avoid a cholinergic crisis. All anticholinesterases have been safely used. Edrophonium may be the drug of choice because its onset of action is rapid and higher doses have a prolonged duration of action. The sensitivity of patients with MG to nondepolarizing relaxants is very variable, depending on the individual patient, the severity of MG, and the treatment. Mann et al.<sup>202</sup> showed that MG patients who have a T4/T1 ratio less than 0.9 in the preanesthetic period show increased sensitivity to atracurium. They suggest that neuromuscular monitoring using train-of-four stimulation should begin in the preinduction period following administration of adequate analgesia (fentanyl, 2 µg/kg). Itoh et al.<sup>203</sup> found that patients with ocular MG were less sensitive to vecuronium than were those with generalized MG. They also found that in patients with clinical MG, sensitivity to vecuronium was unrelated to the presence or absence of antibodies to the AChR. Seronegative patients were as sensitive to vecuronium as seropositive patients.<sup>204</sup> There are conflicting reports as to the sensitivity of patients with MG in remission. All such patients should be considered sensitive to

nondepolarizers until proven otherwise.<sup>205</sup>

Sugammadex is a novel cyclodextrin drug that is designed to bind rocuronium with a great affinity. Before the introduction of sugammadex, anticholinesterase drugs were the only options for antagonism of residual neuromuscular blockade, and in MG patients anticholinesterases must be administered with caution so as to avoid myasthenic or cholinergic crises. Sugammadex has been reported to provide very rapid, complete, and lasting recovery from deep levels of rocuronium-induced neuromuscular blockade in normal patients.<sup>206,207</sup>

Sugammadex has since been reported to safely reverse deep rocuronium-induced neuromuscular blockade within 210 seconds in a patient with MG.<sup>208</sup> Sugammadex offers significant advantages in the management of the MG patient.<sup>209</sup> At the time of writing, this drug has been approved by the Food and Drug Administration for clinical use in the United States.

**Succinylcholine.** Myasthenic patients are resistant to the neuromuscular blocking effects of succinylcholine. The ED<sub>95</sub> is 2.6 times normal in these patients.<sup>210</sup> Clinically, however, the use of succinylcholine has been without incident, with the usual clinical doses producing adequate relaxation for endotracheal intubation and a normal recovery time, despite the occasionally reported early onset of phase II block. Doses of 0.2 to 1 mg/kg have been used in a number of patients with MG, and most did not show fasciculation before becoming paralyzed. Fade in response to train-of-four stimulation was observed in some patients during recovery, but recovery was not delayed. Prior administration of an anticholinesterase may complicate the response to succinylcholine by delaying its metabolism.

When a rapid-sequence intubation of the trachea is required, rapid onset of muscle relaxation may be achieved with succinylcholine or with moderate doses of a nondepolarizer in the latter case, with an associated prolongation of effect. A succinylcholine (1.5 mg/kg)–vecuronium (0.01 mg/kg) sequence has been safely used in three patients with MG for thymectomy. The authors suggested that this technique may be particularly advantageous when rapid-sequence induction of anesthesia is indicated.<sup>211</sup> In the future, a combination technique of intubating dose rocuronium–sugammadex may replace succinylcholine for the MG patient who requires rapid-sequence induction.

**Nonrelaxant Techniques.** Because of concerns over the use of muscle relaxants in MG patients, there are many reports of successful use of nonrelaxant techniques. Della Rocca et al.<sup>212</sup> studied 68 consecutive MG patients undergoing transsternal thymectomy randomized to receive propofol/O<sub>2</sub>/N<sub>2</sub>O/fentanyl or sevoflurane/N<sub>2</sub>O/O<sub>2</sub>/fentanyl. All were tracheally extubated in the operating room, and none required intubation for postoperative respiratory depression. Madi-Jebara et al.<sup>213</sup> described the use of sevoflurane as the sole anesthetic combined with intrathecal sufentanil–

morphine for analgesia in an adult patient who underwent transsternal thymectomy. Abe et al.<sup>214</sup> described propofol anesthesia combined with thoracic epidural anesthesia for thymectomy in 11 patients with MG. Chevalley et al.<sup>215</sup> reported use of propofol combined with epidural bupivacaine and sufentanil in 12 MG patients undergoing similar procedures. They commented that the shift away from use of muscle relaxants provided optimal operating condition and improved patient comfort. Lorimar and Hall<sup>216</sup> used a total intravenous anesthetic technique with propofol and remifentanil for transsternal thymectomy in an MG patient. Politis and Tobias<sup>217</sup> describe rapid-sequence intubation in a myasthenic patient with a full stomach using propofol, lidocaine, and remifentanil.

Baraka et al.<sup>218</sup> described a 19-year-old myasthenic patient with a thymoma who received remifentanil and sevoflurane anesthesia for a 2-hour thymectomy. Although the trachea was extubated 10 minutes after discontinuation of remifentanil, the patient was unresponsive to verbal stimuli and remained somnolent for 12 hours. Because the patient had been receiving pyridostigmine for the months prior to surgery, they suggest that the delayed arousal may have been the result of possible inhibition by pyridostigmine of the nonspecific esterases that normally hydrolyze remifentanil. Ingersoll-Weng et al.<sup>219</sup> reported use of a dexmedetomidine infusion/isoflurane technique for transsternal thymectomy in a 52-year-old woman. The patient was stable at the start of surgery but became asystolic on sternal retraction and received open cardiac massage. Resuscitation was successful, the dexmedetomidine infusion was discontinued, and surgery was completed uneventfully. Several factors may have contributed to the asystolic arrest, including a centrally mediated increase in parasympathetic activity resulting from dexmedetomidine in a patient who was also being treated with pyridostigmine, which also increases vagal tone. Thus, pyridostigmine may have interacted with dexmedetomidine in an additive or synergistic manner.

**Other Drug Interactions.** Medications with neuromuscular blocking properties should be used with caution in patients with MG, particularly if relaxants are being used concurrently. Such drugs include antiarrhythmics (quinidine, procainamide, calcium-channel blockers), diuretics (by causing hypokalemia), nitrogen mustards, quinine, and aminoglycoside antibiotics. Dantrolene has been used safely in a patient with MG.

**Recovery from Anesthesia.** Recovery from anesthesia must be carefully monitored in these patients. Extubation of the trachea should be performed when the patients are responsive and able to generate negative inspiratory pressures of greater than  $-20$  cm H<sub>2</sub>O. After extubation of the trachea, patients are carefully observed in the recovery area or the ICU. As soon as possible, patients should resume their usual pyridostigmine regimen. Cases of mild respiratory depression may be treatable with parenteral

anticholinesterase; more severe cases may require reintubation of the trachea and mechanical ventilation of the lungs. In the immediate postoperative period, postthymectomy patients often show a marked improvement in their condition and a decreased need for anticholinesterase therapy.

## **Postoperative Respiratory Failure**

Myasthenic patients are at increased risk for development of postoperative respiratory failure. There have been several attempts to predict before surgery which patients with MG will require prolonged postoperative ventilation of the lungs.<sup>220</sup> For patients who underwent transsternal thymectomy, positive predictors were a duration of MG more than 6 years, history of chronic respiratory disease other than that directly caused by MG, pyridostigmine dosage more than 750 mg/day, and a preoperative vital capacity less than 2.9 L. This predictive system was not found useful when applied in patients with MG undergoing transsternal thymectomy at other centers, and of no value in patients with MG undergoing other types of surgical procedures.<sup>221</sup> In a study of 52 MG patients following thymectomy, Mori et al.<sup>222</sup> concluded that those patients who received more than 250 mg of pyridostigmine were at greater risk for respiratory failure requiring reintubation. A more recent scoring system to predict postoperative myasthenic crisis and need for ventilatory support has been proposed which cites as its chief risk factors advanced staging of the patient's MG (bulbar involvement and rapid progression conferring greater risk), BMI greater than 28, history of prior myasthenic crisis, duration of symptoms more than 2 years, and association with a pulmonary resection.<sup>223</sup> Each patient should therefore be treated on his or her own merits.

A study of patients undergoing transsternal thymectomy suggested that the need for postoperative mechanical ventilation correlated best with preoperative maximum static expiratory pressure. It was concluded that expiratory weakness, by reducing cough efficacy and ability to clear secretions, was the main predictive determinant. Adequate clearance of secretions is essential in these patients and may occasionally necessitate bronchoscopy.

In general, the postoperative morbidity in terms of respiratory failure is lower after transcervical rather than transsternal thymectomy.<sup>224</sup> Techniques described that may be useful in reducing postoperative ventilatory failure include preoperative plasma exchange and high-dose perioperative steroid therapy. If the anticipated duration of the surgical procedure is 1 to 2 hours, preoperative oral anticholinesterase therapy may be of value because the peak effect of the drug coincides with the conclusion of the surgical procedure and attempts at tracheal extubation.

## Postoperative Care

In the immediate postoperative period, pain relief for patients with MG is usually provided by opioid analgesics, such as meperidine, but in reduced doses. The analgesic effect of morphine and other opioid analgesics has been reported to be increased by anticholinesterases, which has led to the recommendation that the dose of opioid analgesics be reduced by one-third in patients receiving anticholinesterase therapy. Combined regional and general anesthesia techniques have also been used to provide good surgical conditions and improved postoperative analgesia in patients with MG undergoing thymectomy. Combined epidural–general anesthesia has been reported to provide excellent intraoperative and postoperative conditions for both surgeon and patient.<sup>225,226</sup>

### *Myasthenic Syndrome (Eaton–Lambert Syndrome)*

The myasthenic syndrome is a very rare immune-mediated disorder of neuromuscular transmission, associated with antibodies to the presynaptic voltage-gated calcium channel. The prevalence is estimated to be about 1/100,000.<sup>227</sup> It is associated with small cell carcinoma of the lung in 50% to 60% of cases. Complaints of weakness may be mistaken for MG, but in Eaton–Lambert syndrome, symptoms do not respond to administration of anticholinesterases or steroids, and activity improves strength. The defect in this condition is prejunctional, is associated with diminished release of acetylcholine from nerve terminals, and improved by agents such as 4-aminopyridine,<sup>228</sup> guanidine, and germinate that increase repetitive firing. Affected patients are particularly sensitive to the effects of all muscle relaxants, which should be used with great caution or avoided entirely.<sup>229</sup> Other therapies have included immunosuppression, immune globulins, and plasmapheresis.<sup>230</sup>

The possibility of Eaton–Lambert syndrome should be considered in all patients with known malignant disease and those patients undergoing diagnostic procedures for suspected carcinoma of the lung. Anesthesia considerations in these patients are essentially the same as in those with MG.<sup>231,232</sup>

## Postoperative Management and Complications

### *Postoperative Pain Control*

After extubation of the trachea, respiratory therapy and pain management become critical components of postoperative care. Adequate **11** postoperative pain control is necessary to ensure a good respiratory

effort.<sup>233</sup> Administration of intravenous opioids has been the standard form of pain management for years. The administration of sufficient opioid to treat pain adequately may cause sedation and respiratory depression. Patient-controlled analgesia (PCA) has been reported to decrease the amount of postoperative pain, drug use, sedation, and pulmonary complications.<sup>234</sup> PCA also eliminates the delays associated with personnel-administered medications and in general is very well accepted by patients.

There are other intravenous medications that can be used for pain management in addition to opioids. Low-dose ketamine infusion at 0.05 mg/kg/hr was reported to be a useful adjunct to epidural analgesia for postthoracotomy pain management.<sup>235</sup> Small doses of ketamine added to morphine for PCA administration have been shown to reduce the amount of morphine administered and improve respiratory parameters.<sup>236</sup> It reduced the incidence of oxygen desaturation below 90% during the first three postoperative nights. Ketamine may provide an anti-inflammatory effect. A meta-analysis indicated a reduction of interleukin 6,<sup>237</sup> and a subsequent prospective study did not corroborate that finding.<sup>238</sup> Ketamine can also be administered via the epidural route to relieve post thoracotomy pain.<sup>239</sup>

Gabapentin has also been successful in reducing pain following thoracic surgery.<sup>240</sup> Gabapentin may also reduce the incidence of postoperative delirium, and one approach could be to administer 900 mg 1 to 2 hours preoperatively.<sup>241</sup> Gabapentin has been reported to be not effective in reducing ipsilateral shoulder pain.<sup>242</sup> The injection of the periphrenic fat pad has been shown to reduce the ipsilateral shoulder pain that may occur following thoracic surgery.<sup>243</sup>

Intercostal nerve blocks can decrease pain and improve postoperative respiratory function. The intercostal blocks can be performed internally or externally before or after surgery using a standard technique. However, the easiest method during thoracic surgery is to have the surgeon perform the blocks under direct vision from inside the thorax while the chest is open. Bupivacaine 0.25% to 0.5%, in doses of 2 to 5 mL, can be placed in the five intercostal spaces around the incision and in intercostal spaces where chest tubes will be placed. This provides 6 to 24 hours of moderate pain relief, but patients still complain of diaphragmatic and shoulder discomfort caused by the chest tubes. Larger volumes of local anesthetics should not be used in the intercostal space because of the high absorption rate and attendant systemic toxicity that can be produced, as well as the possibility of pushing the drug centrally and producing a paravertebral sympathetic or epidural block with central sympatholysis and severe hypotension. The intraoperative placement of catheters in intercostal grooves allows for a continuous postoperative intercostal nerve block. The technique reduces pain and improves pulmonary function. Placement of a catheter in the paravertebral space allows for

blockade of multiple levels of intercostal nerves. This technique has been reported to provide good analgesia, and with fewer side effects than epidural analgesia.<sup>244</sup> Paravertebral block may be as effective as epidural analgesia for pain relief following thoracic surgery, and is a good alternative.<sup>245,246</sup> Another approach to postoperative pain control after thoracic surgery is the use of epidural or subarachnoid opioids (see [Chapter 20](#)). Epidural morphine produces profound analgesia lasting from 16 to 24 hours after thoracotomy and does not cause a sympathetic block or sensory or motor loss. These are significant advantages over systemic opioids or infiltration of local anesthetics. Epidural opioids are most effective at alleviating pain when administered at the thoracic level. Epidural morphine has been shown to decrease pain and improve respiratory function in postthoracotomy patients.

On the basis of a meta-analysis of 100 studies in the National Library of Medicine's PubMed database from 1966 to 2002, Block et al.<sup>247</sup> concluded that epidural analgesia was superior to parenteral medication; this was true regardless of agent used in the epidural catheter or the level of catheter placement. There may be a reduction in both morbidity and mortality with epidural or spinal analgesia.<sup>248</sup> The technique most commonly employed in academic medical centers in the United States is an infusion of bupivacaine together with a narcotic such as fentanyl administered via a thoracic epidural catheter.<sup>249</sup> Data in the pediatric population are limited; in one study of adolescent patients, the use of thoracic epidural analgesia provided better postoperative pain relief following minimally invasive pectus excavatum repair.<sup>250</sup> Acetaminophen may be a useful adjunct to thoracic epidural analgesia for treatment of ipsilateral shoulder pain following thoracotomy.<sup>251</sup> Ketorolac may be given postoperatively, but carries a risk of bleeding if given intraoperatively.

Subarachnoid (intrathecal) morphine, in a dose of 10 to 12  $\mu\text{g}/\text{kg}$ , has been successfully used after thoracic surgery.<sup>252,253</sup> With this technique, the drug acts directly on the spinal cord, and analgesia can be produced with a smaller dose than by the epidural or intravenous routes. When morphine is given intrathecally before the induction of anesthesia, a decrease in the dose of anesthetic drugs required may occur. All patients who have received subarachnoid or epidural opioids must be closely observed for potential side effects, including delayed respiratory depression, urine retention, pruritus, nausea, and vomiting. These effects appear to be dose-related and may be reversed with naloxone. Despite over 30 years of usage, it is still not clear what dosage is optimal for this type of surgery.<sup>254</sup>

Noxious stimuli, including surgical incision, may lead to changes in the central nervous system that exacerbate postoperative pain. The administration of analgesic agents before surgery is termed preemptive analgesia and may prevent these neuroplastic changes, thereby decreasing postoperative pain.

This has more recently been termed preventive analgesia. In an early study of preemptive analgesia, the administration of lumbar epidural fentanyl before thoracotomy incision reduced postoperative pain scores and use of PCA morphine by a small but significant amount, compared with administration of lumbar epidural fentanyl after skin incision.<sup>255</sup> On the basis of a meta-analysis of randomized controlled studies published between 1966 and 2004, Bong et al.<sup>256</sup> concluded that thoracic epidural preemptive analgesia did not provide a statistically significant reduction in postoperative pain, but was associated with a trend toward a reduction in the incidence of such pain. A subsequent study investigating the preemptive analgesic effect of infiltration of the surgical incisions with lidocaine prior to bilateral VAT incisions did help relieve pain for 24 hours, but not thereafter.<sup>257</sup> In that study, since there was a bilateral incision, the infiltration was only done on one side, and each patient served as his or her own control.

Interpleural analgesia is another technique for postoperative pain treatment. The injection of local anesthetic between the pleural layers can block multiple intercostal nerves and/or pain fibers traveling with the thoracic sympathetic chain. The surgeon can place the catheter under direct vision while the chest is open. The chest tubes should not be suctioned for approximately 15 minutes after injection of local anesthetic to avoid loss of the anesthetic into the drainage. The surgeon can also place in the wound a soaker catheter, through which local anesthetics can be administered postoperatively. The On-Q PainBuster (I-Flow Corporation, Lake Forrest, CA) can be used for this purpose, and is an effective adjunct in alleviating pain following thoracic surgery.<sup>258</sup> There may be chronic pain following thoracotomy, and also following VAT, even though the incisions are smaller with this approach.<sup>259,260</sup> In one report, women were more likely than men to suffer from both perioperative pain and chronic pain.<sup>261</sup> If it occurs, it is important to treat this chronic postoperative pain early and aggressively.<sup>262</sup>

There is a high incidence of chronic pain following thoracotomy.<sup>263,264</sup> Approximately one-third of these have a neuropathic component.<sup>265</sup> Chronic post thoracotomy pain has been reported to occur with an incidence of approximately 30% to 50%.<sup>266,267</sup> Successful prevention and management of post thoracotomy chronic pain is hindered by an inadequate understanding of the pathophysiology. Thoracic epidural analgesia may reduce development of this chronic pain syndrome.

Peripheral nerve stimulation may provide relief in some cases.<sup>268</sup> Preventive analgesia has replaced the term preemptive analgesia, and involves treatment from before incision continuously until after wound healing is complete. Although ketamine reduces pain acutely, it does not have a long-term effect, either intravenously or by the epidural route. Although celecoxib has been shown to improve acute postoperative pain following

thoracic surgery as an adjunct to epidural analgesia (Senard), there is no data on an impact on post thoracotomy pain syndrome. Once developed, post-thoracotomy chronic pain is difficult to treat, as it is a form of neuropathic pain.

In recent years, the use of VAT has become more common, and is often the initial approach for thoracic surgery. Although there can be expected to be less pain and respiratory impairment following VAT compared with thoracotomy, it is still important to have a pain management strategy as there can be a significant amount of postoperative pain. Acute postoperative pain may be either myofascial or neuropathic in origin. These can cause neuroplastic changes, which may result in chronic pain. In one study, there was a 47% incidence of chronic pain reported following VAT.<sup>269</sup> The incidence of chronic pain after VAT may be comparable with that following thoracotomy. The pain that occurs may be related to trauma to intercostal nerves by insertion of the surgical trocars or by compression during the surgery. In addition, an incision will be required to extract a lobe in the case of a lobectomy, which may exacerbate pain further.

If there is a relatively high likelihood of the surgeon converting the VAT to a thoracotomy, it may be preferable to place a thoracic epidural. If the preoperative lung function is poor, such that the patient may have difficulty breathing adequately postoperatively or may not tolerate systemic opioids, it also may be more prudent to place an epidural for that situation also. In contrast, for patients with good lung function who are scheduled to undergo a VAT in which a thoracotomy is unlikely, an epidural is probably unnecessary. The use of intercostal or paravertebral block combined with systemic opioids via PCA should be sufficient. In the United Kingdom, that approach has been reported to be more common for VATS lobectomy than the use of epidural analgesia.<sup>270</sup> In that survey, only 46% of patients undergoing VATS had a thoracic epidural placed. In contrast with an epidural, the paravertebral block is unilateral, and does not cause a sympathectomy. The administration of local anesthetic via the chest tubes is another approach which can successfully treat postoperative pain.<sup>271</sup> In a recent update in which the literature was reviewed regarding pain management for VAT, it was concluded that an epidural is not necessary.<sup>272</sup> The use of a single shot, multilevel, paravertebral block has been recommended for VATS in a recent update on the use of paravertebral blocks for thoracic surgery. The placement of a paravertebral catheter for VAT was shown to be effective for postoperative pain management in a recent prospective randomized trial.<sup>273</sup>

## ***Complications Following Thoracic Surgery***

### **Atelectasis**

Patients who require thoracotomy often have pre-existing pulmonary disease that, when combined with the operative procedure, is likely to result in significant pulmonary dysfunction and possibly pneumonia. There is a reduction in respiratory complications with epidural analgesia including atelectasis and pneumonia.<sup>274</sup> Atelectasis, the most significant cause of postoperative morbidity, has been reported to occur in up to 100% of patients undergoing thoracotomy for pulmonary resection. It occurs more commonly in the basal lobes than in the middle or upper lung regions. It may be secondary to reduction of normal respiratory effort due to splinting from pain, obesity, intrathoracic blood and fluid accumulation, and decreased compliance, all of which lead to rapid, shallow, constant  $V_T$ . Such a respiratory pattern produces small airway closure and obstruction with inspissated secretions, resulting ultimately in alveolar air resorption and terminal airway collapse. A poor cough and limited clearance of secretions add to the problem. Other sources of atelectasis include mucus plugging, which can obstruct a lobe or even an entire lung, and incomplete re-expansion of the remaining lung tissue after one-lung anesthesia.

The diagnosis of atelectasis can be made by clinical findings, chest radiography, or arterial blood gas analysis. This problem is best resolved by increasing resting lung volume or FRC. The latter can be increased by an increase in transpulmonary pressure (difference between airway pressure and interpleural pressure) or in lung compliance.

The tracheas of many patients can be extubated shortly after thoracic surgical procedures. These patients should be observed in the operating room for at least 5 minutes following extubation, and many will require a high  $FIO_2$  by face mask. Some patients with COPD undergoing extensive thoracic surgical procedures require postoperative ventilation to avoid atelectasis and other pulmonary complications. Mechanical ventilation increases airway pressure and, to a lesser extent, interpleural pressure; therefore, transpulmonary pressure increases.

The use of incentive spirometry and CPAP has been shown to reduce postoperative complications. Additional modalities that may be helpful in preventing atelectasis include bronchodilator treatment, coughing and clearance of secretions, chest physiotherapy, mobilizing the patient, and providing adequate analgesia. Atelectasis caused by collapse of lung tissue distal to a mucus plug can be treated by positioning the patient in the lateral decubitus position with the fully expanded lung in the dependent position. This improves  $V/Q$  matching and facilitates clearance of mucus from the nondependent obstructed lung. However, the patient should not be placed with the operative side in the dependent position after a pneumonectomy because of the risk of cardiac herniation.

The other major complications after thoracic surgery can be grouped into

cardiovascular, pulmonary, and related problems.

## **Cardiovascular Complications**

Cardiovascular complications are often the most difficult to manage in patients with associated respiratory insufficiency. The low cardiac output syndrome and postoperative cardiac dysrhythmias may be life-threatening. Invasive hemodynamic monitoring may be needed to assist in diagnosis and fluid management therapy. Other diagnostic modalities, such as echocardiography, may be required to rule out the presence of pericardial effusions or tamponade after opening the pericardium during certain types of thoracic surgical procedures. The low cardiac output syndrome must be differentiated from hypovolemia resulting from intrathoracic hemorrhage, tamponade, pulmonary emboli, or the effects of mechanical ventilation with PEEP. Postoperative fluid administration can lead to pulmonary edema resulting from the resection of lung tissue and the concomitant reduction of the pulmonary vascular bed. Re-expansion of a chronically collapsed lung may in some cases lead to re-expansion pulmonary edema (RPE); rapid re-expansion and drainage of large amounts of pleural fluid increase the risk for RPE.<sup>275</sup> A postoperative pulmonary embolism can originate from the remaining pulmonary artery stump. Therapeutic interventions for postoperative myocardial dysfunction include inotropic drugs, vasodilators, and combinations of these drugs, as needed, to improve ventricular function. The goal is to shift the Starling function curve up and to the left by reducing preload of either the left or right side of the heart and increasing cardiac output. Vasodilators are very effective at decreasing right ventricular afterload and improving right ventricular function because this side of the heart is especially afterload-dependent. Combinations of inotropes and vasodilators, such as dopamine and nitroglycerin, or combined drugs, such as milrinone, can be especially useful in the treatment of right-sided heart failure.

Postoperative cardiac dysrhythmias are common after thoracic surgery. Patients following pulmonary resection have postoperative supraventricular tachycardias with a frequency and severity proportional to both their age and the magnitude of the surgical procedure. Many factors contribute to these dysrhythmias, including underlying cardiac disease, degree of surgical trauma, intraoperative cardiac manipulation, stimulation of the sympathetic nervous system by pain, a reduced pulmonary vascular bed, effects of anesthetics and cardioactive drugs, and metabolic abnormalities.

In a series of 300 thoracotomies for lung resection, atrial fibrillation occurred in 20% of patients with malignant disease but in only 3% with benign disease.<sup>276</sup> A similar incidence of dysrhythmias is observed after

pneumonectomies. Multifocal atrial tachycardia often occurs in patients with COPD and concomitant right-sided cardiac dysfunction. The right side of the heart may be further strained by the reduction in the size of the pulmonary vasculature from the lung resection, especially after right pneumonectomy. Historically, the primary antidysrhythmic drug was used to treat atrial tachycardias in thoracic surgical patients. The prophylactic use of digitalis in thoracic surgical patients is controversial, particularly in patients with signs of congestive heart failure. Arguments against its use include the potential toxic effects of the drug and the difficulty in assessing adequacy of digitalization in the absence of heart failure. A prospective, placebo-controlled, randomized study demonstrated no advantage to prophylactic digitalization of patients undergoing thoracic surgery.<sup>277</sup> Part of the argument for its use is the drug's efficacy in reducing the incidence of potentially fatal complications in older patients. In some studies, it has been reported to reduce the incidence of perioperative dysrhythmias. If digitalis therapy is to be instituted, normokalemia should be ensured to reduce the likelihood of digitalis toxicity.

More recently, newer drugs have replaced digitalis for dysrhythmia control. Supraventricular tachycardias can also be treated with other agents such as  $\beta$ -blockers or calcium-channel-blocking drugs, after ruling out underlying reversible physiologic abnormalities, such as hypoxia. Verapamil has been the standard treatment for these problems until the introduction of the ultrashort-acting  $\beta$ -blocker, esmolol. Esmolol has been shown to be equally effective in controlling the ventricular rate in patients with postoperative atrial fibrillation or flutter and in increasing the conversion rate to regular sinus rhythm from 8% to 34%. Owing to its short duration of action ( $\beta$  elimination half-life of 9 minutes) and  $\beta_1$ -cardioselectivity, it is the drug of choice in the postoperative period to control these dysrhythmias. Esmolol, in an intravenous loading dose of 500  $\mu\text{g}/\text{kg}$  given over 1 minute followed by an infusion of 50 to 200  $\mu\text{g}/\text{kg}/\text{min}$ , has been shown to be effective in the control of supraventricular tachycardias. Amiodarone has been reported to be effective in restoring and maintaining sinus rhythm.<sup>278</sup>

## **Bleeding and Respiratory Complications**

Hemorrhage and pneumothorax are always major concerns after intrathoracic surgery. Although there is less pain following VAT compared with thoracotomy, the risk of bleeding and intraoperative complications may be higher.<sup>279</sup>

Because of these problems, interpleural thoracostomy tubes with an underwater seal system are routinely used after thoracic surgery. Slippage of a suture on any major vessel or airway in the chest can lead to the slow or rapid development of hypovolemic shock or a tension pneumothorax.

Drainage of more than 200 mL/hr of blood is an indication for surgical re-exploration for hemorrhage. Management of the pleural drainage system is fraught with confusion. The chest bottles must be kept below the level of the chest, and the tubes should not be clamped during patient transport. These tubes can be lifesaving, but errors in technique can lead to serious complications. The creation of a pneumothorax in the nonoperative chest by central venous catheter placement is very hazardous because this lung is essential both intraoperatively during one-lung anesthesia and postoperatively after contralateral lung resection. Dehiscence of the bronchial stump may lead to the formation of a BPF, which carries a mortality rate of 20%. Surgical treatment may be needed, in which case ventilation of the patient's lungs may be difficult because of loss of  $V_T$  through the fistula. A double-lumen endobronchial tube positioned in the contralateral main stem bronchus or the use of HFJV may be required for safe management. HFJV allows ventilation with lowered peak airway pressures. However, there have been reports in which ventilation by HFJV was difficult. If a double-lumen endobronchial tube is placed, the lung with the fistula can be ventilated independently with either CPAP or HFJV.

## **Neurologic Complications**

Central and peripheral neurologic injuries can occur during intrathoracic procedures. Such injuries often result in serious and disabling loss of function. Peripheral nerves can also be injured, either in the chest or in other parts of the body, by pressure or stretching. The nerve injury may be apparent immediately after surgery or may not become obvious until several days later. These patients often complain of a variety of unpleasant sensations, including paresthesias, cold, pain, or anesthesia in the area supplied by the affected nerves. The brachial plexus is especially vulnerable to trauma during thoracic surgery, owing to its long superficial course in the axilla between two points of fixation, the vertebrae above, and the axillary fascia below. Stretching may be the primary cause of damage to the brachial plexus, with compression playing only a secondary role. Branches of the brachial plexus may also be injured lower in the arm by compression against objects such as an ether screen or other parts of the operating table. Intrathoracic nerves can be directly injured during a surgical procedure by being transected, crushed, stretched, or cauterized. The recurrent laryngeal nerve can become involved in lymph node tissue and injured at the time of a node biopsy, especially when the biopsy is performed through a mediastinoscope. This nerve can also be injured during tracheostomy or radical pulmonary dissections. The phrenic nerve may be injured during pericardiectomy, radical pulmonary hilar dissections, division of the diaphragm during esophageal surgery, or

dissection of mediastinal tumors.

Prevention is the treatment of choice for these intraoperative nerve injuries. Analgesics may be necessary to control postoperative pain in the distribution of the nerve injury and to aid in maintaining joint mobility during the healing phase.

## **Anesthesia for Children with Congenital Heart Disease**

- Preoperative Evaluation
- Premedication
- Monitoring
- Anesthetic and Intraoperative Management
- Tracheal Extubation and Postoperative Ventilation
- Hybrid Procedures in Pediatric Cardiac Surgery

## **KEY POINTS**

- 1 When treating myocardial ischemia, decreasing O<sub>2</sub> demand is more important than modifying O<sub>2</sub> supply.
- 2 The critical factors that modify coronary blood flow are the perfusion pressure and vascular tone of the coronary circulation, the time available for perfusion (determined mainly by heart rate), the severity of intraluminal obstructions, and the presence of (any) collateral circulation.
- 3 Slow rate, small chamber size, and adequate perfusion pressure are the goals in patients with coronary artery disease.
- 4 The pulmonary artery catheter is not a reliable monitor for detection of myocardial ischemia.
- 5 There is no “ideal” anesthetic in cardiac surgery.
- 6 In aortic stenosis, a preload-dependent, hypertrophic ventricle requires adequate diastolic time and perfusion pressure.
- 7 In chronic aortic insufficiency, a dilated ventricle requires increased preload and decreased afterload.
- 8 In mitral stenosis, the left ventricle is “lazy” and “underused” and requires a slow heart rate to fill.
- 9 In mitral regurgitation, a preload-dependent and dilated left ventricle benefits from afterload reduction and fast heart rate.
- 10 The most critical factor governing the selection and dose of the anesthetics and adjuvants is the degree of ventricular dysfunction.

- 11 Fast-track anesthetic techniques depend on higher concentration of inspired volatile agents, use of vasoactive medications ( $\beta$ -blockers), and smaller doses of benzodiazepines and opioids.
- 12 The combination of systolic systemic and diastolic pulmonary pressures characterizes the performance of the left ventricle, and the combination of systolic pulmonary and central venous pressures characterizes the performance of the right ventricle.

## Introduction

Anesthetizing patients who undergo cardiac surgery is exciting, intellectually challenging, and emotionally rewarding. The cardiac anesthesiologist should have a thorough understanding of normal and altered cardiac physiology, cardiovascular and anesthetic medications pharmacology, and be familiar with the physiologic alterations associated with cardiopulmonary bypass (CPB) and the surgical procedures. This chapter presents a brief overview of the critical physiologic and technical considerations during cardiac surgical procedures.

## Coronary Artery Disease

The prevention or treatment of myocardial ischemia during coronary artery bypass graft (CABG) surgery decreases the incidence of perioperative myocardial infarction. The hemodynamic management should avoid factors that increase myocardial oxygen demand ( $MV \cdot O_2$ ), particularly during the vulnerable pre-CPB period, while optimizing oxygen delivery to the myocardium, since it is well recognized that most ischemic events occur with minimal or no change in  $MV \cdot O_2$ .<sup>1,2</sup> The determinants of myocardial oxygen supply and demand are shown in [Figure 39-1](#) and are also discussed in [Chapter 12](#), Cardiac Anatomy and Physiology.

### *Myocardial Oxygen Demand*

The principal determinants of  $MV \cdot O_2$  are wall tension and contractility.<sup>3</sup> According to Laplace law, wall tension is directly proportional to intracavitary pressure and radius and inversely proportional to wall thickness. Therefore,  $MV \cdot O_2$  can be reduced by interventions that decrease intraventricular pressure and prevent or promptly treat ventricular distention.

### *Myocardial Oxygen Supply*

- 1** Increases in myocardial oxygen requirements can be met only by increasing the coronary blood flow. Arterial blood oxygen content and

myocardial oxygen extraction are infrequent reasons for intraoperative myocardial ischemia because oxygenation and blood volume are usually well controlled during anesthesia. In addition, since the coronary sinus blood is desaturated ( $PO_2$  in the range of 15 to 20 mmHg), further oxygen extraction is inadequate to meet a significantly increased  $MV \cdot O_2$ . Therefore, the principal mechanism for matching oxygen supply to alterations in  $MV \cdot O_2$  is exquisite regulation and control of coronary blood flow.

### Coronary Blood Flow

**2** The critical factors that modify coronary blood flow are the perfusion pressure and vascular tone of the coronary circulation, the time available for perfusion (determined mainly by heart rate), the severity of intraluminal obstructions, and the presence of (any) collateral circulation. The area most vulnerable to ischemia is the subendocardium of the left ventricle (LV), because it is directly exposed to the intracavitary pressure and because it has the greatest metabolic requirements due to its greater systolic shortening than other areas of the myocardium.<sup>4</sup>

**Figure 39-1** Determinants of myocardial oxygen balance. P, intracavitary pressure; R, ventricular radius; h, wall thickness; AoDP, diastolic arterial pressure; LVEDP, left ventricular end-diastolic pressure; Hb, hemoglobin;  $SatO_2$ , arterial oxygen saturation.

**Figure 39-2** The pressure relationships between the aorta (1) and the left ventricle (2) determine coronary perfusion pressure. In coronary artery disease, myocardial perfusion may be compromised by decreased pressure distal to a significant stenosis (1a) (not quantifiable clinically) and/or by an increase in left ventricular end-diastolic

pressure (2a). (Adapted from Gorlin R. *Coronary Artery Disease*. Philadelphia, PA: WB Saunders; 1976:75, with permission.)

Perfusion of the LV subendocardium takes place almost entirely during diastole, whereas the right ventricular subendocardium is perfused in diastole and systole, assuming pulmonary hypertension is not present. This temporal disparity is explained by the different intraventricular pressures developing during systole.

The LV coronary perfusion pressure is often defined as the gradient between aortic diastolic (or mean) pressure and LV diastolic pressure (LVDP; usually approximated by the pulmonary artery occlusion pressure). In the presence of intraluminal obstruction or increased myocardial vascular tone, this pressure gradient is reduced (Fig. 39-2). A low LVDP is ideal for improving perfusion (higher pressure gradient) and reducing  $MV \cdot O_2$  (decreased LV volume and wall tension). On the other hand, increasing perfusion pressure by raising the aortic pressure will increase  $MV \cdot O_2$ . However, this is not as important, when one considers that tachycardia is the most important cause of intraoperative and perioperative ischemia.

Alterations in the tone of the small intramyocardial arterioles regulate diastolic vascular resistance, allowing the matching of oxygen supply with  $MV \cdot O_2$  over a wide range of perfusion pressures.<sup>5</sup> The difference between auto regulated (basal) flow, and blood flow available under conditions of maximal vasodilation is termed *coronary vascular reserve* and is normally three to five times higher than basal flow. As epicardial coronary stenosis becomes more pronounced, progressive vasodilation of these resistance vessels allows preservation of basal flow, but at the cost of reduced reserve. Once perfusion pressure decreases to below 40 mmHg, autoregulation of subendocardial coronary flow is lost. Whenever  $MV \cdot O_2$  increases above available reserve, signs, symptoms, and metabolic evidence of ischemia develop.

Reversible ischemia may be caused by an inadequate supply of oxygen to the myocardium and/or the inability to respond to increased  $MV \cdot O_2$ . Irreversible injury to the myocardium can occur if coronary blood flow is occluded for longer than 20 minutes, leading to myocardial cell death and necrosis. Supply-induced ischemia results from a transient coronary occlusion from vasospasm or temporary thrombus that leads to transmural ischemia and decreased LV compliance. Demand-induced ischemia results from the inability to increase coronary blood flow and oxygen delivery to the myocardium in response to increases in  $MV \cdot O_2$ . In either case, the result is subendocardial ischemia and decreased LV compliance.<sup>6</sup>

In reversible ischemia, the myocardium remains viable and can be differentiated into stunned or hibernating myocardium. Stunning refers to a state of abnormal function that occurs after an acute, discrete episode of

ischemia. No cell death occurs in stunning, but it may take several days or longer for the myocardium to recover, even though adequate blood flow has been restored. Hibernating myocardium refers to a chronic state of reduced coronary blood flow and abnormal function usually secondary to a fixed stenosis. In response to decreased oxygen supply, hibernating myocardial cells downregulate their metabolism and oxygen demand to maintain viability.<sup>7</sup>

Dead myocardium and viable myocardium (stunned or hibernating) may both appear hypokinetic on echocardiography making the two difficult to distinguish. Studies such as single photon emission CT (SPECT) or low-dose dobutamine echocardiography can help to differentiate viable myocardium that may benefit from revascularization. The current data for revascularization in patients with CAD and LV systolic dysfunction remains inconclusive with the most recent guidelines for CABG surgery published in 2011 recommending that the choice of revascularization in these patients should be based on clinical variables such as coronary anatomy, presence of diabetes mellitus or chronic kidney disease, magnitude of LV systolic dysfunction, patient preferences, clinical judgment, and consultation between the interventional cardiologist and the cardiac surgeon.<sup>8</sup>

### *Hemodynamic Goals*

The primary goal of any successful cardiac anesthetic is prevention of myocardial ischemia and prompt identification and treatment of new ischemic episodes. The anesthetic interventions are geared at reducing and controlling the factors (Table 39-1) that increase  $MV \cdot O_2$  (heart rate, contractility, and wall tension). The first intervention is to optimize coronary blood flow, that is, maintain coronary perfusion pressure, while keeping in mind that the peripheral arterial systolic pressure is different (usually higher) than the aortic root pressure, and to increase diastolic time. Thus, the cardiac goals for patients with coronary artery disease are slow (heart rate), small (ventricular size), and well perfused (adequate blood pressure). Preoperative medications that may benefit coronary patients include statins<sup>9</sup> and angiotensin-converting enzyme inhibitors (to stabilize the atherosclerotic plaque) as well as  $\beta$ -blockers (to control heart rate).<sup>10</sup> Volatile anesthetics offer cardioprotection when applied prior to or even after the ischemic insult. A reduction in mortality and morbidity has been shown in patients undergoing CABG and aortic valve (AV) surgery. However, it is very difficult to associate these beneficial effects to pre- or postconditioning mechanisms.<sup>11</sup>

**Table 39-1** Coronary Artery Disease: Hemodynamic Goals

Preload	↓	A smaller heart size (TEE dimensions) decreases wall tension and PADP (LVEDP) and increases perfusion pressure gradient
Afterload	Maintain	Hypertension is better than hypotension
Contractility	↓	If LV function is normal
Rate	↓	
Rhythm	Sinus	Correct arrhythmias
MVO <sub>2</sub>		Monitor for and treat "supply"-related disturbances
Post-CPB		No need for increased PADP (LVEDP)

↑, increase; ↓, decrease; PADP, pulmonary artery diastolic pressure; LVEDP, left ventricular end-diastolic pressure; MVO<sub>2</sub>, myocardial oxygen consumption; CPB, cardiopulmonary bypass; TEE, transesophageal echocardiography.

### Monitoring for Ischemia

The continuous analysis and display of the ST segment in multiple leads (most commonly leads II and V<sub>4</sub> or V<sub>5</sub>) is considered standard and recommended by the 2011 AHA/ACCF practice guidelines.<sup>8</sup> Patients likely to develop right ventricular ischemia or those with disease of the right coronary artery might benefit from monitoring of leads V<sub>4R</sub> or V<sub>5R</sub>.

Favorable conditions for  $MV \cdot O_2$  are those of lower heart rate and higher blood pressure rather than tachycardia and hypotension. Neither the ratio of mean arterial pressure over heart rate nor the diastolic to systolic pressure–time index is any more predictive or reliable than the product of heart rate and pressure (RPP),<sup>12</sup> which was once, but no longer, considered a reliable correlate of  $MV \cdot O_2$ .

Certain changes of the invasively monitored hemodynamic waveforms with a pulmonary artery catheter (PAC) are suggestive of adverse hemodynamics. A sudden elevation in mean pulmonary artery occlusion pressure indicates LV dysfunction, which may be differentiated further into (i) primarily systolic dysfunction if there is an increase in the height of *v* wave indicating left atrial pressure hypertension that is associated with ischemia-induced papillary muscle dysfunction and/or mitral regurgitation (MR), or (ii) primarily diastolic dysfunction if there is a large *a* wave indicating decreased LV compliance. PAC-based monitoring of pressures, saturation of mixed venous blood in oxygen, and thermodilution cardiac output are common perioperative practices in cardiac surgery centers.<sup>13,14</sup> The 2011 AHA/ACCF CABG practice guidelines recommend the insertion of a PAC in a hemodynamically compromised patient, while recognizing that center-specific

practices vary.<sup>8</sup> The PAC may be of little value as a monitor of myocardial ischemia<sup>15</sup> or indicate abnormal regional myocardial wall function,<sup>16</sup> whereas high-risk cardiac surgical patients may be safely managed without routine use of a PAC.<sup>17</sup> Compared with transesophageal echocardiography (TEE), PAC predicted normal left ventricular function well, but performed poorly in judging preload and ventricular dysfunction in the management of critically ill patients in the intensive care unit (ICU).<sup>18</sup> Other studies showed no benefit from PACs in high-risk surgical patients,<sup>19,20</sup> but these studies may not reflect the current era of perioperative management of such patients. It is difficult to determine the value of PAC in diagnosis and treatment when the physician's ability for correct interpretation of PAC information is still in doubt.<sup>21</sup> The most recent American Society of Anesthesiologists Practice Guidelines concluded that the evidence regarding the benefit that cardiac surgery patients receive from PAC is conflicting.<sup>22</sup>

Since its introduction in the 1980s, TEE has become an invaluable diagnostic and monitoring tool during cardiac surgery. TEE permits assessment of ventricular volume, global and regional function, estimation and quantitation of valvular pathology, measurement of valve gradients and calculation of filling pressures, visualization of the thoracic aorta, and detection of intracardiac air. The recent introduction of real-time three-dimensional TEE introduced a real revolution in perioperative imaging. Practice guidelines for perioperative TEE have been recently published by the ASA.<sup>23</sup> Experienced cardiac anesthesiologists who are supported by continuous quality programs perform comprehensive TEE studies<sup>24</sup> and interpret TEE examinations at a level comparable with physicians whose primary practice is echocardiography.<sup>25</sup>

The American Society of Echocardiography/Society of Cardiovascular Anesthesiologists task force for intraoperative echocardiography has published guidelines for performing a comprehensive intraoperative echocardiographic examination.<sup>26</sup> These recommendations describe a series of standard tomographic views of the heart and great vessels that should be included in a complete intraoperative echocardiographic examination. With experience, a thorough examination can be performed in less than 10 minutes.

### *Selection of Anesthetic*

**5** There is no one “ideal” anesthetic for patients with coronary artery disease. The choice of anesthetic should be based on known hemodynamic, pharmacologic, and pharmacokinetic effects of each drug as they apply to the particular patient, the experience of the anesthesiologist, and the relative cost–benefit of each agent, and should depend primarily on the extent of pre-existing myocardial dysfunction. If drugs are titrated to the desired effect,

cardiovascular changes are minimized in healthy, as well as in patients with severe myocardial depression to facilitate a safe anesthetic. Most patients with mild or even moderate dysfunction may benefit from some degree of myocardial depression, which leads to decreased oxygen demand, and may alleviate or at least reduce episodes of ischemia.

Early extubation is common practice and is achieved by multiple approaches.<sup>27,28</sup> Volatile anesthetics with low-dose narcotics or total intravenous anesthesia with short-acting drugs (e.g., midazolam, alfentanil, remifentanil, propofol) have been used to achieve early extubation. The increased use of benzodiazepines and volatile agents has been associated with low incidence of awareness.<sup>29</sup> Intraoperative clinical variables, such as inotropic requirements or transfusion for bleeding, should be considered in the timing of postoperative extubation after fast-track cardiac surgery.<sup>30</sup> In general, the use of low-dose opioid based general anesthesia and time-directed protocols for fast-track interventions have similar risks of mortality and major postoperative complications to conventional (not fast-track) care, and appear to be safe in patients considered to be at low to moderate risk. However, despite a reduced time to extubation and shortened length of stay in the ICU, fast-track extubation protocols have not been shown to reduce the hospital length of stay.<sup>31</sup>

## **Opioids**

The primary advantages of opioids are lack of myocardial depression, maintenance of a stable hemodynamic state, and reduction of heart rate. The current practice is to supplement the opioid with benzodiazepines and volatile agents. The planned time of extubation is now one of the major factors determining the selection and dosage of opioid. Shorter-acting opioids (sufentanil and remifentanil) produce equally rapid extubation, similar ICU stay, and similar costs to fentanyl. Thus, any of these opioids can be used for fast-track cardiac surgery.<sup>32</sup> The beneficial cardioprotective and anti-inflammatory effects of morphine have been reconsidered recently,<sup>33,34</sup> bringing back into the foray the opioid that reinvigorated the practice of cardiac anesthesia.<sup>35</sup>

## **Inhalation Anesthetics**

The desirable features of volatile anesthetics include dose-dependent hemodynamic changes, easy reversibility, titratable myocardial depression, amnesia, and suppression of sympathetic responses to surgical stress and CPB. Volatile anesthetics protect the myocardium from ischemia and reperfusion injury and reduce myocardial infarct size.<sup>36</sup> This beneficial effect has been

shown when volatile anesthetics are administered before a period of prolonged ischemia (“anesthetic preconditioning”) as well as during reperfusion (“anesthetic postconditioning”).<sup>37</sup> However, it is difficult to ascertain whether these laboratory-proven benefits have contributed to improved myocardial protection in clinical practice.<sup>38</sup> An anesthetic based primarily on volatile agents may cause systemic hypotension (whether induced by decreased contractility or vasodilation), which may compromise the oxygen supply and lack of postoperative analgesia. Instead, balanced techniques based on combinations of opioids and any of the volatile anesthetics are advantageous with minimal untoward effects.

Isoflurane is a coronary vasodilator, as are the other volatile anesthetics (although to a lesser degree). This dose-related effect is clinically insignificant in doses less than 1 MAC. Clinical studies using isoflurane to clinical rather than pharmacologic end points have not shown increased episodes of ischemia or a worsened outcome.<sup>39</sup> Desflurane and sevoflurane have the fastest recovery of all volatile anesthetics. Desflurane has a rapid uptake and distribution, allowing it to be useful in cases in which hemodynamic changes mandate rapid changes in anesthetic depth. It has a cardiac profile similar to that of isoflurane. When studying sympathetic nervous system activity, Helman et al.<sup>40</sup> found an increase in sympathetic activity and myocardial ischemia in patients anesthetized with desflurane as the sole anesthetic agent for coronary artery bypass surgery compared with patients anesthetized with sufentanil. Compared with isoflurane, in a technique combining fentanyl with the inhalational anesthetic, sevoflurane had an acceptable cardiovascular profile prior to CPB and similar outcome data.<sup>41</sup>

### *Intravenous Sedative Hypnotics*

An alternative adjuvant anesthetic to a low-dose opioid technique is a titratable intravenous infusion of a short-acting sedative, such as midazolam,<sup>42</sup> propofol, or dexmedetomidine.<sup>43</sup> These can be continued postoperatively in the ICU and afford a predictable and fairly rapid awakening after discontinuation.<sup>44</sup> When compared with volatile anesthetics, propofol was associated with less favorable cardiac function, higher need for inotropic support, and elevated plasma troponins after cardiac surgery in elderly patients.<sup>45,46</sup>

### *Treatment of Ischemia*

The use of anesthetics or vasoactive drugs is aimed at decreasing heart size, decreasing heart rate, and improving myocardial perfusion pressure. The principal vasoactive drugs are nitrates,  $\beta$ -blockers, peripheral

vasoconstrictors, and calcium entry blockers. Clinical scenarios for their use are given in [Table 39-2](#). Volatile anesthetics can also be used to control blood pressure and reduce contractility.

## Nitrates

Nitroglycerin (TNG) is the drug of choice for the treatment of acute myocardial ischemia. Its action is via systemic venodilation that decreases LV preload, wall tension,  $MV \cdot O_2$ , and coronary arterial dilation, which is operative in both stenosed coronaries and collateral beds.<sup>47</sup> There is no evidence for the prophylactic use of TNG for prevention of either intraoperative ischemic episodes or postoperative cardiac complications.<sup>48</sup> At higher doses, TNG dilates systemic arteries and may cause systemic hypotension, which is counterproductive for treatment of myocardial ischemia, as is compensatory tachycardia that may increase  $MV \cdot O_2$ . The recommended TNG dose is 0.5 to 3  $\mu\text{g}/\text{kg}/\text{min}$  and is reduced in the presence of hepatic and/or renal disease. TNG may cause methemoglobinemia especially in patients with methemoglobin reductase deficiency; this complication is more likely when large doses are administered over a prolonged time.<sup>49</sup>

**Table 39-2** Treatment of Intraoperative Ischemia

Clinical Manifestation	Suggested Intervention
<b>Increased Demand</b>	
↑ Heart rate	Treat usual reasons including inadequate anesthesia, administer $\beta$ -blocker
↑ Blood pressure	↑ Anesthetic depth
↑ PCWP	Nitroglycerin
<b>Decreased Supply</b>	
↓ Heart rate	Atropine, pacing
↓ Blood pressure	↓ Anesthetic depth, administer vasoconstrictor
↑ PCWP	Nitroglycerin, inotrope
<b>No Changes</b>	
	Nitroglycerin, calcium channel blockers, consider heparin

↑, increase(d); ↓, decrease(d); PCWP, pulmonary capillary wedge pressure.

## Sodium Nitroprusside

Sodium nitroprusside (SNP) decreases peripheral vascular resistance via its metabolic or spontaneous reduction to nitric oxide. Similar to TNG, SNP improves ventricular compliance in the ischemic myocardium. The recommended SNP dose is 0.5 to 3  $\mu\text{g}/\text{kg}/\text{min}$  and should be reduced in the

presence of hepatic and/or renal disease. Adverse effects include cyanide and thiocyanate toxicity, rebound hypertension, intracranial hypertension, blood coagulation abnormalities, increased pulmonary shunting, and hypothyroidism. In vitro findings suggest that cardiac surgical patients may be at increased risk of cyanide toxicity in response to the perioperative administration of SNP.<sup>50</sup> Cyanide is a metabolite of SNP; toxic blood levels ( $> 100 \mu\text{g/dL}$ ) occur when more than 1.0 mg/kg SNP is administered within 2 hours or when more than 0.5 mg/kg/hr is administered within 24 hours. The presenting signs of cyanide toxicity include the triad of elevated mixed venous  $\text{O}_2$  ( $\text{SVO}_2$ ), increasing requirements for SNP (tachyphylaxis), and metabolic acidosis.<sup>51</sup> In addition, the patient may appear flushed. Greater risk of cyanide toxicity exists in patients who are nutritionally deficient in cobalamine (vitamin  $\text{B}_{12}$  compounds) or in dietary substances containing sulfur. Measurement of blood cyanide and pH will enable detection of abnormalities in high-risk patients for whom larger than recommended amounts of SNP have been used (8 to 10  $\mu\text{g/kg/min}$ ). Treatment should consist of discontinuing infusion, administering 100%  $\text{O}_2$ , administering amyl nitrate (inhaler) or intravenous sodium nitrite and intravenous thiosulfate, except in those patients with abnormal renal function, for whom hydroxocobalamin is recommended. Circulating levels of thiocyanate increase when renal function is compromised, and central nervous system abnormalities result when thiocyanate levels reach 5 to 10  $\mu\text{g/dL}$ . Lowering the SNP dose requirement or, better, replacing SNP with nicardipine, metoprolol, or esmolol reduces or eliminates the consequent accumulation of cyanide. SNP deteriorates in the presence of light and the solution container should be wrapped in nontransparent material. Other drugs should not be infused in the same solution as SNP.

## **Vasoconstrictors**

Vasoconstrictors (phenylephrine, norepinephrine, vasopressin) are useful adjuncts in the prevention and treatment of ischemia because they increase systemic blood pressure, thereby improving coronary perfusion pressure, albeit at the expense of increasing afterload and perhaps  $\text{MV} \cdot \text{O}_2$ . In addition, concomitant venoconstriction increases venous return and LV preload. TNG is sometimes added to counteract any increase in preload. In most situations, the increase in coronary perfusion pressure more than offsets any increase in wall tension. Peripheral vasoconstriction is needed during episodes of systemic hypotension, especially those caused by reduced surgical stimulation or drug-induced vasodilation. No one vasoconstrictor is superior to all others. Occasionally, a combination of vasoconstrictors (e.g., norepinephrine and vasopressin) may be needed to achieve the desired blood pressure.<sup>52</sup>

## **$\beta$ -Blockers**

$\beta$ -Adrenergic blockade improves myocardial oxygen balance by decreasing the chronotropic and inotropic state. Indications for  $\beta$ -blockers include treatment of sinus tachycardia not caused by light anesthesia or hypovolemia, prophylaxis of, and slowing the ventricular response to, supraventricular dysrhythmias, hyperdynamic states, and control of ventricular dysrhythmias.<sup>53,54</sup> The use of  $\beta$ -blockers should aim at reducing the heart rate and increasing the diastolic filling time without, at the same time, decreasing the perfusion pressure and cardiac output. These therapy targets are even more important, since the POISE study revealed that death and stroke were side effects of  $\beta$ -blockers.<sup>55,56</sup> Nowadays intravenous preparations include, metoprolol, labetalol, esmolol and rarely propranolol. Propranolol is a nonselective  $\beta$ -blocker with an elimination half-life of 4 to 6 hours. Metoprolol is similar to propranolol but has the purported advantage of  $\beta_1$ -selectivity and is less likely to trigger bronchospasm in patients with reactive airway disease. Labetalol combines  $\beta$ -blocking properties with those of  $\alpha$ -blockade and is useful in treating hyperdynamic and hypertensive situations. Esmolol is a short-acting  $\beta_1$ -blocker that is cardioselective, with a half-life of only 9.5 minutes. It is particularly useful in treating transient increases in heart rate owing to episodic sympathetic stimulation.

## **Calcium Channel Blockers**

Calcium channel blockers depress contractility, reduce coronary and systemic vascular tone, decrease sinoatrial node firing rate, and impede atrioventricular conduction<sup>57,58</sup> at a remarkably variable degree. The negative inotropic effect is greatest with verapamil and less with nifedipine, diltiazem, and nicardipine (in decreasing order). Verapamil is particularly useful in the treatment of supraventricular tachycardia for slowing the ventricular response in atrial fibrillation and/or flutter, but its myocardial depressant effects limit its usefulness. In patients with reduced myocardial function, intravenous diltiazem is preferred. Calcium channel blockers have been found to have cardioprotective effects during reperfusion. Nicardipine in particular has coronary antispasmodic and vasodilatory effects more than systemic arterial vasodilatory effects.<sup>59</sup>

Nifedipine, and nicardipine are prominent systemic arterial dilators and are used in the treatment of postoperative hypertension in cardiac surgical patients.<sup>60</sup> The newer agent clevidipine was a better antihypertensive agent than SNP or TNG and was equivalent to nicardipine.<sup>61</sup> Magnesium has coronary arterial dilating properties, reduces the size of myocardial infarction in the setting of acute ischemia, and decreases mortality associated with infarction.<sup>62</sup> In addition, it is an antiarrhythmic and minimizes myocardial

reperfusion injury. Although magnesium was found to prevent atrial fibrillation in coronary artery surgery,<sup>63</sup> in patients treated with  $\beta$ -blockers, the addition of prophylactic IV magnesium did not reduce the incidence of atrial arrhythmias.<sup>64</sup>

The most recent guidelines for CABG surgery were published in 2011.<sup>65</sup> They recommend:

- Volatile agent–based anesthetic aimed at early tracheal extubation
- Adequate perioperative analgesia
- Anesthetic care by a fellowship-trained or experienced, board-certified, TEE-trained anesthesiologist
- Utilization of intraoperative TEE for evaluation of acute, persistent, and life-threatening hemodynamic changes, for monitoring of ventricular function and regional wall motion abnormalities, and for concomitant valvular surgery
- Augmentation of the coronary arterial perfusion pressure to reduce the risk of perioperative myocardial ischemia and infarction
- Administration of  $\beta$ -blockers to reduce the incidence (or complications) of atrial fibrillation and cardiac mortality (particularly in patients with LVEF > 30%)
- Administration of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers perioperatively
- Selective use of PAC
- Multimodal approach for management of perioperative bleeding and transfusion, based on use of lysine analogues, point-of-care testing, discontinuation of antiplatelet medications for at least 5 days preoperatively, among others.

## Valvular Heart Disease

Alterations in loading conditions are the initial physiologic burdens imposed by valvular heart lesions, both stenotic and regurgitant: LV afterload is increased in aortic stenosis (AS), LV preload is increased in aortic insufficiency and MR, and both are decreased in mitral stenosis, whereas the right ventricle (RV) faces progressively increasing left atrial and pulmonary artery pressure. Compensatory mechanisms consist of chamber enlargement, myocardial hypertrophy, and variations in vascular tone and level of sympathetic activity. These mechanisms in turn induce secondary alterations, including altered ventricular compliance, development of myocardial ischemia, cardiac dysrhythmias, and progressive myocardial dysfunction.

Myocardial contractility in patients with MR is often transiently depressed

but may progress to irreversible impairment even in the absence of clinical symptoms. Conversely, the patient with AS may complain of dyspnea, not because of impaired systolic function, but because the reduced ventricular compliance causes left atrial hypertension and pulmonary vascular congestion.

The patient presenting for valve repair or replacement may have pulmonary hypertension, significant ventricular dysfunction, and chronic arrhythmias. For a safe anesthetic, understanding the altered loading conditions, preserving the compensatory mechanisms, maintaining circulatory homeostasis, and anticipating problems that may arise during and after valve surgery are important. In this section, we briefly describe the pathophysiology, desirable hemodynamic profile, and other pertinent anesthetic considerations for each valvular lesion.

TEE has become the standard of care in the perioperative management of patients undergoing valve surgery. TEE can further refine the preoperative diagnosis, identify valvular pathology and the mechanism of disease, and quantify the degree of stenosis and/or regurgitation. A detailed review of the perioperative role of TEE is presented in [Chapter 27](#).

## **Aortic Stenosis**

AS is the most common valvular disease in the United States. In a normal adult, the AV is composed of three semilunar cusps attached to the wall of the aorta. The normal AV area is 2 to 4 cm<sup>2</sup>. The AV cusps are suspended from the sinuses of Valsalva. The AV cusps and the corresponding sinuses are named according to their relation to the coronary ostia: left, right, and noncoronary (opposite the interatrial septum). On the ventricular side of the AV is the oval-shaped LV outflow tract (LVOT). Its borders are the inferior surface of the anterior leaflet of the mitral valve, the interventricular septum, and the LV wall. The normal diameter of the LVOT is 2.2 ± 0.2 cm.

Calcific AV disease has many similar features with coronary artery disease. What in the past was thought to be “degenerative” is a disease continuum, similar to atherosclerosis. The mechanism is the increased mechanical stress (higher on the aortic side of AV cusps, in the flexion area) that causes endothelial disruption and leads to lipoprotein deposition, chronic inflammation, and cusp calcification.<sup>66</sup> Increased calcification eventually leads to cusp immobility and outflow obstruction. Clinical factors associated with AS include older age, male gender, smoking, hypertension, and hyperlipidemia. Patients with bicuspid AV (increased mechanical stress) or with altered mineral metabolism (Paget disease, renal failure) have a higher prevalence of calcific AS disease. Rheumatic disease (an autoimmune disease, rarely seen in developed countries, leading to calcification and fusion along

1

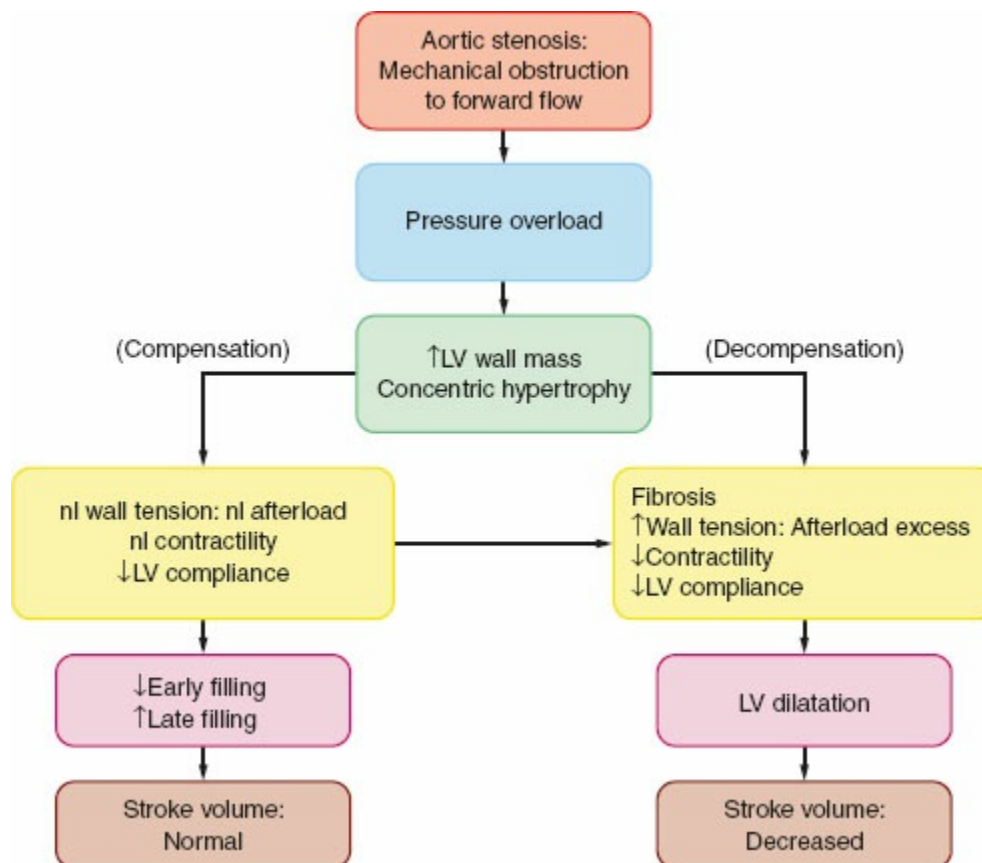

the commissures) causes mixed AS and AV regurgitation and usually coexists with mitral valve disease.

## Pathophysiology

The classic symptoms of AS are angina (35%), syncope (15%), and dyspnea (50%) and are harbingers of poor outcome (death) within 5, 3, and 2 years, respectively, unless the AV is replaced. The progressive narrowing of the AV area results in chronic obstruction to LV ejection. As LV systolic pressure increases to preserve forward flow, concentric LV hypertrophy, in which the LV wall gradually thickens but the cavity size remains unchanged, is the compensatory response that normalizes the concomitant increase in LV wall tension. Contractility is preserved and ejection fraction is maintained at a normal range until late in the disease process (Fig. 39-3). Signs and symptoms of AS usually occur when the AV orifice is reduced to less than 0.8 to 1.0 cm<sup>2</sup>.<sup>67</sup>

The relaxation of the thickened LV walls is slow (“stiff” LV), early diastolic LV filling is delayed, and LA contraction becomes critical for maintaining adequate stroke volume. In AS, the “atrial kick” may account for up to 30% to 40% of LV end-diastolic volume. The ventricular filling pressure, as reflected by pulmonary capillary wedge pressure, may vary widely with only small changes in ventricular volume (reduced compliance). Additionally, the hypertrophic LV myocardium has increased basal  $MV \cdot O_2$ , and demand further increases because of the elevated LV systolic pressure. As the capillary density is often inadequate for the hypertrophic muscle, any reduction in the coronary perfusion pressure (as when the aortic diastolic pressure is decreased and/or the LV filling pressure is increased) may compromise supply and vasodilatory reserve. These are more critical in the presence of coronary artery obstruction. Such AS patients often present with heart failure.

**Figure 39-3** Pathophysiology of aortic stenosis. LV, left ventricle; nl, normal.

There is an inverse relationship between systolic wall stress (afterload) and LV ejection fraction. In patients with a substantial transvalvular pressure gradient (mean  $>40$  mmHg), AV replacement corrects the afterload excess and improves outcome. In an LV with reduced contractility or decreased stroke volume the transvalvular pressure gradient is less than critical ( $<40$  mmHg: “pseudo” or “low-gradient” AS) despite an echocardiographically stenosed AV. Although the response to pharmacologic intervention with dobutamine may clarify the diagnosis (increased SV and AS: true AS vs. increased AV area: less than severe AS vs. lack of SV increase: LV dysfunction and implications for increased surgical risk), surgical intervention has better long term than medical management alone.<sup>68</sup> In the high surgical risk AS patient, the option of a percutaneous transcatheter AV replacement (TAVR) is accepted as an alternative to surgical AVR.<sup>69</sup>

## Anesthetic Considerations

 The ideal hemodynamic environment for the patient with AS is summarized in [Table 39-3](#). Noncardiac surgery in patients with asymptomatic severe AS may not be associated with complications, provided that their hemodynamics are appropriately monitored.<sup>70,71</sup> Although some studies report a marked increase in perioperative death and infarction rates, others do not.<sup>72,73</sup> The reasons for these differences are not clear, but

appropriate monitoring and perioperative management are considered essential for safe outcomes in noncardiac surgery.<sup>74</sup> The perioperative management should aim at (a) avoidance and immediate detection and treatment of systemic arterial hypotension, (b) maintaining coronary perfusion pressure to prevent the vicious cycle of hypotension-induced ischemia, subsequent ventricular dysfunction, and worsening hypotension, (c) avoiding extremes of heart rate, tachycardia as well as, bradycardia (despite an increase in diastolic time the stroke volume does not increase in an LV with concentric hypertrophy, and causes a fall in cardiac output and further hypotension; this is especially pertinent in the elderly or diabetic patient with sinus node disease and reduced sympathetic responses).

**Table 39-3** Aortic Stenosis: Hemodynamic Goals

Parameter	Goal	Comment
Preload	Maintain or ↑	
Afterload	Maintain or ↑	To maintain coronary perfusion gradient
Contractility		Usually not a problem, may require inotropic support if hypotension persists
Rate		Avoid bradycardia (↓ CO) and tachycardia (ischemia)
Rhythm	Sinus	May need cardioversion or β-blockers in non-sinus or fast rhythms
MVO <sub>2</sub>		Treat tachycardia and hypotension (ischemia is an ever-present risk)
Post-CPB	↑ Contractility	
↑ Blood pressure	↑ Contractility (suspected myocardial stunning); ↑ blood pressure	

↑, increase(d); ↓, decrease(d); CO, cardiac output; CPB, cardiopulmonary bypass; MVO<sub>2</sub>, myocardial oxygen consumption.

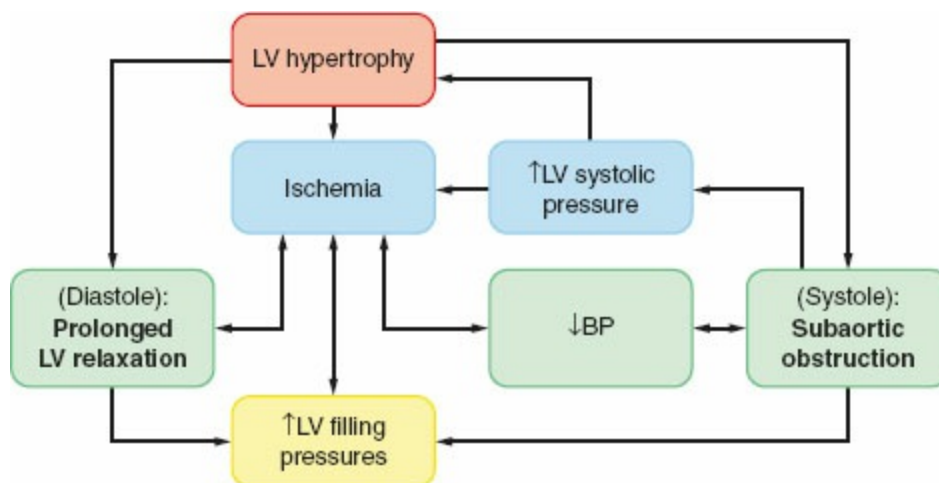

Ischemia may be difficult to detect because the characteristic electrocardiographic changes are often obscured by signs of LV hypertrophy and strain, and elevated LV filling pressures do not necessarily reflect increased volume.<sup>68</sup> If TNG is used, it should be titrated to effect with minimal effects on ventricular volume. In the presence of LV dysfunction, nicardipine<sup>75</sup> should be carefully titrated to lower afterload without affecting ventricular volume. The utility of TEE in diagnosing and grading the severity of AS is described in [Chapter 27](#).

## Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is a genetically determined disease characterized by histologically abnormal myocytes and myocardial hypertrophy developing a priori, in the absence of a pressure or volume overload. The LV has a relatively small cavity relative to the wall thickness and a hyperdynamic function.<sup>76,77</sup>

### Pathophysiology

 The physiologic consequences of hypertrophic cardiomyopathy are similar to those detailed for AS and are depicted in [Figure 39-4](#). A subset of patients (20% to 30%) have some degree of subvalvular obstruction (hypertrophic obstructive cardiomyopathy), which may result in an LVOT gradient from a combination of anatomic (systolic septal bulging into the LVOT, malposition of the anterior papillary muscle) and functional (drag forces, and hyperdynamic LV contraction causing a Venturi effect) factors. The LVOT gradient is dynamic in nature and increases when the LV cavity decreases (increased contractility and heart rate or decreased preload or afterload). The rapid blood ejection through the narrowed LVOT area pulls the anterior mitral valve leaflet closer to the septum (systolic anterior motion) and results in a variable MR jet, which, in the absence of organic mitral disease, is directed posteriorly.<sup>78</sup>

**Figure 39-4** Pathophysiology of primary left ventricular (LV) hypertrophy in hypertrophic cardiomyopathy. BP, blood pressure.

**Table 39-4** Hypertrophic Cardiomyopathy: Hemodynamic Goals

Parameter	Goal	Comment
Preload	Maintain or ↑	Treat as in aortic stenosis
Afterload	↑	Treat hypotension aggressively with $\alpha$ -adrenergic agonists
Contractility	↓	
Rate	Maintain	$\beta$ -Blockers
Rhythm	Sinus	Consider atrial pacing modalities (PAC, esophageal)
MVO <sub>2</sub>		Not a problem
Post-CPB		Start with volume and vasoconstrictors; avoid inotropes. Check carefully for residual LVOT gradient and SAM; rule out ventricular septal defect

↑, increase; ↓, decrease; LVOT, left ventricular outflow tract; LVEDP, left ventricular end-diastolic pressure; LV, left ventricle; PAC, pulmonary artery catheter; MVO<sub>2</sub>, myocardial oxygen consumption; CPB, cardiopulmonary bypass; SAM, systolic anterior motion.

In hypertrophic cardiomyopathy the myocardial oxygen balance is tenuous, and angina during exercise occurs even in the absence of coronary artery disease, if the coronary blood flow is unable to meet the demands of the hypertrophied myocardium.

### Anesthetic Considerations

Treatment options for hypertrophic cardiomyopathy include pharmacologic “thinning” of the proximal interventricular septum with intracoronary alcohol injection (provided that the diastolic septal thickness at the site of injection is <15 mm), cardiac pacing, and surgical septal myectomy that is aimed to decrease the flow gradient (target is <30 mmHg at rest or <50 mmHg during exercise). The anesthetic management of patients with hypertrophic cardiomyopathy is similar to that for AS and focuses on (a) avoiding bradycardia and tachycardia, (b) maintaining LV filling and avoiding the factors predisposing to outflow tract obstruction or ischemia (Table 39-4), (c) avoiding increases in myocardial contractility for which the volatile anesthetics are useful, and (d) maintaining sinus rhythm since LV preload is dependent on atrial contraction; if junctional rhythm occurs, these patients may need atrial pacing with a transesophageal pacing probe or a PAC with pacing capability.

Although infrequent, valvular AS may occasionally coexist with hypertrophic cardiomyopathy and may explain unanticipated difficulties in separating from bypass or unexpected increased pressure gradient following a seemingly uncomplicated AV replacement. Nowadays, a comprehensive TEE

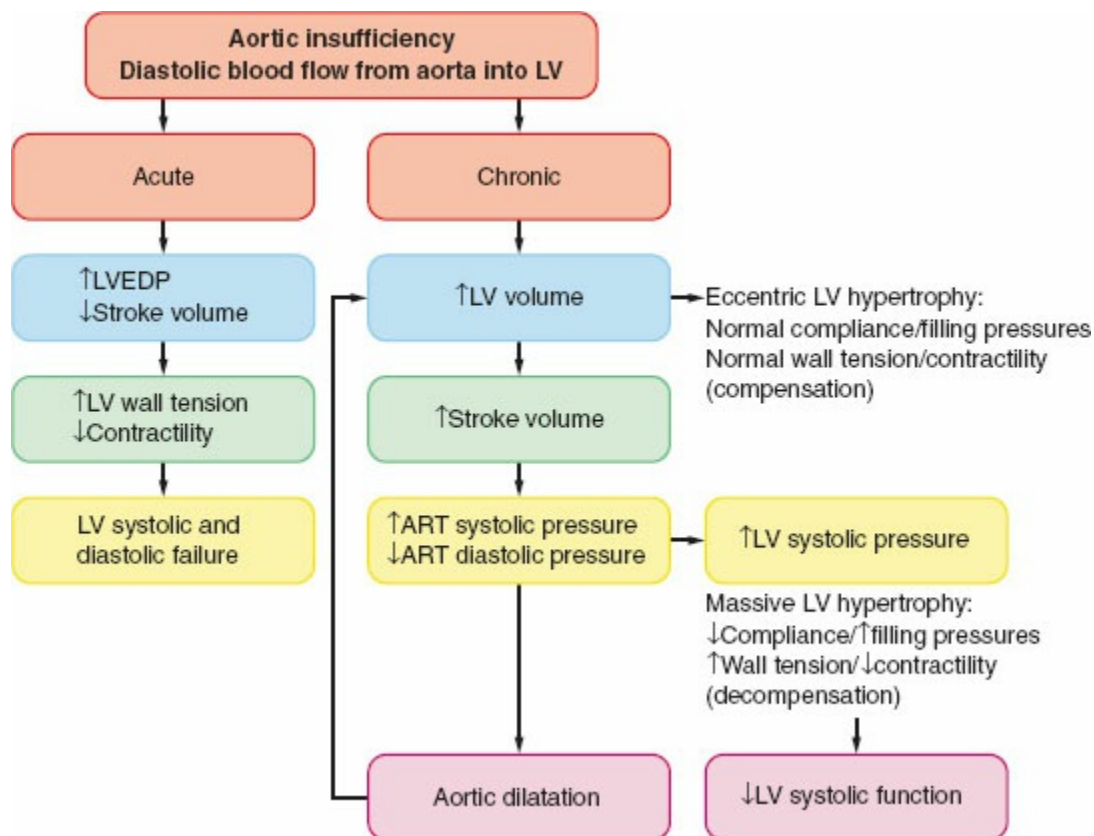

examination of the LVOT area proximal to the AV should resolve such dilemmas. A dynamic LVOT obstruction may also result following MV repair, if an elongated anterior mitral leaflet is brought closer to the interventricular septum (anterior septal motion observed echocardiographically), and should be similarly treated.<sup>79</sup>

## Aortic Insufficiency

Aortic valve insufficiency (AI) is the result of annular dilatation or structural AV cusp lesions. Chronic annular dilatation occurs with aneurysms (Marfan syndrome). Structural AV cusps lesions from calcific degeneration, rheumatic disease, or in bicuspid AV result in abnormal cusp motion and loss of coaptation and eventually AI. Acute AI is caused by bacterial endocarditis, aortic dissection, or trauma.

### Pathophysiology

**2** In AI, blood flows retrograde during diastole into the LV from the aorta and leads to volume and pressure overload (Fig. 39-5). In chronic AI, the LV cavity increases gradually and out of proportion to the LV wall thickness (eccentric LV hypertrophy), thus increasing the LV wall stress. The LV end-diastolic pressures are usually within the normal range, evidence of a significant increase in chamber compliance. As a result, and in contrast to AS, considerable fluctuations in LV volume can occur with only minimal changes in LV filling pressure. Although the LV may eject more than twice the normal cardiac output,  $MV \cdot O_2$  does not increase extraordinarily because the cost for muscle shortening (volume work) is low. The diastolic runoff and the moderate vasodilation reduce the LV afterload and increase the arterial pulse pressure. Thus, patients may be relatively symptom-free even when contractility is reduced. This is important in terms of planning the anesthetic, but perhaps even more so with respect to the timing of AV replacement. Ideally, the valve should be replaced just prior to the onset of irreversible myocardial damage. These patients should undergo AV replacement before LV ejection fraction decreases (<50%) or the LV dilates (LV end-diastolic diameter <65 mm).<sup>80,81</sup> Therefore, continued echocardiographic follow-up of these patients is paramount to detect decreased LV contractility.

**Figure 39-5** Pathophysiology of aortic insufficiency. LVEDP, left ventricular end-diastolic pressure; LV, left ventricle; ART, arterial.

In acute AI, the previously normal in size and compliance LV is faced with a rapidly increased end-diastolic volume and pressure whereas the diastolic aortic to LV pressure gradient is acutely decreased.<sup>82</sup> These will decrease the myocardial contractility and perfusion gradient with severe congestive heart failure as the cardinal clinical sign. The compensatory mechanisms of tachycardia and peripheral vasoconstriction further increase the  $MV \cdot O_2$ . In such acutely ill patients, emergent AV replacement is required, whereas in less severe circumstances, mild systemic vasodilation and inotropic support may return hemodynamics toward normal.

## Anesthetic Considerations

The main goal is to avoid further increases in LV wall stress (Table 39-5).<sup>7</sup> Arterial vasodilation (nicardipine or SNP) promotes forward flow, although additional intravascular volume may be necessary to maintain adequate preload. The ideal heart rate is somewhat controversial; tachycardia reduces the diastolic runoff from the aorta to the LV, thereby reducing LV volume and wall tension, and increases the diastolic blood pressure and coronary perfusion gradient, thus offsetting any increase in  $MV \cdot O_2$  secondary to increased heart rate. Bradycardia should be avoided as it results in ventricular distention, elevations in left atrial pressure, and pulmonary congestion.

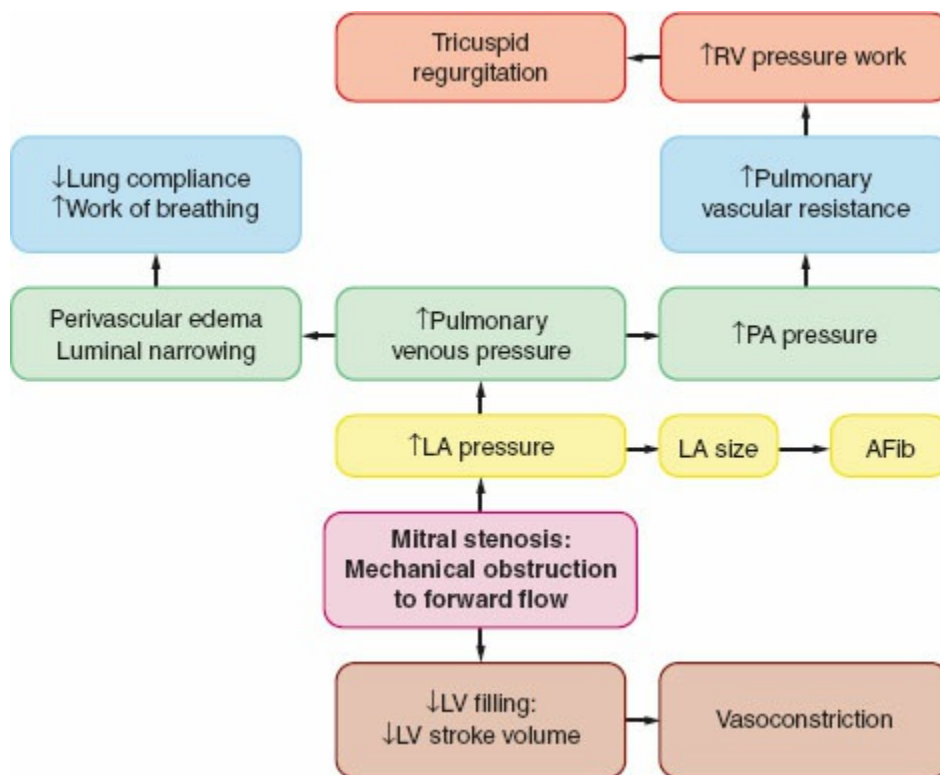

**Table 39-5** Aortic Insufficiency: Hemodynamic Goals

Parameter	Goal	Comment
Preload	↑ Slightly	↑ Slightly
Afterload	↓	Anesthetic depth ↑ or vasodilators (to decrease regurgitant fraction)
Contractility		Usually adequate
Rate	↑	Reduces ventricular volume and increases diastolic aortic pressure
Rhythm		Usually sinus; not a problem
MVO <sub>2</sub>		Usually not a problem
CPB		Beware (and observe) for ventricular distention pre- and post-AXC: regurgitant flow increases if ↓ HR and in non-beating heart

↑, increase; ↓, decrease; MVO<sub>2</sub>, myocardial oxygen consumption; CPB, cardiopulmonary bypass; AXC, aortic cross-clamp; HR, heart rate.

Ventricular distention may occur with the onset of CPB in the setting of bradycardia or unexpected ventricular fibrillation (ineffective systolic ejection). Contextual monitoring with TEE, invasive pressure lines, and visual inspection of the heart is especially important. If LV distention occurs, insertion of an LV vent or immediate cross-clamping of the aorta should alleviate the problem. The approach to CPB is equally important: after application of the aortic cross-clamp, the incompetent AV prevents the cardioplegia delivered to the aortic root from reaching the coronary system. Instead, cardioplegia will fill and distend the LV, causing ischemia since the diastolic arrest of the heart is not achieved. In the presence of AI, the heart is arrested by injecting cardioplegia directly into the coronary ostia (after aortotomy) or retrograde, into the coronary sinus. The utility of TEE in diagnosing and grading the severity of AI is described in [Chapter 27](#).

**Figure 39-6** Pathophysiology of mitral stenosis. RV, right ventricle; PA, pulmonary artery; LA, left atrium; AFib, atrial fibrillation; LV, left ventricle.

## Mitral Stenosis

Mitral valve stenosis (MS) develops from leaflet thickening, commissural fusion, and chordal shortening and fusion due to chronic inflammation. The most frequent cause of MS is atherosclerosis-associated mitral annular calcification and endocarditis; rheumatic fever is a rare etiology in the United States.<sup>83</sup>

## Pathophysiology

The spectrum of physiologic disruption in patients with MS is presented in **Figure 39-6**. Progressive decrease of the mitral valve area (MVA) impedes the blood flow from the left atrium (LA) to the LV, resulting in a pressure gradient across the MV during diastole. With worsening MS, the LV stroke volume is limited. The LV dysfunction is caused by the combination of decreased preload and increased afterload (from reflex vasoconstriction). Proximal to the decreased MVA, the LA pressure (LAP) is elevated. According to the formula by Gorlin and Gorlin<sup>84</sup>:

$$\text{Valve area} = \text{flow} / (K \cdot \sqrt{\text{Pressure gradient}}) \quad \text{or}$$

$$\text{Pressure gradient} = [\text{flow} / (K \cdot \text{MVA})]^2$$

where flow is cardiac output/diastolic filling time; pressure gradient is the

difference between LAP and LVDP; and  $K$  is a hydraulic pressure constant (this calculation assumes no regurgitant flow). At a constant MVA, rearrangement of the Gorlin formula reveals the clinical variables determining the elevated LAP in MS:

$$\text{LAP} - \text{LVDP} = [(\text{cardiac output})/(\text{diastolic time})/(K \cdot \text{MVA})]^2$$

$$\text{or LAP} = \text{LVDP} + [\text{flow}/(K \cdot \text{MVA})]^2$$

Therefore, increased cardiac output or decreased diastolic filling period results in a geometric elevation of LAP. This explains why tachycardia or increased forward flow, seen classically with pregnancy, thyrotoxicosis, or infection, can precipitate pulmonary edema in a patient with MS. Similarly, atrial fibrillation causes hemodynamic deterioration because the rapid ventricular rate decreases the diastolic filling time, thereby increasing the LAP pressure. Upstream from the LA, a persistently elevated LAP eventually leads to LA dilatation and is reflected through the pulmonary circulation increasing the work of breathing. This causes right ventricular pressure overload with compensatory right ventricular hypertrophy. The progression and severity of pulmonary hypertension is variable and at some point irreversible reactive changes in the pulmonary vasculature (rales on auscultation, hemoptysis) occur. Once pulmonary vascular hypertension has developed, the operative risk is increased (12% vs. 3% to 8%).<sup>85</sup> Right ventricular dysfunction, tricuspid annular dilatation, and insufficiency (engorged neck veins) may develop once the right heart function worsens.

MS is not an LV problem, but mimics left heart failure, with pulmonary congestion and decreased systemic flow. The only definitive treatment is relief of obstruction with MV replacement; balloon valvuloplasty and open commissurotomy are palliative interventions. The medical therapy should aim at decreasing the heart rate (with  $\beta$ - or calcium channel blockers) or treating the cause(s) responsible for the increased diastolic transmitral flow. The measured pulmonary capillary wedge pressure is higher than the true LVDP at least by the amount of the transmitral diastolic pressure gradient.

## Anesthetic Considerations

**8** The hemodynamic goals listed in [Table 39-6](#) are the cornerstones of prebypass anesthetic management ([Table 39-6](#)). Avoiding tachycardia helps prevent episodes of LA and pulmonary hypertension, potential right ventricular dysfunction, as well as inadequate LV filling with concomitant systemic hypotension. Preoperative maintenance of rate-control with  $\beta$ -blocking drugs, selection of anesthetics that minimize the risk of tachycardia, and attainment of anesthetic levels deep enough to suppress autonomic

responses are methods to achieve these goals. Factors inducing pulmonary vasoconstriction, such as hypoxia, hypercarbia, and acidosis must be prevented to avoid the potential for right heart failure.

Treatment of hypotension in patients with MS can present a challenging dilemma, because hypovolemia is not usually the cause. The response to volume administration is often disappointing; instead, a vasoconstrictor is used to offset mild peripheral vasodilation, bearing in mind the effect of pulmonary vasoconstriction on right ventricular function. A drug with some inotropic effect, such as ephedrine or epinephrine, is preferred instead of relying on a pure vasoconstrictor, such as phenylephrine. In separating from CPB, attention is on avoiding right ventricular failure (discussed subsequently); more commonly, however, there is LV dysfunction. This may be because of intraoperative injury or sudden increase in flow to, and distention of, the chronically underloaded LV. After bypass, prominent *v* waves may be present in the pulmonary capillary wedge pressure waveform, reflecting the increased LV filling, assuming a cardiac output increased from preinduction values. The echocardiographic evaluation of MS is described in [Chapter 27](#).

**Table 39-6** Mitral Stenosis: Hemodynamic Goals

Parameter	Goal	Comment
Preload	Maintain	Maintain, avoid hypovolemia
Afterload		Prevent ↑ RV afterload (due to pulmonary vasoconstriction hypoxia, hypercarbia); treat systemic hypotension with vasopressors
Contractility	↑ RV	May be decreased in long-standing pulmonary hypertension; (LV: usually intact)
Rate	Maintain	At low end of normal; avoid and treat tachycardia
Rhythm		Control ventricular response in atrial fibrillation
M $\dot{V}$ O <sub>2</sub>		Not a problem
Post-CPB		LV preload and filling pressures may be elevated; cardiac function does not improve immediately

↑, increase(d); RV, right ventricle; M $\dot{V}$ O<sub>2</sub>, myocardial oxygen consumption; CPB, cardiopulmonary bypass; MV, mitral valve; LV, left ventricle.

## Mitral Regurgitation

In MR, the valve is incompetent during systole and blood regurgitates from the LV to the LA. Etiologies of MR include excessive motion of one or both

leaflets (prolapse or flail due to degenerative disease, or ruptured chordae tendineae following acute myocardial infarction), restricted leaflet motion due to rheumatic heart disease or myocardial ischemia (functional MR), or leaflet perforation from endocarditis. In functional MR the leaflet structure is normal, but the valve is incompetent due to either decreased LV systolic pressure (ischemic cardiomyopathy) that fails to “close” the leaflets or a dilated annulus (the fiber ring from where the leaflets are suspended) that decreases the coaptation surface of the leaflets (Table 39-7).

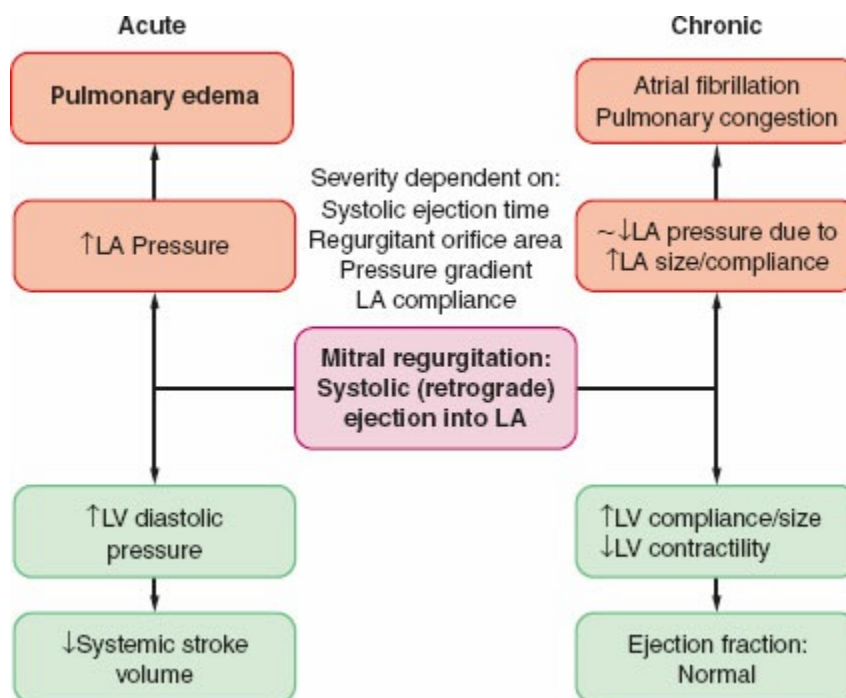

## Pathophysiology

Volume overload similar to that described with AI is the cardinal feature of MR (Fig. 39-7). The LA acts as a low-pressure outlet during LV ejection; with the onset of ventricular systole blood is ejected retrograde (there is no isovolumetric contraction period) and the total LV output consists of forward (systemic, via the aorta) and retrograde (into the LA) blood volumes. The aftermaths of MR are atrial and ventricular chamber enlargement (due to “back-and-forth” blood flow), LV wall hypertrophy (to compensate for the increased wall tension from chamber enlargement), and increased blood volume. The LV compliance is increased so that the large LV end-diastolic volume does not cause striking increase in LVDP. Initially, there is no concomitant increase in oxygen requirements because the systolic work is not increased. As a result, patients may have minimal symptoms as well as normal or slightly reduced ejection fraction, despite progressive myocardial dysfunction and decreased contractility. The regurgitant blood volume is related to the size of the regurgitant MV orifice, the systolic ejection time, the pressure gradient across the MV, and the LA compliance. The regurgitant MV orifice size, in turn, depends on the type of MR mechanism and LV size. Therefore, increases in heart rate, reduction of preload, and arterial dilators are effective in reducing the regurgitation of blood volume from the LV to LA.

**Table 39-7** Mechanisms of Mitral Regurgitation

Cause	Characteristics	Location
Degeneration	Excessive motion due to prolapse or flail Redundant tissue Ruptured chordae	Leaflet
Rheumatic	Thickened, calcified, restricted leaflets Commissural fusion	Leaflet
Congenital	Cleft mitral valve, double orifice mitral valve	Leaflet
Miscellaneous	Drug-related (fenfluramine)	Leaflet
Endocarditis	Perforation(s) Vegetations	Leaflet
Myocardial infarction	Papillary muscle rupture	Tensor apparatus
Dilated cardiomyopathy	Annular dilatation	Annulus
Ischemic heart disease	Papillary muscle dysfunction	Tensor apparatus

Repairing or replacing the MV increases the LV afterload and unmasks any underlying myocardial dysfunction. Administration of inotropes and/or vasodilators, as well as judicious increase in preload, may be necessary to successfully separate from bypass.

**Figure 39-7** Pathophysiology of mitral regurgitation. LA, left atrial; LV, left ventricular.

**Table 39-8** Mitral Regurgitation: Hemodynamic Goals

Parameter	Goal	Comment
Preload	↑ Slightly	
Afterload	↓	With anesthetics, arterial vasodilators
Contractility		(May be ↑) titrate myocardial depressants carefully
Rate	↑ Slightly	↑ Avoid bradycardia
Rhythm		Control ventricular response if atrial fibrillation present
MVO <sub>2</sub>		Compromised if MR coexists with ischemic heart disease
Post-CPB		↑ Inotropy (afterload is increased with competent valve)

↑, increase(d); ↓, decrease(d); MVO<sub>2</sub>, myocardial oxygen consumption; MR, mitral regurgitation; CPB, cardiopulmonary bypass.

Acute-onset MR has a different hemodynamic picture; acute LA and LV volume overload occurs in the absence of compensatory LV enlargement. The acutely increased LV filling pressure is transmitted to the pulmonary vasculature, and concomitant to the decrease in cardiac output pulmonary edema develops. In the setting of acute myocardial infarction, contractility may be inadequate despite pharmacologic support, and intra-aortic balloon assistance and emergency surgery may be lifesaving.

### Anesthetic Considerations

Selection of anesthetics that promote vasodilation and tachycardia is ideal in the patient with MR (Table 39-8). In chronic MR, vasoactive medications are usually not necessary because of LV compensatory mechanisms. However, patients with acute MR may need aggressive pharmacologic management. In the absence of acute deterioration, pharmacologic intervention is not needed usually until the postbypass period. However, vasodilators and inotropes may lead to reoccurrence or worsening of MR if, following MV repair surgery, the anterior mitral leaflet is “sucked in” towards the intraventricular septum and results in LVOT obstruction. This pathophysiologic and clinical picture is similar to that of hypertrophic cardiomyopathy. The risk of systolic anterior motion after MV repair is increased when the anterior leaflet is longer than the posterior leaflet or when there is a narrow angle between the mitral and aortic annuli. If this scenario is suspected, a trial of volume expansion and vasoconstrictors is indicated. The echocardiographic evaluation of MR and its surgical treatment is described in Chapter 27.

### Aortic Diseases

Acquired (hypertension, inflammation, deceleration trauma, or iatrogenic trauma) and genetic (connective tissue disorders, bicuspid AV) conditions are the cause of aortic diseases: aortic dissection, intramural hematoma, and aortic aneurysm. Weakening of the media layers of the aorta (the term *cystic medial degeneration* denotes the disappearance of smooth muscle cells and the degeneration of elastic fibers) leads to increased wall stress, which induces dilatation of the aortic lumen and formation of aneurysm, which may coexist with intramural hemorrhage or aortic dissection, or even lead to rupture.

## Aortic Dissection

Aortic dissection<sup>86</sup> is one of the features of the acute aortic syndromes, which also include intramural hematoma and penetrating ulcer. Connective tissue disorders, such as Marfan syndrome and Ehlers–Danlos syndrome affect mostly the young (age <40 years), whereas hypertension is the most common risk factor in older patients. Aortic dissection is caused by a tear in the aortic intima and media, which propagates proximal and distally, creating a false lumen within the aortic media. When the false lumen involves aortic vessels, it causes malperfusion of vital organs (brain, spinal cord, abdominal organs). Rupture of the false lumen into the pericardium can cause cardiac tamponade, whereas interference with the AV may cause AI. Acute aortic dissection of the ascending aorta (type A) has a mortality rate of 1% to 2% per hour after onset of symptomatology and is a true surgical emergency. An aortic dissection distal to the left subclavian artery is called type B, has a 30-day mortality of 10%, and may be managed medically or with insertion of a scaffold (stent). Intramural hematoma originates from ruptured vasa vasorum in the media and is considered a precursor to classic dissection. Intramural hematoma has the same prognosis as aortic dissection and is treated similarly.

Severe neck or chest pain (type A) or back or abdominal pain (type B) is the most common symptom, although many patients have atypical symptoms mimicking stroke, myocardial infarction, vascular embolization, and abdominal pathology. Some diabetics may be totally asymptomatic. Syncope may indicate cardiac tamponade or cerebral hypoperfusion. Pulse deficits in extremities and/or differences in blood pressure are a significant sign and are related to impaired blood flow to a limb. It is important to diagnose correctly the type of dissection as this determines the proper treatment. A variety of diagnostic techniques are accurate (contrast-enhanced spiral computed tomography scanning or magnetic resonance imaging are slightly more sensitive and specific than TEE, which is more portable and available at bedside).<sup>87</sup>

Patients with a high clinical suspicion of acute aortic dissection may be sent directly to the operating room for TEE-based diagnostic workup and

preparation for surgery, thus expediting surgical intervention.<sup>88</sup> Two-dimensional TEE identifies the intimal tear in 61% of the patients.<sup>89</sup> Apart from direct visualization of intimal tear and flap (the aortic wall separating the two lumens), the site of injury, thrombosis of the false lumen, coronary involvement, intramural hematoma, pericardial effusion, and AI can be diagnosed with high sensitivity and specificity.<sup>90</sup> However, dissections in the distal ascending aorta and proximal arch are difficult to visualize because of interposition of the left main stem bronchus between the esophagus (TEE) and aorta. Surgery is the definitive treatment for patients with type A acute aortic dissection to decrease mortality associated with aortic rupture, pericardial tamponade, and AI. It involves implantation of a composite graft in the ascending aorta with or without reimplantation of the coronary arteries. Type B aortic dissections can be managed medically if chronic or with implantation of a graft via an open or closed (percutaneous) approach if complicated (malperfusion symptomatology).

### **Anesthetic Considerations**

Acute aortic dissection is a surgical emergency. Adequate intravenous access and invasive hemodynamic monitoring, including TEE, are mandatory. The hemodynamic goals are shown in [Table 39-9](#).

**Table 39-9** Acute Aortic Dissection: Hemodynamic Goals

Parameter	Goal	Comment
Preload	↓	If acute AI; (must ↑ further in tamponade)
Afterload	↓	With anesthetics, analgesics, arterial dilators (nitroprusside, nicardipine): keep systolic BP <100–120 mmHg
Contractility	Maintain or ↑	Titrate myocardial depressants carefully
Rate	↓ to <60–80 bpm	Use β-blocker; ensure contractility is adequate
Rhythm		Control ventricular response (If atrial fibrillation present)
MVO <sub>2</sub>		Compromised if aortic dissection involves coronary vessels
CPB		Alternate site of inflow (arterial) cannulation, deep hypothermic circulatory arrest possible if cerebral vessels are involved

↑, increase(d); ↓, decrease(d); AI, aortic insufficiency; BP, blood pressure; bpm, beats per minute; MVO<sub>2</sub>, myocardial oxygen consumption; CPB, cardiopulmonary bypass.

## Aortic Aneurysm

Aortic aneurysms may involve one or more aortic segments (aortic root, ascending aorta, arch, descending aorta). Most patients are asymptomatic at the time of diagnosis. Aortic root aneurysms may cause AI (diastolic murmur or heart failure). When large, aortic aneurysms may cause local mass effect such as compression of the trachea (cough), esophagus (dysphagia), and/or recurrent laryngeal nerve (hoarseness). Detection and sizing can be done with contrast-enhanced computed tomography scanning and magnetic resonance angiography. The risk for rupture increases abruptly as aortic aneurysms reach a diameter of 6 cm.<sup>91</sup> Surgery is indicated for ascending aorta aneurysms greater than 5.5 cm or descending aortic aneurysms greater than 6 cm.<sup>92</sup> Composite aortic repair (Bentall procedure) using a tube graft with a prosthetic AV sewn into one end is performed for aortic root aneurysm associated with AI.<sup>93</sup> Alternatively, if AI is due to aortic root dilation, a valve-sparing procedure (preservation of the native AV cusps) is performed.<sup>94</sup>

The surgical replacement of aortic arch aneurysm requires circulatory arrest during the construction of distal anastomosis and carries a risk of neurologic damage from global ischemic injury or embolization of atherosclerotic debris. Cerebral protection methods during replacement of the

aortic arch include use of deep hypothermic circulatory arrest with or without arrest of cerebral circulation. Retrograde (via a superior vena cava cannula) or selective antegrade (direct cannulation of cerebral vessels) cerebral perfusion is employed to improve outcomes by providing perfusion to the brain and flush out particulate matter from the cerebral and carotid arteries, with, so far, disputed results.<sup>95</sup>

Surgical replacement of the descending aorta is associated with postoperative paraplegia secondary to interruption of spinal cord blood supply (13% to 17%). A variety of methods (cerebrospinal fluid drainage, reimplantation of critical spinal arteries, maintenance of distal aortic perfusion with the use of an LA–left femoral artery bypass circuit, intraoperative epidural cooling, or use of somatosensory evoked potentials) are being used to avoid this complication, although outcome is heavily influenced by hospital and surgeon volume.<sup>96</sup> Alternatively, a transluminally placed endovascular stent-graft can be inserted.<sup>97</sup> [Chapter 40](#) reviews recent advances in vascular stenting.

## Anesthetic Considerations

The anesthetic technique is centered around two major organ systems: (1) preservation of cardiac function (most crucial in surgery of descending aortic aneurysms, where the “clamp-and-go” surgical technique imposes great fluctuations in systemic afterload and hemodynamic instability), and (2) neurologic integrity (in arch or descending aortic operations). Drainage of cerebrospinal fluid will augment the spinal cord perfusion pressure. Usually, increments of 10 mL are drained at a time and the cerebrospinal fluid pressure is monitored continuously, keeping a cerebrospinal fluid pressure below 15 mmHg at all times.<sup>98,99</sup> Left heart bypass (LA to femoral artery) provides nonpulsatile retrograde aortic perfusion and supplements blood flow during aortic flow interruption, but does not perfuse the excluded aortic segment. Blood is actively removed via a cannula inserted inside the LA and advanced distal to the aortic interruption site. This technique ameliorates LV stress by reducing LV preload and afterload. The bypass flow depends on adequate preload (as assessed by the pulmonary arterial diastolic pressure or LV size via TEE) and low-normal afterload distal to the aortic cross-clamp. Too high flow of the bypass system will lead to hypotension, whereas increased pump flow will help decrease systemic hypertension proximal to the aortic interruption.

## Cardiopulmonary Bypass

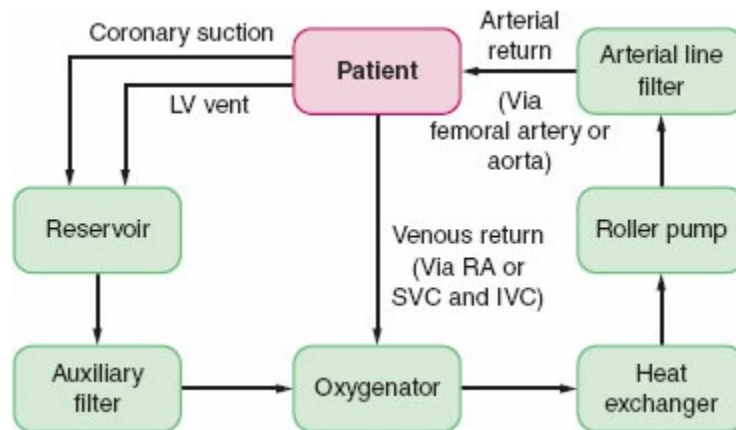

### Circuits

A CPB circuit consists of tubing (cannulae) that drain venous and return arterial blood; an oxygenator, where gas exchange occurs; and a mechanical pump that provides systemic perfusion (Fig. 39-8). The initiation of CPB involves the drainage of venous blood to the CPB machine. This is accomplished by placing a large-bore cannula(e) into the right atrium from which blood is drained to the venous reservoir of the CPB machine. For nonintracardiac procedures, a multi-orifice “dual-stage” cannula that drains blood from the right atrium, coronary sinus, and inferior vena cava is often used. However, where a bloodless field is required single cannula drainage may be suboptimal. In this case individual “single-stage” cannulae are placed into the superior and inferior venae cavae and then snared, thus preventing systemic venous blood from entering the heart. During CPB, venous drainage is passive and depends on several factors: proper placement of appropriately sized cannulae, intravascular volume status, and a hydrostatic pressure gradient (the difference in height between the right atrium and the venous reservoir). In the event of poor venous drainage, adjustment of the venous cannulae, raising the height of the operating table, or application of suction usually corrects the problem.

From the venous reservoir, blood enters the oxygenator/heat exchanger, which acts as an artificial lung, and the blood is oxygenated and carbon dioxide is removed. Blood may then be warmed/cooled and returned to the arterial circulation via a large “arterial” cannula placed in the ascending aorta, femoral, or axillary arteries. This cycle of venous blood returning to the CPB machine where it is then oxygenated and returned to arterial circulation continues for the duration of CPB.

Other ancillary functions of the CPB machine include delivery of cardioplegia, cardiotomy suction (scavenging shed blood from the surgical field), and venting (to decompress the LV and aspirate air from the heart during de-airing procedures). Venting prevents ventricular distention that may lead to myocardial ischemia and is particularly important in patients with aortic insufficiency. Common LV vent sites include a cannula placed in the pulmonary artery, left atrium or LV via the left superior pulmonary vein or the aortic root.

In addition to providing cardiopulmonary support, CPB circuits contain filters for the removal of bubbles and debris, in-line blood gas monitors, and volatile agent vaporizers. Warning monitors are placed in key locations of the CPB circuit. These monitors are used to detect low blood levels in the venous reservoir/oxygenator (to prevent entrainment of air to the arterial side of the circuit), high systemic line pressure (to diagnose possible arterial cannula obstruction/aortic dissection; both cause elevated line pressure), and bubbles.

**Figure 39-8** The basic circuit for cardiopulmonary bypass. LV, left ventricle; RA, right atrium; SVC, superior vena cava; IVC, inferior vena cava. (Adapted from Thomson IR. Technical aspects of cardiopulmonary bypass. In: Thomas SJ, ed. *Manual of Cardiac Anesthesia*. 2nd ed. New York: Churchill Livingstone; 1993:480, with permission.)

## Oxygenators

The use of membrane oxygenators in modern CPB machines eliminates the destructive blood–gas interface seen with older bubble oxygenators. Membrane oxygenators use bundles of hollow microporous fibers contained in a plastic housing. Within this housing, blood flows around the fibers while fresh gas is passed through the fibers. The micropores act as channels allowing the diffusion of both oxygen and carbon dioxide. With this arrangement  $PO_2$  on CPB is controlled by changes in  $FIO_2$  and carbon dioxide elimination by changes in total gas flow or “sweep rate.”

## Pumps

**7** During CPB, a mechanical pump is required to provide systemic perfusion and circulatory support. Centrifugal and roller pumps are used in clinical practice. Roller pumps are the simplest and earliest type of pump. A length of tubing is placed in the periphery of a rigid curved housing. At the center of this housing are two metal arms set 180 degrees apart with rollers at each end. When the arm rotates, the tubing is alternately compressed and released against the housing. Alternately compressing and releasing the tubing generates forward flow without the possibility of retrograde flow. This permits constant flow over a range of arterial resistance.

Roller pumps are simple and easy to use. The disadvantages include destruction of blood elements, spallation (development of plastic microemboli due to tubing compression), and complications from inflow and outflow occlusion of the pump. If pump inflow is occluded, negative pressure will develop in the roller head causing cavitation or the development of microscopic bubbles. If pump outflow becomes occluded, excessive pressure

may develop proximal to the occlusion, causing the tubing connections to separate or the tubing to burst.

Centrifugal (CPs) or constrained vortex pumps have supplanted roller pumps for providing systemic support but they are still used for delivering cardioplegia and providing vent/cardiectomy suction.

CPs use magnetically controlled impellers placed within a rigid plastic housing. The impeller rotates to provide kinetic energy, that is then transferred to blood that becomes flow. The impeller is magnetically coupled to an electric motor located in the CPB machine and by rotating rapidly, a pressure drop across the impeller is generated, which creates a constrained vortex causing the displacement of blood. One major difference between roller head and centrifugal pumps is that flow from centrifugal pumps will vary with changes in pump preload and afterload. It is for this reason that a flow meter must be placed on the arterial side of the bypass circuit. Advantages of centrifugal pumps include less blood trauma, lower line pressures, lower risk of massive air emboli, and elimination of tubing wear and spallation.

Some potential complications of CPB include aortic dissection due to aortic cannulation (manifests as low blood pressure on CBP with high line pressure), catastrophic CPB machine failure (a hand crank may be used to mechanically operate the biohead of a centrifugal pump to develop adequate pump flow), and massive air emboli.

## *Heat Exchanger*

A heat exchanger is a counter current device where either heated or cooled water is circulated around a conducting material with good thermal properties that is in contact with the patient's blood. In this way blood is subsequently warmed or cooled and maintained at a desired temperature.

## *Prime*

The fluid contained within the CPB tubing is called prime. Using crystalloid solutions, such as lactated Ringer solution, allows the CPB prime to achieve similar osmolarity and electrolyte composition as blood. Other solutions such as albumin (to decrease postoperative edema), mannitol (to promote diuresis), additional electrolytes (calcium to prevent hypocalcemia due to citrate in transfused blood), and heparin (to ensure a safe level of anticoagulation) may be added to the prime. Many institutions use a standard volume prime for all adult patients, and others use a minimum volume based on body weight or body surface area (the average prime volume is about 1,500 mL). To prevent excessive dilutional anemia and decrease in oxygen-

carrying capacity, blood may be added to the pump prime prior to initiating CPB in children, small adults, and patients with preoperative anemia. The lowest safe hematocrit on CPB is debated, but hematocrits of 22% are well tolerated.<sup>100</sup> Despite limited data the trend currently favors higher levels to avoid renal and neurologic consequences. Dilutional anemia on CPB is useful to the degree that it offsets changes in blood viscosity due to hypothermia. Thus, dilutional anemia may improve systemic flow. The use of cerebral oximetry on CPB may help identify patients at risk neurologic injury due to low intraoperative hematocrit or low flow. In an attempt to reduce the systemic inflammatory reaction, hemodilution, and coagulopathy associated with standard CPB circuits, miniaturized circuits have been developed. These miniaturized CPB circuits have a decreased surface area and consist of a smaller arterial venous loop/venous reservoir, pump, oxygenator, and filter. This reduction in surface area, and to a lesser extent a reduction in pump prime, may reduce blood usage.

### **Anticoagulation**

Contact between patient's blood and components of the CPB circuit initiates activation of the coagulation cascade. To prevent thrombosis of the CPB circuit (and the patient's death), systemic anticoagulation is required prior to insertion of cannulae and initiation of CPB. The anticoagulant of choice is heparin, a polyionic mucopolysaccharide. Following intravenous injection, the peak onset of heparin is less than 5 minutes with a half-life of approximately 90 minutes in normothermic patients. In hypothermic patients, there is a progressive and proportional increase in the half-life of heparin. The anticoagulant effect of heparin is derived from its ability to potentiate the activity of antithrombin III (AT). Heparin's binding to AT alters its structural configuration and increases its thrombin inhibitory potency more than 1,000-fold. By inhibiting thrombin, AT prevents formation of fibrin clot via both the intrinsic and extrinsic pathways, in addition to inhibiting factors IX, Xa, XIa, XIIa, kallikrein, and plasmin. In patients receiving heparin preoperatively and those with congenital AT deficiencies, higher than expected doses of heparin are required to achieve adequate anticoagulation.

In the event of inadequate anticoagulation due to a relative or absolute deficiency of AT, exogenous AT can be administered in the form of a commercially available concentrate. Postoperative heparin rebound and subsequent bleeding may be a concern following the administration of exogenous AT.

Currently, the two methods for determining adequate heparinization are measurement of the activated clotting time (ACT) or blood-heparin concentrations. The ACT test consists of adding blood to tubes containing

either diatomaceous earth (celite) or kaolin, warming and rotating the tube, and then recording the time required for clot formation. Generally, ACTs above 480 seconds are considered acceptable for the initiation of CPB. Measuring heparin levels intraoperatively is an alternative method for determination of anticoagulation levels. In this method, known doses of protamine are added to a heparinized sample of blood sequentially, until the optimum dose of protamine that produces a clot in the shortest amount of time is determined. By knowing the neutralization ratio of heparin and protamine (usually 1 mg of protamine to 100 U of heparin), the heparin concentration in the sample can be determined. This method will correctly diagnose inadequate anticoagulation despite a therapeutic ACT.

Partial thromboplastin time is not used in cardiac surgery to measure heparin action. This is due to the fact that modern partial thromboplastin time assays are so sensitive that heparin levels far lower than those used for safe initiation of CPB cause the sample blood to become almost unclottable within the time frame of the test.

Allergies to heparin are rare; more commonly, patients may present with a history of heparin-induced thrombocytopenia (HIT). There are two subtypes of HIT. The first is generally mild and consists of a transient decrease in platelet count following the administration of heparin a few days following surgery. The second type is more severe, characterized by autoimmune-mediated decrease in the platelet count due to the formation of antigenic heparin compounds (anti-PF4) that activate platelets in the face of endothelial injury. This predisposes to platelet clumping and microvascular thrombosis. This thrombosis may occur anywhere in the body and cause bowel or limb ischemia to name a few. In patients with HIT who require systemic anticoagulation, heparin alternatives should be used instead. These include defibrinogenating agents (ancrod obtained from pit viper venom), hirudin, bivalirudin, and factor X inhibitors. Hirudin, which is isolated from the salivary gland of the medicinal leech (*Hirudo medicinalis*), and bivalirudin (hirulog) are both direct inhibitors of thrombin. Their action is independent of AT. The use of these agents is uncommon and the reader is advised to consult one of the several reviews on this subject.<sup>101</sup>

### **Blood Conservation in Cardiac Surgery**

Blood and blood components are finite resources that are increasingly difficult to replace because of declining donation and restrictions on those that may donate. In addition, patients are increasingly demanding “bloodless” surgeries to lessen the risks of blood transfusion (infection, incompatibility reactions, transfusion error). However, because of the nature of cardiac surgery, the risk of blood and blood product transfusion is high. Bleeding as a result of

reoperation, use of anticoagulants/platelet function inhibitors, and residual surgical bleeding contribute to this risk. Furthermore, the inherent risk of platelet dysfunction and coagulopathy due to CPB cannot be eliminated. The use of a multimodal approach to blood conservation including intraoperative autologous blood donation, the scavenging and reinfusion of shed blood, the use of antifibrinolytics ( -aminocaproic acid, tranexamic acid), and other conservation techniques may all help to reduce the need for transfusion.<sup>102,103</sup>

Intraoperative autologous hemodilution is a well-described method of removing whole blood from a patient prior to systemic heparinization and CPB. Returning this blood following the separation from CPB returns red blood cells, active platelets, and functional coagulation factors that may mitigate surgical bleeding. Contraindications to intraoperative autologous blood donation include preoperative anemia, unstable angina/high-grade left main coronary artery disease, and aortic stenosis. Blood salvage (cell saver) is another key method of intraoperative blood conservation in cardiac surgery. Following processing, units of shed blood may have hematocrits of 70%. Unfortunately, as platelets and coagulation factors are removed in the washing process, reinfusion of shed blood may worsen the CPB-associated coagulopathy by promoting a dilutional thrombocytopenia and reduction of clotting factors. Contraindications to the use of intraoperative cell salvage include infection, malignancy, and the use of topical hemostatic agents.

Antifibrinolytic use in cardiac surgery is the standard in most cardiac centers, with -aminocaproic acid being the primary agent used in the United States. The lysine analogues -aminocaproic and tranexamic acid bind to plasminogen and block its ability to bind at lysine residues of fibrinogen. This prevents the lysis of fibrin clots. Administration of these antifibrinolytics decreases bleeding after CPB and reduces the risk of blood transfusion.<sup>104</sup>

Hemodilution due to the CPB prime is one undesired by-product of extracorporeal circulation. One method that has been used with success to avoid excess hemodilution and reduce the need for blood transfusion is retrograde autologous priming (RAP). In RAP, the crystalloid prime contained within the CPB circuit is displaced prior to the initiation of CPB and replaced by blood drained retrograde via the arterial and venous cannulae. RAP reduces hemodilution and diminishes the drop in systemic vascular resistance (SVR) associated with the initiation of CPB. When using this technique, care must be taken to avoid acute hypovolemic hypotension. Reported benefits of RAP include reduced extravascular lung water and weight gain.<sup>105</sup>

Ultrafiltration is another technique used in conjunction with CPB to reduce postoperative bleeding and transfusion needs. During ultrafiltration (hemoconcentration), plasma water is separated from low-molecular-weight solutes, intravascular cell components, and plasma proteins with a semipermeable membrane, using a hydrostatic pressure differential created by

external suction. Conventional ultrafiltration is initiated during rewarming and is practiced more often in pediatric cardiac surgery. Advantages of hemoconcentration include a reduction in free water, increase in hemoglobin and hematocrit, preservation of hemostasis, and a decrease in levels of circulating inflammatory mediators.<sup>106</sup>

## **Myocardial Protection**

The most common method of myocardial protection used today is that of intermittent hyperkalemic cold cardioplegia and systemic hypothermia. Systemic hypothermia is beneficial for both myocardial and neurologic protection during cardiac surgery. The benefits of hypothermia are a reduction in metabolic rate and oxygen consumption, preservation of high-energy phosphate substrates, and a reduction in excitatory neurotransmitter release. For each degree centigrade reduction in temperature, there is an 8% reduction in metabolic rate, so that at 28°C there is an approximate reduction in metabolic rate of 50%. Moderate systemic hypothermia can be achieved with either passive or active cooling. Using passive cooling, or “drifting” the patient’s core temperature is allowed to equalize with the ambient temperature. This may be a slow or rapid process depending on variables such as patient’s body surface area exposed and ambient temperature. Most patients undergoing cardiac surgery are actively cooled and then rewarmed using a heat exchanger.

The fundamental concept of cold cardioplegia is that a cold solution (10° to 15°C) of either blood or crystalloid with a supranormal concentration of potassium is injected into the coronary arteries or veins to induce diastolic electrical arrest. Cardioplegia may be employed via an antegrade, retrograde, or a combination of the two routes. Antegrade cardioplegia solution is injected via the aortic root following aortic cross-clamp which then follows the normal anatomic flow of blood into the native coronaries. In patients with severe coronary artery disease or AI, antegrade cardioplegia may provide inadequate myocardial protection due to an incompetent AV allowing cardioplegia to flow into the LV, bypassing the coronary ostia causing left ventricular distention and ischemia. In cases of significant AI, following aortic cross-clamping, an aortotomy is made and cardioplegia is delivered antegrade via handheld cannulae placed in the individual coronary ostia under direct vision. During coronary artery bypass surgery, individual grafts may be used to deliver cardioplegia once distal anastomoses have been completed. This will ensure the delivery of antegrade cardioplegia distal to any obstructive coronary artery disease. Retrograde cardioplegia is employed for myocardial protection by placing a catheter inside the coronary sinus. Retrograde cardioplegia is then injected via the cardiac venous system,

bypassing obstructed coronaries and achieving greater myocardial protection. To maximize myocardial protection, both anterograde and retrograde are often used in combination. Depending on the time required for surgical repair, multiple injections of cardioplegia may be necessary to wash out metabolic by-products, add new high-energy and oxygen-carrying substrates, and maintain hypothermic diastolic arrest. There is gaining interest in single-dose cardioplegia solutions such as del Nido cardioplegia. This agent is administered once and is has been reported to protect aged cardiomyocytes during cardioplegic arrest and reperfusion.<sup>107</sup>

For the anesthesiologist monitoring a patient on CPB, the sentinel events of cardioplegic electrical arrest and resumption of electrical activity must be observed closely. LV distention and lack of rapid electrical arrest may be evidence of poor myocardial protection and the possibility of difficulty in separation from CPB. TEE is particularly helpful in diagnosing ventricular distention and its relief by venting or manual decompression of the LV.

## Preoperative and Intraoperative Management

The preoperative visit should focus on the cardiovascular system but should not disregard the assessment of pulmonary, renal, hepatic, neurologic, endocrine, and hematologic functions. The depth and detail of the explanation should be custom-tailored to each patient and the anticipated events from transport to the operating room until emergence should be discussed with the patient.

**Table 39-10** Preoperative Findings Suggestive of Ventricular Dysfunction

<p><b>History</b>            CAD: previous MI, chest pain/pressure            CHF (intermittent or chronic): fatigue, DOE, orthopnea, PND, ankle swelling</p> <p><b>Physical Examination</b>            Vital signs: hypotension, tachycardia (severe CHF)            Engorged neck veins, apical impulse displaced laterally, S<sub>3</sub>, S<sub>4</sub>, rales, pitting edema, pulsatile liver, ascites</p> <p><b>Electrocardiogram</b>            Ischemia/infarct, rhythm, conduction abnormalities</p> <p><b>Chest Radiography</b>            Cardiomegaly, pulmonary vascular congestion/pulmonary edema, pleural effusion, Kerley B lines</p> <p><b>Cardiovascular Testing</b>            Catheterization data: LVEDP &gt;18 mmHg, EF &lt;0.4, CI &lt;2.0 L/min/m<sup>2</sup></p>
------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

CAD, coronary artery disease; MI, myocardial infarction; CHF, congestive heart failure; DOE, dyspnea on exertion; PND, paroxysmal nocturnal dyspnea; LVEDP, left ventricular end-diastolic pressure; EF, ejection fraction; CI, cardiac index.

Pertinent findings suggestive angina or ischemia-induced left and/or right ventricular dysfunction ([Table 39-10](#)), should be integrated to plan for monitoring and anesthetic techniques.

It is important to evaluate for conditions commonly associated with heart disease, such as hypertension, diabetes mellitus, and cigarette smoking, as well as the presence of pulmonary hypertension. Higher systemic arterial pressures may be desirable throughout surgery in patients with a history hypertension or evidence of carotid artery disease. Renal function must also be evaluated, since it is commonly affected postoperative.

### *Current Drug Therapy*

Almost without exception all cardiovascular drugs are continued until the time of surgery.<sup>108</sup> Interactions between these drugs and anesthetics are more often beneficial than harmful in maintaining hemodynamic control during periods of surgical stress and reducing morbidity and mortality. Contrary to common belief, there is a potential long-term benefit of ACE inhibitors provided that dosing is adjusted so that hypotension is avoided.<sup>109</sup> On the other hand, the protracted hypotension encountered on bypass and associated with poor outcome has been associated with preoperative  $\beta$ -blockers or calcium channel blockers.<sup>110</sup> Most cardiac antidysrhythmics should also be continued to the time of surgery.

### *Physical Examination*

Physical examination should be part of the preoperative evaluation; signs of cardiac decompensation such as an S<sub>3</sub> gallop, rales, jugular venous distention, or pulsatile liver should be sought. Routes for vascular access should be assessed, and the pulse of peripheral arteries should be evaluated. As always, the airway should be carefully evaluated with respect to ease of mask ventilation and tracheal intubation. Other pertinent points are described in [Table 39-11](#).

**Table 39-11** Preoperative Physical Examination

Parameter	Scope
Vital signs	Current values and range
Height, weight	For calculations of drug dosages, pump flow, cardiac index
Airway	Evaluate, identify difficulties for ventilation, intubation
Neck	Landmarks for jugular vein cannulation Vein engorgement (CHF) Bruits (carotid artery disease)
Heart	Murmurs: Characteristic of valve lesions, S <sub>3</sub> (elevated LVEDP), S <sub>4</sub> (decreased compliance), click (MVP prolapse) Lateral PMI displacement (cardiomegaly) Precordial heave, lift (hypertrophy, wall motion abnormality)
Lungs	Rales (CHF) Rhonchi, wheezes (COPD, asthma)
Vasculature	Peripheral pulses Sites for venous and arterial access
Abdomen	Pulsatile liver (CHF, tricuspid regurgitation)
Extremities	Peripheral edema (CHF)
Nervous system	Motor or sensory deficits

CHF, congestive heart failure; LVEDP, left ventricular end-diastolic pressure; MVP, mitral valve prolapse; PMI, point of maximal impulse; COPD, chronic obstructive pulmonary disease.

## Premedication

These days, sedation is almost always given in the operating room after completion of regulatory paperwork. Premedication will assist in providing a calm, anxiety-free, arousable, and hemodynamically stable patient who is prepared for surgery. Selection of drug and dosage depends on the patient's age, cardiovascular state, level of anxiety, and location. Although heavy premedication is ideal there is inadequate time for premedication for the same-day-admit patient. Inadequate sedation may predispose to hypertension, tachycardia, or coronary vasospasm, and precipitate myocardial ischemia.

## Monitoring

We emphasize only those aspects of monitoring particularly relevant to cardiac surgery because other monitoring techniques used commonly in cardiac surgery and other procedures are discussed extensively in [Chapters 26](#) and [37](#).

## Pulse Oximeter

Vascular cannulations may be challenging and the preinduction period may be

prolonged. The pulse oximeter should be the first monitor placed to detect clinically unsuspected episodes of hypoxemia and tachycardia during the preinduction period.

## **Electrocardiogram**

Regional ischemia may be diagnosed by appropriate lead monitoring: Lead II (and/or leads III, aVF) for the inferior myocardium (right coronary artery distribution), leads V<sub>4</sub> or V<sub>5</sub> for the anterior myocardium (left anterior descending [LAD] artery), and leads I and aVL for the lateral LV myocardial walls (circumflex artery). A strip-chart recorder or the “freeze pane” function of the hemodynamic monitor is useful for analysis and documentation of ST segment alterations and complex dysrhythmias.

## **Temperature**

Central temperature can be measured with urinary bladder catheter or with a thermistor from a PAC.<sup>111</sup> Depending upon the case, nasopharyngeal or tympanic temperature probes may be used (as in cases of deep hypothermic circulatory arrest). Rectal and skin probes record peripheral temperatures, which lag behind central measurements during both cooling and rewarming periods.

## **Arterial Blood Pressure**

Systemic arterial pressure should always be monitored invasively. The radial artery is usually cannulated,<sup>112</sup> although the femoral, brachial, and axillary arteries may also be used. The exact site is often a matter of personal or institutional preference. Criteria include convenience, selection of the arterial site with the “fullest” or most bounding pulse, and avoidance of the dominant hand. Occasionally, the site of surgery dictates appropriate placement; for example, the right radial artery should be used for procedures involving the descending thoracic aorta because the left subclavian artery may be included in the proximal aortic clamp. Following CPB, radial artery pressure is often misleading and may be as much as 30 mmHg lower than central aortic pressure. The mechanism may be due to peripheral vasodilation during rewarming or marked vasoconstriction.<sup>113</sup> Whenever a pressure discrepancy is suspected, the central aortic pressure should be estimated (by palpation by the surgeon) or directly measured (via femoral artery catheterization or with a needle placed directly into the aorta). Timely recognition will avoid unnecessary treatment of presumed hypotension. The gradient usually disappears within 45 minutes of separation from bypass. The optimal management of blood pressure during and immediately after CPB remains

## Central Venous Pressure and Pulmonary Artery Catheter

Access to the central circulation is mandatory for infusion of cardioactive drugs. In addition, right atrial (RAP) or central venous pressure (CVP) reflect right ventricular filling pressure and is of critical importance whenever right ventricular dysfunction is suspected. The relationship between the transduced RAP and the LV filling pressure is less predictable, more so in the presence of severe LV failure, pulmonary hypertension, or reduced LV compliance. The insertion of a PAC provides a better estimation of LV filling via measurement of the pulmonary capillary wedge pressure, although TEE data are far more accurate, because the actual volume can be better estimated. The PAC-facilitated calculation of stroke volume, cardiac output, PVR, and SVR offer additional information to guide hemodynamic and anesthetic management.

Indications for PAC insertion vary greatly among institutions.<sup>22</sup> In some, PAC are used routinely, whereas in others they are limited to patients with severe cardiac dysfunction or pulmonary hypertension. Insertion of a pacing PAC can be helpful whenever exact control of rate and rhythm is desirable before access to the epicardium is possible, for example, in patients with hypertrophic cardiomyopathy or those with significant bradycardia secondary to  $\beta$ -blockade. Before preinduction insertion of the PAC, in order to determine the baseline hemodynamics prior to the anesthetic induction, one should consider the anxiety and discomfort it may cause the patient.

The PAC often migrates distally with cardiac manipulation, as well as with acute preload changes. Therefore, it is prudent to pull the PAC back a few centimeters prior to the initiation of CPB to prevent permanent wedging or possible pulmonary artery rupture.<sup>115</sup> Despite the controversy concerning the routine use of these catheters, there is no disagreement that the capability to estimate or measure cardiac output and ventricular filling pressures must be available in any institution performing cardiac surgery.<sup>65</sup> Whether this is done with a PAC or TEE is immaterial. At any time, the ability of the practitioner to interpret correctly the PAC or TEE data cannot be overemphasized.

## Echocardiography

The detection of ischemia by real-time evaluation of new regional wall motion abnormalities and the assessment of valvular function (before and after intervention) and of the ascending aorta with TEE have been mentioned. It is well known that, following CPB, the LV filling pressure, irrespective of the site of measurement (LV end-diastolic pressure, LA, pulmonary capillary wedge pressure), is a poor and often misleading indicator of LV volume status.<sup>116</sup> The estimation of LV volume with TEE should direct fluid infusion

and selection of vasoactive drugs, particularly in patients who are difficult to wean from CPB. In addition, residual valve lesions, intracardiac air, or new areas of ischemia or global dysfunction (due to prolonged CPB, inadequate cardioplegia or reperfusion injury) can be detected with TEE. Please see [Chapter 27](#) for a review of TEE applications.

## **Central Nervous System Function and Complications**

Monitoring of the brain during CPB is difficult because of lack of standardized equipment or criteria. Neurologic complications after cardiac surgery can be devastating. The 1- and 5-year survival rates after stroke are about 65% and 45%, respectively, compared with more than 90% and 80% to 85% for patients not having stroke.<sup>117</sup> Many investigators have focused on methods to determine the etiology and improve the detection, prevention, and treatment of postoperative neurologic complications in patients undergoing cardiac surgery. The incidence of stroke after CABG surgery ranges from less than 1% (for patients <64 years) to more than 5% to 9% (for patients >65 years).<sup>118</sup> The incidence of subtle cognitive deficits that can be elicited by detailed neuropsychometric testing is much higher (60% to 70%). It is known that the neuropsychiatric deficits do improve over the initial 2 to 6 months after cardiac surgery; however, a significant percentage of patients (13% to 39%) have residual impairment. The etiology of perioperative neurologic complications is believed to be predominantly due to emboli (air, atheroma, other particulate matter) and not to hypoperfusion in susceptible patients (e.g., pre-existing cerebrovascular disease). Most overt strokes after cardiac surgery are focal and likely due to macroemboli, whereas the cognitive changes are subtle and probably result from microemboli. Risk factors for neurologic complications include advanced age (>70 years), pre-existing cerebrovascular disease (e.g., carotid artery stenosis >80%), history of prior stroke, peripheral vascular disease, ascending aortic atheroma, and diabetes. Operative factors include the duration of CPB, intracardiac procedure (e.g., valve replacement), excessive warming during and following CPB, and perhaps perfusion pressure on CPB.<sup>119,120</sup> Intraoperative hyperglycemia, which could theoretically result in worsened neurologic damage, has not been associated with poorer neurologic outcome.

The role of TEE in evaluating the ascending and descending aorta has been described previously. Management options for patients with severely diseased aortas, especially those with mobile atheromas who are at increased risk of stroke, include hypothermic fibrillatory arrest with LV vent and no aortic cross-clamp, single cross-clamp (i.e., distal and proximal grafts performed during same cross-clamp), relocation of proximal grafts to area of nondiseased aorta, no proximal grafts (internal mammary arteries only) either on CPB or

using off-pump coronary artery bypass, or hypothermic circulatory arrest with resection and graft replacement of the diseased aortic segment. The technical means for cerebral protection such as the use of 20- to 40- $\mu$ m arterial line filters and membrane oxygenators, newer modifications of the basic CPB apparatus, or the use of specialized equipment or procedures (including hypothermia and “tight” glucose control) have unproven benefit on neurologic outcomes.<sup>121</sup> Hypothermia is excellent in that it decreases cerebral metabolic rate and prolongs ischemic tolerance. However, during routine CPB the patient is normothermic when the risk of embolization is highest: during rewarming and unclamping of the aorta and with initial ventricular ejection.

### *Selection of Anesthetic Drugs*

The choice of anesthetic has no effect on the outcome in CABG patients, as shown by Tuman<sup>122</sup> and Slogoff.<sup>123</sup> The most critical factor governing the selection and dose of the anesthetics and adjuvants is the degree of ventricular dysfunction. Any anticipated difficulties during tracheal intubation, the expected duration of surgery, and the anticipated time of tracheal extubation should be considered as well. The anesthetic depth should be rapidly adjustable, so as to counteract the varying intensity of surgical stress. The most intense stimulation and sympathetic response is expected during tracheal intubation, incision, sternotomy, pericardiotomy, and manipulation of the aorta. On the other hand, the period of preparing and draping following intubation of the trachea requires minimal levels of anesthetic, as does the period of hypothermic bypass. **10**

Nowadays, volatile anesthetics are used as primary anesthetics and as adjuvants to prevent or treat “breakthrough” hypertension. They favorably balance the myocardial oxygen supply and demand by reducing contractility and afterload. At the same time, any unwanted declines in coronary perfusion pressure must be prevented or treated. Volatile agents have been used successfully in all types of valve surgery without untoward effects, although they are sometimes associated with more hemodynamic variability than is seen with opioids. Volatile anesthetics have been associated with cardioprotective effects from ischemia and reperfusion and allow for more rapid recovery of contractile function on reperfusion.<sup>11</sup> The ability to rapidly increase and decrease the alveolar concentration allows easy adjustment to the variable levels of surgical stimulation. Volatile anesthetics are also administered during CPB through a vaporizer mounted on the pump; they are also appropriate in the postbypass period, assuming cardiac function is **11** adequate. The use of volatile anesthetics in combination with short-acting opiates or hypnotics is more relevant nowadays, because of the relatively “fast-track” postoperative treatment.

## Opioids

Opioids lack negative inotropic effects in the doses used clinically and have thus found widespread use as the primary agents for cardiac surgery. This era began in 1969, when high doses of morphine were used to anesthetize patients for AV replacement.<sup>35</sup> However, hypotension, histamine release, increased fluid requirements, and, often, inadequate anesthesia resulted in a decline in the use of morphine in favor of the more potent fentanyl and its analogues. Aside from bradycardia, fentanyl and its analogues are relatively devoid of cardiovascular effects and have proved to be effective anesthetics. As a primary anesthetic agent, fentanyl (50 to 100 µg/kg) or sufentanil (10 to 20 µg/kg) and oxygen provide hemodynamic stability, although they do not consistently prevent a hypertensive response to periods of increased surgical stimulation. The use of high-dose opioids prolongs the time until emergence and extubation when compared with techniques primarily based on volatile anesthetics and is no longer in fashion. In addition, although high doses of opioids produce unconsciousness and characteristic electrocardiographic slowing, recall of intraoperative events is not eliminated. Therefore, a current-era cardiac anesthetic includes benzodiazepines to provide amnesia and volatile anesthetics or vasodilators to control hypertension. Superiority of any one opioid has not been demonstrated for either coronary or valvular surgery. Remifentanyl, an ultrashort-acting opioid, undergoes hydrolysis by nonspecific esterases in minutes. Its predictable and rapid elimination is unaffected by hepatic or renal disease, making it an optimal drug for infusion techniques. Combinations of the fentanyl-type drugs and benzodiazepines, whether given concomitantly or as premedication, result in hypotension secondary to a fall in SVR. Any opioid in high doses can produce excessive bradycardia. Abdominal and chest wall rigidity commonly occur with rapid injection of high doses of opioids and can be severe enough to render ventilation impossible. A low dose (priming) of nondepolarizing muscle relaxant should be given prior to a high-dose opioid administration.

## Induction Drugs

Benzodiazepines, barbiturates, propofol, and etomidate can be used as supplements to either inhalation or opioid anesthetics, or as sole induction drugs in patients with cardiac disease depending on the adequacy of ventricular function and baseline sympathetic tone. All dosages must be altered to fit the clinical situation. Etomidate is favored for induction in patients with limited cardiac reserve, but rarely administered repeatedly or for prolonged periods because of the risk of adrenal dysfunction associated with prolonged use.

## Neuromuscular Blocking Drugs

Muscle relaxants are components of a balanced anesthetic for cardiac surgery. Although they are not essential to surgical exposure of the heart, muscle paralysis facilitates intubation of the trachea and attenuates skeletal muscle contraction during defibrillation. They are necessary to prevent or treat opioid-induced truncal rigidity. The chief criteria for selection are the hemodynamic and pharmacokinetic properties associated with each relaxant, the patient's myocardial function, the presence of coexisting disease, current pharmacologic regimen, and anesthetic technique.<sup>124</sup>

### *Intraoperative Management*

In this section we describe the anesthetic management of a patient undergoing a cardiac surgical procedure from the time of arrival in the operating room until his/her care is transferred to ICU personnel. Anticipation of needs specific to each stage of the procedure and immediate availability of necessary equipment and medications prevent untoward hemodynamic aberrations and last-minute rushed decisions.

### **Preparation**

The operating room must be readied prior to arrival of the patient. Heparin may be drawn up prior to induction of anesthesia in the unlikely event of the need to “crash” onto CPB. Typed and cross-matched blood should be available in the operating suite. [Table 39-12](#) provides a checklist to aid in proper preoperative preparation of the operating room.

**Table 39-12 Anesthetic Preparation for Cardiac Surgery**

<b>Anesthesia Machine</b>
Routine check
<b>Airway</b>
Nasal cannula for O <sub>2</sub>
Ventilation/intubation equipment, including difficult airway devices
Suction
Inspired gas humidifier
<b>Circulatory Access</b>
Catheters (peripheral and central venous and arterial access)
Intravenous fluids and infusion tubing and pumps
Fluids warmer
<b>Monitors</b>
Standard ASA: ECG leads, blood pressure cuff, pulse oximeter, neuromuscular blockade monitor
Temperature probes (nasal, tympanic, bladder, rectal)
Transducers (arterial, pulmonary, and central venous pressure) zeroed and functioning
Cardiac output computer: Proper constant inserted
Awareness monitor (BIS)
Anticoagulation (ACT) monitor(s)
Recorder/printer
<b>Medications</b>
General anesthetic: hypnotic/induction, amnestic/benzodiazepine, volatile, opioid, muscle relaxant
Heparin (predrawn)
Cardioactive
• Predrawn: nitroglycerin/nicardipine, CaCl <sub>2</sub> , phenylephrine/ephedrine, epinephrine
• Infusions: nitroglycerin, inotrope
Antibiotics
<b>Miscellaneous</b>
Pacemaker with battery
Defibrillator/cardioverter with external paddles and ECG cables
Ultrasound system for central venous line insertion
Compatible blood in operating room

ASA, American Society of Anesthesiologists; ECG, electrocardiogram; BIS, bispectral index; ACT, activated clotting time.

## Preinduction Period

The patient's general status and level of anxiety and the effectiveness of premedication (if ordered) should be assessed prior to entry to the operating room. Peripheral oxygen saturation monitor, ECG leads, and noninvasive blood pressure cuff are placed, and a set of baseline vital signs are recorded. Any angina should be promptly treated with supplemental oxygen, additional sedation, intravenous nitroglycerin, or, if related to anxiety-induced hypertension or tachycardia, with  $\beta$ -blocker and prompt induction of general anesthesia if possible.

Peripheral intravenous cannulae are inserted after site infiltration with local anesthetic (additional routes for infusion are desirable in patients

undergoing repeat cardiac surgery). Although some anesthesiologists induce anesthesia and insert arterial and central venous cannulas following tracheal intubation, others prefer to have one or both of these cannulae inserted prior to induction of anesthesia. Preinduction or postinduction insertion of central venous or PAC has been discussed previously. Surface ultrasound for central venous access should be the standard practice, and at all times sterile barrier technique should be adhered to.<sup>125,126</sup> Once hemodynamic monitoring is established, baseline values for all pressures and cardiac output should be recorded, and baseline determinations of arterial blood gases, hematocrit, blood glucose, and activated coagulation time should be obtained.

Throughout the preinduction period, the anesthesiologist must never divert his or her attention from the patient. Continuous monitoring of the vital signs, careful observation of the patient, and periodic verbal contact facilitate detection of hemodynamic or ECG abnormalities, increased anxiety, or excessive response to intravenous sedation.

## **Induction and Intubation**

The exact choice and sequence of drugs are a subtle—sometimes not so subtle—combination of art and science. The choice of specific agents (e.g., sedative, opioid, volatile drug, muscle relaxant), dose, and speed of administration depends primarily on the patient's cardiovascular reserve and desired cardiovascular profile. A smooth transition from consciousness to blissful sleep is desired without untoward airway difficulties (e.g., coughing, laryngospasm, truncal rigidity) or hemodynamic responses (e.g., hypotension from relative overdose, loss of sympathetic tone, or myocardial depression; hypertension caused by airway insertion; or jaw thrust). A “slow cardiac induction” sometimes causes, rather than alleviates, these potential problems. However, awake tracheal intubation, after proper sedation, may be appropriate in an obese patient with a wide neck if ventilation and intubation appear to be difficult. The necessity for individual approach to each patient cannot be overemphasized.

Deep planes of anesthesia, brief duration of laryngoscopy, and innumerable pharmacologic regimens have been proposed for eliminating the hypertension and tachycardia associated with intubation of the trachea. None is uniformly successful, and all drug interventions carry some degree of risk, even though they may be small. In patients with a slow heart rate prior to induction of anesthesia, the reflex response to tracheal intubation is primarily vagal, and severe bradycardia and rarely sinus arrest can occur. Identification of persistently abnormal hemodynamics or ischemia should be sought and treated.

## **Preincision Period**

The period of time from tracheal intubation until skin incision is one of minimal stimulation as the surgical team attends to insertion of a urinary bladder catheter, temperature probe, positioning, preparing, and draping. As a result, hypotension often develops, regardless of the anesthetic used. It may be necessary to reduce the anesthetic depth or alternatively support the systemic pressure with a vasoconstrictor. The potential risks of vasoconstriction in patients with poor left or right ventricular performance must be kept in mind. The anesthetic depth should be increased immediately prior to incision and sternotomy.

## **Incision to Bypass**

As previously emphasized, the prebypass period is characterized by periods of intense surgical stimulation that may cause hypertension and tachycardia, or induce ischemia. Anticipating these events and deepening the anesthetic may be effective, but a vasodilator or other adjuvant is often required. Hypotension can occur during the less stressful moments before CPB, but it is more commonly associated with cardiac manipulation in preparation for, and during, atrial cannulation. This may interfere with venous return or produce episodic ectopic beats or sustained supraventricular dysrhythmias, and atrial fibrillation is not uncommon. Depending on the blood pressure and heart rate response, appropriate treatment may range from observation to vasoconstrictors, cardioversion, or rapid cannulation and institution of bypass. Maintaining adequate intravascular volume may attenuate the extent of hypotension. This is a critical period, and continuous observation of the surgical field is essential.

It is important to identify any new ischemia pre bypass with ST segment analysis and frequent TEE examination. If it occurs, it should be treated appropriately and the surgeon notified. Communication between the anesthesiologist and the surgeon is necessary to keep both apprised of the situation and to ensure the heart gets a periodic “rest during periods of manipulation.” In rare cases of inadvertent injury of a cardiac chamber and uncontrollable bleeding, heparin is administered and CPB commences via femoral vessel cannulation, using field suction as the major means of venous return.

## **Cardiopulmonary Bypass**

After heparin administration, the cannulae are inserted, and adequate levels of anticoagulation are checked to ensure the patient is ready for the institution of CPB ([Table 39-13](#)). Attention is focused on adequacy of venous

drainage (no pulsatility on CVP or PA waveforms), unobstructed arterial return (appropriate systemic arterial pressure), sufficient gas exchange, and provision of necessary anesthetics and muscle relaxants. The anesthetic requirements are decreased if systemic hypothermia is used.

Once full CPB is established, it is no longer necessary to ventilate the lungs. During the initial minutes of CPB, systemic arterial pressure initially drops to 30 to 40 mmHg as pulsatile flow ceases and the hemodilution effect of the CPB prime becomes apparent. Once adequate mixing is obtained, blood pressure increases to levels determined primarily by flow rate, and secondarily by total vascular resistance (Table 39-14). There is no consensus as to what constitutes the ideal blood pressure or flow rate for adequate vital organ perfusion, especially of the brain, during bypass.<sup>114</sup> Commonly, flow rates are maintained at approximately 50 to 60 mL/kg/min, with systemic blood pressures in the 50 to 60 mmHg range, whereas some believe that older patients benefit from a higher blood pressure (>70 mmHg).<sup>127</sup>

### Monitoring and Management during Bypass

The common causes of blood pressure changes during CPB are listed in Table 39-14. Of primary importance is continuous observation of the surgical field and cannulae to exclude mechanical obstruction to flow. Attention can then be directed to other causes of hypotension or hypertension and their treatment. Additional areas that require periodic monitoring and occasional intervention during CPB are also described in Table 39-14. Maintenance of adequate depths of anesthesia is obviously important during CPB, although clinical signs are few. Anesthetic requirements are decreased during the period of hypothermia but return toward normal when the patient is rewarmed.

**Table 39-13** Checklist before Initiating Cardiopulmonary Bypass

<p><b>Laboratory Values</b></p> <p>Heparinization adequate (ACT or other method)</p> <p>Hematocrit</p> <p><b>Anesthetic</b></p> <p>Maintenance: amnestics, opioids, muscle relaxants are supplemented</p> <p><b>Monitors</b></p> <p>Arterial pressure: initial hypotension (followed by recovery)</p> <p>CVP: if low, indicates adequate venous drainage</p> <p>PCWP: if elevated, indicated LV distention (inadequate drainage, AI)</p> <p>Pull back PAC 1–2 cm</p>	<p><b>Patient/field</b></p> <p>Cannulae in place</p> <ul style="list-style-type: none"> <li>• No kinks or clamps or air locks</li> <li>• Arterial cannula is free of bubbles</li> </ul> <p>Face</p> <ul style="list-style-type: none"> <li>• Suffusion? ACT, activated clotting time; CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure; LV, left ventricle; AI, aortic insufficiency; PAC, pulmonary artery catheter; SVC, superior vena cava.

Arterial pH and mixed venous oxygen saturation, often measured online,

are used to assess the adequacy of perfusion. Urine output is monitored, but it is influenced by so many variables (e.g., arterial and venous pressure, flow rate, temperature, diuretic history) that it is difficult to draw meaningful conclusions from this measurement.<sup>128</sup> In addition, postoperative renal failure develops from either aggravation of pre-existing renal dysfunction or persistent low cardiac output following bypass. Although many institutions administer diuretics routinely, they are just as assiduously avoided elsewhere.

**Table 39-14** Checklist during Cardiopulmonary Bypass

Laboratory values	Heparinization adequate ABGs Hematocrit, Na <sup>+</sup> , K <sup>+</sup> , ionized Ca <sup>2+</sup> , glucose	ACT or other method Is there acidosis?
Anesthetic	Discontinue ventilation	
Monitors		
Arterial hypotension	Inadequate venous return  Pump Arterial cannula Decreased vascular tone Transducer/monitor malfunction	Venous cannula malposition, clamp, kink, air lock Bleeding, hypovolemia, IVC obstruction, table too low Poor occlusion, low flow Misdirected, kinked, partially clamped, aortic dissection Anesthetics, hemodilution, idiopathic Radial artery cannula malpositioned, dampened waveform
Arterial hypertension	Pump Arterial cannula Vasoconstriction Transducer/monitor malfunction:	High flow Misdirected Light anesthetic plane, response to hypothermia Radial artery cannula malpositioned/kinked
Venous pressure	Decreased Increased	Transducer higher than atrial level? True obstruction of chamber drainage (CVP: Right, PCWP/ LA: left heart)
Adequate body perfusion	Flow and pressure? Acidosis Mixed venous blood oxygen saturation	
Temperature		
Urine output		
Patient/field	Heart Cyanosis, venous engorgement, skin temperature Movement Signs of light anesthesia/hypercapnia	Distention, fibrillation  Breathing/diaphragmatic movement
Support	Assist/adequacy of pump flow	Anesthetics/vasodilators for hypertension Constrictors for hypotension

ACT, activated clotting time; ABGs, arterial blood gases; IVC, inferior vena cava; CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure; LA, left atrium; EEG, electroencephalogram.

## Rewarming

When surgical repair is nearly complete, gradual rewarming of the patient begins. A gradient of 4° to 6°C is maintained between the patient and the perfusate to prevent formation of gas bubbles, and blood temperature should be less than 37°C. A slower rate of rewarming has been associated with better cognitive function 6 weeks post CABG surgery.<sup>129</sup> Patient awareness becomes a possibility as the potentiation of anesthetic effects due to hypothermia dissipates. If adequate doses of anesthetics have not been given, administration during rewarming should be considered to prevent recall of intraoperative events. Targeting an end-tidal concentration of the inhaled

agent between 0.7 and 1.3 MAC is as effective as maintaining a BIS value between 40 and 60.<sup>130</sup> Use of volatile anesthetics is helpful if a smooth CPB course is anticipated and early weaning from mechanical ventilation and tracheal extubation are planned. On completion of the surgical repair any residual intracardiac air is removed as the anesthesiologist is vigorously ventilating the lungs to remove air from the pulmonary veins and aid in filling the cardiac chambers. TEE is particularly useful in assessing the effectiveness of the de-airing process. The heart is defibrillated (if needed) and externally paced or allowed to beat (if native rhythm is present) in preparation to separate from CPB.

### **Discontinuation of Cardiopulmonary Bypass**

Prior to discontinuing CPB, the patient should be normothermic, no frank surgical bleeding must be present, the appropriate ABG values must be checked, the pulmonary compliance must be evaluated, and ventilation of the lungs must begun (Table 39-15). If necessary, heart rate and rhythm are regulated either pharmacologically or electrically (appropriate pacing, defibrillation, cardioversion), and vasoactive infusions started. The venous cannula(e) are then occluded incrementally and sufficient pump volume is transfused into the patient, while the bypass flow is slowly decreased (Fig. 39-9). During this time, the cardiac function is constantly evaluated from hemodynamic and TEE data and direct inspection of the heart, and the need for vasoactive or cardioactive drugs is re-assessed. The potential disparity between radial artery and aortic pressures must be kept in mind. Contractility, rhythm, and ventricular filling are continuously evaluated by careful observation of the beating heart and TEE. For example, a low blood pressure and a vigorously contracting, relatively empty ventricle suggest that volume and perhaps a vasoconstrictor are all that is needed to wean the patient from CPB, whereas adequate blood pressure in the presence of a sluggish and overdistended heart may be treated with a vasodilator and/or a small dose of an inotrope. Figure 39-10 presents a general approach to termination of CPB.

Inadequate cardiac performance must prompt a search for possible causes (Table 39-16); structural defects require more than mere regulation of inotropes or vasodilators. If the clinical picture is suggestive of coronary air emboli with diffuse ST segment elevation and a hypocontractile heart, continuous support on CPB with a high perfusion pressure and an unloaded ventricle is indicated to expel the air bubbles from the coronary circulation.

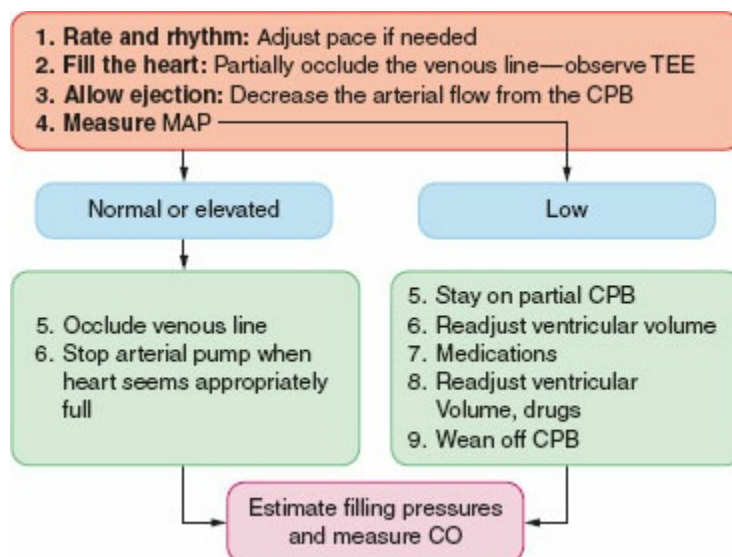

**Table 39-15** Checklist before Separation from Cardiopulmonary Bypass

<b>Laboratory Values</b>
Hematocrit, ABGs
K <sup>+</sup> : possibly elevated (cardioplegia)
Ionized Ca <sup>2+</sup>
<b>Anesthetic/machine</b>
Lung compliance: Evaluate (hand ventilation)
Lungs are expanded, no atelectasis, both are ventilated (manual or mechanical)
Vaporizers: Off
Alarms: On
<b>Monitors</b>
Normothermia (37°C nasopharyngeal, 35.5°C bladder, 35°C rectal)
ECG: Rate, rhythm, ST
Transducers re-zeroed and leveled
Arterial and filling pressures
Recorder (if available)
<b>Patient/field</b>
<i>Look at the heart!</i>
De-aired: Check lead II, TEE
Eyeball contractility, size, rhythm
LV vent clamped/removed, caval snares released
Bleeding: No major sites (grafts, suture lines, LV vent site)
Vascular resistance: CPB flow $\propto$ MAP + resistance
<b>Support</b>
As needed

ABGs, arterial blood gases; ECG, electrocardiogram; TEE, transesophageal echocardiography; LV, left ventricle; CPB, cardiopulmonary bypass; MAP, mean arterial pressure.

**Figure 39-9** Weaning from cardiopulmonary bypass. While on cardiopulmonary bypass (CPB), the venous return to the heart is diverted from the right atrium (RA) to the CPB reservoir. The drainage is passive (by gravity). From the venous reservoir, the blood is “ventilated,” CO<sub>2</sub> is removed, and O<sub>2</sub> is added, and then returned to the patient, usually into the aorta but occasionally via the femoral or axillary arteries. During weaning from CPB, the venous return to the CPB is reduced by gradually occluding the venous cannula, directing more of its contents to the right heart and lungs. LV, left ventricle.

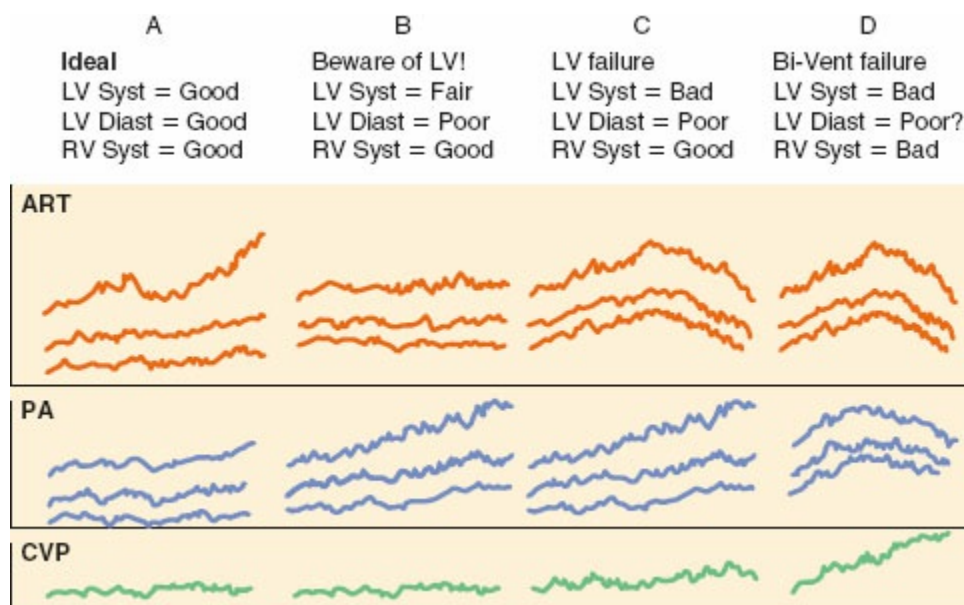

**Figure 39-10** General approach to termination of cardiopulmonary bypass (CPB). TEE, transesophageal echocardiographic; MAP, mean arterial pressure; CO, cardiac output.

An approach to patients with inadequate cardiac output is summarized in [Table 39-17](#). The heart rate is adjusted first. Following that, ventricular filling is optimized by transfusing blood from the CPB pump. It is important not to overdistend the heart by transfusing to an arbitrary level of filling pressure because this may result in further myocardial dysfunction. It is important to image the cardiac chambers by TEE and directly look at the heart when **12** evaluating the response to small incremental volume infusions. The ratio of systemic to pulmonary artery pressure is also helpful<sup>131</sup>; if increasing, the pulmonary artery pressure should increase at the same degree/rate as the systemic pressure ([Fig. 39-11A](#)). Change in opposite directions (e.g., pulmonary pressure increases and systemic pressure decreases; see [Fig. 39-11C](#)) is suggestive of LV failure, whereas an increasing CVP and decreasing pulmonary artery pressure indicate right ventricular failure.

If pharmacologic support is required, an integration of cardiac physiology (see [Chapter 12](#)) and pharmacology will lead to an appropriate selection. Numerous algorithms are available to guide decision making; one is presented in [Figure 39-12](#). This algorithm uses systemic arterial and pulmonary artery pressures and cardiac output. If TEE is available, myocardial contractility and valvular function can be more readily assessed. After integrating available data, a diagnosis is made and appropriate treatment is begun. Continual reassessment of the situation is necessary to document the efficacy of treatment or to suggest new diagnoses and therapeutic approaches. If cardiac output is low and systemic pressure is adequate ([Fig. 39-12A](#)), an arteriolar dilator may improve forward flow by decreasing afterload. If systemic pressure is too low ([Fig. 32-12C and D](#)), thus prohibiting the use of vasodilators, an inotrope should be selected instead. Each inotropic drug has a distinct profile with respect to its effects on rate, contractility, SVR and PVR,

and cardiac dysrhythmogenic potential (Table 39-18). If these initial therapies are insufficient to promote adequate forward flow, various combinations of drugs may be tested. If systemic perfusion is still inadequate, mechanical circulatory support (MCS) is required.

**Figure 39-11** Hemodynamic abnormalities on termination of cardiopulmonary bypass. LV, left ventricle; syst, systolic; diast, diastolic; RV, right ventricle; ART, arterial pressure; PA, pulmonary artery; CVP, central venous pressure.

**Table 39-16** Etiology of Right or Left Ventricular Dysfunction after Cardiopulmonary Bypass

<b>Ischemia</b>
Inadequate myocardial protection
Intraoperative infarction
Reperfusion injury
Coronary spasm
Coronary embolism (air, thrombus, calcium)
Technical difficulties (kinked or clotted grafts)
<b>Uncorrected Structural Defects</b>
Nongraftable vessels, diffuse coronary artery disease
Residual or new valve pathology
Hypertrophic cardiomyopathy
Shunts
Preexisting cardiac dysfunction
<b>CPB-related Factors</b>
Excessive cardioplegia
Unrecognized cardiac distention

A therapeutic approach to right ventricular failure (Fig. 39-12D) is outlined in Table 39-19. When pulmonary arterial pressure is normal or decreased, the cause is usually severe right ventricular ischemia secondary to intraoperative events or air. The initial response is to return to full CPB, improve perfusion, and await recovery and improvement of contractility. If

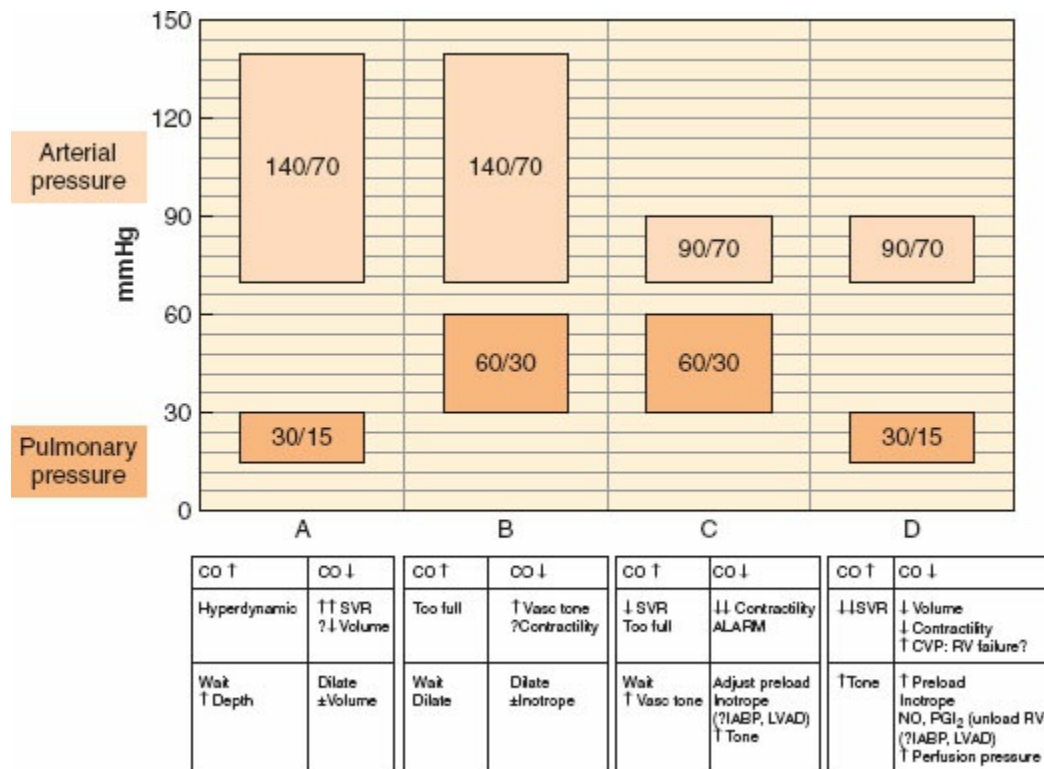

this does not occur, inotropic and vasodilator therapy is established. In patients who have right ventricular failure secondary to high PVR, the mainstay of therapy is reduction of PVR with vasodilators, such as inhaled prostaglandin I<sub>2</sub> (PGE<sub>2</sub>) or nitric oxide, and inotropic support. The phosphodiesterase III inhibitors, amrinone and milrinone, are particularly useful because they significantly decrease PVR and increase contractility. Overdistention of the ventricle must be assiduously avoided. Combination therapy with differential infusions refers to infusion of inotropes with vasoconstrictive properties into the left side of the circulation to maintain systemic perfusion, while avoiding an increase of the pulmonary circulation resistance. Persistent right ventricular failure precluding separation from CPB may require the insertion of a right ventricular assist device (RVAD).

**Table 39-17** Steps for Improving Systemic Flow

1	Heart rate (A-, V-, A/V-pacing) and rhythm
2	Preload: Optimize (beware of altered compliance postbypass)
3-4	Afterload reduction if blood pressure is high and/or contractility augmentation (inotrope if low CO)
5	Preload: Recheck and adjust
6	Combine therapies
7	IABP
8	VAD

A, atrial; V, ventricular; CO, cardiac output; IABP, intra-aortic balloon pump; VAD, ventricular assist device.

Retrospective studies of patients undergoing CABG either alone or in combination with valve surgery showed that wall motion score index, combined CABG and mitral valve surgery, LV ejection fraction more than 35%, reoperation, moderate-to-severe MR, and aortic cross-clamp time were independent predictors for use of inotropes (39% of patients).<sup>132</sup> The use of more than one vasoactive drug or the need for mechanical support were found to be independent predictors of mortality and adverse outcome postoperatively.<sup>133</sup>

**Figure 39-12** Algorithm for the diagnosis and treatment of hemodynamic abnormalities on termination of cardiopulmonary bypass. CO, cardiac output; SVR, systemic vascular resistance; vasc, vascular; IABP, intra-aortic balloon pump; LVAD, left ventricular assist device; CVP, central venous pressure; RV, right ventricle; NO, nitric oxide; PGI<sub>2</sub>, prostacyclin; ?, possibly.

**Table 39-18** Medications Given by Continuous Infusion

Drugs	Usual Initial Dose (µg/kg/min)	Usual Dose Range (µg/kg/min)
Amrinone <sup>a</sup>	2–5	2–20
Dopamine	2–5	2–20
Dobutamine	2–5	2–20
Epinephrine	0.01	0.01–0.1
Isoproterenol <sup>b</sup>	0.05–1	0.1–1
Lidocaine	20	20–50
Milrinone	50 µg/kg over 3 min	0.3–0.7
Nitroglycerin	0.5	0.5–5
Nitroprusside	0.5	0.5–5
Norepinephrine	0.1	0.1–1
Phenylephrine	1	1–3
Prostaglandin E <sub>1</sub>	0.05–0.1	0.05–0.2
Vasopressin		0.0004

<sup>a</sup>Requires initial bolus of 750 µg/kg over 3 min before start of infusion.

<sup>b</sup>For chronotropic effect following cardiac transplantation, doses of 0.005–0.010 µg/kg/min are used.

## Intra-aortic Balloon Pump

The simplest and most readily available mechanical support device is the

intra-aortic balloon pump.<sup>132</sup> It consists of a 25-cm long, sausage-shaped balloon composed of nonthrombogenic polyurethane mounted on a 90-cm vascular catheter. It is usually inserted into the femoral artery, either percutaneously or after surgical exposure, and advanced so the distal tip is below the left subclavian artery (to prevent emboli to the head vessels) and the proximal above the renal arteries.<sup>134</sup> Occasionally, when peripheral vascular disease prohibits passage of the balloon via the femoral artery, it is inserted via the ascending aorta.

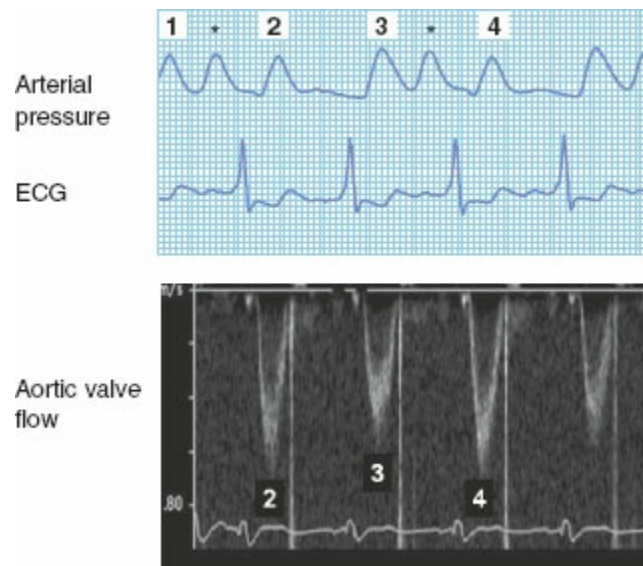

**Table 39-19** Right Ventricular Failure

	Pulmonary Artery Pressure			
	Increased		Normal or Decreased	
	<i>CVP Increased</i>	<i>CVP Decreased</i>	<i>CVP Increased</i>	<i>CVP Decreased</i>
<b>Diagnosis</b>	RV and LV failure	LV failure	RV failure	Hypovolemia
<b>Management</b>	Inhaled NO or PGI <sub>2</sub> , PDE-III Inotropes Differential infusions RVAD	Support on CPB	High perfusion pressure ?CABG	Volume

CVP, central venous pressure; RV, right ventricle; LV, left ventricle; NO, nitric oxide; PGI<sub>2</sub>, prostaglandin I<sub>2</sub>; PDE-III, phosphodiesterase III inhibitor; CPB, cardiopulmonary bypass; RVAD, right ventricular assist device; CABG, coronary artery bypass graft.

The intra-aortic balloon pump decreases  $MV \cdot O_2$  and increases oxygen supply to the myocardium. It uses synchronized counterpulsation to assist a beating, ejecting heart: blood volume is moved in a direction “counter” to normal flow. The balloon is inflated during diastole and deflated during systole. The balloon inflation elevates aortic diastolic blood pressure (diastolic augmentation), thus increasing the coronary perfusion gradient proximally, and enhances forward flow distally. During the subsequent systole and balloon deflation, the LV ejects facing a lower systemic diastolic pressure (systolic unloading, reduced  $MV \cdot O_2$ ) (Fig. 39-13). Proper timing of balloon deflation is necessary to reduce end-diastolic pressure as much as possible to maximally off-load the ventricle. The indications and contraindications for intra-aortic balloon pump placement are listed in Table 39-20. Myocardial function often improves with the use of the intra-aortic balloon pump, and systemic perfusion and vital organ function are preserved.<sup>135</sup> It is crucial to control heart rate and suppress atrial and ventricular dysrhythmias to ensure proper balloon timing. As cardiac function returns, the assist ratio is gradually weaned from every beat to every other beat and so on and, assuming no further cardiac deterioration, until it is removed.

**Figure 39-13** The physiologic effects of intra-aortic balloon pump (IABP) counterpulsation. The IABP is inflated during diastole (*asterisk*), every other beat (rate 1:2). The arterial systolic pressure is decreased after IABP augmentation (compare beats 2 and 4 with beats 1 and 3). The diastolic arterial pressure is augmented during IABP inflation (*asterisk*). The flow through the aortic valve (approximate stroke volume) as demonstrated with pulsed wave Doppler echocardiography shows the increased forward flow after augmentation (beats 2 and 4). ECG, electrocardiogram.

Complications associated with the intra-aortic balloon pump are primarily related to ischemia distal to the site of balloon insertion. Direct trauma to the vessel, arterial obstruction, and thrombosis are most common, although aortic perforation and balloon rupture occur rarely. Platelet destruction and thrombocytopenia may also occur.

### Ventricular Assist Device

Infrequently (1%), the heart is unable to meet systemic metabolic demands despite revascularization, maximal pharmacologic therapy, and insertion of the intra-aortic balloon pump. Under these circumstances, devices that provide cardiac output and/or bypass either the LV or RV are required. MCS is increasingly an option for patients suffering from either an acute or chronic myocardial insult. Maintenance of systemic perfusion, correction of metabolic acidosis, ventricular decompression, and reduced myocardial oxygen consumption by MCS may aid in myocardial recovery.<sup>136</sup> Where myocardial recovery is not possible, MCS can act as a bridge to allow for cardiac transplantation and has now become a destination therapy in its own right.

**Table 39-20** Intra-aortic Balloon Pump Indications and Contraindications

<b>Indications</b>
<i>Complications of myocardial ischemia</i>
Hemodynamic: Cardiogenic shock
Mechanical: Mitral regurgitation, ventricular septal defect
Intractable dysrhythmias
Extension of infarct: Postinfarction angina
<i>Acute cardiac instability</i>
Angina: Unstable, preinfarction
Catheterization laboratory mishap: failed PTCA
Bridge to transplantation
Cardiac contusion
? Septic shock
<i>Open heart surgery</i>
Separation from cardiopulmonary bypass
Ventricular failure: Right or left
Increasing inotropic requirement
Progressive hemodynamic deterioration
Refractory ischemia
<b>Contraindications</b>
Severe aortic insufficiency
Inability to insert
Irreversible cardiac disease (patient is not a transplant candidate)
Irreversible brain damage

PTCA, percutaneous transluminal coronary angioplasty; ?, possibly.

MCS can provide short or long-term support to a single failing ventricle or provide biventricular support to both ventricles. Ventricular assist devices (VAD) are named for the ventricles that is supported, that is, left ventricular assist device (LVAD), RVAD, or in biventricular support (BiVAD). The length of MCS support anticipated will often dictate the type of device that is used to provide MCS.

In an LVAD, the blood is drained to the device (which assumes the function of the failing ventricle) via a cannula placed in either the LA or the LV apex and is ejected into the systemic circulation via a cannula or graft placed in the aorta. In an RVAD, a cannula is placed in the right atrium to divert blood from the RV, which is then ejected into the pulmonary artery.

The types of MCS devices that are available include extracorporeal and fully implantable devices.<sup>137</sup> Extracorporeal devices use cannulae that divert the patient's blood to a pump or biohead that is outside the body and deliver it back to the systemic circulation. By adding an oxygenator to these extracorporeal devices extracorporeal membrane oxygenation (ECMO) can be provided. Once MCS is no longer required the device can be explanted. If there is no meaningful cardiac recovery long-term options are utilized. Long-term options include fully implantable devices that are placed in the patient's abdominal cavity with only the control lines exiting the body and can allow patients to return of the activities of daily living.

For acute short-term MCS of the LV, RV, or BiV the Thoratec CentriMag is

often used. This device is composed of a single-use centrifugal pump, a motor, and a primary drive console. Using a bearingless magnetically levitated impeller, it provides continuous flow via a centrifugal-type rotary blood pump. The pump can rotate at speeds of 1,500 to 5,500 rpm and can provide flow rates of up to 9.9 L/min. Other short-term devices include the Abiomed AB5000 (Abiomed, Danvers, MA) and Thoratec PVAD (Thoratec Laboratories, Pleasanton, CA). Another short-term VAD that is inserted intravascularly and be used during high-risk coronary intervention or as a bridge to recovery is the Abiomed Impella (Abiomed).<sup>138</sup> This device is a catheter-based intravascular microaxial blood pump. This axial flow pump is capable of delivering either 2.5 or 5 L/min of flow (depending on the device used). It can be placed either percutaneously or via a cut down in either the femoral or axillary artery. The device is placed within the aorta with the distal/inflow portion crossing the AV and resting in the LV. LV blood is diverted to the outflow portion of the device via an impeller pump to the distal aorta providing improved systemic perfusion.

Long-term VADs include the Thoratec Heartmate II which uses nonpulsatile axial flow (Thoratec Laboratories, Pleasanton, CA).

### *Anesthetic Considerations for MCS*

When considering an anesthetic plan for a patient requiring MCS one must take into account the degree of myocardial dysfunction. This may involve one or both ventricles. In addition to standard monitoring, preinduction arterial blood pressure monitoring is essential. The ablation of high sympathetic tone that heart failure patients possess may be catastrophic and cause cardiac arrest on the induction of anesthesia. As such, agents that maintain hemodynamic stability are chosen for these patients. These include the use of etomidate as an induction agent (due to its lack of vasodilatation and myocardial depression) and a careful “balanced technique.” Incremental doses of midazolam and etomidate followed by a potent opioid (such as fentanyl or sufentanil) and neuromuscular blockade if titrated carefully are usually tolerated. One caveat is that, due to the slow circulation times in heart failure patients, care must be taken to allow medications time to circulate and reach the desired effect. Overzealous dosing may cause cardiovascular collapse. A good rule of thumb is that a 20% decrease in blood pressure should be treated using a direct acting agent such as phenylephrine or norepinephrine. This allows for a margin of safety and may prevent profound hypotension due to the long circulation time if the blood pressure is treated only as the patient becomes hypotensive. Volatile anesthetic agents are generally well tolerated in low doses. Following the induction of anesthesia a PAC and TEE are routinely placed. The PAC provides important information such as CVP (indication of RV function), pulmonary artery pressures, mixed venous

oxygen saturation, and cardiac output. TEE is used in both the pre- and post-implant period.

Important information that needs to be determined by TEE prior to the initiation of CPB include anything that would restrict or impair LVAD filling (mitral stenosis, tricuspid regurgitation, severe RV dysfunction), the presence of aortic insufficiency (causing LV dilatation), and other anatomic issues that impact LVAD placement (PFO/ASD, intracardiac thrombus, severe atherosclerosis of the ascending aorta). Post-implant TEE is used to assess the adequacy of de-airing maneuvers, proper cannula position, and RV size and function.<sup>139</sup>

### *Considerations for VAD Patients*

An in-depth discussion of the considerations for VAD patients is beyond the scope of this chapter and the reader is advised to consult one of the excellent review articles on the subject.<sup>140</sup>

Whether RVAD or LVAD support is required, several issues exist in common for both. In each case, maintenance of adequate preload is essential for proper device function. Once the failing ventricle is mechanically supported, the “cardiac output” of that chamber(s) is dependent upon adequate preload to fill the device and normal to low vascular resistance to promote forward flow and provide adequate systemic perfusion. Low to normal PVR is especially important in patients with an LVAD. The RV is exquisitely sensitive to changes in afterload and a failing RV will not “fill” the left side of the heart and therefore limit LVAD output. Despite extreme care, severe RV failure requiring biventricular support still occurs in approximately 30% of patients requiring an LVAD. Inotropic agents such as epinephrine, dobutamine, and milrinone as well as inhaled agents such as nitric oxide and iloprost are often used to support the RV and help maintain low PVR. Unfortunately, agents that lower PVR also tend to lower SVR. In addition, patients undergoing LVAD implantation tend to manifest profound vasodilatation following CPB. Vasopressin by virtue of not increasing PVR is preferred over norepinephrine as a vasopressor especially in patients with pulmonary hypertension.<sup>141</sup>

For patients on MCS that require noncardiac surgery the maintenance of adequate volume status and careful safeguarding of low to normal vascular resistance is important. The use of a PAC or TEE should be tailored to the specific patient and procedure. However, TEE is recommended in the case of patients with impaired RV function or in procedures with the potential for large volume shifts/transfusion requirements. No specific anesthetic technique is recommended in patients with MCS; however, abrupt changes in SVR due to neuraxial techniques such as spinal anesthesia make them less desirable. Patients with fully implantable devices should be considered at risk for

pulmonary aspiration and treated accordingly.<sup>142,143</sup> Of note, in the event of cardiac arrest, chest compression is contraindicated due to the possible disruption or displacement of the VAD cannulae.

### *Postcardiopulmonary Bypass*

Continued vigilance is mandatory during decannulation, protamine administration, “drying up,” and chest closure. Anesthetics are administered as clinically indicated. Transient atrial or junctional dysrhythmias may be caused by removal of the atrial cannulae. Heparin is reversed with protamine following removal of the venous cannulae, whereas the arterial return cannula remains in place for transfusion of blood to the systemic circulation as needed. When this is completed and bleeding is controlled the arterial cannula is removed, and if bleeding is considered to be under control the chest is closed. During decannulation, the possibility exists for unexpected bleeding from the atrial or aortic suture lines, and this sometimes requires rapid transfusion. Continued vigilance for new ischemia (manifested by ST segment changes, ectopy, atrial dysrhythmia, regional wall motion abnormalities by TEE) is important because it may indicate a correctable problem with the grafts. All valve procedures are assessed by TEE for adequacy of the repair or replacement (i.e., perivalvular leak, residual stenosis).

### **Reversal of Anticoagulation**

Protamine, a polycationic protein derived from salmon sperm, is used to neutralize heparin. The initial and total doses administered vary widely. Some use a fixed ratio of protamine to heparin, others use 1-mg protamine to 100-U heparin, and still others look to automated protamine titrations to suggest the initial dose. Regardless of the method selected, further requirements are assessed by repeated measures of the activated coagulation time or other clotting assay(s), as well as by the appearance of the surgical field.<sup>144</sup>

Protamine administration is associated with a broad spectrum of hemodynamic effects.<sup>145</sup> Idiosyncratic responses include type I anaphylactic reactions and both immediate and delayed anaphylactoid responses. True anaphylaxis is rare and characterized by increased airway pressure, vasodilation with systemic hypotension, and skin flushing. Increased incidence of reactions has been reported in patients sensitized to protamine from previous cardiac catheterization, hemodialysis, cardiac surgery, or exposure to neutral protamine Hagedorn insulin. Perhaps the most devastating complication associated with protamine is sudden and profound pulmonary hypertension accompanied by an elevated CVP, RV failure, and systemic

hypotension. This complication, which may occur in approximately 1% of patients, is mediated by release of thromboxane and C5a anaphylatoxin. The reaction is extremely short-lived, and although reinstatement of CPB is required on rare occasions, it is usually not necessary. Whether protamine is administered via the RA, LA, or aorta, or peripherally, probably makes no difference to the occurrence of this rare reaction. Because systemic hypotension is more likely with rapid injection of protamine, slow administration into a peripheral venous site is advisable.

## **Postbypass Bleeding**

Persistent oozing following heparin reversal is not uncommon. The usual causes include inadequate surgical hemostasis or reduced platelet count or function, and neither is identified by a prolonged activated coagulation time. Insufficient doses of protamine, dilution of coagulation factors, thrombocytopenia, and platelet dysfunction, and rarely “heparin rebound,” belong in the differential diagnosis. Blood product transfusion based on point of care testing has been proven effective in treating nonsurgical bleeding.<sup>146</sup>

After adequate hemostasis is obtained, the chest is closed. This is occasionally associated with transient decreases in blood pressure, which usually respond to volume infusion. If hypotension persists, the chest should be reopened to rule out cardiac tamponade, a kinked coronary bypass graft, or other problems.

As the surgeon completes skin closure, the anesthesiologist prepares for an orderly transfer of the patient from the operating room to the recovery room or ICU. Medicated infusions must be maintained, as clinically indicated, with portable infusion pumps. Additional syringes with emergency cardiac medications and necessary equipment for airway management should be carried, and blood pressure(s) and ECG constantly monitored.

## **Minimally Invasive Cardiac Surgery**

Despite advantages in cardiac surgery and perfusion technology, the deleterious effects of CPB and aortic cross-clamping are well documented. The desire to avoid these complications, as well as complications associated with sternotomy, was a factor leading to the development of minimally invasive techniques not requiring CPB.<sup>147</sup> As the population ages, older patients with multiple comorbid medical conditions requiring surgery are increasingly common. Avoidance of aortic manipulation and cross-clamping especially in elderly patients is associated with lower stroke rates.<sup>148</sup>

Newer procedures include minimally invasive direct coronary artery bypass (MIDCAB), off-pump coronary artery bypass (OPCAB), robotic

surgery,<sup>149</sup> and percutaneous valve repair/replacement performed in the catheterization laboratory or a hybrid operating room,<sup>69,150</sup> MIDCAB is considered as an alternative to angioplasty for single-vessel LAD coronary artery disease. It is performed via a left thoracotomy using one-lung ventilation. In OPCAB surgery the exposure is via a sternotomy and CPB is not used. The development of retractors and stabilization devices allows the surgeon to operate on the beating heart without causing arrhythmia or hypotension. Other advances include the use of intracoronary shunts and sutureless anastomotic devices. OPCAB can provide complete multivessel coronary revascularization. Alternate incisions tutored as “minimally invasive” provide limited exposure and increase surgical difficulty. A type of minimally invasive cardiac surgery uses port access technology, with the assistance of a robotic system. A period of single-lung ventilation may be required under capnothorax for insertion of surgical access ports. Catheters are placed percutaneously in the femoral artery and internal jugular vein to facilitate CPB. These catheters include an endovascular aortic balloon that acts as cross-clamp, a modified PAC to act as an LV vent, and a coronary sinus catheter placed for retrograde cardioplegia administration.<sup>151</sup>

Changes in surgical technique have forced changes in anesthetic technique.<sup>152</sup> Shorter-acting agents are used to facilitate early extubation. The hemodynamics are monitored constantly and rapid intervention is needed in the face of changing hemodynamics. One major problem associated with OPCAB is that exposure of the diseased coronaries and subsequent graft placement requires positioning of the heart that is often associated with hypotension and ischemia. In such cases, standard monitors used in cardiac surgery may not be useful in detecting ST-T wave changes, because the positioning and retraction of the heart often results in a low-amplitude ECG with axis deviation. The placement of laparotomy pads in the pericardial well or lifting the heart out of the chest, makes TEE unreliable in detecting regional wall motion changes signifying ischemia. In addition, displacement of the heart may cause falsely elevated central venous and pulmonary pressures despite the presence of hypovolemia. Sudden changes in pulmonary artery pressure may be related to acute MR due to surgical positioning. Direct observation of the heart and communication with the surgeon are critical in managing hemodynamic swings.<sup>153,154</sup>

The coronary artery to be anastomosed is isolated proximally and distally using either an occluder clip or a snare. Following such an occlusion there is usually a period of myocardial ischemia. Pre-existing high-grade lesions might have caused formation of collateral circulation, which may ameliorate potential ischemia. Right coronary lesions will predispose to bradycardia, atrial dysrhythmias, and heart block. For these reasons, immediate access to cardiac pacing and cardioversion are essential. Left-sided coronary lesions

may cause malignant ventricular dysrhythmias and hemodynamic collapse.

Several techniques are used to avoid rapid hemodynamic changes. These include optimizing preload prior to positioning, judicious use of inotropes and  $\alpha$ -agonists, and placing the patient in Trendelenburg position, which allows redistribution of intravascular volume to support the heart in the vertical position.

Normothermia contributes to early extubation as well as prevention of coagulopathy. Aggressive pain control improves patient satisfaction and contributes to early extubation. Techniques for pain control in OPCAB and minimally invasive surgery include systemic opioids and nonsteroidal agents such as ketorolac (in patients without renal insufficiency), local infiltration of the surgical incision, and regional anesthesia. Regional techniques including thoracic epidurals and neuraxial narcotics are used with great success, although anticoagulation is a concern in patients with central regional anesthetics.<sup>155</sup> Anticoagulant protocols are controversial. Both heparin and protamine doses vary between centers. Some do not routinely reverse heparin or administer reduced doses of protamine because of the suspicion that OPCAB may cause hypercoagulability.<sup>156</sup>

Despite great interest in OPCAB as a way to decrease the complications associated with CPB, many remain skeptical as to the benefits. Several studies have shown the superiority of OPCAB in regard to improved neurologic outcome, whereas others have not.<sup>157,158</sup> Despite disappointing results in regard to neurocognitive and overall outcome, several short-term outcomes are improved following OPCABG. These include shorter ICU stays, decreased utilization of hospital resources, and decreased incidence of atrial fibrillation.<sup>159</sup>

Many have argued that the advantages of traditional CABG over OPCAB include a still bloodless field allowing for a better anastomosis and long-term graft patency.<sup>160</sup> Other studies have refuted this to prove equal long-term graft patency rates.<sup>161</sup> The proponents of OPCAB tend to be very familiar with the technique and perform off-pump surgery frequently. This frequency seems to make them technically facile in the peculiarities unique to OPCAB surgery. As such, this may account for varying results from center to center. Currently, there is no consensus as to the superiority of standard CABG versus OPCAB.

## Postoperative Considerations

### *Bring Backs*

Postoperative re-exploration is needed in 4% to 5% of cases. The indications are persistent bleeding, cardiac tamponade, and, infrequently, unexplained

poor cardiac performance. Surgery is usually required within the first 24 hours but also later in cases of delayed tamponade. The possibility of cardiac tamponade must always be included in the differential diagnosis of the postoperative “dwindles” because the classic symptoms and signs are often absent.

## Tamponade

In tamponade, the intracardiac pressures are deceptively elevated and do not reflect the actual intracardiac pressure or volume. Because the surrounding (intrapericardial) pressure is increased, the distending (transmural) pressure (intracavitary pressure–extracavitary pressure) is actually decreased. Cardiac chamber collapse is a critical feature of cardiac tamponade, and the chambers with the lowest intracardiac pressure (atria in systole and RV in diastole) are most likely to be compressed. The stroke volume is limited, and tachycardia maintains the cardiac output. Peripheral vasoconstriction to preserve venous return and systemic blood pressure is another compensatory mechanism. Myocardial ischemia may occur because of the tachycardia and reduced coronary perfusion pressure.

Clinically, awake patients present with dyspnea, orthopnea, tachycardia, paradoxical pulse, and hypotension, but the intubated, sedated, and mechanically ventilated patient in the postoperative care unit following cardiac surgery may have varied clinical and hemodynamic presentations. In the cardiac surgical patient the diagnosis of tamponade should be considered whenever hemodynamic deterioration or signs of low cardiac output occur. In postoperative cardiac patients, the pericardium is no longer intact, and loculated areas of clot may compress only one chamber, causing isolated increases in filling pressure (i.e., mimicking right and/or left ventricular dysfunction). Urine output is usually diminished. Serial chest films typically show progressive mediastinal widening. Diastolic collapse of the RA and right ventricular and/or LV diastolic collapse are the most sensitive and specific echocardiographic signs of cardiac tamponade.<sup>162</sup> In addition, there is excessive respiratory variation of the Doppler flow velocities across the tricuspid and mitral valves. The existing extracardiac compression augments the respiration-induced ventricular interdependence and affects the diastolic filling of the two ventricles differently. During mechanical inspiration the increased intrathoracic pressure will impede the RV and augment the LV filling. As a result, the diastolic tricuspid flow will show marked decrease as the filling gradient between the extrathoracic veins and the intrathoracic RV is further reduced. At the same time, the diastolic mitral flow will increase as the increased intrathoracic pressure, which is transmitted to the intrathoracic pulmonary veins, increases the filling gradient of the LV. The opposite effects

take place during mechanical exhalation when the effects of positive ventilation dissipate. A TTE approach to document these reciprocal changes may be limited, as a retrosternal collection may be difficult to visualize in the postoperative patient, whereas subcostal views are rarely feasible early in the postoperative period because of the presence of chest tubes, pacemaker wires, and/or local tenderness in the subxiphoid area. TEE is a better diagnostic tool in the immediate postoperative period.

The treatment for cardiac tamponade is surgical. The selected anesthetic drugs should preserve the compensatory mechanisms that sustain forward flow. Drugs with vasodilator (either venous or arteriolar) or myocardial depressant properties should be avoided in patients with serious hemodynamic compromise and dosages of any induction agent should be appropriately reduced. Ketamine, because of its sympathomimetic effects, may be helpful in preserving heart rate and blood pressure response. It is not, however, a panacea and can induce hypotension in patients under maximal sympathetic stress. If on reopening the chest there is minimal fluid or if the patient shows little improvement, a thorough search for other causes of inadequate cardiac performance, such as clotted or kinked grafts, myocardial ischemia, or valve malfunction, is indicated.

## **Pain Management**

Early awakening and extubation have brought the problem of postoperative pain management in cardiac surgery into focus. The standard practice has been intravenous opioids given as needed followed by conversion to oral pain medications. However, the quest is on to find an ideal postoperative pain management technique to complement the goal of early extubation and maximize patient satisfaction.<sup>163</sup> Several studies have shown the benefits of intrathecal administration of opioids.<sup>164</sup> The addition of nonsteroidal anti-inflammatory agents may play an increasing role. In cardiac patients with severe pain associated with sternal fractures due to the sternal retraction device during internal mammary harvest, epidural analgesia has been shown to be safe and effective and results in improved postoperative pulmonary function.

## **Anesthesia for Children with Congenital Heart Disease**

Because “anatomy dictates the physiology,” the anesthetic management of children with congenital heart disease (CHD) requires knowledge of anatomic defects, planned surgical procedures, and comprehensive understanding of the altered physiology. The overall incidence of CHD varies between 4 and 12 per 1,000 live births. CHD can be cyanotic or

acyanotic. The best way to understand the impact of a congenital defect and how anesthetic agents will interact with this defect is to envision the path blood must follow to maintain flow to the pulmonary arteries and aorta. [Table 39-21](#) classifies various types of lesions by their physiologic impact; however, it must be remembered that there is often more than one defect present.

## *Preoperative Evaluation*

### **History**

In infancy, heart failure usually becomes manifest through feeding difficulties, easy fatigability, vomiting, lethargy, and labored breathing. In the older child, heart failure causes easy fatigability, shortness of breath, and dyspnea on exertion. Child's age and weight, presence of an upper respiratory tract infection, baseline arterial saturation, and anticipated durations of surgery and CPB must be taken into consideration.<sup>165</sup>

In addition, a detailed medication and surgical history should be obtained. The previous surgical procedures may be key to understanding the patient's anatomy.

### **Physical Examination**

The physical examination of a child should seek signs and symptoms of poorly compensated congenital cardiac lesions. These children most often present with failure to thrive, which could be due to pulmonary hypertension and/or poor peripheral oxygenation and organ perfusion. The physical examination should seek to discover other signs of congestive heart failure, such as irritability, diaphoresis, tachycardia, rales, jugular venous distention, and hepatomegaly. Clinical examination of extremities should include evaluation of cyanosis, clubbing, edema, pulse volume, and blood pressure. In children with Blalock–Taussig shunts (subclavian artery to pulmonary artery), upper extremity pulses may be absent or reduced on the side of the shunt. It is important to measure blood pressure in the arms as well as in the legs in all patients in whom CHD is suspected; thus, coarctation of aorta will not be missed. Auscultation of the heart in these patients can reveal different types of murmurs depending on the lesions ([Table 39-22](#)).

**Table 39-21** Physiologic Effects of Congenital Cardiac Lesions

Volume overload (ventricle or atrium) resulting in increased pulmonary blood flow
• Atrial septal defect: ↑ flow, ↓ pressure
• Ventricular septal defect: ↑ flow, ↑ pressure
• Patent ductus arteriosus: ↑ flow, ↑ pressure
• Endocardial cushion defect: ↑ flow, ↑ pressure
Cyanosis resulting from obstruction to pulmonary blood flow
• Tetralogy of Fallot
• Tricuspid atresia
• Pulmonary atresia
Pressure overload to the ventricle
• Aortic stenosis
• Coarctation of the aorta
• Pulmonary stenosis
Cyanosis due to a common mixing chamber
• Total anomalous venous return
• Truncus arteriosus
• Double outlet right ventricle
• Single ventricle
Cyanosis due to separation of the systemic and pulmonary circulation
• Transposition of the great vessels

↑, increase; ↓, decrease.

The possibility of associated congenital anomalies should be considered. The overall incidence of extracardiac anomalies among children with CHD may be as high as 20%.<sup>166</sup>

### Laboratory Evaluations

The presence of anemia in these patients may require priming of the extracorporeal circuit with red blood cells. Children with cyanotic lesions manifest with polycythemia. Polycythemia results as a consequence of bone marrow stimulation (via release of erythropoietin from the kidneys) from arterial desaturation. Increased red cell mass can lead to hyperviscosity, peripheral sludging, and reduced oxygen delivery. Sludging is augmented by dehydration from preoperative fasting and by hypothermia from low ambient operating room temperatures. In patients with hematocrit above 70%, consideration should be given to preoperative electrophoresis if symptomatic hyperviscosity is present. Cyanotic children with low hematocrit may exhibit hypoxic spells more readily than if the hematocrit were normal. Polycythemia can induce a low-grade disseminated intravascular coagulation with activation of fibrinolysis, degranulation of platelets, and consumption of coagulation factors. Newborns often have inadequate liver-dependent coagulation factors because of immaturity of hepatic function. Platelet count, prothrombin time, and partial thromboplastin time should be evaluated.

**Table 39-22** Classification of Cardiac Murmurs

<b>Systolic</b>
Stenotic semilunar valves
Regurgitant atrioventricular valves
Atrial septal defect
Ventricular septal defect
Coarctation of the aorta
<b>Diastolic</b>
Regurgitant semilunar valves
Stenotic atrioventricular valves
Mitral flow rumble
Tricuspid flow rumble
<b>Continuous</b>
Patent ductus arteriosus
Arteriovenous fistula
Excessive bronchial collaterals
Aortopulmonary window
Venous hum
Surgical shunt
Severe peripheral pulmonic stenosis

Children on diuretic therapy are at risk for hypokalemia, particularly if they are receiving digitalis. Infants, particularly those with congestive heart failure, are also at risk for both hypoglycemia and hypocalcemia. Children who have undergone major cardiac procedures earlier in their lives may have been exposed to blood or blood products and are at increased risk of having abnormal serum antibodies to various blood antigens. Hence, samples of a child's blood should be sent to the blood bank for possible cross-matching.

### **Cardiac Evaluations**

Echocardiography delineates most of the cardiac anatomy and permits noninvasive measurement of ventricular size and function, cardiac output, and severity of valve dysfunction. Cardiac catheterization is reserved for patients with poor echocardiographic windows and when there is intervening bone or air-filled lung (e.g., scoliosis or abnormalities of the peripheral pulmonary arteries). The chest radiograph of a child with CHD should be evaluated for cardiac position, size, shape, abnormal vessels, right aortic arch, scimitar syndrome (hypoplasia/aplasia of one or more lobes of right lung and hypoplasia of right pulmonary artery), aberrant pulmonary vessels, abnormal position of bronchi, vascular rings, or associated pulmonary abnormalities (e.g., pneumonia, atelectasis, or emphysema). The ECG should be reviewed for rate and rhythm abnormalities.

### **Premedication**

The purpose of the premedication is to have a calm child without

oversedation, loss of protective airway reflexes, or hemodynamic compromise. This will facilitate the separation of the child from the parents and ease the fear and anxiety associated with the perioperative period. Details on this topic are provided in [Chapters 42](#) and [43](#).

## **Monitoring**

In addition to standard monitors, additional monitors used during open heart procedures include peripheral and central temperature monitoring, invasive blood pressure monitoring, CVP monitoring (which can include right atrial or left atrial pressure line placement by the surgeon intraoperatively), and TEE.

## **Anesthetic and Intraoperative Management**

Inhalational agents hold a prominent place as induction as well as maintenance agents in pediatric cardiac anesthesia. However, patients with poor ventricular function and those with critical dependence on SVR and/or PVR will need intravenous access preinduction and avoidance or limitation of anesthetic agents that can further compromise hemodynamic function. The choice of anesthetic agents following induction is governed by ventricular function (presence or absence of congestive failure), anticipated use of CPB, and the possibility of mechanical ventilation or tracheal extubation at the end of the case. Opioids are used routinely to limit the stress response in the prebypass phase of pediatric cardiac surgery. Neonates and infants undergoing cardiac surgery and deep hypothermic CPB can generate a significant hormonal stress response. No specific relationship between opioid dose and stress response has been established. Details of dose and side effects are provided in [Chapters 42](#) and [43](#). Of special note is the marked reduction in neuromuscular blocking requirements during hypothermic bypass.

The many advances in the CPB and surgical and anesthetic techniques have significantly improved the survival of children with CHD.<sup>167</sup> However, CPB produces marked hemostatic derangements including:

- Dilution of blood clotting factors
- Activation of the clotting cascade and consumption of clotting factors and platelets
- Reduction in coagulation enzymatic activity
- Activation of the fibrinolytic pathway.
- Aminocaproic acid or tranexamic acid has been used to attenuate coagulopathy during pediatric cardiac surgery associated with CPB.

Hemodilution is a prominent problem in CPB in pediatric and neonatal populations. Modified ultrafiltration during pediatric CPB reduces total body water and serum levels of inflammatory mediators. In neonates, modified

ultrafiltration results in an elevated hematocrit, improved pulmonary compliance in the immediate postbypass period, and probably improved cerebral metabolic recovery after deep hypothermic circulatory arrest, although the long-term benefit on outcome is unclear.<sup>168</sup> Separation from CPB will require pharmacologic and/or pacing support in some patients. In lesions in which the presence of increased PVR is known or suspected, addition of nitric oxide may be of benefit. Inhaled nitric oxide works via cGMP, causing pulmonary vasodilatation. It is truly selective for the pulmonary vascular bed and, in addition, should improve the ventilation/perfusion matching in the lungs.

Drugs that are useful in the postbypass period are given in [Table 39-18](#).

### *Tracheal Extubation and Postoperative Ventilation*

Children with simple lesions who have undergone CPB for procedures that do not involve ventricular incisions (atrial septal defect, ventricular septal defect without failure repaired across the tricuspid valve) can often have the endotracheal tubes removed at the conclusion of surgery or shortly thereafter in the ICU.<sup>169,170</sup>

Children most at risk for ventilatory failure following cardiac surgery include:

- Patients with complex surgeries requiring long bypass time and circulatory arrest time
- Patients less than a year of age and those well under their predicted weight
- Patients with Down syndrome
- Patients with pulmonary hypertension requiring preoperative ventilatory support
- Patients with postoperative cardiovascular and pulmonary complications

In some cases, nasal continuous positive airway pressure can be employed instead of mechanical ventilation. In patients with Fontan physiology (passive pulmonary circulatory), decreasing PVR is paramount and is very much dependent on adequate ventilation, usually through mechanical means. The potentially detrimental effects of endotracheal intubation and positive pressure ventilation offset this advantage. Positive pressure ventilation is known to have a deleterious effect on pulmonary blood flow in patients with Fontan physiology. Resumption of pain-free spontaneous respiration does enhance hemodynamic performance in these patients.<sup>169</sup>

Regional anesthetic techniques can be used to supplement intraoperative anesthesia and provide postoperative analgesia. For example, caudal (epidural) opioids can be used in repair of coarctation of the aorta in the older

child or ligation of a patent ductus arteriosus. Some physicians have used caudal or intrathecal morphine for cases involving CPB (and concomitant heparin administration), although this is not a common practice. The recommendation has been made that one allow 60 minutes to elapse between placement of a neuraxial block and administration of heparin, although there is no evidence to support this time interval.<sup>171</sup> Reported benefits of regional techniques include decreased stress response, improved pulmonary and gastrointestinal function, and resultant potential for cost reduction.<sup>172</sup> However, it is difficult to establish the superiority of a regional technique compared with intravenous analgesia.<sup>173</sup>

### **Hybrid Procedures in Pediatric Cardiac Surgery**

Hybrid pediatric cardiac surgery is an emerging field that reaches across interdisciplinary lines and combines skills and techniques traditionally used by pediatric cardiac surgeons and interventional pediatric cardiologists. Advantages of hybrid procedure are real-time feedback obtained by continuous transesophageal echocardiographic monitoring, avoidance of CPB, ventricular incisions, or muscle transections.<sup>174</sup>

# 40 Anesthesia for Vascular and Endovascular Surgery

ELIZABETH A. VALENTINE • E. ANDREW OCHROCH

## Introduction and Overview

### Vascular Disease

Pathophysiology of Atherosclerosis

Concurrent Vascular Disease in Vascular Surgery Patients

Medical Optimization Prior to Vascular Surgery

Preoperative Anesthesia Evaluation for Vascular Surgery

### Open Vascular Surgery

Cerebrovascular Disease

Aortic Reconstruction

Peripheral Artery Disease

### Endovascular Surgery

Carotid Artery Stenting

Endovascular Aortic Repair

Endovascular Management of Peripheral Artery Disease

## Conclusion

## KEY POINTS

- 1 Atherosclerosis is the most common underlying pathophysiologic mechanism for the development of cardiovascular disease.
- 2 The same risk factors that lead to coronary artery disease also lead to vascular disease in other major vascular beds, including the cerebral, aortic, and peripheral circulation.
- 3 Improvements in the medical management of patients with atherosclerotic risk factors with antiplatelet agents,  $\beta$ -blockers, angiotensin-converting enzyme inhibitors, statins, and strict glucose control have revolutionized the management of vascular surgery patients. Meticulous optimization of comorbid conditions plays a critical role in the reduction of perioperative morbidity and mortality in this patient population.
- 4 Most vascular surgery patients are at elevated perioperative risk of major adverse cardiac events, which remain the single most important cause of both short- and long-term morbidity and mortality following vascular

surgery.

- 5 The pathophysiology of aneurysmal aortic disease is a clinically distinct degenerative process, although many of the risk factors are shared between degenerative and atherosclerotic vascular disease.
- 6 Endovascular procedures have transformed the field of vascular surgery with an increasing number of procedures being performed via a minimally invasive approach. Perioperative improvements in morbidity and mortality must be weighed against the long-term risks of decreased durability and increased need for repeat intervention.

## Introduction and Overview

Atherosclerotic cardiovascular disease (ASCVD) is the most important cause of morbidity and mortality in both the United States and throughout the world. More than 80 million adults in the United States carry a diagnosis related to ASCVD. Globally, ASCVD has overtaken communicable diseases as the leading cause of death worldwide. ASCVD currently accounts for more than 17.3 million deaths worldwide per year, and this number is expected to increase to greater than 23.6 million deaths by 2030 due to an aging population.<sup>1,2</sup> Advances in medical management have led to an overall decrease in the total number of deaths attributable to ASCVD over recent years, although nearly one out of every three deaths in the United States is related to ASCVD.<sup>3,4</sup>

Emphasis on increased screening and the increasing age of the population in Western societies will likely increase the number of vascular procedures performed on a yearly basis. It has been estimated that 1 to 2 million vascular procedures will be performed annually in the United States by the year 2030.<sup>5</sup> Improvements in optimal medical management may delay the need for surgical interventions until severe systemic ASCVD disease is present. As a result of recent advances in endovascular techniques, many patients who previously would be deemed too high risk for the operating room are increasingly considered surgical candidates. This combination of a high-risk patient population and complex, high-risk surgical procedures makes vascular anesthesia challenging even for the experienced clinician. Despite both the medical and surgical issues that this patient population presents, surgical mortality has fallen from greater than 25% for major aortic reconstruction in the 1960s to as low as 3% today. This is largely due to improved perioperative optimization and management. The anesthesiologist may have greater influence in reducing morbidity and mortality in vascular surgery than in any other area of anesthesia.

This chapter begins with a discussion of the pathophysiology of ASCVD and a suggested approach to the preoperative evaluation and perioperative optimization of vascular surgery patients. Coronary artery disease (CAD) will

be discussed in particular detail, given the high incidence of concomitant CAD in vascular surgery patients and the increased morbidity and mortality in this patient population. The specific surgical goals, anatomic considerations, and perioperative concerns for cerebrovascular, aortic, and lower extremity revascularization will be discussed in the context of optimal anesthetic management and accounting for surgical technique (open versus endovascular repair).

## Vascular Disease

### *Pathophysiology of Atherosclerosis*

**1** Atherosclerosis is the most common pathophysiologic mechanism underlying cardiovascular disease. At its simplest definition, atherosclerosis is a generalized inflammatory disorder of the arterial tree. Putative mechanisms include endothelial damage, hemodynamic shear stress, inflammation from chronic infections, hypercoagulability with resultant thrombosis, and the destructive effect of low-density lipoproteins (LDLs). Atherosclerotic plaque formation is a complex process involving endothelial dysfunction, lipid deposition, smooth muscle proliferation, and the proliferation of inflammatory and immunogenic mediators.<sup>6</sup>

The development of atherosclerosis occurs in two stages: injury and response to injury. An intact vascular endothelium serves as a barrier between the blood and the more thrombogenic subendothelial tissues. Injured epithelial cells express leukocyte adhesion molecules that increase the adherence of macrophages and other leukocytes. Increased permeability of the damaged endothelium permits entry of leukocytes and LDL particles into the subendothelial space, and modified LDL particles induce leukocyte adhesion. The earliest recognizable lesion of atherosclerosis is this “fatty steak” which is comprised of lipid-rich macrophages and T lymphocytes that accumulate within the intima of the vessel wall. Monocyte-derived macrophages act as scavenging and antigen-presenting cells and produce further proinflammatory mediators. A variety of cytokines and growth factors (including monocyte chemoattractant protein-1, macrophage and granulocyte-macrophage colony stimulating factors, intercellular adhesion molecule-1, tumor necrosis factor  $\alpha$ , and interleukins 1, 3, 6, 8, and 18) further recruit activated immune and smooth muscle cells.<sup>7,8</sup> In this enriched environment, macrophages transform into foam cells. Foam cells and extracellular lipid form the core of the plaque, which is surrounded by smooth-muscle cells and a collagen-rich matrix.<sup>6</sup> The progression of atherosclerotic plaque ultimately narrows the intravascular lumen and contributes to an imbalance between oxygen supply and demand. Depending on location of the atherosclerotic

plaque, the end result is ischemia of the coronary, cerebral, mesenteric, or peripheral circulation.

**Figure 40-1** Rate of cardiovascular death, myocardial infarction, or major adverse cardiac event by presence, severity, and extent of coronary artery disease (CAD). Both obstructive and nonobstructive atherosclerotic plaque may result in significant cardiovascular morbidity and mortality. Overall disease burden may be as important a contributor as individual plaque characteristics to adverse events. (Reprinted with permission from Bittencourt MS, Hultén E, Ghoshhajra B, et al. Prognostic value of nonobstructive and obstructive coronary artery disease detected by coronary computed tomography angiography to identify cardiovascular events. CAD is coronary artery score, SIS is coronary segment involvement score. *Circ Cardiovasc Imaging*. 2014;7:282–291.)

The traditional teaching is that of the “vulnerable plaque” model. That is, over time, inflammatory mediators and proteolytic enzymes may weaken the thin fibrous cap overlying the atheromatous plaque, making it particularly prone to ulceration and rupture. Exposure of blood to the necrotic, lipid-rich central core can result in acute thrombosis. Plaque rupture has been detected in up to 60% to 70% of cases of acute coronary syndromes,<sup>9</sup> making treatment of presumed high-risk lesions the focus of great effort. More recent evidence, however, suggests that although such high-risk features may be valuable as a surrogate for overall disease burden, no conclusive evidence exists to support that high-risk plaque characteristics are an independent risk factor for a clinical event.<sup>10,11</sup> Focus on overall atherosclerotic disease burden rather than individual plaque features may be as, if not more, important (Fig. 40-1). When plaque rupture is the culprit event, platelets play a pivotal role. Platelet polymorphisms have been found to be an independent risk factor following vascular surgery.<sup>12</sup>

### Concurrent Vascular Disease in Vascular Surgery Patients

The underlying risk factors for atherosclerotic disease are similar regardless of plaque location, though individual risk factors may be more

strongly associated with disease in one vascular bed than another. Some risk factors, such as a strong family history, nonwhite ethnicity, male gender, and increasing age, are outside a patient's control. Modifiable risk factors include smoking, atherogenic dyslipidemia (hypertriglyceridemia, elevated LDL, and decreased high-density lipoprotein [HDL]), abdominal obesity, hypertension, insulin resistance, renal insufficiency, and proinflammatory states.<sup>13,14</sup> With aggressive lifestyle and pharmacologic interventions, atherosclerotic disease progression can be significantly slowed.

ASCVD in one vascular bed often predicts significant disease in other areas of the body (Fig. 40-2).<sup>13</sup> The presence of cerebrovascular disease (CVD) has long been used as a surrogate marker for CAD. Multiple studies have demonstrated an association between carotid intima-media thickness (CIMT) and CAD and cardiovascular death. A meta-analysis of the literature demonstrated that for each 0.1-mm increase in CIMT, the future risk of myocardial infarction (MI) was increased by 10% to 15%.<sup>15</sup> Conversely, every 0.01 mm/yr decrease in the progression of CIMT has been associated with a nearly 20% reduction of the risk of nonfatal MI.<sup>15</sup> The overall presence of carotid atherosclerotic plaque, independent of CIMT, also predicts an increase in incidence of MI and cardiovascular death.<sup>16</sup>

**Figure 40-2** Typical overlap of atherosclerotic cardiovascular disease by vascular bed. Atherosclerotic disease in one vascular bed often predicts disease in other areas. (Reprinted with permission from Norgren L, Hiatt WR, Dormandy JA, et al. Inter-Society Consensus for the Management of Peripheral Arterial Disease [TASC II]. *J Vasc Surg.* 2007;45[Suppl S]:S5–S67. Copyright © 2007 The Society for Vascular Surgery. Published by Mosby, Inc. All rights reserved.)

Hertzer et al.<sup>17</sup> performed coronary angiography on 1,000 consecutive patients presenting for elective vascular surgery and identified an overall prevalence of CAD of approximately 50% in this patient population. Severe, correctable CAD was noted in 25% of the entire series (Table 40-1). Surgically correctable disease was more frequent in patients with known risk factors for coronary disease than those without (34% vs. 14%). Subsequent analysis

demonstrated that the severity of CAD could be accurately predicted by clinical risk factors.<sup>18</sup> The absence of: (1) diabetes mellitus, (2) prior angina, (3) previous MI, or (4) history of congestive heart failure (CHF) predicted the absence of severe CAD with a positive predictive value of 96%. The absence of critical CAD (greater than or equal to 70% stenosis of left main or triple vessel disease) could be predicted with a positive predictive value of 94% in patients without (1) prior angina, (2) previous MI, or (3) history of CHF.

**Table 40-1** Coronary Artery Disease (CAD) Severity for Vascular Surgery Patients Who Underwent Routine or Selective Coronary Angiography<sup>a</sup>

	Patients with Coronary Artery Disease	
	Routine Surveillance (%)	Suspected Disease (%)
Normal coronaries	14	4
Mild to moderate CAD	49	18
Advanced but compensated CAD	22	34
Severe, correctable CAD	14	34
Severe, inoperable CAD	1	10

<sup>a</sup>A significant portion of patients who underwent coronary artery angiography prior to vascular surgery were found to have advanced disease. This held true even for patients without a high clinical suspicion for significant coronary artery disease.

Adapted with permission from Hertzner NR, Beven EG, Young JR, et al. Coronary artery disease in peripheral vascular patients: a classification of 1000 coronary angiograms and results of surgical management. *Ann Surg.* 1984;199:223–233.

The clinical prevalence of CAD or CVD in patients with diagnosed peripheral artery disease (PAD) ranges from 40% to 60%. The extent of CAD, measured by either computed tomography (CT) detection of coronary artery calcium or coronary angiography, correlates with the ankle–brachial index.<sup>13</sup> Approximately 10% to 30% of patients with documented CAD have concurrent PAD. Concurrent carotid and peripheral arterial disease occurs in approximately 25% to 50% of patients. Autopsy studies have demonstrated that patients with fatal MI are twice as likely to have a significant disease in the cerebral and peripheral arterial beds.

### **Medical Optimization Prior to Vascular Surgery**

Cardiovascular complications are a major source of morbidity and mortality following vascular surgery. Nearly 10% of patients demonstrate evidence of significant myocardial injury in the perioperative period, and 2% of patients suffer a major adverse cardiac event (MACE).<sup>19–21</sup> Patient who experience an MI following noncardiac surgery have an elevated in-hospital mortality rate

of 15% to 25%, and nonfatal perioperative MI is an independent predictor for cardiovascular death in the 6 months following surgery.<sup>20,22,23</sup> Thus, **3** medical optimization of ASCVD in the perioperative period has been a focus of significant study.

Lifestyle modifications such as regular exercise, weight loss, diet modification, and smoking cessation may forestall the progression of atherosclerotic disease and improve fitness for surgery. Patients undergoing vascular surgery should also be aggressively treated for underlying medical conditions that predispose to ASCVD such as hypertension, dyslipidemia, and diabetes. Improvements in pharmacologic therapy have revolutionized the care of patients with atherosclerotic disease. It is worth noting that many of the landmark trials that currently dictate recommendations for surgical intervention were performed at a time when best medical therapy for atherosclerotic disease was significantly limited as compared to today. In the modern era of multimodal treatment with  $\beta$ -blockade, statins, intensive glucose control, antiplatelet therapies, and pharmacologic aids for smoking cessation, it is conceivable that a larger number of patients may be appropriately managed with medical, rather than surgical, therapy. That is, with improved medical management, the number needed to operate on to prevent an untoward cardiovascular event may be even higher than the literature suggests.

Perhaps the most widely studied medical intervention in the perioperative period is the use of  $\beta$ -blockade. A significant proportion of postoperative ischemic events are thought to be secondary to a persistently exaggerated sympathetic response. Substantial elevations in heart rate increase myocardial oxygen demand while simultaneously decreasing oxygen supply, with resultant demand ischemia. It has been proposed that modulating this heart rate response may decrease both the incidence and severity of the ischemia (Fig. 40-3).<sup>24,25</sup> Several randomized controlled studies demonstrated a significant benefit to  $\beta$ -blockade as a means to reduce the risk of MACE,<sup>25-27</sup> although other studies have failed to validate these findings.<sup>28-30</sup> Some of the most compelling evidence in support of perioperative  $\beta$ -blockade came from the Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography Study Group (DECREASE-1 and DECREASE-IV),<sup>26,31</sup> the validity of which has been called into question in light of allegations of scientific misconduct. The PeriOperative ISchemic Evaluation (POISE-1) trial, a large randomized controlled trial of more than 8,000 patients, found that perioperative  $\beta$ -blockade was associated with a decrease in perioperative MI, at the expense of an even greater increased risk of death or stroke.<sup>32</sup> In light of these new findings, updated recommendations for the role of perioperative  $\beta$ -blockade in noncardiac surgery were released by the American College of Cardiology (ACC) and American Heart Association (AHA).<sup>19</sup> This systemic

review examined 17 large (>100 patients) randomized controlled or cohort studies comparing perioperative  $\beta$ -blockade against placebo in adult patients undergoing noncardiac surgery. For patients started on  $\beta$ -blockade 1 day or less before surgery, this review demonstrated an overall moderate reduction in nonfatal MI, even with the exclusion of the DECREASE studies. There was, however, an overall increased risk of all-cause death and trend toward increased risk of cardiovascular death. There was also a significant increase in the risk of nonfatal stroke, as well the risk for significant hypotension and bradycardia, in the group receiving  $\beta$ -blockade. For patients in whom  $\beta$ -blockade was initiated 2 or more days prior to surgery, current data were deemed insufficient to recommend for or against  $\beta$ -blockade therapy in the perioperative period. Further multicenter, randomized controlled trials are needed to address this gap in knowledge.

**Figure 40-3** ST segment changes with heart rate (HR) during an ischemic episode. Tachycardia can increase the myocardial oxygen demand (due to increased work) while decreasing supply (due to decreased diastolic filling time), culminating in demand ischemia. (Reprinted with permission from Mangano DT, Hollenberg M, Fegert G, et al. Perioperative myocardial ischemia in patients undergoing noncardiac surgery—I: Incidence and severity during the 4 day perioperative period. The Study of Perioperative Ischemia [SPI] Research Group. *J Am Coll Cardiol.* 1991;17:843–850.)

The 2014 update to the ACC/AHA clinical practice guideline for perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery also made specific recommendations regarding the management of perioperative  $\beta$ -blockade.<sup>33</sup> This task force recommended that  $\beta$ -blockers should be continued in the perioperative period in patients who are chronically on  $\beta$ -blocker therapy (Class I, Level of Evidence B) and that it may be reasonable to begin  $\beta$ -blockers in the perioperative period on those patients with intermediate- to high-risk myocardial ischemia noted on

preoperative testing (Class IIb, LOE C) or in patients with three or more cardiac risk factors (Class IIb, LOE B). It is reasonable to start such therapy in advance of surgery to establish safety and tolerability (Class IIb, Level of Evidence: B). They further recommend that  $\beta$ -blockers should not be started on the day of surgery (Class III, LOE B).

Studies of perioperative  $\beta$ -blockade specific to the vascular surgery population have found similar conclusions to those in the general surgical population. A recent retrospective cohort analysis of the Society for Vascular Surgery Vascular Quality Initiative (SVS-VQI) found that, exclusive of high-risk open abdominal aortic aneurysm repair (OAR), preoperative institution of  $\beta$ -blockade did not decrease mortality or rate of MACE, but did increase the rates of other adverse events following major vascular surgery.<sup>34</sup> The Perioperative Beta Blockade (POBBLE)<sup>30</sup> trial evaluated more than 100 patients undergoing infrarenal vascular surgery and the Metoprolol after Vascular Surgery (MaVS)<sup>28</sup> included nearly 500 patients undergoing abdominal aortic surgery, axillofemoral revascularization, or infrainguinal revascularization. Both studies failed to find a significant difference in MACE between patients who received  $\beta$ -blockers in the perioperative period and placebo. A recent Cochrane Review concluded that there is no evidence that perioperative  $\beta$ -blockade reduces all-cause mortality, cardiovascular mortality, nonfatal MI, arrhythmia, heart failure, stroke, or composite cardiovascular events in patients undergoing vascular surgery.<sup>35</sup> It further concluded that strong evidence suggests that  $\beta$ -blockade increases the risk of perioperative bradycardia and hypotension.

As a result of a shift in both the strength and direction of evidence, the practice of  $\beta$ -blocker initiation in the immediate perioperative period has precipitously declined over recent years (Fig. 40-4), although the practice remains relatively common in patients with higher cardiac risk and those undergoing vascular surgery.<sup>36</sup> The choice of  $\beta$ -blocker in the perioperative period has also been studied. An epidemiologic analysis of nearly 40,000 high-risk patients found a decreased mortality at both 30 days and 1 year in patients who received atenolol as compared to metoprolol.<sup>37</sup> A retrospective analysis of nearly 60,000 patients found that both preoperative metoprolol (compared to atenolol) and intraoperative metoprolol (compared to esmolol or labetalol) was associated with an increased risk of stroke after noncardiac surgery.<sup>38</sup>

The marked sympathetic stimulation that occurs in the perioperative period has led to significant interest in  $\alpha_2$ -adrenergic agonists to blunt the surgical stress response and reduce cardiovascular morbidity and mortality. Evidence for the utility of  $\alpha_2$ -agonists in the perioperative period is conflicting. Several studies have suggested that the perioperative use of  $\alpha_2$ -agonists reduces intraoperative myocardial ischemia, postoperative

catecholamine levels, and mortality in high-risk noncardiac surgery.<sup>39,40</sup> A recent meta-analysis<sup>41</sup> found data to be encouraging, but insufficient, to suggest that this class of medication can reduce the risk of cardiac morbidity and mortality, and a second specific to the vascular surgery population found a decreased risk of mortality and perioperative MI.<sup>42</sup> Despite these encouraging results, other evidence calls the perioperative benefit of  $\alpha_2$ -agonists into question. The PeriOperative ISchemic Evaluation-2 (POISE-2) trial was a multicenter, international, randomized, blinded trial that evaluated over 10,000 patients with, or at risk for, ASCVD undergoing noncardiac surgery.<sup>43</sup> In this study,  $\alpha_2$ -agonists did not reduce the incidence of perioperative MI or the composite outcome of death or nonfatal MI. Patients receiving  $\alpha_2$ -agonists had more clinically significant hypotension and an increase incidence of nonfatal cardiac arrest. In light of these recent findings, the most recent ACC/AHA guidelines state that  $\alpha_2$ -agonists are not recommended for prevention of MACE in patients undergoing noncardiac surgery (Class III; LOE B).<sup>33</sup> Although evidence to support the initiation of  $\alpha_2$ -agonists is lacking, it is important to recognize that the abrupt discontinuation of this class of medication in patients who are chronic users can result in a rebound sympathetic surge including profound hypertension and tachycardia, diaphoresis, and pulmonary edema. Thus, the relative risks and benefits of continuing versus withdrawing this class of medication must be considered in patients who chronically receive  $\alpha_2$ -agonists.

**Figure 40-4** Temporal trends in  $\beta$ -blockade initiation within 30 days of surgery from 2003 to 2012. Following the influential POISE trial, the practice of perioperative  $\beta$ -

blockade initiation within 30 days of surgery decreased significantly. ACC/AHA, American College of Cardiology/American Heart Association. (Reprinted with permission from Paterno E, Wang SV, Schneeweiss S, et al. Patterns of beta-blocker initiation in patients undergoing intermediate- to high-risk noncardiac surgery. *Am Heart J*. 2015;170:812–820.e6.)

Renin–angiotensin system (RAS) blockers (including angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers) are a commonly used class of antihypertensive agents that have several benefits in regard to prevention of acute cardiovascular events independent of their antihypertensive effects. The RAS has been shown to influence the progression of ASCVD via effects on inflammation, endothelial function, and overall plaque stability.<sup>44</sup> RAS blocking agents have demonstrated beneficial effects on ventricular remodeling following acute MI,<sup>45</sup> ischemia–reperfusion injury,<sup>46</sup> and perioperative acute kidney injury.<sup>47</sup> Despite beneficial long-term effects, a recent large, retrospective study in the cardiac surgery population found an increased risk of perioperative morbidity (including significant vasoplegia, need for inotropic support, dysrhythmia, and renal dysfunction) and mortality when ACE inhibitors were continued in the perioperative period.<sup>48</sup> A similar association was found between perioperative RAS blockade and 30-day mortality following major vascular surgery.<sup>49</sup> To date, no studies provide definitive evidence for the independent ability of RAS blockers to reduce perioperative cardiovascular risk, and further randomized controlled trials are warranted. The most recent ACC/AHA guidelines suggest that continuation of RAS blocking agents is reasonable in the perioperative period (Class IIa; LOE B), and that if they stopped preoperatively, it is reasonable to restart as soon as clinically feasible (Class IIa; LOE C).<sup>33</sup> However, many choose to hold this class of medication in the preoperative period due to a well-recognized association between RAS blocking medications and refractory vasoplegia.

Statins are widely utilized for both primary and secondary prevention of ASCVD for their beneficial effects on lipid profile. More recent evidence also suggests more pleiotropic effects on events critical to the surgical stress response. Statins have been shown to inhibit the inflammatory response, reduce ischemia–reperfusion injury, reduce thrombosis, enhance fibrinolysis, decrease platelet reactivity, and restore endothelial function.<sup>50,51</sup> Use of preoperative statins has been associated with reduced cardiac morbidity and mortality following both cardiac and vascular surgery.<sup>52–57</sup> The abrupt discontinuation of statins interferes with endothelial functioning and increases markers of inflammation and oxidative stress in acute coronary syndromes,<sup>58</sup> and the discontinuation of statins in the postoperative period is similarly associated with increased in-hospital death and myonecrosis.<sup>52,54</sup> A recent

meta-analysis demonstrated a reduction in all-cause mortality, combined fatal and nonfatal cardiovascular disease, combined fatal and nonfatal coronary events, and combined fatal and nonfatal stroke in patients treated with statins for primary prevention of ASCVD.<sup>59</sup> Meta-analyses specific to the vascular surgery population have had conflicting results. One analysis found no difference in 30-day mortality or MACE in patients not already receiving a statin medication following noncardiac vascular surgery,<sup>60</sup> whereas another found no significant difference in cardiovascular mortality but a lower risk of all-cause mortality, MI, stroke, and the composite outcome of MI, stroke, and death.<sup>61</sup> The ACC/AHA recommendations propose that patients who take a statin should be continued on this medication during the perioperative period (Class I; LOE B). They further suggest that it is reasonable to initiate treatment in patients undergoing vascular surgery if statin naïve (Class IIa; LOE B).<sup>33</sup>

Antiplatelet agents are commonly employed for secondary prevention of MACE. Multiple studies have found that antiplatelet agents, and particularly dual antiplatelet therapy (DAPT), can reduce the rate of ischemic events. A recent retrospective review found that aspirin withdrawal precedes more than 10% of acute cardiovascular events.<sup>62</sup> Patients who have suffered previous ischemic stroke should be continued on mono or dual antiplatelet therapy,<sup>63</sup> and evidence suggests that patients undergoing carotid endarterectomy (CEA) have a lower rate of perioperative stroke when antiplatelet agents are continued in the perioperative period.<sup>64,65</sup> Similarly, DAPT is essential following coronary stent implantation.<sup>33</sup> Despite the purported benefits of antiplatelet agents, however, a recent review from the Vascular Quality Initiative found no difference in the rate of in-hospital MI or death in patients who did and did not receive antiplatelet agents before major vascular surgery.<sup>66</sup> There was, however, an increased rate of blood loss for all procedures and increased transfusion rate for infrainguinal bypass. Similarly, the POISE-2 trial found no difference in the primary outcome of composite of death or nonfatal MI at 30 days between those who did and did not receive aspirin, or in the secondary outcome which also included nonfatal stroke.<sup>67</sup> A greater risk of major bleeding was observed in the aspirin group. In contrast to these two trials, a recent prospective review from the Vascular Study Group of New England evaluated the use of clopidogrel, aspirin, or DAPT for more than 10,000 patients at 15 centers undergoing nonemergent CEA, lower extremity bypass, endovascular aortic repair (EVAR), and OAR and found no difference in major bleeding complications between the three groups.<sup>68</sup> Thus, although the use of antiplatelet agents is important for long-term management of ASCVD, the purported risks and benefits of antiplatelet therapy in the perioperative period must be carefully weighed in noncardiac, noncarotid vascular surgery.

The lack of perceived benefit of aspirin on perioperative MI observed in the Vascular Quality Initiative and POISE-2 studies may be related to a difference in the causative mechanism of MI in the perioperative period compared to the nonoperative setting. Specifically, type I MI (characterized by morphologically complex coronary plaque prone to rupture and thrombus) may not be the dominant mechanism in the perioperative setting. A recent study demonstrated that this “classic” lesion occurs in only 45% of perioperative MI.<sup>69</sup> Rather, the increase in major bleeding caused by antiplatelet agents may lead to a demand ischemia related to anemia, tachycardia, and hypotension (type II MI).<sup>67,69</sup> The most recent ACC/AHA guidelines suggest that the management of perioperative antiplatelet therapy should be determined by consensus of the treating clinicians (Class I; LOE C). It may be reasonable to continue aspirin in patients undergoing nonemergent/nonurgent noncardiac surgery who have not had previous coronary stenting when the perceived risk of MACE outweighs the risk of increased bleeding (Class IIb; LOE B). These guidelines recommend against the initiation or continuation of aspirin in patients undergoing elective noncardiac, noncarotid surgery who have not had previous coronary stenting (Class III; LOE B), unless the risk of ischemic event is greater than the risk of surgical bleeding (Class III; LOE C).<sup>33</sup>

Hyperglycemia has been associated with increased morbidity and mortality in critically ill patients. Of the oral hypoglycemic agents, it is reasonable to hold sulfonylureas due to the risk of hypoglycemia in the settling of preoperative fasting. Metformin is associated with lactic acidosis and should also be held preoperatively due the increased risk of lactic acidosis with hypovolemia and renal dysfunction (which may be comorbid or provoked by iodinated contrast agents used during endovascular procedures). Patients on these medications can be managed with insulin, which is the treatment modality most intensively studied in the perioperative period. Initial work suggested that tight glucose control (glucose 80 to 110 mg/dL) in critically ill patients led to significant decrease in mortality and multiorgan system failure, resulting in a call for stringent control of hyperglycemia in hospitalized patients.<sup>70</sup> Subsequent studies, however, have failed to replicate these results and instead have found an increase in unrecognized hypoglycemia and an increased risk of death in patients in the intensive glucose control group.<sup>71,72</sup> Hyperglycemia may exacerbate neurologic injury and thus may be especially important for carotid and thoracic aortic procedures with elevated risk of perioperative stroke. In the intraoperative period, both hyperglycemia (glucose >200 mg/dL) and tight glucose control (glucose <140 mg/dL) have been associated with an increased risk of adverse outcomes.<sup>73</sup> Thus, although severe hyperglycemia should be avoided, it is likely prudent to maintain glucose levels in the 140 to 180 mg/dL range

rather than attempt normoglycemia.

It has been suggested that anemia (hematocrit <28%) may increase the incidence of postoperative myocardial ischemia and MACE in high-risk patients undergoing noncardiac surgery,<sup>74</sup> and a traditional practice is to transfuse patients deemed high risk for adverse cardiac events to a hematocrit of 30%. More recently, two studies have suggested no benefit to liberal (hemoglobin goal 10 to 12 mg/dL) rather than restrictive (hemoglobin goal 7 to 8 mg/dL) transfusion practices.<sup>75,76</sup> The Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair (FOCUS) trial,<sup>80</sup> in specific, found no outcomes differences between patients transfused intraoperatively with a restrictive versus liberal strategy, even in a perceived high-risk population. In vascular surgery, specifically, perioperative transfusion has been independently associated with increased 30-day morbidity and mortality.<sup>77</sup> Decision for perioperative transfusion should be based on evidence of compromised end organ perfusion, rate and cause of blood loss, and likelihood of obtaining control of ongoing hemorrhage. Hypothermia is also associated with increased adrenergic tone and postoperative myocardial ischemia and events in vascular surgery patients.<sup>78</sup> In addition, maintaining perioperative normothermia reduces blood loss and transfusion requirement by clinically important amounts.<sup>79</sup> Therefore, aggressive heat conservation and warming measures are appropriate perioperatively. Shivering should be avoided in the perioperative period to prevent increased myocardial demand, and extubation should be postponed in hypothermic patients.

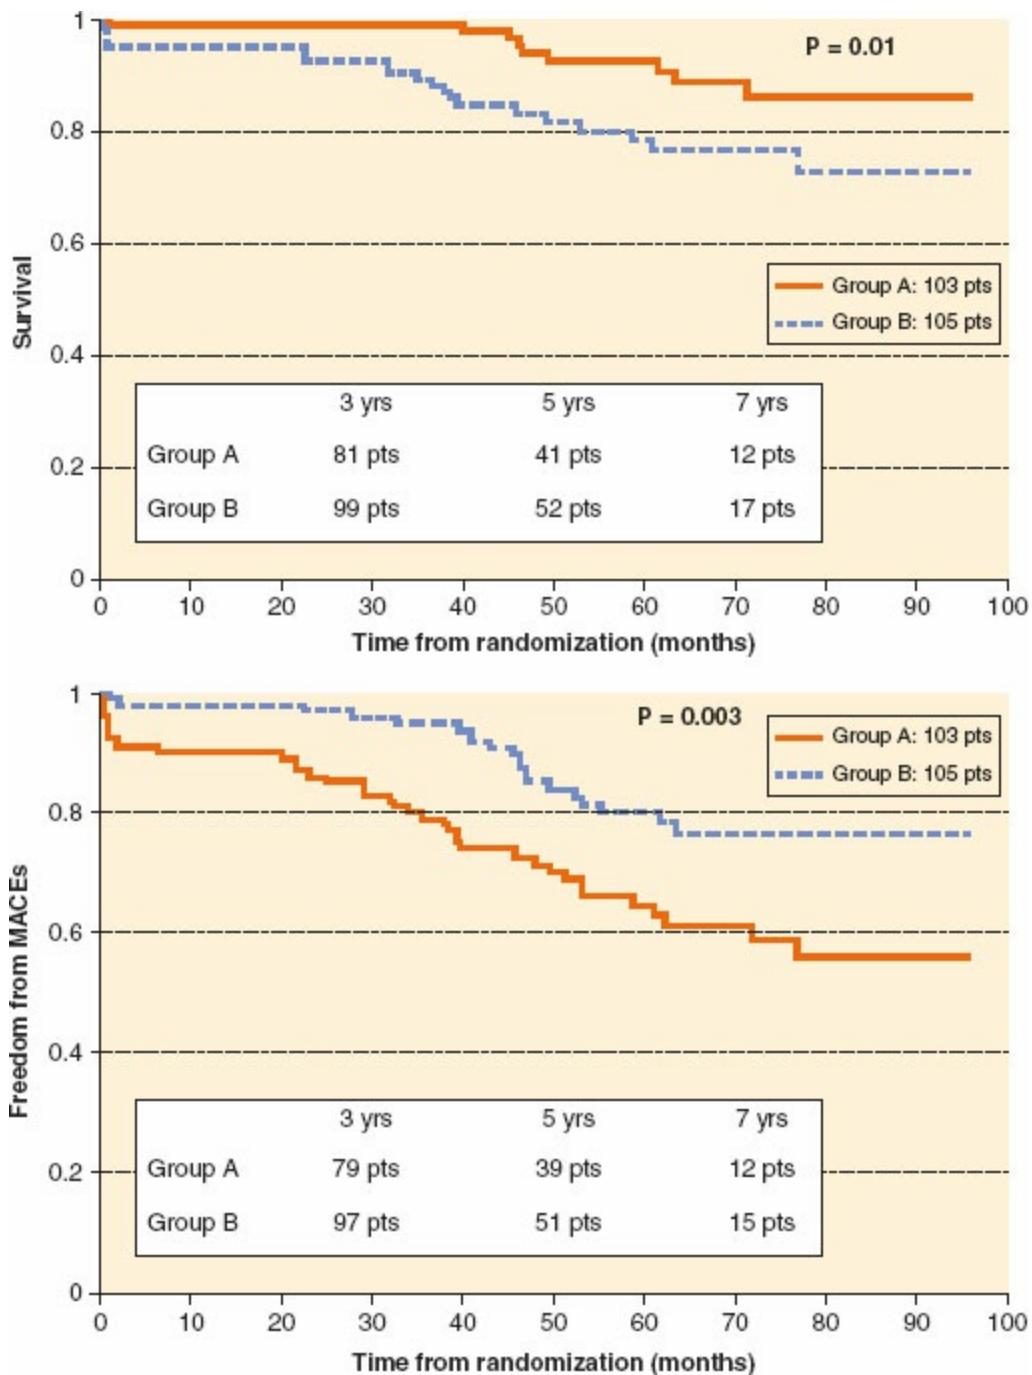

Cardiac morbidity and mortality is higher following vascular surgery than after other types of noncardiac surgery, and the presence of uncorrected CAD appears to double the 5-year mortality following vascular surgery. Given the high likelihood of concurrent CAD in patients presenting for vascular surgery, and given that myocardial revascularization may have long-term benefits in patients with triple vessel CAD, left main disease, or poor left ventricular (LV) function, the question of preoperative coronary revascularization prior to elective vascular surgery has been a subject of study. Initial observational studies suggested that preoperative cardiac revascularization improves patient outcomes prior to high-risk noncardiac surgery.<sup>80,81</sup> Whether preoperative coronary revascularization actually protects against perioperative MACE is controversial in prospective studies. Monaco and colleagues<sup>82</sup> randomized more than 200 patients undergoing vascular surgery to routine preoperative coronary angiography versus selective angiography based on the results of noninvasive testing and risk stratification. Myocardial revascularization was more common in the routine surveillance group, although there was no significant difference in in-hospital MACE rate between groups. Notably, however, long-term survival and freedom from death/cardiovascular events

was improved in the group who underwent routine preoperative coronary angiography (Fig. 40-5). The multicenter Coronary Artery Revascularization Prophylaxis (CARP) trial evaluated more than 500 patients who underwent prophylactic cardiac revascularization prior to major vascular surgery based on the presence of ischemia on a noninvasive stress imaging study.<sup>83</sup> Patients were randomized to either percutaneous coronary intervention (PCI) or coronary artery bypass (CABG). With aggressive medical therapy (>80% of patients on  $\beta$ -blockers, >70% on aspirin, and >50% on statins in both groups), no long-term benefit was noted with preoperative revascularization. A subsequent subgroup analysis examined the value of CABG versus PCI and found that patients who underwent CABG had fewer MIs and shorter hospital stays than their counterparts in the PCI group.<sup>84</sup> This difference may be due to more complete revascularization in the CABG group. It is worth noting that the CARP study randomized patients on the basis of abnormal stress testing, whereas the Monaco study performed coronary angiography on all patients in the routine group. Thus, in the CARP study, patients with CAD but limited or no ischemia at stress testing may have missed on a benefit to revascularization prior to the procedure. Furthermore, most patients in the CARP trial had single-vessel or two-vessel disease with normal LV ejection fraction. Exclusion criteria in this study included left main disease or ejection fraction less than 20%, thus limiting patients with more severe disease. A subsequent analysis of the CARP data found that patients with unprotected left main disease may be the only subset of patients who benefits from prophylactic revascularization.<sup>85</sup> In large part due to the CARP trial, preoperative coronary revascularization (either surgical or interventional) is not recommended prior to even high-risk surgery, unless revascularization is independently indicated according to current practice guidelines.<sup>86,87</sup>

For patients who have suffered recent MI who need noncardiac surgery, evidence suggests that the risk of postoperative MI decreases significantly with time. Furthermore, the risk of postoperative MI may be modified by the occurrence and type of revascularization performed (CABG vs. PCI) prior to elective surgery.<sup>88,89</sup> Current guidelines recommend waiting at least 60 days following MI before elective noncardiac surgery in the absence of intervention.<sup>33</sup> For patients for whom preoperative coronary revascularization is deemed necessary prior to elective surgery, the timing of originally proposed procedure depends on the type of coronary intervention performed. The most recent ACC/AHA guidelines make no specific recommendation on appropriate timing on noncardiac surgery following CABG. In this case, the clinical urgency of the procedure, medical optimization, and overall fitness of surgery must all be taken into consideration. Specific recommendations are made following PCI, and the ACC/AHA released a focused update on duration of dual antiplatelet therapy (DAPT) for patients with CAD in 2016.<sup>90</sup> The

updated guidelines suggest delaying elective noncardiac surgery 30 days following bare metal stent (BMS) placement and ideally 6 months following drug eluting stent (DES) placement (Class I; LOE B-NR). For patients treated with DAPT following coronary stent placement who must undergo surgical procedures that mandate discontinuation of their platelet receptor inhibitor (P2Y12) therapy, it is recommended that aspirin be continued when possible and the P2Y12 inhibitor be restarted as soon as possible following surgery (Class 1; LOE C-EO). A consensus decision among treating clinicians as to the relative risk of surgery and the discontinuation or continuation of antiplatelet agents can be useful (Class IIa; LOE C-EO). Elective noncardiac surgery after DES placement for whom P2Y12 inhibitor must be discontinued may be considered after 3 months if the risk of further delaying surgery outweighs the expected risk of stent thrombosis (Class IIb; LOE C-EO). Elective noncardiac surgery should not be performed within 30 days following BMS placement or within 3 months for DES implantation in patients in whom DAPT will need to be discontinued perioperatively (Class III; LOE B-NR).

**Figure 40-5** Cumulative survival and freedom from major adverse cardiac event for routine versus selective coronary angiography prior to major vascular surgery in intermediate- to high-risk patients. Long-term survival, and survival free from MACE, were greater in the group who underwent routine preoperative coronary angiography. (Reprinted with permission from Monaco M, Stassano P, Di Tommaso L, et al. Systematic strategy of prophylactic coronary angiography improves long-term outcome after major vascular surgery in medium- to high-risk patients: a prospective, randomized study. *J Am Col Cardio*. 2009;54:989–996.)

### Preoperative Anesthesia Evaluation for Vascular Surgery

The purpose of the preoperative anesthesia evaluation is to delineate the extent of any underlying comorbid pathology and medically optimize the

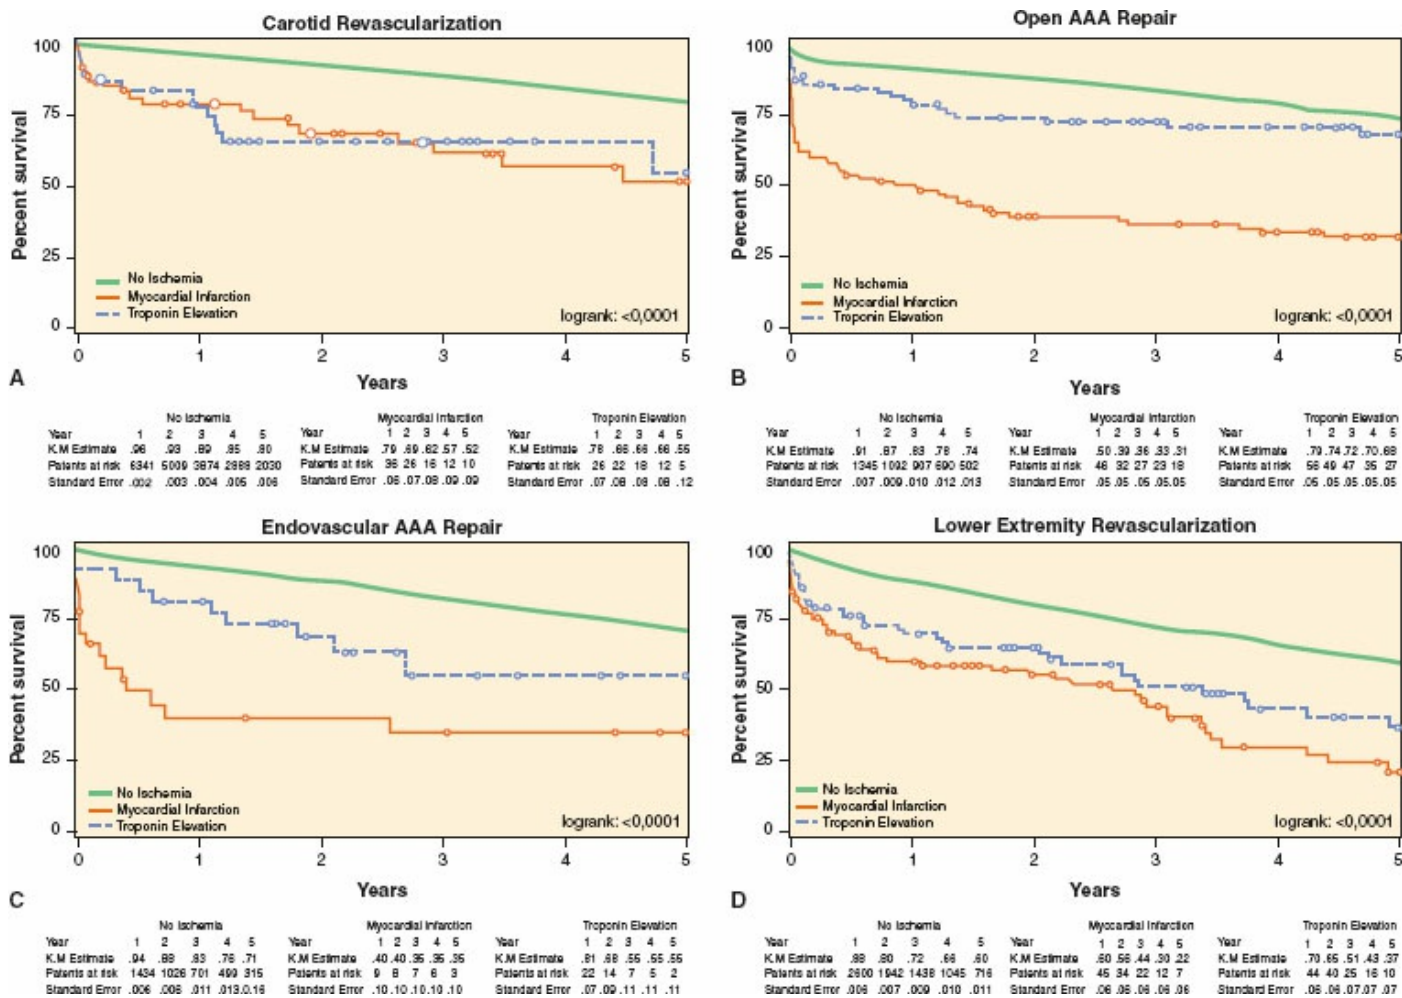

patient for surgery. In vascular surgery, the preoperative assessment predominantly focuses on the presence of, or risk factors for, coronary or noncoronary ASCVD. A careful history must be taken to define the extent of any diagnosed ASCVD and to screen for any undiagnosed concurrent disease (e.g., angina or equivalent, symptoms of transient ischemic attack (TIA), or mesenteric or peripheral ischemia). Physical examination should evaluate for any evidence of end organ involvement (e.g., diminished pulses, S4 gallop, or residual deficit from previous stroke) or cardiovascular decompensation (e.g., new or worsened murmur, jugular venous distention, third heart sound on cardiac auscultation, rales, shortness of breath, or peripheral edema). It is important to evaluate the control of any comorbid conditions such as diabetes or hypertension. The strong association between smoking and vascular disease mandates a thorough assessment of any underlying pulmonary disease. Medications should be optimized as discussed earlier.

For any major vascular surgery, it is prudent to obtain baseline laboratory studies. A complete blood count should be obtained due to the risk of major blood loss and possibility of concurrent medical diseases that may predispose to anemia. Coagulation studies should be considered if the patient is on anticoagulant medications or if regional anesthesia is anticipated. A metabolic panel should be obtained due to an increased likelihood of underlying renal insufficiency with resultant electrolyte abnormalities. It is also useful to have a baseline given an elevated risk of postoperative renal dysfunction. Cardiac biomarkers (e.g., troponin I, N-terminal pro-brain natriuretic peptide, cystatin C, and C-reactive protein) and risk factors identified on advanced imaging modalities (coronary artery calcium scores or CIMT) have long been studied for their ability to predict long-term cardiovascular outcomes; their utility in the perioperative setting to predict high-risk patients, however, is a relatively new area of interest.<sup>91</sup> A preoperative 12-lead electrocardiogram (ECG) is reasonable as a baseline because of the increased risk of perioperative MACE. A preoperative echocardiogram to assess LV function is reasonable for patients with previously documented LV dysfunction, worsening clinical status or if not assessed within the previous year, or for patients with dyspnea of unknown origin.<sup>33</sup> Routine echocardiography in asymptomatic patients cannot be recommended.

Determining which patients require additional preoperative cardiac testing is a source of frequent debate. Vascular surgery patients are known to be at elevated risk of perioperative MACE. It has been predicted that postoperative troponin elevation and MI predict a 26% and 55% lower survival rate, respectively, in the 5 years following vascular surgery compared with patients who do not experience an event (Fig. 40-6).<sup>92</sup> Thus, significant effort has focused on identifying patients at elevated cardiac risk. Conversely, over utilization of advanced testing modalities can put undue

stress on the health-care system, result in false positive tests, delay necessary surgery, and ultimately cause patient harm in further invasive workup and treatment. The most well-recognized clinical practice guidelines for perioperative cardiovascular evaluation for patients undergoing noncardiac surgery are jointly developed by the ACC/AHA and were most recently revised in 2014 (Fig. 40-7).<sup>33</sup> The first step in evaluation for fitness for surgery is to determine the urgency of surgery. Clinical emergencies (e.g., ruptured abdominal aortic aneurysm [AAA]) should proceed to the operating room without delay and with best medication optimization, recognizing that the risk of perioperative MACE is elevated in this situation. Situations that are urgent, but not emergent (e.g., critical limb ischemia [CLI]) may allow for an abbreviated cardiac workup, if such workup will impact clinical management. The second step is to evaluate whether the patient has an acute coronary syndrome (new, crescendo, or unstable angina; MI within the last 60 days) or other major cardiac pathophysiology (symptomatic heart failure; new or worsening valvular heart disease; or unstable arrhythmia or conduction disease). If present, these conditions should be evaluated and optimized per clinical practice guidelines prior to elective surgery. The third step involves estimation of perioperative risk of MACE based on combined clinical and surgical risk factors. Commonly used estimations include the American College of Surgeons National Surgical Quality Improvement Program risk calculator<sup>93</sup> or the revised cardiac risk index (RCRI)<sup>94</sup> with an estimation of surgical risk; however, The Vascular Study Group of New England developed a vascular surgery-specific model for the prediction of cardiac events that more accurately predicted the risk of cardiac complications in vascular surgery patients than the RCRI, which was found to underestimate the risk of MACE by 1.7- to 7.4-fold in vascular surgery patients.<sup>95</sup> Independent predictors of MACE in this study included: increasing age, smoking, insulin-dependent diabetes, CAD, CHF, abnormal cardiac stress test, long-term  $\beta$ -blocker therapy, chronic obstructive pulmonary disease, and elevated creatinine. Regardless of the risk calculator used, functional status dictates the necessity for further cardiac workup prior to surgery for any patient deemed at elevated (>1%) risk of perioperative MACE. Patients with moderate (4 metabolic equivalents [METs]) to excellent (>10 METs) exercise capacity may proceed to surgery with no further cardiac testing. For patients with poor or unknown functional capacity, a collaborative decision must be made between the patient and treating clinicians to determine the next step. Further cardiac testing (in the form of stress testing or cardiac catheterization) is reasonable if the results of the additional testing will change management decisions (e.g., coronary revascularization prior planned surgery or alternate plan for palliative care). Since most vascular surgery patients will fall in the elevated risk category and many will have poor to unknown functional status

due to comorbid conditions, additional cardiac testing is not unreasonable prior to major vascular procedures.

**Figure 40-6** Univariate Kaplan–Meier (K–M) survival curves, stratified according to postoperative myocardial ischemia, for different major vascular surgical procedures. Vascular surgery patients who suffer from perioperative myocardial ischemia have significantly worse outcomes with decreased survival at 5 years for (A) carotid, (B) open aortic, (C) endovascular aortic, and (D) peripheral interventions. AAA, abdominal aortic aneurysm. (Reprinted with permission from Simons JP, Baril DT, Goodney PP, et al. The effect of postoperative myocardial ischemia on long-term survival after vascular surgery. *J Vasc Surg.* 2013;58:1600–1608.)

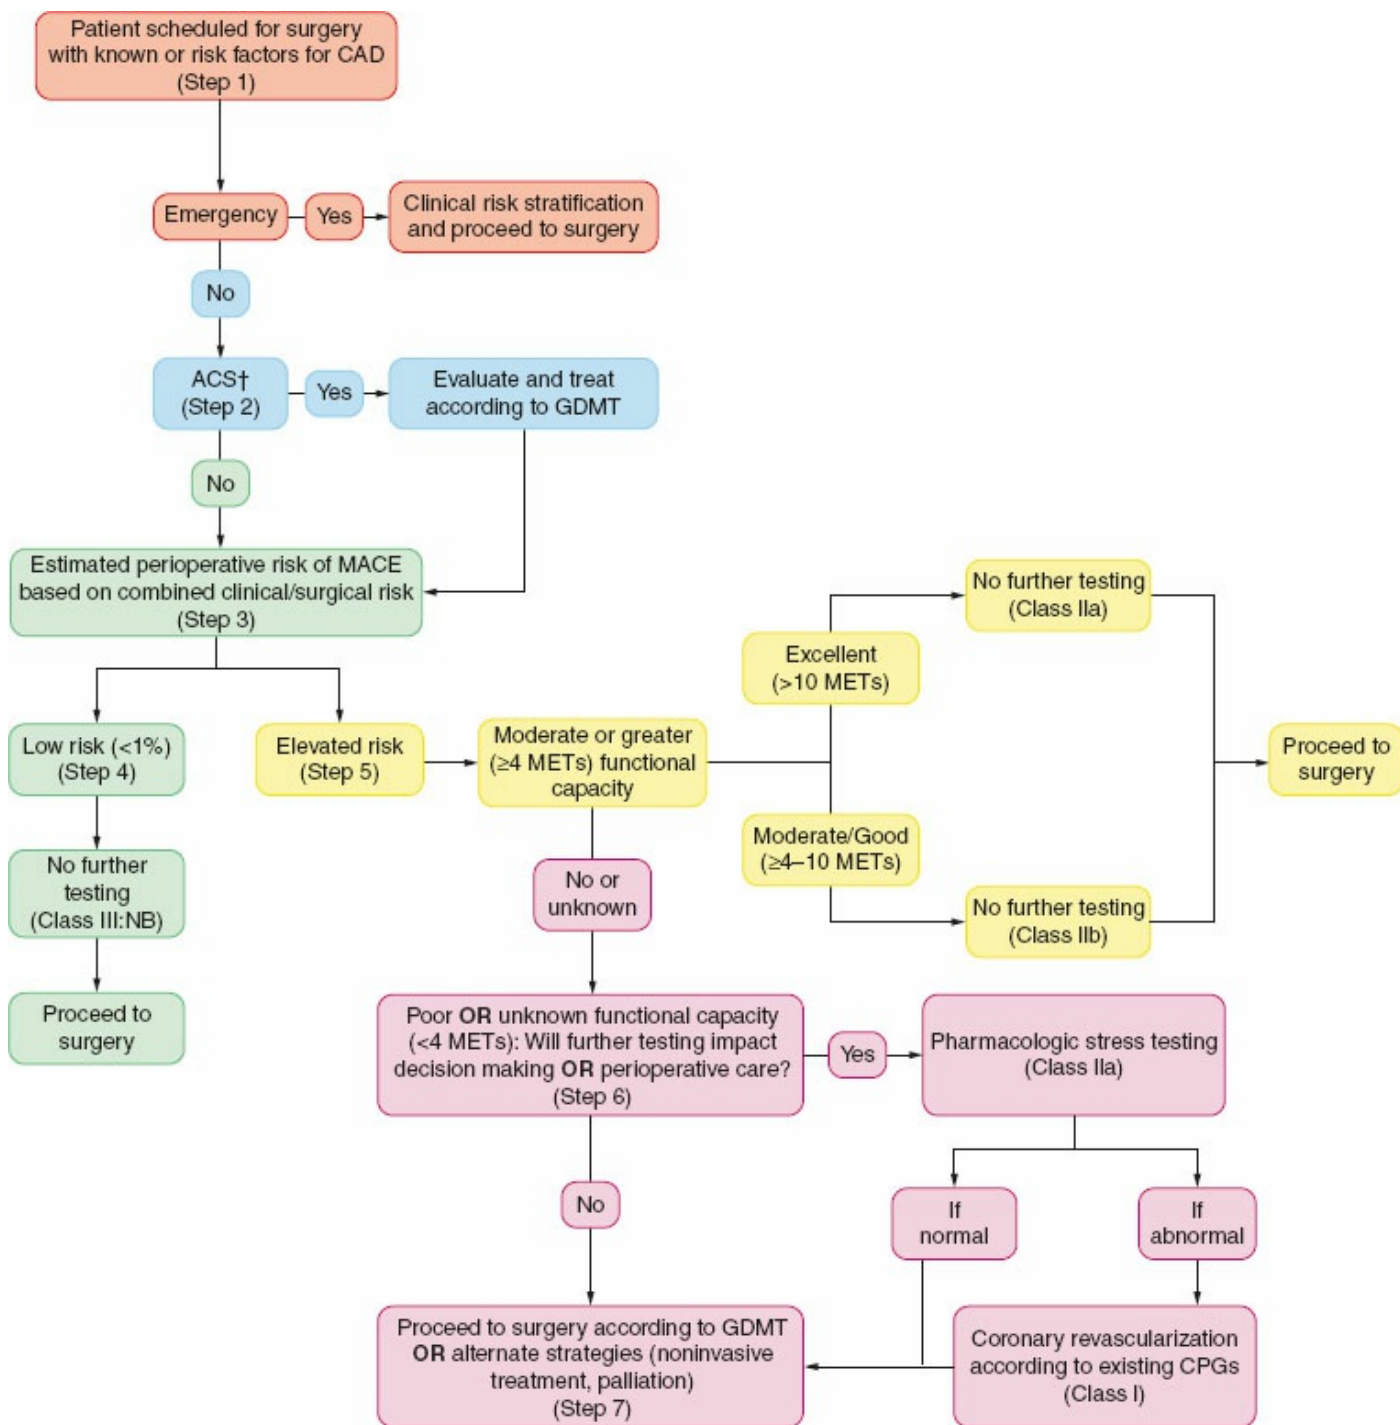

## Open Vascular Surgery

### Cerebrovascular Disease

An imbalance between cerebral oxygen supply and demand leads to cerebral ischemia, which can be temporary or permanent. Nearly 800,000 patients per year suffer a stroke in the United States, and nearly 6.6 million patients in total have suffered a stroke for an overall prevalence of almost 3%.<sup>3</sup> From 2001 to 2011, the number of stroke deaths declined by more than 20%,

primarily due to intensive efforts to control cardiovascular risk factors. Efforts to control hypertension appear to have had the greatest influence on the decline in stroke mortality, although improved management of diabetes mellitus and hyperlipidemia, as well as smoking cessation campaigns, have also contributed. The use of DAPT (aspirin plus clopidogrel) has been proven effective for both primary and secondary prevention of stroke in patients with cardiovascular risk factors.<sup>96</sup> Despite an overall decrease in stroke-related mortality, it is still the fourth leading cause of death in the United States.<sup>3</sup> Equally importantly, the combination of a significant psychological consequences and new disability may lead to profound impact on quality of life. Stroke has been called the most burdensome chronic condition.

Most strokes are ischemic, rather than hemorrhagic, in origin. Carotid atherosclerotic disease accounts for approximately 20% of all ischemic strokes, although the mechanism of pathophysiology is typically embolic rather than occlusive. Stroke symptomatology depends on the distribution of ischemia. Carotid disease may manifest as transient attacks of monocular blindness (amaurosis fugax), paresthesia, weakness or clumsiness, facial drooping, or speech problems. These symptoms may resolve spontaneously after a short period. Any focalized neurologic deficit lasting less than 24 hours' duration with no evidence of permanent infarction is known as a TIA. It has been estimated that up to 15% of strokes are heralded by TIA,<sup>97</sup> and the most important risk factor for future stroke is the presence of recent TIA symptoms. The risk of stroke following TIA is elevated in the initial days to weeks following the initial event.<sup>98,99</sup> Thus, TIA symptoms should prompt an immediate workup and referral for definitive intervention.

**Figure 40-7** Proposed algorithm for cardiovascular evaluation and management of patients undergoing noncardiac surgery. In this most recent iteration of the ACC/AHA clinical practice guidelines, individual consideration of patient medical versus surgical risk has been combined into overall perioperative risk. A combination of clinical urgency, patient risk of major adverse cardiac event, and patient functional status helps to guide the necessity of further preoperative cardiac work up. CAD, coronary artery disease; ACS, acute coronary syndrome; GDMT, guideline directed medical therapy; MACE, major adverse cardiac event; MET, metabolic equivalent; NB, no benefit; CPG, clinical practice guideline. (Reprinted with permission from Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2014;130:2215–2245.)

Several high profile randomized controlled trials have demonstrated clinical benefit for CEA for both symptomatic and asymptomatic carotid atherosclerosis. The North American Symptomatic Carotid Endarterectomy (NASCET) trial,<sup>100,101</sup> European Carotid Surgery Trial (ECST),<sup>102</sup> and Veterans Affairs Cooperative Studies (VACS) Program,<sup>103</sup> all demonstrated a benefit for CEA over best medical management for severe (greater than 70% to 80%) internal carotid artery (ICA) stenosis occlusion. Subsequent pooled analyses<sup>104,105</sup> found a significant 5-year benefit to surgery for patients with greater than 70% stenosis, a marginal benefit for patients with 50% to 70% stenosis, no benefit in patients with 30% to 49% stenosis, and an increased risk of ipsilateral ischemic stroke in patients with less than 30% stenosis. There was no benefit to treatment of lesions of less than 50% stenosis. The Asymptomatic Carotid Atherosclerosis Study (ACAS)<sup>106</sup> and the Asymptomatic Carotid Surgery Trial (ACST)<sup>107,108</sup> demonstrated a reduced risk of stroke for asymptomatic carotid disease, albeit less robust. A meta-analysis of trials of asymptomatic patients found a small absolute risk reduction of about 1% per year for surgical intervention for patients with 50% to 70% stenosis.<sup>109</sup> Because the morbidity of the surgical procedure is reasonably high, and the risk of an ischemic event is reasonably low in asymptomatic patients, CEA is justifiable only if the operative morbidity and mortality is lower than the natural risk of ischemic events in an untreated patient. It is important to recognize that these trials were performed when best medical therapy consisted primarily of aspirin therapy. The relative risk reduction of surgical intervention may be less robust in the current era of multimodal medical treatment with diet and lifestyle changes; smoking cessation campaigns; dual antiplatelet agents; and aggressive management of blood pressure, hyperlipidemia, and diabetes. Randomized controlled trials in the modern era of medical management have not been performed.

## **Preoperative Evaluation and Preparation**

The appropriate timing for CEA has been subject to debate. There has been concern that operative risk may be increased early after a neurologic event, particularly for large or evolving strokes.<sup>110</sup> However, it is known that transient neurologic symptoms are a harbinger of things to come. In one study of more than 1,700 patients who presented with index TIA, more than 10% returned with an acute stroke within 90 days, and nearly half of these strokes occurred within 2 days.<sup>111</sup> Analysis of pooled data from the NASCET and ECST trials demonstrated that for patients with greater than or equal to 70% stenosis, the attributable risk reduction for any ipsilateral stroke or any stroke or death within 30 days decreased from 30% when surgery occurred within 2 weeks to 18% at 2 to 4 weeks and 11% at 4 to 12 weeks.<sup>110,112</sup> Thus,

for symptomatic patients in whom surgical intervention is warranted, most recent recommendations favor definitive intervention within 2 weeks of the index event.<sup>113</sup>

It is reasonable to obtain a cardiac evaluation due to the known association between carotid and CAD; however, definitive intervention should not be delayed for extensive cardiac evaluation even in those patients with known cardiac disease because of the urgent nature of the surgery. It is prudent to treat all patients undergoing CEA as if they have underlying CAD with strict hemodynamic control. Fifty percent of patients with TIA or stroke due to CVD will have an abnormal stress test despite no report of angina; in 60% of these patients, the CAD will be severe by coronary angiography.<sup>114</sup> The approach to patients with both severe CAD and CVD is controversial, with proponents for both staged and synchronous repair. Because these operations are relatively rare (especially in symptomatic patients), current evidence comes primarily from poor-quality case series performed over many years, making generalizability to current practice difficult. Current guidelines provide no clear consensus on how this situation should be managed. The risk associated with both staged and combined CEA–CABG procedures in the asymptomatic population may outweigh any benefit unless the lesion is particularly high risk, such as contralateral complete occlusion or bilateral severe stenosis.<sup>115</sup>

## **Neurophysiologic Monitoring and Preserving Neurologic Integrity during Carotid Endarterectomy**

Most strokes in the perioperative period are embolic in origin. Hypoperfusion related to temporary occlusion (“cross-clamping”) of the carotid artery during surgery can also lead to cerebral ischemia. Cross-clamping acutely disrupts blood flow to the ipsilateral hemisphere, even if flow was markedly diminished by severe stenosis. In this case, blood supply to the brain will depend entirely on collateral flow from an intact circle of Willis. Autopsy studies have found that the majority of specimens demonstrated anatomic anomalies in the circle of Willis.<sup>116</sup> Hypoplasia was the most frequently noted anomaly (24%) (Fig. 40-8), and an incomplete circle due to complete absence of a vessel was noted in an additional 6%. Furthermore, even an anatomically intact circle of Willis may not provide adequate cerebral blood if collateral perfusion is compromised by occlusive disease of the contralateral carotid or vertebral arteries, or if the patient becomes relatively hypotensive compared to baseline. Phenylephrine infusions are commonly used to augment cerebral blood flow but the practice has been associated with an increase in postoperative MI following CEA.<sup>117</sup> However, the short-term use of phenylephrine to augment cerebral collateral perfusion pressure, particularly

in instances of electroencephalogram (EEG)-detected reversible cerebral ischemia, seems to be without significant long-term detriment to the heart.

**Figure 40-8** Intact and hypoplastic circle of Willis. (A) demonstrates an anatomically normal circle of Willis. (B) demonstrates hypoplastic (a) anterior and (b) posterior communicating arteries. (Reprinted with permission from Iqbal S. A comprehensive study of the anatomical variations of the circle of Willis in adult human brains. *J Clin Diagn Res.* 2013;7:2423–2427.)

A temporary carotid shunt can be employed to bypass the cross-clamp and restore cerebral blood flow. Significant practice variation exists among surgeons regarding the use of carotid shunts in CEA. Some surgeons never use shunts and rely on expedient surgery and meticulous hemodynamic control (including permissive hypertension) to maintain adequate collateral cerebral perfusion pressures. Others may shunt selectively based on changes in neurophysiologic monitoring, and still others shunt routinely. Shunt placement is not an entirely benign undertaking, with morbidity including atheromatous or air emboli, arterial dissection, nerve injury, hematoma, infection, and long-term restenosis. Perhaps most compellingly, shunting has been demonstrated to be unnecessary in approximately 85% of patients.<sup>118</sup> Furthermore, a shunt is only beneficial if the cause of neurologic dysfunction is inadequate blood flow. However, the majority of studies suggest that as many as 65% to 95% of all neurologic deficits during CEA are caused by thromboembolic events. A recent review of the literature found no difference in outcomes including rate of all stroke, ipsilateral stroke, or death up to 30 days after surgery between selective and routine shunting.<sup>119</sup>

Neurophysiologic monitoring is commonly employed to assess overall cerebral perfusion and to help determine which patients may benefit from carotid shunting. Some monitoring techniques, such as electroencephalography (EEG), somatosensory evoked potentials (SSEP), and

motor evoked potentials (MEP), assess the overall integrity of cerebral function. Others, including transcranial Doppler (TCD) or carotid stump pressure, assess the blood flow in the large cerebral vessels. A third group, including near-infrared spectroscopy (NIRS) and jugular venous bulb saturation, estimate cerebral metabolism.<sup>120</sup> The gold standard for cerebral monitoring remains serial neurologic examination on an awake patient. No matter the modality employed, the goal of neurophysiologic monitoring is to identify patients who may benefit from selective shunting and to avoid shunting in patients where it is unnecessary.

**Figure 40-9** Characteristic electroencephalogram (EEG) changes with reduction in cerebral blood flow. Decreases in cerebral blood flow are associated with characteristic changes in the EEG and predictable cellular response. CBF, coronary blood flow; EEG, electroencephalogram; ATP, adenosine triphosphate. (Reprinted with permission from Foreman B, Claassen J. Quantitative EEG for the detection of brain ischemia. *Crit Care*. 2012;16[2]:216.)

EEG monitoring is perhaps the most commonly employed neurophysiologic monitor for carotid surgery. EEG records the electrical activity of the brain, and changes in cerebral blood flow can be reflected in the EEG waveform. Normal cerebral blood flow is approximately 50 mL/min/100 g brain tissue. In the perioperative period, decreases in cerebral blood flow as low as approximately 22 mL/min/100 g brain tissue may be well tolerated with no EEG changes.<sup>121</sup> EEG deterioration usually begins below a threshold of approximately 15 to 18 mL/min/100 g brain tissue, and frank cellular failure appears to occur below 10 to 12 mL/min/100 g brain tissue (Fig. 40-9).<sup>122</sup> The most common manifestations of cerebral ischemia

on EEG are ipsilateral slowing and/or attenuation. Deterioration in EEG can be noted within seconds of carotid cross-clamping, and these changes are typically reversible with appropriate augmentation of hemodynamics and/or temporary shunt placement.

EEG monitoring is not without limitations. The sensitivity of EEG for predicting cerebral ischemia is poor; in one series of more than 300 patients, EEG identified cerebral ischemia in fewer than 60% of patients with a false positive rate of 1%.<sup>123</sup> In patients with pre-existing or fluctuating neurologic deficits, the EEG may be falsely negative. In these patients, there may be areas of brain parenchyma that are electrically silent or immediately adjacent to regions of infarction, and therefore not reliably monitored by EEG. These still-viable regions may progress to irreversible injury over the length of the procedure. EEG monitors cortical structures and not deep brain structures, and strokes in this distribution will be missed. Interpretation of EEG may be complicated by other intraoperative parameters such as hypothermia or rapid or sudden changes in anesthetic depth. This may be particularly relevant when propofol-based anesthetics are used, although in general EEG changes secondary to anesthetic agents are more likely to be bilateral, whereas changes due to cross-clamping or hypoperfusion tend to involve the ipsilateral hemisphere. Finally, it is important to recognize that EEG is a global monitor of cerebral activity. It is unable to reliably detect strokes related to smaller thromboembolic phenomena, which is the most likely etiology of perioperative stroke.

SSEP monitoring employs electrical stimuli to peripheral nerves and evaluates the amplitude and latency of the signal over the cerebral cortex. In contrast to EEG, which only evaluates cortical functioning, SSEP monitoring also reflects the deep brain structures. Most commonly, the median and/or tibial nerves are assessed. A decrease in signaling for the median nerve suggests hypoperfusion in the watershed of the middle cerebral artery, whereas deterioration of tibial nerve signaling may reflect ischemia of the parenchyma supplied by the anterior cerebral artery.<sup>120</sup> A decrease in signal amplitude of greater than 50% is typically accepted as indicative of ischemia, which may occur when cerebral blood flow is critically low (i.e., at 15 mL/min/100 g brain tissue). SSEP monitoring may be particularly useful in patients with baseline cerebral ischemia in whom EEG interpretation is more difficult. Although some studies have been optimistic about the value of SSEP monitoring in the detection of cerebral ischemia, others have questioned both the sensitivity and specificity of SSEP for the detection of cerebral ischemia. A recent comparison of different neurophysiologic monitoring demonstrated a sensitivity of approximately 80% and a specificity of 57% for the detection of cerebral ischemia.<sup>124</sup> Furthermore, SSEPs are sensitive to virtually all commonly used anesthetic agents which may complicate intraoperative

interpretation and lead to a high false positive rate. A light plane of anesthesia must be maintained if increased latencies and decreased amplitude of SSEP are to be ascribed to inadequate cerebral perfusion. False negatives with intraoperative SSEP monitoring has also been described; focal ischemia of the internal capsule has been suggested as a potential mechanism in this circumstance. Monitoring motor, rather than sensory, evoked potentials is one mechanism to overcome this problem. To monitor MEP, transcranial electrodes are utilized to stimulate the cerebral cortex, and motor response in the contralateral extremity is recorded. In one recent study, the use of MEP in addition to SSEP was more sensitive for detection of cerebral ischemia.<sup>125</sup> In this study, there were no false negative results with MEP as compared to a 1.5% false negative rate when SSEPs were used alone. MEPs, however, can be exquisitely sensitive to anesthetic interference (neuromuscular blockade, in particular, is avoided) and may be more prone to false positives and unnecessary intervention (such as blood pressure augmentation or temporary shunt placement).

TCD measures the maximum velocity of blood flow through the middle cerebral artery as a surrogate for cerebral blood flow. TCD may be particularly useful in the detection of microembolic phenomena that may be missed by more global measures of cerebral functioning. In a small case series, TCD predicted neurologic events despite a normal intraoperative EEG.<sup>126</sup> Detection of microembolic showers, particularly during surgical manipulation, may allow for the operative team to alter the surgical plan to prevent further neurologic insult. TCD is also useful in confirming that cerebral blood flow remains at an acceptable level after carotid cross-clamping or, if a shunt is used, to confirm that flow through the shunt is adequate. TCD may be particularly useful in postoperative surveillance because most strokes occur after, rather than during, CEA. In addition to microembolic showers, TCD can also identify patients with acute postoperative thrombosis or those at risk for cerebral hyperperfusion syndrome.<sup>127</sup> TCD has the benefit of being quick, easy to apply, is more easily interpretable without expertise (as compared to EEG or evoked potentials), and allows for serial evaluation. Disadvantages to TCD include operator dependence and technical limitation. In approximately 10% to 20% of patients, adequate temporal windows (a prerequisite for accurate monitoring) cannot be obtained.

Carotid stump pressure estimates ipsilateral hemispheric blood flow by directly measuring the pressure in the carotid stump distal to the clamp. Purported advantages of this technique are that it is a direct gauge of collateral cerebral perfusion, quick to obtain, cost effective, and does not require sophisticated equipment or expert interpretation. Stump pressures greater than 40 to 50 mmHg are generally considered adequate to avoid

temporary shunt placement, although a critical value for stump pressure is not known.<sup>121</sup> Some patients may have adequate perfusion below values of 40 to 50 mmHg, whereas others may not have sufficient collateral flow despite maintaining stump pressure above this range. A retrospective series of more than 400 patients performed under regional anesthesia found that a stump pressure cutoff of 40 mmHg was as reliable as EEG monitoring in predicting cerebral ischemia on cross-clamp application during CEA.<sup>128</sup> The generalizability to patients undergoing CEA under general anesthesia is unclear.

NIRS uses the relative absorption of specific wavelengths of light by oxyhemoglobin and deoxyhemoglobin to estimate frontal lobe cerebral perfusion (rSO<sub>2</sub>) and estimate cerebral oxygen balance. A decrease in rSO<sub>2</sub>, theoretically, reflects a decrease in cerebral blood flow below a critical level. NIRS is easily portable, inexpensive, and simple to interpret without special training.<sup>121</sup> Limitations include potential inaccuracy over areas of previous infarction, as well as in the fact that NIRS is a global assessment of cerebral oxygenation only in the frontal grey matter. Thus, ischemia in other areas of the brain may be missed. Data on the sensitivity and specificity of NIRS for predicting cerebral ischemia during CEA are conflicting. One study performed under regional anesthesia demonstrated that a drop in rSO<sub>2</sub> more than 19% following carotid cross-clamping has sensitivity of 100% and specificity of 98% (yielding PPV of 82% and NPV of 100%) for predicting need for temporary shunt placement,<sup>129</sup> whereas another using the same device and ischemic threshold demonstrated a sensitivity of 60% and a specificity of 25%.<sup>130</sup> Whether these results are applicable to CEA performed under general anesthesia is unclear.

## **Anesthetic Considerations for Carotid Endarterectomy**

In general, premedication with sedatives is avoided to facilitate rapid emergence and immediate assessment of a neurologic examination. If deemed necessary, the smallest effective dose of midazolam should be titrated to effect. Once in the operating room, standard monitors should be applied. Invasive blood pressure monitoring is recommended due to the potential for hemodynamic lability as a result of surgical or anesthetic manipulation. Care should be taken to maintain hemodynamics within 20% of the patient's baseline range due to potential shifts in cerebral autoregulation. Rarely is invasive central monitoring with a central venous or pulmonary artery catheter necessary, unless dictated by specific patient risk factors. At least one medium- to large-bore intravenous access should be obtained, although the risk of major blood loss or fluid shifting in this procedure is low.

CEA can be performed under either general or regional anesthesia. A

regional anesthetic allows for continuous monitoring of a patient's neurologic status, which is the ultimate monitor for cerebral ischemia. An abrupt change in mental status will alert the operative team sooner and more definitely than indirect neuromonitoring methods and will also avoid morbidity associated with unnecessary interventions. Regional anesthesia avoids hemodynamically labile periods such as induction and emergence of general anesthesia as well as the need to administer negative inotropic anesthetic agents to patients with underlying cardiovascular disease. Superficial cervical plexus blockade has been found to be as efficacious as deep or combined block while avoiding the known complications of a deep cervical plexus block.<sup>131</sup> Complications associated with deep cervical plexus block include accidental subarachnoid injection with resultant brainstem anesthesia; intravascular injection with potential seizure; or accidental blockade of the phrenic, vagus, or recurrent laryngeal nerves with respiratory complications. Patient cooperation is vital as the patient will have to lie still for the duration of the operation (inability to communicate, orthopnea, and painful arthritis are relative contraindications) and patients cannot be claustrophobic as the surgical drapes will be in close proximity to the patient's face.

General anesthesia affords improved patient comfort, particularly for highly anxious patients, and may allow for more frank intraoperative communication amongst the operative team. Perhaps most compellingly, it avoids an urgent conversion to general anesthesia should complications arise such as deterioration of neurologic status or oversedation. It is not uncommon for the operating room table to be positioned with the head away from the anesthesia provider to allow the surgical team adequate room to work. Thus, emergent conversion to general anesthesia, with an ongoing operation in the neck, is not a trivial task. Overall conversion rates to general anesthesia are generally less than 5%<sup>132</sup>; nevertheless, the ability to rapidly convert to general anesthesia in case of surgical or anesthetic misadventure must be ensured.

Whether one anesthetic technique is superior to the other has been the subject of extensive debate. The most well-known study in this patient population is the General Anesthesia versus Local Anesthesia for carotid surgery (GALA) trial,<sup>132</sup> an international, multicenter, randomized controlled trial of more than 3,500 patients. There was no difference in the primary end point of proportion of patients with stroke, MI, or death between randomization and 30 days after surgery between the two groups. A recent meta-analysis of 14 randomized trials involving more than 4,500 operations (the largest trial included being the GALA trial) similarly demonstrated no difference in death, stroke, or MI rates between the general and local anesthesia groups (Fig. 40-10).<sup>133</sup> There were also no difference in major morbidity, postoperative cardiovascular or pulmonary complications, hospital

length of stay, or patient satisfaction between the two groups. Currently available literature does not suggest a benefit of one anesthetic approach over another. Rather, a mutually agreeable decision should be made between the surgeon and anesthesiologist, bearing in mind patient preference and potential limitations. Regardless of technique chosen, the anesthetic goals are the same: mitigate perioperative cerebral insult, ensure hemodynamic stability, and allow for a smooth and rapid emergence for anesthesia to allow for early neurologic assessment.

General anesthesia for CEA is typically performed with an endotracheal tube (ETT), although the use of laryngeal mask airway (LMA) has been described. ETT offers a more secure airway, potential better control of gas exchange, and may distort the anatomy of the neck less than an LMA. LMA may cause less hemodynamic lability during periods of induction and emergence since direct laryngoscopy is avoided. General anesthesia is maintained at a “light” level that ensures amnesia but minimally interferes with neurophysiologic monitoring. Typically, a balanced technique is employed and a variety of agents have been successfully employed. General anesthesia is typically induced with a short-acting hypnotic agent, titrated to effect. Both etomidate and propofol decrease cerebral metabolic rate and thus cerebral oxygen requirements. Etomidate may preserve cardiovascular stability and thus be beneficial for patients in whom cardiac reserve is limited. The addition of a short-acting opioid such as fentanyl or remifentanyl is frequently employed to blunt the hemodynamic stimulation of intubation. The trachea may be sprayed with atomized lidocaine prior to intubation in an attempt to minimize stimulation by the ETT during surgery and to prevent coughing upon emergence. Small amounts of short-acting opioid can be titrated intraoperatively as needed; however, large doses or long-acting opioids are typically avoided so as to not confound the neurologic examination at the end of surgery. The combined use of a cervical plexus block and/or surgeon-administered local anesthetic can significantly reduce or eliminate the need for perioperative opioids. Muscle relaxation is not mandated for this surgery, but often allows for the “lighter” plane of anesthesia and reduces muscular interference with the EEG.

General anesthesia can be maintained with either volatile or intravenous agents. No evidence has reliably demonstrated a benefit for one technique over another.<sup>134,135</sup> All of the commonly used volatile agents decrease cerebral metabolic rate and oxygen requirements to a comparable degree.<sup>136</sup> No differences in intraoperative hemodynamics have been described between inhalational and intravenous anesthetic techniques. Patients undergoing a propofol-based anesthetic have been noted to have fewer intraoperative regional wall motion abnormalities suggestive of ischemia than those undergoing isoflurane-based anesthetics; however, no postoperative

differences in troponin levels, EKG changes, or clinical outcomes were noted in study.<sup>135</sup> The transient intraoperative regional wall motion abnormalities were attributed to isoflurane-induced ventricular loading changes as a result of arterial and venous dilation and unrelated to myocardial oxygen balance. Intravenous anesthesia with propofol and remifentanyl may be associated with less hemodynamic lability upon emergence of anesthesia,<sup>134</sup> at the expense of longer recovery room stays and medical intervention for hypertension.<sup>135</sup> The authors attribute this difference not to the ultrashort duration of action of analgesia, but rather the more rapid awakening from propofol/remifentanyl than isoflurane/fentanyl-based regimens. This assertion is supported by comparable pain scores and analgesic requirements. The more rapid recovery from intravenous-based anesthetic techniques and ability to obtain a postoperative neurologic examination makes intravenous-based anesthetics attractive to many providers. Intravenous regimens had the added benefit of lower rates of postoperative nausea and vomiting, which prevents retching on a fresh neck incision and may decrease the risk of postoperative hematoma, a feared complication. Intravenous techniques, at approximately nine times the cost of inhalational based anesthetics, were less cost effective in comparison. Regardless of whether an inhalation or intravenous based technique is chosen, short-acting agents are preferable to allow for rapid awakening. Desflurane or sevoflurane may be preferable to isoflurane due to their rapid offset and salutary effects, on cognitive recovery and cerebral ischemia.<sup>136</sup>

Normocapnia should be maintained during CEA. Hyperventilation may lead to cerebral vasoconstriction and decrease cerebral blood flow during critical periods of carotid cross-clamping. Hypercapnia may be equally detrimental if it leads to dilation of the cerebral vasculature in normal areas of the brain, whereas vessels in ischemic areas are already maximally dilated and are unable to further respond. The net effect is a “steal” phenomenon with diversion of blood flow from hypoperfused to normal areas of the brain. Hypothermia can depress cerebral activity and decrease cellular oxygen requirements below the minimum levels normally required to maintain cellular viability. In theory, hypothermia represents the most effective method of cerebral protection; even a mild decrease in temperature may reduce ischemic damage to the brain. However, even mild hypothermia can induce shivering that significantly increases myocardial oxygen consumption and work.<sup>137</sup> Currently, the literature provides no definitive evidence to support the hypothesis that hypothermia protects that brain sufficiently to justify the myocardial risks imposed by hypothermia and shivering.

**Figure 40-10** Odds ratio for outcome of (A) stroke or death, or (B) death for carotid endarterectomy performed under general versus local anesthesia. Plots show odds ratios and 95% confidence interval for the specified outcomes. No difference in any of the primary outcomes was noted in either the GALA trial or a meta-analysis of the literature. GA, general anesthesia; LA, local anesthesia. (Reprinted with permission from Lewis SC, Warlow CP, Bodenham AR, et al. General anaesthesia versus local anaesthesia for carotid surgery [GALA]: a multicentre, randomised controlled trial. *Lancet*. 2008;372:2132–2142.)

Patients are nearly always extubated at the end of the surgical procedure. A deep extubation may be considered in those patients who were easy to

ventilate, intubate, and are at minimal risk for aspiration. The rationale for deep extubation is to mitigate the hemodynamic lability that may accompany emergence and to prevent coughing or straining against an ETT with a fresh vascular anastomosis in the neck. Tight blood pressure control must continue through extubation and into the postoperative period. Whether performed before or after extubation, neurologic integrity must be confirmed prior to leaving the operating room. New neurologic deficits may lead to noninvasive imaging, cerebral angiography, or surgical re-exploration. It is rare to require postoperative intensive care unit (ICU) monitoring, and this is typically limited to particularly high-risk patients. In one study, postoperative ICU surveillance was necessary only for patients with four or more of the following risk factors: stroke, CHF, chronic kidney failure, hypertension, dysrhythmia, and MI.<sup>138</sup>

## Postoperative Considerations

The paradox of carotid surgery is that, though the goal is to reduce the long-term patient risk of stroke, the patient is put at small but real risk of perioperative stroke. The incidence of postoperative stroke following CEA has been estimated to be approximately 6%.<sup>101,102</sup> Three interventions in the modern era, however, have decreased the incidence of perioperative stroke to approximately 1%: improved perioperative medication management (namely, DAPT), perioperative neurophysiologic monitoring (primarily intraoperative TCD and completion angiography), and perioperative hemodynamic control (preventing cerebral hyperperfusion and hemorrhage).<sup>139</sup> Cerebral hyperperfusion syndrome (CHS) is a rare but devastating complication of CEA, reported in 0% to 3% of cases.<sup>140</sup> CHS occurs as a consequence of impaired cerebral autoregulation following relief of high grade stenosis, which may result in ipsilateral cerebral edema, headache, seizures, focal neurologic deficit, or intracerebral hemorrhage. Management of CHS consists of pharmacologic control of hypertension and limitation of rises in cerebral perfusion. Early recognition and treatment is paramount, and complete recovery is possible.

Hemodynamic lability is common in the perioperative period; hypertension is more common than hypotension. Both acute tachycardia and hypertension may precipitate acute myocardial ischemia and failure, and hypertension is associated with CHS as discussed earlier. Post-CEA hypertension is significantly associated with adverse events such as stroke, death, and a trend toward cardiac complications, whereas postoperative hypotension and bradycardia do not appear to correlate with adverse primary or secondary outcomes. A large review of more than 60,000 patients suggests the risk of perioperative MI is below 1%.<sup>141</sup> Despite the low incidence, MI

remains a leading cause of death following CEA. Appropriate perioperative medication management as discussed earlier is critical to decrease the risk of MACE. Uncontrolled pain may contribute to hemodynamic lability, although it is important to balance pain control with the need to follow neurologic status. Total perioperative fluid should be limited in this case due to relatively small intraoperative losses (either blood or evaporative), a short surgical time with limited exposure, and frequent diastolic dysfunction. Fluid overload is relatively common cause of demand ischemia, congestion, and respiratory or cardiovascular morbidity following CEA. Other common causes of hypertension should also be ruled out such as full bladder, hypoxemia, or hypercarbia. Once secondary causes of hypertension are ruled out, pharmacologic treatment should be initiated with goal hemodynamics typically within 20% of the patient's baseline values. In some centers, a postoperative ECG is to be obtained in the recovery room to evaluate for new ischemia.

Postoperative respiratory insufficiency following CEA may result from underlying pulmonary pathophysiology, recurrent laryngeal nerve or hypoglossal nerve injury, neck hematoma, or altered carotid body chemoreceptor response to hypercapnia or hypoxia. Surgical manipulation may damage the nerve supply to the carotid body, resulting in impaired chemo- and baroreceptor responses. Although unilateral loss of carotid body chemoreceptor function is unlikely to be significant, a bilateral loss may prevent the patient from appropriately increasing ventilation in response to hypercapnia or hypoxemia. This may be particularly important for a patient undergoing CEA who has had previous contralateral surgery. Supplemental oxygen should be utilized in the postoperative period. Similarly, drugs that depress respiratory drive (e.g., narcotics) should be limited and avoided whenever possible. Cranial nerve injury is usually temporary.

Wound hematomas develop in up to 2% of patients following CEA. Small hematomas which are likely caused by venous oozing may be managed conservatively with reversal of residual heparin or with compression. A rapidly expanding hematoma is a clinical emergency and must be evaluated immediately due to the risk of tracheal compression and impending loss of airway. Impaired lymphatic drainage can produce sudden and severe pharyngolaryngeal edema; it is prudent to have difficult airway equipment (including videolaryngoscopy, small ETT, and surgical airway equipment) available prior to reinstrumentation of the airway. A high index of suspicion for arterial bleeding may preclude the ability to open and evacuate the hematoma at bedside. Management of a rapid enlarging or symptomatic hematoma is best undertaken in the operative room, both for airway management and surgical re-exploration.

## Aortic Reconstruction

Surgical manipulation of the aorta can result in significant and potentially catastrophic effects on patient hemodynamics. The anesthetic management of aortic reconstruction is perhaps the most technically challenging for the vascular anesthesiologist. Aortic surgery typically comes in two flavors: reconstruction for aneurysmal disease or reconstruction for aortic dissection. 

An aneurysm is defined as a greater than 50% dilation of normal expected arterial diameter; for most patients, this corresponds to an abdominal aortic diameter greater than 3.0 cm. The abdominal aorta is the most frequent location of arterial aneurysm and is approximately nine times more common than a thoracic aortic aneurysm.<sup>142</sup> Thoracic aortic aneurysms may involve the ascending (40%), descending (35%), or aortic arch (15%).<sup>143</sup> Approximately 15% involve both the thoracic and abdominal aorta. Thoracic aortic aneurysms are discussed in more detail in [Chapter 39](#) (Anesthesia for Cardiac Surgery). AAAs are classified as infrarenal, juxtarenal, or suprarenal. Approximately 85% of AAAs are infrarenal, with a minority involving the suprarenal aorta.<sup>144</sup> It is vital to understand the location of the aneurysm because it will dictate the level of aortic cross-clamp applied, which has significant implications to the anesthetic management.

Though many of the risk factors are shared between the two 5 processes, the pathophysiology of aortic aneurysm formation is distinct from atherosclerotic disease. Aortic aneurysm formation is a degenerative process involving the degradation of aortic wall connective tissue (primarily, the medial and adventitial layers), inflammation and immune responses, and biomechanical wall stress.<sup>145</sup> The size of the aortic aneurysm is the single most important predictor of subsequent rupture and mortality. A prospective study followed 300 consecutive patients who were initially managed nonoperatively.<sup>146</sup> The median increase in aneurysm diameter was 0.3 cm per year. The 6-year cumulative incidence of rupture was 1% in patients among patients with aneurysms less than 4.0 cm, 2% for patients with aneurysms 4.0 to 4.9 cm, but 20% among patients with aneurysms more than 5.0 cm in diameter ([Fig. 40-11](#)). Current recommendations are for serial monitoring of known aneurysms and surgical repair when AAAs exceed 5.5 cm or descending thoracic aortic aneurysms exceed 6.5 cm.<sup>147,148</sup> Other risk factors for rupture include rapid growth, symptomatology (e.g., abdominal or back pain), aneurysm shape (saccular vs. fusiform), sex, family history, and degree of control of other comorbidities. Aneurysm rupture is nearly always lethal with mortality rates of 85% to 90%.<sup>149</sup> Thus, close follow-up for known aneurysms is essential, particularly as they enlarge.

Acute aortic dissection is a life-threatening medical catastrophe that is

associated with very high rates of morbidity and mortality. More than 20% of patients with aortic dissection die before hospital admission.<sup>150</sup> The hallmark lesion of aortic dissection is a tear in the intimal layer of the arterial wall that creates a false lumen, which is then propagated by pulsatile blood flow. Aortic dissections are classified anatomically and temporally. Acute dissections are those in which clinical symptomatology has lasted fewer than 14 days. Dissections with symptoms exceeding 2 weeks' duration are deemed chronic. Approximately half of aortic dissections originate from the ascending aorta; ascending aortic aneurysms are a surgical emergency. Death from an ascending aortic aneurysm is usually due to acute aortic regurgitation, pericardial tamponade, or myocardial ischemia secondary to coronary ostial compromise. The next most common site of origin is just distal to the left subclavian artery, in the vicinity of the ligamentum arteriosum. Isolated abdominal aortic dissections are rare, with a reported incidence of 1.3%.<sup>151</sup> Death from acute descending aortic dissection is typically secondary to end-organ compromise due to malperfusion of the visceral vessels. Uncomplicated descending aneurysms may be managed medically, whereas complicated (i.e., visceral or limb compromise) require surgical intervention.

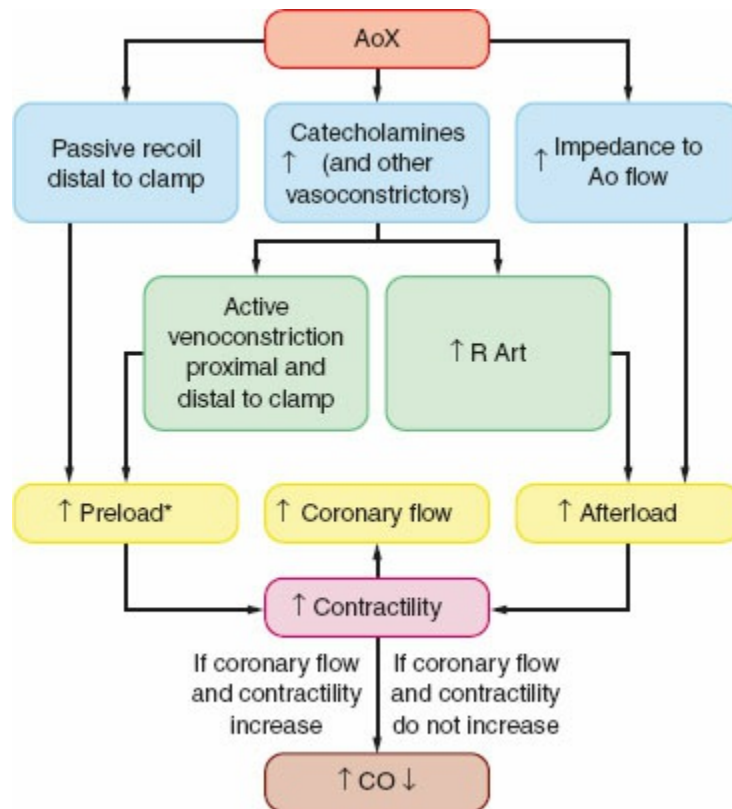

**Figure 40-11** Cumulative incidence of abdominal aortic aneurysm rupture, according to aneurysm diameter at diagnosis. The incidence of rupture is significantly higher for aneurysms greater than 5.0 cm in diameter. (Reprinted with permission from Guirguis EM, Barber GG. The natural history of abdominal aortic aneurysms. *Am J Surg.* 1991;162:481–483.)

## Pathophysiology of Aortic Occlusion and Reperfusion

The pathophysiologic response to aortic cross-clamping depends on the level of the occlusion, the overall volume status of the patient, and overall cardiac function (Fig. 40-12).<sup>152</sup> Aortic cross-clamping has little to no effect on heart rate. The most dramatic and consistent effect of aortic cross-clamping is an increase in systemic vascular resistance and mean arterial pressure as a result of the sudden impedance to aortic flow. The extent to which afterload increases depends upon the level the cross-clamp applied. Infrarenal cross-clamping may increase arterial blood pressure 2% to 10%, where as a supraceliac clamp has a significantly greater effect and may increase the mean arterial pressure up to 50% (Table 40-2).

A complex interaction between splanchnic venous tone, blood volume redistribution, coronary blood flow, and myocardial contractility may result in an increase or decrease in cardiac preload, central filling pressures, and cardiac output (Fig. 40-13). Placement of the aortic cross-clamp results in blood volume redistribution proximal to the clamp placement. Infraceliac cross-clamping is relatively well tolerated compared with supraceliac cross-clamping. With lower clamping, blood volume can shift into the compliant splanchnic vasculature, thus limiting preload changes. With the placement of a supraceliac cross-clamp, the splanchnic circulation is unable to absorb this shift in blood volume. Instead, the decrease in splanchnic arterial flow is associated with a decrease in venous capacitance as a result of elastic recoil. The net result is an increase in venous return, central filling pressures, and cardiac output. The increase in preload and afterload increases myocardial work, which in turn leads to coronary vasodilation to maximize coronary blood flow and oxygen delivery. Patients with limited cardiac reserve, such as those with a decreased ejection fraction or significant CAD (in whom the coronary vasculature is already maximally dilated), may not tolerate this increase in myocardial work. In such cases, myocardial ischemia or failure may develop. New LV wall abnormalities have been demonstrated in up to one-third of patients with a suprarenal aortic cross-clamp placement, and more than 90% of patients with a supraceliac aortic cross-clamp.<sup>153</sup> Patients with an infrarenal cross-clamp, by comparison, did not have evidence of regional wall motion abnormalities during cross-clamp placement. Despite a decrease in ejection fraction, cardiac output and stroke volume increased by expanding the cavity size of the left ventricle.

**Figure 40-12** Systemic hemodynamic response to aortic cross-clamping (AoX). Preload does not necessarily increase. The most dramatic and consistent effect of aortic cross-clamping is an increase in systemic vascular resistance and mean arterial pressure as a result of the sudden impedance to aortic flow. Ao, aorta. (Adapted with permission from Gelman S. The pathophysiology of aortic cross-clamping and unclamping. *Anesthesiology*. 1995;82:1026–1060.)

Anticipation of aortic cross-clamp placement should prompt hemodynamic manipulation. A pragmatic approach is to initially use esmolol to decrease heart rate to a target of around 60 to 65 beats per minute. This decreases the risk of myocardial oxygen imbalance. Direct vasodilators are then employed to control arterial pressure. This can be accomplished via bolus (+/- continuous infusion) of intravenous vasodilating agents (e.g., sodium nitroprusside, nitroglycerin, or nicardipine), local anesthetic administration via thoracic epidural, or deepening of anesthetic depth. The goal is to offset the increase in afterload and myocardial work with systemic vasodilation. It is important to recognize that attempts to normalize systemic vascular resistance above the level of the clamp can even further compromise blood flow distal to the clamp. The administration of sodium nitroprusside has been shown to decrease aortic pressure distal to the level of cross-clamp placement; this decrease was unresponsive to increases in preload via volume challenge or cardiac output.<sup>154</sup> It is critical to maintain a perfusion pressure below the level of the cross-clamp that will not potentiate visceral or spinal cord ischemia.

**Table 40-2** Effect of Level of Aortic Occlusion on Changes in Cardiovascular Variables<sup>a</sup>

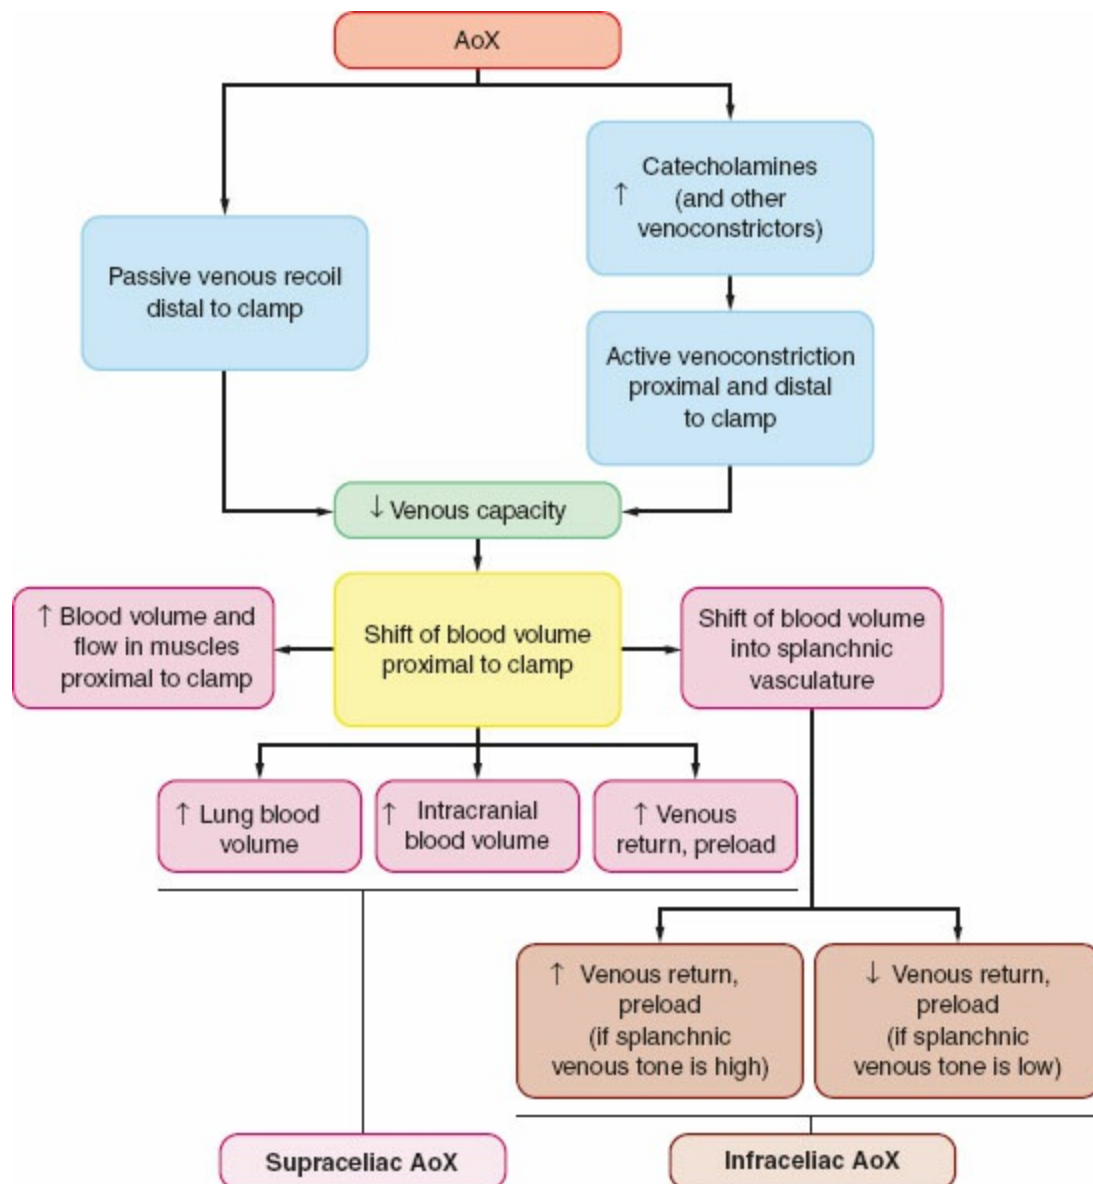

Cardiovascular Variable	% Change in Variable, by Level of Aortic Occlusion		
	<i>Supraceliac</i>	<i>Suprarenal</i>	<i>Infrarenal</i>
Mean arterial blood pressure	54	5	2
Pulmonary capillary wedge pressure	38	10	0
End diastolic area	28	2	9
End systolic area	69	10	11
Ejection fraction	-38	-10	-3
Abnormal motion of wall, % of patients	92	33	0
New myocardial infarction, % of patients	8	0	0

<sup>a</sup>The degree of hemodynamic derangements with aortic cross clamping is dictated in large part by the level of aortic occlusion.

Adapted with permission from Roizen MF, Ellis JE, Foss JF, et al. Intraoperative management of the patient requiring supraceliac aortic occlusion.

In: Veith FJ, Hobson RW, Williams RA, et al. New York, NY: McGraw-Hill; 1994:256.

There are two distinct aortic unclamping events. Even if the initial aortic clamp was supraceliac, the anastomosis is most commonly infrarenal. Once the proximal anastomosis is made, the clamp is moved from native aorta to graft in order to allow reperfusion of the celiac and renal beds. This is usually hemodynamically insignificant due to the relatively short duration of ischemia and rapid reapplication of the cross-clamp distal to the visceral vessels until the distal anastomosis (or, in the case of bifurcated graft, anastomoses) are complete. The subsequent release of the distal clamp(s) results in the release of inflammatory mediators, decreased cardiac output, hypoxemia-mediated vasodilation, and a reactive hyperemia that ultimately culminates in profound vasodilation and arterial hypotension (Fig. 40-14). Systemic vascular resistance may decrease up to 80%, with similarly profound decrease in LV pressure. A relative central hypovolemia develops as blood pools in tissue distal to the cross-clamp. Various therapies have been employed to counteract this response, with no evidence to suggest superiority of one method over another. Most anesthesiologists employ some degree of volume loading during the period of cross-clamp application. Vasoconstrictors such as phenylephrine or norepinephrine, or inotropic agents such as epinephrine or calcium chloride are frequently employed in conjunction with volume loading. It may also be prudent to decrease anesthetic depth and/or discontinue epidural infusions in anticipation of these predictable changes. Preferable to pharmacologic manipulation is a gradual release of the cross-clamp to allow for a slow, controlled release of vasoactive and cardiodepressant mediators. If bilateral iliac clamps are employed, the lower extremities can be reperfused sequentially to allow for a more controlled release and appropriate resuscitation. Clear communication with the vascular surgeon is vital to coordinate appropriate management. For example, bleeding at the anastomosis requires immediate re-clamping; if vasopressors and inotropes are administered as boluses and then the clamp is reapplied, profound proximal hypertension can ensue.

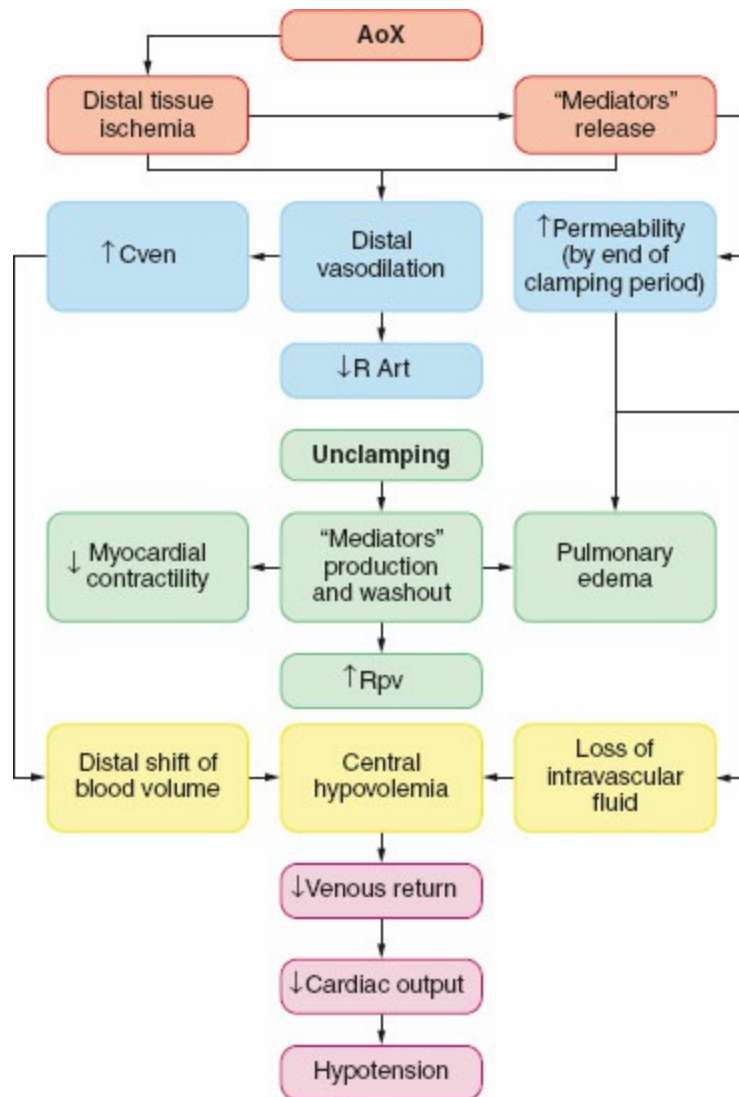

**Figure 40-13** Blood volume redistribution following aortic cross-clamp (AoX) placement. Passive venous recoil distal the aortic cross-clamp results in a shift in blood volume from distal to the aortic occlusion to proximal to the occlusion. If the aorta is occluded above the level of the celiac axis, the splanchnic reserve is redistributed to the organs and tissues proximal to the clamp. If an infraceliac cross-clamp is placed, the blood volume may shift into the splanchnic system in addition to other organs proximal to the clamp. The ability to shift into or out of the splanchnic vasculature accounts for variability in preload augmentation. (Adapted with permission from Gelman S. The pathophysiology of aortic cross-clamping and unclamping. *Anesthesiology*. 1995;82:1026–1060.)

## Renal Hemodynamics and Renal Protection

Postoperative mortality is four- to fivefold higher in those who develop acute renal failure when compared with those who do not. Preoperative renal dysfunction is the most powerful predictor of postoperative renal dysfunction. There is no proven renal protective strategy other than minimizing the length of ischemia and avoidance of profound or prolonged hypotension.<sup>155,156</sup>

Though the level of the cross-clamp can markedly impact renal blood flow, renal failure is a commonly encountered source of perioperative morbidity even with infrarenal cross-clamp placement. The incidence of acute renal failure is approximately 5% following infrarenal cross-clamping and approaches 13% after suprarenal cross-clamping. With suprarenal occlusion, renal blood flow decreases by up to 80%. Blood flow is not only reduced but also redistributed, favoring flow to the cortical and juxtamedullary layers over the hypoxia-prone renal medulla.<sup>157</sup> Even with an infrarenal occlusion, renal blood flow is decreased by nearly 50% compared to baseline, whereas renal vascular resistance increases by almost 70%. These alterations are predominantly a result of neurohumoral activation rather than due to changes in hemodynamics or cardiac output. Physiologic fluctuations do not immediately revert after the release of cross-clamping and may persist for at least 30 minutes beyond systemic cardiovascular return to baseline. Thus, tincture of time may be the best management of decreased urine output in the immediate post-cross-clamping period.

Many different pharmacologic methods of renal protection have been advocated, most centering on improving renal blood flow or glomerular flow. Mannitol increases diuresis and functions as a free radical scavenger. No clinical trials to date have demonstrated any reduction in the incidence of postoperative renal failure in patients undergoing repair of an AAA who have been given mannitol.<sup>158</sup> Diuretics, and particularly loop diuretics, are often considered in the case of low urine output, despite the fact that no significant correlation has been demonstrated between intraoperative mean urinary output or lowest hourly urinary output and the development of acute renal insufficiency.<sup>159</sup> The use of diuretic medications for the sole purpose of increasing urine output only converts an oliguric to polyuric renal failure. In the interim, significant fluid shifting may result in depletion of intravascular volume, adding further renal insult. Diuretics should be reserved only for patients who are demonstrably volume overloaded and then used judiciously to effect. Dopamine does not appear to improve postoperative renal dysfunction. Fenoldopam, a selective dopamine agonist, has shown promise in some clinical trials but results have been conflicting in cardiovascular surgery.<sup>156,160,161</sup> Ali and colleagues<sup>162</sup> investigated the role of ischemic preconditioning on renal and myocardial injury with aortic cross-clamping and found a beneficial effect on both. In this study, ischemic preconditioning was found to decrease the incidence of postoperative renal insufficiency by 23%.

**Figure 40-14** Hemodynamic response to aortic cross-clamp (AoX) release. A complex cascade of events, including release of inflammatory mediators, distal vasodilation, increased vascular permeability, and decreased myocardial contractility results in a relative central hypovolemia, decreased cardiac output, and systemic hypotension. (Adapted with permission from Gelman S. The pathophysiology of aortic cross-clamping and unclamping. *Anesthesiology*. 1995;82:1026–1060.)

## Spinal Cord Ischemia and Protection

The spinal cord is supplied primarily by the single anterior and paired posterior spinal arteries, arising from the posterior circulation (Fig. 40-15). The posterior spinal arteries supply approximately 25% of spinal cord blood flow and supply the sensory tracts of the posterior columns. The anterior spinal artery supplies the anterolateral cord, including motor tracts, and supplies 75% of the spinal cord blood flow. The anterior spinal artery is fed by a series of radicular arteries arising from the aorta, although collateralization is variable. This leaves areas of the spinal cord vulnerable to watershed ischemia, particularly with aortic occlusion or prolonged hypotension. The single most important radicular artery supplying the thoracolumbar cord is derived from the artery of Adamkiewicz. The artery of

Adamkiewicz originates between T8 and T12 in 75% of cases and at the level of L1 or L2 in an additional 10% of cases.

**Figure 40-15** Vascular supply to the spinal cord. The singular anterior spinal artery and paired posterior spinal arteries arise from the posterior circulation and provide blood supply to the spinal cord. Radicular arteries arising from the aorta supplement this blood supply. The artery of Adamkiewicz is the most clinically significant contributor. Variability in collateral flow helps to explain, in part, the unpredictability of paraplegia following aortic surgery. (Adapted from Piccone W, DeLaria GA, Najafi H. Descending thoracic aneurysms. In: Bergan JJ, Yao JST, eds. *Aortic Surgery*. Philadelphia, PA: WB Saunders; 1989:249.)

Spinal cord ischemia is a feared complication of aortic reconstruction and occurs in up to 10% of patients involving a distal aortic repair. Pertinent risks for spinal cord ischemia include previous aortic surgery (particularly with vascular exclusion of major thoracic radicular collaterals), open surgical repair, aortic cross-clamp location and duration, length of aortic replacement, and intraoperative hypotension/hypoperfusion. The definitive measures to prevent spinal cord ischemia are a short cross-clamp time, maintenance of normal cardiac function, and higher perfusion pressures. Segmental sequential surgical repair may minimize the duration of ischemia to any given vascular bed. A markedly reduced incidence of neurologic deficits has been reported in

thoracoabdominal aortic repairs when distal aortic perfusion is used in combination with cerebral spinal fluid (CSF) drainage, placed either prophylactically or for rescue.<sup>166,164</sup> The rationale behind CSF drainage is that spinal cord perfusion pressure can be augmented either by increasing the forward driving pressure (MAP) or by relieving any obstructing pressure (CSF pressure). In the setting of aneurysmal disease and major vascular reconstruction, it may be practically problematic to augment MAP to the degree necessary to ensure adequate perfusion. Autoregulatory mechanisms that occur with aortic cross-clamping results in a reflexive increase in CSF pressure, effectively lowering spinal cord perfusion pressure. CSF drainage, then, favors improved spinal cord perfusion. When employed, CSF monitoring is usually continuous, and CSF is slowly removed to maintain a CSF pressure less than 12 mmHg. Although commonly used in thoracic or thoracoabdominal aortic repairs (see [Chapter 39](#), Anesthesia for Cardiac Surgery), this technique is less commonly employed for isolated AAAs unless there has been previous extensive thoracic aortic artery replacement as the artery of Adamkiewicz is less likely at risk.

### **Anesthetic Management of Open Aortic Reconstruction**

Abdominal aortic reconstruction may be approached via a transabdominal or retroperitoneal approach. In the first case, a thoracoabdominal midline incision is performed and the aorta is accessed via the peritoneum. This allows generous exposure and is usually favored for complex aortic reconstruction or replacement. In the retroperitoneal approach, incision is made over the lateral border of the left rectus muscle, from the level of the 12th rib to several centimeters below the umbilicus. This approach allows access to the aorta from the crux of the diaphragm to its bifurcation. Benefits of the retroperitoneal approach include comparable surgical exposure with decreased fluid shifting, fewer postoperative pulmonary complications, faster return of bowel function, shorter ICU stays, and decreased hospital costs with average savings of \$4,000 to \$5,000.<sup>165</sup> This technique may be favored in cases of significant truncal obesity, chronic obstructive pulmonary disease, intra-abdominal adhesions, and juxtarenal aneurysms. Regardless of the surgical technique employed, OAR requires a large vertical incision. Barring contraindication to neuraxial instrumentation, an epidural catheter should be considered. A functional epidural may be used intraoperatively to manage the hemodynamic lability of aortic cross-clamping, decrease postoperative sympathetic stimulation, aid in postoperative pain control, and potentially aid in weaning from mechanical ventilation. Although most ischemic complications are the result of dislodgment of atheromatous material off the diseased aorta and not de novo clot formation, most surgeons administer

intravenous heparin to reduce the risk of thromboembolic events before aortic cross-clamping. If neuraxial instrumentation is attempted, heparin dosing should be delayed per current guidelines.<sup>166</sup> In the case of traumatic placement or intravascular catheter, a frank consideration of the risks and benefits of proceed to surgery versus delaying the case must be undertaken by the operative team due to the small but catastrophic risk of epidural hematoma.

General anesthesia is typically employed for open repair of AAA. Induction of general anesthesia and intubation can be associated with dramatic hemodynamic lability and sympathetic stimulation, which may put the aneurysm at risk of rupture. It is prudent to ensure adequate blood product availability in the operating room and large-bore peripheral intravenous access prior to the induction of general anesthesia. There is no single “best” induction technique; regardless of agents chosen, the goal is a smooth induction with stable hemodynamics and avoidance of tachycardia or hypertension. Preinduction placement of an arterial line may aid in appropriate titration of induction agents. Central venous catheterization is generally employed for monitoring volume trends and for the reliable delivery of vasoactive medication. Cardiac function is commonly assessed with either a pulmonary artery catheter or transesophageal echocardiography. Either technique can provide valuable information about cardiac functioning and volume status. Echocardiography is the most sensitive marker for new regional wall motion abnormalities and direct visualization of appropriate ventricular filling. Pulmonary artery catheterization can be useful both intraoperatively and postoperatively to guide resuscitation. The use of pulmonary artery catheters has been the subject of debate, with conflicting evidence as to their benefit in high-risk surgical patients.<sup>167,168</sup> A study by Berlaak and colleagues<sup>169</sup> concluded that the use of pulmonary artery catheters to “tune up” patients undergoing vascular surgery was associated with fewer adverse intraoperative events and decreased postoperative cardiac morbidity. As with any monitor, the information obtained is only as good as the clinician interpreting and intervening upon the data.

Virtually all anesthetic drugs and techniques have been described for aortic reconstructive surgery. The ability to maintain hemodynamic equilibrium and attend to detail is far more important than is the choice of drug. Volatile agents may improve preconditioning mechanisms should myocardial ischemia occur.<sup>162,170</sup> These effects have been demonstrated in animal models and in cardiac, although not vascular surgery. The maintenance anesthetic is designed to maintain hemodynamics within 20% of the baseline range. An array of short-acting vasoactive agents (including vasodilators, vasopressors, and inotropes) should be on hand to immediately treat hemodynamic lability.

For the period prior to cross-clamp placement, the patient is kept slightly hypovolemic (typically, as assessed by CVP, pulmonary catheter wedge pressure or echocardiography) to limit hypertensive extremes with aortic occlusion. At the time of cross-clamp placement, vasodilating infusions may be required. Alternatively, deepening the anesthetic or injection of the epidural catheter with local anesthetic will increase vasodilation, although both of these approaches require careful attention to avoid unintended hypotension. When there is concern about spinal cord perfusion, it may be prudent to allow permissive hypertension, to the extent possible, above the level of the clamp to provide higher distal perfusion pressure and avoid distal ischemia. This choice may come at the expense of myocardial well-being.

After the vascular clamps are placed and the aneurysm sac is incised, blood loss is swift from any vessels arising from the aorta between the two clamps. Adequate peripheral and central venous access is imperative. Blood loss can be considerable without the onset of hypotension or tachycardia because a significant portion of the vascular tree is excluded from circulation during aortic occlusion. An autotransfusion device should be employed to reduce the amount of autologous blood needed. It is prudent to volume load during the period of aortic cross-clamping in anticipation for the vasoplegic washout and reactive hyperemia that will occur with the removal of aortic cross-clamp. It is the practice of the authors to resuscitate with a combination of crystalloid, colloid, and blood products as the clinical scenario dictates to a CVP or pulmonary capillary wedge pressure 2 to 3 mmHg higher than the initial wedge pressure, or according to echocardiographic estimates of volume. This augmentation of central volume will then fill the increased capacitance distal to the aortic clamp when it is subsequently released.

Immediately prior to the removal of the aortic clamp, vasodilating agents are discontinued. The surgeon opens the aortic clamp gradually to ensure that severe hypotension or bleeding does not develop. Ongoing fluid resuscitation and vasopressor and inotropic support is frequently necessary. Severe refractory hypotension can be temporarily abated with reapplication of the aortic cross-clamp until appropriate measures can be instituted. Over the course of the reconstruction, there may be frequent instances of cross-clamp application and release to limit the ischemic time to vital organs and to “test” the anastomoses. It is imperative for the anesthesiologist to be flexible and adaptable, and to have a variety of short-acting vasoactive agents available for hemodynamic manipulation. Each time the cross-clamp is removed, a “washout” of vasoactive agents occurs with the potential for hemodynamic instability. Central and pulmonary filling pressures may be elevated despite systemic hypotension because of the washout of lactic acid and other inflammatory mediators, which results in pulmonary vasoconstriction and cardiac stunning.

At the end of the procedure, the decision regarding emergence and extubation must take into account any ongoing hemodynamic instability, metabolic derangements, and ongoing need for resuscitation.  $\beta$ -Blocking agents are continued in the perioperative period, as tolerated. Reinstitution of the epidural catheter allows for adequate pain control and may help with weaning from mechanical ventilation, particularly in those with concomitant chronic obstructive pulmonary disease. For those patients who remain intubated, the use of the epidural catheter for pain control permits a reasonably light intravenous sedation, which allows for continued monitoring of neurologic status.

### **Peripheral Artery Disease**

It has been estimated that up to 20% of the population is affected by PAD. Though the majority of patients are asymptomatic, PAD is a risk factor for adverse cardiovascular events, with an annual rate of 5% to 7%.<sup>13,171</sup> Risk factors include nonwhite race, male gender, age, smoking, diabetes, hypertension, dyslipidemia, chronic renal insufficiency, hyperviscous/hypercoagulable states, hyperhomocysteinemia, and patients with elevated inflammatory markers. There are three clinical indications for elective surgery for PAD: intermittent claudication (IC), ischemic rest pain or ulceration, or gangrene.

Most patients with PAD have either asymptomatic disease or IC, defined as reproducible discomfort in a defined muscle group that is induced by activity and relieved with rest. Approximately 10% to 35% of patients with PAD will present with symptoms of IC.<sup>172</sup> The clinical manifestations of IC depend on the location of the occlusion, its severity, and the presence (or absence) of collateral blood flow. Aortoiliac occlusive disease (AIOD), or “inflow” disease, tends to result in claudication in the buttock or hip. AIOD disease usually originates in the distal aorta or proximal common iliac arteries. “Outflow” disease, defined as femoropopliteal or infrapopliteal lesions, results in claudication of the thigh or leg.

IC is the first and most common symptom associated with PAD. The natural history of PAD is typically indolent with a slow, progressive decline in function. Aggressive management of risk factors with pharmacologic, exercise, and lifestyle modification prevents disease progression in the vast majority of cases.<sup>13</sup> Because of the relatively slow and benign progression of symptoms, the decision for surgical intervention for IC must be individualized. Decision making should consider response to therapy, loss of function, and effect on quality of life.<sup>173</sup> A very active person may be debilitated by relatively mild symptoms, whereas more severe symptoms may be well tolerated by a sedentary individual.

CLI occurs when the existing arterial blood flow is unable to meet even basal metabolic demands, resulting in rest pain, ulceration, and gangrene. CLI is an especially aggressive manifestation of PAD associated with more severe, multisegmental occlusion. Risk factors for accelerated disease progression include age, diabetes, smoking, and hyperlipidemia.<sup>13</sup> PAD progresses to CLI in approximately 1% to 2% of the population. Patients with CLI may have progressive ischemia and are at variable risk for imminent limb loss; thus, urgent surgical intervention is warranted. It is estimated that within 1 year, 25% of patients will progress to amputation, and an additional 25% will die from cardiovascular causes.<sup>13,173</sup> Not surprisingly, these patients also have more severe ASCVD in other vascular beds. Approximately 50% of patients with CLI will have concomitant CAD, with a higher mortality from MI or stroke amongst patients with CLI compared to less aggressive forms of PAD. These patients, then, are at elevated perioperative risk due to both medical and surgical factors related to disease severity.

AIOD may be repaired via direct reconstruction (aortoiliac or aortofemoral bypass), or with extra-anatomic reconstruction (axillary-femoral +/- femoral-femoral bypass). Direct reconstruction has better long-term patency rates (greater than 80%), at the expense of greater perioperative morbidity and mortality. Extra-anatomic bypass, although less morbid, has also proven less durable, with 5-year patency rates are reported between 55% and 80%.<sup>171,174</sup> As such, extra-anatomic bypass is typically reserved for patients deemed particularly high risk for direct surgical reconstruction such as previous graft or stent complication, infection, or previous intra-abdominal surgery with resultant abdominal adhesions. Open revascularization of infrainguinal disease depends on the level of the lesion(s), and may involve the femoral, popliteal, or infrapopliteal vessels.

## **Anesthetic Management of Lower Extremity Revascularization**

The anesthetic management of AIOD depends on whether anatomic or extra-anatomic bypass is performed. Anesthetic considerations for aortofemoral bypass are similar to OAR. Barring contraindication, a preinduction epidural catheter should be considered for postoperative pain control. General anesthesia with an ETT is typically employed due to length of the case as well as the potential for hemodynamic lability. Large-bore peripheral IV access and an arterial line should be placed to help guide resuscitation and to allow instantaneous assessment of hemodynamic changes. Although aortic cross-clamping and uncross-clamping is required for aortofemoral bypass, it is typically better tolerated than for aneurysmal disease because the patient is already accustomed to high aortic resistance. Hemodynamics tend to be more stable both as a result of clamp location (typically, distal aortic) as well as the

likelihood of extensive collateralization related to chronic atherosclerotic obstruction. This stands in stark contrast to aneurysmal disease, which has limited preexisting collateral flow. Central venous access is reasonable to ensure reliable delivery of necessary vasoactive medications. Additional cardiac monitoring, such as pulmonary artery catheter placement or transesophageal echocardiography, may be considered depending on patient and surgical factors.

By definition, extra-anatomic bypass does not involve aortic manipulation and thus avoids the need for aortic cross-clamping and uncross-clamping. Typically, extra-anatomic bypass is undertaken from the axillary artery to the ipsilateral femoral artery, +/- subsequent femoral to femoral artery bypass. Typically, less hemodynamic lability is noted with axillary and femoral artery cross-clamping than with aortic cross-clamping. Thus, although large-bore peripheral IV and arterial line placement is still prudent, the need for extensive central or cardiac monitoring is less critical unless independently indicated due to medical comorbidities. Arterial line placement should be contralateral to the surgical bypass, as arterial cross-clamp placement will render an ipsilateral arterial line nonfunctional. The extra-anatomic bypass must be tunneled subcutaneously in the mid-axillary line to prevent kinking of the graft, which may be more sympathetically stimulating than cross-clamp placement. Close attention must be paid to prevent untoward hemodynamic swings or patient movement during this period.

The choice of anesthetic technique for infrainguinal revascularization is individualized for each patient. Lower extremity revascularization can be performed under general, neuraxial, or regional anesthesia. Purported benefits of regional anesthesia include avoidance of hyperdynamic responses to tracheal intubation and extubation, blunted perioperative catecholamine response, improved vascular blood flow, higher graft patency rates, and lower pulmonary complications. A recent review of the NSQIP database compared nearly 15,000 receiving neuraxial (spinal or epidural) versus general anesthesia for lower extremity revascularization.<sup>175</sup> In this study, neuraxial anesthesia was associated with a decreased likelihood of reintervention, decreased rates of graft failure, and decreased rates of postoperative respiratory and cardiovascular complications. In an analysis of patients in the NSQIP database with CLI, however, no differences in perioperative morbidity were noted between patients who underwent general versus neuraxial anesthesia.<sup>176</sup> A Cochrane review of general versus regional anesthesia for lower extremity revascularization concluded that there was insufficient evidence to rule out clinically important differences for most clinical outcomes (mortality, MI, or rate of lower-limb amputation).<sup>177</sup> Thus, anesthetic technique should be governed by clinical expertise, patient, and

surgeon preferences.

Morbidity and mortality following lower extremity revascularization is typically cardiac in origin. Perioperative MI is reported to occur in 4% to 15% of patients undergoing peripheral vascular surgery and accounts for more than 50% of perioperative mortality.<sup>178</sup> A recent review of the NSQIP database suggests an overall cardiac mortality rate of 2.7% with 30-day combined mortality/major morbidity rate of nearly 20%.<sup>179</sup> Patients who undergo surgery for CLI as compared to IC are at increased risk, likely due to greater disease burden and more technically challenging repairs due to multilevel, extensive disease.

## Endovascular Surgery

**6** The advent of the endovascular era has revolutionized the field of vascular surgery. Endovascular procedures are minimally invasive and are generally associated with decreased perioperative mortality and major morbidity, shorter hospital and intensive care stays, and quicker return to baseline function, particularly for the elderly or frail. In addition to a lower level of surgical stress, endovascular techniques may obviate the need for general anesthesia. Despite overall improvements in short- and intermediate-term outcomes, long-term benefits to endovascular repairs have not been sustained. In addition, endovascular repairs have proven less durable and more prone to reintervention than traditional open repairs. In this section, we will consider the anesthetic implications for endovascular approaches to vascular disease.

### Carotid Artery Stenting

Carotid artery angioplasty and stenting was first described in the late 1970s and early 1980s, but early complications related to distal plaque embolization during stent deployment limited initial enthusiasm for an endovascular approach to cerebral vascular disease. The development of embolic protection devices in the 1990s led to a renewed interest in an endovascular approach to carotid disease, especially in patients deemed high risk for open surgery. Five landmark randomized controlled trials have compared traditional open CEA to carotid artery stenting.<sup>180–184</sup> A recent meta-analysis of these data concluded that, for symptomatic patients, carotid artery stenting was associated with a decreased risk of perioperative MI at the expense of an increased risk of the primary composite outcome of death or any stroke as well as an increased risk of perioperative stroke.<sup>185</sup> There was no difference in rates of death or major disabling stroke. Recent work by Kuliha and colleagues<sup>186</sup> demonstrates an increase in silent ischemia in patients who undergo carotid artery stenting

compared to CEA but no significant difference in postoperative cognitive function.

These findings stand in contrast to other head-to-head trials of endovascular versus open repairs (such as treatment of aortic and peripheral disease, discussed later), where short-term perioperative morbidity and mortality tend to be improved with endovascular treatment. Most of the differences in perioperative morbidity were limited to the elderly. Long-term outcomes beyond the perioperative period, including functional outcomes, are comparable between patients who undergo open versus endovascular intervention for carotid disease. Thus, a short-term increased risk of minor, nondisabling stroke must be weighed against a decreased risk of perioperative MI. At present, the contemporary literature fails to reach a consensus on the superiority of either open or endovascular technique for the treatment of carotid disease. Individual medical, surgical, and operator considerations must be weighed in the decision for open versus endovascular repair. Though CEA remains the gold standard for repair, continuous advances in endovascular techniques, and particularly in cerebral protection devices, is changing the trends in the management of carotid disease. Recent 30-day perioperative outcomes reported from the Safety and Efficacy Study for Reverse Flow Used During Carotid Artery Stenting Procedure (ROADSTER) trial, utilizing a novel transcrotid neuroprotection system, has reported the lowest perioperative stroke rates (1.4%) for endovascular techniques.<sup>187</sup> Current data suggests that the use of carotid artery stenting is increasing, from less than 3% of interventions in 1998 to more than 13% in 2008.<sup>188</sup> Carotid stenting is strongly preferred over open repair for reoperation, in patients who have had neck radiation, and very high lesions.

A major benefit of carotid artery stenting lies in the ability to continuously monitor neurologic integrity during the procedure. The minimally invasive vascular approach requires little, if any, sedation beyond local anesthetic to the access site. It is vital that the patient remains alert and cooperative with the proceduralist for serial neurologic examinations. A candid preoperative discussion to set appropriate patient expectations is perhaps the most critical anesthetic intervention. The lowest necessary doses of short-acting sedatives should be titrated to effect; patient disinhibition must be avoided. Standard intraoperative monitoring and a single medium- to large-bore peripheral intravenous line is typically sufficient for the procedure; invasive arterial access may be considered but is rarely warranted. In an emergency, arterial pressure may be monitored from the surgical access site. It is important to recognize that carotid angioplasty and stent deployment may trigger the carotid baroreceptor reflex, with resultant bradycardia and hypotension, similar to external carotid manipulation. If this occurs, cessation of manipulation should extinguish the response; prophylaxis with an

anticholinergic agent may be considered. Altered postoperative carotid baroreceptor function is possible as with open repair; hemodynamic instability should be treated as for CEA.

## *Endovascular Aortic Repair*

Prior to the endovascular era, options for AAA management were limited to OAR or medical management. Morbidity and mortality associated with OAR is significant. At the same time, risk of rupture increases significantly as aneurysms enlarge, with near 100% mortality rate for out-of-hospital rupture. The advent of the endovascular era revolutionized the management of AAAs. Parodi<sup>189</sup> pioneered an endovascular approach to aortic aneurysms in the early 1990s. Initially, this technique was reserved for high-risk patients with straightforward anatomy deemed unfit for open surgical repair. Recent advances in stent technology and surgical skill, including customized fenestrated stents and chimney techniques, have made endovascular repair an option for patients who previously would have been considered unfit due to anatomic considerations. In fact, the broad application of EVAR technology has rapidly overtaken the use of OAR as the primarily modality for AAA treatment over the last decade.<sup>190,191</sup> In 2000, EVAR accounted for 5.2% of AAA repairs. In 2004, EVAR surpassed OAR as the more commonly employed technique. By 2010, this percentage had risen dramatically to 74%. Endovascular repair has also become the treatment modality of choice for complicated acute type B dissections.<sup>192</sup>

Several rigorous, large, multicenter, randomized controlled trials have addressed the issue of open versus endovascular aneurysm repair.<sup>193–196</sup> The Dutch Randomized Endovascular Aneurysm Management (DREAM), EndoVascular Aneurysm Repair (EVAR), and Open Versus Endovascular Repair (OVER) trials all demonstrated significantly lower perioperative mortality with EVAR than with OAR, although this benefit was lost in intermediate- to long-term follow-up. The Aneurysme de l'aorte abdominale: Chirurgie versus Endoprothese (ACE) trial, in contrast, found no significant difference in perioperative or longer-term mortality between the EVAR and OAR groups, although it is worth noting that these patients were considered low- to intermediate-risk for surgery. Taken together, a pooled analysis of these results suggests a decrease in short-term mortality, but no significant difference in either intermediate- (up to 4 years) or long-term outcomes.<sup>197</sup> Major operative morbidity, including myocardial, neurologic, and renal complications, were similar in pooled analysis. Pulmonary complications were found to be significantly higher in the OAR compared to EVAR group, and a similar trend was noted in pulmonary-related deaths. The long-term reintervention rate was significantly higher in the EVAR than OAR group; the

unique complication profile of endovascular repair necessitates a lifetime of surveillance. In general, the majority of reinterventions are also endovascular with low associated morbidity and mortality. Even so, repeated exposure to radiation and contrast exposure, and potentially surgery and anesthesia, should be considered when deciding between open- versus endovascular-based interventions. An otherwise young, fit patient with a lower perioperative risk profile may be a reasonable candidate for OAR to avoid the associated risks of lifetime surveillance and potential for reintervention; however, a recent review of the NSQIP database suggests that the perioperative reduction in mortality and major morbidity persists even in patients deemed low risk for infrarenal OAR.<sup>198</sup>

The EVAR-2 trial was designed to compare maximum medical therapy versus EVAR in patients deemed unfit for OAR.<sup>199</sup> Patient factors that were associated with ineligibility for OAR included major cardiac, pulmonary, or renal comorbidities. This trial concluded that EVAR reduces aneurysm-related, but not overall, mortality as compared to medical therapy. Presumably, the same factors that made patients too high risk for OAR likely contributed to a high subsequent rate of all-cause mortality. Thus, the authors suggest that patients with a poor life expectancy due to coexisting disease do not benefit from EVAR. The EVAR-2 study has been criticized both for methodologic flaws that may have biased against the EVAR group as well as unacceptably high mortality rates.<sup>200</sup> A more recent evaluation of patients considered unfit for surgery at single, high-volume center demonstrated a survival benefit, even in a presumed high-risk population.<sup>201</sup> Pertinently, patients in this study were more likely to be optimized with antiplatelet and statin agents than the patients enrolled in EVAR-2, which may also have made them better surgical candidates. In addition, endovascular repair was undertaken at a single, high volume center. This is in contrast to EVAR-2 in which multiple centers, with variable expertise, took part. As with most interventions, proceduralist experience and skill is likely associated with outcomes and success.

A question that persists after the EVAR-2 trial is which patients, in particular, should be considered high risk for endovascular repair. Egorova and colleagues<sup>202</sup> evaluated close to 67,000 patients who underwent EVAR in the inpatient Medicare database. A risk model for perioperative mortality was developed and validated. [Table 40-3](#) lists the baseline risk factors that significantly predicted mortality with a corresponding score. The vast majority of patients (96.6%) had additive scores below ten, which correlated with a 30-day mortality of less than 5%, whereas less than 1% had a mortality rate greater than 10%. The authors conclude that although a high-risk cohort exists that should not be treated with EVAR due to prohibitively high 30-day mortality, that cohort is quite small. Giles et al.<sup>203</sup> also developed an aneurysm scoring system that was predictive of mortality for both open and

endovascular repair. The EVAR Risk Assessment model<sup>204</sup> has been shown to predict not only perioperative mortality but also morbidity, mid-term survival, and reintervention rates. The eight variables included in this model were aneurysm size, age, ASA, gender, creatinine, aortic neck angle, infrarenal neck diameter, and infrarenal neck length.

**Table 40-3** Risk Scores for 30-day Mortality for EVAR Patients<sup>a</sup>

Risk Factor	Score
Renal failure with dialysis	7
Lower extremity ischemia	5
Age ≥85 yrs	4
Liver disease	3
Congestive heart failure	3
Age 80–84 yrs	2
Female	2
Neurologic comorbidity	2
Chronic pulmonary disease	1
Surgeon case experience <3	1
Hospital annual volume <7	1
Age 57–59 yrs	1

<sup>a</sup>A total score between 10 and 12 predicts a 5% mortality rate. A total score greater than 13 predicts a 10% operative rate.

## Evolution of Endovascular Repair for Complex Aneurysms

The field of endovascular surgery has rapidly expanded since Parodi<sup>189</sup> first described the use of a custom-made Dacron tube endograft, which limited its use to infrarenal aortic segments only. The development of bifurcated and modular grafts soon followed, allowing for the extension beyond the aortic bifurcation. Until recently, however, device design constraints excluded patients with more complicated anatomy from endovascular repair. For example, patients with juxta- or suprarenal aneurysms, in whom the visceral vasculature may arise from the aneurysmal aorta, were not candidates for endovascular repair because blood flow to critical organs would be interrupted. Similarly, up to 15% of infrarenal aneurysms have an inadequate length of normal infrarenal aorta to allow for an adequate proximal seal without compromising visceral blood flow. Recent advances in stent technology have revolutionized management of these more complicated repairs. The development of branched or fenestrated grafts (f-EVAR) allows for continued blood flow to visceral organs while still permitting proximal graft extension. These devices are custom made based on three-dimensional reconstructions (typically, CT angiography) so that the fenestrations or

branches are appropriately positioned for the corresponding arterial orifices. Because they are custom designed, these devices are both costly and take significant time to manufacture. Thus, they are typically not an option for emergent repair. An alternative technique is that of a chimney graft (Ch-EVAR). With this approach, a distinct endograft is positioned in parallel to the body of the main aortic stent graft (between the aortic wall and the main stent) to allow for preserved flow to the visceral branch (Fig. 40-16). The “snorkel” technique allows for blood flow from above the level of the main stent while the “periscope” technique allows blood flow from below. The end result is preservation of visceral blood flow to vessels that otherwise would have been excluded by the main body of the graft. A “sandwich” technique has even been described, in which the visceral snorkels are sandwiched between two segments of aortic grafts. Chimney grafts are available “off the shelf” and thus remain an option in urgent situations in which no time exists to manufacture a custom made fenestrated stent. They are also less prohibitively expensive than their custom made counterparts.

**Figure 40-16** Snorkel and periscope stents. Coaxial placement of stents into vital mesenteric vessels allow for both adequate blood flow to visceral organs and exclusion of the aneurysm sac for supra- or juxtarenal aneurysms or aneurysms with insufficient proximal (A) or distal (B) landing zones. In the case of a periscope, blood exiting the body of the main stent flows back up into the coaxial periscope, providing blood flow to the visceral branch that would otherwise be excluded from the circulation. (Reprinted with permission from Wilson A, Zhou S, Bachoo P, et al. Systematic review of chimney and periscope grafts for endovascular aneurysm repair. *Br J Surg*. 2013;100:1557–1564.)

No randomized controlled trials exist to compare the use of open, fenestrated, or chimney techniques for complex aneurysm repairs. It is important to recognize the inherent bias in the published literature. Patient cohorts are likely not comparable based on pre-existing morbidity, complexity of anatomy, and urgency of procedure. A recent systematic review demonstrated a trend toward decreased perioperative mortality with f-EVAR

compared to OAR, although this difference did not reach statistical significance.<sup>205</sup> Similar trends were appreciated in perioperative cardiovascular and pulmonary morbidity, blood loss, and hospital and ICU length of stay. A second systemic review and meta-analysis of the existing literature have found f-EVAR to have acceptable short- and mid-term outcomes in terms of mortality, technical success rate, target vessel patency rate, and need for reintervention.<sup>206</sup> As with any new technique, an early steep learning curve must be considered in the interpretation of these data. In addition, this technique was primarily reserved for high-risk patients who were not suitable candidates for open repair in the early years. Further study is warranted now that f-EVAR is a standard practice in major aortic centers to evaluate outcomes.

The perioperative mortality rate for Ch-EVAR has been demonstrated to be comparable to OAR (4% to 5%) but higher than for standard EVAR.<sup>207</sup> Both the medical complexity of the patient and surgical complexity of the aneurysm are likely to account for this difference. One concern for the Ch-EVAR approach is an increased risk of type I endoleak (discussed later) due to the coaxial deployment of the main and chimney stents. A review of the literature concluded that Ch-EVAR clearly produced more endoleaks than f-EVAR, although many of these were successfully treated intraoperatively with additional balloon dilation or disappeared during subsequent follow-up.<sup>205</sup> Ch-EVAR was also associated with an increased risk of ischemic stroke compared to either OAR or f-EVAR. The chimney technique requires vascular access from the brachial or axillary artery in order to appropriately align and deploy the chimney graft. This upper extremity approach, particularly with an atherosclerotic or difficult arch anatomy, increases the risk for iatrogenic stroke.<sup>205</sup> An increasing amount of data suggests that this is a safe and valuable technique, particularly for complex patients with urgent need for surgical repair.<sup>65</sup> The technical success and patency rates in the short- and intermediate-term is promising for both f-EVAR and Ch-EVAR, although long-term results have yet to be determined.

## **Anesthetic Management of Endovascular Aneurysm Repair**

EVAR can be successfully performed under almost any type of anesthesia including local, regional, neuraxial, and general techniques. Which technique is employed will depend on a variety of factors. Concurrent use of antiplatelet agents or therapeutic anticoagulation may preclude the use of neuraxial or regional anesthetics. Patient factors, such as inability to lie flat for an extended period or an inability to effectively communicate, may sway the provider toward general anesthesia. Finally, surgical considerations such as anticipated duration or difficulty of surgery must be considered. Many

nonrandomized analyses address the question of local or regional versus general anesthesia for EVAR. A study of more than 5,500 patients who underwent EVAR repair in 164 centers under general, regional, or local anesthesia demonstrated that local or regional techniques resulted in reduced operative time, ICU admissions, duration of hospital stay, and a number of systemic complications.<sup>208</sup> A review of more than 5,500 patients in the NSQIP database demonstrated a decrease in pulmonary morbidity and a 10% to 20% decrease in hospital length of stay when local or regional anesthesia was utilized as compared to general anesthesia.<sup>209</sup> A meta-analysis of the current literature suggests a decrease in operative time, hospital stay, and postoperative complications with local compared to general anesthesia, in spite of the fact that patient receiving local anesthesia tended to be older with an increase burden of cardiovascular or respiratory disease.<sup>210</sup> However, there are no randomized controlled trials to suggest the superiority of one technique over another.

The minimally invasive nature of EVAR means that hemodynamic changes should be relatively insignificant during the case; however, the possible need for urgent conversion must always be considered. Perioperative conversion rates from EVAR to OAR is less than 1% and may occur in the setting of difficult arterial access, vessel dissection, poor anatomic parameters, stent malposition or migration, or aneurysm rupture. The ability to rapidly convert to general anesthesia is necessary if other techniques are primarily employed. Adequate resuscitative equipment such as cell saver and rapid infusion devices should be readily available. Two large-bore peripheral intravenous should be placed and adequate blood product availability should be ensured.

Short periods of hypertension and increased afterload should be anticipated if aortic ballooning is needed for stent deployment, analogous to external cross-clamping. Most stents self-deploy without ballooning. These episodes typically do not require intervention due to their brevity. Blood loss should be minimal in experienced hands. In case of rupture, emergent proximal control is first obtained via endoscopic balloon occlusion which is then replaced with cross-clamp upon open conversion. In this setting, proximal arterial access is indispensable due to the hemodynamic changes anticipated during OAR. Central venous access is not typically warranted for EVAR because hemodynamic changes are rare during routine surgery, vasoactive infusions are rarely warranted, and postoperative ICU stay is rare. Exceptions to this rule may include thoracic endovascular aneurysm repair (TEVAR) cases or complicated repairs including snorkel/periscope techniques. Central venous access may be considered for TEVAR for the ability to rapidly place a pulmonary artery catheter should that case convert to an open TAAA, which would require cardiopulmonary bypass (discussed in [Chapter 39, Anesthesia for Cardiac Surgery](#)). Central venous access may be considered for

snorkel/chimney cases because each additional stent placed requires separate arterial sheaths. These cases can be longer, more complicated, and associated with greater blood loss. Thus, more aggressive resuscitation and/or vasoactive infusions may be necessary. Before device insertion, systemic anticoagulation with intravenous heparin will be requested with a goal activated clotting time of 200 seconds or longer. At the time of device deployment, the patient will be asked to hold their breath (or, for anesthetized patients, a request will be made to hold ventilation) to allow for accurate stent deployment. At the same time, a request for temporary lowering of the mean arterial pressure may be made to minimize distal migration of the stent. After device deployment, a completion angiogram is performed to evaluate for technical success and any complications related to the procedure, anticoagulation is reversed, and the patient is typically extubated in the operating room.

### **Complications of Endovascular Aneurysm Repair**

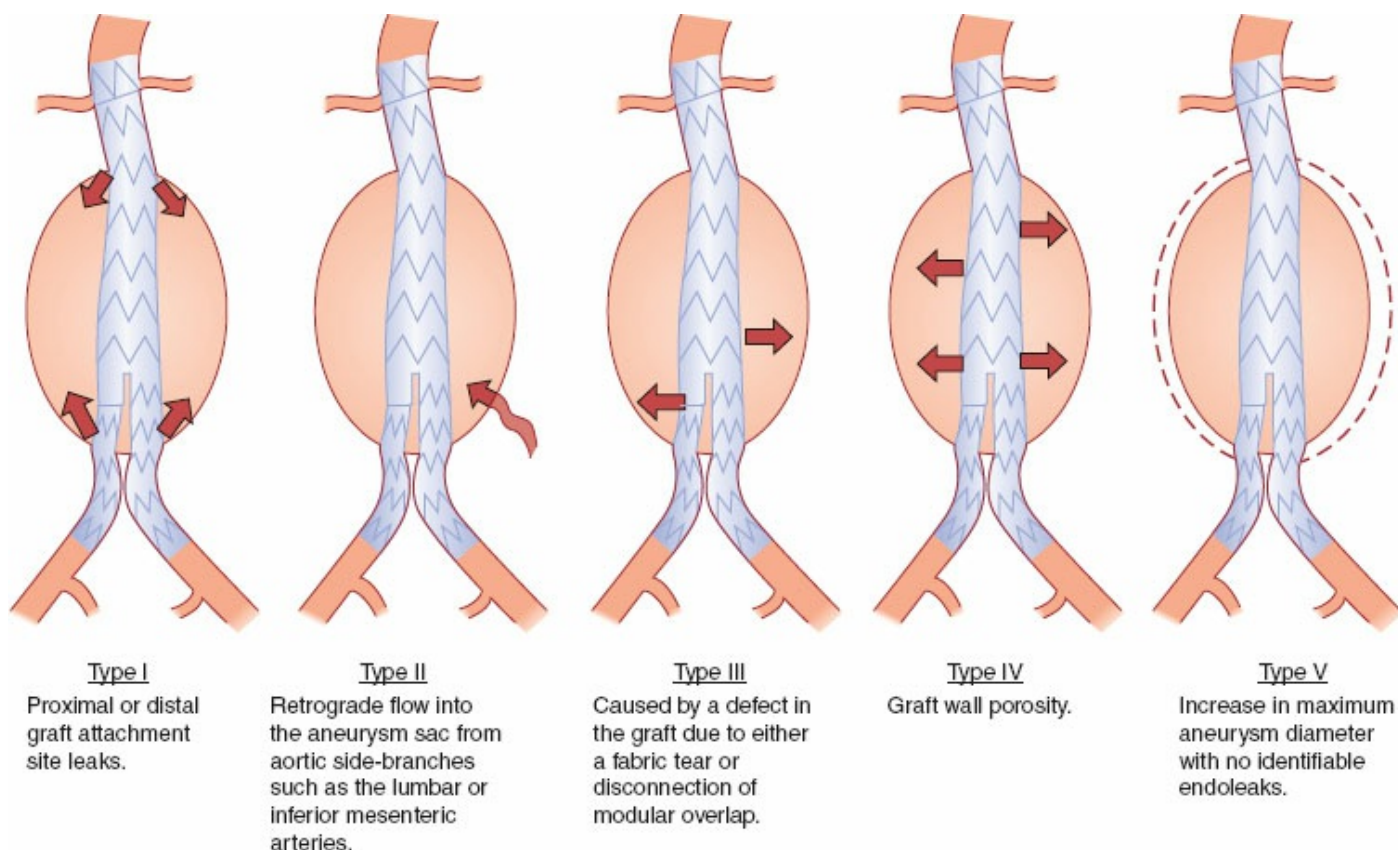

The unique complication profile related to endovascular repair mandates a lifetime of surveillance and a higher rate for reintervention as compared to OAR (29.6% vs. 18.1%).<sup>193</sup> Most reinterventions are graft-related complications including endoleaks, stent graft occlusion, migration, kinking, or infection. The majority of reinterventions tend to be catheter-based with limited morbidity and mortality. Nevertheless, each iterative intervention exposes the patient to the risks of radiation, iodinated contrast dye, and potentially the risks of anesthesia.

The most common indication for reintervention following EVAR is for endoleak. An endoleak is characterized by persistent blood flow into the aneurysm sac outside of the stent graft. The failure to exclude the aneurysm from the circulation may cause an increase in sac pressure over time, expansion, and potential rupture. Endoleaks complicate approximately 10% to 25% of EVAR cases<sup>211,212</sup> and require reintervention in upward of 12%.<sup>212</sup> Five types of endoleaks exist (Fig. 40-17). Types I and III involve direct communication with the systemic arterial circulation and thus mandate reintervention. Type I endoleaks are typically treated with repeat balloon molding or proximal or distal stent extension, whereas stent relining is the treatment for Type III endoleaks. The treatment of Type II endoleaks, caused by retrograde filling of the aneurysm sac by branch vessels, is controversial. Though retrograde flow can lead to aneurysm enlargement and increase in sac pressure, the majority of these aneurysms remain stable or decrease in size due to low flow and spontaneous thrombosis.<sup>211</sup> The EUROSTAR registry found no significant difference in the rate of aneurysm rupture between patients with and without type II endoleak.<sup>213</sup> If treatment is warranted,

endovascular embolization of the feeding vessel is typically employed. Type IV endoleaks are related to graft porosity and are typically self-limited once the patient's coagulation status returns to baseline. Type V endoleak, also called "endotension," refers to an enlarging aneurysm sac without demonstrable endoleak. The etiology of endotension has not been completely elucidated. Although there may be a role for conservative management or endovascular reintervention, open conversion is the mainstay of management for endotension. Endoleak remains the single leading cause of late (more than 30-day) conversion to open repair, accounting for more than 60% of late reinterventions.<sup>214</sup> The incidence of late conversions has been reported to be as low as 2% but more recent evidence suggests a rate as high as 4%. This may be related to the increased number of endovascular repairs, and particularly complex endovascular repairs, performed. Late conversion to open repair is a technically challenging procedure with a relatively high mortality rate, particularly if performed emergently. Mortality rates for nonelective repair have been reported to be as high as 30%.<sup>214</sup>

The pulsatile nature of blood flow results in an ongoing downward pressure on the stent graft and may result in stent migration. Over time, this may re-expose the aneurysm to systemic pressurization. Risk factors include aneurysm anatomy (e.g., hostile angulation of the aortic neck or short proximal landing zone) and graft properties (e.g., inadequate fixation and short overlaps).<sup>212</sup> Aortic stent graft infection occurs in up to 1% of cases and may be a result of direct primary contamination or occur later from a secondary source. Clinical findings may be nonspecific such as fever, back pain, or leukocytosis. Initial treatment involves broad spectrum antibiotics but may require explantation of the stent graft and open bypass. Stent graft kinking or infolding occurs in less than 5% of cases but may result in flow-restricting stenosis, graft thrombosis, and occlusion. Acute occlusion is frequently treated with catheter-directed thrombolysis or may be treated with mechanical thrombectomy if pharmacologic treatment is contraindicated.

Renal damage after EVAR is multifactorial. Preoperative renal insufficiency best predicts perioperative renal failure/dialysis need. Serial creatinine or GFR should be followed to ensure that the patient has sufficiently recovered from diagnostic angiography prior to surgery. The best way to limit renal damage is to limit contrast use. Gadolinium and CO<sub>2</sub> have been used. Better x-ray equipment and operator experience allows for lower contrast dosing. Preoperative fluid loading with 1 mL/kg/hr over 12 hours prior to surgery seems to be optimum management, but most patients are outpatients. Thus initial fluid loading seems prudent. Sodium bicarbonate infusions and N-acetyl cysteine infusions may play a small role in preventing renal damage.

**Figure 40-17** Types of endoleaks. Five types of endoleaks exist depending on the mechanism of persistent blood flow. Subsequent management depends on the type of endoleak present. The possibility of endoleak requires lifelong surveillance following EVAR, and endoleak remains the primary indication for late reintervention. ## Endovascular Management of Peripheral Artery Disease

The Inter-Society Consensus for the Management of PAD (TASC II) recommends endovascular revascularization for focal, discrete lesions and open surgical revascularization for severe disease.<sup>13</sup> Evidence suggests, however, that national trends in revascularization approach skew heavily toward endovascular repair even for more diffuse, complex disease. Endovascular interventions have increased more than threefold while open peripheral bypass surgery has decreased by more than 40% in recent years.<sup>215</sup> This trend is likely due, in large part, to continued improvement in technology available for endovascular repair (e.g., stents, imaging techniques, and drug–device combinations).<sup>216</sup> This paradigm shift is reflected in the most recent recommendations from the Society for Vascular Surgery practice guidelines, which endorses endovascular treatment as a reasonable first-line approach in most circumstances, even for complex disease.<sup>171</sup> In some cases, a hybrid approach to PAD may be employed. In one study, nearly 25% of complex AIOD repairs combined open femoral endarterectomy with

endovascular iliac intervention due to disease severity.<sup>217</sup> In other cases, a percutaneous approach to femoropopliteal disease may be combined with traditional open surgery below the knee. The development of hybrid operating rooms, with a full array of imaging equipment, allows for real-time decision making and completion of multiple procedures (both endovascular and open) under one anesthetic. Ultimately, the decision making must take into account disease severity and location, patient risk factors, and proceduralist skill.

Few randomized controlled trials exist to guide management decisions for the surgical management of PAD; the majority of the evidence is based on observational data. No large randomized controlled trials have compared open versus endovascular repair for complex AIOD. A systematic review of more than 5,300 patients undergoing open versus endovascular repair demonstrated greater perioperative morbidity and mortality but better long-term durability with open repair.<sup>218</sup> A recent meta-analysis of endovascular revascularization of AIOD demonstrated 4- to 5-year primary patency rates from 60% to 86% and secondary patency rates from 80% to 98%.<sup>219</sup> The majority of reinterventions in this study were percutaneous or noninvasive in nature. The Bypass versus Angioplasty in Severe Ischaemia of the Leg (BASIL) trial was a multicenter, randomized controlled trial that demonstrated that endovascular therapy resulted in less short-term morbidity and similar amputation-free survival for femoropopliteal disease.<sup>220</sup> For patients who survived at least 2 years, however, open revascularization was associated with increased overall survival and a trend toward amputation-free survival.<sup>221</sup> A recent meta-analysis evaluating endovascular versus surgical revascularization for femoropopliteal disease endorses an endovascular approach as first-line therapy.<sup>61</sup> Endovascular repair of infrapopliteal disease has traditionally been reserved for patients with CLI due to limited success and unacceptable rates restenosis, dissection, and thrombosis early after the intervention. However, the advent of new technologies (namely, drug eluting stents) is changing the treatment paradigm for infrapopliteal disease. Several recent randomized controlled trials and meta-analyses support the use of drug eluting stents for symptomatic infrapopliteal disease that is anatomically suitable for intervention.<sup>222</sup>

Endovascular repair of PAD is typically performed under local anesthesia or monitored anesthesia care. Small doses of short-acting agents should be utilized to allow for patient cooperation throughout the procedure. The patient must be able to tolerate lying flat on the procedure table for several hours. Patients who are particularly anxious or who are unable to cooperate may require general anesthesia. Because the risk of blood loss is minimal and significant hemodynamic alterations are not anticipated intraoperatively, invasive hemodynamic monitoring is rarely indicated for these procedures. A

single medium- to large-bore intravenous line is sufficient for vascular access.

## Conclusion

Vascular surgery patients are generally elderly patients with significant cardiovascular disease in multiple vascular beds. They frequently have complex medical problems including CAD, COPD, diabetes mellitus, and renal insufficiency. A thorough preoperative evaluation for concurrent disease and pharmacologic optimization is paramount. The use of preoperative cardiac testing is controversial but current recommendations suggest it is reasonable to obtain preoperative cardiac testing for patients with poor or unknown exercise capacity if it will change perioperative management. Major morbidity in the perioperative setting is related to cardiovascular events; therefore, the heart should be the major focus of the anesthesiologist's attention. The skill of the anesthesiologist can greatly influence perioperative outcome. The field of vascular surgery is increasingly moving toward an endovascular focus. Improvements in imaging technique, equipment, and proceduralist skill are pushing the frontiers of what can be accomplished via minimally invasive techniques. Consequently, open repair is increasingly reserved for more severe or surgically complex disease. Endovascular surgery has its own unique complication profile that mandates a lifetime of surveillance. Long-term outcomes of many recent advances remain to be seen.

## **KEY POINTS**

- 1 As oxygen consumption increases during pregnancy, the maternal cardiovascular system adapts to meet the metabolic demands of a growing fetus.
- 2 Airway edema may be particularly severe in women with preeclampsia, in patients placed in the Trendelenburg position for prolonged periods, in those who have pushed during the second stage of labor, or with concurrent use of tocolytic agents.
- 3 A rapid-sequence induction of anesthesia, application of cricoid pressure, and intubation with a cuffed endotracheal tube are recommended for all pregnant women receiving general anesthesia after 20 weeks of gestation.
- 4 The driving force for placental drug transfer is the concentration gradient of free drug between the maternal and fetal blood.
- 5 Labor analgesia may benefit mother and fetus and should not be withheld if requested.
- 6 Although the case-fatality rate (maternal mortality) with general anesthesia remains greater than that with neuraxial anesthesia, in recent years, mortality during general anesthesia has decreased while mortality during neuraxial anesthesia has increased.

- 7 By virtue of age and gender as well as reduced epidural pressure after delivery, pregnant women are at a higher risk for developing postdural puncture headache.
- 8 Pregnancy and parturition are considered “high risk” when accompanied by conditions unfavorable to the well-being of the mother, fetus, or both.
- 9 Preeclampsia is considered severe if it is associated with severe hypertension, significant thrombocytopenia, or end-organ damage.
- 10 Hemorrhage is the leading cause of maternal mortality worldwide.
- 11 Heart disease during pregnancy is a leading nonobstetric cause of maternal mortality.
- 12 Obese parturients are more likely to have antenatal comorbidities, which may adversely affect outcome.
- 13 When a mother requires surgery during pregnancy, there is no data to suggest that any one anesthetic technique is preferred over another, provided oxygenation and blood pressure are maintained and hyperventilation is avoided.

## Physiologic Changes of Pregnancy

During pregnancy, there are major alterations in nearly every maternal organ system. These changes are initiated by hormones secreted by the corpus luteum and placenta. The mechanical effects of the enlarging uterus and compression of surrounding structures play an increasing role in the second and third trimesters. This altered physiologic state has relevant implications for the anesthesiologist caring for the pregnant patient. The most relevant changes involving hematologic, cardiovascular, ventilatory, metabolic, and gastrointestinal functions are considered in [Table 41-1](#).

### *Hematologic Alterations*

Increased mineralocorticoid activity during pregnancy produces sodium retention and increased body water content. Thus, plasma volume and total blood volume begin to increase in early gestation, resulting in a final increase of 40% to 50% and 25% to 40%, respectively, at term. The relatively smaller increase in red blood cell volume (20%) accounts for a reduction in hemoglobin concentration (from 12 g/dL to 11 g/dL) and hematocrit (to 35%).<sup>1</sup> Plasma expansion and the resultant relative anemia of pregnancy plateau at approximately 32 to 34 weeks of gestation. The leukocyte count ranges from 8,000 to 10,000/mm<sup>3</sup> throughout pregnancy. Several procoagulant factor levels increase during pregnancy, most notably fibrinogen, which doubles in mass. Anticoagulant activity decreases, as evidenced by decreased protein S concentrations and activated protein C

resistance, and fibrinolysis is impaired. Increases in D-dimer and thrombin-antithrombin complexes indicate increased clotting and probable secondary fibrinolysis. Indeed, pregnancy has been referred to as a state of *chronic compensated disseminated intravascular coagulation*.<sup>2,3</sup> These coagulation changes peak at the time of parturition.<sup>4</sup> The platelet count is decreased in pregnant women, due to both dilution and increased consumption, and 6% to 15% of pregnant women at term have a platelet count below  $150 \times 10^9/L$ , compared with only 1% of age-matched nonpregnant controls. A further 1% of women at term have platelet counts below  $100 \times 10^9/L$ .<sup>5</sup>

**Table 41-1** Summary of Physiologic Changes of Pregnancy at Term

Variable	Change	Amount
Plasma volume	↑	40–50%
Total blood volume	↑	25–40%
Hemoglobin	↓	11–12 g/dL
Fibrinogen	↑	100%
Serum cholinesterase activity	↓	20–30%
Systemic vascular resistance	↓	50%
Cardiac output	↑	30–50%
Systemic blood pressure	↓	Slight
Functional residual capacity	↓	20–30%
Minute ventilation	↑	50%
Alveolar ventilation	↑	70%
Oxygen consumption	↑	20%
Carbon dioxide production	↑	35%
Arterial carbon dioxide tension	↓	10 mmHg
Arterial oxygen tension	↑	10 mmHg
Minimum alveolar concentration	↓	32–40%

↑, increase; ↓, decrease.

Serum cholinesterase activity declines to a level of 20% below normal by term and reaches a nadir in the puerperium. However, it is doubtful that moderate succinylcholine doses lead to prolonged apnea in otherwise normal circumstances.<sup>6</sup> Although the total amount of protein in the circulation increases, plasma protein concentration declines to below 6 g/dL at term because of dilution from increased plasma volume.<sup>7</sup> The albumin-globulin ratio declines because of the relatively greater reduction in albumin concentration. A decrease in serum protein concentration may be clinically significant because the free fractions of protein-bound drugs can be expected to increase.

### Cardiovascular Changes

As oxygen consumption increases during pregnancy, the maternal cardiovascular system adapts to meet the metabolic demands of a growing fetus. Systemic vascular resistance (SVR) declines as maternal vessels lose their responsiveness to angiotensin and other pressors.<sup>8,9</sup> As a result,

cardiac output increases by 30% to 50% above that of the nonpregnant state due primarily to a 20% to 50% increase in stroke volume and also to mild elevations in heart rate. Arterial blood pressure decreases slightly because the decrease in peripheral resistance exceeds the increase in cardiac output. Additional increases in cardiac output occur during labor (when cardiac output may reach 12 to 14 L/min) and also in the immediate postpartum period because of added blood volume from the contracted uterus. These changes are exaggerated in multiple gestation pregnancies.<sup>10</sup>

Supine hypotensive syndrome, which affects some women, occurs because the supine position leads to vena cava occlusion and thus decreased preload to the heart, resulting in lowered cardiac output and blood pressure, tachycardia, maternal mental status changes, nausea, and presyncope. From the second trimester, vena cava compression by the enlarged uterus becomes progressively more important, reaching its maximum at 36 to 38 weeks of gestation, after which it may decrease as the fetal head descends into the pelvis.<sup>11</sup> Studies of cardiac output, measured with the patient in the supine position during the last weeks of pregnancy, have indicated a decrease to nonpregnant levels; however, this decrease was not observed when patients were in the lateral decubitus position.<sup>12</sup> Therefore, left uterine displacement by placing a wedge under the right hip or providing left lateral pelvic tilt should be applied routinely during the second and third trimesters of pregnancy; many women may remain susceptible to vena cava compression unless provided with 30 degrees of tilt.<sup>11</sup>

Changes in the electrocardiogram (ECG) may also occur. In addition to heart rate increases, left axis deviation is observed in the third trimester. There is also a tendency toward premature atrial contractions, paroxysmal supraventricular tachycardia, and ventricular dysrhythmias.<sup>13,14</sup>

## *Respiratory Changes*

Respiratory adaptations are necessary for adaptation to increasing metabolic demands, mechanical effects of the enlarging uterus, and cardiovascular changes of pregnancy. Increased extracellular fluid and vascular engorgement and hormonal changes may lead to edema of the upper airway. Many pregnant women complain of difficulty with nasal breathing, and the friable nature of the mucous membranes during pregnancy can cause severe bleeding, especially on insertion of nasopharyngeal airways or nasogastric or endotracheal tubes. Airway edema may be particularly severe in women **2** with preeclampsia, in patients placed in the Trendelenburg position for prolonged periods, or with concurrent use of tocolytic agents. It may also be difficult to perform laryngoscopy in obese or short-necked parturients or those with enlarged breasts. Use of a short-handled laryngoscope may prove

helpful. Mallampati scores increase during pregnancy and worsen further throughout labor when oropharyngeal volume also decreases.<sup>15,16</sup>

 The diaphragm is displaced cephalad as the uterus increases in size.

This is accompanied by an increase in the anteroposterior and transverse diameters of the thoracic cage so that total lung capacity decreases only slightly. From the fifth month, functional residual capacity (FRC) decreases by 20% to 30%, as do its subcomponents, expiratory reserve volume (ERV; 15% to 20%) and residual volume (RV; 20% to 25%). Concomitantly, there is an increase in inspiratory reserve volume. In most pregnant women, a decreased FRC does not cause problems, but those with pre-existing alterations in closing volume as a result of smoking, obesity, or scoliosis may experience early airway closure with advancing pregnancy, leading to hypoxemia. The Trendelenburg and supine positions also exacerbate the abnormal relationship between the closing volume and FRC. The FRC returns to normal shortly after delivery.

Airway resistance usually remains unchanged due to the competing effects of progesterone-induced relaxation of bronchiolar smooth muscle versus factors associated with increased airway resistance such as upper airway edema. Progesterone induces increases in minute ventilation, which increases from the beginning of pregnancy to a maximum of 50% above nonpregnant values at term. This is accomplished by a 30% to 50% increase in tidal volume and a small increase in respiratory rate. Alveolar dead space increases such that the dead space to tidal volume ratio remains unchanged. After delivery, as blood progesterone levels decline, ventilation returns to normal within 1 to 3 weeks.

## **Metabolism**

Basal oxygen consumption increases during early pregnancy, with an overall increase of 20% by term; CO<sub>2</sub> production increases. However, increased alveolar ventilation leads to a reduction in the partial pressure of carbon dioxide in arterial blood (PaCO<sub>2</sub>) to 28 to 32 mmHg and an increase in the partial pressure of oxygen in arterial blood (PaO<sub>2</sub>) to 106 mmHg. The plasma buffer base decreases from 47 to 42 mEq/L; therefore, the pH remains practically unchanged. The maternal uptake and elimination of inhalational anesthetics are enhanced because of increased alveolar ventilation and decreased FRC. Also, the decreased FRC and increased metabolic rate predispose the mother to development of hypoxemia during periods of apnea/hypoventilation, such as may occur during airway obstruction or prolonged attempts at tracheal intubation.<sup>17</sup>

Human placental lactogen and cortisol increase the tendency toward hyperglycemia and ketosis, which may exacerbate pre-existing diabetes

mellitus. The patient's ability to handle a glucose load is decreased, and the transplacental passage of glucose may stimulate fetal secretion of insulin, in turn leading to neonatal hypoglycemia in the immediate postpartum period.<sup>18</sup>

## **Gastrointestinal Changes**

Pregnant women are at increased risk for aspiration of gastric contents compared to the general population. Aspiration pneumonitis is estimated to occur in 0.1% of cesarean deliveries performed under general anesthesia. Airway difficulties present during pregnancy may contribute to this risk.<sup>19</sup> In addition, gastric secretions are more acidic. Gastric emptying time is not prolonged during pregnancy, but overall gastrointestinal transit time is prolonged. In two contemporary studies of obese and nonobese, nonlaboring parturients at term, gastric emptying did not differ after ingestion of a moderate amount (300 mL) of water versus after an overnight fast.<sup>20,21</sup> Recent obstetric anesthesia practice guidelines by the American Society of Anesthesiologists and the Society for Obstetric Anesthesia and Perinatology allow for oral intake of modest amounts of clear liquids in uncomplicated laboring patients and for similar intake in patients scheduled for uncomplicated cesarean delivery up to 2 hours prior to induction of anesthesia; they recommend against ingestion of solid food during labor.<sup>22</sup> However, the guidelines state that patients with additional risk factors for aspiration (e.g., morbid obesity, diabetes, difficult airway) or patients at increased risk for operative delivery (e.g., nonreassuring fetal heart rate [FHR] pattern) may have further restrictions of oral intake.

The lower esophageal sphincter (LES) may become distorted and incompetent and progesterone may decrease its tone. The risk of regurgitation depends, in part, on the gradient between the LES and intragastric pressures. The gravid uterus may increase intra-abdominal and intragastric pressures, decreasing the gradient. After succinylcholine administration in most patients, the gradient increases because the increase in LES pressure exceeds the increase in intragastric pressure. However, in parturients with "heartburn," the LES tone is greatly reduced.<sup>23</sup>

The efficacy of prophylactic nonparticulate antacids may be diminished by inadequate mixing with gastric contents, improper timing of administration, and the tendency for antacids to increase gastric volume. Administration of histamine (H<sub>2</sub>) receptor antagonists, such as ranitidine, may be useful. A case can be made for the administration of intravenous metoclopramide before elective cesarean delivery. This dopamine antagonist hastens gastric emptying and increases resting LES tone in both nonpregnant and pregnant women.<sup>24</sup> The aforementioned American Society of Anesthesiologists and Society for Obstetric Anesthesia and Perinatology practice guidelines advise practitioners

to consider the administration of nonparticulate antacids, H<sub>2</sub> receptor antagonists, and/or metoclopramide for aspiration prophylaxis before surgical procedures and to use neuraxial anesthesia whenever possible.<sup>22</sup> A rapid-3 sequence induction of anesthesia, application of cricoid pressure, and intubation with a cuffed endotracheal tube are recommended for pregnant women receiving general anesthesia from 20 weeks of gestation, or earlier, if symptoms of reflux are present. These recommendations also pertain to women in the immediate postpartum period because there is uncertainty as to when the risk for aspiration of gastric contents returns to normal.

### **Altered Drug Responses**

The minimum alveolar concentration (MAC) for inhalation agents is decreased by 8 to 12 weeks of gestation and may be related to an increase in progesterone levels.<sup>25</sup> In addition, maximal cephalad block level after neuraxial administration of local anesthetics is higher in the second and third trimesters of pregnancy.<sup>26</sup> Epidural venous engorgement, which decreases intrathecal volume, may lead to increased local anesthetic spread. Pregnancy increases median nerve sensitivity to lidocaine block<sup>27</sup> and in vitro preparations from pregnant animals demonstrate increased susceptibility to local anesthetic blockade. This increased sensitivity may be due to progesterone or other hormonal mediators.

### **Placental Transfer and Fetal Exposure to Anesthetic Drugs**

Most drugs, including many anesthetic agents, readily cross the placenta. Several factors influence the placental transfer of drugs, including physicochemical characteristics of the drug itself, maternal drug concentrations in the plasma, properties of the placenta, and hemodynamic events within the fetomaternal unit.

Drugs cross biologic membranes by simple diffusion, the rate of which is determined by the Fick principle, which states that:

$$Q/t = KA(C_m - C_f)/D$$

where  $Q/t$  is the rate of diffusion,  $K$  is the diffusion constant,  $A$  is the surface area available for exchange,  $C_m$  is the concentration of free drug in maternal blood,  $C_f$  is the concentration of free drug in fetal blood, and  $D$  is the thickness of the diffusion barrier.

The diffusion constant ( $K$ ) of the drug depends on physicochemical characteristics such as molecular size, lipid solubility, and degree of ionization. Compounds with a molecular weight less than 500 Da are

unimpeded in crossing the placenta, whereas those with molecular weights of 500 to 1,000 Da are more restricted. Most drugs commonly used by the anesthesiologist have molecular weights that permit easy transfer.

Drugs that are highly lipid soluble cross biologic membranes more readily. The degree of ionization is important because the nonionized moiety of a drug is more lipophilic than the ionized one. Local anesthetics and opioids are weak bases, with a relatively low degree of ionization and considerable lipid solubility. In contrast, muscle relaxants are more ionized and less lipophilic, and their rate of placental transfer is therefore more limited.

The relative concentrations of drug existing in the nonionized and ionized forms can be predicted from the Henderson—Hasselbalch equation:

$$\text{pH} = \text{pKa} + \log(\text{base})/(\text{cation}).$$

The pKa is the pH at which the concentrations of free base and cation are equal. The ratio of base to cation becomes particularly important with local anesthetics because the nonionized form penetrates tissue barriers, such as the placenta. For the amide local anesthetics, the pKa values (7.7 to 8.1) are sufficiently close to physiologic pH so that changes in maternal or fetal acid–base status may significantly alter the proportion of ionized and nonionized drugs present. At equilibrium, the concentrations of nonionized drug in the fetal and maternal plasma are equal. In an acidotic fetus, local anesthetics may be relatively more ionized than in maternal blood, and “ion trapping” may occur, leading to fetal drug accumulation.<sup>28</sup>

The effects of maternal plasma protein binding on the rate and amount of drug transferred to the fetus are not so well understood. In sheep, the low fetomaternal ratio of bupivacaine plasma concentrations has been attributed to the difference between fetal and maternal plasma protein binding, rather than to extensive fetal tissue uptake.<sup>29</sup> However, if enough time is allowed for fetomaternal equilibrium to be approached, substantial accumulation of highly protein-bound drugs, such as bupivacaine, can occur in the fetus.<sup>30</sup>

**4** As already stated, the driving force for placental drug transfer is the concentration gradient of free drug between the maternal and fetal blood. On the maternal side, the following factors interact: The dose administered, the mode and site of administration, and, in the case of local anesthetics, the use of vasoconstrictors. The rates of distribution, metabolism, and excretion of the drug, which may vary at different stages of pregnancy, are equally important. In general, higher doses result in higher maternal blood concentrations. The absorption rate varies with the site of drug injection. Compared with other forms of administration, an intravenous bolus results in the highest blood concentrations. Increased maternal blood concentrations after repeated administration of a drug greatly depend on the dose and

frequency of reinjection, in addition to the kinetic characteristics of the drug. The elimination half-life of amide local anesthetic agents is relatively long, so repeated injections may lead to accumulation in the maternal plasma. In contrast, 2-chloroprocaine, an ester local anesthetic, undergoes rapid enzymatic hydrolysis in the presence of pseudocholinesterase. After epidural injection, the mean half-life in the mother is approximately 3 minutes. After reinjection, 2-chloroprocaine can be detected in the maternal plasma for only 5 to 10 minutes, and no accumulation of this drug is evident.<sup>31</sup>

## **Placenta**

Maturation of the placenta can affect the rate of drug transfer to the fetus, as the thickness of the trophoblastic epithelium decreases from 25 to 2 mm at term. Uptake and biotransformation of anesthetic drugs by the placenta would decrease the amount transferred to the fetus. However, placental drug uptake is limited, and there is no evidence to suggest that this organ metabolizes any of the agents commonly used in obstetric anesthesia.

## **Hemodynamic Factors**

Any factor decreasing placental blood flow (e.g., aortocaval compression, hypotension, or hemorrhage) can decrease drug delivery to the fetus. During labor, uterine contractions intermittently reduce perfusion of the placenta. If a uterine contraction coincides with a rapid decline in plasma drug concentration after an intravenous bolus injection, by the time perfusion has returned to normal, the concentration gradient across the placenta has been greatly reduced. Thus, an intravenous injection of diazepam, administered at the onset of contraction compared to during uterine diastole, results in less drug being delivered to the fetus.

Several characteristics of the fetal circulation delay equilibration between the umbilical arterial and venous blood, and thus delay the depressant effects of anesthetic drugs (Fig. 41-1). The liver is the first fetal organ perfused by the umbilical venous blood, which carries drug to the fetus. Substantial uptake by this organ has been demonstrated for a variety of drugs, including thiopental, lidocaine, and halothane. During its transit to the arterial side of the fetal circulation, the drug is progressively diluted as blood in the umbilical vein becomes admixed with fetal venous blood from the gastrointestinal tract, the lower extremities, the head and upper extremities, and finally, the lungs. Because of this unique pattern of fetal circulation, continuous administration of anesthetic concentrations of nitrous oxide during elective cesarean sections caused newborn depression only if the induction-to-delivery interval exceeded 5 to 10 minutes. Rapid transfer of inhalation

agents, including halothane, enflurane, and isoflurane, results in detectable umbilical arterial and venous concentrations after 1 minute.<sup>32</sup> Because of the rapid decline in maternal plasma drug concentrations, administration of thiopental or thiamylal as a single-bolus injection not exceeding 4 mg/kg was followed by fetal arterial concentrations of barbiturate below a level that would result in neonatal depression.<sup>33</sup>

Fetal regional blood flow changes can also affect the amount of drug taken up by individual organs. For example, during asphyxia and acidosis, a greater proportion of the fetal cardiac output perfuses the fetal brain, heart, and placenta. In asphyxiated baboon fetuses, infusion of lidocaine resulted in increased drug uptake in the heart, brain, and liver compared with control fetuses that were not asphyxiated.<sup>34</sup>

**Figure 41-1** Diagram of the circulation in the mature fetal lamb. The numerals indicate the mean oxygen saturation (%) in the great vessels of six lambs: Right ventricle (RV), left ventricle (LV), superior vena cava (SVC), inferior vena cava (IVC), brachiocephalic artery (BCA), foramen ovale (FO), ductus arteriosus (DA), ductus venosus (DV). (Adapted from Born GVR, Dawes GS, Mott JC, et al. Changes in the heart and lungs at birth. *Cold Spring Harb Symp Quant Biol.* 1954;19:103.)

## Fetus and Newborn

Any drug that reaches the fetus undergoes metabolism and excretion. In this respect, the fetus has an advantage over the newborn in that it can excrete the drug back to the mother once the concentration gradient of the free drug across the placenta has been reversed. With the use of local anesthetics, this may occur even though the total plasma drug concentration in the mother may exceed that in the fetus because there is lower protein binding in fetal plasma.<sup>29</sup> There is only one drug, 2-chloroprocaine, that is metabolized in the fetal blood so rapidly that even in acidosis, substantial accumulation in the fetus is avoided.<sup>31</sup>

In both the term and the preterm newborn, the liver contains enzymes essential for the biotransformation of amide local anesthetics. The metabolic clearance in the newborn is similar to, and renal clearance greater than, that in the adult. Elimination half-life is prolonged in the newborn due to a greater volume of distribution of the drug. Prolonged elimination half-lives in the newborn compared with the adult have been noted for other amide local anesthetics.<sup>35</sup>

It is not completely understood whether the fetus and the newborn are more sensitive than the adult to the depressant and toxic effects of local anesthetics. The relative central nervous system (CNS) and cardiorespiratory toxicity of lidocaine has been studied in adult ewes and lambs (fetal and neonatal).<sup>36</sup> The doses required to produce toxicity in the fetal and neonatal lambs were greater than those required in the adult, although serum concentrations at which toxicity occurred were not different. In the fetus, this was attributed to placental clearance of drug into the mother and better maintenance of blood gas tensions during convulsions. In the newborn, a larger volume of distribution was thought to be responsible for the higher doses needed to induce toxic effects.

Bupivacaine has been implicated as a possible cause of neonatal jaundice because its high affinity for fetal erythrocyte membranes may lead to a decrease in filterability and deformability, rendering them more prone to hemolysis (see [Chapter 41](#)). However, studies have failed to show increased bilirubin production in newborns whose mothers received bupivacaine for epidural anesthesia during labor and delivery.<sup>37</sup> Finally, observational neurobehavioral studies have revealed subtle changes in newborn neurologic and adaptive functions. In the case of most anesthetic agents, these changes are minor and transient, lasting for only 24 to 48 hours.

## **Analgesia for Labor and Vaginal Delivery**

Most women experience moderate-to-severe pain during parturition. In the first stage of labor, pain is caused by uterine contractions, associated with dilation of the cervix and stretching of the lower uterine segment. Pain

impulses are carried in visceral afferent type C fibers accompanying the sympathetic nerves. During the first stage of labor, pain is referred to the T10 to L1 spinal cord segments. In the late first and second stages of labor, additional pain impulses from distention of the vaginal vault and perineum are carried by the pudendal nerves, composed of sacral fibers (S2 to S4).

Well-conducted obstetric analgesia, in addition to relieving pain and anxiety, may have other benefits. Pain may result in maternal hypertension and reduced uterine blood flow. During the first and second stages of labor, epidural analgesia blunts the increases in maternal cardiac output, heart rate, and blood pressure that occur with painful uterine contractions and “bearing-down” efforts.<sup>38</sup> In reducing maternal secretion of catecholamines, epidural analgesia may convert a previously dysfunctional labor pattern to normal. Maternal analgesia may also benefit the fetus by eliminating maternal hyperventilation, which can result in reduced fetal arterial oxygen tension because of a leftward shift of the maternal oxygen–hemoglobin dissociation curve.

The most frequently chosen methods for relieving the pain of parturition are psychoprophylaxis, systemic medication, and regional analgesia. Inhalation analgesia, conventional spinal analgesia, and paracervical blockade are less commonly used. General anesthesia is rarely necessary but may be indicated for uterine relaxation in complicated deliveries. Labor varies in length and intensity, as do individual tolerance to pain and desire for pain relief. Women should be educated about the options for labor analgesia and supported in their choice for method of pain control. Analgesia should not be withheld if requested.<sup>39</sup> Neonatal outcomes appear to be similar for healthy women who deliver without pharmacologic analgesia and for women who receive analgesia. 5

### *Nonpharmacologic Methods of Labor Analgesia*

Nonpharmacologic methods to relieve the pain of childbirth include childbirth education, emotional support, massage, aromatherapy, audiotape, and therapeutic use of hot and cold. More advanced techniques that require specialized training or equipment include hydrotherapy, intradermal water injections, biofeedback, transcutaneous electrical nerve stimulation (TENS), acupuncture or acupressure, and hypnosis. Conclusions regarding the efficacy of most of these techniques are not possible, as the techniques have been inadequately studied.<sup>40</sup>

### **Prepared Childbirth and Psychoprophylaxis**

The philosophy of prepared childbirth maintains that lack of knowledge,

misinformation, fear, and anxiety can heighten a patient's response to pain and consequently increase the need for analgesics. The most popular method of prepared childbirth was introduced by Lamaze. It provides an educational program on the physiology of parturition and attempts to diminish cortical pain perception by encouraging responses such as specific patterns of breathing and focused attention on a fixed object.<sup>41</sup> Scientific data as to whether childbirth education and psychoprophylaxis are effective in reducing childbirth pain are inconsistent and lack scientific rigor. Education, intense motivation, and cultural influences can influence the affective and behavioral responses to pain, although their true effect on pain sensation is less clear.

### **Other Nonpharmacologic Methods**

Continuous labor support refers to the presence during labor of nonmedical support by a trained person. Prospective, controlled trials and several systematic analyses have concluded that women who receive continuous labor support have shorter labors, fewer operative deliveries, fewer analgesic interventions, and better overall satisfaction.<sup>42</sup> Systematic reviews of randomized controlled trials of hydrotherapy (water baths) have concluded that women experience less pain and use less analgesia, without change in the duration of labor, rate of operative delivery, or neonatal outcome.<sup>43</sup> Intradermal water injection consists of the injection of 0.05 to 0.1 mL of sterile water at four sites on the lower back to treat back pain during labor. Although some randomized controlled trials have found that the technique is effective in reducing severe back pain during labor, a 2012 meta-analysis of seven studies concluded that there is little robust evidence that sterile water injections are effective for low back pain or other labor pain.<sup>44</sup> Hypnosis requires prenatal training of the mother by a trained hypnotherapist. A meta-analysis of seven randomized controlled trials concluded that the small number of trials precluded drawing conclusions about the usefulness of hypnotherapy for pain management during labor, although the technique shows some promise.<sup>45</sup> The results of studies using TENS are inconsistent, but in general, labor pain does not appear to be lessened by TENS, nor does it lower the use of other analgesic modalities.<sup>46</sup> In a meta-analysis including 13 trials, women who were randomized to receive acupuncture or acupressure versus control (no or "false" acupuncture) had modestly lower pain scores.<sup>47</sup> Similarly, relaxation techniques may also reduce pain intensity and improve satisfaction with pain relief compared to standard care.<sup>48</sup>

### **Systemic Medication**

The advantages of systemic analgesics include ease of administration and

patient acceptability. However, the drug, dose, time, and method of administration must be chosen carefully to avoid maternal or neonatal depression. Opioids are used most commonly, although tranquilizers and ketamine are used occasionally.

## Opioids

Systemic opioids are commonly administered for labor analgesia, although existing data suggest that they provide little significant analgesia (see [Chapter 20](#)).<sup>49–51</sup> Meperidine has historically been the most commonly used systemic analgesic for the treatment of labor pain. Meperidine can be administered by intravenous injection (effective analgesia in 5 to 10 minutes) or intramuscularly (peak effect in 40 to 50 minutes). However, in the past decade, because of concerns of lack of efficacy and the presence of side effects, there has been a move away from its use for both labor pain and other pain conditions.<sup>51</sup> The major side effects are a high incidence of nausea and vomiting, maternal sedation, dose-related depression of ventilation, orthostatic hypotension, and the potential for neonatal depression. Meperidine may cause transient alterations of the FHR, such as decreased beat-to-beat variability and mild tachycardia. The risk of neonatal depression is related to the interval from the last drug injection to delivery. The placental transfer of an active metabolite, normeperidine, which has a long elimination half-life in the neonate (62 hours), has also been implicated in contributing to neonatal depression and subtle neonatal neurobehavioral dysfunction.

Synthetic opioids such as fentanyl, alfentanil, and remifentanil are more potent than meperidine; however, their use during labor is limited by their short duration of action. These drugs offer an advantage when analgesia of rapid onset but short duration is necessary (e.g., with forceps application). For more prolonged analgesia, fentanyl or remifentanil can be administered with patient-controlled delivery devices.<sup>52</sup> However, patient-controlled analgesia (PCA) administration of opioids does carry with it the potential for drug accumulation and the risk of neonatal depression. Remifentanil has the theoretical advantage of rapid onset and offset compared with the other opioids. Bolus doses ranging from 0.2 to 1  $\mu\text{g}/\text{kg}$  with lockout intervals from 1 to 5 minutes and background infusion rates from 0 to 0.1  $\mu\text{g}/\text{kg}/\text{min}$ <sup>53</sup> have been described. However, as with other systemic opioid techniques, it is unclear whether remifentanil PCA can provide satisfactory analgesia without an unacceptably high incidence of maternal, fetal, and neonatal side effects.<sup>54</sup>

Opioid agonists–antagonists, such as butorphanol and nalbuphine, have also been used for obstetric analgesia. These drugs have the proposed benefits of a lower incidence of nausea, vomiting, and dysphoria, as

well as a “ceiling effect” on depression of ventilation. Butorphanol, 1 to 2 mg, or nalbuphine, 10 mg by intravenous or intramuscular injection, is probably the most popular. Unlike meperidine, these drugs are biotransformed into inactive metabolites and have a ceiling effect on depression of ventilation.

Naloxone, a pure opioid antagonist, should not be administered to the mother shortly before delivery to prevent neonatal ventilatory depression because it reverses maternal analgesia at a time when it is most needed. In addition, in some instances, it has caused maternal pulmonary edema and even cardiac arrest. If necessary to correct respiratory depression, the drug should be given directly to the newborn intramuscularly (0.1 mg/kg).

## **Ketamine**

Ketamine is a potent analgesic. However, it may also induce unacceptable amnesia that may interfere with the mother’s recollection of the birth. Nonetheless, ketamine is a useful adjuvant to inadequate regional analgesia during vaginal delivery or for obstetric manipulations. In low doses (0.2 to 0.4 mg/kg), ketamine provides adequate analgesia without causing neonatal depression. Constant communication is required with the patient to ensure that she is awake and able to protect her airway.

## ***Regional Analgesia***

Regional techniques provide excellent analgesia with minimal depressant effects on the mother and the fetus. The regional techniques most commonly used in obstetric anesthesia include central neuraxial blocks (spinal, epidural, and combined spinal/epidural [CSE]), paracervical and pudendal blocks, and, less frequently, lumbar sympathetic blocks (LSBs). Hypotension resulting from sympathectomy is the most frequent complication of central neuraxial blockade. Therefore, maternal blood pressure should be monitored at regular intervals, typically every 2 to 5 minutes for approximately 15 to 20 minutes after the initiation of the block and at routine intervals thereafter. The use of regional analgesia may be contraindicated in the presence of coagulopathy, acute hypovolemia, or infection at the site of needle insertion. Chorioamnionitis without frank sepsis is not a contraindication to central neuraxial blockade in obstetrics, provided antibiotics have been administered.

Because of ethical considerations and methodologic difficulties, it is difficult to design clinical studies to examine the effects of neuraxial analgesia on the progress of labor and mode of delivery. Randomized controlled trials have found no difference in the rate of cesarean delivery in women who received neuraxial compared with systemic opioid labor analgesia.<sup>55</sup> Meta-analyses suggest that neuraxial analgesia does not prolong the first stage of

labor, although the data are heterogeneous.<sup>55</sup> There has been concern that early initiation of epidural analgesia during the latent phase of labor (<4 cm cervical dilation) in nulliparous women may result in a higher incidence of dystocia and cesarean delivery. However, large randomized trials and a meta-analysis of these trials found no difference in the rate of cesarean delivery in women randomized to early neuraxial compared with systemic opioid analgesia.<sup>56</sup> Neuraxial analgesia is, however, associated with prolongation of the second stage of labor in nulliparous women, possibly owing to a decrease in expulsive forces or malposition of the vertex.<sup>55</sup> Although the American College of Obstetricians and Gynecologists (ACOG) traditionally defined abnormally prolonged second stage of labor as more than 3 hours in nulliparous women with epidural analgesia and more than 2 hours in women without epidural analgesia, a 2014 consensus document developed jointly by the ACOG and the Society for Maternal-Fetal Medicine (SMFM) stated that “a specific absolute maximum length of the time spent in second stage labor beyond which all women should undergo operative delivery has not been identified.” In addition, they suggested that longer durations (beyond the traditional 3 hours) may be appropriate on an individual basis.<sup>57</sup> Prolongation of the second stage in women with epidural analgesia may be minimized by the use of dilute local anesthetic solutions in combination with opioid.<sup>58</sup>

## **Epidural Analgesia**

Epidural analgesia may be used for pain relief during labor and vaginal delivery, and if necessary, converted to anesthesia for cesarean delivery. Effective analgesia during the first stage of labor may be achieved by blocking the T10 to L1 dermatomes with low concentrations of local anesthetic, usually combined with lipid-soluble opioids. Combining drugs allows the use of lower doses of both drugs, thus minimizing side effects and complications of each. For the second stage of labor and delivery, the nerve block should be extended to include the S2 to S4 segments in order to block pain from vaginal and perineal distension and trauma.

Long-acting amides such as bupivacaine or ropivacaine are most frequently used because they produce excellent sensory analgesia while sparing motor function, particularly at low concentrations (<0.1%). Although some studies have found that ropivacaine is associated with less motor blockade than equipotent doses of bupivacaine, there was no difference in the rate of instrumental vaginal delivery among women randomized to receive epidural levobupivacaine, bupivacaine, or ropivacaine for maintenance of labor analgesia.<sup>59</sup>

Analgesia for the first stage of labor may be achieved with 5 to 10 mL of bupivacaine or ropivacaine (0.125%) combined with fentanyl (50 to 100 µg)

or sufentanil (5 to 10 µg). There is controversy regarding the need for an epidural test dose when using dilute solutions of local anesthetic. Because catheter aspiration is not always diagnostic, particularly when using single-orifice epidural catheters, some experts believe that a test dose should be administered to improve detection of an intrathecally or intravascularly placed catheter.

Analgesia may be maintained with a continuous infusion (8 to 12 mL/hr) of bupivacaine (0.0625% to 0.1%) or ropivacaine (0.08% to 0.15%). The addition of fentanyl (1 to 2 µg/mL) or sufentanil (0.3 to 0.5 µg/mL) allows for more dilute local anesthetic solutions to be administered. Alternatively, analgesia may be maintained with patient-controlled epidural analgesia (PCEA) with similar solutions of local anesthetic and opioid. PCEA resulted in greater patient satisfaction, a lower average hourly dose of bupivacaine (and therefore less motor block), and less need for physician interventions<sup>60,61</sup> compared with a continuous epidural infusion. Protocols for PCEA vary widely. Data are conflicting as to whether a background infusion improves analgesia; however, a background infusion may be helpful in selected parturients (e.g., nulliparas with long labors).<sup>61,62</sup> Common PCEA parameters include a parturient-administered bolus dose of 5 to 10 mL, a lock-out interval of 10 to 20 minutes, and a background infusion of 0 to 10 mL/hr. Thirty percent to 50% of the hourly dose is often administered as a background infusion.

The timed, or programmed intermittent epidural bolus technique is a new method for maintaining epidural analgesia. In this technique, the pump is programmed to deliver a bolus dose at regular intervals. Presumably, the bolus administration of drugs into the epidural space results in better distribution of the drug solution. Randomized controlled trials comparing this technique with continuous epidural infusion or with PCEA have shown lower anesthetic dose, greater patient satisfaction, and a lower incidence of motor block and instrumental vaginal delivery.<sup>63</sup>

Women with hemodynamic stability and preserved motor function who do not require continuous fetal monitoring may ambulate with the assistance of a partner during the first stage of labor. Before ambulation, women should be observed for 30 minutes after initiation of neuraxial blockade to assess maternal and fetal well-being.

During delivery, the sacral dermatomes may be blocked with 10 mL of bupivacaine (0.25% to 0.5%), lidocaine (1.0%), or 2-chloroprocaine (2% to 3%). Many parturients have adequate analgesia for delivery without an additional bolus dose, particularly if epidural analgesia has been maintained for a long interval (hours). However, instrumental vaginal delivery may require a denser block than that obtained with dilute local anesthetic solutions.

## Spinal Analgesia

A single subarachnoid injection for labor analgesia has the advantage of fast and reliable onset of neural blockade, and it is technically easier to initiate compared with epidural analgesia. However, repeated intrathecal injections may be required for a long labor, thus increasing the risk of postdural puncture headache (PDPH). Spinal analgesia with fentanyl (15 to 25  $\mu\text{g}$ ) or sufentanil (2 to 5  $\mu\text{g}$ ) in combination with plain bupivacaine (1.25 to 2.5 mg) may be appropriate in the multiparous patient whose anticipated course of labor does not warrant a catheter technique (duration, 1.5 hours). A potential disadvantage of single-shot spinal analgesia is that the duration of labor, even in a rapidly progressing multiparous woman, may be longer than anticipated. Furthermore, if the woman requires an urgent cesarean delivery, a new anesthetic will need to be initiated. However, spinal anesthesia (a “saddle block”) is a safe and effective alternative to general anesthesia or pudendal nerve block for instrumental delivery in parturients without pre-existing epidural analgesia.

## Combined Spinal/Epidural Analgesia

CSE analgesia is an ideal analgesic technique for use during labor. CSE analgesia combines the rapid, reliable onset of profound analgesia resulting from spinal injection with the flexibility and longer duration associated with a continuous epidural technique. After identification of the epidural space using a conventional (or specialized) epidural needle, a longer (127 mm), pencil-point spinal needle is advanced into the subarachnoid space through the epidural needle. After intrathecal injection, the spinal needle is removed and an epidural catheter is inserted. Intrathecal injection of fentanyl (10 to 25  $\mu\text{g}$ ) or sufentanil (2 to 5  $\mu\text{g}$ ) alone or more commonly in combination with bupivacaine (1.25 to 2.5 mg) produces profound analgesia lasting for 90 to 120 minutes with minimal motor block. Spinal opioid alone provides complete analgesia for the early latent phase of labor. However, the addition of bupivacaine is necessary for satisfactory analgesia during advanced labor. Continuous epidural analgesia, PCEA, or programmed intermittent epidural bolus may be initiated following the spinal injection to maintain analgesia.

The most common side effects of intrathecal opioids are pruritus, nausea, vomiting, and urinary retention. The incidence of pruritus is lower if opioid is coadministered with local anesthetic.<sup>64</sup> Rostral spread resulting in delayed respiratory depression may occur; the risk is highest in the first 30 minutes after injection. It is rare with the use of fentanyl or sufentanil. Transient nonreassuring FHR patterns may occur after initiation of either epidural or spinal analgesia, with or without opioids; however, the incidence may be higher after CSE compared to epidural analgesia. Presumably, uterine

tachysystole and decreased uteroplacental perfusion occur as a result of rapid decrease in circulating maternal epinephrine levels after initiation of analgesia or as a result of hypotension after sympatholysis. The incidence of emergency cesarean delivery, however, is no greater after CSE than after conventional epidural analgesia.<sup>65,66</sup>

Mothers in early labor, or with preload-dependent medical conditions (e.g., aortic stenosis), may particularly benefit from opioid-only CSE analgesia. Spinal opioid provides complete analgesia without the need for local anesthetic in early labor, thus avoiding an acute decrease in preload, and almost always allowing motivated women to ambulate because there is no motor block. Multiparous women with advanced cervical dilation also benefit from CSE analgesia in which both intrathecal opioid and local anesthetic are injected. The onset of sacral analgesia is accomplished significantly faster with much less drug than initiation of lumbar epidural analgesia. Some experts advocate the cautious use of CSE analgesia in women who may require urgent cesarean delivery or are at increased risk from general anesthesia (e.g., morbidly obese or anticipated difficult airway) because the epidural component of a CSE is not initially tested. However, epidural catheters sited as part of a CSE technique fail less during labor and intrapartum cesarean delivery compared to catheters sited with a traditional epidural technique.<sup>67,68</sup>

### **Paracervical Block**

Bilateral paracervical block interrupts transmission of nerve impulses from the uterus and cervix during the first stage of labor. Five to ten milliliters of dilute local anesthetic solution is injected submucosally via a needle guide in the vagina into the left and right lateral vaginal fornices. Although paracervical block effectively relieves pain during the first stage of labor, the technique has fallen out of favor during childbirth because it is associated with a high incidence of fetal asphyxia and poor neonatal outcome, particularly with the use of bupivacaine. Performing the block with dilute local anesthetic solutions, allowing 5 to 10 minutes to elapse between injections on the left and right sides, and limiting the block to women with less than 8 cm cervical dilation, may decrease the incidence of complications.

### **Paravertebral Lumbar Sympathetic Block**

Paravertebral LSB is a reasonable alternative when contraindications exist to central neuraxial techniques. LSB interrupts the painful transmission of cervical and uterine impulses during the first stage of labor.<sup>69</sup> Although there is less risk of fetal bradycardia with LSB compared with paracervical blockade, unfamiliarity and technical difficulties associated with the

performance of the block and risks of intravascular injection have decreased its use in standard practice.

## Pudendal Nerve Block

The pudendal nerves, derived from the sacral nerve roots (S2 to S4), supply the vaginal vault, perineum, rectum, and parts of the bladder. The nerves are easily anesthetized transvaginally where they loop around the ischial spines. Ten milliliters of dilute local anesthetic solution deposited behind each sacrospinous ligament can provide adequate anesthesia for outlet forceps delivery and episiotomy repair.

## Inhalation Analgesia and General Anesthesia

Inhalation labor analgesia is uncommon in the United States, although its use is more common in other parts of the world (see [Chapter 18](#)). Nitrous oxide, 50% by volume, is the most commonly used inhalation agent for analgesia during labor. The mother is trained to intermittently self-administer the gas at the onset of a contraction. Studies are conflicting as to whether nitrous oxide provides benefit to the parturient; its safety for the fetus and the neonate has also not been well studied.<sup>70,71</sup> A major disadvantage of inhalation analgesia is the need for a waste gas scavenging system.

General anesthesia is rarely used for vaginal delivery, and precautions against gastric aspiration must always be observed (see General Anesthesia in the section Anesthesia for Cesarean Delivery). General anesthesia may be required when time constraints prevent induction of regional anesthesia. Potent inhalation drugs (1.5 to 2 MAC for short periods) can provide uterine relaxation for obstetric maneuvers such as second twin delivery, breech presentation, or postpartum manual removal of a retained placenta. However, in current practice, intravenous nitroglycerin (50 to 250  $\mu\text{g}$ ) has largely replaced the need for general anesthesia for uterine relaxation.

## Anesthesia for Cesarean Delivery

The most common indications for cesarean delivery include arrest of dilation, nonreassuring fetal status, cephalopelvic disproportion, malpresentation, prematurity, prior cesarean delivery, and prior uterine surgery involving the corpus. The choice of anesthesia depends on the urgency of the procedure, the condition of the mother and the fetus, and the mother's wishes.

A 2001 survey of obstetric anesthesia practices in the United States revealed that most patients undergoing cesarean delivery do so under spinal or epidural anesthesia.<sup>72</sup> Neuraxial techniques have several advantages, such

as:

- Prevent airway manipulation
- Lessen the risk of gastric aspiration
- Avoid the use of depressant anesthetic drugs
- Allow the mother to remain awake during delivery
- May be associated with less operative blood loss

Compared with general anesthesia, there is also less immediate neonatal depression after neuraxial compared with general anesthesia.

## **Neuraxial Anesthesia**

Blockade to the T4 dermatome is necessary to perform cesarean delivery without maternal discomfort. The most common complication of neuraxial anesthesia is hypotension and the attendant risk of decreased uteroplacental perfusion (see Hypotension in the section on Anesthetic Complications). Measures to decrease the incidence and severity of hypotension include left uterine displacement, intravenous fluid administration, and the liberal use of vasopressors to prevent and treat hypotension.

Most anesthesiologists administer a nonparticulate antacid before induction of anesthesia for pulmonary aspiration prophylaxis. Some practitioners also administer an H<sub>2</sub> receptor antagonist and metoclopramide. Sedative premedication is usually not necessary. Intraoperative monitoring mimics that for all anesthetics, although blood pressure should be measured frequently (every several minutes) for the first 20 minutes after initiation of anesthesia. Although supplemental oxygen is frequently administered, there is no evidence of benefit to the mother, the fetus, or the neonate.<sup>73</sup>

Multimodal analgesia, including systemic nonsteroidal anti-inflammatory drugs and neuraxial opioids and/or local anesthetics, is optimal for postoperative pain management.

Although postcesarean delivery analgesia should take the nursing infant into account, very small amounts of drugs administered to the mother actually cross into breast milk, and even smaller amounts are absorbed from the neonatal gut. Prolonged (12 to 24 hours) postoperative pain relief in the postpartum patient can be provided by intrathecal morphine (100 to 150 µg)<sup>74</sup> or epidural morphine (3.5 to 4.0 mg).<sup>75</sup> PCEA with a dilute solution of local anesthetic and lipid-soluble opioid is another option after epidural anesthesia. Side effects of neuraxial morphine include nausea, vomiting, and pruritus. Delayed respiratory depression is a rare but potentially devastating complication; therefore, patients who receive neuraxial opioids must be monitored carefully in the postoperative period.<sup>76</sup> Morbidly obese women may be at higher risk for respiratory depression. Abdominal wall nerve block techniques (transversus abdominis plane [TAP] block) have also been

described after cesarean delivery. Intrathecal morphine provides superior and longer-lasting analgesia compared to bilateral TAP block,<sup>77</sup> but TAP block is useful for women who do not or cannot receive neuraxial opioid analgesia.

## **Spinal Anesthesia**

Subarachnoid block is probably the most commonly administered neuraxial anesthetic for cesarean delivery because of its simplicity, speed of onset, and reliability. It is an alternative to general anesthesia for almost all but the most emergent of cesarean deliveries. Hyperbaric 0.75% bupivacaine (12.5 to 13.5 mg [1.6 to 1.8 mL]) is the most commonly used local anesthetic in the United States. It reliably provides 90 to 120 minutes of surgical anesthesia.

Despite an adequate dermatomal level for surgery, women may experience varying degrees of visceral discomfort and nausea and vomiting, particularly during exteriorization of the uterus and traction on abdominal viscera. Improved perioperative anesthesia and analgesia can be provided with the addition of fentanyl (10 to 20 µg), sufentanil (2.5 to 5 µg), or morphine (0.1 to 0.15 mg) to the local anesthetic solution. Fentanyl has a rapid onset, but is short acting and provides little additional postoperative analgesia. In contrast, morphine has a longer latency than fentanyl, but will also provide anesthesia for 12 to 18 hours after delivery.

## **Lumbar Epidural Anesthesia**

In contrast to spinal anesthesia, epidural anesthesia is associated with a slower onset of action and a larger drug requirement to establish adequate sensory block. The major advantages of epidural compared with single-shot spinal anesthesia are the ability to titrate the extent and duration of anesthesia. To avoid unintentional intrathecal or intravascular injection, correct placement of the epidural needle and catheter is essential. This is especially true because epidural anesthesia for cesarean delivery necessitates the administration of large doses of local anesthetic.

Aspiration of the epidural catheter for blood or cerebrospinal fluid is not reliable for detection of catheter misplacement, particularly with single-orifice catheters. Thus, most anesthesiologists administer a test dose before the initiation of surgical anesthesia. A small dose of local anesthetic (e.g., lidocaine, 45 mg, or bupivacaine, 5 mg) readily produces identifiable sensory and motor blocks if injected intrathecally. Addition of epinephrine (15 µg) with careful hemodynamic monitoring may signal intravascular injection if followed by a transient increase in heart rate and blood pressure. The use of an epinephrine test dose (15 µg) in obstetrics is controversial because false positive results do occur (10% increase in heart rate), especially in laboring women. In addition, epinephrine may reduce uteroplacental perfusion. Rapid

injection of 1 mL of air with simultaneous precordial Doppler monitoring appears to be a reliable indicator of intravascular catheter placement.<sup>78</sup> It has also been suggested that fentanyl (100 µg) may be used to test epidural catheter placement.<sup>79</sup> A negative test, although reassuring, does not eliminate the need for incremental administration of local anesthetic.

The most commonly used agents for obstetric epidural anesthesia are 2% lidocaine with epinephrine, 5 µg/mL (1:200,000) and 3% 2-chloroprocaine. Adequate anesthesia is usually achieved with 15 to 25 mL of local anesthetic solution, administered in divided doses over 5 to 10 minutes. 2-Chloroprocaine provides rapid onset of a reliable block with minimal risk of systemic toxicity because of its extremely high rate of metabolism in maternal and fetal plasma. However, 2% lidocaine with epinephrine and sodium bicarbonate (1 mEq/10 mL lidocaine) and fentanyl may also be used when the rapid conversion of pre-existing epidural labor analgesia to surgical anesthesia is required for urgent cesarean delivery.<sup>80</sup> Lidocaine has an onset and duration intermediate to those of 2-chloroprocaine and bupivacaine. Lidocaine should be administered with epinephrine, as lidocaine without epinephrine does not consistently provide satisfactory surgical anesthesia. Bupivacaine is no longer commonly used for obstetric epidural anesthesia, as it is associated with a greater risk of local anesthetic systemic toxicity (LAST) compared with other amide local anesthetics. Unintentional intravascular injection of bupivacaine is associated with a high incidence of maternal mortality.<sup>81</sup> Ropivacaine 0.5% combined with fentanyl may be used for surgical anesthesia, as the risk of toxicity is less than that of bupivacaine. A meta-analysis of studies comparing different anesthetic solutions for extension of labor epidural analgesia for cesarean delivery concluded that ropivacaine provided denser anesthesia compared with bupivacaine or levobupivacaine.<sup>80</sup>

### **Combined Spinal/Epidural Anesthesia**

Advantages of CSE anesthesia for cesarean delivery include the rapid onset of a dense block with a low anesthetic dose, and the ability to extend the duration of anesthesia, and perhaps to provide continuous postoperative analgesia. There is a lower incidence of breakthrough pain and intraoperative shivering, and maternal satisfaction was higher after CSE compared with epidural anesthesia for cesarean delivery.<sup>82</sup> Several variations of the CSE technique have been described. The standard technique uses the same spinal dose of local anesthetic as one would use for standard spinal anesthesia. In sequential CSE anesthesia, a smaller spinal dose is expected to result in inadequate anesthesia for some patients. After 15 minutes, if anesthesia is inadequate, the block is extended by injecting supplemental local anesthetic via the epidural catheter.<sup>83</sup> Although the incidence of hypotension is lower

with this technique compared with full-dose spinal anesthesia, the induction to incision time is prolonged. A third technique is also associated with a lower incidence of hypotension without prolonging onset time. A small dose of spinal local anesthetic is followed by the routine injection of additional anesthetic through the epidural catheter approximately 5 minutes after the intrathecal dose.<sup>84</sup> Bupivacaine doses from 6 to 12 mg have been described for CSE anesthesia.

## General Anesthesia

General anesthesia may be necessary when absolute or relative contraindications exist to neuraxial anesthesia (e.g., coagulopathy, or moderate or severe aortic stenosis), or when the need for emergency delivery precludes central neuraxial blockade. General anesthesia should be used cautiously in women with asthma, upper respiratory tract infection, obesity, or a history of difficult tracheal intubation. Preoperative airway evaluation is particularly important in pregnant women because the inability to intubate the trachea and provide effective ventilation is the leading cause of maternal death related to anesthesia.<sup>85</sup> Equipment to manage the difficult airway should be immediately available.<sup>22</sup> Mallampati classification scores worsen during labor in some parturients.<sup>86</sup> If airway difficulties are anticipated, a neuraxial anesthetic technique should be considered or an awake tracheal intubation performed. Pulmonary aspiration prophylaxis should be administered and the patient should be positioned with left lateral tilt to prevent aortocaval compression. Monitoring mimics that for all anesthetics.

To minimize the risk of hypoxemia during induction, denitrogenation for 3 to 5 minutes with a tight-fitting mask is essential. In an emergency, four deep breaths with 100% oxygen may suffice. A “defasciculating” dose of a nondepolarizing muscle relaxant is not necessary. Although somewhat controversial,<sup>87</sup> a rapid-sequence induction is usually performed. Induction with a sedative–hypnotic (e.g., propofol [2 mg/kg], ketamine [1 mg/kg], or etomidate [0.2 to 0.3 mg/kg]) is followed by succinylcholine (1 to 1.5 mg/kg) to facilitate tracheal intubation. A trained assistant applies cricoid pressure until the airway is properly secured with a cuffed endotracheal tube. Once correct placement of the endotracheal tube is confirmed with capnography and auscultation, the obstetrician may proceed with incision.

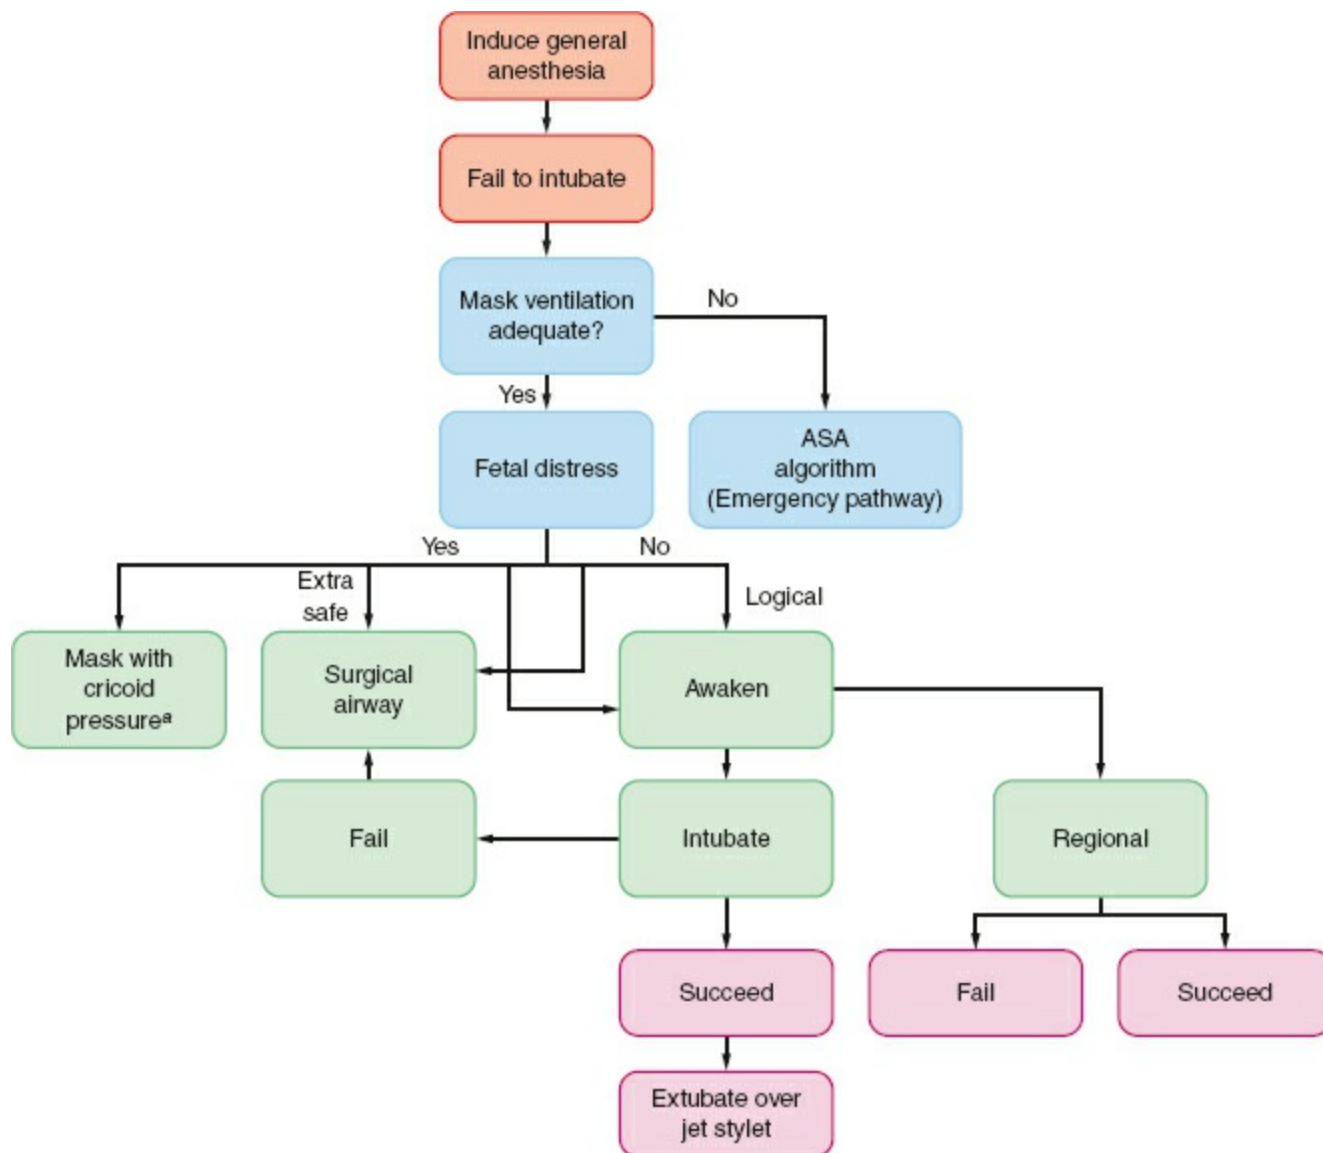

Historically, succinylcholine has been the preferred muscle relaxant. However, the availability of sugammadex may change this practice. High-dose rocuronium (1.0 mg/kg) may be a safe alternative if deep neuromuscular blockade can be rapidly reversed with sugammadex.<sup>88</sup>

If there is difficulty in securing the airway, the mother should be

ventilated with 100% oxygen before a subsequent attempt at tracheal intubation is made. Although some experts advise attempting to maintain cricoid pressure throughout, this practice may actually make visualization of the glottis and mask ventilation more difficult in some patients.<sup>89</sup> The American Society of Anesthesiologists' Difficult Airway Algorithm should be modified to include assessment of fetal status and the need for immediate delivery (Fig. 41-2).<sup>90</sup> It may be safer for the mother to allow her to awaken and to reassess the method of induction and intubation, rather than to persist with traumatic efforts at tracheal intubation. However, if the fetus is in extremis, airway management with a mask or supraglottic airway device may be an acceptable alternative.<sup>90</sup>

In the interval between intubation and delivery, anesthesia is maintained with a 50:50 mixture of nitrous oxide in oxygen and a volatile anesthetic agent. In the past, it was common to limit the volatile agent concentration to 0.5 MAC to limit fetal exposure before delivery and to limit uterine relaxation after delivery. However, the incidence of intraoperative awareness appears to be unacceptably high with this technique.<sup>91</sup> Indeed, a significant number of women had bispectral index values greater than 60 during general anesthesia with sevoflurane 1% in nitrous oxide 50%.<sup>92</sup> Therefore, higher concentrations of volatile agent should be used before delivery. After delivery, the nitrous oxide concentration can be increased and/or an intravenous amnestic (e.g., midazolam) and opioids can be administered.

General anesthesia for cesarean delivery is associated with lower neonatal Apgar scores at 1 minute compared with neuraxial anesthesia<sup>93</sup>; however, the Apgar scores at 5 minutes are comparable. Therefore, an individual trained in neonatal resuscitation should be present at delivery of the infant. After delivery, prophylactic intravenous oxytocin is administered to decrease the risk of uterine atony and anesthesia may be deepened with an opioid and benzodiazepine, as necessary. At the end of the procedure, the mother's trachea is extubated once she is awake and extubation criteria have been met. The usual blood loss during cesarean delivery is 750 to 1,000 mL; transfusion is rarely necessary.

**Figure 41-2** Management of the difficult airway in pregnancy with special reference to the presence or absence of fetal distress. When mask ventilation is not possible, the clinician is referred to the American Society of Anesthesiologists' (ASA) algorithm for emergency airway management found in [Chapter 28](#). <sup>a</sup>Conventional face mask or laryngeal mask airway. In: Chestnut DH, ed. *Obstetric Anesthesia: Principles and Practice*. 3rd ed. St. Louis: Elsevier-Mosby; 2004:550.)

## Anesthetic Complications

### Maternal Mortality

A review of maternal mortality data from the US Centers for Disease Control and Prevention found that anesthesia-related maternal mortality decreased by nearly 60% from the dates 1979 to 1990 versus 1991 to 2002.<sup>85</sup> Historically,

**6** general anesthesia has been associated with a higher rate of anesthesia-related deaths than neuraxial anesthesia. During the most recent period,

case-fatality rates from general anesthesia fell, whereas those for neuraxial anesthesia rose. The risk ratio for general to neuraxial was 1.7 (95% confidence interval 0.6 to 4.6). Anesthesia-related mortality was most often associated with cesarean delivery (86%). The leading causes of death were intubation failure or induction problems (23%), respiratory failure (20%), and high spinal or epidural block (16%).<sup>85</sup>

### *Pulmonary Aspiration*

The risk of inhalation of gastric contents may be increased in pregnant women, particularly if difficulty occurs with airway management. Women who have recently eaten, are laboring, received systemic opioids, or have frequent heartburn are of greatest concern. Comprehensive airway evaluation, prophylactic administration of nonparticulate antacids, and use of regional anesthesia decrease the risk of aspiration. General anesthesia may be unavoidable occasionally; therefore, awake intubation may be indicated in women in whom airway difficulties are anticipated.

### *Hypotension*

Neuraxial anesthesia is frequently associated with hypotension. Labor lowers the risk of hypotension in term pregnant women compared with nonlaboring women. Blood pressure should be monitored frequently (every 2 to 3 minutes) after the induction of neuraxial anesthesia. Techniques to reduce the incidence of hypotension during neuraxial anesthesia include left uterine displacement, intravenous fluid, and vasopressor administration. Maintaining the maternal blood pressure close to baseline reduces the incidence of maternal nausea and vomiting and is associated with higher umbilical artery pH values.<sup>94</sup> The administration of an intravenous bolus of crystalloid solution (1,000 to 1,500 mL) at the time of induction of neuraxial analgesia (co-load) is as effective as administration of the same volume of solution prior to the initiation of anesthesia (preload).<sup>95</sup> Colloid (500 mL) is superior to crystalloid solution in preventing hypotension<sup>96</sup> and may be considered in woman at high risk for hypotension or its consequences.

Phenylephrine is equally efficacious to ephedrine for treating maternal hypotension and results in less fetal acidosis.<sup>97</sup> Ephedrine crosses the placenta to a greater extent than phenylephrine and undergoes less early metabolism.<sup>98</sup> Stimulation of fetal  $\beta$ -adrenergic receptors by ephedrine increases the fetal metabolic rate; however, the clinical significance of this effect is not known. Phenylephrine may be administered as a bolus dose (100 to 150  $\mu$ g) to treat hypotension<sup>99</sup> or as a continuous prophylactic infusion (starting rate, 25 to 50  $\mu$ g/min).<sup>100</sup> Managing spinal anesthesia-induced hypotension using a

prophylactic phenylephrine infusion results in fewer physician interventions and less patient nausea than treating hypotension with bolus-dose phenylephrine after it occurs.<sup>101</sup>

## **Total Spinal Anesthesia**

High or total spinal anesthesia is a rare complication of intrathecal or epidural local anesthetic injection that occurs after excessive cephalad spread of local anesthetic in the subarachnoid or epidural space. Unintentional intrathecal administration of epidural medication as a result of dural puncture or catheter migration may also result in this complication. There is rapid ascent of sensory–motor blockade and patients may complain of dyspnea, inability to phonate, and difficulty swallowing. Profound hypotension may lead to brainstem and cerebral hypoperfusion and cause loss of consciousness. Immediate vasopressor administration, continued fluid administration, left uterine displacement, and leg elevation might be necessary to achieve hemodynamic stability. Reverse Trendelenburg position should not be used if hyperbaric anesthetic solution was used for spinal blockade, as there is a risk of cerebral hypoperfusion. Rapid control of the airway is essential, and endotracheal intubation may be necessary to ensure oxygenation without aspiration.

## **Local Anesthetic Systemic Toxicity**

LAST may occur after unintended intravascular injection or drug accumulation (see [Chapter 22](#)). Resuscitation equipment (intravenous access, airway equipment, emergency drugs, and suction equipment) should always be available when using local anesthetics. To avoid systemic toxicity of local anesthetic agents, strict adherence to recommended dosages, methods to detect misplaced needles and catheters, and fractional administration of the induction dose are essential.

Despite these precautions, life-threatening convulsions and, rarely, cardiovascular collapse may occur. Seizure activity should be treated with an intravenous benzodiazepine, such as midazolam (1 to 5 mg), or other sedative–hypnotic. Hemodynamics, ventilation, and oxygenation must be maintained. Lipid emulsion (20%, 1.5 mL/kg over 1 minute, followed by 0.25 mL/kg/min for at least 10 minutes after attainment of hemodynamic stability) should be administered concurrent with basic and advanced cardiac life support protocols.<sup>102</sup> Vasopressin, along with calcium channel blockers and  $\beta$ -adrenergic blockers should be avoided. Amiodarone may be used to treat ventricular dysrhythmias, particularly those due to bupivacaine. Failure to respond to lipid emulsion and vasopressor therapy should prompt

consideration of cardiopulmonary bypass. Perimortem cesarean delivery may be required to relieve aortocaval compression and to ensure the efficacy of cardiac massage.<sup>103</sup>

## Postdural Puncture Headache

By virtue of age and gender, pregnant women are at a higher risk for developing PDPH (see [Chapter 35](#)). In addition, after delivery, reduced epidural pressure may increase the risk of cerebrospinal fluid leakage through the dural rent, and estrogen withdrawal after delivery may exacerbate vascular headaches. **7**

The incidence of PDPH is related to the diameter of the dural puncture, ranging from in excess of 70% after the use of 16-gauge spinal needles to less than 1% with 25- or 26-gauge spinal needles. The incidence of cephalalgia is reduced with the use of pencil-point needles (Whitacre or Sprotte), compared with cutting bevel (Quincke) needles. Conservative treatment is indicated in the presence of mild-to-moderate discomfort, and includes bed rest, hydration, and simple analgesics. Caffeine (500 mg intravenously or 300 mg orally) has also been used in the treatment of PDPH, but the therapeutic effect is transient. Severe headache that does not respond to conservative measures for 24 hours is best treated with an autologous epidural blood patch. Using aseptic technique, approximately 20 mL of the patient's blood is injected into the epidural space close to the site of dural puncture.<sup>104</sup> Prophylactic administration of autologous blood (after delivery, before removal of the epidural catheter) does not influence the incidence and severity of PDPH, although the duration of headache is less, compared with expectant management.<sup>105</sup> Data supporting the use of intrathecal catheter placement for prevention of PDPH are inconsistent.<sup>106</sup>

## Nerve Injury

Neurologic sequelae of central neuraxial blockade, although rare, have been reported. Pressure or trauma exerted by a needle or catheter on spinal nerve roots or the spinal cord produces immediate pain. Needle or catheter advancement should stop immediately on patient complaint of paresthesia or pain, and if the symptom does not resolve within seconds, the needle or catheter should be withdrawn and repositioned. Anesthetics should *not* be injected when there are paresthesias. Infections are rare; epidural abscess is usually caused by skin contaminants and meningitis by contamination of drugs or needles with clinicians' nasopharyngeal flora.<sup>107</sup> Epidural hematoma can also occur, usually in association with coagulation defects. Nerve root irritation may have a protracted recovery, lasting weeks or months.

Postpartum peripheral nerve injury as a result of instrumentation, lithotomy position, or compression by the fetal head is not uncommon and is not related to neuraxial anesthesia.<sup>108</sup>

## Management of High-risk Parturients

Pregnancy and parturition are considered “high risk” when accompanied by conditions unfavorable to the well-being of the mother, the fetus, or both. Maternal problems may be related to pregnancy, such as preeclampsia–eclampsia and other hypertensive disorders of pregnancy, or antepartum hemorrhage resulting from placenta previa or abruptio placentae. Diabetes mellitus, cardiac, chronic renal, neurologic, or sickle cell disease; and asthma, obesity, and drug abuse are not related to pregnancy but affect or are affected by it. Advanced maternal age (AMA)—usually defined as age 35 or more at the time of delivery—is associated with an increased risk of maternal and fetal complications. Prematurity (gestation of <37 weeks), postmaturity ( $\geq 42$  weeks), intrauterine growth retardation (IUGR), and multiple gestation are fetal conditions associated with increased risk. During labor and delivery, fetal malpresentation (breech, transverse lie), placental abruption, compression of the umbilical cord (prolapse, nuchal cord), precipitous labor, or intrauterine infection (prolonged rupture of membranes) may increase the risk to the mother or the fetus.

In general, the anesthetic management of the high-risk parturient is based on the same maternal and fetal considerations as the management of healthy mothers and fetuses. These include maintenance of maternal cardiovascular function and oxygenation, maximization of uteroplacental blood flow, and creation of optimal conditions for a painless, atraumatic delivery of an infant without significant drug effects. However, there is less physiologic reserve because many of these functions may be compromised before the induction of anesthesia. For example, significant acidosis is prone to develop in fetuses of diabetic mothers when delivered by cesarean section with spinal anesthesia complicated by even brief maternal hypotension. Because the high-risk parturient may have received a variety of drugs, anesthesiologists must be familiar with potential interactions between these drugs and the anesthetic drugs they plan to administer.

### Hypertensive Disorders of Pregnancy

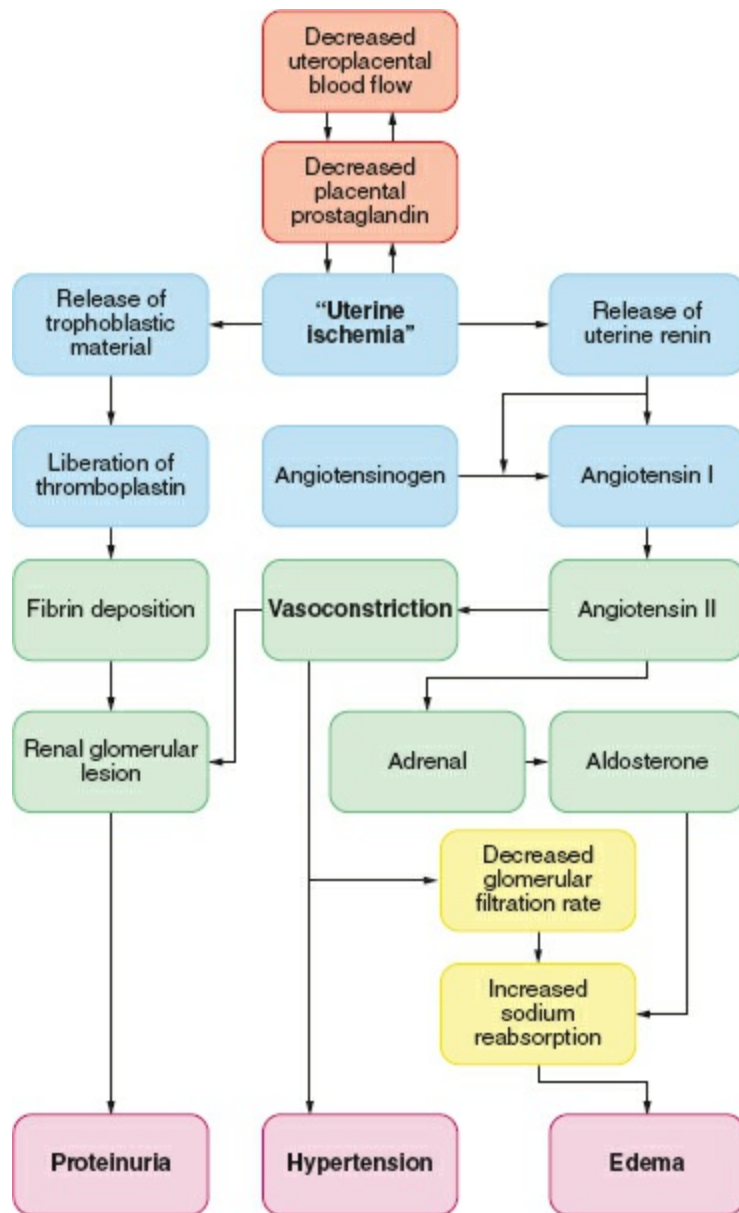

Hypertensive disorders, which occur in up to 10% of pregnancies, are a major cause of maternal morbidity and mortality.<sup>109</sup> The ACOG<sup>110</sup> has modified the diagnosis and management of hypertensive disorders of pregnancy. The four categories are as follows. *Gestational hypertension*

which describes the development of elevated blood pressure after 20 weeks of gestation without proteinuria or severe features of preeclampsia. *Chronic hypertension* is pre-existing hypertension or hypertension developing before 20 weeks of gestation. *Chronic hypertension with superimposed preeclampsia* includes elevated blood pressure with new onset of proteinuria or other signs/symptoms of preeclampsia. The ACOG task force<sup>110</sup> does not recommend treatment of hypertension unless the blood pressure is above 160 mmHg systolic or 110 mmHg diastolic to minimize fetal risk. Above these parameters, treatment is indicated to reduce maternal risk. *Preeclampsia/eclampsia* is the fourth category. *Preeclampsia* is defined by hypertension with proteinuria or any of the severe features of preeclampsia. Proteinuria is no longer necessary for the diagnosis of preeclampsia. Mild preeclampsia has been replaced by preeclampsia without severe features. *Eclampsia* is present if convulsions occur. Preeclampsia–eclampsia is a disease of unknown etiology but is unique to human pregnancy. Symptoms can appear before the 20th week, with a hydatidiform mole. The condition requires the presence of a trophoblast but not a fetus.<sup>110</sup>

Many of the symptoms associated with preeclampsia, including placental ischemia, systemic vasoconstriction, and increased platelet aggregation, may result from an imbalance in placental production of prostacyclin and thromboxane (Figs. 41-3 and 41-4). During normal pregnancy, the placenta produces equivalent quantities of these prostaglandins, whereas in preeclamptic pregnancy, there is seven times more thromboxane than prostacyclin.<sup>111</sup> An alternative etiology may be related to an inhibition of the normal trophoblastic migration of placental arterioles during the second trimester, thus preventing a low-resistance, high-flow placental circulation from developing.<sup>112</sup> Endothelial dysfunction is central to the development of preeclampsia. In preeclamptic women, there appears to be an imbalance between proangiogenic factors (vascular endothelial growth factor [VEGF]) and antiangiogenic factors (soluble fms-like tyrosine kinase 1 [sFlt-1]). Increased sensitivity to angiotensin II has also been observed in patients with preeclampsia. This may be the result of the presence of autoantibodies to the angiotensin AT-1 receptor.

**Figure 41-3** Proposed scheme of pathophysiologic changes in toxemia of pregnancy. (Reprinted with permission from Speroff L. Toxemia of pregnancy: mechanism and therapeutic management. *Am J Cardiol.* 1973;32:582.)

Placental ischemia results in a release of uterine renin and an increase in angiotensin (Fig. 41-3). Widespread arteriolar vasoconstriction occurs, causing hypertension, tissue hypoxia, and endothelial damage. Adherence of platelets at sites of endothelial damage results in coagulopathy. Enhanced angiotensin-mediated aldosterone secretion may lead to increased sodium reabsorption and edema. Proteinuria may also be attributed to placental ischemia, which would lead to local tissue degeneration and a release of thromboplastin with subsequent deposition of fibrin in constricted glomerular vessels, as well as increased permeability to albumin and other plasma proteins. Furthermore, there is believed to be a decreased production of prostaglandin E, a potent vasodilator secreted in the trophoblast, which normally would balance the hypertensive effects of the renin-angiotensin system. The HELLP syndrome is a particular form of severe preeclampsia

characterized by hemolysis, elevated liver enzymes, and low platelet count (thrombocytopenia). In contrast to preeclampsia, elevations in blood pressure and proteinuria may be mild.

9

**Figure 41-4** Comparison of the balance in the biologic actions of prostacyclin and thromboxane in normal pregnancy with the imbalance of increased thromboxane and decreased prostacyclin in preeclamptic pregnancy. (Reprinted with permission from Walsh SW. Preeclampsia: an imbalance in placental prostacyclin and thromboxane production. *Am J Obstet Gynecol.* 1985;152:335.)

Severe features of preeclampsia include:

- Severe hypertension
  - Systolic blood pressure more than 160 mmHg
  - Diastolic blood pressure more than 110 mmHg
- Thrombocytopenia (platelet count  $< 100 \times 10^9/L$ )
- Impaired liver function
- Renal insufficiency (either serum creatinine concentration  $> 1.1$  mg/dL, or doubling of the baseline serum creatinine concentration)
- Pulmonary edema
- New-onset cerebral or visual disturbances

Severe preeclampsia–eclampsia is a multisystem disease. Global cerebral blood flow is not diminished, but focal hypoperfusion may occur. Postmortem examination has revealed hemorrhagic necrosis in the proximity of thrombosed precapillaries, suggesting intense vasoconstriction. Cerebral edema and small foci of degeneration have been attributed to hypoxia. Petechial hemorrhages are common after the onset of convulsions. Symptoms related to these changes include headache, vertigo, cortical blindness, hyperreflexia, and convulsions. Blood pressure elevation correlates poorly with the incidence of seizures. Cerebral hemorrhage and edema account for 50% of deaths with preeclampsia–eclampsia. Intense ocular arteriolar constriction may cause blurred vision, even temporary blindness. In severe cases, heart failure may result due to peripheral vasoconstriction and increased blood viscosity secondary to hemoconcentration. Left ventricular hypertrophy, subendocardial hemorrhages, and fatty and hyaline degeneration may occur.

Decreased blood supply to the liver may lead to periportal necrosis. Subcapsular hemorrhage results in epigastric pain. Rarely, there is rupture of the overstretched liver capsule and massive hemorrhage into the abdominal cavity. There may be elevated aspartate aminotransferase, lactate dehydrogenase, and alkaline phosphatase, whereas bilirubin is unaltered.

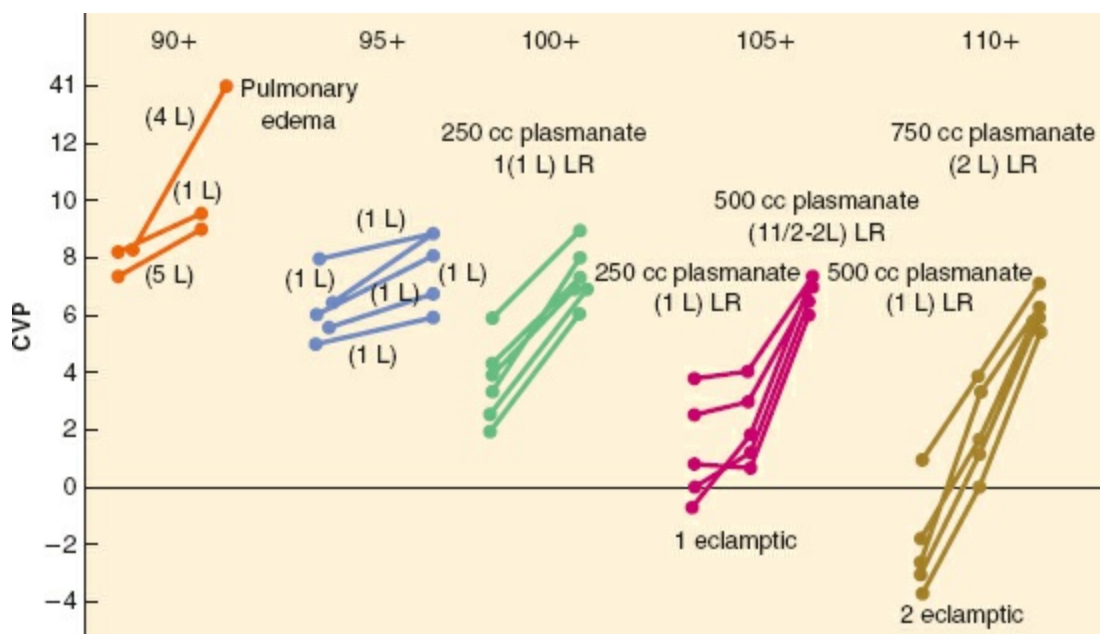

In the kidneys, there is swelling of glomerular endothelial cells and deposition of fibrin, leading to a constriction of the capillary lumina. Renal blood flow and glomerular filtration rate decrease, resulting in reduced uric acid clearance and, in severe cases, reduced clearance of urea and creatinine. Oliguria and proteinuria are characteristic symptoms of severe preeclampsia. The severity of renal involvement is reflected in the degree of proteinuria, which may reach nephrotic levels of 10 to 15 g/24 hr.

A mild pulmonary ventilation–perfusion imbalance has been reported in severe cases. It is not believed to be clinically important because the arterial oxygen tension was within normal limits. In contrast, airway edema, which may also occur in severe preeclampsia, is of great concern because it may lead to difficulty in tracheal intubation. Pulmonary edema occurs in approximately 2% of severe preeclamptic patients as a result of heart failure, circulatory overload, or aspiration of gastric contents during convulsions.

A reduction in intervillous blood flow may result from vasoconstriction or the development of occlusive lesions in decidual arteries, despite the elevated maternal blood pressure. Reduced placental blood flow leads to chronic fetal hypoxia and malnutrition. The risks of IUGR, premature birth, and perinatal death are substantially higher than in normal pregnancies and correlate with the severity of preeclampsia.

Although preeclampsia is accompanied by exaggerated retention of water and sodium, a shift of fluid and proteins from the intravascular into the

extravascular compartment may result in hypovolemia, hypoproteinemia, and hemoconcentration. This phenomenon may be further affected by proteinuria. The risk of uteroplacental hypoperfusion and poor fetal outcome correlates with the degree of maternal plasma and protein depletion. The mean plasma volume in women with preeclampsia was found to be 9% less than normal, and in those with severe disease, 30% to 40% below normal.<sup>113</sup> The inverse relationship between the intravascular volume and the severity of hypertension was confirmed with measurements of central venous pressure (CVP) (Fig. 41-5). Volume expansion may improve maternal tissue perfusion in patients with severe preeclampsia, but must be performed cautiously because of the risk of pulmonary edema.

**Figure 41-5** Initial central venous pressure measurements (three or more recordings of maternal diastolic pressure) and intravenous volume replacement required to attain the range of 6 to 8 cm H<sub>2</sub>O in five groups of women with preeclampsia classified according to the severity of the disease (by diastolic blood pressure). LR, lactated Ringer solution. (Reprinted with permission from Joyce TH III, Debnath KS, Baker EA. Preeclampsia: relationship of CVP and epidural analgesia. *Anesthesiology*. 1979;51:S297.)

Adherence of platelets at sites of endothelial damage may result in consumptive coagulopathy and thrombocytopenia. It is usually mild, with the platelet count in the range of  $100 \times 10^9/L$  to  $150 \times 10^9/L$ . High-dose steroids (>24 mg of  $\beta$ - or dexamethasone in 24 hours) used to accelerate fetal lung maturity have been shown to prevent a worsening in platelet count or even increase platelet count in women with the HELLP syndrome (Fig. 41-6).<sup>114</sup> Elevated levels of fibrin degradation products are found less frequently, and plasma fibrinogen concentrations remain normal unless there is a placental abruption. Prolongation of prothrombin and partial thromboplastin

times indicates consumption of procoagulant. Bleeding time is no longer considered a reliable test of clotting.

## General Management

The definitive treatment of preeclampsia/eclampsia remains delivery of the fetus and placenta. Management is usually symptomatic until the obstetrician determines that delivery is appropriate. The goals are to prevent or control convulsions, improve organ perfusion, normalize blood pressure, and correct clotting abnormalities. The obstetric management of preeclamptic women without severe features is similar to that of healthy pregnant women because bed rest and antihypertensive therapy are not recommended; however, after 37 weeks of gestation, delivery is indicated. Delivery is indicated in severe cases if there is nonreassuring fetal status or if the pregnancy is beyond 34 weeks of gestation. In severe cases, aggressive management should continue for at least 24 to 48 hours after delivery.

**Figure 41-6** Mean platelet count in women with HELLP syndrome without steroids, and before and after standard steroid (<24 mg/day) and high steroid (>24 mg/day) therapy. (Adapted with permission from O'Brien JM, Milligan DA, Barton JR. Impact of high dose corticosteroid therapy for patients with HELLP [hemolysis, elevated liver function tests, and low platelets] syndrome. *Am J Obstet Gynecol.* 2000;183:921.)

The mainstay of anticonvulsant therapy is magnesium sulfate (see [Chapter 16](#)). Magnesium is only recommended for women with severe preeclampsia. The patient usually receives an intravenous loading dose of 4 g in a 20% solution over 5 minutes. Therapeutic blood levels are maintained by continuous infusion of 1 to 2 g/hr. Magnesium may cause mild peripheral arterial vasodilation. Magnesium ions cross the placenta readily and may lead to fetal and neonatal hypermagnesemia. There is poor correlation between magnesium concentrations in the umbilical cord blood and the incidence of low Apgar scores and depression of ventilation at birth, which are more likely due to fetal asphyxia and prematurity. In fact, there is evidence that magnesium therapy is neuroprotective for the fetus and reduces the risk of

cerebral palsy.<sup>115</sup>

Magnesium potentiates the duration and intensity of action of depolarizing and nondepolarizing muscle relaxants by decreasing the amount of acetylcholine liberated from the motor nerve terminals, diminishing the sensitivity of the end plate to acetylcholine, and depressing the excitability of the skeletal muscle membrane. Magnesium may also increase the severity of hypotension under regional anesthesia and make it more difficult to treat. Judicious hydration with a balanced salt solution may be required to replace intravascular volume. In all cases, careful monitoring of arterial pressure and urine output should be started as soon as possible. Invasive arterial blood pressure monitoring may be useful for patients with severe preeclampsia, but CVP monitoring is infrequently used. Monitoring should be extended into the postpartum period.

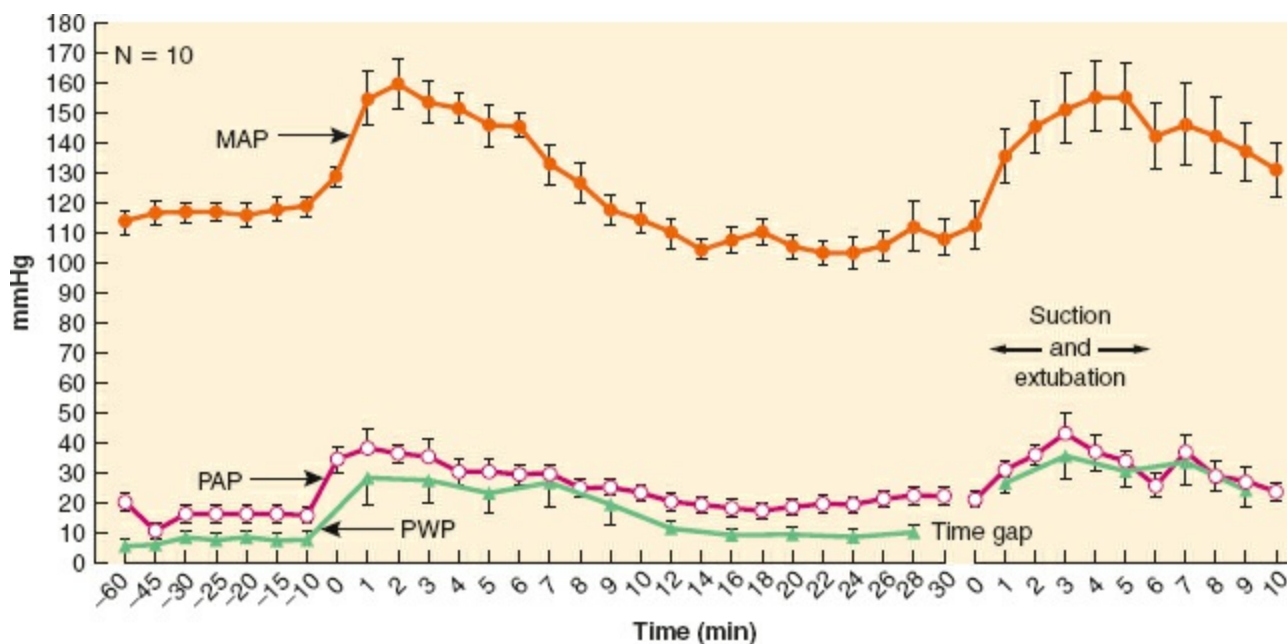

Antihypertensive therapy in preeclampsia is used to lessen the risk of cerebral hemorrhage in the mother while maintaining, even improving, tissue perfusion. Hydralazine is the most commonly used vasodilator in preeclampsia because it increases uteroplacental and renal blood flow. Nitroprusside, a potent vasodilator of resistance and capacitance vessels, with an immediate but evanescent action, is useful in preventing dangerous elevations in systemic and pulmonary artery blood pressure during laryngoscopy and intubation, and is ideal for treatment of hypertensive emergencies. Other agents used to control maternal blood pressure in preeclampsia include nitroglycerin and labetalol. Consumption coagulopathy may require infusion of fresh whole blood, platelet concentrates, fresh frozen plasma, and cryoprecipitate (see [Chapter 17](#)). Neuraxial anesthesia is contraindicated in patients with severe coagulopathy.

## **Anesthetic Management**

Epidural, spinal, or CSE analgesia or anesthesia for labor and delivery should no longer be considered contraindicated in preeclamptic parturients, provided there is no severe clotting abnormality or plasma volume deficit.<sup>116</sup> In volume-repleted patients positioned with left uterine displacement, neuraxial analgesia does not cause an unacceptable reduction in blood pressure and leads to a significant improvement in placental perfusion.<sup>117</sup> With the use of radioactive xenon, it was shown that the intervillous blood flow increased by approximately 75% after the induction of epidural analgesia (10 mL of bupivacaine 0.25%).<sup>118</sup>

For cesarean delivery, the sensory level of anesthesia must extend to T3 to T4, making adequate fluid therapy and left uterine displacement even more critical. The use of spinal anesthesia in severely preeclamptic women has been discouraged in favor of the continuous epidural technique. The concern is

related to the fact that severely preeclamptic women can have significant intravascular volume deficits related to widespread arteriolar vasoconstriction, which may result in catastrophic hypotension with the sudden onset of extensive sympathectomy associated with spinal anesthesia. In fact, women with severe preeclampsia appear to be at lower risk of hypotension than normotensive women having cesarean delivery.<sup>119</sup> Furthermore, studies to date have shown that the incidence and severity of hypotension is similar in women with severe preeclampsia having a cesarean delivery with spinal compared with epidural anesthesia.<sup>120,121</sup> Thus, spinal anesthesia is emerging as a suitable alternative to epidural anesthesia for cesarean delivery in severely preeclamptic women. It is important to note that severely preeclamptic women need to be adequately prepared prior to neuraxial anesthesia with judicious hydration and control of blood pressure.

**Figure 41-7** Mean and SE of mean arterial pressure (MAP), mean pulmonary artery pressure (PAP), and pulmonary wedge pressure (PWP) in patients with severe preeclampsia receiving thiopental and nitrous oxide (40%) with 0.5% halothane anesthesia for cesarean section. (Reprinted with permission from Hodgkinson R, Husain FJ, Hayashi RH. Systemic and pulmonary blood pressure during cesarean section in parturients with gestational hypertension. *Can Anaesth Soc J.* 1980;27:389.)

General anesthesia in preeclamptic patients has its particular hazards. Rapid-sequence induction of anesthesia and intubation of the trachea are occasionally difficult because of a swollen tongue, epiglottis, or pharynx (see [Chapter 28](#)). In patients with impaired coagulation, laryngoscopy and intubation of the trachea may provoke profuse bleeding. Marked systemic and pulmonary hypertension occurring at intubation and extubation enhance the risk of cerebral hemorrhage and pulmonary edema ([Fig. 41-7](#)). However,

these hemodynamic changes can be minimized with appropriate antihypertensive therapy, such as administration of labetalol or nitroprusside infusion. The use of ketamine and ergot alkaloids should be avoided. Magnesium may prolong the effects of all muscle relaxants through its actions on the myoneural junction. Therefore, relaxants should be administered with caution (using a nerve stimulator) to avoid overdosage. General anesthesia may be necessary in acute emergencies, such as abruptio placentae, and in patients who do not meet the criteria for neuraxial anesthesia.

## **Obstetric Hemorrhage**

Worldwide, hemorrhage remains the leading cause of maternal mortality, 10 causing 25% of peripartum deaths. The vast majority of these deaths occur in the developing world; however, there is evidence that the rate and severity of hemorrhage are increasing in developed nations, including the United States.<sup>122,123</sup> Obstetric hemorrhage can be defined in four “categories”: Abnormal tissue (placentation), abnormal tone (atony), abnormal coagulation, and trauma (uterine rupture, cesarean delivery).

Antepartum hemorrhage occurs in association with placenta previa (abnormal placental implantation on the lower uterine segment and partial-to-total occlusion of the internal cervical os) and abruptio placentae. Placenta previa complicates approximately 0.4% of pregnancies, resulting in up to 0.9% incidence of maternal mortality and a 17% to 26% incidence of perinatal mortality. Risk factors for placenta previa include previous cesarean delivery, uterine surgery, or pregnancy termination. Other risk factors include smoking, AMA, multiparity, multiple gestation, and cocaine abuse. The risk for placenta previa increases in a “dose-dependent” manner with the number of previous cesarean deliveries and greater parity. The relative risk is 4.5 (95% confidence interval, 3.6 to 5.5) with one previous cesarean delivery, and it increases to 44.9 (95% confidence interval, 13.5 to 139.5) with four prior cesarean deliveries.<sup>124,125</sup> The diagnosis should be suspected whenever a patient presents with painless, bright red vaginal bleeding, usually after the seventh month of pregnancy. Placenta previa may also be associated with an unstable or abnormal lie. The diagnosis is confirmed by ultrasonography. If bleeding is not profuse and the fetus is immature, obstetric management is conservative to prolong pregnancy. Admission to a high-risk unit is advisable if contractions or acute bleeding are present. Intravenous access and typed and cross-matched blood should be available at all times. In severe cases, or if the fetus is mature at the onset of symptoms, prompt delivery is indicated, usually by cesarean section.

Anesthesia for delivery of patients with placenta previa may be with neuraxial anesthesia, provided the mother is hemodynamically stable. Past

recommendations for general anesthesia to provide “more control” are not supported by the literature, as there is no difference in complications between the two techniques, except that general anesthesia is associated with greater blood loss and greater need for transfusion. An emergency hysterectomy may be required if there is severe hemorrhage, even after delivery of the placenta, because of uterine atony. The risk of severe hemorrhage after attempted removal of the placenta is greatly increased in patients who have undergone prior uterine surgery, including cesarean delivery. This is related to a higher incidence of placenta accreta, which results from the penetration of myometrium by placental villi. The risk of placenta accreta in women with previa increases from 3% in primary cesarean section to 61% in quaternary section.<sup>126</sup> Indeed, placenta accreta is becoming the leading cause of cesarean hysterectomy, and the rate of cesarean hysterectomy due to abnormal placentation has increased from 33/100,000 deliveries in 1994 to 1995 to 41/100,000 deliveries in 2006 to 2007.<sup>127</sup> The average blood loss during delivery of patients with placenta accreta is 3 to 5 L.

When placenta accreta is suspected or known, delivery is usually scheduled at 36 to 37 weeks of gestation via cesarean hysterectomy. Under controlled, elective conditions, complications can be minimized. Some institutions may use occlusive balloon catheters placed in the internal iliac arteries prior to surgical delivery. In the face of bleeding with either placenta previa or accreta, when maintenance of fertility is desired, arterial embolization or ligation, uterine compression sutures, and/or methotrexate therapy may be attempted to avoid hysterectomy.<sup>128</sup>

Abruptio placentae complicates approximately 1% of deliveries, usually in the final 10 weeks of gestation. Risk factors include smoking, trauma, cocaine abuse, multiple gestation, hypertension, preeclampsia, AMA, and preterm premature rupture of membranes. Complications include Couvelaire uterus (when extravasated blood dissects between the myometrial fibers), renal failure, disseminated intravascular coagulation, and anterior pituitary necrosis (Sheehan syndrome). The maternal mortality rate is high (1.8% to 11.0%), and the perinatal mortality rate is even higher, in excess of 50%. The diagnosis of abruptio placentae is based on the presence of uterine tenderness and hypertonus as well as vaginal bleeding of dark, clotted blood. Bleeding may be concealed if the placental margins have remained attached to the uterine wall. If the blood loss is severe (> 2 L), there may be changes in the maternal blood pressure and pulse rate, indicative of hypovolemia. Fetal movement may increase during acute hypoxia or decrease if hypoxia is gradual. Fetal bradycardia and death may ensue. When placental separation is more than 50%, stillbirth is the likeliest outcome. Management of abruption depends on presentation, gestational age, and the degree of compromise. Management of milder cases of abruption includes artificial rupture of

amniotic membranes and oxytocin augmentation of labor, if required. Distant from term, expectant management with close observation is reasonable. In the presence of nonreassuring fetal status, an emergency cesarean delivery may be performed. If fetal death has occurred, usually with severe abruption, vaginal delivery is reasonable if the mother is stable.

Postpartum hemorrhage is usually defined as blood loss greater than 500 mL after vaginal delivery or greater than 1,000 mL after cesarean section. The incidence of postpartum hemorrhage is increasing in the United States, mainly due to an increase in uterine atony.<sup>122,123</sup> Predisposing factors to atony include multiple gestations, labor induction or augmentation, cesarean delivery, polyhydramnios, chorioamnionitis, hypertensive disorders of pregnancy, retained products of conception, and antepartum hemorrhage. Treatment of postpartum hemorrhage may require aggressive uterotonic therapy for atony, intrauterine balloon tamponade or evacuation of the uterus for retained products of conception (Table 41-2). If there is a need for dilation and curettage, the anesthesiologist may be asked to provide uterine relaxation. This can be accomplished with volatile agents if the patient is under general anesthesia or with intravenous nitroglycerin if regional anesthesia or general anesthesia is used.

The anesthesiologist's role in management of obstetric hemorrhage includes both maternal resuscitation and provision of anesthesia for cesarean delivery, cesarean hysterectomy, or dilation and curettage. The choice of anesthetic technique depends on the anticipated duration of surgery, maternal condition and volume status, the potential for coagulopathy, and urgency of the procedure. General anesthesia is indicated in the presence of uncontrolled hemorrhage and/or severe coagulation abnormalities. Neuraxial anesthesia, usually continuous epidural anesthesia, has been successfully used for hysterectomy in planned, controlled situations. A saddle block is an option for anesthesia when dilation and curettage for treatment of postpartum hemorrhage is indicated and the patient is hemodynamically stable.

**Table 41-2** Uterotonic Therapy

Drug	Dose	Side Effects
Oxytocin	20–40 U in 1,000 mL LR by continuous IV infusion	Hypotension, tachycardia
Ergot alkaloids (Methergine)	0.2 mg IM q2–4h prn	Hypertension, vasoconstriction Coronary vasospasm Bronchospasm
Carboprost	0.25 mg IM q15–60 min prn	↑ cardiac output ↑ pulmonary vascular resistance Bronchospasm Nausea
Misoprostol	800–1,000 µg PR/ PV/PO q2h	Fever Nausea
Dinoprostone	20 mg PO q2h	Hypotension Nausea

LR, Lactated Ringer solution; IV, intravenous; IM, intramuscularly; prn, as needed; PR, rectally; PV, vaginally; PO, orally.

Maternal resuscitation in the setting of hemorrhage may require rapid securing of the airway if significant hemodynamic instability occurs, in addition to obtaining large-bore intravenous, arterial, and possibly central venous access. All of these tasks may be challenging in the parturient and consideration should be given to performing them in advance of hemorrhage when hemorrhage is anticipated. Prompt transfusion of blood component therapy is crucial for replacement of blood loss, maintenance of tissue oxygenation, and correction of coagulopathy. In recent years, transfusion rates for postpartum hemorrhage have increased 92% in the United States.<sup>123,129,130</sup>

The practice of transfusing packed red blood cells and fresh frozen plasma in a 1:1 ratio decreases mortality from hemorrhage in trauma patients. Early administration of platelets and cryoprecipitate has also become common in *hemostatic resuscitation protocols* for major traumatic hemorrhage, and crystalloid and colloid administration is minimized in favor of blood products (see [Chapter 53](#)). Hypothermia, metabolic acidosis, and coagulopathy commonly occur in traumatic and obstetric hemorrhage. Because of these commonalities, it has become common to extend these successful transfusion practices from the trauma literature to obstetric practice. Transfusion of cryoprecipitate or better, fibrinogen concentrate, should be incorporated early in obstetric hemorrhage because decreased fibrinogen levels strongly correlate with increased severity of postpartum hemorrhage.<sup>129,131</sup> Obstetric hemorrhage is associated with the rapid development of consumptive and dilutional coagulopathy and can be quickly assessed using point-of-care

testing of clotting with thromboelastography (TEG) or rotational thromboelastometry (ROTEM) (see [Chapter 17](#)).

Other options are available to decrease transfusion requirements and reduce blood loss. Intraoperative cell salvage, formerly shunned because of concerns about the risk of amniotic fluid contamination of red cells, has been implemented safely during cesarean section in many centers.<sup>132</sup> There is also increasing interest in the use of prohemostatic agents for the treatment of obstetric hemorrhage. The antifibrinolytic drug tranexamic acid has been shown to decrease bleeding in both elective cesarean section and postpartum hemorrhage and is recommended for early use in resuscitation by a European task force<sup>131</sup>; however, further studies are needed to confirm its safety.<sup>133</sup> Case reports and series also describe the safe and effective use of activated recombinant factor VII for intractable hemorrhage.<sup>134</sup>

## **11** *Heart Disease*

Heart disease during pregnancy occurs in about 1.6% of patients and is a leading nonobstetric cause of maternal morbidity and mortality, with a mortality rate ranging from 0.4% among patients in class I or II of the New York Heart Association's functional classification to 6.8% among those in classes III and IV. Medical and surgical advancements have changed the types of cardiac problems seen in pregnancy. Patients with congenital heart disease are reaching childbearing age, and the number of patients with rheumatic heart disease has declined. Older parturients may present with aortic stenosis and insufficiency associated with a bicuspid aortic valve. AMA and obesity may be associated with coronary artery disease and myocardial ischemia. Deaths associated with congenital heart disease have decreased, but there appears to be an increase in deaths described as sudden arrhythmic death syndrome (SADS).<sup>135</sup> Peripartum cardiomyopathy continues to be associated with a high rate of maternal morbidity and mortality.<sup>136,137</sup>

Cardiac decompensation occurs most commonly at times of maximum hemodynamic stress—in the third trimester of pregnancy, during labor and delivery, and during the immediate postpartum period. The increase in maternal blood volume, which occurs at 20 to 24 weeks of gestation, may also precipitate cardiac decompensation. During labor, cardiac output increases progressively above antepartum levels; with each uterine contraction, approximately 200 mL of blood moves into the central circulation. Consequently, stroke volume, cardiac output, and left ventricular work increase, and each contraction consistently increases cardiac output by 10% to 25% above that of uterine diastole. The greatest change occurs immediately after delivery of the placenta, when cardiac output increases to an average of 80% above prepartum values; in some patients, it may increase

by as much as 150%.

Evaluation of pre-existing heart disease is crucial and a multidisciplinary approach is necessary when managing patients with complicated cardiac disease during pregnancy and parturition.<sup>138</sup> Many symptoms of pregnancy can mimic those of cardiac disease, complicating new diagnoses of cardiac disease during pregnancy. Labored breathing and venous stasis from aortocaval compression may mimic pulmonary and peripheral edema associated with congestive heart failure. Flow murmurs may be difficult to distinguish from those due to organic lesions. Finally, elevation of the diaphragm causes the heart to rotate, signs of which may be mistaken for cardiac hypertrophy. For the anesthesiologist, it is particularly important to understand how the hemodynamic consequences of different anesthetic techniques might adversely affect mothers with specific cardiac lesions. Invasive monitoring during labor and delivery is rarely indicated. Exceptions are patients with pulmonary hypertension, right-to-left shunts, or coarctation of the aorta. Because hemodynamic changes observed during labor and delivery persist into the postpartum period, if used, invasive monitoring should continue for 24 to 48 hours postpartum.

## **Congenital Heart Disease**

Many patients with successful surgical repair of congenital heart defects are asymptomatic with minimal cardiac findings. Patients with uncorrected or partially corrected lesions may have serious cardiac decompensation with pregnancy. This includes patients with corrected tetralogy of Fallot who may have recurrence of a small ventricular septal defect or develop outflow obstruction. Neuraxial labor analgesia is recommended to minimize hemodynamic changes associated with pain. Maintenance of SVR and venous return is necessary to prevent an increase in right-to-left shunt. Phenylephrine should be used to minimize and/or treat reduction in SVR associated with sympathetic blockade.

Patients with corrected ventricular septal defects or atrial septal defects require no special care, nor do those with small asymptomatic atrial septal defects or ventricular septal defects. In symptomatic patients, neuraxial analgesia will minimize the increase in SVR associated with elevated catecholamines due to pain and may slightly decrease SVR, thus minimizing left-to-right shunting through the defect. Large ventricular septal defects or atrial septal defects are associated with pulmonary hypertension. Patients with these lesions require invasive monitoring and an analgesic technique that maintains SVR, heart rate, and pulmonary vascular resistance.

Eisenmenger syndrome occurs when uncorrected left-to-right shunt results in pulmonary hypertension, which, when severe, reverses flow to a right-to-

left shunt. Pregnancy is not well tolerated and mortality can approach 30%, most commonly from embolic phenomena. Management of these patients is challenging. Invasive monitoring of arterial and cardiac filling pressures is indicated. The right ventricle is at greater risk of dysfunction than the left ventricle. Thus, measuring the right atrial pressure is useful in this setting. Implementing labor analgesia that does not lead to deleterious hemodynamic changes is a challenge; opioid-based neuraxial techniques (e.g., CSE, continuous spinal) combined with a dilute local anesthetic may be the best option.

Cesarean delivery is most often accomplished under general anesthesia in women with Eisenmenger syndrome. It should be recognized that arm-to-brain circulation times are rapid owing to right-to-left intracardiac shunts; drugs given intravenously have a rapid onset of action. In contrast to parenteral drugs, the rate of rise of arterial concentrations of inhaled drugs is slow because of decreased pulmonary blood flow. The myocardial depressant and vasodilating actions of volatile drugs may be hazardous in patients with Eisenmenger syndrome, and nitrous oxide, which may increase pulmonary vascular resistance, should be avoided. Positive-pressure ventilation (PPV) of the lungs may also decrease pulmonary blood flow. Sympathetic blockade with CSE anesthesia may lead to cardiovascular decompensation. Thus, maintenance of preload using phenylephrine and fluids, guided by CVP measurements, is essential if regional anesthesia is selected. Hemodynamic monitoring for 48 hours postpartum is essential.

## Valvular Heart Disease

The decrease in incidence of rheumatic heart disease in the developed world has resulted in fewer parturients with valvular heart disease. Aortic stenosis is now likely associated with a bicuspid valve in the patient with AMA. [Table 41-3](#) summarizes the management goals of patients with valvular heart disease.

Patients with prosthetic heart valves present a different challenge in pregnancy. Bioprostheses avoid the risk of thrombosis and the need for anticoagulation. There is, however, concern that pregnancy hastens the rate of valve deterioration. Mechanical valves require anticoagulation. Compared to heparin, warfarin is associated with a lower incidence of thrombosis, but also an unacceptable fetal risk. Unfractionated heparin (UFH) and low-molecular-weight heparin (LMWH) do not cross the placenta but it is more difficult to ensure appropriate anticoagulation. The American College of Cardiology recommends any of the following options once pregnancy is confirmed<sup>138</sup>:

- Continue warfarin until 36 weeks, then convert to UFH or LMWH.

- Use UFH or LMWH from 6 to 12 weeks and after 36 weeks; use warfarin from 12 to 36 weeks.
- Use LMWH throughout pregnancy.

**Table 41-3** Hemodynamic Goals with Valvular Lesions

Lesion	Goal
Aortic stenosis	Sinus rhythm Maintain HR Avoid ↓ SVR Maintain venous return
Aortic insufficiency	Mild ↑ HR Avoid ↑ SVR
Mitral stenosis	Sinus rhythm ↓ HR Maintain SVR Maintain venous return
Mitral insufficiency	Sinus rhythm Mild ↑ HR Avoid ↑ SVR Avoid ↑ venous return

SVR, systemic vascular resistance; HR, heart rate.

### Primary Pulmonary Hypertension

Primary pulmonary hypertension (PPH) is seen predominantly in young women. Pulmonary hypertension is defined as mean pulmonary artery pressure over 25 mmHg at rest or 30 mmHg with exercise. The cause is unclear but is associated with endothelial dysfunction. Although uncommon in pregnancy, PPH is associated with a very high maternal mortality; pregnancy is discouraged and termination is advised should pregnancy occur.

The mode of delivery of these patients is contentious. Vaginal delivery is associated with smaller hemodynamic shifts and less risk for bleeding. However, emergency cesarean delivery for maternal or fetal deterioration may be needed. Planned cesarean delivery may offer the advantages of ensuring optimal conditions and the availability of experienced staff.

Pain during labor and vaginal delivery is especially detrimental because it may further increase pulmonary vascular resistance and decrease venous return. Neuraxial analgesia is useful for preventing pain-induced increases in pulmonary vascular resistance. Dilute local anesthetic solutions with the addition of opioids will minimize the decrease in SVR. General and epidural anesthesia have been used for cesarean delivery. Spinal anesthesia may result in a sudden decrease in SVR and is thus not recommended for cesarean delivery. Risks of general anesthesia include increased pulmonary artery pressures during laryngoscopy and tracheal intubation, the adverse effects of PPV on venous return, and the negative inotropic effects of volatile anesthetics. Nitrous oxide may further increase pulmonary vascular resistance

and should not be used. In addition to oxygen, the administration of isoproterenol, inhaled nitric oxide, calcium channel blockers, or sildenafil may be useful for decreasing pulmonary vascular resistance. Hemodynamic monitoring, including systemic and pulmonary arterial pressures, remains controversial in these patients, with no evidence to support the use of pulmonary artery catheters. Pulmonary artery rupture and thrombosis are risks of pulmonary artery catheters in the presence of pulmonary hypertension, but some argue that the benefits in these critically ill patients offset these potential hazards. Maternal mortality is estimated between 30% and 55%, with most deaths due to right heart failure that occurs during labor and the early postpartum period.<sup>138</sup>

### **Cardiomyopathy of Pregnancy**

Cardiomyopathy of pregnancy is left ventricular failure occurring late in pregnancy or in the first 6 weeks postpartum. It occurs in approximately 1 in 3,000 births and is associated with a maternal mortality of 25% to 50%. It is a diagnosis of exclusion, the etiology thought to be related to myocarditis or an abnormal immune response. Risk factors include AMA, multiparity, multiple gestation, obesity, hypertension, and preeclampsia.<sup>137,139</sup> Good long-term prognosis is related to recovery of left ventricular function within 6 months of delivery. A left ventricular ejection fraction of less than 25% at diagnosis is associated with poor long-term outcome, even with recovery after pregnancy, and these patients should be counseled against future pregnancies. If the cardiomyopathy persists, the mortality may be as high as 50%; many patients with persistent cardiomyopathy become transplant candidates. Medical management includes preload optimization, afterload reduction, and therapy to improve myocardial contractility. Patients may require thromboprophylaxis. Intrapartum anesthetic management is directed at minimizing cardiac stress and thus decompensation, and may be aided by invasive hemodynamic monitoring.

### **Coronary Artery Disease and Myocardial Infarction**

Acute myocardial infarction during pregnancy is rare, occurring in 1 in 10,000 to 30,000 women. It is associated with a maternal mortality as high as 37% as well as a high infant mortality rate (9%). As more women with risk factors become pregnant, this complication will increase in frequency. The left anterior descending artery is most commonly affected, with 47% of infarcts associated with coronary spasm (i.e., normal angiogram) and another 16% associated with coronary artery dissection. Risk factors include smoking, obesity, AMA, diabetes, hypertension, and hyperlipidemia. Women older than 35 years are at greatest risk; the risk is 30-fold higher in women older than 40

years, compared to women younger than 20 years. The ergot alkaloids should be avoided because they can lead to coronary vasospasm, as can cocaine use.<sup>140</sup>

Diagnosis may be difficult as symptoms of ischemia may mimic common nonspecific complaints during pregnancy. Thus the greatest obstacle to diagnosis is a low index of suspicion. Cardiac troponin I levels are increased if cardiac muscle injury occurs; however, preeclampsia and gestational hypertension may also increase troponin levels. Therefore, ECG is an important diagnostic tool.

Delivery within 2 weeks of the infarct is associated with a high rate of reinfarction and death. Thus, delaying delivery, if possible, should be considered. Vaginal delivery is associated with lower morbidity and mortality than cesarean delivery. Intrapartum monitoring should mimic intraoperative monitoring of the nonobstetric patient with a recent myocardial infarction.

In the event of cardiac arrest in late pregnancy, left lateral displacement of the uterus should be achieved, and if cardiopulmonary resuscitation is unsuccessful, the fetus should be delivered within 5 minutes to improve maternal and infant survival.<sup>141</sup>

## **Sudden Arrhythmic Death Syndrome**

SADS is defined as sudden cardiac death where all other causes are eliminated. Under this diagnosis are those cases where the heart is normal on autopsy and all stimulant drugs ruled out as a cause of death. Some are identified as likely due to conduction defects by examination of relatives; the remainder are presumed to be related to arrhythmias.<sup>135</sup> An association between obesity and SADS has been suggested.

## **Diabetes Mellitus**

Diabetes occurs in approximately 3% of pregnancies and 8% of gravidae of AMA. The incidence is increasing, in parallel with the increase in population obesity and type 2 diabetes.<sup>142</sup> Gestational diabetes mellitus is diabetes or glucose intolerance that is first diagnosed during pregnancy. Gestational diabetes mellitus is associated with increased adverse outcomes, including macrosomia, neonatal hypoglycemia, hyperbilirubinemia, and intrauterine fetal demise, as well as an increased risk of obesity and diabetes in offspring later in life. Women with gestational diabetes mellitus are at increased risk for development of type 2 diabetes later in life.

Pre-existing type 1 or 2 diabetes is also associated with adverse pregnancy outcomes, including congenital malformations. Vasculopathy, nephropathy, and retinopathy may be exacerbated by pregnancy. Tight glycemic control

before and during pregnancy may decrease the risk of adverse outcomes. Although a rare occurrence, normal physiologic changes of pregnancy contribute to a propensity for diabetic women, especially type 1 diabetics, to develop diabetic ketoacidosis (DKA).<sup>143</sup> DKA occurs at lower glucose levels in pregnancy due to enhanced lipogenesis and ketogenesis.  $\beta$ -Adrenergic therapy and steroid administration may also increase the likelihood of developing DKA. Although maternal mortality from DKA is unusual, fetal mortality is high.

Guidelines for the management of pregnant diabetics focus on glycemic control. A blood sugar of 60 to 120 mg/dL is desirable and insulin therapy is needed if fasting blood sugar levels are above 100 mg/dL.<sup>144</sup> Maternal insulin requirements increase progressively during the second and third trimesters. Fetal surveillance is more intense in diabetic women. Antenatal surveillance with twice weekly nonstress tests often begins at 28 weeks. Delivery at 38 weeks of gestation may be considered if estimated fetal weight exceeds 4,500 g or fetal surveillance indicates the need for delivery.

There is no compelling evidence that one analgesic or anesthetic technique is superior to another when caring for diabetic parturients. Patients with pregestational diabetes should be assessed for comorbidities. Neuraxial labor analgesia does not appear to alter peripartum insulin and glucose requirements. Intrapartum blood glucose levels should be monitored frequently, and glucose administration and insulin therapy should be titrated to maintain maternal glucose concentration between 60 and 120 mg/dL. Insulin requirements decrease shortly after delivery.

## Obesity

In the United States, over 60% of the adult population is overweight or obese; not surprising, obesity in pregnancy mimics this incidence. Obese women **12** are more likely to have antenatal comorbidities, such as chronic hypertension, diabetes mellitus, and preeclampsia.<sup>145</sup> Obstetric outcome may also be affected by maternal obesity; there is a greater risk of fetal congenital cardiac anomalies, macrosomia, and shoulder dystocia. Abnormal labors and failed inductions of labor, are more likely to occur. Overall cesarean delivery rates, and specifically emergency cesarean delivery rates, increase with increasing body mass index. Preanesthetic evaluation of the obese parturient should be performed with anticipation of these complications and a multidisciplinary care plan should be generated. Careful airway evaluation is required, and alternative airway equipment must be readily available, especially as the use of general anesthesia for cesarean delivery is higher in the obese parturient than in her nonobese peers. In addition, the extent of comorbidities such as hypertension and diabetes mellitus should be assessed,

as these occur more frequently in obese patients.<sup>146</sup> Continuous neuraxial analgesia is the preferred option for pain relief during labor because it provides excellent pain relief without sedation/obtundation and prevents additional demands on the cardiorespiratory system of the obese patient. Most importantly, a well-functioning neuraxial anesthetic for labor may also be used for anesthesia for instrumental vaginal or cesarean delivery, thus avoiding airway manipulation. For cesarean delivery, the choice of anesthetic depends on maternal and fetal conditions. The panniculus must be positioned carefully to prevent cardiorespiratory compromise. A continuous neuraxial anesthetic technique should be considered over a “single-shot” technique because there may be unpredictable spread of local anesthetic and because a prolonged surgical duration can be anticipated. Thus, the procedure itself may outlast the effective anesthesia from the latter. Obesity is associated with an increased risk for maternal death related to increased incidence of infection, diabetes, preeclampsia, and thromboembolism. Anesthesia-related maternal mortality is also increased, primarily related to airway difficulties.

### **Advanced Maternal Age**

As reproductive technologies improve and more women are delaying childbearing, pregnancies in women of AMA will become more prevalent. In 2002, almost 14% of all births in the United States occurred in women aged 35 years or older.<sup>147</sup> In 2003, the percentage of primiparas 35 years and older was 10%.<sup>148</sup> In Canada in 2002, live births to women 30 to 34 years old accounted for 30.6% of all births; to women aged 35 to 39 years old, 14.1%; and to women 40 years and older, 2.6%. Some studies have reported higher maternal morbidity as well as perinatal morbidity and mortality in older gravidae,<sup>149-151</sup> suggesting that pregnancy in older women may be a “medical problem.” As we care for these patients, we must remember that healthy women of AMA will likely have uncomplicated pregnancies and deliveries; the incidence of complications is largely related to comorbidities, which occur at a greater incidence in older women. In one study, almost half of the pregnant women older than 45 years of age had pre-existing medical problems.<sup>150</sup> Cleary-Goldman et al.<sup>151</sup> found that 38% of 36,000 patients older than 35 years of age took medication for pre-existing conditions. In addition, many older pregnant patients have been infertile or subfertile or had a previous poor obstetric outcome. Seven percent had prior preterm delivery and 26% had a previous miscarriage.<sup>152</sup> Obstetric management should be focused on the patient’s comorbidities.

AMA is independently associated with gestational diabetes, preeclampsia, placental abruption, and cesarean delivery. Older gravidae are more likely to have a weight of more than 70 kg, hypertension, diabetes mellitus, and a bad

obstetric history. These medical problems complicate the pregnancy and its management. Pregestational hypertension occurs more frequently in patients over 30 years of age.<sup>153</sup> Patients with chronic hypertension are more likely to develop superimposed preeclampsia (78%), deliver by cesarean section (71%), and deliver before 37 weeks of gestation than normotensive patients. Hypertensive parturients are at greater risk for placental abruption, congestive heart failure, pulmonary edema, and hypertensive encephalopathy. Further, older parturients are more likely to require prolonged hospitalization and are more likely to be admitted to the intensive care unit than younger parturients.

Cesarean delivery is performed more frequently in those with AMA. In some patients, the need for cesarean delivery is related to coexisting problems such as hypertension, preeclampsia, placental abruption, or fetal macrosomia. AMA is also independently associated with an increased likelihood for cesarean delivery. Lin et al.<sup>154</sup> reported that over a 5-year period, “request cesarean delivery” rates rose steadily in all patients but rose disproportionately in patients with AMA. Women over the age of 34 years were twice as likely to request cesarean delivery compared with those aged 25 years or younger. The cesarean delivery rate for mothers of 30 to 34 years of age was 37%, and for mothers older than 34 years, it was 48%.<sup>154</sup> The complex sociodemographic explanation for the increased requests for cesarean delivery is yet to be fully ascertained and the long-term medical cost has yet to be defined.<sup>155,156</sup> Cesarean delivery is associated with increased maternal risks compared with uncomplicated vaginal delivery. These include short-term risks of cesarean delivery such as hemorrhage, infection, ileus, and aspiration pneumonitis. In addition, hysterectomy occurs 10 times more frequently following cesarean delivery compared with vaginal delivery. The risk of maternal death is 16 times greater. Long-term morbidity includes adhesions, bowel obstruction, bladder injury, and increased risk for placenta previa or ectopic pregnancy in subsequent pregnancies.<sup>157</sup>

Older women may believe that their age makes their infant more vulnerable and, as such, that a controlled cesarean delivery is safer than a vaginal delivery. Other explanations for increased requests for cesarean delivery include concerns about physical stamina, protection of the pelvic floor from damage, refusal to undergo labor pain, and social convenience. Patient beliefs run counter to the many studies that show that cesarean delivery in the absence of clinical indications increases maternal mortality and perinatal morbidity.<sup>155,156</sup>

Perinatal complications are also significant in patients with AMA; multiple gestations,<sup>157</sup> both iatrogenic and naturally occurring, are more common in older gravidae. The incidence of miscarriage, congenital anomalies, preterm delivery, low birth weight, and intrauterine and neonatal death also increase

with age.

## Preterm Delivery

Preterm labor and delivery (before 37 completed weeks of gestation) present a significant challenge to the anesthesiologist because both mother and infant may be at risk. Although preterm deliveries occur in 8% to 10% of all births, they account for approximately 80% of early neonatal deaths. In general, the mortality and morbidity rates are higher among preterm infants than among small-for-gestational-age infants of comparable weight. Severe problems that may develop in preterm infants are respiratory distress syndrome, intracranial hemorrhage, hypoglycemia, hypocalcemia, and hyperbilirubinemia. With improved neonatal intensive care, preterm infants who weigh over 1,500 g often survive without severe long-term impairment. The very low-birth-weight infant (<1,500 g) is still at greater risk for significant long-term impairment.<sup>158</sup>

Obstetricians will try to stop preterm labor to enhance fetal lung maturity. Delaying delivery by even 24 to 48 hours may be beneficial if glucocorticoids are administered to the mother. Various agents have been used to suppress uterine activity (tocolysis), including ethanol, magnesium sulfate, prostaglandin inhibitors, *b*-sympathomimetics, and calcium channel blockers (Table 41-2). Magnesium sulfate may also be used to improve neonatal outcomes; available evidence suggests that if given early (before 30 to 33 weeks), it may reduce the risk for cerebral palsy.<sup>159</sup>

It is thought that the premature infant is more vulnerable than the term newborn to the effects of drugs used in obstetric analgesia and anesthesia. However, there have been few systematic studies to determine the maternal and fetal pharmacokinetics and dynamics of drugs throughout gestation. There are several postulated causes of enhanced drug sensitivity in the preterm newborn, including:

- Less protein available for drug binding
- Higher levels of bilirubin, which may compete with the drug for protein binding
- Greater drug access to the CNS because of a poorly developed blood-brain barrier
- Greater total body water and lower fat content
- A decreased ability to metabolize and excrete drugs

However, these deficiencies of the preterm infant may not be as serious as we have been led to believe. Serum albumin and  $\alpha_1$ -acid glycoprotein concentrations are lower in the preterm fetus; however, this would primarily affect drugs that are highly bound to these proteins. Most drugs used in anesthesia exhibit only low-to-moderate degrees of protein binding in the

fetal serum.

In selection of the anesthetic drugs and techniques for delivery of a preterm infant, concerns regarding drug effects on the newborn are far less important than prevention of asphyxia and trauma to the fetus. For labor and vaginal delivery, well-conducted neuraxial anesthesia is advantageous in providing good perineal relaxation. Preterm infants with breech presentation are usually delivered by cesarean as are very low-birth-weight infants (<1,500 g). If neuraxial anesthesia is used, nitroglycerin should be available for uterine relaxation. If vaginal delivery occurs with a breech infant and there is head entrapment, general anesthesia or nitroglycerin may be needed for uterine relaxation.

## Substance Abuse

Nearly 90% of women who abuse tobacco, drugs, or alcohol are of childbearing age. The most commonly abused substances in society as well as in pregnancy are alcohol, tobacco, cocaine, marijuana, opioids, caffeine, amphetamines, and to a lesser extent, hallucinogens and solvents. Substance abuse may significantly impact intrapartum anesthetic management and may result in obstetric crises that require the intervention or assistance of an obstetric anesthesiologist. Diagnosis of the patient who is not under the effect of a substance at admission may be made when she, or her infant, develops withdrawal symptoms or the newborn is diagnosed with a syndrome related to in utero exposure. Women often abuse more than one drug, so the newborn's problems may reflect the impact of multiple drug exposures.

### Tobacco Abuse

Smoking is the most commonly abused substance in pregnancy. Smoking during pregnancy has been associated with miscarriages, IUGR, and increased risk of premature rupture of membranes, placental previa, abruptio placentae, preterm delivery, impaired respiratory function in newborns, and sudden infant death syndrome. The pregnant patient is at greater risk for bronchitis, pneumonia, and asthma. Nicotine causes vasoconstriction and thus may decrease placental blood flow and oxygen delivery to the fetus; of interest, smoking appears to be protective for the development of preeclampsia.

### Alcohol

In a pregnant female, heavy alcohol consumption may be associated with liver disease, coagulopathy, cardiomyopathy, and esophageal varices; it can also alter drug metabolism. In the fetus, alcohol has been linked to fetal

alcohol syndrome. The prevalence of fetal alcohol syndrome is approximately one-third of infants of heavy maternal drinkers (>28 g absolute alcohol or two drinks per day). Neurobehavioral deficit and IUGR have been demonstrated in infants of moderate drinkers (>14 g absolute alcohol or 1 drink per day). The parturient who abuses alcohol is at further increased risk for aspiration compared with the average pregnant individual. She may have hepatic dysfunction, cardiac failure, or coagulopathy. Acute alcohol withdrawal may present within 6 to 48 hours of abstinence; thus, it may occur intrapartum or postpartum. The signs and symptoms of alcohol withdrawal include nausea and vomiting, hypertension, tachycardia, dysrhythmias, seizures, and cardiac failure. These are easily mistaken for other disease entities.

## Opioids

Opioid abuse has multiple implications for both mother and fetus. The intravenous opioid abuser may have septic thrombophlebitis, human immunodeficiency virus, endocarditis, or hepatitis. These patients are at an increased risk for developing preeclampsia and third-trimester bleeding. They will develop withdrawal symptoms should an agonist/antagonist be administered for pain relief in labor.

The anesthetic management of a chronic opioid user should include the continuation of opioids throughout labor and into the postpartum period to prevent acute opioid withdrawal. These patients are likely to have increased opioid requirements. Those patients with a history of opioid abuse who are on methadone maintenance should have a stable peripartum course. Neuraxial anesthesia is safe in these patients, but one must continue a maintenance dose of systemic opioid to prevent withdrawal symptoms, despite neuraxial labor analgesia. Neonates will have neonatal abstinence syndrome, which will require close observation and treatment.<sup>160</sup>

## Marijuana

Marijuana is frequently abused by women of childbearing age. Delta-9-tetrahydrocannabinol (THC) readily crosses the placenta and may directly affect the fetus. It has been associated with preterm labor and IUGR. The parturient who chronically uses marijuana has an increased incidence of respiratory problems, including bronchitis and emphysema, and thus may be at risk for respiratory complications related to general anesthesia. Acute marijuana use may be associated with cardiovascular stimulation at moderate doses and myocardial depression at higher doses.

## Cocaine

Women acutely ingesting cocaine generally display euphoria, tachycardia, and hypertension. More serious manifestations may include seizure and coma, myocardial infarction, pulmonary edema, or subarachnoid hemorrhage. Sudden death may occur from a lethal ventricular dysrhythmia. Cocaine use in the first trimester may cause congenital anomalies. Later in pregnancy, cocaine use may be associated with premature labor, IUGR, and nonreassuring fetal status because of uteroplacental insufficiency or placental abruption. Therapy is supportive, primarily aimed at controlling cardiovascular and CNS consequences of cocaine use. Hypertension related to acute cocaine ingestion may be the primary etiology of cerebral hemorrhage, or cocaine may cause vasospasm and cerebral infarction. Pure  $\beta$ -antagonist drugs should be avoided because of the potential for worsening hypertension related to unopposed  $\alpha$ -receptor stimulation by cocaine. The choice of anesthetic depends on maternal and fetal conditions, the planned procedure (vaginal or cesarean delivery), and urgency. General anesthesia may be associated with uncontrolled hypertension/tachycardia and life-threatening dysrhythmias in women using cocaine. Neuraxial anesthesia may also be complicated by cocaine use. Cocaine is a local anesthetic, and systemic toxicity may be additive when using amide local anesthetics for epidural anesthesia. Esters compete with cocaine for metabolism, resulting in decreased metabolism of both drugs. Chronic cocaine use may be associated with thrombocytopenia. The incidence and severity of hypotension related to neuraxial anesthesia may be greater in chronic cocaine-abusing parturients compared with controls, and hypotension may be more difficult to treat. Direct-acting agents are more effective and predictable in chronic cocaine abusers. Fetal exposure to cocaine may alter the developing brain, contributing to an increased susceptibility to addiction.<sup>161</sup>

**Table 41-4** Anesthetic Considerations Associated with Cocaine and/or Amphetamine Abuse

- Uncontrolled hypertension
- Cardiac dysrhythmias (ventricular tachycardia/fibrillation)
- Myocardial ischemia
- Ephedrine-resistant hypotension with neuraxial blockade (use direct-acting agent)
- Acute intake may increase MAC of volatile agents
- Chronic use may decrease dosage of anesthetic agents
- May have increased sensitivity to arrhythmogenic effects of volatile agents

MAC, minimum alveolar concentration.

## Amphetamines

Amphetamines are noncatecholamine sympathomimetic drugs. They are often abused in conjunction with other CNS stimulants such as cocaine. They can be taken orally or intravenously (methamphetamine) or smoked, as crystal methamphetamine. Ecstasy is an analog of methamphetamine that has become tremendously popular in young adults. Amphetamine use leads to an increased release of norepinephrine, leading to hypertension, tachycardia, dysrhythmias, dilated pupils, hyperpyrexia, proteinuria, agitation, confusion, and seizures. These signs and symptoms closely resemble those of cocaine abuse. Methamphetamine abuse has been associated with stroke in pregnant women as well as fetal and infant deaths. Amphetamines taken early in pregnancy can result in fetal anomalies and low birth weight infants. Later in pregnancy, placental abruption may lead to fetal death. The anesthetic management of patients who abuse amphetamines is similar to that of cocaine abusers (Table 41-4).

## Fetal Monitoring

The development of biophysical monitoring of the fetus during labor and delivery has had a tremendous impact on obstetric practice since the early 1970s. Monitoring procedures are now performed routinely, and it is important that the anesthesiologist understand the basic principles of the technology as well as the interpretation of results. With the growing sophistication of electronic devices, and specifically the science of telemetry, surveillance of both mother and fetus may take place without the loss of maternal freedom and activity that monitoring entailed in the past.

### *Electronic Fetal Monitoring*

Intrapartum electronic fetal heart rate (FHR) monitoring is the most common obstetric procedure performed.<sup>162</sup> An electronic fetal monitor is a two-channel recorder of FHR and uterine activity. In the internal system, the fetal ECG is obtained from an electrode attached to the presenting part. Intrauterine pressure is measured continuously with a transducer connected to a saline-filled catheter that is inserted transcervically. Internal monitoring is quantitative but requires rupture of the membranes and a cervical dilation of at least 1.5 cm. In addition, the presenting part must be in the true pelvis. External fetal monitoring uses data obtained indirectly from transducers secured to the mother's abdomen with adjustable straps. Ultrasound cardiography is the most commonly used method of obtaining FHR signals. Uterine activity is monitored with a tocodynamometer triggered by the changing shape of the uterus during the contraction. Indirect monitoring is mostly qualitative. Its advantage is that it can be applied

without rupture of membranes, even before the onset of labor.

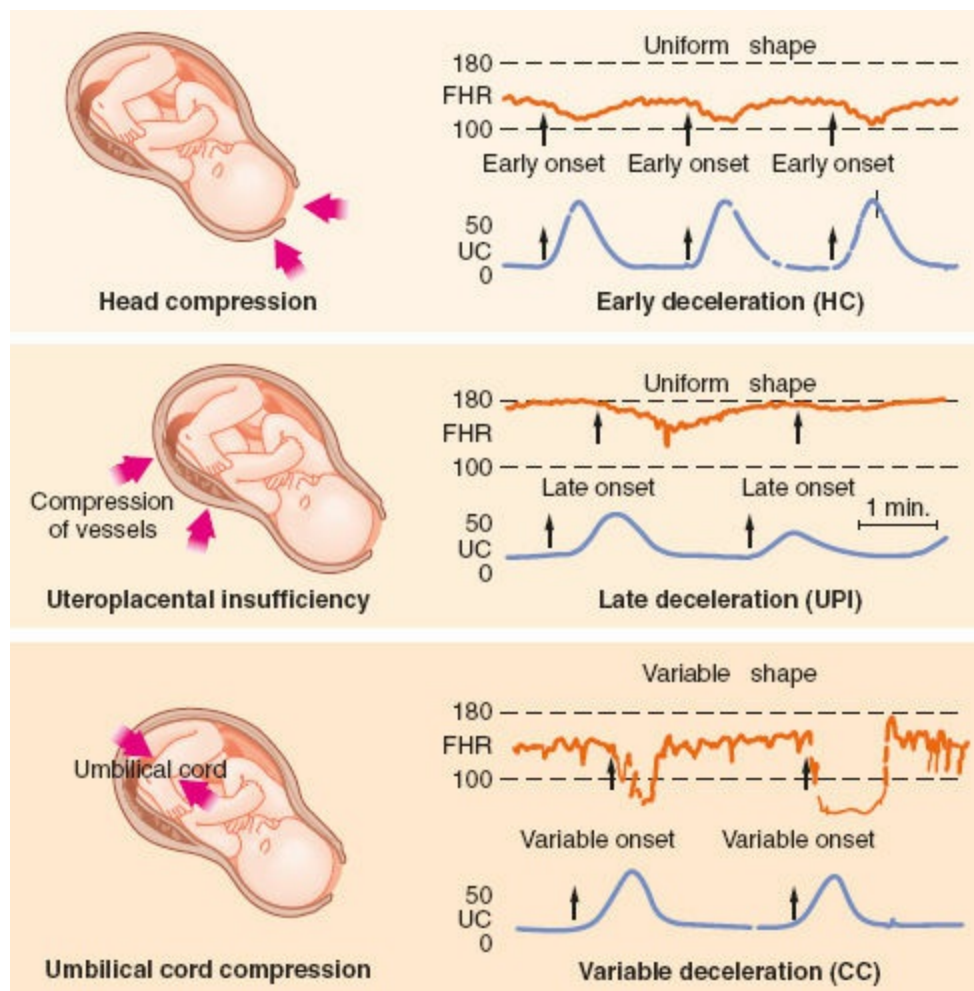

The following variables are considered when fetal well-being is being assessed: Uterine activity, baseline heart rate and variability, presence of accelerations, and periodic decelerations. Cervical dilation and descent of the presenting part during the first stage of labor result primarily from uterine contractions. During the active phase, contractions should occur every 2 to 3 minutes, with peak intrauterine pressures of 50 to 80 mmHg and resting pressures of 5 to 20 mmHg. When more than five contractions occur in 10 minutes, it is termed tachysystole. Tachysystole is sometimes seen after neuraxial labor analgesia and may result from a sudden drop in serum catecholamines, which normally serve to relax the uterus.<sup>163</sup> Poor uterine contractility may result from overdistention (polyhydramnios, multiple gestation) or aortocaval compression. The addition of epinephrine to a local anesthetic solution may have a dose-related inhibitory effect on uterine activity.

The baseline FHR is the mean rate during a 10-minute segment and ranges between 110 and 160 beats per minute in the normal fetus.<sup>162</sup> Persistently elevated rates may be associated with chronic fetal distress, maternal fever, or administration of drugs such as ephedrine and atropine. Abnormally low rates may be encountered in fetuses with congenital heart block or as a late occurrence during the course of fetal hypoxia and acidosis.

Baseline FHR variability refers to fluctuations in baseline FHR that are irregular in amplitude and frequency; baseline variability is quantified as the amplitude of the peak to the trough heart rate and normally ranges between 6 and 25 beats per minute.<sup>162</sup> Baseline variability reflects the beat-to-beat adjustments of the parasympathetic and sympathetic nervous systems to a variety of internal and external stimuli and is mediated by the CNS, the peripheral nervous system, and the cardiac conduction system itself. Presence of normal variability is a reassuring sign of normal fetal acid–base status. Fetal CNS depression by asphyxia may decrease baseline variability. Therefore, a smooth FHR tracing may be an ominous finding. However, drugs that depress the CNS (sedatives, opioids, barbiturates, anesthetics) can also decrease FHR variability. Atropine may decrease variability by blocking the transmission of control impulses to the cardiac pacemaker.

An acceleration of FHR is an abrupt increase over baseline and is a reassuring sign that the fetus is not acidemic.<sup>162</sup> Periodic FHR decelerations occur in association with uterine contractions (Fig. 41-8). There are three patterns observed: Early, late, and variable. Early decelerations are characterized by a symmetrical gradual decrease in FHR. The fetal heart usually begins to slow with the onset of the contraction, nadirs with the peak of the contraction, and returns to the baseline as the uterus relaxes. Early decelerations reach a nadir 30 seconds or more after the onset of the

deceleration.<sup>162</sup> This type of deceleration has been attributed to fetal head compression, leading to increased vagal tone. It is not ameliorated by increasing fetal oxygenation but is blocked by atropine administration. Early decelerations are transient and well tolerated by the fetus; there is no systemic hypoxemia or acidosis.

**Figure 41-8** Classification and mechanism of fetal heart rate patterns. HC, head compression; UPI, uteroplacental insufficiency; CC, cord compression. (Adapted from Hon EH. *An Introduction to Fetal Heart Rate Monitoring*. New Haven, CT: Harty Press; 1969:29.)

Late decelerations are also symmetric and gradual in onset. However, they begin after the onset of uterine contraction and the low point of the deceleration occurs well after its peak, at least 30 seconds after the onset of the deceleration.<sup>162</sup> CNS or myocardial ischemia resulting from uteroplacental insufficiency and fetal hypoxemia may cause late decelerations.

Variable decelerations are the most common periodic pattern observed in the intrapartum period. They are variable in shape and abrupt in onset, with the heart rate nadir occurring within 30 seconds of the onset.<sup>162</sup> Variable decelerations occur due to umbilical cord compression that results in activation of the carotid baroreceptor reflex. Although the initial FHR changes

are of reflex origin, if the cord compressions are frequent or prolonged, fetal asphyxia may result in fetal hypoxemia and CNS insult or direct myocardial depression. If late or variable decelerations are recurrent (occur with at least one-half of contractions) or prolonged ( $\geq 15$  beats per minute below baseline lasting  $\geq 2$  minutes but  $< 10$  minutes), there is a significant correlation with fetal acidosis and delivery may be undertaken.<sup>164</sup>

The ACOG currently recommends a three-tiered system for the evaluation of FHR tracings.<sup>162</sup> Category I tracings are those with normal baseline and variability, and no late or variable decelerations. They correlate strongly with normal fetus acid–base status at the time of observation. Category II tracings include all those that are not classified as either category I or III. They are predictive of neither normal nor abnormal acid–base status, and require continued observation and assessment. Category III tracings are abnormal. They are characterized by absent variability with any one of the following: Recurrent late decelerations, recurrent variable decelerations, or bradycardia (FHR  $< 100$  beats per minute). Sinusoidal patterns (a sine-wave like pattern) also fall into category III. Category III tracings may be corrected by improving fetal oxygenation, which may be accomplished with oxygen administration to the mother, correction of maternal hypotension or aortocaval compression, or by taking measures that reduce uterine activity. If the heart rate pattern does not respond to these conservative measures, imminent delivery may be required (Fig. 41-9).

Currently, experts agree regarding the reassuring value of a normal category I FHR tracing. There is also consensus regarding the potentially ominous nature of category III tracings. However, FHR patterns between these extremes present a clinical dilemma. The high false positive rate of FHR monitoring may lead to unnecessary cesarean deliveries. Recent recommendations regarding the approach to a category II tracing emphasize that clinicians should consider time spent with a category II tracing and progress of labor when determining delivery plans.<sup>164</sup> A recent ACOG Practice Bulletin opines not only the high false positive rate of nonreassuring FHR tracings for predicting adverse neonatal outcomes but also the excessive inter- and intraobserver variabilities in interpretation. It also notes that the practice is associated with an increase in both instrumental vaginal and cesarean deliveries, without decreasing the incidence of cerebral palsy. The bulletin recommends continuous FHR analysis for high-risk conditions, although it allows for intermittent auscultation in an uncomplicated patient.<sup>162</sup>

## Three-Tier Fetal Heart Rate Interpretation System

### Category I

*Category I fetal heart rate (FHR) tracings include all of the following:*

- Baseline rate: 110–160 beats per minute (bpm)
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: present or absent
- Accelerations: present or absent

### Category II

*Category II FHR tracings include all FHR tracings not categorized as Category I or Category III.*

*Category II tracings may represent an appreciable fraction of those encountered in clinical care.*

*Examples of Category II FHR tracings include any of the following:*

#### **Baseline rate**

- Bradycardia not accompanied by absent baseline variability
- Tachycardia

#### **Baseline FHR variability**

- Minimal baseline variability
- Absent baseline variability not accompanied by recurrent decelerations
- Marked baseline variability

#### **Accelerations**

- Absence of induced accelerations after fetal stimulation

#### **Periodic or episodic decelerations**

- Recurrent variable decelerations accompanied by minimal or moderate baseline variability
- Prolonged deceleration  $\geq 2$  minutes but  $< 10$  minutes
- Recurrent late decelerations with moderate baseline variability
- Variable decelerations with other characteristics, such as slow return to baseline, “overshoots,” or “shoulders”

### Category III

*Category III FHR tracings include either:*

- Absent baseline FHR variability and any of the following:
  - Recurrent late decelerations
  - Recurrent variable decelerations
  - Bradycardia
- Sinusoidal pattern

**Figure 41-9** Three-tiered fetal heart rate interpretation system. ## Ancillary Tests and Fetal Pulse Oximetry

Fetal scalp pH testing has been used in the past to determine the presence of acidemia in fetuses with indeterminate FHR tracings; however, its use is decreasing, and less invasive ancillary tests such as vibroacoustic stimulation and digital scalp stimulation are more commonly employed. The elicitation of accelerations with such stimuli indicates acidemia is unlikely.

Fetal pulse oximetry is a technique in which a sensor is placed through the cervix in contact with fetal skin that evaluates intrapartum fetal oxygenation.

Fetal O<sub>2</sub> saturation between 30% and 70% is considered normal, and saturation readings consistently below 30% for a prolonged period of time may be associated with fetal acidemia. The technique was initially touted as an adjunct to FHR monitoring in the hope that it could reduce the incidence of unnecessary cesarean delivery associated with that methodology. Unfortunately, two large studies failed to demonstrate a reduction in the incidence of cesarean delivery with the use of fetal pulse oximetry. Moreover, neonatal outcomes did not differ between subjects managed with versus without fetal pulse oximetry.<sup>165,166</sup> Similarly disappointing results have been seen with the addition of fetal ECG ST analysis to cardiotocography.<sup>167</sup> The ACOG does not currently endorse the routine use of fetal pulse oximetry or fetal ECG ST analysis.<sup>167</sup>

## Newborn Resuscitation in the Delivery Room

Of the approximately 3.5 million infants newly born in the United States each year, 10% require resuscitation in the delivery room.<sup>168</sup> The following factors may contribute to depression of the newborn: Medications used during labor and delivery, including anesthetic agents, birth trauma, and birth asphyxia (i.e., hypoxia and hypercapnia with metabolic acidosis).

### *Fetal Asphyxia*

Fetal asphyxia, the best-studied cause of neonatal depression, usually develops as a result of interference with maternal or fetal perfusion of the placenta. As stated previously, the normal fetus is neither hypoxic nor acidotic before labor. Experimental data have revealed that transplacental gradients for pH and PCO<sub>2</sub> are approximately 0.05 pH units and 5 mmHg, respectively. Although oxygen tension is low, oxygen saturation is relatively high (80% to 85%) by virtue of the leftward shift of the fetal oxyhemoglobin dissociation curve.

During labor, uterine contractions decrease or even eliminate the blood flow through the intervillous space of the placenta. On the fetal side, cord compression occurs during the final stages of approximately one-third of vaginal deliveries. Thus, mild degrees of hypoxia and acidosis occur even during normal labor and delivery and play an important role in initiation of ventilation immediately after birth. On average, healthy, vigorous infants have an oxygen saturation of 21%, a pH of 7.24, and a PCO<sub>2</sub> of 56 mmHg at birth.

Severe fetal asphyxia occasionally develops as a result of maternal or fetal complications, such as uterine hyperactivity, premature separation of the placenta, maternal hypotension, a tight nuchal cord, or a prolapsed cord.

During asphyxia, changes in acid–base status are rapid. The decrease in pH results from accumulation of carbon dioxide (respiratory acidosis) and end products of anaerobic metabolism (metabolic acidosis). After oxygen stores are exhausted, the ability of fetal brain and myocardium to derive energy from anaerobic metabolism is essential for survival. However, anaerobic glycolysis is pH dependent, and its rate is greatly diminished when the pH decreases below 7. Other untoward effects of severe hypoxia and acidosis include depression of the myocardium, resulting from a decrease in its responsiveness to catecholamines; a shift to the right of the fetal oxyhemoglobin dissociation curve, resulting in reduced oxygen delivery; and an increase in pulmonary vascular resistance, which plays an important role during circulatory readjustment at birth.

### *Neonatal Adaptations at Birth*

During birth and through the early hours and days of life, many morphologic and functional changes take place, with the cardiovascular and ventilatory systems undergoing the most dramatic alterations. In the normal newborn, two events occur almost simultaneously and within seconds of delivery: The end of umbilical circulation through the placenta and expansion of the lungs. These events change the fetal circulation toward the adult type.

Survival of the neonate depends primarily on prompt establishment of effective ventilation and expansion of the lungs, which dilates the pulmonary vascular bed, resulting in decreased resistance and a significant increase in pulmonary blood flow. Pulmonary vascular resistance further decreases as oxygen tension increases and carbon dioxide levels decrease. As soon as pulmonary resistance decreases, the foramen ovale, which is a communication between the right and the left atrium, undergoes functional closure because of relative pressure changes across the valve of the foramen (Fig. 41-1). Cessation of the umbilical circulation reduces pressure in the inferior vena cava and right atrium, whereas the increase in pulmonary blood flow increases venous return and pressure in the left atrium. The ductus arteriosus does not constrict abruptly or completely after birth; functional closure may take hours, even days. Thus, shunting may still occur in the neonatal period, its direction depending on relative resistances in the pulmonary and systemic vascular beds. The smooth muscle of the ductus arteriosus constricts in response to increased oxygen tension in the newborn's blood. Catecholamines, which exist in increased concentrations in the newborn, particularly during the first 3 hours of life, also constrict the ductus arteriosus. In contrast, prostaglandins I<sub>2</sub> and E<sub>2</sub>, produced by the wall of the ductus arteriosus, relax the ductal smooth muscle. Administration of prostaglandin synthesis inhibitors to fetal animals promotes closure of the ductus arteriosus.

Cardiac output and its distribution also increase; left ventricular output increases approximately 150 to 400 mL/kg/min. Cardiac output changes closely parallel the increase in oxygen consumption. The redistribution of cardiac output also leads to increases in myocardial, renal, and gastrointestinal blood flow, and decreases in cerebral, adrenal, and carotid flow.

During fetal life, respiratory gas exchange takes place through the placenta. Delivery of the infant's trunk relieves the thoracic compression that occurs as the infant passes through the birth canal, and the thorax and the lungs expand. Most infants initiate respiratory efforts a few seconds after birth. Negative pressures in excess of 40 cm H<sub>2</sub>O bring about the initial entry of air into fluid-filled alveoli. In the mature, normal neonate, the lungs expand almost completely after the first few breaths, and the pressure-volume changes achieved with each respiration resemble those of the adult. After lung expansion, the FRC approximates 70 mL in the term newborn and changes little over the first 6 days of life. The tidal volume varies between 10 and 30 mL, the breathing frequency ranges from 30 to 60 breaths per minute, and minute ventilation exceeds 500 mL. After delivery and prompt lung expansion, reoxygenation is rapid, but it takes 2 to 3 hours to achieve a relatively normal acid-base balance, primarily by pulmonary excretion of carbon dioxide. By 24 hours, the healthy neonate has reached the same acid-base state as that of the mother before labor.

## Resuscitation

The delivery room must be prepared for adequate and prompt treatment of severe neonatal depression at birth. Members of the delivery room team should be trained in resuscitation methods because both mother and infant may encounter difficulty simultaneously. One person should be designated specifically to care for the newborn during every delivery. When continued resuscitation is anticipated, a team of skilled personnel should be present. Every piece of apparatus necessary for emergency resuscitation should be checked carefully before delivery (Table 41-5). An overview of resuscitation in the delivery room is provided in Figure 41-10.

## Evaluation and Treatment

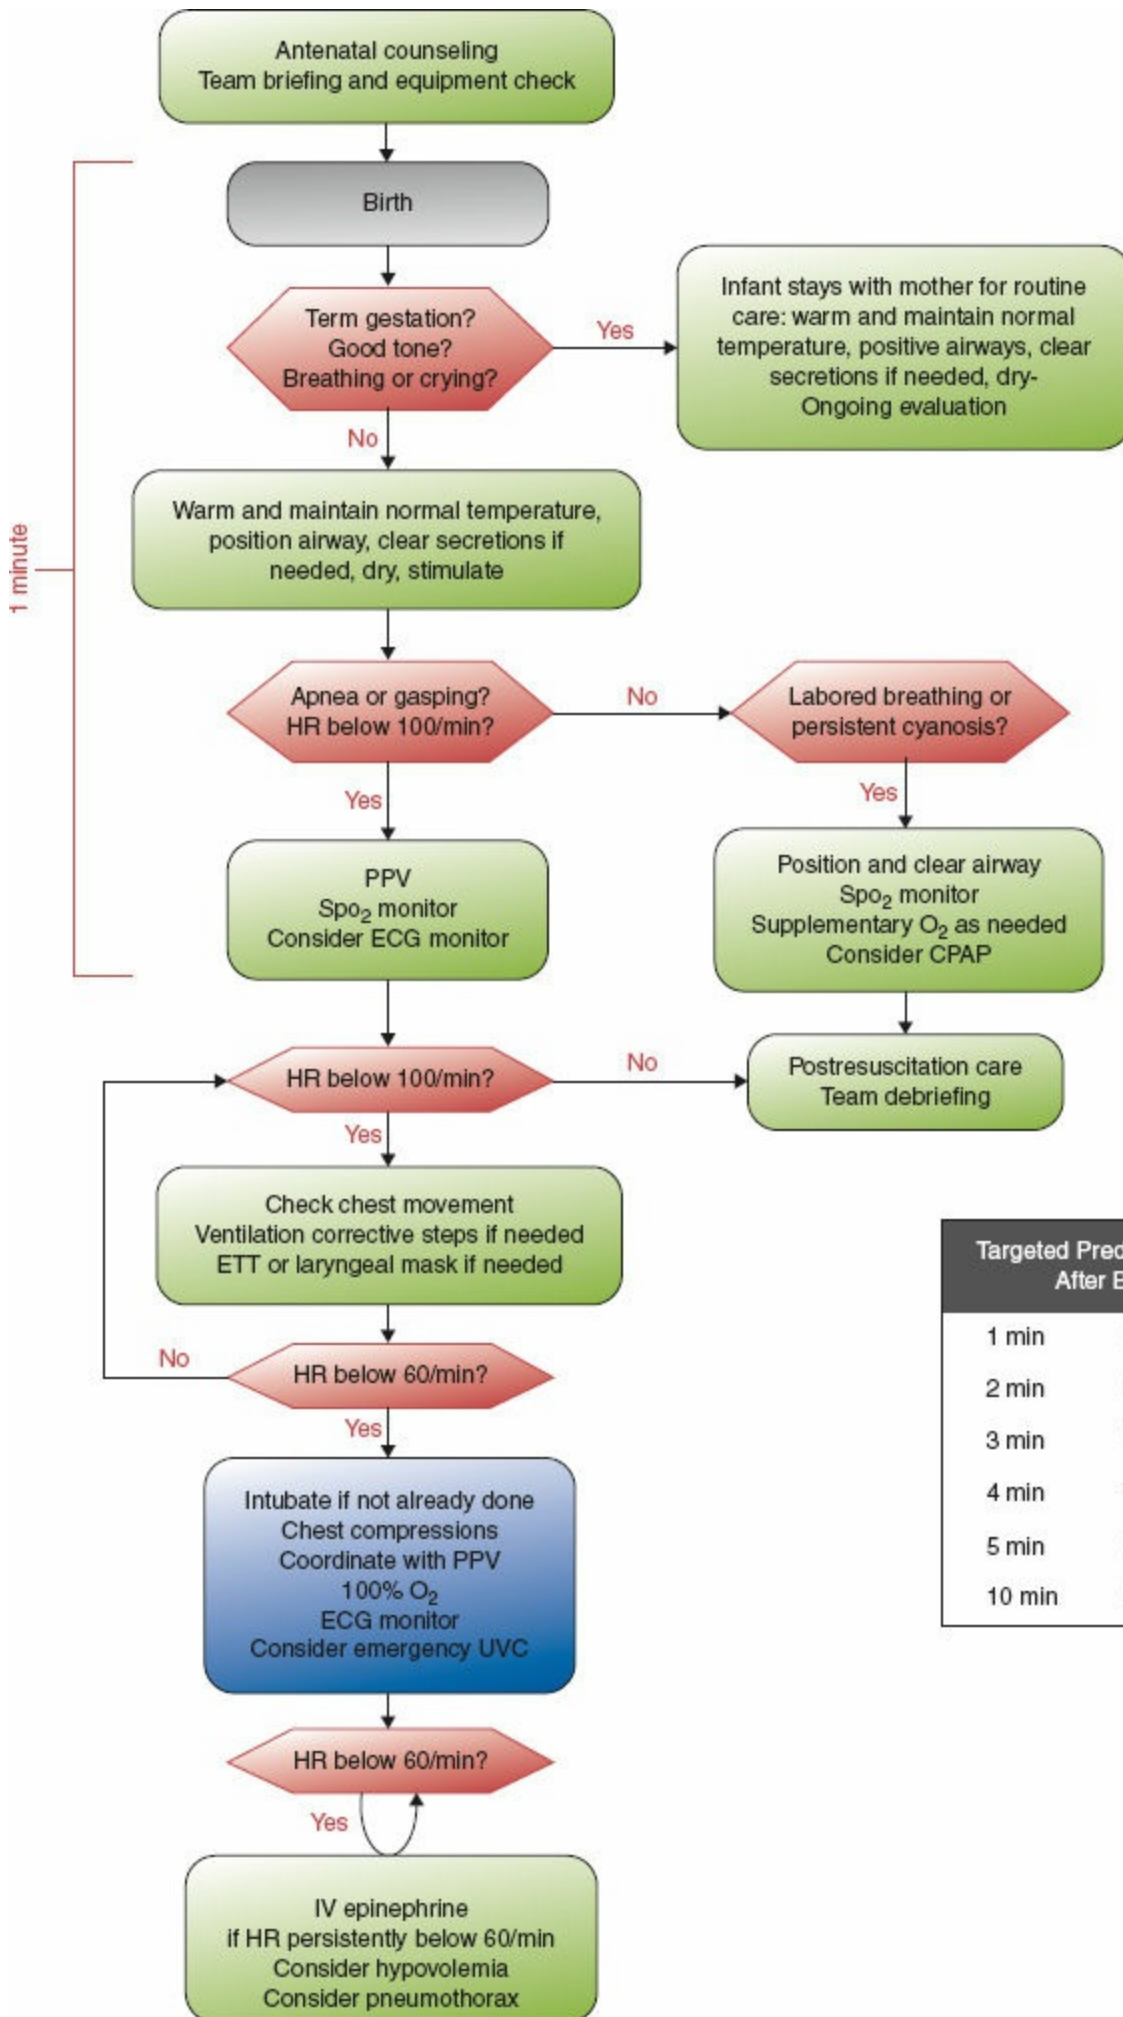

The American Heart Association has released guidelines to advise the practitioner providing neonatal resuscitation.<sup>168</sup> Immediately after delivery, the infant should be held head-down while the cord is clamped and cut. The initial appraisal of the newborn should start from the moment of birth, with particular attention paid to determining the answer to three

questions:

- Is the newborn the result of a term gestation?
- Is the newborn crying or breathing vigorously?
- Does the newborn have good muscle tone?

Targeted Productal SpO <sub>2</sub> After Birth	
1 min	60%–65%
2 min	65%–70%
3 min	70%–75%
4 min	75%–80%
5 min	80%–85%
10 min	85%–95%

**Figure 41-10** American Heart Association neonatal resuscitation algorithm. HR, heart rate; PPV, positive pressure ventilation; SpO<sub>2</sub>, pulse oximeter; ECG, electrocardiogram; ETT, endotracheal tube; UVC, umbilical vein catheter; IV, intravenous; CPAP, continuous positive airway pressure. (Reprinted with permission from Perlman JM, Wyllie J, Kattwinkel J, et al. Neonatal resuscitation algorithm—2015 update. Part 13: Neonatal resuscitation 2015 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. *Circulation*. 2015;132(Suppl 2):S543.)

**Table 41-5** Resuscitation Equipment in the Delivery Room

Radiant warmer  
Suction with manometer and suction trap  
Suction catheters  
Wall oxygen with flow meter  
Resuscitation bag ( $\leq 750$  mL)  
Infant face masks  
Infant oropharyngeal airways  
Endotracheal tubes—2.5, 3, 3.5, and 4 mm  
Endotracheal tube stylets  
Laryngoscope(s) and blade(s)  
Sterile umbilical artery catheterization tray  
Needles, syringes, three-way stopcocks  
Medications and solutions  
1:10,000 Epinephrine  
Volume expanders

If the answer to all three questions is “yes,” then the baby does not require further resuscitation and should be placed skin to skin with its mother if practical. If the answer to any of the above questions is “no,” then further resuscitation should be provided, with the following steps taken in the order listed.

### *Initial Stabilization*

One should place the infant supine under a radiant heat source, with the head kept low in the sniffing position. Breathing should be stimulating by slapping the infant’s soles lightly or rubbing the back. Suctioning is only needed in the presence of obvious secretions, as it may provoke vagally-induced bradycardia.

### *Assessment of Respirations and Heart Rate*

Presence of respiration versus apnea is assessed, and respiratory efforts are judged as unlabored versus gasping or labored.

An assistant should listen to the heartbeat immediately, indicating the rate by finger movement, or the rate can be detected from pulsation of the umbilical cord. Normally, the newborn’s heart rate is above 100 beats per minute.

## Ventilation

If the newborn is apneic or gasping, or if the heart rate is below 100 beats per minute after initial stabilization, then positive pressure ventilation (PPV) should begin. PPV via bag and mask should be instituted at a rate of 40 to 60 breaths per minute. The initial breath may require pressures of 30 to 40 cm H<sub>2</sub>O. Subsequent inflation pressures should be reduced to 15 to 20 cm H<sub>2</sub>O in an infant with normal lungs. A small plastic oropharyngeal airway may help maintain patency of the upper airway. Endotracheal intubation may be required if bag–mask ventilation is ineffective or prolonged. The administration of oxygen is controversial because studies demonstrate that both hypoxemia and excessive oxygen administration may be harmful to babies, and two recent meta-analyses suggest that room air resuscitation is associated with lower mortality than that with 100% oxygen.<sup>169,170</sup> Therefore, it is recommended that preductal pulse oximetry guides oxygen therapy with attention to target saturations listed in the box in [Figure 41-10](#), and that oxygen therapy be titrated to positive heart rate response.

**Table 41-6** Therapeutic Guidelines for Neonatal Resuscitation

Drug or Volume Expander	Concentration	Dosage	Route/Rate
Epinephrine	1:10,000	0.01–0.03 mg/kg (IV) 0.05–0.1 mg (IT)	IV or IT Give rapidly
Volume expanders	PRBCs Normal saline Lactated Ringer	10 mL/kg	Give over 5–10 min

IV, intravenously; IT, intratracheally; PRBCs, packed red blood cells.

## Chest Compressions

After adequate ventilation with oxygen for 30 seconds, if the heart rate is below 60 beats per minute, then chest compressions should be initiated. It is recommended that the operator encircle the chest with both hands, supporting the back with his hands and compressing the chest with his thumbs; alternatively, one may compress with two fingers. Compressions should take place on the lower third of the sternum, to a depth that is one-third of the anterior–posterior diameter of the chest. Care must be taken not to interfere with ventilation. Recommendations call for a 3:1 compression to ventilation ratio, with 90 compressions and 30 breaths delivered per minute.

Cardiac massage and ventilation should be maintained until the heart rate exceeds 60 beats per minute.

## Medications and Volume Expansion

Persistent neonatal bradycardia is most often a result of hypoxemia, and usually responds to ventilatory efforts. If the heart rate continues at less than

60 beats per minute despite adequate ventilation with 100% oxygen, then the newborn may need epinephrine, volume expansion, or both. It is recommended that epinephrine be administered intravenously as soon as access is established, at a dose of 0.01 to 0.03 mg/kg. In the absence of intravenous access, one may consider endotracheal administration of 0.05 to 0.1 mg/kg.

The use of naloxone or other medications in the delivery room is no longer recommended.

Hypovolemia frequently follows severe birth asphyxia because a greater-than-normal portion of fetal blood remains in the placenta. The infant may appear pale and have low arterial pressure, tachycardia, and tachypnea. If heart rate does not respond to other measures, then acute blood volume expansion may be accomplished with the intravenous administration of normal saline or Lactated Ringer solution, 10 mL/kg over 5 to 10 minutes, or, when blood loss is suspected, a similar volume of O-negative blood. Albumin is not recommended (Table 41-6).

### The APGAR Score

The scoring system introduced by Apgar is a useful method of clinically evaluating the infant, particularly at 1 and 5 minutes after delivery (Table 41-7).

**Table 41-7** APGAR Scores

Sign	0	1	2
Heart rate	Absent	<100 beats/min	>100 beats/min
Respiratory effort	Absent	Slow, irregular	Good, crying

Color	Pale, blue	Body pink, extremities blue	Completely pink

### Diagnostic Procedures

After the neonate is successfully resuscitated and stabilized, several diagnostic procedures may be indicated. To rule out choanal atresia, each nostril should be obstructed. Because newborns must breathe through their noses, occlusion of the nostril on the patent side causes respiratory obstruction. To rule out esophageal atresia, a suction catheter is inserted into the stomach. Gastric contents are aspirated; volume in excess of 12 mL after vaginal delivery and 20 mL after cesarean delivery may result from an abnormality of the upper gastrointestinal tract.

## Exit Procedure

The EXIT (ex utero intrapartum treatment) procedure, which maintains uteroplacental support for a period of time after partial delivery of the fetus, is employed for certain fetal conditions that pose an immediate threat to neonatal life on separation from the placental circulation. The most common indications are treatment of large fetal neck masses and reversal of tracheal occlusion from clips placed for congenital diaphragmatic hernia.<sup>171</sup> The usual procedure involves partial delivery of the fetus, surgical treatment of fetal pathology (e.g., attainment of a patent fetal airway), and, finally, delivery of the fetus and clamping of the umbilical cord.

Anesthetic considerations include maintenance of uterine relaxation during the phase of fetal manipulation, administration of fetal anesthesia, ensuring adequate fetal oxygenation, fetal monitoring, and rapid reversal of uterine relaxation after cord clamping to minimize maternal blood loss. Most often the mother is anesthetized with deep inhalation general anesthesia following a standard rapid-sequence induction. Maintenance of anesthesia with high concentrations of volatile anesthetic agents provides for uterine relaxation during the procedure, although a report highlighted the use of intravenous nitroglycerin for this purpose.<sup>172</sup> The use of high inspired inhalational anesthesia or nitroglycerin may be associated with maternal hypotension. Therefore, intravenous vasopressors may be required in order to ensure adequate uteroplacental blood flow. Use of volatile anesthetic concentrations less than 2 MAC is recommended to minimize untoward effects on uterine blood flow.<sup>173</sup> An FIO<sub>2</sub> of 1 helps maximize oxygen delivery to the placental unit.

Inhalational anesthetics rapidly cross the placenta and contribute to fetal anesthesia; intravenous opioids may be used to provide additional fetal anesthesia.<sup>173</sup> Intramuscular anesthetic agents, neuromuscular blocking agents, and atropine are administered to the fetus as needed after partial delivery. During the period of fetal manipulation, FHR and oxygenation can be monitored by sterile ultrasound and pulse oximetry sensors. A retrospective review of 31 EXIT procedures reported a mean FHR of 153 beats per minute and a mean fetal oxygen saturation of 71%.<sup>171</sup> After cord clamping, uterine relaxation must be reversed rapidly by decreasing the inspired concentration of inhalation agent and administering uterotonic agents such as oxytocin, so as to minimize maternal blood loss. The retrospective study previously referenced reported a mean maternal estimated blood loss of 848 mL and a mean duration of uteroplacental support of 30 minutes.<sup>171</sup>

Usually, two anesthetic teams are employed: One to tend to the mother and the other to care for the fetus/newborn. Communication and coordination between surgical, pediatric, anesthesia, and nursing teams is mandatory for successful outcomes.

## Anesthesia for Nonobstetric Surgery in the Pregnant Woman

In the United States, approximately 1% of pregnant women require nonobstetric surgical interventions during pregnancy.<sup>174</sup> The most frequent nonobstetric procedures are excision of ovarian cysts, appendectomy, cholecystectomy, breast biopsy, and surgery related to trauma. Serious conditions such as intracranial aneurysms, cardiac valvular disease, and pheochromocytoma present rarely during pregnancy and may not require surgical intervention until postpartum. Treatment of an incompetent cervix (cervical cerclage) typically occurs in early pregnancy or midpregnancy.

The goal for treating patients undergoing nonobstetric operative procedures is the same as with any patient; safe perioperative care. This goal is complicated by the need to consider the well-being of both mother and fetus. That said, surgical outcomes in pregnant patients are similar to nonpregnant patients. Miscarriage and rate of birth defects are not significantly different when compared to the general obstetric population.<sup>175</sup> One does need to recognize the effects of the patient's altered physiology. Induction and emergence from anesthesia is more rapid than in the nonpregnant state because of increased minute ventilation, decreased FRC, and the decreased MAC of volatile agents, which may be seen as early as 8 to 10 weeks of gestation. Supine hypotensive syndrome can occur as early as the second trimester. Gastric emptying is essentially normal in the first two trimesters, but is prolonged in the third. Gastroesophageal sphincter tone is decreased after 20 weeks, thus caution regarding the unprotected airway is essential.<sup>23</sup> The effects of altered physiology during pregnancy are not limited to general anesthesia. There is an increased effect of local anesthetics during pregnancy; thus, the amount of local anesthetic administered should be reduced by 25% to 30% during any stage of pregnancy.

Teratogenicity may be induced at any stage of gestation. However, most of the critical organogenesis occurs in the first trimester (days 13 to 60). Although many commonly used anesthetics are teratogenic at high doses in animals, few, if any, studies support teratogenic effects of anesthetic or sedative medications in the doses used for human anesthesia care. Medicinal doses of benzodiazepines are safe when needed to treat perioperative anxiety.

Nitrous oxide has also been suggested to be teratogenic in animals when administered for prolonged periods (1 to 2 days).<sup>176</sup> Its effect on DNA synthesis is of concern for its use in humans. Although teratogenesis has been seen only in animals under extreme conditions, not likely to be reproduced in clinical care, some believe that nitrous oxide use is contraindicated in the first two trimesters.

One of the largest studies regarding reproductive outcome after surgery

during pregnancy is a Swedish registry review covering the years 1973 to 1981.<sup>177</sup> During this period, there were a total of 720,000 births, 5,405 of them after anesthesia and surgery during pregnancy. The results of this study are reassuring in that there was no increased incidence of congenital anomalies or stillbirths among infants exposed in utero to maternal surgery and anesthesia. However, in this group, there was an increased frequency of very low and low birth weights, and of deaths within 168 hours after delivery. The reasons for this are unclear and are not related to any specific type of operation. The authors postulated that the maternal illness itself might have been a major contributor to adverse neonatal outcome.

Recent studies showing accelerated neuronal cell death in immature rat brain exposed to anesthetics raise concerns regarding use of general anesthetics.<sup>178</sup> It is premature to suggest that impairment seen in the developing rat brain with general anesthesia can be extrapolated to humans. Further human studies are also inconclusive regarding anesthesia exposure in utero or in early childhood.<sup>179</sup>

Intrauterine fetal asphyxia is avoided by maintaining maternal PaO<sub>2</sub>, PaCO<sub>2</sub>, and uterine blood flow. PaCO<sub>2</sub> can affect uterine blood flow as maternal alkalosis may cause direct vasoconstriction. Alkalosis also shifts the oxyhemoglobin dissociation curve, resulting in the release of less oxygen to the fetus at the placenta. Maternal hypotension leads to a reduction in uterine blood flow and thus fetal hypoxia. Uterine hypertension, as occurs with increased uterine irritability, will also decrease uterine blood flow.

To summarize, elective surgery should be delayed until the patient is no longer pregnant and she has returned to her nonpregnant physiologic state (approximately 2 to 6 weeks postpartum). Procedures that can be scheduled with some flexibility but cannot be delayed until postpartum are best scheduled in the second trimester. This lessens the risk for teratogenicity (first-trimester medication administration) or preterm labor (greater risk in the third trimester) (Fig. 41-11).

If emergency surgery is required, there is no data to suggest that any **13** well-conducted anesthetic is preferred over another, provided oxygenation and blood pressure are maintained and hyperventilation is avoided. Despite this statement, regional anesthesia should be considered as it minimizes fetal exposure to medications. Left uterine displacement should be used during the second and third trimesters, and aspiration prophylaxis should be administered to all pregnant patients after approximately 20 weeks of gestation. At a minimum, pre- and postoperative FHR and uterine activity should be assessed.<sup>180</sup>

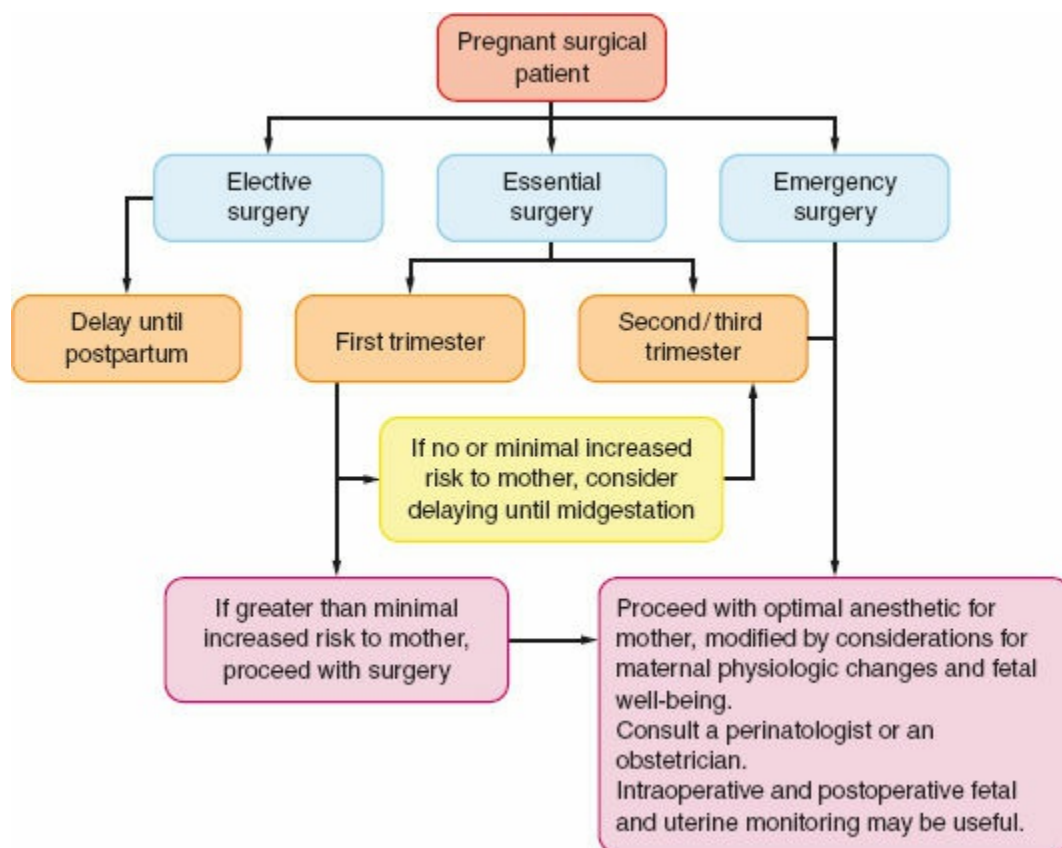

## *Practical Suggestions*

It is generally agreed that only surgical procedures that cannot be delayed for months, including emergency surgery, should be performed during pregnancy, particularly in the first trimester. The possibility of pregnancy should be considered in all female surgical patients of reproductive age. On the basis of the maternal and fetal hazards already described, the  following approach to anesthesia is suggested (Fig. 41-11):

1. Anesthesiologists and surgeons should obtain consultation from an obstetrician before performing nonobstetric surgery in pregnancy.
2. The patient's apprehension should be allayed as much as possible by personal reassurance during the preanesthetic visit and by adequate sedation and premedication.
3. Pain should be relieved whenever present.
4. A nonparticulate antacid (15 to 30 mL), should be administered within half an hour before induction of anesthesia. Ranitidine and metoclopramide may be useful.
5. Beginning in the second trimester, uterine displacement must be maintained at all times.
6. Hypotension related to spinal or epidural anesthesia should be prevented as much as possible by rapid intravenous infusion of crystalloid solution during induction of anesthesia. If the mother becomes hypotensive, ephedrine or phenylephrine should be promptly administered intravenously.
7. General anesthesia should be preceded by careful denitrogenation.
8. The risk of aspiration should be minimized by application of cricoid pressure and rapid tracheal intubation with a cuffed tube.
9. To reduce fetal hazard, particularly during the first trimester, it appears preferable to choose drugs with a long history of safety. These drugs include thiopental, morphine, meperidine, muscle relaxants, and low concentrations of nitrous oxide.
10. Avoid maternal hyperventilation and monitor end-expiratory PaCO<sub>2</sub> or arterial blood gases.
11. FHR may be monitored continuously or intermittently throughout surgery and anesthesia, provided that placement of the transducer does not encroach on the surgical field (this becomes technically feasible from the 16th week of pregnancy). The decision to monitor the fetus should be made in conjunction with the obstetrician based on the severity of maternal disease, the potential for fetal jeopardy, whether the fetus is viable, and whether a physician able to perform a cesarean delivery plans to be immediately available. Uterine tone may also be monitored with an external tocodynamometer if the uterus reaches the umbilicus or above.
12. Monitoring uterine activity should be continued after the operation,

and tocolytic agents may be required.

# 42 Neonatal Anesthesia

JUSTIN B. LONG • SANTHANAM SURESH

## Physiology of the Infant and the Transition Period

- The Cardiovascular System
- The Pulmonary System
- The Renal System
- Fluid and Electrolyte Therapy in the Neonate
- Blood Component Therapy in the Neonate
- The Hepatic System
- Anatomy of the Neonatal Airway
- Anesthetic Drugs in Neonates

## Anesthetic Management of the Neonate

- Preoperative Considerations
- Intraoperative Considerations
- Impact of Surgical Requirements on Anesthetic Technique
- Uptake and Distribution of Anesthetics in Neonates
- Anesthetic Dose Requirements of Neonates
- Regional Anesthesia
- Postoperative Pain Management
- Postoperative Ventilation

## Special Considerations

- Maternal Drug Use during Pregnancy
- Temperature Control and Thermogenesis
- Respiratory Distress Syndrome
- Postoperative Apnea
- Retinopathy of Prematurity
- Neurodevelopmental Effects of Anesthetic Agents

## Surgical Procedures in Neonates

- Surgical Procedures in the First Week of Life
- Surgical Procedures in the First Month of Life

## Summary

## Acknowledgment

## KEY POINTS

- 1 Understanding the physiologic changes that occur during the transition

from fetal to neonatal life is crucial to the anesthetic management of the neonate. The circulatory, pulmonary, hepatic, and renal systems are all affected in this process.

- 2 Important physiologic and anatomic factors account for the rapid rate of desaturation observed in neonates. These include an increase in oxygen consumption, a higher closing volume, a high ratio of minute ventilation to functional residual capacity, and a pliable rib cage.
- 3 Persistent pulmonary hypertension of the newborn is a pathologic condition that can be primary but is often secondary to other conditions, including meconium aspiration, sepsis, congenital diaphragmatic hernia, or pneumonia. Understanding the pathophysiologic characteristics of this condition helps guide therapy.
- 4 Knowledge of the major anatomic differences between the infant and the adult airway helps one understand why the infant's airway is often described as "anterior" and why airway management may be challenging. These differences include a relatively large tongue, a cephalad glottis with anterior slanting vocal folds, a larger occiput, and a narrowing at the cricoid ring.
- 5 Careful attention must be given to the choice of anesthetic agents and dosing of such agents in the neonatal population. Ongoing maturational changes in the renal and hepatobiliary systems, which occur during the first 30 days of life, will affect the metabolism and elimination of many anesthetic agents.
- 6 Although a host of anesthetic techniques are available, including regional anesthesia, multiple factors are considered when choosing an anesthetic plan for the neonate. These include the surgical requirements, the need for postoperative ventilation, the cardiovascular stability of the neonate, and the anticipated method of postoperative pain control.
- 7 Special considerations must be addressed when planning an anesthetic for a neonate. Some of the controversial issues include the risk of postoperative apnea, the role of oxygen concentration in the development of retinopathy of prematurity, and the neurocognitive effects of anesthetic agents on the fetal and neonatal brain.
- 8 True surgical emergencies are uncommon in the neonatal period. Knowledge of conditions with comorbidities, such as tracheoesophageal fistula, omphalocele, and congenital diaphragmatic hernia, and a thorough preoperative evaluation and stabilization of such neonates cannot be overemphasized.

## **Physiology of the Infant and the Transition Period**

An infant's first year of life is characterized by a miraculous growth in size

and maturity. The body weight alone changes by a factor of three, and there is no other period in extrauterine life when changes occur so rapidly. Before birth, fetal growth and development depend on the genetic composition of the fetus, the mother's placental function, and potential exposure to chemicals or infectious agents that can affect the mother, fetus, or both. After birth, the newborn must rapidly adjust to the extrauterine environment to survive. The dramatic changes in functions of several systems will determine the viability of the neonate, as well as its ability to grow and develop properly.

The newborn period has been defined as the first 24 hours of life, and the neonatal period as the first 28 days of life. There is significant change 1 in many physiologic systems during both of these periods. The first 72 hours are especially significant for the cardiovascular, pulmonary, and renal systems. The changes in these systems are interrelated; inadequate progression of change or a disease state altering one of these systems can quickly alter the maturation of one or more of the other systems. Understanding the differences in these systems from the older child, as well as the changes that occur in the neonatal period, is important in developing a comprehensive anesthetic approach.

## *The Cardiovascular System*

### **Fetal Circulation**

The fetal circulation is characterized by a parallel system in which both ventricles pump most of their output into the systemic circulation. Less than 10% of the combined cardiac output goes through the fetal circulation as a result of the ductus arteriosus (Fig. 42-1A). The placenta provides oxygenated blood into the ductus venosus, the inferior vena cava, and then into the right atrium. In the right atrium, the majority of the oxygenated blood primarily flows through the foramen ovale into the left atrium, bypassing the right ventricle and the pulmonary vascular bed. This preferential flow across the foramen occurs because of the relatively low pressure in the left atrium compared with that of the right atrium. Some blood from the right atrium does flow through the right ventricle and into the main pulmonary artery. The pulmonary vascular resistance is quite high in utero because of alveolar collapse and compression of blood vessels, inhibiting flow through the pulmonary circulation. The pulmonary vascular resistance is also high at this point because of the relatively low  $P_{aO_2}$  and pH of the blood that does flow through the vessels. Some blood in the pulmonary artery does flow through the pulmonary circulation and then into the left atrium, but the majority of flow goes through the ductus arteriosus into the descending aorta.

**Figure 42-1 A:** Schematic representation of the fetal circulation. Oxygenated blood leaves the placenta in the umbilical vein (*vessel without stippling*). Umbilical vein blood joins blood from the viscera (represented here by the kidney, gut, and skin) in the inferior vena cava. Approximately half of the inferior vena cava flow passes through the foramen ovale to the left atrium, where it mixes with a small amount of pulmonary venous blood, and this relatively well-oxygenated blood (denoted by *stippling*) supplies the heart and brain by way of the ascending aorta. The other half of the inferior vena cava stream mixes with superior vena cava blood and enters the right ventricle (blood in the right atrium and ventricle has little oxygen). Because the pulmonary arterioles are constricted, most of the blood in the main pulmonary artery flows through the ductus arteriosus (DA) so the descending aorta's blood has less oxygen (*heavy stippling*) than does blood in the ascending aorta (*light stippling*). **B:** Schematic representation of the circulation in the normal newborn. After expansion of the lungs and ligation of the umbilical cord, pulmonary blood flow and left atrial and systemic arterial pressures increase. When left atrial pressure exceeds right atrial pressure, the foramen ovale closes so all inferior and superior vena cava blood leaves the right atrium, enters the right ventricle, and is pumped through the pulmonary artery toward the lung. With the increase in systemic arterial pressure and decrease in pulmonary artery pressure, flow through the ductus arteriosus becomes left to right, and the ductus constricts and closes. The course of circulation is the same as in the adult. (Reprinted with permission from Phibbs R. Delivery room management of the newborn. In: Avery GB, ed. *Neonatology, Pathophysiology and Management of the Newborn*. 2nd ed. Philadelphia, PA: JB Lippincott; 1981:184.)

### Changes at Birth

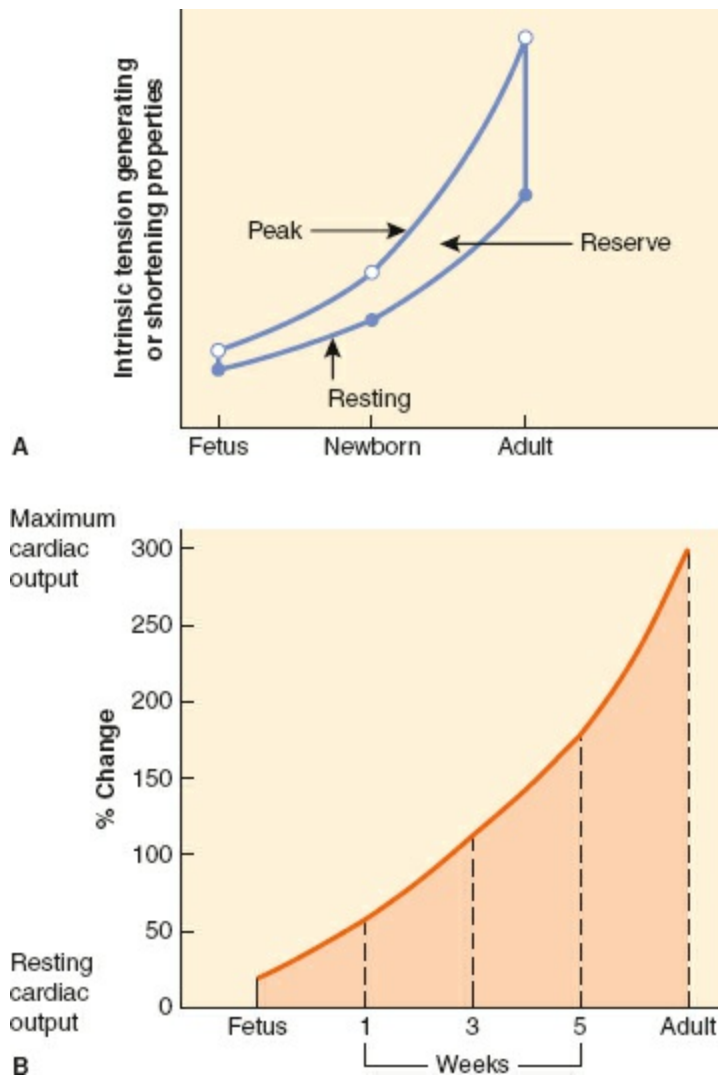

After birth, all of these shunts are eliminated or start to close quickly.<sup>1</sup> The placental shunt is eliminated and the ductus venosus is closed. The newborn's left ventricle is now pumping blood into the higher pressure systemic circulation exclusively. Expansion of the lungs and initiation of breathing lead to dramatic changes in both the circulatory and pulmonary systems (Fig. 42-1B). As alveoli fill with air, the compression of the pulmonary alveolar capillaries is relieved, reducing pulmonary vascular resistance and promoting flow through the pulmonary circulation. This blood is now oxygenated, raising the arterial PO<sub>2</sub>, and further reducing pulmonary vascular resistance. Although the change in the first minutes to hours is dramatic, it usually takes 3 to 4 days for the pulmonary vascular resistance to decrease to normal levels. The foramen ovale will usually functionally close in the first hour of life as the increase in left atrial pressure from increased pulmonary circulation after the initiation of breathing exceeds right atrial pressure. The foramen is closed by a flap of tissue. This foramen can reopen if there is a relative increase in right atrial pressure such as is seen with elevated pulmonary vascular resistance or fluid overload. Anatomic closure usually occurs in the first year of life, but may remain probe-patent into adulthood in 10% to 20% of patients. The ductus arteriosus starts to close in the first day of life and is usually functionally closed in the second day of life. In utero, patency of the ductus was maintained by the combined relaxant effects of low oxygen tension and endogenously produced prostaglandins, especially prostaglandin E<sub>2</sub>. In a full-term neonate, oxygen is the most important factor controlling ductal closure. When the PaO<sub>2</sub> of blood in the ductus rises to about 50 mmHg, the muscle in the vessel constricts. It should be noted that the ductus of a preterm infant is less responsive to increased oxygen, even though its musculature is developed.

Myocardial function is different in the neonate. The neonatal cardiac myocyte has less organized contractile elements than the child or adult.<sup>2</sup> Not only are there fewer myofibril elements, but they are not organized in parallel roles, as seen in the child and adult heart, making them less efficient. The neonate myocyte also has a less mature sarcoplasmic reticulum system. The underdeveloped sarcoplasmic reticulum is associated with a decrease in Ca<sup>2+</sup>-adenosine triphosphatase activity, an important component of contractility. As the sarcoplasmic reticulum matures, the efficiency of calcium transport and subsequent contractility increases.<sup>3</sup> The neonatal myocardium cannot generate as much force as that of the older child and is relatively noncompliant. Consequently, there is limited functional reserve in the neonatal period, with afterload increases particularly poorly tolerated. After birth, there are dramatic changes in the myocardium. As the work of the ventricles increases secondary to high stroke volume and increased vascular resistance, these myocytes grow quickly in number and size. This growth is

more dramatic in the left ventricle than the right ventricle because of the rise in systemic vascular resistance and fall in pulmonary vascular resistance. Cardiac output is markedly different in the neonate, up to 400 mL/kg/min, falls in infancy to around 200 mL/kg/min, and is 100 mL/kg/min by adolescence approaching adult values of 70 to 80 mL/kg/min.

Especially in the first 3 months of life, the parasympathetic nervous system influence on the heart is more mature than the sympathetic system and the myocardium does not respond to inotropic support as well as the older child or adult. There is animal evidence that there are maturational changes in  $\beta$ -adrenergic receptor function that explain the decreased responsiveness to inotropes in the neonate.<sup>4</sup> The neonatal myocardium has increased glycogen stores and higher rates of anaerobic glycolysis, which may explain its relative resistance to hypoxia and better performance in the presence of an ischemic insult. Because the myocardium is relatively noncompliant in the newborn, preload changes can increase stroke volume and cardiac output, but not as effectively as in the older child.<sup>5</sup> In other words, the Frank–Starling relationship is present in the neonatal heart, but is not as effective as in the adult. Therefore, the clinical implication of a noncompliant ventricle is that, in the absence of significant increases in stroke volume, cardiac output is not well maintained in the presence of bradycardia. Finally, neonates have immature baroreceptors. The baroreceptor is responsible for reflex tachycardia that occurs in response to hypotension. Therefore, the immaturity of this reflex would limit the neonate's ability to compensate for hypotension by increasing heart rate. In addition, the baroresponse of the neonate is more depressed than that of the adult at the same level of anesthesia.

In summary, the neonatal heart has some significant differences when compared to the mature heart. Resting cardiac output is much higher relative to body weight than in the adult because of the higher O<sub>2</sub> consumption per kilogram of body weight. Stimulation of the myocardium produces a limited increase in contractility and cardiac output. The sympathetic nervous system, which usually provides the important chronotropic and inotropic support to the mature circulation during stress, is severely limited in the neonate because of relative lack of development when compared with the parasympathetic nervous system. Even in the absence of stress, the neonatal heart has limited ability to increase cardiac output compared with the mature heart (Fig. 42-2). The resting cardiac output of the immature heart is close to the maximal cardiac output, so there is limited reserve. The mature heart can increase cardiac output by 300%, whereas the immature heart can only increase cardiac output by 30% to 40%.

**Figure 42-2** Schema of reduced cardiac reserve in fetal and newborn animal hearts compared with adult hearts. **A:** In the newborn infant, resting cardiac muscle performance is close to a peak of ventricular function because of limitations in diastolic, systolic, and heart rate reserve. **B:** Similarly, pump reserve early in life is limited by these factors and by much higher resting cardiac output relative to body weight, compared with that in adults. **Table 42-1** Normal Blood Gas Values in the Neonate

Subject	Age	PO <sub>2</sub> (mmHg)	PCO <sub>2</sub> (mmHg)	pH
Fetus (term)	Before labor	25	40	7.37
Fetus (term)	End of labor	10–20	55	7.25
Newborn (term)	10 min	50	48	7.2
Newborn (term)	1 h	70	35	7.35
Newborn (term)	1 wk	75	35	7.4
Newborn (preterm, 1,500 g)	1 wk	60	38	7.37

## The Pulmonary System

The pulmonary system develops rapidly during the last trimester, with important changes in both the number of alveoli and the maturity of the pulmonary vascular system.<sup>6</sup> These systems have not matured enough to provide adequate gas exchange until about 24 to 26 weeks' gestation. The airways and alveoli continue to grow after birth, with alveoli increasing in number until about 8 years of age.<sup>7</sup> With the initiation of ventilation, the pulmonary system changes dramatically. The alveoli transition from a fluid-filled to an air-filled state and a normal ventilatory pattern with normal volumes develops in the first 5 to 10 minutes of life. In order to adequately expand the collapsed and fluid-filled alveoli, the newborn will generate an initial negative intrathoracic pressure in the range of 40 to 60 cm H<sub>2</sub>O. By 10 to 20 minutes of life, the newborn has achieved its near-normal functional residual capacity (FRC), and the blood gases stabilize with the establishment of increased pulmonary blood flow. [Table 42-1](#) lists the normal blood gases for the various periods of life. The initial breaths to expand the lungs and subsequently maintain FRC are necessary components of the stabilization of the ventilatory system, as well as the circulatory system. Failure to do so will quickly lead to deterioration of both systems.

**2** Tidal volume is roughly the same in the neonate as the child or adult on a volume/kilogram body weight measure, but the respiratory rate is increased. Closing volumes are particularly high and may be within the range of the normal tidal volume ([Fig. 42-3](#)). This increased minute ventilation mirrors the higher oxygen consumption in neonates, which is about double that seen in an adult. Because the FRC in the newborn is comparable to that of the older child or adult, but the minute ventilation is much higher, the ratio of minute ventilation to FRC is two to three times higher in the newborn. The clinical significance of this ratio is twofold. First, anesthetic induction with a volatile anesthetic agent should be faster, as should emergence. Second, the decrease in FRC relative to minute ventilation and oxygen consumption means that there is less "oxygen reserve" in the FRC compared to that of older children and adults. There will be a more rapid drop in arterial oxygen levels in the newborn in the presence of apnea or hypoventilation. [Table 42-2](#) compares normal respiratory parameters in the normal newborn and adult.

**Figure 42-3** Static lung volumes of infants and adults. CC, closing capacity; FRC, functional residual capacity; VC, vital capacity. (Reprinted with permission from Smith CA, Nelson NM. *Physiology of the Newborn Infant*. 4th ed. Springfield, IL: Charles C Thomas; 1976:207.)

Lung compliance is relatively low, but chest wall compliance is relatively high, compared to that of older children. The pliable rib cage gives less mechanical support than in the older child, leading to significant retractions with less efficient gas exchange and functional airway closure, thus increasing the work of breathing. The intercostal muscles are poorly developed at birth, with the diaphragm providing most of the gas exchange. The diaphragm in the neonate has two types of fibers, the type 1, slow twitch, high-oxidative fibers that give sustained contraction with very little fatigue, and the type 2, fast twitch, low-oxidative fibers that give quick contractions but fatigue easily. The distribution of these fibers in the newborn shows only about 25% type 1 fibers, whereas 55% of the fibers are type 1 in the mature diaphragm at about 2 years of age. The preterm newborn has even fewer type 1 fibers at birth, in the 10% range. This relative lack of type 1 fibers means that the newborn, especially the preterm, is at risk for diaphragmatic fatigue in the presence of significant resistance to ventilation or periods of hyperventilation.

Finally, the continued presence of surfactant is necessary to maintain both the distensibility of the alveoli and the maintenance of an FRC at exhalation. Decreased surfactant production, due to prematurity or other conditions such as maternal diabetes, can cause respiratory distress syndrome (RDS). The decreased surfactant can cause alveolar collapse, decrease in lung compliance, hypoxia, increased work of breathing, and respiratory failure. Commercially available surfactant is extraordinarily useful to both treat and prevent RDS in susceptible patients. In addition, surfactant can improve gas exchange in preterm neonates who may not have RDS, but are stressed by sepsis, heart failure, or other systemic problems.<sup>8</sup> Delivered through an endotracheal tube,

it can be used prophylactically in the very preterm newborn to prevent RDS, as well as treat neonates who have developed RDS.

**Table 42-2** Comparison of Normal Respiratory Values in Infants and Adults

Parameter	Infant	Adult
Respiratory frequency (breaths/min)	30–50	12–16
Tidal volume (mL/kg)	7	7
Dead space (mL/kg)	2–2.5	2.2
Alveolar ventilation (mL/kg/min)	100–150	60
Functional residual capacity (mL/kg)	27–30	30
Oxygen consumption (mL/kg/min)	7–9	3

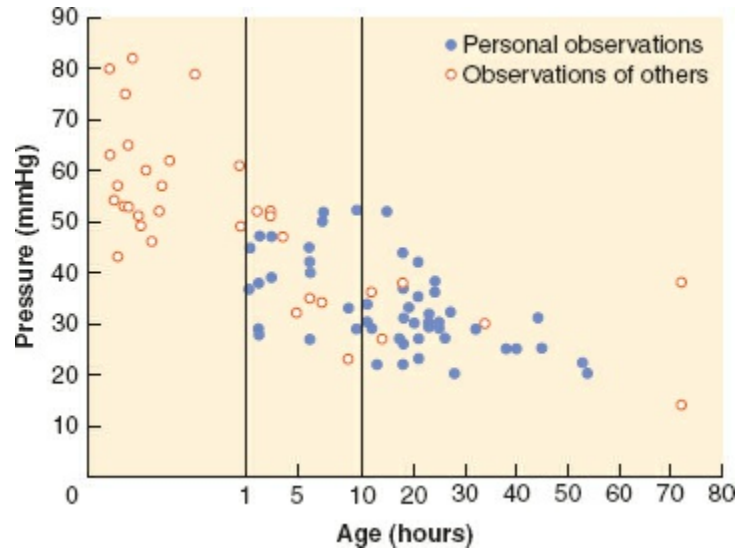

In addition to the mechanical aspects of the pulmonary system, control of breathing has unique aspects in the neonatal period, especially in the preterm neonate. Neonates respond less to hypercapnia than the older child. In addition, neonates respond to hypoxia with a brief period of hyperventilation, followed by hypoventilation. The initial hyperventilatory response is prevented by hypothermia, further increasing risk of hypoventilatory response to hypoxia. Finally, a periodic breathing pattern is common in neonates, especially in preterm newborns, and can persist up to a year of age.

### Persistent Pulmonary Hypertension of the Newborn

**3** The pulmonary circulation is extremely sensitive to oxygen, pH, and nitric oxide, a variety of mediators such as adenosine and prostaglandins, and mechanical factors such as lung inflation. [Figure 42-4](#) illustrates the correlation of the mean pulmonary artery pressure with age during the first 3 days of life. Hypoxia and acidosis, along with inflammatory mediators, may cause pulmonary artery pressure either to persist at a high level or, after initially decreasing, to increase to pathologic levels. The result is termed *persistent pulmonary hypertension of the newborn* (PPHN), sometimes referred to as *persistent fetal circulation*. PPHN occurs in term and preterm infants, usually caused by precipitating conditions such as severe birth asphyxia, meconium aspiration, sepsis, congenital diaphragmatic hernia (CDH), and maternal use of nonsteroidal anti-inflammatory drugs with in utero constriction of the ductus arteriosus, although it is often idiopathic. Other risk factors include maternal diabetes, maternal asthma, and cesarean delivery.<sup>9</sup>

Elevated pulmonary vascular resistance causes both the ductus arteriosus and foramen ovale to remain open, with subsequent right-to-left shunting which bypasses the pulmonary circulation. These changes result in profound hypoxia from right-to-left shunting and a normal or elevated PaCO<sub>2</sub>. The hypoxemia is often noted to be out of proportion to the other presenting signs

of respiratory and cardiovascular compromise. Treatment starts with correcting any predisposing disease (hypoglycemia, polycythemia) and improving poor tissue oxygenation. The response to therapy is often unpredictable. However, the goals are to achieve a PaO<sub>2</sub> of 60 to 100 mmHg and maintain normocapnia.<sup>10</sup>

**Figure 42-4** Correlation of mean pulmonary arterial pressure with age in 85 normal-term infants studied during the first 3 days of life. (Adapted from Emmanouilides GC, Moss AJ, Duffie ER, et al. Pulmonary arterial pressure changes in human newborn infants from birth to 3 days of age. *J Pediatr.* 1964;65:327.)

In addition to standard mechanical ventilation, high-frequency ventilation, exogenous surfactant, inhaled nitric oxide (iNO), alkalization, and extracorporeal membrane oxygenation (ECMO) have been used with varying degrees of success. In particular, the use of iNO is becoming more common and is indicated when the newborn expresses an oxygen index of 15 or more. However, iNO has not been shown to reduce the need for ECMO in neonates with congenital diaphragmatic hernia.<sup>11,12</sup> iNO remains the only United States Food and Drug Administration (FDA) approved medication for treatment of PPHN. Additional vasodilator therapy with prostacyclin (epoprostenol), phosphodiesterase inhibitors (sildenafil), and endothelin receptor antagonists (bosentan) has enjoyed varying levels of success beyond the neonatal period, into infancy. Success in treatment, and survival, varies directly with correction the underlying cause. Significant prognostic factors for PPHN are the ability of therapy to reduce pulmonary vascular resistance and the occurrence of associated complications, such as ischemic encephalopathy.

Maintenance of right ventricular function is paramount to survival in PPHN. Use of dobutamine in a normotensive patient may provide inotropy and decreased systemic vascular resistance, which could increase right-to-left shunting and offload the right ventricle.<sup>13</sup> Therapy is now often guided with

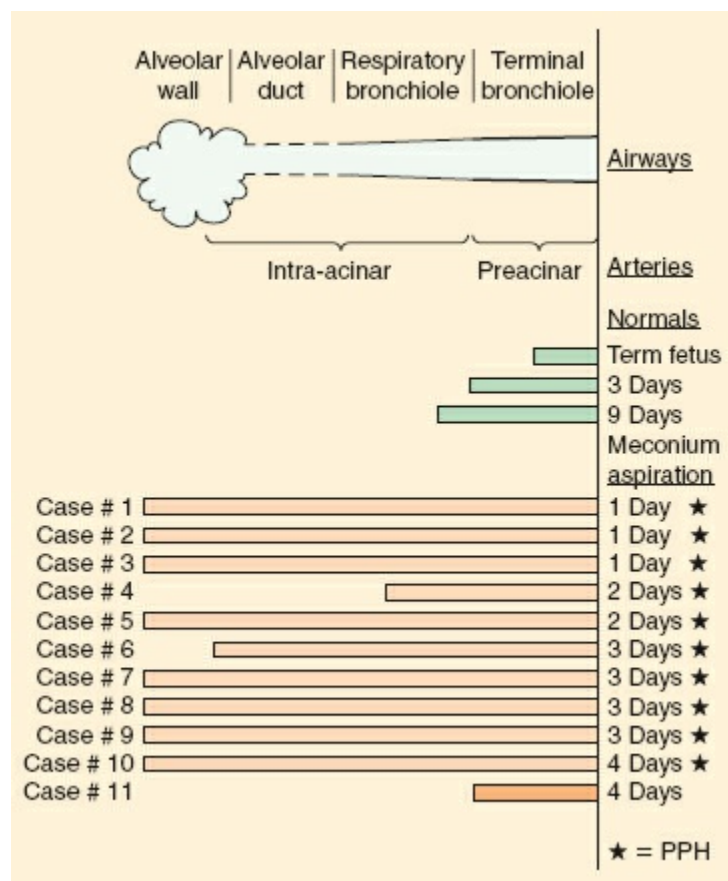

the use of point-of-care echocardiography as its availability continues to grow and technology improves.<sup>14</sup> Preoperative assessment of the echocardiogram by the pediatric anesthesiologist may help predict what problems may be encountered in the operative environment. Also, the availability of very small transesophageal echocardiogram (TEE) probes make the possibility of real-time monitoring of cardiac function in the operating room a reality. However, insertion of even the smallest TEE probes requires close attention to ventilator parameters in very small (< 3 kg) neonates.<sup>15</sup>

## **Meconium Aspiration**

One of the most important pulmonary challenges in the newborn period is *meconium aspiration*. Interference with the normal maternal placental circulation in the third trimester may cause fetal hypoxia. Fetal hypoxia can result in an increase in the amount of muscle in the blood vessels of the distal respiratory units. [Figure 42-5](#) illustrates the muscle increase found in blood vessels of a series of 11 infants who died of PPHN.<sup>16</sup> Chronic fetal hypoxia leads to the passage of meconium in utero. The fetus breathes in utero so the meconium mixed with amniotic fluid enters the pulmonary system. Meconium aspiration can be a marker of chronic fetal hypoxia in the third trimester. This condition is different from the meconium aspiration that occurs during delivery. Meconium at birth is thick and tenacious, and mechanically obstructs the tracheobronchial system. Meconium aspiration syndrome leads to varying degrees of respiratory failure, which can be fatal in spite of all treatment modalities.

Current recommendations for intubation and suctioning for newborns at delivery with frank meconium aspiration or meconium staining (approximately 10% of newborns) emphasize a conservative approach.<sup>17</sup> Routine oropharyngeal suctioning of meconium is recommended immediately at the time of delivery, but tracheal intubation and suctioning should be performed selectively. If the newborn is vigorous and crying, no further suctioning is needed. If meconium is present and the newborn is depressed, the trachea should be intubated and meconium and other aspirated material suctioned from beneath the glottis. If meconium is retrieved and no bradycardia is present, reintubate and suction. If there is bradycardia, administer positive pressure ventilation and consider suctioning again later once the neonate is stabilized.

**Figure 42-5** Diagram of muscle extension along pulmonary arterial branches (*shaded bars*). In the normal newborn, virtually no intra-acinar artery is muscular. In 9 of 10 infants with meconium aspiration and persistent pulmonary hypertension (PPH), muscle extended into the most peripheral arteries; the infant with meconium aspiration without PPH (case 11) had normal intra-acinar arteries. (Reprinted with permission from Murphy JD, Vawter GF, Reid LM. Pulmonary vascular disease in fetal meconium aspiration. *J Pediatr*. 1984;104:758.)

## The Renal System

In utero, most of the fetal waste material is removed by the maternal placenta. In effect, the fetal kidneys are passive, receiving relatively little renal blood flow and having a low glomerular filtration rate (GFR).<sup>18</sup> There are four major reasons for the low renal blood flow and GFR: low systemic arterial pressure, high renal vascular resistance, low permeability of the glomerular capillaries, and the small size and number of glomeruli. In utero, the kidneys receive only about 3% of the cardiac output, whereas they will receive about 25% of cardiac output in adulthood. At birth, this changes dramatically. The systemic arterial pressure increases and the renal vascular resistance decreases, and the kidneys now receive a progressively increased part of the cardiac output. At birth, the GFR is low, but increases significantly in the first few days of life, doubles in the first 2 weeks, and reaches adult levels by about 2 years of age. The limited ability of the newborn's kidney to concentrate or dilute urine results from this low GFR and decreased tubular

function. However, during the first 3 to 4 days, the circulatory changes increase renal blood flow and GFR, improving the neonate's ability to concentrate and dilute the urine. Part of the improvement in renal function is the establishment of gradients in the medullary interstitium that promotes resorption of sodium. This maturation continues in the normal, full-term neonate and the kidneys are approximately 60% mature by 1 month of age. Urine output is low in the first 24 hours, but increases to an expected level of at least 1 to 2 mL/kg/hr. Urine output, after the first day of life, of less than 1 mL/kg/hr should be considered indicative of either hypovolemia or decreased renal function from another cause.

Despite rapid maturation of renal function and increased capacity of the neonatal kidneys, they still have limitations. From an anesthetic standpoint, the half-life of medications excreted by means of glomerular filtration will be prolonged.<sup>19</sup> The relative inability to conserve water means that neonates, especially in the first week of life, tolerate fluid restriction poorly. In addition, the inability to excrete large amounts of water means the newborn tolerates fluid overload poorly. The newborn kidney is better able to conserve sodium than excrete sodium, making hyponatremia a risk if excess sodium is administered. However, because of the lack of tonicity in the medullary interstitium shortly after birth, there will be some obligate sodium loss in the first days of life. Sodium loss improves as the countercurrent multiplier is developed in the interstitium.

### ***Fluid and Electrolyte Therapy in the Neonate***

Total body water (TBW), which is usually described in terms of percent of body weight, varies by both age and gestational status. The highest TBW is found in the fetus, but decreases to about 80% of body weight for a term neonate at birth. Preterm neonates have a higher TBW than term infants, 85% of body weight, up to 90% of body weight in very low-birth-weight (VLBW) preterm neonates. TBW decreases during the first 6 months of life to about 60% of body weight, remaining this level through childhood.

TBW is distributed between two compartments, intracellular fluid (ICF) and extracellular fluid (ECF). The ECF volume is larger than the ICF volume in the fetus and newborn, usually in the 40% (ECF) and 20% (ICF) of body weight ranges. This ratio is the inverse of the ECF and ICF relationship observed in infants and children. There is a significant diuresis and natriuresis after birth that produces a decrease in the ECF volume. In addition, ICF volume increases because of the growth of cells in the body. The ECF and ICF volumes (20% and 40% of body weight) approach adult values per body weight by about 1 year of age. This dramatic shift is beneficial to the child, especially in increasing the mobility of reserves in the face of dehydration.

Fluid can be easily mobilized from ICF volumes to replenish intravascular volume that is lost from fasting, fever, diarrhea, or other causes. Thus, an infant or child is better situated to maintain intravascular volume in these situations than a neonate.

The ECF is divided into the plasma and the interstitial fluid. The plasma water is usually about 5% of body weight and the related blood volume, assuming a hematocrit of 45%, is about 8% of body weight in infants and children. The water content is slightly higher in neonates and may approach 10% of body weight in preterm neonates. The interstitial fluid, usually about 15% of body weight, can demonstrate large increases in disease states such as liver failure, heart failure, renal failure, and other causes fluid retention, such as pleural effusions or ascites. Any condition that decreases oncotic pressure, such as loss of albumin in liver failure, promotes the loss of fluid into the interstitial fluid. On the other hand, raised hydrostatic pressures, such as seen in heart failure, can result in fluid leaving the plasma and accumulating in the interstitial space. Conditions that result in translocation of fluid from the plasma to the interstitial spaces, whether because of decreased oncotic pressure or increased hydrostatic pressure, are of significant consequence to the neonate. Loss of fluid from the plasma volume compromises the intravascular volume, potentially decreasing the perfusion of vital organs and systems.

The blood volume in the normal full-term newborn is approximately 90 mL/kg and approximately 100 mL/kg in preterm, VLBW, or critically ill newborns. However, these estimates of intravascular volumes are variable between studies. Approximately half of the intravascular volume in a newborn is plasma volume. For all practical purposes, electrolyte values in the neonatal period are the same as in the child and adult with the exception of potassium, which can be about 1 to 2 mmol/L higher than average for the first 2 days of life.<sup>20</sup>

Maintenance fluid requirements increase during the first days of life. They have been estimated to be 60, 75, 90, 105, 120, 135, and 150 mL/kg/24 hr for the first 7 days of life, respectively. For the rest of the neonatal period, a maintenance rate of 150 mL/kg/24 hr is appropriate.<sup>21</sup>

The appropriate type of maintenance fluid depends on several issues. Because of ongoing sodium loss secondary to the inability of the neonatal distal tubule to respond fully to aldosterone, intravenous fluids in the neonate must contain some sodium. Most operations on neonates involve loss of blood and ECF, which must be replaced with a fluid of similar electrolyte content (i.e., a near-isotonic solution such as lactated Ringer or PlasmaLyte). Hypotonic solutions should not be used to replace these losses because they can cause significant hyponatremia. Thus, if the neonate is already stable on a maintenance solution, it is reasonable to continue this maintenance at a

constant rate, adding balanced salt solution, colloid, or blood products as needed to offset ongoing surgical or insensible losses.

The other issues for fluid choice in the neonate center on appropriate glucose administration. In most cases, maintenance fluids containing 10% glucose and 0.2% saline with 20 mmol/L of potassium are reasonable in the first 48 hours of life. Beyond that time period, full-term infants may do well with 5% glucose instead of 10%, although preterm infants will often require the higher glucose load longer. Newborns of diabetic mothers, those who are small for gestational age, and those who have had continuous glucose infusions stopped have particular problems with hypoglycemia. These infants need to have their blood glucose values monitored. Neonates who are scheduled for surgery and have been receiving intravenous (parenteral) nutrition or supplementary glucose must continue to receive that fluid during surgery or must have their glucose levels monitored because of concerns of hypoglycemia. There is little consensus on the issue of what constitutes hypoglycemia.<sup>22</sup>

The concern about hypoglycemia must be balanced against the potential augmentation of ischemic injury from iatrogenic hyperglycemia. Interestingly, there are observational reports examining neonates undergoing cardiac surgery in which high glucose concentrations during or after the surgery were not associated with worse neurodevelopmental outcomes.<sup>23</sup> This finding supports the contention that avoiding hypoglycemia may be preferable to restricting glucose in newborns and risking hypoglycemia, at least in those having cardiac surgery.

### ***Blood Component Therapy in the Neonate***

Most of the basic principles of blood component therapy are the same in newborns and older children and adults. The first principle is to ensure adequate circulating intravascular volume and add components, as needed. However, there are a few important differences. These differences are related to the interconnection of maternal and fetal blood circulations and the flow of some, but not all elements, across the placenta, the incompletely developed immune system of the neonate, and the small intravascular volume of the neonate. The indications in the perioperative period for red blood cells are similar to those for adults, but the target values in available guidelines are higher.<sup>24</sup> Transfusion is indicated for a hemoglobin less than 10 g/dL for major surgery or in a newborn with moderate cardiopulmonary disease, whereas transfusion for a hemoglobin less than 13 g/dL is indicated in a newborn with severe cardiopulmonary disease. Platelets should be kept above 50,000/ $\mu$ L for invasive procedures. These recommendations are based on expert consensus and older pediatric data, not prospective studies in neonates

specifically.

The hemoglobin in transfused blood is hemoglobin A, as opposed to the hemoglobin F, which is present in the neonatal circulation at birth. An advantage of the transfused blood is better release of oxygen at the tissue level from hemoglobin A. Fresh blood cells have the advantage of lower potassium levels than older blood, although washed or frozen cells prevent this problem. This difference becomes especially important during rapid, massive transfusion. Transfusion-associated graft-versus-host disease is a rare but potentially deadly complication of red blood cell transfusion. Transfused lymphocytes in the donor blood attack the recipient bone marrow and other tissues, causing fever, pancytopenia, diarrhea, and hepatitis. To prevent this, gamma irradiation of cellular blood components is used to destroy lymphocytes and prevent transfusion-associated graft-versus-host disease. Therefore, irradiated blood is routinely used for transfusion of preterm infants and, in many centers, for all neonates and infants under 6 months of age. Leukocyte reduction by filtration is also used to reduce cytomegalic virus transmission, decrease risk of alloimmunization, and decrease febrile hemolytic transfusion reactions. There is decrease in retinopathy of prematurity (ROP), bronchopulmonary dysplasia, and length of hospital stay when leukocyte reduction is used for transfusions in premature neonates.<sup>25</sup> Finally, because there is very weak expression of the ABO antigens at birth, ABO typing, Rh typing, and an initial antibody screen are commonly done prior to transfusion, although crossmatching is not always needed.

### *The Hepatic System*

The functional capacity of the liver is immature in the newborn, especially synthetic and metabolic functions. Although most enzyme systems for both normal function and drug metabolism are present at birth, the systems have not yet been induced.<sup>26</sup> In utero, the maternal circulation and metabolism were responsible for the majority of drug elimination. As the newborn develops, the different hepatic metabolic pathways mature at different rates. Conjugation by sulfation and acetylation are relatively well developed in the newborn, with conjugation with glutathione and glucuronidation less well developed.<sup>27</sup> Some of these pathways do not achieve adult levels of activity until after 1 year of age.<sup>28</sup> Because of this immaturity, some drugs that undergo hepatic biotransformation, such as morphine, have prolonged elimination half-lives in newborns. Other drugs, such as lidocaine, do not undergo prolonged elimination in the newborn. In some drugs, such as caffeine, the lack of hepatic metabolism of the drug is balanced by excretion of an increased amount of unchanged drug through the kidney. Up to 85% of unmetabolized caffeine may be found in the urine in the newborn, compared

with 1% in the adult.<sup>29</sup>

Finally, decreased metabolism of a drug may actually increase its safety profile. Acetaminophen undergoes less biotransformation by the cytochrome P450 system in the newborn, producing less reactive metabolites that are toxic. Paradoxically, neonates can tolerate dosages of acetaminophen that would be hepatotoxic in adults.<sup>30</sup> Synthetic function of the liver is also altered in the neonatal period. Levels of albumin and other proteins necessary for binding of drugs are low in term newborns (and are even lower in preterm infants) and impacts the ability to bind drugs, producing greater levels of free drug. This phenomenon is especially true for the binding of alkaline drugs that bind to  $\alpha$ -1-acid glycoprotein, such as synthetic opioids and local anesthetics. The ability to bind to existing albumin may also be altered by hyperbilirubinemia for some medications. The need for exogenous vitamin K in the newborn is a consequence of this decreased ability. Because of decreased synthetic function, neonatal hepatic glycogen stores are low, especially in the preterm infant, increasing the risk of hypoglycemia in response to stress.

### *Anatomy of the Neonatal Airway*

**4** The anatomic and maturational factors unique to the neonatal airway are important to understand in order to effectively manage the airway (Fig. 42-6). Although traditional teaching is that all neonates, especially preterm infants, are *obligate* nasal breathers, the majority of neonates are actually *preferential* nose breathers.<sup>31</sup> Anything that obstructs the nares can compromise the neonate's ability to breathe.<sup>32</sup> For this reason, bilateral choanal atresia of the nasopharynx can be a life-threatening surgical condition for the neonate. The airway needs to be secured or the atresia opened to ensure adequate ventilation. The large tongue occupies relatively more space in the infant's oropharynx, promoting both soft tissue obstruction of the upper airway and increasing the difficulty of direct laryngoscopic examination and intubation of the infant's trachea. In the normal adult, the glottis is at the level of C5–C6. In the full-term infant, the glottis is at the level of C4, and in the premature infant, it is at the level of C3. The combination of a large tongue and a relatively cephalad glottis means that on laryngoscopic examination it is more difficult to establish a direct line of vision between the mouth and the larynx; there is relatively more tissue in a smaller distance. Therefore, the infant's larynx appears to be *anterior*, although the more anatomically accurate description is *cephalad*. The epiglottis is omega- or tubular-shaped, with a stubby base and thick, bulky aryepiglottic folds, making it difficult to elevate with a laryngoscope blade. Because the tip of the epiglottis lies at C1, its close apposition with the soft palate allows the

newborn to simultaneously suckle and breathe, which contributes to the *preferential* nasal breathing found in the neonate. The vocal cords are anterior-slanting, making visualization more challenging. The slanting also occasionally provides some obstruction to the passage of the endotracheal tube, which is especially true with either nasal or “blind” intubation attempts because the bevel of the tube may hang up in the anterior commissure of the angulated vocal cords instead of easily passing into the subglottic larynx.

**Figure 42-6** Complicating anatomic factors in infants. (Adapted from Smith RM. *Smith's Anesthesia for Infants and Children*. 4th ed. St Louis: Mosby; 1980:16.)

The neonatal subglottic area is funnel-shaped, unlike the infant, child, or adult airway (Fig. 42-7). In adults, the narrowest aspect of the upper airway is at the vocal cords, but in the neonate there is further narrowing ending at the level of the cricoid ring, the first complete cartilaginous ring. Although studies have challenged the funnel shape in infants and children, there has been no study further clarifying this relationship in neonates.<sup>33,34</sup> Because this narrowing is susceptible to trauma from intubation or too large an endotracheal tube, uncuffed tubes have traditionally been used in the neonatal period, although cuffed tubes are increasingly popular. The use of newer cuffed, small volume, high resistance endotracheal tubes have been demonstrated to provide an adequate airway with marginal changes to the diameter of the airway leading most practitioners to now use a cuffed tube, in even neonates and young infants.<sup>35</sup> Though cuffed endotracheal tubes may be gaining ground in use, it does not appear that they have supplanted the use of uncuffed endotracheal tubes in neonates.<sup>36</sup> Although the glottic opening may actually be the smallest measured point in the pediatric airway, it is more distensible than the cricoid ring, the first complete cartilaginous ring in the airway, thus, the cricoid ring is functionally the smallest cross-sectional area in

the airway. An endotracheal tube that passes easily through the glottic opening may not advance beyond the less distensible cricoid ring.

**Figure 42-7** Configuration of the adult (**A**) versus the infant (**B**) larynx. The adult larynx has a cylindrical shape. The infant larynx is funnel-shaped because of the narrow, undeveloped cricoid cartilage. A, Anterior; P, Posterior. (Adapted from *The pediatric airway*, In: Ryan JF, Coté CJ, Todres ID, eds. *A Practice of Anesthesia for Infants and Children*. 2nd ed. Orlando, FL: Grune & Stratton; 1992:61.)

Finally, the infant has a large occiput so the head flexes forward onto the chest when the infant is lying supine with his or her head in the midline. Further flexion of the neck can cause obstruction. Extreme extension can also obstruct the airway, so a midposition of the head with slight extension is preferred for airway maintenance. Rarely, this may require placing a small roll at the base of the neck and shoulders.

### Anesthetic Drugs in Neonates

**5** The pharmacokinetics of drugs in neonates are different than in older children and adults. Factors affecting the metabolism of drugs in neonates include a larger volume of distribution, decreased protein binding, decreased body fat percentage, and immature renal and hepatic function. The following physiologic changes alter pharmacokinetics and pharmacodynamics in neonates:

- Volume of distribution. Total body water represents a greater proportion of body weight in premature and full-term neonates, which increases the necessary dose for medications that are water-soluble.
- Protein binding. Neonates have decreased protein and hence have a decrease in protein binding of most drugs. This leads to increased free drug levels, which leads to increased activity and toxicity of drugs that are predominantly protein bound.
- Fat content. Neonates have a decreased amount of fat and muscle mass, which leads to greater levels of drugs that are primarily redistributed

to muscle and fat. Decreased renal and hepatic function predisposes neonates to increased blood levels from normal doses that are used for induction and maintenance of anesthesia.

Neurotoxicity of anesthetic agents is a topic that has received much attention in the literature as well as in popular media. However, most surgical procedures in the neonatal period are not elective. There is a detailed discussion of neurotoxicity of anesthetic agents presented in [Chapter 43](#).

## **Intravenous Agents**

### *Anticholinergics*

Anticholinergics, such as atropine and glycopyrrolate, are used frequently in neonates. They may be helpful in decreasing secretions and the response to vagal stimulation on intubation. The dose of atropine is 10 µg/kg if given intravenously and 20 µg/kg if given intramuscularly. Intramuscular administration may be desirable in certain situations, prior to induction of anesthesia, especially in emergency surgeries. Caution should be exercised if neonates have other associated congenital abnormalities, particularly narrow angle glaucoma in which case anticholinergics could increase intraocular pressure. Glycopyrrolate, a synthetic quaternary ammonium compound, has a longer duration of action than atropine and may potentially have less central effects because of decreased penetration of the blood–brain barrier.

### *Midazolam*

Midazolam is a water-soluble benzodiazepine that can be used for premedication in infants prior to surgery. Clearance of midazolam is lower in neonates and premature infants, and hence caution has to be exercised with the amount of midazolam used. If combined with opioids, intravenous midazolam can cause severe hypotension. A common modality for midazolam administration in neonatal intensive care units is by continuous infusion. If a patient is receiving midazolam infusion, care should be taken to avoid large doses of opioids to prevent hypotension.

### *Sedative/Hypnotics*

The common sedative/hypnotics used in neonates include propofol, thiopental, and ketamine.

### *Thiopental*

Because of an ongoing shortage of thiopental in North America, it is now rarely used there. Because of the large volume of distribution in neonates, it may be necessary to use large doses of thiopental for induction of anesthesia.

However, because of its reduced clearance, the effect may last longer than anticipated. Thiopental can cause hypotension in neonates who are volume depleted, especially in infants presenting for emergency surgery. It should be avoided in neonates with congenital heart disease because of its effect on myocardial function, leading to hypotension. A dose of 2 to 4 mg/kg is usually well tolerated by most neonates for induction of anesthesia. When compared with intubation without any hypnotic, the use of intravenous thiopental demonstrated adequate maintenance of heart rate and blood pressure.<sup>37</sup>

### *Propofol*

Propofol, a phenol derivative sedative/hypnotic, is a commonly used induction agent in infants and children. In a randomized trial comparing intravenous propofol with atropine, succinylcholine, and morphine, it was noted that propofol maintained adequate hemodynamics in neonates.<sup>38</sup> There is variability in elimination of propofol in neonates and preterm infants with longer elimination times.<sup>39</sup> Hence, while using propofol, it is important to reduce the dose to ensure early wake up and extubation. Propofol is the most commonly used intravenous induction agent in the United States.

### *Ketamine*

Ketamine, an *N*-methyl-D-aspartic acid (NMDA) antagonist, is used for induction of anesthesia in neonates who may have cardiovascular instability. An induction dose of 2 mg/kg intravenously with a higher dose of 4 to 7 mg/kg is used intramuscularly. Although it produces hemodynamic stability, it can cause an increase in oral secretions. There have been significant alterations in excitotoxic cells in the animal model when exposed to NMDA receptor antagonists like ketamine with resultant concern about potential neurodegenerative changes with their exposure.<sup>40</sup> All of these experimental models were using very high doses of ketamine, unlike what is routinely recommended for induction of anesthesia in neonates. In addition, there are also other sets of experimental data in animal studies that demonstrate a beneficial effect of ketamine in an experimental pain model.<sup>41</sup> Ketamine is still used frequently in neonates with congenital heart disease for induction of anesthesia.

### *Dexmedetomidine*

Dexmedetomidine is an  $\alpha$ -2 receptor agonist that can be used for sedation in neonates. Although it, as many drugs, has not been FDA-approved for use in the neonatal population, some centers have begun to employ this drug in the intensive care unit or as an adjunct to general anesthesia. FDA phase 2/3

trials indicate that dexmedetomidine is effective for sedation of term and preterm neonates undergoing mechanical ventilation, but preterm neonates exhibited decreased plasma clearance and increased elimination half-life of the drug. A study of 127 infants and neonates revealed that dexmedetomidine is likely to be safe in this patient population at doses similar to those used in adult intensive care for sedation, 0.2 to 0.6 µg/kg/hr.<sup>42</sup> Blood pressure and heart rate should be monitored as drop in systolic blood pressure and episodes of bradycardia may be noted. Dexmedetomidine may reduce required doses of midazolam and fentanyl needed to achieve the same level of sedation. Animal studies suggest that dexmedetomidine may be less neurotoxic than other traditionally used agents, such as midazolam.<sup>43</sup> Although much work remains to be done with this drug in the neonatal population, it is emerging as a viable sedative in neonates.

## Opioids

Opioids are used extensively in the management of anesthesia in neonates. The advantage of using opioids is their ability to maintain cardiovascular stability during major surgery. The common opioids used in neonates include fentanyl, morphine, and remifentanyl. Infants who are on long-term doses of opioids may develop dependence and have to be placed on methadone, a longer-acting opioid.<sup>44</sup>

### *Fentanyl*

This synthetic opioid is commonly used for sedation in the neonate in the intensive care unit as well as in the operating room. A dose of 2 to 4 µg/kg/hr can maintain hemodynamic stability in these infants during surgery. The pharmacokinetics of fentanyl have been well studied in newborns.<sup>45</sup> The use of fentanyl in association with benzodiazepines may lead to hypotension and hemodynamic instability. Caution must be exercised when the combination is administered during the perioperative period. Fentanyl may result in respiratory depression even with small doses. Continuous infusions may predispose to respiratory depression more frequently than bolus doses.<sup>46</sup> Chest wall rigidity and glottic rigidity have been described with fentanyl.<sup>47</sup> Small doses, as little as 1 to 2 µg/kg, can result in significant chest wall rigidity, leading to desaturation and need for mechanical ventilation. There is no significant maturational change in the brain associated with fentanyl, compared with morphine. Hence, the sensitivity to fentanyl will not significantly change as the infant matures significantly. Fentanyl still continues to be the mainstay in newborns for sedation and analgesia.

### *Morphine*

The kinetics of morphine have been studied in newborns. Premature babies have been shown to have decreased clearance. Morphine clearance (range, 0.8 to 6.5 mL/min/kg) directly correlates with gestational age ( $r = 0.60$ ;  $p < 0.01$ ) and birth weight ( $r = 0.55$ ;  $p < 0.01$ ).<sup>48</sup> Because of decreased clearance, dosing in neonates, especially premature infants, should occur on a 4- to 6-hour basis to allow for more predictable clearance of the drug.<sup>49</sup> Morphine is used frequently in the intensive care unit for postoperative pain control. Morphine infusions in the perioperative period have resulted in minor prolongation of postoperative ventilation. However, increased incidence of apnea or hypotension was not observed in neonates despite prolonged morphine infusions after successful extubation.<sup>50</sup>

Morphine is metabolized to morphine-3-glucuronide and morphine-6-glucuronide. Morphine-6-glucuronide predisposes to respiratory depression. The sensitivity to morphine-6-glucuronide increases with age because of increased maturation of the neuronal receptors.<sup>51</sup> A minority of infants who are scheduled for surgery may have been on ECMO. Kinetics of morphine have been carefully studied in neonates undergoing ECMO and do not show significant variability.<sup>52</sup>

### *Remifentanyl*

Remifentanyl is an ultra short-acting opioid that is metabolized by nonspecific esterases in plasma and tissues and has a half-life of less than 10 minutes. The pharmacokinetics of remifentanyl in neonates are similar to that of older children.<sup>53</sup> Remifentanyl can be used for maintenance of anesthesia with avoidance of volatile anesthetic agents. The use of remifentanyl infusion facilitated tracheal extubation in infants in a randomized trial when compared with volatile agents.<sup>54</sup>

### *Methadone*

Methadone is a long-acting opioid that is used in neonates and infants in neonatal intensive care units, particularly when withdrawal from opioids is suspected. The pharmacokinetics of methadone are being studied in neonates; however, published data is not available. The FDA “black box” warning against the use of methadone in patients with prolonged QT intervals on their electrocardiogram is a valid concern and infants on long-term methadone use should be carefully monitored with serial ECGs. However, it is used frequently in managing opioid tolerance without significant complication.<sup>44</sup>

## **Neuromuscular Blocking Agents**

Neuromuscular blocking agents (NMBAs) are frequently used during neonatal anesthesia to facilitate tracheal intubation, assist with controlled ventilation,

relax abdominal musculature, and ensure immobility. Factors that influence the choice of agent include the time of onset, duration of action, cardiovascular effects, drug availability, and mechanism of clearance/elimination.

### *Succinylcholine*

Succinylcholine, the only depolarizing muscle relaxant available, has the most rapid onset time of all the NMBAs. Neonates and infants have a larger ECF volume, leading to a larger volume of distribution and an increased dose requirement compared with children and adults. Thus, the recommended intravenous dose of succinylcholine for neonates and infants is 3 mg/kg, compared with 2 mg/kg in children, with an onset time of 30 to 45 seconds and duration of 5 to 10 minutes. The recommended intramuscular dose of succinylcholine is 4 mg/kg, with an onset time of 3 to 4 minutes and duration of approximately 20 minutes. Caution should be exercised when administering a second dose of succinylcholine because this can lead to vagally mediated bradycardia or sinus arrest. Pretreatment with atropine is recommended.<sup>55</sup>

The more recent succinylcholine controversy has called into question the use of succinylcholine in boys younger than 8 years. The reports of hyperkalemia with cardiac arrest in such children with unrecognized muscular dystrophy have led some clinicians to take the position that succinylcholine should not be used routinely for this group of patients. The occurrence of this problem is somewhere in the range of 1 in 250,000 anesthetics, with a mortality rate of 50%. Although a concern in young children, it is not a problem in the neonatal period. Succinylcholine is still recommended in rapid-sequence situations, potential difficult airway, or if there are airway emergencies with progressive desaturation. When it is evident that a neonatal airway is obstructed by laryngospasm or other reason and no progress is made in ventilation, intramuscular or intravenous succinylcholine should be administered. Hyperkalemia can be recognized by peaked T waves. However, the clinician may not see this particular electrocardiographic change because it occurs 2 to 3 minutes after drug administration, when the anesthesiologist is tending to the airway. The hyperkalemia interferes with cardiac conduction, leading to a bradycardia and, if severe enough, cardiac arrest. The drug of first choice is intravenous calcium chloride, 10 mg/kg. The use of sodium bicarbonate, 1 mEq/kg, to treat any metabolic acidosis that may occur with arrest is also believed to be useful because alkalosis decreases hyperkalemia. At the same time, the patient should be hyperventilated to reduce PaCO<sub>2</sub>, thereby inducing respiratory alkalosis. If there is refractory hypotension, one option is to administer epinephrine 5 to 10 µg/kg. One of the actions of epinephrine is to stimulate the sodium–potassium pump and cause potassium to re-enter the cell, thereby reducing the serum level. If there

is no response at this dose level, it should be increased incrementally until there is a response. Finally, magnesium has been described as a treatment for hyperkalemia, because it also antagonizes the effects of hyperkalemia, as does calcium. However, it is typically only employed for this purpose in the setting of digoxin toxicity.

## **Nondepolarizing Agents**

The neonate's neuromuscular junction is more sensitive to nondepolarizing muscle relaxants, and the neonate has a larger volume of distribution because of a large ECF volume. These two effects tend to balance each other; therefore, the dose of a nondepolarizing muscle relaxant for an infant is similar to that for a child on an mg/kg basis. Ongoing organ maturation has a tremendous impact on the metabolism and clearance of the nondepolarizing agents. As a result, there is considerable variability and unpredictability in the duration of action of these agents in the neonatal period. Dosing should be titrated to effect and, when possible, guided by monitoring neuromuscular function with a nerve stimulator. However, reliable twitch monitoring may be challenging in this age group.

## **Intermediate Nondepolarizing Agents**

### *Rocuronium*

Rocuronium appears to be the drug of choice among the intermediate-acting, nondepolarizing muscle relaxants for neonates. The intubating dose of rocuronium is 0.6 mg/kg. The length of action of rocuronium in the neonate is similar to that in the older infant or child following an equipotent dose.<sup>56</sup> Smaller doses (0.45 mg/kg) have been demonstrated to provide adequate relaxation and predictable recovery in newborn infants. However, if a larger dose of rocuronium, 1 to 1.2 mg/kg, is administered to avoid using succinylcholine during a rapid-sequence induction, then rocuronium will be a relatively long-acting muscle relaxant. Rocuronium is metabolized by the liver; however, there are no active metabolites of rocuronium which is unlike vecuronium. Rocuronium has mild vagolytic properties and may slightly increase heart rate.

### *Vecuronium*

Although vecuronium is considered an intermediate-acting muscle relaxant in children and adults, in infants younger than 1 year it is considered to be a long-acting muscle relaxant. The duration of action of vecuronium is approximately twice that observed in children because of liver immaturity. Vecuronium undergoes primarily hepatic metabolism with production of

active metabolites that are dependent on renal excretion. The recommended dose of vecuronium is 0.1 to 0.15 mg/kg, with an onset time of 90 seconds and duration of action of 60 to 90 minutes in the neonate. Even with increased doses, vecuronium has no effect on the cardiovascular system.

### *Pancuronium*

Pancuronium is a long-acting NMBA with a pharmacokinetic profile similar to vecuronium. The recommended dose of 0.1 to 0.15 mg/kg has an onset time of 120 seconds and duration of 60 to 75 minutes. Unlike vecuronium, however, pancuronium primarily undergoes renal excretion. Pancuronium has vagolytic and sympathomimetic actions that cause tachycardia and an increase in blood pressure.<sup>57</sup> In a relatively normal neonate with a normal blood pressure and normal blood volume, the use of pancuronium may result in hypertension, which has the potential to increase blood loss and increase the risk of hemorrhage in the extremely premature neonate. The risk for prolonged neuromuscular blockade in neonates, especially with altered renal function, makes pancuronium less desirable in neonates and infants undergoing minor outpatient surgical procedures. The use of pancuronium for prolonged durations especially in the intensive care units can lead to muscle weakness. Prolonged use has also been associated with sensorineural hearing loss in infants.<sup>58</sup>

### *Cis-atracurium*

Cis-atracurium is an intermediate-acting NMBA of the bisbenzyltetrahydroisoquinolinium class. The unique aspect of this agent within its class is a lack of histamine release. The most important fact about this drug is its degradation through Hoffman elimination, which is an organ-independent chemodegradative mechanism. Because its elimination is not kidney or liver dependent, it offers a reliable recovery time even in neonates. In fact, when used for prolonged infusion in infants and neonates in intensive care, it offers a more reliable recovery time than vecuronium.<sup>59</sup> One theoretical concern with administration of cis-atracurium is the accumulation of one metabolite, laudanosine, which can decrease the seizure threshold. However, this does not seem to be relevant at clinical doses of cis-atracurium.<sup>60</sup> The typical dose is 0.15 to 0.2 mg/kg, has an onset time of 150 seconds, and a half-life of approximately 25 minutes.

### *Reversal Agents*

The unpredictable nature of the NMBAs in the neonatal population, as well as the inability to accurately assess neuromuscular function in many situations, necessitates reversal of all nondepolarizing NMBA in neonates. The two

commonly used reversal agents are edrophonium and neostigmine. Edrophonium in a dose of 1 mg/kg achieves a 90% reversal of a neuromuscular block in 2 minutes, whereas neostigmine in a dose of 0.07 mg/kg requires 10 minutes for a 90% reversal of neuromuscular block. This difference in time to peak effect allows the anesthesiologist to decide which agent is needed. Anticholinergic drugs like atropine or glycopyrrolate are coadministered to decrease the incidence of bradycardia. Neostigmine is the most common agent used for reversal of nondepolarizing muscle relaxants in neonates. The advantages of edrophonium over neostigmine are a more rapid reversal and fewer muscarinic side effects, but edrophonium is still less commonly used in clinical practice due to its shorter duration of action. Neostigmine administered without an anticholinergic is the most common drug error leading to perioperative cardiac arrest in the pediatric population.<sup>61</sup>

## **Volatile Agents**

Volatile agents are used for maintenance of anesthesia in the neonatal period. Although halothane was the most commonly used volatile agent for many years and had a reasonable safety profile, the introduction of sevoflurane has clearly made a difference to the use of volatile agents in neonates. Isoflurane is used for maintenance of anesthesia for longer surgical procedures and desflurane may be desirable for rapid awakening in certain cases. Each of these agents will be discussed here.

### *Halothane*

Halothane is still commonly used in developing countries and in veterinary medicine, although it is not currently used in the United States nor is it frequently used in other developed countries. Its long history for induction of anesthesia and its ease of use still make it a desirable agent in children. Halothane has a weak muscle relaxant property, facilitating induction and intubation without the use of a muscle relaxant. Halothane is a potent bronchodilator and may reduce the airway reflexes associated with intubation. The use of high doses of halothane for procedures including bronchoscopic evaluation of the airway may lead to significant myocardial depression. Infants less than 8 weeks old and with a history of RDS with longer period of preoperative fasting are prone to hypotension. Halothane also sensitizes the myocardium to cardiac dysrhythmias. Animal experiments demonstrate the increased sensitivity to epinephrine with halothane when compared with isoflurane or sevoflurane. Hence, when concurrent exogenous catecholamines are administered (including epinephrine in local anesthetic solution), careful attention to the maximum dose should be carefully

monitored.

### *Isoflurane*

Isoflurane has become a common maintenance volatile agent in neonates and infants. Its pungent odor does not allow its use for mask induction. Isoflurane has a greater effect in potentiation of muscle relaxation and hence plays an important role as a maintenance anesthetic. It is important to remember that the dose of muscle relaxants should be reduced when isoflurane anesthesia is used because of potentiation. The dose of rocuronium bromide may have to be reduced to 0.45 mg/kg compared with a normal maintenance dose of 0.6 mg/kg.<sup>56</sup> Isoflurane has less myocardial depression when compared with halothane in neonates.<sup>62</sup>

### *Sevoflurane*

This volatile agent offers an advantage for rapid induction and rapid awakening. It has a less pungent smell than isoflurane, making it ideal for mask induction. Its pharmacodynamics have been studied in neonates and children with a reasonable safety profile.<sup>63</sup> In children with congenital cardiac disease, it has been shown to produce fewer hemodynamic changes when compared with isoflurane.<sup>64</sup> Although it produces less myocardial depression, it has a greater effect on respiratory depression compared with halothane. Minute ventilation and respiratory frequency were significantly lower during sevoflurane than halothane anesthesia (4.5 compared with 5.4 L/m<sup>2</sup>/min, and 37.5 compared with 46.7 breaths per minute, respectively,  $p < 0.05$ ). There was also significantly less thoracoabdominal asynchrony during sevoflurane anesthesia.<sup>65</sup>

### *Desflurane*

Desflurane was touted to be the best volatile agent in children because of its partition coefficient being close to that of nitrous oxide, thereby allowing a rapid uptake. However, the pungent nature of the drug has made it nearly impossible to use for inhalation induction of anesthesia. When compared with sevoflurane, infants who were preterm were noted to wake up sooner with desflurane, but there were no reductions in postoperative respiratory events.<sup>66</sup> 1 MAC of desflurane in a neonate is estimated to be 9.2% end-tidal.<sup>67</sup> Pungency increasing the risk of laryngospasm and bronchospasm make this volatile agent less attractive in neonates, but its rapid elimination and awakening have secured its place in regular clinical use. In an animal model using neonatal mice, mice exposed to desflurane had greater neuroapoptosis than mice exposed to equipotent doses of isoflurane or sevoflurane.<sup>68</sup>

## Local Anesthetics

Local anesthetic solutions are represented by two main classes, the amino-amides (amides) and the amino-esters (esters). The main difference between the two classes is that the amides undergo enzymatic degradation by the liver and the esters are hydrolyzed by plasma cholinesterases.

### *Amides*

These are commonly used local anesthetic solutions in neonates and infants. Local anesthetics used in common clinical practice belonging to this class include lidocaine, bupivacaine, ropivacaine, and levobupivacaine. The main characteristics differentiating these drugs are their speed of onset, duration of action, and potential for cardiac toxicity. The ability of neonatal liver enzymes to metabolize and their ability to oxidize and reduce these drugs are decreased when compared with adults.<sup>69</sup> At approximately 3 months of age, the conjugation of these drugs in the liver reaches adult levels. Older children can also achieve higher levels of local anesthetic solution than adults because of alteration in pharmacokinetics of the drugs.

Local anesthetic solution levels have been shown to be higher in children undergoing intercostal nerve blocks compared with adults.<sup>70</sup> After caudal administration of local anesthetics, peak plasma level is obtained in children and adults in approximately 30 minutes.<sup>71</sup> The steady-state volume of distribution ( $V_{dss}$ ) for amides is increased in children compared with adults, although clearance (CL) is similar.<sup>71</sup> Elimination half-life ( $t_{1/2}$ ) is related to the volume of distribution and clearance as follows:  $t_{1/2} = (0.693 \times V_{dss})/CL$ . This results in a larger  $V_{dss}$  and prolongation of the elimination half-life, especially if a continuous infusion is used. Also, due to decreased circulating  $\alpha$ -1-acid glycoprotein levels in neonates, more free (active) local anesthetic circulates in the bloodstream.

The systemic absorption of local anesthetics is often based on the site of injection. On a decreasing scale, the incidence of complications with local anesthetic solution injections decreases, with the highest concentrations seen in the intercostal area followed by the caudal space, the epidural space, and peripheral nerve blocks. With newer techniques in regional anesthesia, including ultrasound guidance, the volume and dose of local anesthetic solution can be significantly reduced.<sup>72</sup>

**Bupivacaine.** Bupivacaine is one of the most commonly used local anesthetic solutions in infants and children. The pharmacokinetics and the pharmacodynamics have been well studied in infants and children. The concentration of the local anesthetic solution used depends on the site of injection, the desired density of blockade (motor and sensory), and the potential for cardiovascular and neurotoxicity. The concomitant use of other

local anesthetics including infiltration anesthesia must be taken into account before a total volume of local anesthetic solution is determined. This is especially true in neonatal surgery in which large quantities of local anesthetic solution can sometimes be injected for skin infiltration. If upper safe limits are likely to be approached, it is reasonable to avoid local anesthetic solution for infiltration and use a dilute epinephrine solution instead for vasoconstriction. The preferred concentration for peripheral nerve blockade is 0.25% bupivacaine or 0.2% ropivacaine, and the preferred concentration for single dose caudal is 0.25% or 0.125% solution of bupivacaine or 0.2% ropivacaine. When a continuous infusion is desired, a 0.1% or 0.125% solution of bupivacaine is preferred. In premature infants and in infants weighing under 1 kg, we prefer using 0.0625% bupivacaine, or intermittent bolus dosing every 12 hours. Although clear guidelines do not exist for local anesthetic solutions, a rough rule of thumb is to use 0.2 mg/kg/hr for continuous infusions of bupivacaine and 2 mg/kg for bolus doses.<sup>73</sup>

**Metabolism and Toxicity.** Bupivacaine in the circulation is heavily bound to  $\alpha$ -1-acid glycoprotein. Levels of this circulating protein are lower in the neonatal period.<sup>74</sup> Bupivacaine is a racemic mixture of the levo and dextro enantiomers. Although the levo enantiomer is the active form that provides the clinical effect of the local anesthetic solution, the dextro enantiomer is responsible for the adverse effects related to local anesthesia, including cardiac toxicity and neurotoxicity.

The major adverse effect of bupivacaine is toxicity related to the cardiovascular and the CNS systems. Local anesthetics have the ability to cross the blood–brain barrier and can cause alterations in the CNS functions. Continuous infusions in neonates can predispose them to CNS toxicity sooner than older infants.<sup>75</sup> In pediatric patients, the incidence of cardiac toxicity occurs sooner than neurotoxicity,<sup>75</sup> which may be partly because children may be anesthetized and devastating neurotoxicity may not be noticed until significant cardiac toxicity is seen. Manifestation of bupivacaine toxicity may also be affected by the concomitant use of volatile agents for general anesthesia.

**Dosage.** Bupivacaine can be used for most peripheral nerve blocks as well as for epidural and caudal infusions in infants and children. The maximum dosage suggested for bolus injections in the caudal space or epidural space for older children is 4 mg/kg and 2 mg/kg for neonates and infants.<sup>73</sup> Dosage recommendations for continuous infusions is 0.4 mg/kg/hr in older children and 0.2 mg/kg/hr in neonates and infants.<sup>26</sup> The concentration of the solution used for peripheral nerve blocks is usually 0.25%, bearing in mind the ceiling

limit for maximum dosage. Higher concentration such as 0.375% may be necessary for surgical blockade without sedation. An example of a continuous infusion in a 4-kg neonate will be 0.2 mg/kg/hr; this will be equivalent to 0.8 mL/hr of a 0.1% solution of bupivacaine (1 mg/mL of bupivacaine).

**Ropivacaine.** Ropivacaine is an amide local anesthetic. It is a levo enantiomer with relatively less cardiovascular and CNS side effects compared with bupivacaine.<sup>76</sup> The pharmacokinetics of ropivacaine are such that caudal blocks with ropivacaine (2 mg/kg) in children (aged 1 to 8 years) result in plasma concentrations of ropivacaine well below toxic levels in adults.<sup>76</sup> This dose was also noted to produce less motor block, but provide adequate analgesia. Mean maximum plasma concentration of total ropivacaine at 2 mg/kg was 0.47 mg/L. A threshold of CNS toxicity was noted at a plasma concentration of 0.6 mg/L. Body weight-adjusted clearance was the same as in adults (5 mL/min/kg). Ropivacaine clearance depends on the unbound fraction of ropivacaine rather than the liver blood flow.

**Toxicity.** Although the safety of ropivacaine has been demonstrated in animal experiments, there have been reports of CNS toxicity and cardiac toxicity associated with the use of epidural ropivacaine. It is important to understand that an overdose of ropivacaine can cause toxicity, making close attention to dosage as important with ropivacaine as with other local anesthetics. Our recommended dose is bolus dose of 2 mg/kg and an infusion rate of 0.2 mg/kg/hr in neonates.

**Levobupivacaine.** Levobupivacaine is a newer levo enantiomer that has fewer adverse effects than bupivacaine.<sup>77</sup> There are fewer pediatric trials available in literature. Because of the common use of bupivacaine in children and its low incidence of complications, levobupivacaine is not used abundantly in general pediatric anesthesiology practice. It is currently not available for use in the United States, although it is widely used in other parts of the world.

**Toxicity.** Levobupivacaine, in the animal model, has been shown to have less cardiac toxicity with lower degree of myocardial depression than bupivacaine. Although it is less toxic, the recommended doses remain the same for levobupivacaine as bupivacaine.

**Lidocaine.** Lidocaine is a frequently-utilized amide local anesthetic with an intermediate duration of action. It is a frequently used local anesthetic for postoperative catheter infusions because its level can be measured in most hospital laboratories in a time-efficient manner. A variety of concentrations are readily available on the market. A concentration of 1.5% in the epidural

space is generally considered to be adequate for surgical blockade, whereas peripheral nerve blocks are typically done with 2% for surgical block. Lidocaine has a high hepatic extraction ratio, so its clearance is based on hepatic blood flow. Lidocaine has a longer half-life and volume of distribution in the neonate. Furthermore, the relatively low level of  $\alpha$ -1-acid glycoprotein in neonates increases the proportion that is not protein-bound in the serum. When utilized for spinal blockade, the possibility of transient neurological symptoms is significant, so other local anesthetics have supplanted much of its use in spinal anesthesia.

**Toxicity.** Lidocaine has been an attractive local anesthetic for postoperative continuous infusion in the neonatal population. Because lidocaine has other uses in the intensive care setting, most hospital laboratories can measure its level reasonably quickly. Thus, serum levels of lidocaine may be monitored in the setting of continuous infusions for safety. Furthermore, convulsions are typically noted before the onset of cardiac toxicity, which also confers a greater safety level over bupivacaine.

### *Esters*

Ester local anesthetics are metabolized by plasma cholinesterases. As a result, in populations with lower circulating pseudocholinesterase levels, there is a modestly increased serum half-life of these drugs. This includes infants and neonates particularly. The duration of action of the drug is short; hence, a continuous infusion of chlorprocaine is recommended even when used for only intraoperative anesthesia.

**2-Chloroprocaine.** This drug is experiencing a resurgence within the neonatal population as interest in its safety profile has reinvigorated its use. Even though neonates have a lower level of circulating pseudocholinesterase, the plasma half-life of chlorprocaine remains short. The plasma half-life of chlorprocaine in adults is 23 seconds, whereas in neonates it is 43 seconds. The plasma half-life of lidocaine, an intermediate-acting amide local anesthetic, is 90 to 120 minutes. Thus, the toxicity profile of chlorprocaine is expected to be much better across a range of doses, though studies in neonates have not been specifically designed to answer this clinical question.

**Dosing.** After a bolus dose of 1.5 mL/kg, a continuous infusion of chlorprocaine at 1.5 mL/kg/hr of 3% 2-chloroprocaine has been used to achieve a level of T4 to T2 through an intravenous catheter placed in the sacral canal.<sup>78</sup> This level will be effective in producing complete surgical anesthesia for neonates' major abdominal surgery. Lower doses such as 1 mL/kg bolus and an infusion of 1 mL/kg/hr have been used successfully for

inguinal and penoscrotal surgery.<sup>79</sup> Given the high concentrations of local that can be used, motor block is easy to achieve with this local anesthetic. Postoperative infusion of chloroprocaine through an epidural catheter is a relatively common practice in neonates as observed in the Pediatric Regional Anesthesia Network (PRAN) database.

### *Management of Local Anesthetic Systemic Toxicity*

Lipid emulsion therapy has been demonstrated to reverse the effects of LAST in experimental animal models.<sup>80</sup> Its effect on human models was parlayed in a case report where lipid was used as a last resort to reverse the effects of bupivacaine following a regional anesthesia technique.<sup>81</sup> Lipid should be readily available if local anesthetics are being used in neonates. There is a report where an infant received a caudal block which resulted in cardiac toxicity which was treated successfully with lipid rescue.<sup>82</sup> Although guidelines for neonatal administration of lipid rescue do not exist, lipid administration across a wide range of doses appears to be safe in neonates.<sup>83</sup> The present recommended dose of lipid rescue for LAST is 1.5 mL/kg bolus, which may be repeated for continued instability, followed by continuous infusion of 0.25 mL/kg/min, which may be increased for continued hypotension.<sup>84</sup>

### **Topical Anesthesia**

Several local anesthetic preparations are now available for topical use. The most common local anesthetic preparations for topical use include lidocaine, tetracaine, benzocaine, and prilocaine. When these are applied to skin they produce effective but relatively short duration of analgesia. One topical anesthetic formulation, eutectic mixture of local anesthetic (EMLA), is a mixture of lidocaine 2.5% and prilocaine 2.5% and is used extensively for topical anesthesia in neonates, particularly for circumcision and venipunctures. The preparation has to be applied under an occlusive bandage for 45 to 60 minutes to obtain effective cutaneous analgesia. Although the incidence of methemoglobinemia from prilocaine is not very common in neonates, caution should be exercised when applying large doses of EMLA for procedures.<sup>85</sup>

Newer topical anesthetic solutions are now available that may offer a faster rate of onset. LMX-4, a 4% liposomal lidocaine solution can be used as topical anesthesia. There is no need for an occlusive dressing when LMX-4 is used, and it has the same efficacy as EMLA.<sup>86</sup> Liposome-encapsulated lidocaine or tetracaine has been shown to remain in the epidermis after topical application, affording a fast and lasting anesthetic effect.

## Anesthetic Management of the Neonate

Effective evaluation, preparation, and anesthetic management of the neonate depend on appropriate knowledge, clinical skills, and vigilance on the part of the anesthesiologist. For safe and effective care, the anesthesiologist must take extraordinary caution to understand the current status of the patient, the nature of the planned surgery, and the potential need for stabilization and preparation before surgery. After ensuring that the patient has been adequately prepared, the anesthesiologist needs to develop a detailed plan that encompasses the issues of anesthetic equipment and monitoring, airway management, drug choice, fluid management, temperature control, anticipated surgical needs, pain management, and postoperative care.

Studies have shown that morbidity and mortality related to anesthesia is higher in infants, especially neonates, compared with infants, older children, and adults.<sup>61,87,88</sup> The rate of major complications may be as high as 23% in neonates undergoing surgical procedures and are more frequent in reoperations, surgery for congenital diaphragmatic hernia, prematurity of less than 32 weeks at birth, and abdominal surgery.<sup>89</sup> There are probably several causes for the higher complication rate observed with neonatal surgery, including the emergent nature of most surgical procedures that are performed at this age, the physiologic instability of the neonate, the relative lack of experience most clinicians have with patients in this age range, and the technical challenges of monitoring and treating a very small patient. Because of the specialized nature of neonatal surgery and care, it is important that each institution that provides care to these patients has the resources of equipment, critical care facilities, nursing, laboratory, blood bank, and social work necessary to meet the needs of these patients and their families, as well as systems in place to guarantee a robust quality assurance emphasis on the provision of care. Both the American Academy of Pediatrics and the American Society of Anesthesiologists have provided guidance to many of the systems issues that should be addressed in institutions caring for these patients.<sup>90</sup> Physicians who agree to participate in this care need to have the preparation and ongoing experience needed to provide a consistent, expert level of care.

In the distant past, concerns about physiologic instability and other challenges of caring for neonates led some practitioners to use minimal or no anesthesia for both minor and major procedures. It is now widely recognized that neonates have stress responses similar to those of older patients, and the lack of adequate anesthetic care is as inhumane in the neonate as it is in the older child or adult.<sup>91</sup> The neurologic system in neonates is sufficiently developed to transmit painful stimuli and lack of pain control may result in a higher morbidity rate, increased pain to subsequent events, and increased neuroendocrine response to painful stimuli.<sup>92</sup> Consequently, the same

attention to adequate analgesia and anesthesia needs to be paid to the neonate as to other patients.

## *Preoperative Considerations*

### **Preanesthetic Evaluation—History**

The preanesthetic planning process starts with an evaluation of the course of intrauterine growth, events of labor and delivery, and the immediate postpartum course of the patient. The amount of history available to the anesthesiologist may vary widely. If the mother had received prepartum and postpartum care in the same institution where the neonate is admitted, a significant amount of detail may be available. If the neonate is transferred from another institution, there may be limited information available. Best efforts should be made to get as much relevant information as possible, with an emphasis on maternal factors that may have affected fetal growth as well as the current status of the neonate. Additional history of the child's course since birth is important, with a particular focus on the signs that identifies the surgical condition that is to be treated. Important factors include the history of feeding and hydration, need for oxygenation or ventilatory support, cardiovascular abnormalities, and any evidence of CNS problems such as seizures or intraventricular hemorrhage. Finally, an estimation of the gestational status is made, with an emphasis on the issues of prematurity and intrauterine growth retardation with subsequent small-for-gestational age status and VLBW neonates.

The World Health Organization's definition of prematurity is less than 37 weeks' gestation at birth. The determination of gestational age is based on the estimated date of full-term delivery, as well as physical examination of the newborn. Although these indicators are generally widely agreed on, they are subject to some degree of variation in interpretation. The greater the degree of prematurity, the more physiologic abnormalities will be expected. The implications for anesthesiologist are that the more preterm a newborn is, the greater the variability of responsiveness to anesthetic agents, fluids, vasoactive medications, and the stress of the surgical procedure.

In addition to prematurity, there is a second, related classification system. Low birth weight, defined as a birth weight of less than 2,500 g, can be due to prematurity, poor intrauterine growth, or both. Prematurity and intrauterine growth retardation are associated with increased neonatal morbidity and mortality, and it is difficult to completely separate factors associated with prematurity from those associated with intrauterine growth retardation. For discussion purposes, preterm infants are often divided into subgroups. Newborns born at 35 to 37 weeks' gestation are considered near

term. These newborns have a lower incidence of major physiologic abnormalities typical of the more preterm newborn. Although they usually do not have significant pulmonary abnormalities, they may have some feeding problems or hyperbilirubinemia. This degree of prematurity does not usually have a significant impact on anesthetic management. However, infants born between 30 and 34 weeks' gestation are much more likely to show some abnormalities related to prematurity that can complicate anesthetic management.<sup>93</sup>

Although RDS had previously been a significant source of morbidity in this population, the widespread use of exogenous surfactant has decreased the incidence dramatically, as well as the later complications of chronic lung disease. This group does have more problems with inadequate feeding, persistent patency of the ductus arteriosus, apnea in response to stress, and temperature instability. However, infants born more prematurely than 30 to 34 weeks' gestation begin to demonstrate significant physiologic abnormalities related to prematurity.

For infants with VLBW, defined as less than 1,500 g, the presence of complicating problems and morbidity and mortality are inversely related to birth weight. Major surgery in VLBW infants is associated with a 50% greater risk of mortality or neurodevelopmental impairment at 18 to 22 months of age versus normal birth weight. RDS is found in approximately 80% of infants weighing 501 to 750 g, in 65% of those 751 to 1,000 g, in 45% between 1,001 and 1,250 g, and in 25% between 1,251 and 1,500 g. In addition, symptomatic intraventricular hemorrhage is found in about 25% of infants weighing 501 to 750 g, in 12% between 751 and 1,000 g, in 8% between 1,001 and 1,250 g, and in 3% between 1,251 and 1,500 g. Other complications, such as sepsis, necrotizing enterocolitis (NEC), and bronchopulmonary dysplasia (BPD) are very high in infants with VLBW. [Table 42-3](#) lists some of the most common abnormalities found in the preterm population that have implications for anesthetic evaluation, preparation, and management.

### **Preanesthetic Evaluation—Physical Examination**

Physical examination of the newborn is focused by the condition requiring surgical intervention. Hydration is often an important issue because of both fasting and losses related to the surgical lesion. Clinical signs of dehydration include a sunken fontanel, poor skin turgor, dry mucous membranes, sunken eyes, poor skin perfusion, delayed capillary refill, hypothermia, tachycardia, or absent urine output. If there are clinical signs of dehydration, efforts should be made to correct the deficits before surgery, except in extreme, life-threatening situations. Physical examination also focuses on the respiratory

and cardiovascular systems. The presence of any cardiovascular abnormalities should be noted, including poor perfusion or pulses, abnormal rhythm or rate, a murmur or gallop, hepatomegaly, or other signs of either heart failure or poor perfusion. The presence of a murmur is of concern in the neonatal period and warrants further evaluation, which is best done by a pediatric cardiologist. An electrocardiogram and echocardiogram will help define whether there is significant cardiovascular disease present that will affect the anesthetic management. Although this evaluation may take some effort and time, it is worthwhile to ensure that the anesthesiologist can plan the child's care with full knowledge of the limitations cardiovascular disease can impose.

**Table 42-3** Abnormalities Associated with the Preterm Infant: Common Anesthetic Concerns

Respiratory	Respiratory distress syndrome Apnea Pneumothorax, pneumomediastinum Pneumonia Pulmonary hemorrhage Bronchopulmonary dysplasia
Cardiovascular	Patent ductus arteriosus Hypotension Bradycardia Pulmonary hypertension Persistent transitional circulation Congenital heart disease
Central nervous system	Intraventricular hemorrhage Hypoxic-ischemic encephalopathy Seizures Kernicterus Drug withdrawal
Metabolic	Hypoglycemia Hyperglycemia Hypocalcemia Hypothermia Metabolic acidosis
Renal	Hyponatremia Hypernatremia Hyperkalemia Poor urine output
Gastrointestinal	Poor feeding Necrotizing enterocolitis Intestinal obstruction
Hematologic	Anemia Hyperbilirubinemia Vitamin K deficiency
Other	Retinopathy of prematurity Sepsis and infections

The respiratory system also must be examined in some detail. The presence of stridor or other evidence of airway obstruction, such as sternal or chest wall retractions, should be identified and investigated. Although upper airway obstruction is relatively rare in the newborn, laryngeal webs, cysts of

the tongue or supraglottic region, vocal cord paralysis after a traumatic delivery, and hemangiomas of the airway can cause obstruction and need to be identified. In addition, newborns that have been previously intubated may have some degree of subglottic edema related to previous intubation. More likely are signs of lower airway disease such as tachypnea, grunting, rhonchi, retractions, and cyanosis. This may be related to the early development of RDS, but may also represent meconium aspiration, pneumonia, pneumothorax, or heart failure. The cause of any respiratory distress needs to be evaluated expeditiously prior to anesthesia to identify treatable causes and begin therapy.

### **Preanesthetic Evaluation—Laboratory**

Most laboratory investigations are related to the underlying surgical condition such as radiography, computed tomography, magnetic resonance imaging, and echocardiography. However, most newborns will have, at a minimum, a blood count and glucose level drawn. The hemoglobin in a newborn is primarily fetal hemoglobin, which has a higher affinity for oxygen than adult hemoglobin. Because of this higher affinity, the hemoglobin dissociation curve is shifted to the left, releasing less oxygen to the tissues than adult hemoglobin. Newborns have a higher hemoglobin than the infant or child, often in the 15 to 18 g/dL range.<sup>94</sup> Rarely, a newborn will have significant polycythemia, with hemoglobin levels above 20 g/dL. If symptomatic, these patients may benefit from therapeutic phlebotomy and volume replacement.

Glucose levels obtained close to the time of the proposed surgery are important. The stressed newborn, especially the stressed preterm or small-for-gestational age newborn, are at particular risk for hypoglycemia.<sup>95</sup> A glucose level between 60 and 80 mg/dL is expected in a full-term newborn, with a preterm often 10 mg/dL below that. Although there is some controversy about what actually constitutes hypoglycemia in these populations, most agree that levels less than 45 mg/dL warrant therapy with additional dextrose. Patients with diabetic mothers, those who have not been receiving either enteral or parenteral feeds, those who are VLBW, and those who have been septic are especially susceptible to hypoglycemia and require frequent monitoring and modification of parenteral fluids.

Other laboratory studies, such as electrolyte determinations and coagulation profiles, are indicated in specific patients. Hypocalcemia, in particular, can be troubling because signs of hypocalcemia are nonspecific. Unexplained hypotension, irritability, or even seizures can be presenting signs. Hypocalcemia is a problem with preterm newborns, but can also be seen in full-term newborns who have a delay in starting enteral feedings. Hyponatremia is not uncommon in newborns who have been receiving

solutions with little or no salt in the first days of life, although hypernatremia may occur if there is inadequate resuscitation of the dehydrated patient when water loss is greater than salt loss. The longer a newborn has received parenteral fluids, the greater the chance of electrolyte abnormalities because of the difficulty in matching ongoing losses with replacement in the presence of an immature kidney.

Coagulation parameters are different in newborns compared with adults.<sup>96</sup> Although platelet counts in term newborns are usually similar to adult values, lower values are frequently seen in the preterm. Unexplained thrombocytopenia can be an early sign of sepsis, and a falling count should be an impetus to look for other signs of sepsis. Other coagulation tests are different in both the full-term and preterm newborn. The prothrombin time and partial thromboplastin time levels are about 10% longer in the newborn, but prothrombin time values approach adult levels in the first week of life and partial thromboplastin time levels within the first month of life. Prevention of early vitamin K deficiency bleeding (VKDB) of the newborn is the purpose of intramuscular vitamin K administration after birth and is standard of care in the United States.<sup>97</sup>

## **Preanesthetic Plan**

The anesthesiologist has a host of anesthetic techniques from which to choose and can tailor the anesthetic to the requirements of the surgery and the condition of the neonate. Major factors that should be considered in planning the anesthetic include (1) anticipated blood loss and necessity for blood products to be available before beginning the case, (2) monitoring requirements, including invasive monitoring techniques, (3) additional equipment needs for airway and vascular access, (4) transport requirements, (5) postoperative recovery location risk of postoperative ventilation requirements, and (6) plan for postoperative pain relief. Both the medical status of the patient and the planned surgical procedure will impact this planning. The anesthesiologist has the responsibility of clarifying any medical issues with the neonatologist before finalizing the plan, as well as clarifying any issues related to the planned procedure with the surgeon. Occasionally, as planning progresses, it becomes obvious that the patient needs further medical resuscitation or evaluation before it is prudent to proceed with the procedure.

Once the anesthetic plan is clear, it should be discussed with the available parent or caregiver who has legal custody of the child. Informed consent is a process by which the anesthesiologist explains his/her understanding of the patient's status, the planned procedure, the plan for anesthetic management, alternatives to the plan, and some discussion of risks and benefits. Although

there may be rare circumstances in which the legal guardian is not available to provide consent, efforts should be made in all except the most emergent of situations to have this discussion. It should be stressed that informed consent is a process, not a document. The goal of informed consent is to help the parent understand what care is being proposed, the risks and benefits involved, and reasonable alternatives. It is the discussion, in terms understandable to the parent, that is the basis of true informed consent.

## **Premedication**

Premedication is not commonly used for neonatal anesthetics. Sedation is not usually necessary and analgesics are rarely indicated before taking the patient to the operating room. Atropine or glycopyrrolate may be used for vagolytic effect before induction. Because of the dominance of the  parasympathetic nervous system, bradycardia on induction or in response to inhalation agents is of concern. Manipulation of the airway or administration of succinylcholine may cause bradycardia in neonates without administration of atropine or glycopyrrolate. Although it is not requisite to administer a vagolytic, it should be among the drugs immediately available and additional vigilance from the anesthesiologist is necessary to quickly respond to bradycardia. Although a dose of 20 µg/kg of atropine is most frequently used to prevent bradycardia, the question of a minimum dose of 100 to 200 µg has been a source of controversy. However, it appears that prior concerns over paradoxical bradycardia with small doses of atropine have not been evident in clinical trials, leading to a practice reversal where the minimum dose of atropine is no longer commonly used.<sup>98</sup>

## ***Intraoperative Considerations***

### **Monitoring**

Neonatal patients are at a disadvantage when it comes to perioperative monitoring because of their small size. Many of the monitoring modalities that are easily employed in older children and adults are very difficult in the neonate. Other monitors that are used may occasionally not provide reliable information for technical reasons. Examples of this include neuromuscular blockade monitoring and automated blood pressure monitoring. Invasive monitoring such as arterial line and central venous line catheters may be technically difficult to insert, especially in the preterm. However, improvements in ultrasound guidance have made line placement much more efficient and the development of small transesophageal echocardiography (TEE) probes has extended this useful monitoring technique into the neonatal population, including premature newborns.<sup>15</sup> The overarching goal of

monitoring should be to establish American Society of Anesthesiologists standard monitors at the beginning of the case and add invasive monitoring, as appropriate.

Although physical observation of the patient is important in preanesthetic evaluation, it is difficult to use this monitor effectively during a surgical procedure. Observation of the patient's color, capillary refill, warmth of skin, muscle tone, fullness of fontanelle, and chest expansion are useful monitors, but they are difficult to reliably observe once the patient is covered with surgical drapes. There is a large dependence on electronic monitors during the majority of the procedure. However, it should be remembered that heart and breath sounds heard through a precordial or esophageal stethoscope, the compliance determined during hand ventilation, the appearance of bleeding in the surgical field, and trends noted in the anesthetic record are all important observations that the anesthesiologist can use as part of the overall assessment of the patient.

Pulse oximetry is one of the most important monitors in neonatal anesthesia. Flexible probes designed for pediatric patients should be used. Placement is sometimes difficult because of the small fingers of the neonate. It may be necessary to place the probe across the web space between the thumb and the first finger, around the lateral aspect of the hand, or on the foot. Many anesthesiologists will place and check two pulse oximeter probes at the beginning of the case because of the clinical experience of having one probe malfunctioning secondary to changes in perfusion during the case. Because there may be differences in preductal and postductal saturations, probes on the left hand or either leg may give lower values than a probe on the right hand in the setting of high pulmonary pressures or low systemic pressures. Especially in the first 2 weeks of life, there is a preponderance of fetal hemoglobin. The pulse oximeter does not compensate for the left shift of the hemoglobin desaturation curve, and pulse oximeter values read about 2% higher than arterial blood saturations.<sup>99</sup>

The hallmark of the pediatric anesthesiologist had been the precordial stethoscope. Precordial stethoscopes have the advantage of being simple and effective in allowing continuous monitoring of heart rate, heart rhythm, strength of heart sounds, and breath sounds. A softening of heart sounds often is indicative of a drop in blood pressure. The esophageal stethoscope is more secure and less susceptible to external noise compared to the precordial stethoscope, while also providing the ability to measure core temperature. However, there has been recent skepticism about the usefulness of the stethoscope,<sup>100</sup> and a survey of pediatric anesthesiologists in the United Kingdom and Ireland revealed relatively little use of the precordial or esophageal stethoscope.<sup>101</sup>

The electrocardiograph is useful primarily to assess heart rate and rhythm.

It is sometimes difficult to get the leads to adhere properly, but wiping the skin with alcohol before placement is often helpful. These leads, once applied, can bind tightly to skin, and care must be taken when removing them to avoid removal of skin, especially in the preterm newborn. ST-T wave abnormalities may be an indicator of significant electrolyte disturbances, but abnormalities related to myocardial ischemia are not common in the perioperative period unless coronary perfusion pressures are compromised.

Blood pressure measurements are important in the management of all newborns. Noninvasive automated machines are commonly used, but it is important that a proper-sized cuff—one-half to two-thirds of the length of the upper arm—be used, and that the arterial indicator, adjacent to the exit of the hoses, be placed over the artery. The cuff should not be routinely cycled excessively, more than every 3 minutes, because of the danger of venous stasis, especially in preterm neonates. In some cases, it is not possible to get reliable readings from an automated machine. An effective alternative is to use a manual cuff and place a Doppler probe over the brachial or radial artery. This system gives reliable systolic blood pressures over a very wide range; the Doppler probe can detect flow, even at very low blood pressures when the automated cuff may fail.

Direct arterial blood pressure monitoring offers the double advantage of accurate blood pressure readings and the ability to withdraw blood samples. A 22-gauge catheter is often used in full-term neonates and a 24-gauge catheter in preterm neonates. A variety of sites can be used, including the radial, dorsalis pedis, and posterior tibial arteries. Less commonly, the brachial or femoral arteries are used. Ultrasound guidance is a valuable tool in the placement of arterial access, even in neonates. It is imperative that ultrasound guidance be attempted before resorting to a cutdown for vascular access. Some patients may come to the operating room with an umbilical arterial line in place. Although these can be used for monitoring, umbilical lines have both infectious and embolic risks, and may be in the way of the surgical field. All arterial lines should be flushed, either continuously or intermittently, with small amounts of heparinized saline, but caution should be used because even small amounts of flush can transmit significant pressure retrograde and cause embolic damage to the brain.

Central venous monitoring is occasionally used in neonatal surgery. Access to blood samples and central venous pressures can be especially useful in procedures, such as gastroschisis repair, in which there are anticipated large changes in both blood loss and third-space losses. Central catheters can also be used for the administration of blood, total parenteral nutrition, and cardioactive drug infusion. Insertion of these lines can be in a variety of sites, including the subclavian, internal jugular, femoral, or external jugular veins using special precautions to maintain sterile technique. The umbilical vein is

not recommended as a site for central monitoring because of the risk of portal vein thrombosis.

Percutaneous insertion may be assisted by ultrasound guidance. Central lines can be both challenging to insert, but also associated with significant complications related to infection, thrombosis, and emboli. Meticulous technique with insertion and maintenance of the line will help minimize these complications. The use of ultrasound guidance is now routine in many US children's hospitals to provide a presumably safe and consistent method for gaining central venous access; however, a meta-analysis did not demonstrate any significant decrease in complications when ultrasound was used to place internal jugular access versus placement by landmark techniques.<sup>102</sup> The rate of complications with central line placement appears to be lowest when the right internal jugular vein is used for central access in infants.<sup>103</sup> Peripherally inserted central catheter (PICC), are now common in neonatal practice and associated with a relatively low rate of complications, especially when the axillary vein site is used for access.<sup>104</sup>

Although there may be some differential between capnography and arterial PCO<sub>2</sub> readings, the trend data are accurate and the shape of the waveform can give significant information about changes in ventilation, obstruction, and rebreathing. Airway pressure measurements are particularly useful in assessing changes in resistance or compliance. Although it has been traditional that hand ventilation was important in determining changes in airway and chest compliance, there is controversy about the reliability of the "feel of the hand on the bag."<sup>105,106</sup> Airway pressure measurements are also useful in adapting adult anesthesia ventilators for use in neonatal and pediatric patients, using peak airway pressures as a guide for setting tidal volume.<sup>107</sup>

## **Anesthetic Systems**

There is a long tradition in pediatric anesthesia of using semi-open, nonrebreathing systems for general anesthesia in newborns. Circuits such as the Jackson-Rees adaptation of the Ayre's T-piece and the Bain circuit have been the most commonly used. These, and related circuits, have the advantages of light weight, easy-to-open valves or lack of valves, rapid response to changes in anesthetic concentration, minimal work of breathing, and high circuit compliance. On the other hand, they require relatively high gas flows and require some modification for mechanical ventilation. These circuits were especially popular when spontaneous ventilation was more commonly used than it is now in neonatal patients. As the use of these circuits has diminished, familiarity with their use and application has dropped in favor of the semi-closed, rebreathing circle systems used in adult patients.

There will be slower change in anesthetic concentration, less circuit compliance, and larger compression volume with these circuits, but they give the advantage of using the same circuit on patients of all ages, less environmental pollution with anesthetic gases, and allow accurate tidal volume delivery with modern anesthesia machines.

Because the loss of both heat and humidity through the endotracheal tube is of concern in the neonate, the anesthetic circuit should incorporate features to minimize water and heat loss. In the past, heated vaporizers were added to the circuit for this purpose. However, there is a danger of patient absorption of water and fluid overload with their use, as well as concerns about overheating the patient or an airway burn. It is now common to use a combination of low gas flows<sup>108</sup> and a disposable, neonatal humidity and heat exchanger to the circuit, with warming of the gases and retention of some of the exhaled humidity.<sup>109</sup>

Finally, the anesthesia machine used for anesthetizing neonates should have the capacity to administer medical air. There are two reasons for this. First, if nitrous oxide is contraindicated, such as in the newborn with bowel obstruction, air is mixed with oxygen to prevent the administration of only 100% oxygen. This is also used to minimize the risk of ROP by avoiding prolonged administration of 100% oxygen in preterm neonates. Second, some patients, such as those with hypoplastic left heart syndrome, may benefit from the administration of air with additional oxygen. Without an air flowmeter in the system, this will not be possible.

### *Induction of Anesthesia*

There is no one method of induction and maintenance of anesthesia that is best for all patients. The current medical status of the patient, the surgical condition, the presence of ongoing fluid or blood losses, the gestational age of the patient, recent fasting, and the experience of the anesthesiologist are all important considerations. Most neonates who come to the operating room will have vascular access already established; if not, the first task before induction is to establish adequate vascular access after applying monitors. Although it may rarely be appropriate to use an inhalational induction if vascular access is difficult in the older newborn, near a month of age, it is mandatory to establish access first in the newborn who is preterm, medically unstable, has a full stomach, has a potentially difficult airway, or has ongoing fluid losses.

### *Airway Management*

Establishing the airway in the neonate requires an appreciation of the differences between the newborn and the adult airway, as discussed earlier. It

is rare to administer anesthesia in the newborn period without establishing an artificial airway. Although, with meticulous technique, a mask airway can successfully be used for short periods of time, the tolerances of mask fit, adequate airway pressure, and avoidance of gastric distention are small, making this a poor choice for any but the briefest of operations. In addition, controlled ventilation is used more commonly today than spontaneous ventilation for surgical procedures, making an artificial airway necessary.

Awake intubation has been used to secure the airway without the danger of loss of airway during the procedure, but it can be a traumatic experience for both the patient and the anesthesiologist, accompanied by pain, bradycardia, breath holding, desaturation, and tissue trauma.<sup>110</sup> The desaturation associated with this technique can be ameliorated by using an oxyscope, a Miller laryngoscope blade that has a side channel to allow insufflation of oxygen during the procedure. However, this technique is usually reserved for patients with severe hemodynamic compromise, an extraordinarily distended and tense abdomen, or a presumed difficult airway, especially the newborn with micrognathia. In the latter situation, the addition of sedation with an opioid or topical application of local anesthetic can help decrease some of the trauma of the procedure. It has also been suggested that an awake intubation may be best for the anesthesiologist who is not very experienced in intubating newborns. It may be better to have a more experienced clinician, if available, attend to the airway in that situation.

Most newborns are intubated after a rapid-sequence induction. Preoxygenation is useful in adding additional safety to the procedure. Although there may be a minor concern about a period of hyperoxia in the preterm, there is no evidence that a short exposure such as preoxygenation will increase the risk of ROP. Agents for induction and muscle relaxation are discussed elsewhere. If there is concern about the difficulty of intubation, it may be prudent to induce anesthesia, ensure adequacy of mask ventilation, and then give the muscle relaxant.

Positioning for intubation is based on the known differences in the neonatal airway. Because of the large occiput, the newborn already has a flexed neck. No changes in position are usually needed, although additional extension of the head may be accomplished by a shoulder roll. A Miller no. 1 blade is commonly used for the full-term newborn and a Miller no. 0 in the preterm, although there are other available blades that individual practitioners may prefer. Sliding the blade down the right side of the mouth allows the blade to be seated with minimal overlap by the tongue (Fig. 42-8). The tip of the blade is advanced to lift the epiglottis directly instead of placing it in the vallecula, as is commonly done with older patients. Every patient's anatomy is different, but if the laryngoscope is advanced in the direction parallel to the handle, one will get the best visualization. If the

glottis is not easily seen, cricoid pressure can be applied with the little finger of the hand holding the handle or by an assistant, often improving the view (Fig. 42-9).

Uncuffed tubes have traditionally been used in newborns to minimize cuff pressure on the subglottic larynx, especially at the level of the cricoid cartilage. Although there has been interest in the use of cuffed tubes in newborns and infants,<sup>111</sup> most clinicians continue to use uncuffed tubes in newborns to maximize the internal diameter (ID) and gas flow characteristics for a given external diameter of tube. Modern cuffed endotracheal tubes make minimal sacrifice in tube diameter to allow for the presence of a cuff, which has renewed interest in cuffed endotracheal tubes. Although various formulas have been proposed for how far to advance an uncuffed tube, it is prudent to use the depth markers at the end of the tube to ensure under direct vision that the tip is advanced 2 or 3 cm past the vocal cords. A 3- or 3.5-mm ID uncuffed tube is usually appropriate for a full-term newborn and a 2.5-mm ID tube is used in preterms, especially those under 1,500 g body weight. Once inserted, the presence of a positive capnograph tracing, bilateral expansion of the thorax, and bilateral breath sounds are used to ensure proper placement. Although some anesthesiologists prefer to advance the endotracheal tube past the carina and then withdraw until bilateral breath sounds are heard, there are two major disadvantages to the technique: trauma to the airway and lack of a guarantee that the tip of the tube is not sitting right at the carina, increasing the chance of migration into a bronchus with head movement. Finally, listen for an air leak at an airway pressure of about 20 cm H<sub>2</sub>O to ensure that the tube is not too large for the airway, increasing the chances of subglottic edema and damage.

**Figure 42-8** Insertion of Miller blade down the right side of the tongue. The blade is then turned and pressure is applied in the direction of the handle.

**Figure 42-9** Cricoid pressure applied with little finger.

If intubation proves difficult, there are a variety of options. A supraglottic airway (SGA) can be used to provide ventilation in newborns as small as 1-kg body weight as preparations are made to use other intubating techniques.<sup>112</sup> The SGA has also successfully been used as the primary airway device in very small patients, but has not been extensively studied.<sup>113</sup> It is possible to use the SGA as a guide for blind intubations in newborns with the use of a stylet tube.<sup>114</sup> The light wand can also be used in newborns,<sup>115</sup> and can be particularly useful in the newborn with micrognathia or retrognathia because of the ability to mold the wand to a “hockey stick” configuration with a sharp angle. Fiberoptic laryngoscopy, the most flexible of intubating tools routinely used in older children and adults, can also be used in the newborn. Fiberscopes are currently available that accept endotracheal tubes as small as 2.5-mm ID, although these scopes do not currently have the ability to change direction and are useful more for confirmation of tube placement. Fiberscopes that can actively change direction accept a 3.5-mm ID tube at the smallest. Insertion of the fiberscope can be done directly or through an SGA. A SGA as a conduit has been particularly useful in directly intubating newborns that could not be visualized by routine approaches.<sup>116</sup>

Finally, an old technique that is used infrequently is digital intubation in which two fingers are advanced along the midline of the tongue and onto the epiglottis, with a stylet tube then advanced between the two fingers.<sup>117</sup> Once the airway is secured, ventilation is usually controlled during neonatal surgical procedures with hand ventilation or, more commonly, mechanical ventilation. After establishing a baseline of acceptable ventilation, it is important to continuously monitor the peak airway pressures, chest expansion, return volume, pulse oximetry, and capnograph tracings for changes. Initial tidal volumes of 6 to 7 mL/kg and rates of 20 to 25 breaths per minute are a reasonable starting point for most patients. With this rate

and volume setting, it would be expected that peak airway pressures be approximately 20 cm H<sub>2</sub>O. A level of positive end-expiratory pressure (PEEP) of 3 to 5 cm H<sub>2</sub>O can be useful in preventing atelectasis. Lung protective strategies applied in the Neonatal Intensive Care Unit (NICU) may be appropriate to continue in the operating room,<sup>118</sup> which is facilitated by the modern anesthesia ventilator. Of course, this strategy must be modified for some patients with severe coexisting disease.

Mechanical ventilation of the neonate can be challenging for the anesthesiologist. Many of the patients presenting for surgery during the neonatal period will have complicating factors such as BPD or frequent mucous plugging that make ventilation continuously challenging during the case. Modern anesthetic systems make ventilation much easier than in the past, even in the smallest patients. Although the standard has been to use pressure control ventilation in this population, all modes of ventilation are now readily available on modern anesthesia machines. In the NICU, volume control ventilation has started to replace pressure control ventilation due to its more predictable and consistent delivery of a set minute ventilation. [Table 42-4](#) shows the modes of ventilation and breath synchronization most commonly used in neonates. Use of high frequency ventilation in the operative setting will require use of a specialized ventilator and close consultation with a critical care physician and respiratory therapist. [Table 42-5](#) lists some of the advantages and disadvantages to use of pressure control, volume targeted, and high frequency ventilation.

**Table 42-4** Common Ventilator Strategies in Neonates

### *Impact of Surgical Requirements on Anesthetic Technique*

**6** Every procedure has its own unique challenges. With any surgery, issues related to presurgical resuscitation, perioperative fluid and blood loss,

heat loss from the surgical field, likely perioperative complications, and the likely need for postoperative intubation and ventilation should be anticipated, both on the basis of experience and communication about the unique needs of the upcoming procedure. There is a dramatic increase in the use of laparoscopic and thoracoscopic approaches to lesions, even in the smallest neonates. The considerations for these approaches are different from open procedures. There may be less blood, fluid, and heat loss, but there are additional issues related to positioning, insufflation pressures in the chest and abdomen, and prolonged surgical time. As new techniques evolve, close communication between the anesthesiologist and the surgeon is necessary to ensure adequate preparation, monitoring, and resolution of problems or complications.

### *Uptake and Distribution of Anesthetics in Neonates*

Various reasons for the faster uptake of anesthetics in infants have been proposed: (1) the ratio of alveolar ventilation to FRC is 5:1 in the infant and 1.5:1 in the adult; (2) in the neonate, more of the cardiac output goes to the vessel-rich group of organs, which includes the heart and the brain; (3) the neonate has a greater cardiac output per kilogram of body mass; and (4) the infant has a lower blood gas partition coefficient for volatile anesthetics. One not well-recognized factor that may result in higher concentrations of volatile anesthetics being administered to infants has to do with the use of nonrebreathing systems such as the Bain or a Mapleson "D" circuit. When an adult circle system is used with infant tubes and bag, the clinician experienced with this equipment is used to reading the inspired, end-tidal, and dialed concentrations of the volatile anesthetic. In the circle system, the inspired concentration is a result of the combination of the end-tidal concentration that is rebreathed through the soda lime absorber and the dialed concentration. The inspired concentration is always lower than the dialed concentration, unless the flow rates are so high that a nonrebreathing system has been created. In the nonrebreathing system, the dialed concentration is the inspired concentration. Clinicians who use both systems are accustomed to these subtle differences. However, if the clinician switches back and forth between the circle system and a nonrebreathing circuit, but does so infrequently, there is a danger of not recognizing the possibility of excessive overpressure of volatile anesthetics with the nonrebreathing systems.

**Table 42-5** Advantages of Particular Ventilator Strategies in Neonates

Mode	Advantages	Disadvantages
Pressure control ventilation	<ul style="list-style-type: none"> <li>• Easy to use due to long-standing widespread use worldwide</li> <li>• Supported by almost all ventilators</li> <li>• Less affected by large leaks around endotracheal tube</li> </ul>	<ul style="list-style-type: none"> <li>• Constant variation in tidal volume and minute ventilation</li> <li>• Rapid changes in lung compliance may lead to volutrauma, hyperventilation, desaturation, or hypoventilation</li> <li>• Increased work of breathing during spontaneous breaths</li> </ul>
Volume-targeted ventilation	<ul style="list-style-type: none"> <li>• Standard, targeted tidal volume, resulting in a predictable minute ventilation</li> <li>• Associated with lower rate of death or bronchopulmonary dysplasia in NICU management of acute respiratory failure<sup>119</sup></li> <li>• Reduces rates of pneumothorax, hypocarbia, days of ventilation, and significant neurologic injury over pressure control ventilation<sup>120</sup></li> </ul>	<ul style="list-style-type: none"> <li>• Requires ventilators with capability of measuring very small tidal volumes</li> <li>• Relies on pressure limits set in ventilator (risk of single point of failure)</li> <li>• More difficult to implement than PCV due to complexity of the ventilators</li> <li>• Large leaks around endotracheal tube may significantly affect reliability of ventilation</li> </ul>
High-frequency ventilation	<ul style="list-style-type: none"> <li>• May provide better ventilation and oxygenation in neonates with severe respiratory disease</li> <li>• Allows for small tidal volumes that are less than total dead space but allow for oxygenation and ventilation</li> <li>• Minimizes barotrauma and volutrauma</li> </ul>	<ul style="list-style-type: none"> <li>• No significant morbidity or mortality advantage over conventional ventilation</li> <li>• Additional cost and difficulty of operation over conventional ventilation</li> <li>• Anesthesia providers are not very familiar with optimization of these devices</li> <li>• Difficult for use during transport or non-ICU locations</li> </ul>

## Anesthetic Dose Requirements of Neonates

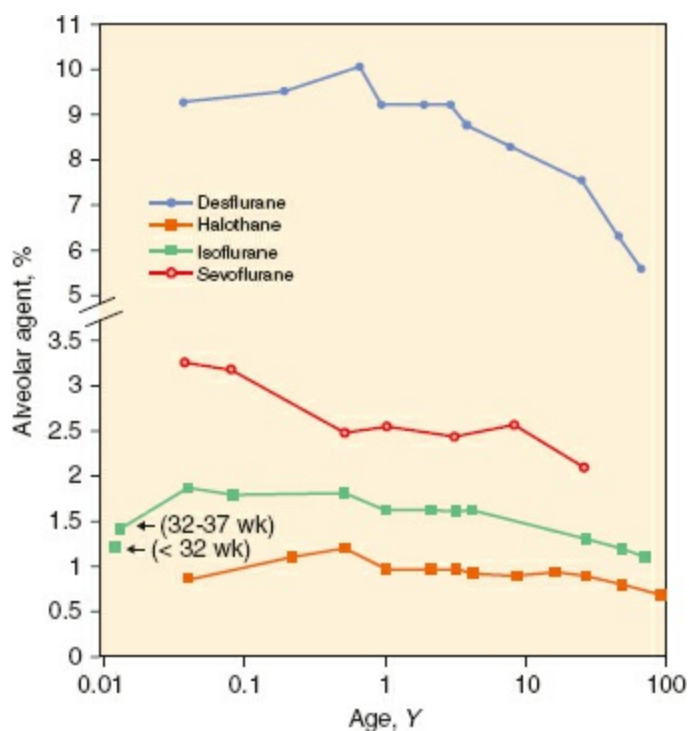

Neonates and premature infants have lower anesthetic requirements than older infants and children.<sup>69</sup> The easiest way to remember the minimum alveolar concentration (MAC) values is that the MAC value in the mature state (i.e., late teenager or adult) is the same as for a full-term infant. By 6 months of age, the MAC value has increased by 50%. In the premature infant, the MAC value decreases by 20% to 30%. However, for sevoflurane anesthesia the highest MAC requirement may be the full-term neonate, decreasing throughout life to adult values (Fig. 42-10).

The reasons for the lower MAC requirements are believed to be an immature nervous system, progesterone from the mother, and elevated blood levels of endorphins, coupled with an immature blood–brain barrier. Progesterone has been shown to reduce the MAC of the pregnant mother. The newborn infant has elevated progesterone levels, similar to those of the mother. Elevated levels of  $\beta$ -endorphin and  $\beta$ -lipotropin have been demonstrated in infants in the first few days of postnatal life. Endorphins do not cross the blood–brain barrier in adults; however, it is believed that the neonate’s blood–brain barrier is more permeable and that endorphins may pass into the CNS, thus elevating the pain threshold and reducing the MAC requirement.

## Regional Anesthesia

There has been a tremendous increase in the use of regional anesthesia in infants and children. In general, regional techniques are combined with general anesthesia to permit early extubation and provide postoperative pain relief. Useful regional anesthesia techniques include spinal anesthesia, caudal anesthesia, epidural analgesia, penile block, and other peripheral nerve blocks (Table 42-6). Regional anesthesia may even have other applications outside surgery, including management of neonatal limb ischemia.<sup>121</sup> Combined regional and general anesthesia is commonly provided for neonates for multiple procedures. The use of ultrasonography has revolutionized the use of regional anesthesia as vascular structures can be easily avoided while still providing a regional blockade.<sup>122</sup> It is important to remember that the dosage of local anesthetic solution used is limited and lipid emulsion is available to potentially treat any intravascular injections.<sup>123</sup> A dose of 1.5 mL/kg of intralipid has been suggested as a rescue dose for toxicity in children.

**Figure 42-10** Effect of age on minimum alveolar concentration (MAC) of anesthetic gases. (Adapted from Greeley WJ. Pediatric anesthesia. In: Miller RD, ed. *Atlas of Anesthesia*. vol 7. Philadelphia, PA: Churchill Livingstone; 1999.)

TAP block (transversus abdominis plane block)
Scalp blocks

## Spinal Anesthesia

Regional anesthesia can be provided as a sole anesthetic or in combination with general anesthesia. The use of sole regional anesthesia in neonates and infants is for avoidance of general anesthetics, for either theoretical decreased risk of apnea or decreased risk of neurotoxicity. Although neurotoxicity trials are still ongoing, it has been shown that spinal anesthesia decreases early apnea following surgery in premature neonates, but does not decrease the risk of overall apnea following surgery in premature neonates.<sup>124</sup> For patients receiving combined general and regional anesthesia, early extubation is possible because the addition of regional anesthetic techniques eliminates the need for intraoperative narcotics in neonates, reduces or eliminates the need for muscle relaxants, and reduces the concentration of volatile agents needed for relaxation.<sup>125</sup> Spinal anesthesia has been reported to be effective when used as the sole anesthetic technique in premature and high-risk infants, but this technique requires excellent cooperation between the anesthesiologist and an experienced surgeon.<sup>126</sup> Although this is technically feasible, because of increasing advancements in general anesthesia techniques, we may be able to provide safer anesthesia with fewer complications by using general anesthesia.<sup>127</sup> Even high doses of spinal anesthetic provide a relatively short time of surgical anesthesia.

Some patients may benefit from providing a caudal block in addition to the spinal anesthetic. This technique seems to provide a longer duration of surgical anesthesia. Total spinal anesthesia, produced either with a primary spinal technique or secondary to an attempted epidural puncture, will present as apnea, rather than as hypotension, because of the lack of sympathetic tone in infants. The exact mechanism for the lack of cardiovascular change with spinal anesthesia in infants and young children is not clear. Consequently, the first indication of a high spinal is falling oxygen saturation rather than a falling blood pressure. Sedation can be added to regional anesthesia but may cause problems with apnea in ex-premature infants.<sup>128</sup>

## Caudal Block

Caudal epidural block is frequently used for abdominal surgery in neonates and is the most commonly used regional anesthetic technique in neonates and infants. There are several different techniques described for performing a caudal block. The landmarks are the coccyx, the two sacral cornua, and the posterior superior iliac spines (Fig. 42-11). Several needle types may be used, but the “pop” through the sacrococcygeal ligament is best observed with a blunt-tipped needle, whereas an intravenous catheter advanced over a needle may provide additional confirmation of sacral canal entry. The caudal space is identified by “pop” through the sacrococcygeal ligament, ease of local anesthetic injection, and absence of subcutaneous swelling upon dose delivery. Once the sacrococcygeal ligament is penetrated and there is a loss of resistance, gentle aspiration is applied to the needle to determine if there is blood or cerebrospinal fluid. Injection of the anesthetic is then attempted. If there is difficulty in injecting the solution, and the tip of the needle is not in the caudal space and it needs to be repositioned. The needle is not advanced up the sacral canal after proper placement in the caudal epidural space has been accomplished, this avoids dural puncture and accidental intrathecal injection. Other methods to identify the caudal space have been described, including stimulating technique<sup>129</sup> and ultrasound guidance.<sup>130</sup> Epinephrine is added to local anesthetic solutions for the purposes of determining if there is an intravascular injection of the anesthetic. Evidence of an intravascular injection include (1) peaked T waves (which may be of relatively short duration), (2) increase in heart rate, and (3) increase in blood pressure. Another technique to minimize the potential difficulties of an intravascular injection is to fractionate the dose by dividing the total dose into three aliquots and waiting approximately 20 to 30 seconds between each aliquot before continuing the injection. Caudal blocks are safe procedures as demonstrated in a large prospective database (PRAN) with very minimal risk overall so long as appropriate precautions are taken during performance.<sup>131</sup>

Caudal anesthesia is particularly effective at reducing the concentrations of volatile anesthetics needed, as well as relaxants and opioids. In addition, a single-injection caudal anesthetic can provide analgesia for 6 to 8 hours. The most common local anesthetics currently in use are 0.125% bupivacaine, 0.25% bupivacaine, or 0.2% ropivacaine. Epinephrine, 1:200,000, is added to local anesthetics to assist in determining if there has been an intravenous injection. Ropivacaine has been reported to be less cardiodepressant than equipotent doses of bupivacaine. If a caudal catheter is placed, an infusion of ropivacaine, bupivacaine, lidocaine, or chloroprocaine can be administered and provide analgesia for several days postoperatively. Current recommendations for infusions in neonates and young infants are for an initial loading dose of 0.2 to 0.25 mg/kg of bupivacaine; after 1 to 2 hours, an

infusion can be begun in a dose of 0.2 mg/kg/hr.<sup>73</sup> The addition of clonidine, 1 to 2 µg/kg, to local anesthetic for caudal block has been used, but may not enhance analgesia.<sup>132</sup> Opioids can also be used for epidural infusions. However, caution must be exercised in neonates and infants who may be prone to apnea with even moderate doses of opioids in the epidural space. Ultrasonography can be used for localization of the caudal space in infants whose anatomy may not be apparent.<sup>130</sup>

**Figure 42-11** Caudal block. The sacral cornua are identified. A stylet needle is introduced into the caudal space through the sacral hiatus. A “pop” is felt as the sacrococcygeal ligament is accessed. After aspiration, 0.8 to 1 mL/kg of local anesthetic solution is injected. This provides analgesia for hernia repair, circumcisions, and lower abdominal surgeries.

## Epidural Analgesia

With the introduction of newer and smaller needles and epidural catheters, we are able to provide epidural analgesia in neonates and infants. Although some practitioners prefer using a caudal route to place catheters in the epidural space, lumbar and thoracic epidural catheters can be easily placed in neonates.<sup>133</sup> Ultrasound or fluoroscopy can be used to provide additional reassurance of successful placement into the epidural space. It is imperative to limit the dose of local anesthetic solution in neonates and children to avoid toxicity.

## Peripheral Nerve Blocks

Common peripheral nerve blocks in neonates include penile blocks, ilioinguinal nerve blocks, lateral femoral cutaneous blocks, transversus abdominis plane (TAP) blocks, brachial plexus blocks, and head and neck blocks for neurosurgical procedures.

## *Penile Block*

This is a relatively simple block that can be performed easily. The dorsal nerves of the penis are located on either side of the shaft of the penis. A ring block using local anesthetic without epinephrine can be used to provide analgesia following circumcision.<sup>134</sup> The dorsal penile nerves may also be approached more proximally, using the pubic symphysis as the primary landmark and injecting the nerves at approximately the 2 o'clock position and 10 o'clock position if the pubic symphysis is at the 12 o'clock position. Because the penis is innervated by the two dorsal penile nerves which are branches of the bilateral pudendal nerves and also innervated by the perineal nerves which are also branches of the pudendal nerves, the ventral surface of the penis may need a ring block with care to avoid the urethra for complete block of the penis. All of these techniques have also been described with ultrasound.<sup>135</sup>

## *Ilioinguinal Nerve Block*

The ilioinguinal and iliohypogastric nerves supply sensory innervation to the inguinal area. These nerves can be easily visualized while operating. However, we find that blockade of these nerves can provide adequate postoperative analgesia (Fig. 42-12). The anterior superior iliac spine is identified. Immediately medial to the anterior superior iliac spine, a needle is inserted toward the umbilicus and local anesthesia is fanned into the area. The advantage with the use of ultrasonography is the ability to significantly reduce the dose of local anesthesia.<sup>72</sup> In fact, that study found the volume for ilioinguinal nerve block can be effectively reduced to 0.075 mL/kg of local anesthetic solution.

**Figure 42-12** Ilioinguinal nerve block. Using a linear ultrasound probe, the anterior superior iliac spine is identified. The layers of the abdomen including the external oblique, transversus abdominis, and iliacus muscles are identified. The ilioinguinal and

iliohypogastric nerves are located under the internal oblique muscle and in the plane between the internal oblique and the transversus abdominis muscle. A 27-gauge needle is inserted under ultrasound guidance in this plane. After aspiration, 0.075 to 0.1 mL/kg of local anesthetic solution is injected. This block can be used for pain relief following hernia surgery.

### *TAP Block*

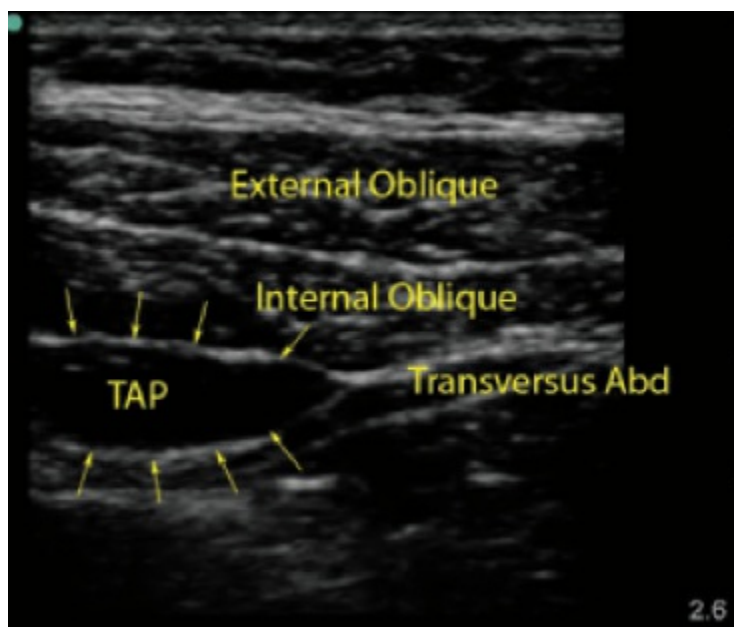

The TAP is a virtual space that exists between the internal oblique and the transversus abdominis muscle. This plane carries the thoracolumbar fibers from T8 to L1 (Fig. 42-13). This block has successfully been used to provide analgesia for infants and neonates undergoing major abdominal surgery, including colostomy placement.<sup>136</sup> This block provides cutaneous pain relief following abdominal procedures but does not provide visceral pain relief. It is a safe block in neonates with no evidence of toxicity.<sup>137</sup>

### *Lateral Femoral Cutaneous Nerve Block*

The lateral femoral cutaneous nerve is a sensory branch of the lumbar plexus that supplies cutaneous innervation over the lateral aspect of the thigh. This block is particularly useful in neonates who undergo muscle biopsies of the lateral thigh.<sup>125</sup>

### *Brachial Plexus Block*

This is performed for major limb surgery including major hand and arm surgical procedures. Using ultrasonography during the axillary approach to identify each branch of the brachial plexus allows selective block of each nerve,<sup>138</sup> thus reducing the total dose of local anesthetic. A single shot supraclavicular approach to the brachial plexus can also be used for providing analgesia for upper extremity surgery. It is important to visualize using ultrasonography because the pleura is relatively close to the area of interest and injection. For sustained pain relief, an infraclavicular catheter may be used and is easily held in place by additional muscle and fascial layers which make this a preferable approach to catheter placement for upper extremity surgery.<sup>139</sup>

**Figure 42-13** TAP (transversus abdominis plane) block using a linear ultrasound probe with a small footprint (25 mm), the abdominal wall is scanned from medial to lateral, the three layers of the abdominal muscles are recognized, a needle is inserted into the space between the internal oblique and the transversus abdominis muscle while hydro-dissecting to find the plane, 0.5 mL/kg of 0.125% bupivacaine is injected into each side to provide analgesia for the abdominal wall.

### *Neurosurgical Blocks*

Peripheral nerve blocks of the head and neck are useful for many surgical procedures. These may be useful in the sick neonate who requires a neurosurgical procedure. Peripheral nerve blocks of the trigeminal nerve and occipital nerve branches may be used to provide analgesia while avoiding general anesthesia.<sup>140</sup>

### *Postoperative Pain Management*

The concepts of postoperative pain management are well known to most anesthesiologists. The use of intraoperative epidural anesthesia followed by postoperative epidural local anesthetics or opioids has been popular in older children and adults, and these techniques are being applied to neonates. In addition, most neonatologists are experienced with the intravenous administration of opioids for patient comfort. Each technique has its own risks and benefits. Commonly used systemic treatments for postoperative pain are listed in [Table 42-7](#).

### **Oral Routes**

Oral routes of medications have been used for decades in neonates and children for managing pain. The commonly used oral analgesics include

nonsteroidal analgesics including acetaminophen (10 to 15 mg/kg) and ibuprofen (5 to 10 mg/kg), and opioids, including hydrocodone (0.1 mg/kg). There may be some pharmacogenetic changes associated with the use of codeine in infants; thus, it is falling out of favor in use across all ages.<sup>141</sup>

**Table 42-7** Postoperative Pain Control for Neonates and Infants

Intravenous
Opioids: morphine, fentanyl, methadone
NSAIDs: ketorolac, ibuprofen
Acetaminophen
Oral
Acetaminophen
Ibuprofen
Hydrocodone
Oxycodone
Codeine
Rectal
Acetaminophen
Diclofenac
Regional and local anesthesia

NSAIDs, nonsteroidal anti-inflammatory drugs.

## Rectal Routes

Rectal suppositories are used frequently in neonates and infants for managing pyrexia. Rectal acetaminophen is commonly used for postoperative analgesia. A larger dose than is usually given orally is needed in infants to achieve good blood levels, because of unreliable absorption. A dose of 20 to 30 mg/kg of rectal acetaminophen is generally recommended for postoperative pain control. Diclofenac, a commonly available rectal suppository in Europe, is frequently used in infants for postoperative pain control.

## Intravenous Analgesia

Opioids are the mainstay of analgesia in neonates and infants in the postoperative period. Morphine and fentanyl are frequently used in the neonatal intensive care unit for analgesia. However, the potential for opioid tolerance after prolonged infusion of opioids is somewhat common. To decrease the likelihood of opioid tolerance,<sup>44</sup> one can rotate opioids or add other medications including continuous intravenous naloxone<sup>142</sup> and intravenous methadone. Other intravenous nonsteroidal anti-inflammatory medications and intravenous acetaminophen, have been introduced. Although not FDA approved for use in neonates, it has been gaining great interest in children for analgesia.<sup>143</sup> It is common to use decreased doses in neonates, 10 mg/kg, whereas the usual dose in older children is 15 mg/kg. Intravenous ketorolac, a nonsteroidal anti-inflammatory drug, has been used successfully

in neonates and infants for pain control at a dose of 0.5 mg/kg.<sup>144</sup>

## ***Postoperative Ventilation***

The choice of an anesthetic drug should be guided by the need for postoperative management of ventilation, as well as the drug's effects on the circulation and other organs. If the surgical procedure or the neonate's condition is such that postoperative ventilation is likely, the prolonged respiratory effects of opioids or any other drug are of little concern. However, if the surgical procedure is relatively short and by itself does not require postoperative ventilation, the clinician should carefully select drugs, as well as doses of anesthetic drugs and relaxants, that will not necessitate prolonged postoperative ventilation or intubation. Postoperative ventilation places the neonate at added risk because of the problems associated with mechanical ventilation, the trauma to the subglottic area, and the potential development of postoperative subglottic stenosis or edema. However, if there is any question about the neonate's ability to maintain protective airway reflexes or normal ventilation after anesthesia, the neonate should be returned to the recovery room or neonatal intensive care unit with the trachea intubated, with controlled mechanical ventilation.

## **Special Considerations**

### ***Maternal Drug Use during Pregnancy***

Many drugs taken during pregnancy can affect the fetus and neonate. One area of special concern is substance abuse. During pregnancy, maternal drug use of cocaine, marijuana, and others leads to a host of problems for the neonate. Cocaine use, for instance, results in a reduced catecholamine reuptake, which may result in the accumulation of catecholamines. This accumulation has circulatory effects on the uterus, the umbilical blood vessels, and the fetal cardiovascular system. Three major problems affecting the infant are premature birth, intrauterine growth retardation, and cardiovascular abnormalities, including low cardiac output.<sup>145</sup> The cardiac output and stroke volume are reduced on the first day of life but return to normal by the second day. The clinical implication of this finding is that these neonates may be unstable enough in the first day of life that it may be advantageous to postpone surgery, if possible, until the second or third day of life. There is also an increase in structural cardiovascular malformations and electrocardiographic abnormalities. The most frequent lesions are peripheral pulmonary stenosis, right ventricular conduction delay, right ventricular hypertrophy, and ST segment and T-wave changes.<sup>146</sup> Preanesthetic history

should elicit the use of drugs, including illicit use, if possible, to evaluate potential alteration of the anesthetic approach.

### ***Temperature Control and Thermogenesis***

The newborn is at risk for significant metabolic derangements caused by hypothermia. Newborns, and especially preterms, do not have the normal compensatory mechanisms that infants and children have when exposed to a cold environment. The newborn does not shiver, increase activity, or effectively vasoconstrict like older children or adults do in response to cold. In addition, the newborn has a larger body surface area-to-weight ratio that promotes heat loss, as well as low levels of subcutaneous fat for insulation. The primary mechanism the newborn has to respond to heat loss is nonshivering thermogenesis.<sup>147</sup> When there is a 2-degree centigrade gradient between core and skin, there is a release of norepinephrine into the bloodstream. Norepinephrine stimulates increased metabolism in a specialized tissue, brown fat, which contains a high concentration of mitochondria and has abundant vascular supply. Stimulated lipolysis results in heat production, with side effects of increased oxygen consumption and production of ketone bodies and water. Ketone production causes both a metabolic acidosis and osmotic diuresis. The aerobic activity results in diversion of cardiac output to the deposits of brown fat around the kidneys, under the sternum, and between the scapulae. Because the diuresis, diversion of cardiac output away from the core circulation, and metabolic acidosis are maladaptive, every effort should be made to prevent nonshivering thermogenesis in the newborn.

Efforts to minimize nonshivering thermogenesis in the newborn are based on minimizing heat loss, both during transport to and from the neonatal intensive care unit and in the operating room. Transport should be done with the newborn in an incubator or in an open bed with overhead heaters. This will prevent heat loss from conduction and radiation. In the operating room, the room temperature is raised to its maximal level to minimize loss by conduction. Placing the patient on a forced-air warming blanket can reduce conductive heat loss. Using plastic wrap or commercially available covers and hats to minimize heat loss from the head and all other areas not in the surgical field is also beneficial. The goal of all these activities is to maintain a neutral thermal environment, minimizing the stress that hypothermia can induce in the perioperative period. A complicating factor is that anesthetic agents can reduce or eliminate thermogenesis, removing any ability to compensate for cold stress.<sup>148</sup>

### ***Respiratory Distress Syndrome***

Because of the enormous technical ability of the neonatologist and the resources of neonatal intensive care units, many small infants survive and some will require surgery. One of the frequent problems of preterm infants is the occurrence of the RDS secondary to a deficiency of surfactant. As discussed earlier, the use of exogenous surfactant has been widely used in premature infants of low birth weight either to prevent or to treat RDS. As a result, fewer infants now die of this entity, and the incidence of complications related to RDS has dropped. One of the long-term consequences of RDS is BPD. BPD refers to a continuum of chronic disease of the lung parenchyma and airways, as well as neurodevelopment that occurs in preterm infants, especially those born under 32 weeks' gestation, who have survived RDS.<sup>149</sup> The theories of the cause of this condition include toxicity from oxygen administration, infection, inflammation, and barotrauma. Characteristics include airway smooth muscle hyperplasia, peribronchiolar fibrosis, enlarged alveoli, and disorganized pulmonary vasculature. Many patients improve as they age, but reactive airways, recurrent pulmonary infections, and a prolonged oxygen requirement are seen in some patients. Anesthetic concerns in these patients include evaluation of baseline oxygenation and potential presence of active bronchoconstriction. These patients often benefit from prophylactic bronchodilator therapy before induction. The baseline measure of oxygenation is important because these patients have less pulmonary oxygen reserve and may desaturate quickly with induction of anesthesia and hypoventilation. In patients with severe BPD, ventilatory management may be complicated by poor lung compliance and hyperinflation, as well as reactive airway disease. Although postanesthetic ventilation is not usually required, a high index of suspicion should be used if there is significant clinical evidence of poor lung function preoperatively.

### *Postoperative Apnea*

Apnea and bradycardia are well-recognized, major complications during and after surgery in neonates. The infants at highest risk are those born prematurely, those with multiple congenital anomalies, those with a history of apnea and bradycardia, and those with chronic lung disease. The etiology of neonatal apnea is multifactorial. Decreased ventilatory control and decreased responsiveness to hypoxia and hypercarbia may be potentiated by anesthetic agents. Respiratory muscle fatigue may also play a role because neonates have a smaller percentage of type I fibers in their diaphragm and intercostal muscles. In addition, hypothermia and anemia also contribute to the development of postoperative apnea.<sup>150</sup> The treatment of postoperative apnea or bradycardia may be as simple as tactile stimulation. However, some infants require mask ventilation or even prolonged intubation and ventilatory

support. Infants with life-threatening apnea and bradycardia before surgery may be receiving CNS stimulants. Caffeine and theophylline (metabolized to caffeine) act by increasing central respiratory drive and lowering the threshold of response to hypercarbia, as well as stimulating contractility in the diaphragm. Caffeine is favored because of its wider therapeutic margin and decreased propensity for toxicity. Administering caffeine prophylactically to infants at risk of postoperative apnea to ensure adequate serum levels may prevent the need for prolonged periods of postoperative ventilatory support. The recommended loading dose is 10 mg/kg caffeine.<sup>151</sup> Spinal anesthesia may reduce the risk of early postoperative apnea, but does not reliably decrease the overall risk of postoperative apnea in premature infants.

The question remains as to which infant should be admitted and monitored after outpatient surgery and for how long. The most conservative approach is to monitor all infants younger than 60 weeks' postconceptual age overnight after surgery. Although the incidence of significant apnea and bradycardia is highest in the first 4 to 6 hours after surgery, it can occur up to 12 hours after surgery. In addition, the incidence of apnea directly correlates to postconceptual age. The risk of apnea goes up the younger the gestational age at birth. An insightful approach to interpreting the various small studies is to stratify the risk of apnea, as done by Cote et al.<sup>150</sup> Using a meta-analysis, the study determined that the risk of apnea could be correlated with a combination of gestational age and postconceptual age. Using 95% confidence limits, the authors found that the probability of apnea in nonanemic infants free of recovery room apnea was not less than 5% until postconceptual age was 48 weeks with gestational age of 35 weeks. This risk was not less than 1%, until a postconceptual age of 56 weeks with a gestational age of 32 weeks or a postconceptual age of 54 weeks and gestational age of 35 weeks. This type of analysis allows the clinician to determine which patients should be admitted on not only the criteria of gestational and postconceptual ages but also the amount of risk they are willing to assume.

## *Retinopathy of Prematurity*

As the survival rate of increasingly preterm infants has grown, there is increasing concern about the development of ROP. The very preterm infant, especially those under 1,200 g of weight, are at highest risk, with an incidence of significant disease about 2%. Acute retinal changes are seen in about 45% of susceptible preterm neonates, but there is spontaneous regression in most, permitting development of normal vision. Other infants will progress to a severe form of ROP and potentially permanent blindness. Several complex factors may be responsible for the development of ROP. In the fetus, developing blood vessels grow gradually

7

4

from the macula toward the edges of the developing retina. In full-term newborns, this process is complete at birth or in the first few weeks, but continues for a longer period in the preterm infant. These growing vessels are at risk for vasoconstriction and subsequent hemorrhage, followed by disorganized neovascularization or scarring. This scarring and lack of normal growth can eventually cause the retinal network to peel away resulting in retinal detachment. The spectrum or stages of disease is classified as follows:

**Stage I.** Mildly abnormal blood vessel growth. Many children who develop stage I improve with no treatment and eventually develop normal vision.

**Stage II.** Moderately abnormal blood vessel growth. Many children who develop stage II improve with no treatment and eventually develop normal vision. The disease resolves on its own without further progression.

**Stage III.** Severely abnormal blood vessel growth. The abnormal blood vessels grow toward the center of the eye instead of following their normal growth pattern along the surface of the retina. Some infants who develop stage III disease improve with no treatment and eventually develop normal vision. However, when infants have a certain degree of stage III and “plus disease” develops, treatment is considered. Plus disease means that the blood vessels of the retina have become enlarged and twisted, indicating a worsening of the disease. Treatment at this point provides a good chance of preventing retinal detachment.

**Stage IV.** Partially detached retina.

**Stage V.** Completely detached retina.

The most common cited cause of ROP is hyperoxia from administered oxygen, but hypoxemia, hypotension, sepsis, intraventricular hemorrhage, and other stresses have been implicated. At one time, there was concern that exposure to bright ambient light could cause ROP, but this has been disproven.<sup>152</sup> Although there may be spontaneous regression in early stages, there may also be progression to advanced stages and retinal detachment. The most common therapies involve using cryotherapy or laser therapy to destroy peripheral areas of the retina, slowing or reversing the abnormal growth of blood vessels. This is done to preserve the central vision from continuing distortion of the abnormal vessels in the periphery, although there is some loss of peripheral vision with this therapy.<sup>153</sup> In advanced stages, partial retinal detachment can be treated with a scleral buckle or vitrectomy.

Cryotherapy and laser therapies, as well as advanced procedures, are usually performed under general anesthesia in the operating room, although it is occasionally done at bedside with sedation in ventilated patients. These surgical procedures do not involve blood loss or significant surgical stress, but they do depend on a still surgical field for periods ranging from 30 to 90 minutes. The primary anesthetic challenge in these patients is related to the

extreme prematurity and small size of the patients. Adequate monitoring, vascular access, and thermal stability are common challenges to management.

The risks of the development of ROP from hyperoxia have been of concern to anesthesiologists who anesthetize preterm infants for any type of surgery. Whether supplemental oxygen during anesthesia contributes to development of ROP has been a long-standing question in neonatal anesthesia. There is no direct answer to this question, but some evidence from a large collaborative study helps provide some guidance. Premature infants with confirmed early stages of ROP and a median pulse oximetry below 94% saturation were randomized to a conventional oxygen arm with pulse oximetry targeted at 89% to 94% saturation or a supplemental arm with pulse oximetry targeted at 96% to 99% saturation for at least 2 weeks.<sup>154</sup> The patients were then re-examined for progression of disease. Use of supplemental oxygen at pulse oximetry saturations of 96% to 99% did not cause additional progression of pre-threshold ROP. This study demonstrates that the use of supplemental oxygen for a prolonged period of time, not just for the short duration of a general anesthetic, was not deleterious as long as the pulse oximetry readings were kept in the 96% to 99% range. Consequently, keeping pulse oximetry readings in this range during an anesthetic should not be responsible for causing a progression of ROP in susceptible patients.

### *Neurodevelopmental Effects of Anesthetic Agents*

There has been recent concern about the potential deleterious impact of anesthetic drugs on the developing brain. A variety of studies have shown that prolonged exposure of animal models to anesthetic agents can lead to neurodegenerative changes in the developing brain of neonatal rats.<sup>155</sup> However, these exposures to volatile agents and ketamine were for prolonged periods, the equivalent of several weeks of continuous exposure in the human. Nonetheless, this is an area of great concern for anesthesiologists.<sup>156</sup> Animal experiments have demonstrated neurocognitive changes in animals exposed to NMDA receptor antagonists like ketamine, volatile agents like isoflurane, as well as other agents including midazolam. The collective data that are currently available in literature do not support the withdrawal of these drugs from the practice of neonatal anesthesia. There has been a general recommendation to delay nonurgent surgery in children under 3 years of age made by the FDA/IARS public/private partnership SmartTots<sup>157</sup>; however, neonatal surgical problems cannot usually be delayed safely for years.

The neurotoxicity data seem to be reproducible in rodents but not in other species. Future prospective trials with prospective neurocognitive testing of infants exposed to anesthesia are needed. There currently exists no conclusive evidence to demonstrate the deleterious effect of inhaled or intravenous

anesthetics on neurocognitive function in neonates and infants. Prospective studies, including a current study randomizing infants to getting a spinal anesthesia versus general anesthesia should be able to provide better information on this very complex problem that may face pediatric anesthesiologists. Early results from a prospective randomized general anesthesia and spinal study (GAS) has demonstrated no significant differences in neurocognitive outcomes in infants undergoing short procedures like hernia repair.<sup>158</sup> Several retrospective studies including data about children from a particular county in Minnesota has some data to lead to believe that there may be an association with the development of learning disability especially when exposed to multiple anesthetics before 2 years of age.<sup>159</sup> Although the data generated a lot of interest, it is important to understand that we need more concrete data and prospective studies to demonstrate that there are indeed clinically apparent neurocognitive changes associated with exposure to anesthesia in neonates and infants.

## **Surgical Procedures in Neonates**

Surgical procedures in neonates are functionally divided into two periods: those performed in the first week and those performed in the first month. There has been a strong trend in recent years to put an emphasis of presurgical stabilization before taking the newborn to the operating room. This has reduced the emergent nature of newborn surgeries. Many procedures that used to be done on an emergent basis, even in the middle of the night, such as repair of CDH or omphalocele, are now done days later, after initial therapy has been instituted. Exceptions to this include gastroschisis, which is usually corrected within 12 to 24 hours, airway lesions such as webs that are causing significant airway obstruction, and acute subdural/epidural hematomas from traumatic delivery. In most cases, however, a period of 1 to 3 days can be allowed for stabilization of the newborn or transport to an appropriate pediatric center for treatment. There is more to neonatal emergency surgery than just the immediate anesthetic and surgical procedures. Many of these infants require the support services of specialized nursing units, pediatric radiologists, pediatric intensive care physicians, specialized laboratory facilities, and they must have their complete care be the main consideration of where their surgery should be done. Many procedures are now performed using laparoscopic techniques which decreases postoperative morbidity and pain and facilitates early extubation.

### ***Surgical Procedures in the First Week of Life***

The most frequent major surgical procedures performed in the first week of life are for CDH, omphalocele and gastroschisis, tracheoesophageal fistula (TEF), intestinal obstruction, and myelomeningocele. Some of these conditions, such as CDH, omphalocele and gastroschisis, and myelomeningocele, are obvious at birth. It may take hours or days for a TEF or intestinal obstruction to manifest. Because of the lack of expertise many hospitals have in the care of these patients, the transfer of these neonates to hospitals with greater expertise is often prudent after initial stabilization of the patient. Most hospitals that have expertise in these patients have a transport team that is well-qualified to help with stabilization and transport. Those centers that do not have transport teams often have extensive protocols and procedures to work with the sending institution to help ensure the safe transfer of the patient.

Two confounding factors in neonatal surgery are prematurity and associated congenital anomalies. The presence of one congenital anomaly

increases the likelihood of another one. In conditions such as TEF, the mortality rate from an associated congenital heart defect is higher than that from the surgical correction of the TEF. Prematurity, particularly when associated with RDS, may adversely affect surgical outcome. The use of surfactant in the treatment of the RDS has greatly increased the number of survivors and has decreased the complexity of the issues of the infant with a combination of TEF and RDS. A neonatologist should be consulted in the case of any neonate with a congenital defect who is considered for surgery. The most serious associated congenital lesion is that of the cardiovascular system. More than 10% of infants with CDH have a cardiac anomaly,<sup>160</sup> with a higher incidence in newborns with associated syndromes, and approximately 15% to 25% of infants with TEF have an associated congenital cardiac anomaly.<sup>161</sup>

## **Congenital Diaphragmatic Hernia**

CDH occurs with an incidence of approximately 1 in 4,000 live births. Traditionally, the mortality rate from CDH was in the range of 40% to 50%. The new strategy of permissive hypercapnia and delayed surgical repair has resulted in survival rates of more than 75% in some centers.<sup>162</sup> However, the morbidity remains high in survivors. A brief discussion of the embryologic characteristics of CDH will help the clinician understand the potentially enormous postoperative problems that may be encountered.

### *Embryology*

Early in fetal development, the pleuroperitoneal cavity is a single compartment. The gut is herniated or extruded to the extraembryonic coelom during the ninth to tenth weeks of fetal life. During this period, the diaphragm develops to separate the thoracic and abdominal cavities (Fig. 42-14). The development of the diaphragm is usually completed by the seventh fetal week. In the ninth to tenth weeks, the developing gut returns to the peritoneal cavity. If there is delay or incomplete closure of the diaphragm, or if the gut returns early and prevents normal closure of the diaphragm, a diaphragmatic hernia will develop, producing varying degrees of herniation of the abdominal contents into the chest. The left side of the diaphragm closes later than the right side, which results in the higher incidence of left-sided diaphragmatic hernias (foramen of Bochdalek). Approximately, 90% of hernias detected in the first week of life are on the left side.

### *Clinical Presentation*

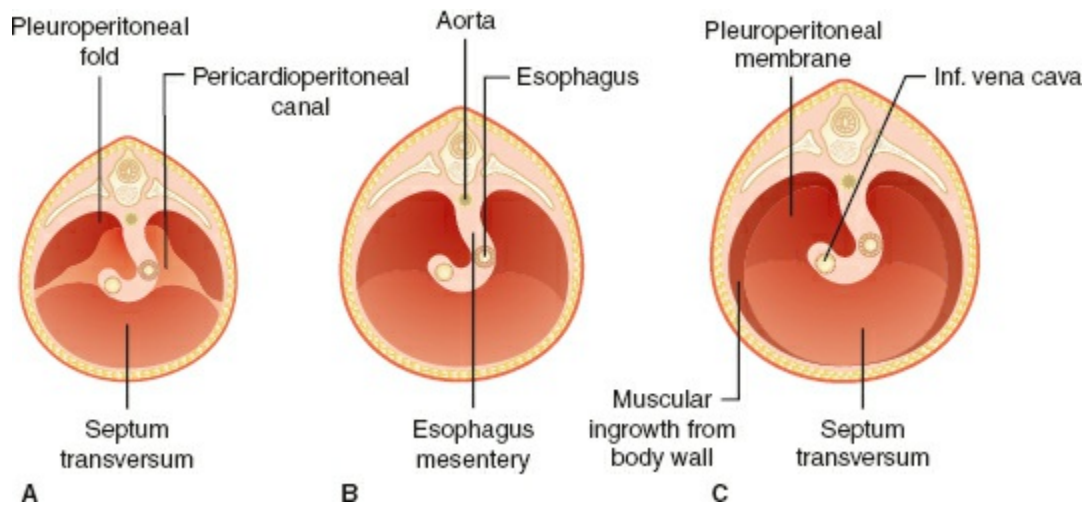

The clinical presentation and the outcome from a diaphragmatic hernia are varied. The bowel contents may compress the lung buds and prevent development, leading to bilateral hypoplastic lungs with very little chance for

survival. In most instances, however, a moderately small diaphragmatic hernia may develop later in fetal life so the lung is normal but compressed by the abdominal viscera. At the mild end of the scale, the infant might have a relatively normal pulmonary vascular bed with varying degrees of persistent pulmonary hypertension that may rapidly revert to normal. In more severe defects, significant pulmonary hypoplasia and abnormal pulmonary vasculature lead to greater mortality, largely a result of ongoing pulmonary hypertension.

After closure of the pleuroperitoneal membrane, muscular development of the diaphragm occurs. Incomplete muscularization of the diaphragm results in the development of a hernia sac because of intra-abdominal pressure. The condition is known as eventration of the diaphragm, and the diaphragm may extend well up into the thoracic cavity. The other possibility is that the innervation of the diaphragm is incomplete and the muscle is atonic. Eventration of the diaphragm is usually not symptomatic in the first week of life.

### *Antenatal Diagnosis*

The diagnosis of CDH can be made prenatally by fetal ultrasonography or fetal magnetic resonance imaging. Antenatal diagnosis has led to the identification of a “hidden mortality” in CDH, fetuses who did not survive gestation and neonates who died before diagnosis. Various factors have been proposed to identify predictability of survival, including early gestation diagnosis, severe mediastinal shift, polyhydramnios, a small lung-to-thorax transverse area ratio, and the herniation of liver or stomach. New techniques in fetal surgery, such as temporary endoscopic fetal tracheal occlusion, may prove beneficial to fetuses with CDH who are identified to be at risk for not surviving to term.<sup>163</sup> The other obvious advantage of prenatal diagnosis is that plans can be made for maternal or neonatal transport to a center with advanced neonatal critical care with availability of ECMO. Early repair, on ECMO, or delayed repair with treatment of pulmonary hypertension on ECMO prior to repair remains an area of controversy, with literature in support of both approaches.<sup>164,165</sup> However, it is clear that introduction of ECMO has improved survival compared to historical data.<sup>166</sup>

**Figure 42-14** Schematic drawings illustrating the development of the diaphragm. **A:** The pleuroperitoneal folds appear at the beginning of the sixth week. **B:** The pleuroperitoneal folds have fused with the septum transversum and the mesentery of the esophagus in the seventh week, thus separating the thoracic cavity from the abdominal cavity. **C:** In a transverse section at the fourth month of development, an additional rim derived from the body wall forms the most peripheral part of the diaphragm. (Adapted from Langman J. Body cavities and serous membranes. In: Sadler TW, ed. *Langman's Medical Embryology*. 5th ed. Baltimore, MD: Williams & Wilkins; 1985:147.)

### Clinical Presentation

The occurrence of symptoms depends on the degree of herniation and interference with pulmonary function. At times, the degree of interference is so great that the neonate's clinical condition begins to deteriorate immediately and, in other situations, it may be several hours before the infant's condition is fully appreciated. In the severely affected newborn, the initial clinical findings are usually classic and readily discerned. The infant has a scaphoid abdomen secondary to the absence of intra-abdominal contents, which have herniated into the chest. Breath sounds on the affected side are reduced or absent. The diagnosis can be confirmed with a radiograph (Fig. 42-15). Immediate supportive care entails tracheal intubation and control of the airway along with decompression of the stomach. Excessive airway pressure carries a high risk for pneumothorax before and after the repair.

### Preoperative Care

CDH was traditionally treated as a surgical emergency. The infants were taken immediately to surgery for decompression and repair. The thought was that removing the abdominal viscera from the thorax would allow for re-expansion of the atelectatic lung and improved oxygenation. However, as the pathophysiology of CDH was more clearly defined—pulmonary hypoplasia associated with a hyperreactive and hypoplastic pulmonary vasculature—a

strategy of preoperative stabilization with delayed surgical repair was adopted.

**Figure 42-15** Infant with left-sided congenital diaphragmatic hernia. Note the loop of bowel gas in left hemithorax.

The stabilization of an infant with CDH may require multiple treatment modalities. The use of aggressive ventilation strategies to induce respiratory alkalosis has been abandoned secondary to the high incidence of iatrogenic lung injury. Conventional ventilation with permissive hypercapnia is now favored. The goal is to maintain preductal arterial saturation above 85% using peak inspiratory pressures below 25 cm H<sub>2</sub>O and allowing the PCO<sub>2</sub> to rise to 45 to 55 mmHg.<sup>162</sup> High-frequency oscillatory ventilation, in addition to nitric oxide, has been used in place of conventional ventilation in an attempt to reduce barotrauma and has been demonstrated to be beneficial.<sup>167</sup> Neonates born with CDH may also have a component of surfactant deficiency, and studies have shown improvement in oxygenation in those infants given surfactant prophylactically. These have been well demonstrated in animal experiments when compared with tracheal ligation.<sup>168</sup>

The use of ECMO in infants with CDH was initiated in the mid-1980s. Despite extensive literature on the subject, there remains an ongoing debate as to whether ECMO improves survival in neonates with CDH. The Congenital Diaphragmatic Hernia Study Group analyzed data from the multicenter CDH Registry and determined that ECMO improves the survival rate in CDH neonates with a predicted high risk of mortality ( $\geq 80\%$ ) based on birth weight and 5-minute Apgar score. A right-sided CDH may carry a higher mortality and morbidity compared with a left-sided defect, despite the use of ECMO.<sup>169</sup> Repair of a right-sided CDH can be seen in [Figure 42-16](#).

### *Perioperative Care*

Because delayed surgical repair of CDH is now the norm, neonates with CDH frequently present to the operating room already intubated and on some form of ventilatory support. Despite a period of preoperative stabilization, some infants still have a component of reactive pulmonary hypertension. The goals of ventilatory management are to ensure adequate oxygenation and avoid barotrauma. Any sudden deterioration in oxygen saturation with or without associated hypotension should raise suspicion of pneumothorax. It is important to avoid hypothermia because this increases the oxygen requirement and could precipitate pulmonary hypertension. Blood loss and fluid shifts are usually not a problem, although maintenance of intravascular volume is essential to avoid acidosis, which could also precipitate pulmonary hypertension. Preoperative preparation may include multimodal treatment of pulmonary hypertension with nitric oxide, sildenafil (PDE-5 inhibitor), milrinone (PDE-3 inhibitor), epoprostenol or iloprost (PGI<sub>2</sub> inhibitor), bosentan (endothelin inhibitor), and imatinib (platelet derived growth factor inhibitor) which have all been attempted with varying degrees of success.<sup>170</sup>

### *Anesthetic Technique*

The anesthetic technique chosen depends on the size of the defect and the anticipated postoperative respiratory status. In those infants who will remain intubated after surgery, inhalation agents and narcotics may be used as tolerated. In those infants with a small defect, who present to the operating room with little or no respiratory distress, it may be beneficial to avoid intraoperative narcotics and provide regional or neuraxial analgesia in anticipation of extubation. The use of nitrous oxide should be avoided, particularly in those situations in which abdominal closure could be difficult. Muscle relaxation is often needed to facilitate abdominal closure.

### *Postoperative Care*

Most infants with CDH require intensive postoperative care. Recovery depends on the degree of pulmonary hypertension and pulmonary hypoplasia. It was previously believed that pulmonary hypoplasia was responsible for most deaths; however, it is now believed that potentially reversible pulmonary hypertension may be responsible for as much as 25% of reported deaths.

**Figure 42-16** Another infant with congenital diaphragmatic hernia. In this patient, the defect is in the right diaphragm. **A:** The liver herniated into the right chest cavity. **B:** The complete repair with Gore-Tex graft material and the liver appropriately located in the abdominal cavity. (Photographs courtesy of Rashmi Kabre, MD.)

There is evidence to suggest that cardiac development is impaired in infants with CDH. Relative left ventricular hypoplasia with an attenuated muscle mass and cavity size have been described.

### **Omphalocele and Gastroschisis**

Although omphalocele and gastroschisis sometimes appear similar and may be confused, they have entirely different origins and associated congenital anomalies.<sup>171</sup> During the fifth to tenth weeks of fetal life, the abdominal contents are extruded into the extraembryonic coelom, and the gut returns to the abdominal cavity at approximately the tenth week. Failure of part of or all the intestinal contents to return to the abdominal cavity results in an omphalocele that is covered with a membrane called the amnion (Fig. 42-17). The amnion protects the abdominal contents from infection and the loss of ECF. The umbilical cord is found at approximately the apex of the sac. Gastroschisis, in contrast, develops later in fetal life, after the intestinal contents have returned to the abdominal cavity. It results from interruption of the omphalomesenteric artery, which results in ischemia and atrophy of the various layers of the abdominal wall at the base of the umbilical cord. The gut

then herniates through this tissue defect. The degree of herniation may be slight, or major amounts of the abdominal viscera may be found outside the peritoneal cavity. The umbilical cord is found to one side of the intestinal contents (Fig. 42-18).

The intestines and viscera are not covered by any membrane and therefore are highly susceptible to infection and loss of ECF. There is a very high incidence of associated congenital anomalies with omphalocele, but much lower with gastroschisis.<sup>172</sup> The Beckwith–Wiedemann syndrome consists of mental retardation, hypoglycemia, congenital heart disease, a large tongue, and an omphalocele. Congenital heart lesions are found in approximately 20% of infants with omphalocele. Other associated congenital defects are found with gastroschisis and omphalocele; most involve the gastrointestinal tract and consist primarily of intestinal atresia, stenosis, or malrotation. Because of the uncovered gut irritating the uterine lining, premature delivery is more common in gastroschisis patients.

### *Antenatal Diagnosis*

The overall incidence of these defects is about 1:5,000 live births. Screening for abdominal wall defects is accomplished through the use of maternal serum  $\alpha$ -fetoprotein (AFP). AFP is a normal protein present in fetal tissues during fetal development. Closure of the abdominal wall and the neural tube (see “Myelomeningocele”) prevents release of large quantities of this protein into the amniotic fluid. High levels of AFP in the amniotic fluid can cross the placenta and be detected in maternal blood. Thus, abnormal levels of maternal serum AFP in the mother raise concerns over the possibility of either an abdominal wall defect or a neural tube defect in the fetus, as do high levels of AFP in fluid obtained during amniocentesis. Levels tend to be higher when the defect is gastroschisis instead of omphalocele. The primary method of definitive fetal diagnosis of gastroschisis and omphalocele is ultrasonography. In a recent study, 88% of patients with gastroschisis and 69% with omphalocele were diagnosed prenatally with ultrasound.<sup>173</sup> An advantage of ultrasound is the ability to diagnose other complicating abnormalities, such as cardiac defects.

## *Preoperative Care*

Most neonates with gastroschisis or omphalocele diagnosed prenatally are delivered by cesarean section. The advantages of this are the ability to prevent trauma to the exposed bowel and to allow better coordination of the various medical specialties needed for immediate surgical management of the defect. Priorities in the delivery room care unique to an infant with gastroschisis are the need to protect the exposed bowel and minimize fluid and temperature loss. An effective way to achieve these goals involves placing the defect and lower body in a sterile, clear plastic bag to protect the defect and minimize heat and fluid loss. The bag can be filled with warm saline and a drawstring can be used to tighten the bag against the infant's body.

Preoperative stabilization of the neonate with an abdominal wall defect includes management of respiratory insufficiency, establishment of adequate intravenous access, and an assessment for associated congenital anomalies. It is expected that a significantly higher incidence of congenital anomalies will be found in omphalocele patients. Respiratory failure at birth in infants with omphalocele is a significant predictor of mortality. Lung hypoplasia and abnormal thoracic development may be significant in infants with large omphaloceles. A difficult airway can be present in the patient with Beckwith–Wiedemann syndrome because of the large tongue.

Surgery is not urgent in the neonate with an omphalocele and can be delayed for several days until the infant is assessed and stabilized. In those infants with severe respiratory distress or congenital heart disease who are too unstable for surgery, nonsurgical treatment with topical antiseptics and delayed closure is an option.<sup>174</sup> Although there has been some interest in nonoperative, bedside-staged closure of gastroschisis defects, primary operative closure continues to be the most common approach.<sup>175</sup>

## *Perioperative Care*

The two major perioperative concerns are fluid loss and ventilation. The fluid volume management of the infant often entails administration of large amounts of full-strength, balanced salt solution. The adequacy of the peripheral circulation and urine output is an indicator of the adequacy of the intravascular volume resuscitation. Both conditions may present an intraoperative challenge to the anesthesiologist because with an omphalocele, after the amniotic membrane is removed, large volumes of fluid may transude or exude from the exposed abdominal viscera. The fluid that is lost is ECF, which should be replaced with a balanced salt solution even in neonates. An arterial line is often used for blood pressure monitoring and frequent blood gas monitoring to assess acid–base status.

If the defect in the abdominal wall is small, a primary repair of the deficit can be accomplished. However, with a large defect, it may be difficult to return the abdominal viscera to the peritoneal cavity because the muscle and peritoneum are underdeveloped. Because of concern for the increase in the volume of gas in the intestine, nitrous oxide should not be used. Muscle relaxation is necessary to allow closure of the abdomen. With moderate size abdominal wall defects, it may not be possible to close the peritoneum, but there may be sufficient skin to close the defect. With large defects, the peritoneal cavity may be too small to contain the viscera, and attempted closure can impair circulation to the bowel, kidneys, and lower extremities, as well as compromise respiration. A pulse oximeter probe on the foot can be helpful in monitoring circulation to the lower extremities during abdominal wall closure.

Attempts have been made to find objective criteria by which to determine whether the infant will tolerate primary closure of the defect, and to avoid or minimize the circulatory and ventilatory problems. One method has been to measure intragastric pressure in infants who undergo primary closure. Intragastric pressure is measured by placing a nasogastric tube in the stomach and using a column of saline to measure the pressure.<sup>176</sup> Studies have used the criteria that if the intragastric pressure was less than 20 mmHg, primary closure can proceed. Above 20 mmHg pressures during closure, delayed closure and placement of a Dacron silo were used. With this approach, primary closure has been successful when used, with faster return to full feeds and shorter hospital length of stay compared with patients treated by delayed closure. Complications have been less with primary closure using this approach. Another method to predict successful closure of abdominal wall defects is to use central venous pressure, an increase with closure of the fascia of greater than 4 mmHg is predictive of unsuccessful primary closure.<sup>177</sup>

If primary closure is impossible, a silo ([Fig. 42-19](#)) is incorporated into the abdominal wall to contain and cover the abdominal viscera. The repair is then staged from this point onward. Every 2 or 3 days, the size of the silo is reduced, in much the same fashion that a tube of toothpaste is squeezed. The infant may feel some degree of discomfort as the peritoneum and skin are stretched. Institutions vary in how they accomplish the delay closure, with some surgeons bringing the patient to the operating room for each stage and others doing this at bedside, often with the assistance of small doses of ketamine or other analgesics. Some of these patients remain on mechanical ventilation during this period, and others are extubated. In either case, both blood pressure and oxygen saturation should be closely monitored during and immediately after each stage of closure to ensure that the increase in abdominal and intrathoracic pressure does not significantly impede ventilation, oxygenation, and venous return. In some cases, further reduction

must be delayed until there is more abdominal growth. This is a situation that requires clinical judgment. After several stages of silo reduction, the final operation is complete closure of the abdominal wall defect under full anesthesia with complete muscle relaxation.

**Figure 42-19** Silo placement on neonate with gastroschisis. The abdominal contents are now within a large silo, suspended above the neonate, with the umbilical cord observed protruding from one side of the defect. (Photograph courtesy of Linda Zekas, MSN, APN.)

### *Postoperative Care*

The postoperative care of infants with omphalocele or gastroschisis is critical. Some need tracheal intubation and assisted ventilation of the lungs for days to weeks. The ventilatory status of the patient is especially critical in omphalocele patients because up to half of these patients are born with pulmonary hypoplasia, making the balance of increased abdominal pressures and adequate ventilation and oxygenation especially challenging. Additional complications include postoperative hypertension and edema of the extremities. The increased abdominal pressure can reduce the circulation to the kidneys, which results in a release of renin. Renin activates the renin-angiotensin-aldosterone system, which is believed to cause the hypertension.

## Tracheoesophageal Fistula

The treatment of esophageal atresia and TEF can be both challenging and satisfying for the anesthesiologist. Death in the perioperative period typically results from prematurity or from an associated congenital heart defect. TEF occurs in approximately 1 in 3,000 live births. Approximately 85% consist of a fistula from the distal trachea to the esophagus and a blind proximal esophageal pouch. In 10% of cases, there is a blind proximal esophageal pouch with no TEF (Fig. 42-20). The embryologic defect results from imperfect division of the foregut into the anteriorly positioned larynx and trachea and the posteriorly positioned esophagus; the division should occur between the fourth and fifth weeks of intrauterine life. Fifty percent of affected infants have associated congenital anomalies, of which approximately 15% to 25% involve the cardiovascular system.

### Clinical Presentation

Atresia of the esophagus leads to inability of the fetus to swallow amniotic fluid and the subsequent development of polyhydramnios. Ultrasound may well raise the possibility of a congenital anomaly. For that reason, if polyhydramnios is present, attempts should be made to pass a nasogastric tube shortly after delivery. Passing a nasogastric tube is not routine in the delivery room; therefore, the diagnosis may not become apparent until the infant is fed. Cyanosis and choking with oral feedings should raise suspicion.

**Figure 42-20** Diagrams of the five most commonly encountered forms of esophageal atresia and tracheoesophageal fistula, shown in order of frequency. (Adapted from Herbst JJ. Gastrointestinal tract. In: Behrman RE, Kleigman RM, Nelson WE, et al., eds. *Nelson's Textbook of Pediatrics*. 14th ed. Philadelphia, PA: WB Saunders; 1992:942.)

There are two major complications of esophageal atresia with a distal tracheal fistula: aspiration pneumonia and dehydration. The presence of a distal TEF increases the likelihood of reflux of gastric juice up the esophagus and into the pulmonary system. Dehydration results from the fact that the proximal esophagus does not communicate with the stomach. Therefore, preoperative preparation of these infants is aimed at evaluation and treatment

of the pulmonary system, as well as at ensuring adequate hydration and electrolyte balance. Rarely, the degree of reflux and pneumonia is so great that a gastrostomy must be performed to protect the pulmonary system, and a period of several days is needed to improve the general condition of the infant. However, if the infant is in good condition, primary repair can be performed at 24 to 48 hours. This consists of ligation of the fistula and a primary repair with approximation of the two ends of the esophagus.

### *Anesthetic Considerations*

The repair of TEF can be done in the conventional method or by using video-assisted thoracoscopic surgery (VATS) method. Both methods and the anesthetic implications for each technique will be described here. The presence of a gastrostomy reduces the potential for reflux of gastric juice during the surgical procedure. If a gastrostomy is present, the gastrostomy tube should be open to air and left at the head of the table under the anesthesiologist's observation to avoid kinking and obstruction.

**Conventional Open TEF Closure.** There are three approaches to tracheal intubation after induction of anesthesia. One is to use an inhalation induction, followed by topical spray of lidocaine and intubation while the infant is breathing spontaneously. Another technique is to use an intravenous or inhalation induction and intubate the trachea after muscle paralysis. This technique may lead to distention of the fistula and stomach with excessive positive-pressure ventilation. When controlled ventilation of the lungs is used, attempts must be made to minimize the distention of the stomach and the potential for reflux. If a gastrostomy tube is in place, the point is moot. A third technique is to intubate the neonates awake with mild sedation. This can protect the airway while reducing the chances of aspiration. Alternatively, because the fistula is usually located just above the carina on the posterior wall of the membranous trachea, the endotracheal tube can be placed just distal to the TEF. To do this, the endotracheal tube is inserted until it enters a main-stem bronchus. This is judged by unilateral expansion of the chest and unilateral breath sounds. The endotracheal tube is then slowly withdrawn until bilateral chest movement and breath sounds are confirmed.

The endotracheal tube might inadvertently enter the fistula when the infant is turned or during surgical manipulation. Intubation of the fistula should be suspected if there is increased difficulty in ventilation of the lungs, as well as decreased oxygen saturation and end-tidal CO<sub>2</sub>. Because these findings may also be present when the lung is packed away to perform the surgery and because there are other explanations for these findings, intubation of the fistula should always be included in the differential diagnosis. At any time ventilation is difficult and desaturation is occurring,

the surgeon must stop the procedure while the situation is clarified. The surgeon will be able to palpate the tip of the tube in the fistula if this is the problem.

The localization and isolation of H-type fistulas can be difficult. In this situation, direct laryngoscopy and bronchoscopy is performed by the surgeon, the fistula is identified, and a guidewire is fed through the fistula tract into the esophagus. The infant is then intubated, with care taken not to dislodge the guidewire. Once intubated, esophagoscopy is performed, the guidewire is visualized and brought out through the mouth. In this way, the surgeon can use fluoroscopy to determine the level of the fistula and decide whether a cervical or thoracic approach is necessary. During surgery, the anesthesiologist can apply traction to the wire loop to facilitate the localization of the fistula by the surgeon.

**Endoscopic TEF Repair.** The use of endoscopic methods for repair of TEF is now popular in pediatric surgery.<sup>178</sup> The infant should be kept spontaneously breathing until the fistula is ligated. Maintenance of spontaneous ventilation can be challenging considering that these infants may not tolerate the use of potent inhalation agents while spontaneous ventilation is established. This approach may shorten the duration of surgical operating time while providing a minimally invasive method. The anesthetic management is challenging.

### *Postoperative Care*

Although there have been great advances in the treatment of TEF and esophageal atresia, postoperative care can be complicated by associated congenital heart disease, RDS, and a need for continued postoperative ventilation. The compression of the lung for several hours, along with pre-existing aspiration pneumonia in some of these infants, suggest the need, in the more difficult cases, for a short period of postoperative ventilation, or at least intubation with PEEP, as the most conservative technique for postoperative airway management. Some infants are in excellent condition at the time of surgery with no complicating factors and, therefore, should be considered for extubation immediately at the end of surgery or shortly thereafter. If extubation of the trachea is planned for the end of surgery, the anesthetic technique must be tailored accordingly. Neuraxial anesthesia as part of the technique is useful in these situations, reducing the concentration of maintenance volatile anesthetics, the amount of muscle relaxants, and the need for intraoperative narcotics. These catheters may remain in place after the procedure to allow for postoperative pain control with local anesthetic by continuous infusion or intermittent bolus. Another option is to place a unilateral, ultrasound-guided paravertebral block which can again provide analgesia for the hemithorax that is the operative site.<sup>179</sup>

A high percentage of infants with esophageal atresia have residual defects of the tracheobronchial tree and esophagus for many years. These defects include tracheomalacia, gastroesophageal reflux, esophageal stricture, and recurrent fistulas.

## **Intestinal Obstruction**

A useful way of classifying gastrointestinal obstruction is to group lesions proximal and distal to the pylorus. Obstruction of the upper gastrointestinal tract is manifested by vomiting, especially after feeds, whereas obstruction of the lower gastrointestinal tract may present with abdominal distention, little or no stool passed, hematochezia, signs of pain, and vomiting.

### *Upper Gastrointestinal Tract Obstruction*

The most common cause of upper gastrointestinal obstruction in the newborn is pyloric stenosis, but pyloric stenosis does not usually present in the first week of life. Other rare causes of obstruction, such as congenital webs, may occur. If there has been persistent vomiting, this usually means that a deficit of fluids or electrolytes will develop in the infant. Persistent vomiting results in the greatest deficit of sodium. Another major concern in the infant with upper gastrointestinal tract obstruction is aspiration of gastric contents.

The anesthetic management of these patients is directed toward ensuring adequate relaxation for abdominal exploration, repair of the congenital defect, and closure of the abdomen. Nitrous oxide can be used in high intestinal obstruction because there is essentially no gas in the upper gastrointestinal tract. The next concern is whether the infant's trachea should be extubated at the end of surgery. If the infant is robust, extubation of the trachea at the end of surgery can be anticipated. The preferred technique is for general anesthesia combined with neuraxial anesthesia. This allows light levels of volatile agent and minimal muscle relaxant use, and results in early extubation. Opioids may be administered, although the impact on the ability to ventilate at the end of the procedure should be considered. If the infant is moderately debilitated or if the surgical incision is extensive, a period of postoperative ventilation may well be indicated, particularly if moderate doses of opioids have been used.

### *Lower Gastrointestinal Tract Obstruction*

Intestinal obstruction in the newborn can result from a variety of lesions. These include imperforate anus, duodenal atresia, jejunoileal atresia (Fig. 42-21), intussusception, malrotation, volvulus, choledochal cyst, or meconium ileus. Although these are all different in etiology, their presentation is similar.

The problems associated with lower gastrointestinal tract obstruction usually develop within 1 to 7 days after birth. It may take this long for the lesion to become evident because it is low in the gastrointestinal tract. An imperforate anus should be recognizable shortly after birth. However, once intestinal obstruction is diagnosed in the newborn, it becomes a surgical emergency as these patients may deteriorate rapidly. Some of these infants may have vomiting secondary to the obstruction, which poses a problem for fluid and electrolyte management. An enormous amount of fluid can be sequestered within the intestinal tract. This fluid is essentially ECF and has high sodium content. Therefore, these infants should be prepared expeditiously for surgery and have a serum sodium level of at least 130 mEq/L as well as a urine output of 1 to 2 mL/kg/hr. In addition to fluid and electrolyte disturbances, delayed diagnosis or treatment of these patients can result in increased abdominal pressure, leading to respiratory embarrassment from pressure on the diaphragm and aspiration pneumonitis, as well as sepsis. Finally, some of these conditions are associated with other congenital anomalies that complicate preanesthetic evaluation and anesthetic management.<sup>180</sup> Duodenal atresia, for instance, can be associated with trisomy 21, cystic fibrosis, imperforate anus, or renal abnormalities.

**Figure 42-21** Jejunal atresia. (Photograph courtesy of Kurt Heiss, MD.)

The preanesthetic evaluation and perioperative management is similar for all these lesions. Preanesthetic evaluation is focused on the stabilization of fluid and electrolyte status, ensuring adequate oxygenation and ventilation, hemodynamic support if the patient is septic, and identification of complicating issues such as other congenital abnormalities.

In the operating room, the need for invasive arterial and central venous monitoring is determined by the current status of the patient and the urgency

of the procedure. The primary anesthetic considerations are the same as those in the preoperative period, including ongoing fluid and electrolyte resuscitation. Because these cases are usually emergent and there may be associated vomiting and abdominal distention, either an awake intubation or rapid-sequence induction and intubation is indicated. Although awake intubation may be the best approach if the patient has a probable difficult airway or has hemodynamic decompensation, a rapid-sequence induction and intubation after preoxygenation is the approach normally taken. Any induction agent can be used if judicious doses are chosen, but ketamine or etomidate are often chosen because of a concern about cardiovascular instability.

Anesthetic agents for maintenance during these cases are chosen on the basis of the patient's status and the likely surgical course. Nitrous oxide should not be used in any infant who has gaseous distention of the intestine, which is easily determined from the preoperative radiograph. Providing adequate muscle relaxation for surgery can be accomplished with various anesthetic techniques such as volatile anesthesia, muscle relaxants, and caudal or epidural block.<sup>181</sup> There is increasing interest in the use of remifentanyl in newborns and infants because of its titratability and short duration of action, potentially increasing the options for extubation at the end of the case for some patients.<sup>182</sup>

The criteria for tracheal extubation at the end of surgery are the same as those described for upper gastrointestinal tract obstruction. When in doubt, it is prudent to leave the tracheal tube in place and provide a period of postoperative ventilation during which the patient's status can be re-evaluated before deciding that extubation is safe.

## **Myelomeningocele**

### *Clinical Presentation*

Myelomeningocele is the most common congenital primary neural tube defect. Despite the known ability of folic acid supplementation during pregnancy to largely prevent this defect, the lesion still occurs in approximately 0.5 to 1 of every 1,000 live births.<sup>183</sup> It results from failure of neural tube closure during the fourth week of gestation. Neural tube defects can be identified on prenatal ultrasound. Elevated maternal serum AFP detects 50% to 90% of open neural tube defects but has a false-positive rate of 5%. Amniotic fluid AFP is more reliable and typically used for confirmation after elevated serum levels.

By definition, the lesion involves both the meninges and neural components, as compared with a meningocele, which does not contain neural elements. The infant is born with a cystic mass on the back comprising a

neural placode, arachnoid, dura, nerve tissue and roots, and cerebrospinal fluid. The lesion most commonly occurs in the lumbosacral or sacral region, although it can extend to the thoracic region. The bony canal is also malformed, leading to multiple orthopedic problems as the child matures. Urologic complications correlate with the level of the spinal lesion.

Newborns born with myelomeningocele have an associated anomaly of the brainstem known as the Arnold–Chiari II (Chiari II) malformation. The Chiari II malformation is characterized by caudal displacement of the cerebellar vermis through the foramen magnum, caudal displacement of the medulla oblongata and the cervical spine, kinking of the medulla, and obliteration of the cisterna magna.<sup>184</sup> The cause of Chiari II malformation rests in the small size of the skull housing the posterior fossa, forcing CNS contents out during development. Hydrocephalus requiring shunting develops in approximately 80% to 90% of infants with myelomeningocele. In contrast, only 20% of patients have symptoms of brainstem dysfunction as a result of the Chiari II malformation, but the mortality rate among those symptomatic patients is high. Complications of brainstem dysfunction include stridor, apnea and bradycardia, aspiration pneumonia, sleep-disordered breathing patterns, vocal cord paralysis, lack of coordination, and spasticity. If the symptoms are not improved by shunting, posterior fossa decompression is necessary.<sup>185</sup>

The infant with a myelomeningocele is usually operated on within the first 24 to 48 hours of life. This reduces the risk for development of ventriculitis or progressive neurologic deficits. Most centers close the defect and place a shunt at the same time. However, some centers may delay placement of a shunt until the infant shows symptoms of hydrocephalus. There is ongoing work to determine the benefits of intrauterine repair of myelomeningocele, hopefully with the benefits of decreased development of a Chiari II malformation, decreased hydrocephalus, and increased lower limb function. As these studies continue, the role of intrauterine repair will become clearer.<sup>186</sup>

### *Preoperative Care*

The preoperative stabilization period focuses on the prevention of infection, maintenance of ECF volume, avoidance of hypothermia, and assessment for other congenital anomalies. The exposed neural placode is susceptible to trauma, leakage, and infection. The infant is usually placed in the prone position, and the placode is covered with warm saline-soaked gauze to prevent desiccation. Because of the high risk of infection, antibiotic therapy is initiated in the preoperative period. Rupture of the cyst on the back can lead to ongoing cerebrospinal fluid leakage. This fluid is replaced with a full-strength, balanced salt solution. The infant is also assessed for any potentially life-threatening congenital anomalies.

## *Perioperative Care*

The high prevalence of clinical latex allergy and latex sensitization in children with myelomeningocele has drawn much attention and led many individuals to believe that these patients have an impaired immune system that makes them more susceptible to latex allergy. The likely cause of the increased incidence of latex sensitization is repeated exposure to latex products through frequent hospitalizations and surgical procedures, as well as a program of daily bladder catheterization for those with neurogenic bladders.<sup>187</sup>

Positioning is critical in the infant with myelomeningocele. For induction of anesthesia, the infant may be placed supine with the defect resting in a “doughnut” to minimize trauma. Alternatively, the induction can be performed with the infant in the lateral position, although this makes intubation more challenging. The infant is turned prone for surgery. Rolls are positioned to ensure the abdomen and chest are free, avoiding pressure on the epidural venous plexus to minimize bleeding and allow adequate ventilation.

In most instances, the infant has an intravenous line placed before surgery and an intravenous induction is performed. Succinylcholine may be used to facilitate intubation without risking hyperkalemia.<sup>188</sup> Because increased intracranial pressure is rarely present before closure of the defect, inhalational induction is an alternative in the infant with difficult intravenous access. The anesthetic management of these newborns is rarely complicated unless there are other congenital anomalies that warrant special attention. There is no particular advantage of one technique over another because of the surgical lesion. Because these patients are usually extubated at the end of the case, a technique that allows this is usually chosen. Regional anesthesia has been reported as a safe adjunct or alternative to general anesthesia in the neonate with myelomeningocele. One small series has been published in which tetracaine spinals were used as the anesthetic for 14 infants undergoing repair of myelomeningocele.<sup>189</sup> In this series, there was no evidence of anesthetic-induced neurologic damage. Of note, 2 of the 14 infants had a postoperative respiratory event (1 transient apnea/bradycardia and 1 brief desaturation with bradycardia). Both of these infants had received intraoperative midazolam for sedation.

## *Postoperative Care*

These infants must be monitored closely in the postoperative period. Respiratory complications, including stridor, apnea and bradycardia, cyanosis, and respiratory arrest, may develop after surgery in these infants with known brainstem abnormalities and potential disorders of central respiratory control. In addition, infants who were not shunted during repair may show signs of hydrocephalus, including lethargy, vomiting, seizures, apnea and bradycardia,

or cardiovascular instability. These infants need to return to the operating room for insertion of a shunt. Although the majority of these patients will eventually require a shunt, a recent survey has shown that only about one-third of the patients receive one during the initial hospitalization.<sup>190</sup>

## **Hydrocephalus**

Hydrocephalus in the first month of life may have several causes. It may occur after closure of a meningomyelocele because of the Chiari II malformation, it may be congenital in origin, or it may be related to intraventricular hemorrhage, especially in the very preterm newborn. The incidence of hydrocephalus has been stable in recent years, with a decrease related to Chiari II malformations, but an increase secondary to hemorrhage in the preterm.<sup>191</sup> The cranial sutures in the neonate are open, so intracranial pressure increases are blunted or minimized. However, infants with hydrocephalus eventually have an increase in head size and sometimes in intracranial pressure, resulting in lethargy, vomiting, and cardiorespiratory problems.

The anesthetic approach and the technique for tracheal intubation depend on the infant's condition. The major concern is protection of the airway and control of intracranial pressure. Awake tracheal intubation, crying, struggling, and straining can increase intracranial pressure. A rapid-sequence induction of anesthesia to control the airway and intracranial pressure is preferred. Volatile drugs, nitrous oxide, and opioids are all reasonable choices for maintenance of anesthesia, with no evidence that one technique is superior. Noninvasive intracranial pressure measurements in neurologically normal preterm infants have shown a decrease in intracranial pressure with all drugs, including ketamine, fentanyl, and isoflurane. The failure of volatile anesthetics and ketamine to increase intracranial pressure as in adults is attributed to the compliance of the neonate's open-sutured cranium. After surgery, the trachea of these infants may remain intubated if they were experiencing periods of apnea or bradycardia before surgery because of the intracranial abnormalities. If not, the trachea can be extubated as soon as the protective reflexes of the airway have recovered.

## ***Surgical Procedures in the First Month of Life***

Surgical procedures in the first month also are considered emergent, or at least urgent, surgery. The most frequent surgical procedures in the first month are exploratory laparotomy for NEC, inguinal hernia repair, correction of pyloric stenosis, patent ductus arteriosus (PDA) ligation, a shunt procedure for hydrocephalus, and placement of a central venous catheter.

## Necrotizing Enterocolitis

NEC is a disease that primarily affects premature infants who have survived the first days of life, although it can be seen in full-term newborns. One of the theories about NEC is that earlier, more rapid feeding places infants at greater risk for development of NEC. The incidence of NEC among VLBW infants varies between 5% and 15%.<sup>192</sup> The exact pathophysiology of NEC has been the source of much study and some controversy, although it is likely multifactorial.<sup>193</sup> The condition is characterized by a cascade of pathologic events, beginning with an immature distal small and sometimes large intestine that has a decreased ability to absorb substrate, leading to stasis. The most common site is the ileocolic region, but can be seen in other areas and can be discontinuous, giving a patchy appearance. Stasis encourages bacterial proliferation, which leads to local infection. The picture is complicated by further pooling of fluid. The ischemia and infection may lead to necrosis of the intestinal mucosa, followed by perforation. The perforation leads to gangrene of the gut wall, fluid loss, peritonitis, septicemia, and disseminated intravascular coagulation. The first signs that NEC may be abdominal distention, irritability, and the development of metabolic acidosis. This may be followed by radiologic evidence of pneumatosis intestinalis, portal venous air, or free abdominal air. NEC is primarily a medical disease and is treated by cessation of oral intake, administration of antibiotics, fluid and electrolyte therapy, insertion of an orogastric tube, hemodynamic support, and in some cases, the insertion of a peritoneal drain.<sup>194</sup> In nonresponsive cases, the infant becomes more septic with severe peritonitis, and the only solution is to perform an exploratory laparotomy to remove the gangrenous bowel and create an ileostomy.

The preoperative problems are an acute abdomen with severe peritonitis, necrosis, and gangrene of the intestine, septicemia, metabolic acidosis, and hypovolemia. These neonates may also have disseminated intravascular coagulation. Preparation of the patient is directed toward stabilization of these problems. By the time the newborn becomes a surgical candidate, the septicemia, coupled with the distended abdomen and the overall clinical deterioration of the infant, often has necessitated the use of intubation and ventilation in the neonatal intensive care unit. Appropriate laboratory investigations include an arterial blood gas, hemoglobin, glucose, electrolytes, and coagulation profile. The deteriorating status of the patient may compromise both resuscitation efforts and the desire to establish adequate vascular access and monitoring, but focused efforts should be made to provide multiple vascular access lines, an arterial line, and central venous access.

The anesthetic requirements are continuation of resuscitation, provision of abdominal relaxation for the surgery, and careful titration of anesthetic drugs. These infants are often so critically ill that they are very sensitive to the

depressant effects of anesthesia. If the patient is not already intubated and ventilated, a rapid-sequence induction with ketamine and succinylcholine is often used. The only caution with this technique is that some patients with NEC have significant hyperkalemia secondary to dead bowel, making the use of succinylcholine problematic. High-dose rocuronium is a reasonable alternative in that situation. Maintenance of anesthesia is usually based on an opioid technique, supplemented with additional doses of ketamine or, if the patient's condition improves, low-dose inhalation agent. The use of nitrous oxide should be avoided because of the gas pockets in the abdomen.

These infants are among the most challenging cases in pediatric anesthesia. The fluid loss can be enormous, both because of surgical losses and third-space losses. Fluid management starts with full-strength, balanced salt solution for maintenance of blood pressure and urine output. Blood products are often needed during these cases. If the hematocrit is below 30% to 35%, red blood cells should be administered. On the basis of both preoperative and intraoperative laboratory work, fresh frozen plasma, platelets, and cryoprecipitate may be needed. Due to bleeding, activated factor 7 or other prothrombotic agents may be needed. Inotropic support may also be needed. The surgical technique and length of surgery is variable, depending on the findings at laparotomy. A combination of bowel resection, primary anastomoses, and enterostomies may be used. At the end of the procedure, these infants are returned intubated and ventilated to the intensive care unit, where resuscitation is continued.<sup>195</sup> Long-term survival is based on several factors, including the degree of prematurity, associated congenital abnormalities, the degree of surviving bowel, the total length of affected bowel, and subsequent complications. Mortality rates, especially in newborns weighing less than 1,500 g, are poor with recent studies demonstrating 25% to 50% mortality before discharge.<sup>196,197</sup>

### **Inguinal Hernia Repair in the Neonate**

The development of a hernia in the premature infant or neonate is a different clinical problem from the development of a hernia in an infant older than 1 year. In infants younger than 2 months who need inguinal hernia repair, there is a higher incidence of prematurity, history of RDS, history of incarceration, and congenital heart disease.<sup>198</sup> In preterms, the incidence of hernia may approach 20% to 30%. There is a concern about new or recurring incarceration in these patients, making hernia repair less an elective procedure than in older infants. Consequently, once identified, these patients usually are repaired within a relatively short time. If the patient is currently hospitalized, it is common to repair the hernia before discharge. Otherwise, the surgery should be scheduled within days to weeks of diagnosis.

## *Anesthetic Techniques for Hernia Repair*

Surgical procedures below the umbilicus can be performed with either general or regional anesthesia. The choice of whether to use general or regional anesthesia depends on the preference of the surgeon and/or the anesthesiologist and expected length of procedure. However, the choice is influenced by the underlying status of the patient, previous complications, and the known risk of preterm patients to develop apnea and bradycardia during and after these procedures. There is a risk in any preterm for apnea and bradycardia after stressful procedures, but this has been most widely studied in association with inguinal hernia repair. Analysis of the many small studies have shown certain common elements.<sup>150</sup> Apneic events are inversely related to both gestational age and postconceptual age. The incidence of apnea is less in small-for-gestational age infants. Anemia increases the incidence of apneic events. Apneic events at home are associated with a higher incidence in the perioperative period. There have been multiple studies that were recently analyzed to determine if the choice of regional or general anesthetic techniques decreased the incidence of apnea and bradycardia.<sup>199</sup> Use of spinal anesthesia without sedatives does not decrease the risk of late apnea in preterm neonates in the best evidence to date. Consequently, the choice of anesthetic should not be based solely on the risk of preventing apneic spells. An adjunct that has some evidence in support of its use to minimize apneic spells is caffeine. The use of preservative-free caffeine in a single dose of 10 mg/kg has been suggested to decrease the incidence of apneic spells.<sup>151</sup>

Regional anesthesia can be used entirely for the surgery or as an adjunct to reduce general anesthetic requirements and provide postoperative analgesia. Other methods of providing intraoperative anesthesia and postoperative analgesia include the ilioinguinal–iliohypogastric nerve block or local infiltration. Ilioinguinal–iliohypogastric nerve block with 0.25% bupivacaine or 0.2% ropivacaine, with epinephrine, can be administered shortly after the induction of general anesthesia and affords excellent postoperative analgesia.

Discharge after inguinal hernia repair to home is an area of some controversy. There is significant institutional variation on the issue of monitoring for postoperative apnea, with the decision to admit overnight usually based on the postconceptual age in preterm neonates. Some centers use 46 weeks postconceptual age as the lower limit for admission, but other centers will use up to 60 weeks postconceptual age as the limit. In our institution, we have used a different approach. In order to make the limit easily understandable and also understanding that the basis of determining gestational age is not precise, we have all preterm infants admitted until they are 6 months of age. This ensures 26 weeks added to gestational age and is a

compromise between the 46-week and 60-week limits, but is easy to administer. However, it may be overly conservative in the 36-week premature infant now 5 months of age. No matter what limits are used, if the infant has apneic or bradycardic spells during the perioperative period, he or she should be monitored in-house until the infant has been apnea-free for at least 12 hours.

## **Pyloric Stenosis**

Pyloric stenosis is a relatively frequent surgical disease of the neonate and infant. It most commonly appears between weeks 2 and 6 of life. The pathologic characteristics include hypertrophy of the pyloric smooth muscle with edema of the pyloric mucosa and submucosa. This process, which develops over a period of days to weeks, leads to progressive obstruction of the pyloric valve, causing persistent vomiting. The vomiting leads to varying losses of fluids and electrolytes. The diagnosis is usually made at an early stage in the development of symptoms, especially with the help of ultrasound, so it is rare to find an infant with severe fluid and electrolyte derangements. However, an infant is occasionally seen whose problem has developed slowly over a period of weeks, resulting in severe fluid and electrolyte derangements. The stomach contents contain sodium, potassium, chloride, hydrogen ions, and water. The classic electrolyte pattern in infants with severe vomiting is hyponatremic, hypokalemic, and hypochloremic metabolic alkalosis with a compensatory respiratory acidosis. The anesthesiologist, pediatrician, and surgeon are all responsible for preparing these infants for surgery. Pyloric stenosis is a medical emergency, not a surgical emergency. The patient should not be operated on until there has been adequate fluid and electrolyte resuscitation. The infant should have normal skin turgor, and the correction of the electrolyte imbalance should produce a sodium level that is greater than 130 mEq/L, a potassium level that is at least 3 mEq/L, a chloride level that is greater than 85 mEq/L (trending upward), and a urine output of at least 1 to 2 mL/kg/hr. These patients need a resuscitation fluid of balanced salt solution and, after the infant begins to urinate, the addition of potassium.

### *Anesthetic Management*

It is prudent to pass a large orogastric tube and aspirate the stomach contents because of the significant volume that may be present.<sup>200</sup> This procedure greatly reduces the quantity of gastric fluid. A rapid-sequence induction is advisable because of the potential for additional volume in the stomach. Although awake intubation had been popular with some clinicians in the past, it is associated with a higher incidence of complications and is traumatic to the child.<sup>110</sup> These patients have been fully resuscitated before coming to

surgery, so there is little reason for an awake intubation. Anesthesia can be maintained by almost any technique the clinician prefers. There has been a need for muscle relaxation only for a short period during pyloromyotomy. Some surgeons may require muscle relaxation because most of these are now performed using minimally invasive laparoscopic procedures (Fig. 42-22). Careful attention has to be paid to ventilation and blood pressure as the abdominal pressure is increased during insufflation for laparoscopy. Controlled ventilation reduces or eliminates the need for muscle relaxants for this surgery. At the end of the case, the patient should be wide awake before extubation. A TAP block can be provided using ultrasound guidance for postoperative pain relief with good analgesia or local infiltration at laparoscopic port sites. Intravenous or rectal acetaminophen is commonly administered for pain relief as well.

### Ligation of a Patent Ductus Arteriosus

As the number of small premature infants who survive has increased, so also has the number of infants who have a PDA with heart failure and respiratory failure. Prostaglandins relax the smooth muscle of the ductus so it cannot constrict. Indomethacin, a prostaglandin synthetase inhibitor, can be administered to encourage closure of the ductus. However, indomethacin is often unsuccessful in the small premature infant because of the lack of muscle within the ductus. Infants with a PDA and heart failure need maximal medical management with fluid restriction, diuretics, and inotropes. These infants are at special risk because of the reduced blood volume and precarious cardiopulmonary system. If the surgery is performed in the operating room, special attention is taken to maintain normothermia, ventilation, and oxygenation during transport. If the surgery is performed at bedside in the neonatal intensive care unit, the anesthesiologist must take time before the procedure to establish where he or she will be situated, where all venous access is, and that all drugs and fluids are already prepared. An opioid-based technique with muscle relaxant is a frequent choice for anesthesia. Probably the biggest challenge during these cases is the diagnosis and management of hypotension. There can be sudden, catastrophic blood loss if the ductus arteriosus ruptures during the procedure. Consequently, syringes of a balanced salt solution, albumin, and blood should be immediately available. The other common cause of hypotension is compression of the lungs, heart, and great vessels by the surgeon as they are gaining exposure. This must be a balance between stopping the procedure to allow the heart and blood pressure to recover versus the need to proceed with the operation. The answer comes in close communication between the anesthesiologist and the surgeon. These patients usually remain intubated after procedure, without a

need to reverse the muscle relaxant. Residual opioid will provide good analgesia for the immediate postoperative period.

**Figure 42-22** Laparoscopic repair of pyloric stenosis. In this image, the surgical cleft created in the hypertrophied muscles of the pylorus can be seen. This surgical intervention is curative of pyloric stenosis. (Photograph courtesy of Timothy Lautz, MD.)

There are two newer techniques for closing the PDA in infants that are increasing in popularity.<sup>201</sup> Video-assisted thorascopic surgery (VATS) uses small endoscopes inserted through a series of small thoracotomy incisions to guide instruments to ligate the ductus. VATS can be done either in the operating room or, rarely, at bedside. The other approach is used by cardiologists in the cardiac catheterization to occlude the ductus arteriosus with a coil. A test clamp is often used to demonstrate continued aortic flow to the lower extremities and an improvement in diastolic blood pressure from decrease of diastolic run-off to the ductus arteriosus.

### **Placement of a Central Venous Catheter**

The use of a central venous catheter for monitoring serum electrolytes, for parenteral nutrition, and for administering medications is a well-established part of modern perioperative care. It can be placed either as part of the surgical procedure or at some other time as a separate procedure. The three major concerns in central venous catheter placement are airway management, pneumothorax, and bleeding. The anesthetic technique depends on the infant's condition. If general anesthesia is selected, then intubation or laryngeal mask airway have each been successfully used. A pneumothorax may occur with attempts at subclavian vein puncture. The first indication of pneumothorax may be a decreasing oxygen saturation, hypotension, or difficulty with

ventilation of the lungs. Because imaging using fluoroscopy is often used for central venous catheter placement, it can be used rapidly to diagnose a pneumothorax. If not, the chest should be rapidly aspirated for both diagnostic and therapeutic reasons. Bleeding is an unusual but serious complication of central venous catheter placement. It usually manifests in the perioperative period as hemothorax or as hypovolemia with a decreasing hematocrit or blood pressure. The establishment of intravenous access placed before proceeding with a central line is problematic for some patients. The reason for the central line may very well be the inability to obtain peripheral access, and the clinician is left with a trade-off between prolonged attempts at starting an intravenous catheter versus proceeding directly to obtain central venous line placement.

PICCs, placed in either the upper extremity or the femoral vein, are now common in practice. Often, these lines may be placed with local anesthetic only or with mild sedation, with ketamine for example. Strict attention to skin preparation, sterile glove and drape use, and minimizing access to the central line are components important to diminish catheter-related sepsis. Subclavian approach has a higher incidence of problems during line placement than internal jugular or femoral approaches, but may have fewer associated infections and fewer overall problems with the line once it is in use. PICCs have not been well-studied in the neonatal population, but continue to grow in their popularity.

## Summary

The anesthetic management of the newborn is among the most **8** challenging to anesthesiologists. A strong knowledge of neonatal anatomy, physiology, and pharmacology is needed, as well as an appreciation of the disease states and surgical procedures that are unique to this population. A thorough preanesthetic evaluation and preparation, a concise plan, and meticulous technique are the basis of an effective approach. The patient's neonatologist or pediatrician and the surgeon are strong allies in providing the best care, and close communication with them is necessary. Finally, the clinical status of a newborn can change remarkably quickly. Strict attention to detail and prospective management are the hallmarks of the anesthesiologist skilled in providing care in these difficult cases. Use of current technology including ultrasound guidance is suggested for facilitating vascular access as well as regional anesthesia for pain management in these fragile infants.

## Acknowledgment

The authors of this edition would like to thank Dr. Steve Hall for his contributions to previous versions of this chapter as well as his career-long dedication to the field of pediatric anesthesiology.

Postoperative Pain

## KEY POINTS

- 1 The airway in infants and children presents unique features that require a clear understanding of the anatomy and physiology of the airway structures. Laryngospasm and airway obstruction increase perioperative morbidity and mortality. Treatment of laryngospasm includes continuous positive airway pressure with 100% oxygen, jaw thrust applied at the condyles of the mandible, and early administration of atropine and propofol and/or succinylcholine to prevent profound desaturation and bradycardia and to relax the vocal cords.
- 2 Evidence in young animals has raised concerns regarding the neurocognitive sequelae after general anesthetics. Recent laboratory evidence however, suggests that exercising and socializing the animals after an anesthetic mitigates the neurocognitive dysfunction. Neurocognitive function in young children assessed 2 years after a simple but brief sevoflurane anesthetic indicates similar neurocognitive function as after spinal anesthesia.
- 3 Drug dosing in children is complex. Several factors influence drug doses including organ homeostasis (cardiopulmonary, renal, and hepatic functions), coexisting diseases, obesity, and developmental maturation of the cytochrome enzyme system. Unusual drug responses may result from single nucleotide polymorphisms (SNPs).
- 4 Understanding the pharmacokinetics and pharmacodynamics of inhaled anesthetics, the most commonly used anesthetics in children, helps to anticipate unexpected responses such as an anesthetic overdose during controlled ventilation or awareness after sub-MAC dosing during stimulation.
- 5 Upper respiratory tract infections (URTIs) are the most common comorbidity in children who present for surgery. Caution should be exercised when anesthetizing infants (<1 year of age) with recent URTIs (i.e., respiratory syncytial and other viruses may be latent) and children with colds in the preceding 2 weeks as the rate of perioperative complications is increased. Surgery should be rescheduled if any one of

the following signs complicates a URTI: fever ( $>38.5^{\circ}\text{C}$ ); the child is not behaving normally (e.g., lack of appetite); purulent, green secretions; or lower respiratory tract signs (e.g., wheezing that does not clear with a deep cough).

- 6 Obstructive sleep apnea (OSA) in children differs from adults in that large tonsils and adenoids are the primary causes of OSA. Perioperative respiratory complications in these children are linked to the severity of intermittent nocturnal desaturation (threshold is oxygen saturation  $[\text{SaO}_2] < 85\%$ ) as hypoxemia upregulates the genes responsible for opioid sensitivity. Emerging evidence suggests that OSA in obese children is complicated by a systemic inflammatory response, resulting in less favorable improvement after adenotonsillar surgery.
- 7 Obesity is the most rapidly growing challenge in pediatric anesthesia. Although laryngoscopy and tracheal intubation has been considered challenging in these patients, a 25-degree head-up position and exaggerated sniffing position such that the tragus lies above a horizontal line through the sternal notch facilitates tracheal intubation. Drug dosing must be adjusted to the appropriate weight scalar for the drug. Perioperative respiratory complications and postoperative admission after surgery are more common in these children.
- 8 Allergies and anaphylaxis during anesthesia in children in North America are most commonly due to latex sensitivity. Antibiotics, particularly the penicillin analogues, constitute a distant second cause. Epinephrine is the definitive treatment. Propofol allergy is extraordinarily rare in children, occurring only in those with documented egg anaphylaxis (not allergy). Although more common in Europe, anaphylaxis to muscle relaxants in children in North America is rare we suspect because of the absence of sensitizing agents (such as pholcodine).
- 9 The philosophical shift in fluid management strategy for most children 6 months of age or older in perioperative volumes has been from hypotonic glucose-containing solutions in 4–2–1 mL/kg/hr to use balanced salt solutions of 10 to 40 mL/kg over 1–4 h. The underlying strategy is to downregulate antidiuretic hormone secretion to avoid perioperative hyponatremia. In neonates and young infants ( $<6$  months), the 4–2–1 mL/kg/hr hypotonic glucose-containing fluid strategy remains appropriate for maintenance.
- 10 Efficient ambulatory surgery in children requires effective preventative pain and vomiting strategies. Pain should be prophylactically managed with local anesthetics and/or systemic analgesics during anesthesia to limit the need for postoperative analgesics. Continuous regional blocks are most effective in appropriate surgery. Prophylactic strategies to prevent postoperative vomiting are most effectively managed with a

combination of aggressive perioperative IV fluid hydration, intravenous (IV) dexamethasone, and serotonin-receptor antagonists and avoiding forcing postoperative fluids. Ex-premature infants and full-term neonates should be monitored postoperatively in hospital until the risk of a perioperative apnea has waned ( $\geq 12$  hours apnea-free).

## Anatomy and Physiology

### 1 Airway

 Understanding the anatomic differences between the infant and adult upper airways is key to managing the infant's airway safely. [Table 43-1](#) summarizes these differences. With a large brain and occiput, the child's head is naturally in the "sniffing" or flexed position. The large tongue/mouth volume ratio presents difficulty if the mouth is closed during mask ventilation, particularly with the narrowed nares. Hence, mask ventilation requires particular skill to avoid airway obstruction. Ensuring safe mask anesthesia and a patent airway requires proper application of the "jaw thrust" as described later while avoiding pressure on the soft tissues in the submental triangle.

**Table 43-1** Anatomic Features of the Upper Airway in Infants Compared with Adults

Head	<p>Larger occiput in the infant naturally positions the head in the "sniffing" position</p> <p>Stabilize the head against lateral rotation</p> <p>Obligate nose breathers for the first few months</p>
Mouth	<p>Relative large tongue volume in the mouth in the infant reduces the available space for instrumentation</p> <p>Edentulous</p>
Neck	<p>Larynx is more cephalad in the neck (C3–C4) in the infant</p> <p>Epiglottis is omega shaped and longer</p> <p>Vocal cords slant caudally at their insertion in the arytenoids</p> <p>Narrowest part of the upper airway is the cricoid ring (a solid circumferential, cartilaginous structure) covered by pseudostratified columnar epithelium</p> <p>Trachea is short (4–5 cm)</p>
Tracheobronchial tree	<p>Acute angle of the right mainstem bronchus at the carina</p> <p>Turbulent gas flow until the fifth bronchial division (resistance is inversely related to the radius to the fifth power)</p>

The most common airway problem in infants and young children is upper

airway obstruction due to laryngomalacia. In this condition, the supraglottic structures converge on the glottic opening during inspiration preventing most, if not all, air entry through the glottis. The net effect is upper airway obstruction. This is characterized by suprasternal and supraclavicular retractions, paradoxical collapse of the chest wall and/or sternum, and exaggerated diaphragmatic excursions. The treatment is constant positive airway pressure. Laryngomalacia usually resolves with age and without treatment.

A number of congenital airway anomalies pose challenges during anesthesia. Pierre Robin sequence (defined as micrognathia, airway distress in the first 24 to 48 hours after birth, and glossoptosis) is a common airway anomaly in which direct laryngoscopy is often difficult. This airway anomaly improves with age, usually resolving by 2 years. In contrast, other airway anomalies become progressively more difficult to manage with age. Treacher Collins syndrome is one such anomaly in which the airway becomes increasingly difficult with age. Several other disorders present primarily as difficult mask ventilation (e.g., Crouzon and Apert diseases and Down syndrome), but tracheal intubation is not a problem. In children, it is uncommon to face a “cannot ventilate, cannot intubate” airway in a child. Nonetheless, it is essential to identify a child’s syndrome and the airway issue if it exists and to design an appropriate treatment strategy.

Covered with pseudostratified, columnar epithelium, the cricoid ring is the only solid cartilaginous and ringed structure within the upper airway. This loosely adherent, columnar epithelium is subject to swelling if irritated, reducing the radius of the lumen. Because airflow in the upper airway is turbulent (Reynolds number  $>4,000$ ), as the lumen of the ring narrows, the pressure drop increases in proportion to radius to the fifth power. Hence, a 50% reduction in the radius of the cricoid ring increases the pressure drop by 32-fold. This increases the work of breathing, which if sustained, may result in respiratory failure.

The short trachea in the infant and child facilitates inadvertent endobronchial intubation. Careful assessment of the position of the tracheal tube in the airway is crucial to avoid this problem. Persistent hemoglobin desaturation ( $\text{SaO}_2 < 85\%$ ) may be the first sign of an endobronchial intubation.

The greater alveolar ventilation to functional residual capacity (FRC) ratio in the child (5:1) compared with the adult (1.5:1) increases the risk of hemoglobin desaturation. The increased alveolar ventilation reflects the increased oxygen consumption per kilogram in the child. This oxygen requirement, combined with the increased compliance of the rib cage (due to both anatomic and physiologic features), reduced compliance of the lungs (due to the relative lack of elastin in the infant), and reduced percent of type

1 fibers (slow-twitch, high oxidative muscle fibers) in the diaphragm predisposes the basal segments of the lungs to atelectasis under the weight of the abdomen. Together, these factors predispose the infant to rapid desaturation and respiratory failure when faced with respiratory difficulties. Additional details of the physiology of the pulmonary system in the neonate may be found in [Chapter 42](#).

## **Cardiovascular**

Once the neonatal heart completes the transition to postnatal life, the changes in the cardiovascular system are less dramatic. In the early years, the heart has reduced ability to increase stroke volume, rendering cardiac output more dependent on heart rate than in the adult. In the infant, atropine increases cardiac output not only by increasing the heart rate but also by augmenting a calcium-dependent force-frequency response.<sup>1</sup> A corollary of this relationship is that hypotension in the child with a normal or increased heart rate is due to hypovolemia and is ideally managed with fluids rather than vasopressors (except possibly in those with congenital heart disease). Systemic vascular tone is poor in children up to 8 years of age, as evidenced by the lack of change in blood pressure when caudal/epidural blocks are administered.

Both heart rate and blood pressure increase with increasing age in childhood ([Table 43-2](#))<sup>2</sup> and these provide a framework from which the definitions of bradycardia and hypotension were developed.

## **Central Nervous System**

### **Physiology**

Oxygen consumption in the brain of children (5.5 mL/100 g/min) is 50% greater than that in adults (3.5 mL/100 g/min).<sup>3</sup> As a result, cerebral blood flow (CBF) differs substantially from adults. In children, overall CBF is 50% to 70% greater than in adults (70 to 110 mL/min/100 g vs. 50 mL/min/100 g). More CBF is directed to gray matter in children, reaching a distribution similar to that in adults by adolescence. Autoregulation is intact in full-term and nonstressed infants. The details of autoregulation in children are not well defined, although evidence indicates there are no age-related changes in autoregulation throughout childhood.

**Table 43-2** Normal Range of Resting Heart Rates and Blood Pressure in Children

Age	Heart Rate (beats/min)	Blood Pressure (mmHg)
0–3 mos	100–150	65–85/45–55
3–6 mos	90–120	70–90/50–65
6–12 mos	80–120	80–100/55–65
1–3 yrs	70–110	90–105/55–70
3–6 yrs	65–110	95–110/60–75
6–12 yrs	60–95	100–120/60–75
>12 yrs	55–85	110–135/65–85

## Neuroapoptosis

That alcohol and NMDA receptor antagonists caused apoptosis (programmed cell death) in newborn rodents led investigators to discover that most general anesthetics and sedatives, which also act on NMDA and GABA<sub>A</sub> receptors, cause apoptosis in newborn rodents and nonhuman primates. Most anesthetics, with the exception of the  $\alpha_2$  agonists, opioids, muscle relaxants, and possibly xenon cause apoptosis and neurocognitive dysfunction in newborn animals. These effects are exacerbated when multiple anesthetics are coadministered and administered for more prolonged periods.<sup>4</sup> If the affected newborns are raised to adulthood, the neurocognitive changes remain. Interestingly, several drugs and interventions dramatically attenuate these effects including melatonin, lithium, hypothermia, and exercise.<sup>5,6</sup>

Whether these effects in newborn animals are translatable to humans remains contentious. First, the positive predictive value of animal effects in humans is less than 10%. Second, the doses of IV anesthetics and sedatives in rodents and primates are up to 10-fold greater than in humans<sup>7</sup>; such large doses may explain, in part, the neurocognitive dysfunction observed after IV anesthetics but do not explain the effects of inhalational anesthetics whose dosing is constant across species. Third, studies in humans who received anesthesia at a young age indicated that neurocognitive dysfunction in those who received anesthesia before the age of 3 years and who received multiple anesthetics was more severe than in those who did not.<sup>4</sup> However, most of those studies were seriously flawed in terms of their design (retrospective), limited external validity (no pulse oximetry or capnography), different anesthetics (halothane), nonstandardized metrics (learning disability tests were not applied equally to all children), and confounding variables (complex pregnancy, drugs such as magnesium) that were not standardized. A large cohort of identical twins who were discordant for general anesthesia at less than 3 years of age tested identically for intellectual aptitude 10 years later.<sup>8</sup>

The 2-year follow-up of children in the prospective, randomized, and blinded GAS (sevoflurane anesthesia vs. spinal anesthesia) study demonstrated identical neurocognitive function in the two groups.<sup>9</sup>

## Pharmacology

3

### *Developmental Pharmacology*

Understanding the pharmacology of drugs in children is a complex subject that is briefly addressed later. Drugs must reach their effect site if they are to be effective. The steps involved in that process include absorption of the drug into the blood, transfer from the blood to the effect site, and termination of its action by redistribution, metabolism, and/or excretion.

The bioavailability of drugs depends on several factors including the route of administration,  $pK_a$ , the solubility of the drug and local perfusion. Some drugs such as midazolam are poorly absorbed from the stomach (15% bioavailability)<sup>10</sup> but are well absorbed from the nares,<sup>11</sup> whereas others such as acetaminophen are well absorbed from the stomach but are poorly and erratically absorbed from the rectum.<sup>12</sup> Age is another factor that may substantially affect drug absorption. For example, gastric juice is closer to neutral pH (pH ~6 to 8) at birth, only reaching adult levels of acidity by ~3 years of age, thus affecting the absorption of lipophilic drugs at neutral pH values.<sup>13</sup> The route of administration also affects whether the drug undergoes first-pass metabolism through the liver. Rectal venous drainage from the superior hemorrhoidal veins drains into the portal venous system, whereas drainage from the middle and inferior hemorrhoidal veins bypasses the liver and flows directly into the iliac veins and into the heart. Hence, drugs that are administered rectally may undergo first-pass hepatic metabolism if they are absorbed via the superior rectal veins. Because drugs may be administered by any of these routes, it is critical to evaluate the bioavailability of the drug via each route and at each age to determine the appropriate dose to achieve a therapeutic blood concentration.

Once in the bloodstream, drugs partition between the protein and lipid-bound fractions and the free or active fraction. Two major proteins that bind drugs are synthesized in the liver: albumin and  $\alpha_1$ -acid glycoprotein. The concentration of albumin, which is reduced at birth and in children with liver disease, cancer, nephropathy, and malnutrition, binds acidic drugs. The concentration of  $\alpha_1$ -acid glycoprotein, which is also reduced at birth but increases with increasing age as well as during periods of stress and inflammation,<sup>14</sup> binds basic compounds such as lidocaine. Hence, the free fraction of lidocaine in young infants will be greater than in older children.<sup>14</sup> With reduced plasma concentrations of both albumin and  $\alpha_1$ -acid glycoprotein

in neonates and infants, the free fraction of drugs increases leading to a greater dose reaching the effect site and exerting physiologic as well as possible toxic effects.

Termination of the action of most IV drugs depends on their metabolism through phase 1 reactions (e.g., hydroxylation and oxidation) and/or phase 2 reactions (e.g., glucuronidation) in the liver. The rates at which these enzyme systems mature vary widely among and within individuals depending on a host of factors. Apart from a few enzyme systems that hold importance in fetal life (e.g., CYP450 3A7),<sup>15</sup> the activities of the vast majority of CYP450 enzyme systems (e.g., CYP450 3A4, 2E1, and 2D6) involved in phase 1 reactions increase from birth, but at varying rates (Fig. 43-1).<sup>15</sup> Moreover, genetic polymorphisms of several families of enzymes (e.g., 2D6) may dramatically affect the activity of the enzyme, resulting in a wide range of activity from zero to rapid and excessive (see Codeine).<sup>16</sup>

Phase 1 reactions are responsible for the majority of drug metabolism in the liver acting via the cytochrome P450 enzyme system: 3A4 metabolizes 50% of our drugs, 2D6 10% to 20%,<sup>16</sup> and 1A2, 2E1, and 2C9 the remainder. These isozyme systems mature from birth reaching adult activity levels by 1 to 5 years of age (Fig. 43-1). Phase 2 enzymes, which conjugate drugs and metabolites for excretion, are also immature at birth, giving rise to concerns about bilirubin toxicity. However, these systems also mature quickly with age.

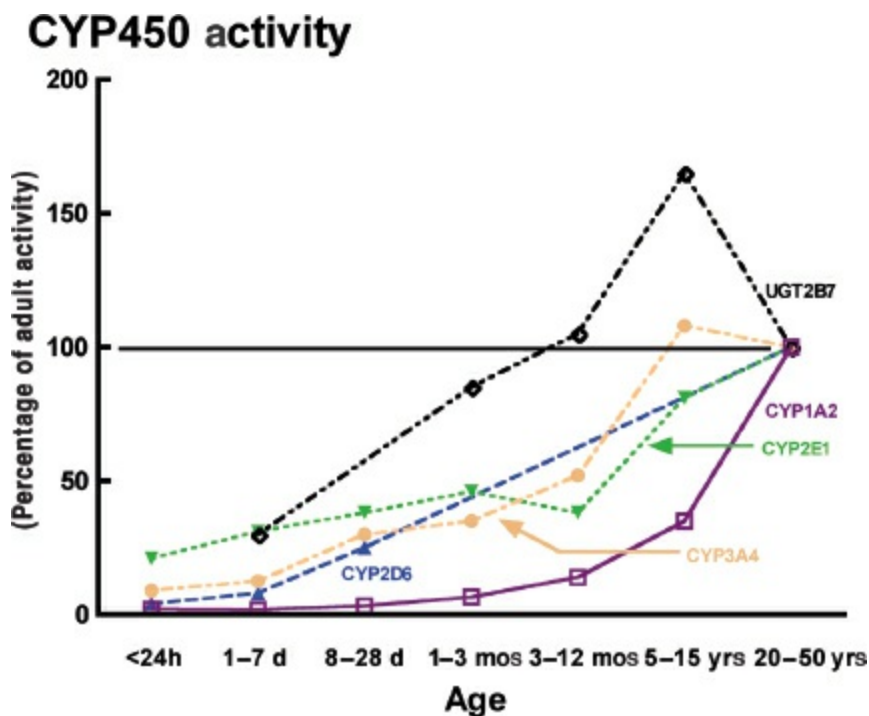

Termination of the action of many drugs in anesthesia depends on either redistribution of the active compound away from the effect site to other vessel-rich organs (see Inhalational Anesthetics section) or muscle, or metabolism in the liver and excretion or direct excretion by the kidneys. Elimination of the metabolic by-products and residual active parent compounds depends on renal perfusion and elimination. The glomerular filtration rate is markedly reduced in the neonate and young infant but matures throughout childhood reaching adult rates by 5 to 15 years of age.<sup>17</sup>

## *Inhalational Anesthetics*

4

The widespread appeal of the current inhalational anesthetics may be attributed to their physicochemical properties (Table 43-3), which provide a rapid onset and offset of action, cardiorespiratory homeostasis, and limited metabolism and toxicity. Halothane has all but disappeared from North American anesthetic practice, having been replaced by sevoflurane as the induction agent of choice in infants and children. Enflurane has been supplanted by its optical isomer, isoflurane, and more recently by desflurane. Desflurane offers the most favorable pharmacokinetic and in vivo metabolic characteristics in terms of its minimal blood and tissue solubilities and

resistance to metabolism, although its use as an induction agent in children is proscribed because it is very irritating to the upper airway. Most recently, the noble gas xenon has generated much interest as an anesthetic because it is safe for the environment, lacks cardiovascular toxicity, and has no serious toxicity either in vivo or in vitro. However, xenon is not widely available (because it must be extracted from the atmosphere), is very expensive, has a minimum alveolar concentration (MAC) of 70%, and causes nausea and vomiting. There are no published data regarding the pharmacology of xenon in children.

<sup>c</sup>Data from Lerman J, Gregory GA, Willis MM, et al. Age and solubility of volatile anesthetics in blood. *Anesthesiology*. 1984;61:139–143.

All of the currently used inhalational anesthetics are methyl ethyl ether compounds with the exception of sevoflurane, which is a methyl isopropyl ether. Their physicochemical and pharmacodynamic effects are summarized in [Table 43-3](#).

## Pharmacokinetics

The rate of increase in alveolar to inspired anesthetic partial pressures—that is, fraction in the alveolus ( $F_A$ ) to fraction in the inspired gas ( $F_I$ ), known as the washin ratio ( $F_A/F_I$ )—depends on six factors ([Table 43-4](#)). The first three determine the delivery of anesthetic to the lungs and the second three determine the removal of anesthetic from the lung. The washin ratio increases from 0 toward 1 in the shape of an exponential curve for all inhalational anesthetics. The order of washin of the anesthetics is inversely related to the solubility of the anesthetics in blood; that is, the smaller the solubility in blood, the more rapid the washin ([Table 43-3](#)).<sup>18,19</sup>

The washin curve for inhalational anesthetics is characterized by the simple exponential equation

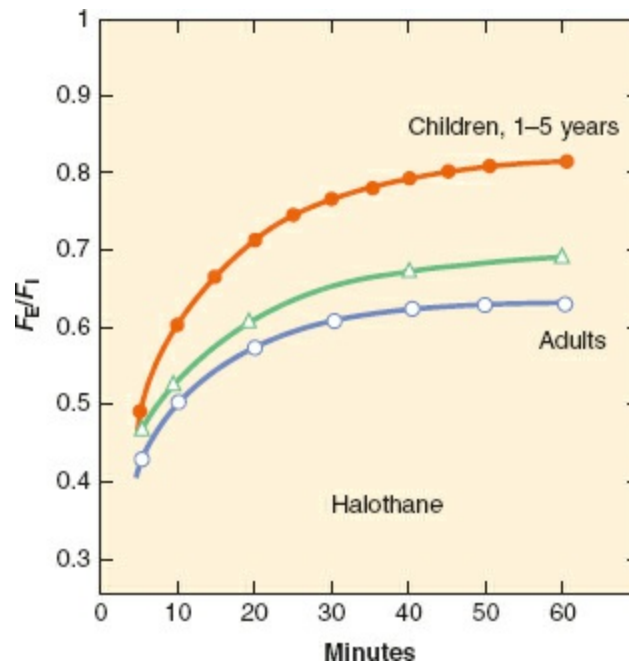

$$F_A/F_I = 1 - e^{-kt} \quad (43-1)$$

**Table 43-4** Determinants of the Washin and Washout of Inhalational Anesthetics

4. Cardiac output
5. Solubility
6. Alveolar to venous anesthetic partial pressure gradient

where  $k$  is a constant ( $k = 1/\text{time constant } (\tau)$ ) and  $t$  is time in minutes.  $\tau$  is the ratio of the volume of the organ to the blood flow to that organ. The smaller the time constant, the more rapidly  $F_A/F_I$  equilibrates. The time constants for most organs in children are less than those in adults, explaining in part the rapid equilibration of halothane in children compared with adults (Fig. 43-2).

In the case of infants and children, four factors explain the more rapid washin of halothane compared with adults. These factors are listed in order of importance from the greatest to the least in Table 43-5.

**Figure 43-2** The more rapid washin of halothane in children compared with adults. The fractional end-tidal to inspired ratio ( $F_E/F_I$ ) of halothane (Y-axis) over time (X-axis). The two lower curves (with open symbols) are from adults. (Adapted from Salanitre E, Rackow H. The pulmonary exchange of nitrous oxide and halothane in infants and children. *Anesthesiology*. 1969;30:391.)

**Table 43-5** Factors That Explain the More Rapid Washin of Inhalational Anesthetics in Children Compared with Adults

- Alveolar ventilation:FRC ratio (5:1 in infants vs. 1.5:1 in adults)
- Greater distribution of cardiac output to the vessel-rich group in infants (vessel-rich group comprises 18% of the body weight in infants compared with 8% in adults)
- Reduced tissue solubility in infants<sup>18</sup>
- Reduced blood solubility in infants<sup>20,21</sup>

The greater alveolar ventilation (VA):functional residual capacity (FRC) ratio in infants and children compared with adults may be attributed to the greater metabolic rate and oxygen demand in children. Increases in alveolar

ventilation speed the equilibration of inspired to alveolar anesthetic partial pressures.<sup>22</sup> The net effect of a greater VA:FRC ratio is a reduction in the time constant, from 0.7 in adults to 0.2 in infants, which explains the speed of equilibration. Although a greater cardiac output should slow the rate of increase in  $F_A/F_I$ , it actually speeds the equilibration in neonates and infants. This paradoxical effect may be attributed to the greater cardiac output perfusing the vessel-rich group (VRG) (comprised of the heart, brain, gastrointestinal organs, kidneys, and endocrine glands) which comprises 18% of the body's weight in infants compared with only 8% in adults. Hence, the greater cardiac output in infants speeds the equilibration of  $F_A/F_I$  in the VRG, which takes up most of the anesthetic during the first couple of hours of anesthesia. The third factor is the reduced tissue solubility in infants compared with that in adults.<sup>18</sup> The solubility of all inhalational anesthetics is reduced in tissues in infants compared with adults including the brain, muscle, and heart. The fourth factor is the reduced solubility of anesthetic in blood in infants, which speeds the washin of inhalational anesthetics in infants.<sup>21</sup>

To understand the relevance of differences in the tissue solubility among age groups,  $\tau$  is defined by

$$\tau = \frac{\text{Brain volume (mL)} \times \lambda_{\text{brain/blood}}}{\text{Brain blood flow (mL/100 g/min)}} \quad (43-2)$$

In the brain, the brain blood flow is 50 mL/100 g/min or 50 mL/100 mL brain/min. In adults,  $\lambda_{\text{brain/blood}}$  is  $\sim 2$ , whereas in the infant it is  $\sim 1$ . Substituting these values into Eq. 43-2 yields  $100 \times 2$  (or 1)/50 or 4 minutes in adults and 2 minutes in children. Because  $4\tau$  are required to achieve 98% equilibration of  $F_A/F_I$ , the partial pressure of brain equilibrates by 16 minutes in adults and 8 minutes in children (excluding the time to equilibrate anesthetic throughout the anesthesia workstation [AWS] and lungs). Hence, we can explain, in part, the sudden and rapid responses to inhalational anesthetic in infants and children compared with adults.

In contrast to the more soluble anesthetics of the past, the current inhalational anesthetics are much less soluble in both blood and tissues. Because changes in alveolar ventilation and cardiac output affect the washin of less soluble anesthetics to a lesser extent than more soluble anesthetics, the effects of the first two factors in [Table 43-5](#) on the washin of sevoflurane and desflurane in young children are attenuated. Therefore, the washin of these anesthetics in this age group may be similar in infants and adults. Furthermore, the solubilities of these agents in blood in infants are similar to those in adults<sup>20</sup>; however, the tissue solubilities in infants compared with adults have not been reported. Hence, we may expect the washin of sevoflurane and desflurane in infants to be, at the most, only marginally more rapid than in adults.

Estimates of the effect site equilibration half-life ( $t_{1/2keo}$ ) for sevoflurane in children and adults have been reported using the bispectral index (BIS) to be 1.2 and 3.2 minutes, respectively.<sup>23,24</sup>

Two additional aspects of the pharmacokinetics of inhalational anesthetics in infants and children merit consideration. The first is the mode of ventilation. The washin of inhalational anesthetics increases rapidly during induction of anesthesia. In dogs, the washin of halothane was well tolerated during spontaneous respiration whether the inspired concentration was 0.4% or 4%.<sup>25</sup> The  $F_A/F_I$  plateaued in all instances at 0.6 to 0.7. As the anesthetic depth increased, ventilation was reduced, decreasing the uptake of anesthetic. As anesthetic was redistributed from the brain and the depth of anesthesia reduced, ventilation increased and the uptake and depth of anesthesia resumed. This process is known as a negative feedback control loop. However, when ventilation was controlled, 85% and 100% of the dogs that received 4% or 6% inspired halothane, respectively, died.<sup>25</sup> Controlled ventilation is a positive feedback control loop in which the delivery of inhalational anesthesia to the lungs continues unabated, deepening the level of anesthesia and thus cardiac output. The decreased cardiac output attenuates the pulmonary blood flow and thus the uptake of and removal of anesthetic from the lung. Thus, the partial pressure of anesthetic within the lungs increases steadily. These greater partial pressures in the lungs equilibrate with the reduced cardiac output, to further depress the VRG, ultimately resulting in a cardiac arrest. This study illustrates the inherent safety of the spontaneous compared with controlled ventilation during inhalational anesthesia in that the former protects against an overdose of an inhalational anesthetic; whether the same benefit holds true for sevoflurane remains unknown. In the past, multiple vaporizers could be used simultaneously, posing a hazard if ventilation were controlled. Interlocking devices were developed to prevent such an anesthetic overdose.

The second issue relates to shunts and their effects on the uptake and distribution of anesthetics. Left-to-right shunts have limited effects on the uptake and distribution of inhalational anesthetics provided the cardiac output is maintained.<sup>5</sup> However, right-to-left shunts present an entirely different and far more complex clinical situation. Irrespective of the source of these shunts (intrapulmonary or intracardiac or both), the washin of less soluble anesthetics are affected to a much greater extent by the presence of these shunts than more soluble anesthetics.<sup>5</sup> That is, it is much more difficult to maintain an adequate depth of anesthesia with sevoflurane in infants with significant right-to-left shunts whether it is an intrapulmonary or intracardiac shunt. To maintain anesthesia in infants with these shunts, supplemental IV anesthesia is often required. Understanding the differential effect of shunts on the washin of inhalational anesthetics is beyond the scope of this chapter, but

the basis may be summarized by the differential effect of ventilation on the washin of less and more soluble anesthetics.<sup>5</sup>

The speed of washout of inhalational anesthetics follows an exponential decay, with the speed inversely related to the solubility of the anesthetics in blood (Table 43-3). That is, the washout is more rapid for anesthetics that are less soluble in blood: desflurane > sevoflurane > isoflurane ≥ halothane.<sup>19,21</sup> The only exception to this rule is the washout of halothane, which overlaps that of isoflurane in part, because the former is extensively metabolized in vivo, 15% to 25% (Table 43-3). Computer simulations demonstrated greater differences in recovery and greater than 90% decrement in the anesthetic concentration among the anesthetics after prolonged anesthesia.<sup>26</sup>

Substituting a less soluble anesthetic for a more soluble one during maintenance of anesthesia has been proposed to accelerate the washout of anesthetics and recovery from anesthesia. However, switching from isoflurane to desflurane 30 minutes before the end of surgery did not speed the recovery compared with a 2 h anesthetic with 1.25 MAC isoflurane in adult volunteers.<sup>27</sup> More recently, charcoal filters have been used to adsorb anesthetics and, when combined with hypercapnic hyperventilation, were shown to rapidly remove anesthetics and speed recovery in adults.<sup>28,29</sup> Comparable washout data in children are lacking.

## Pharmacodynamics

The MAC is that concentration of inhalational anesthetic at which 50% of patients move in response to a skin incision. In children, the MAC is known to vary substantively with age. That is, as the fetus matures and reaches term, the MAC increases peaking in infants 1 to 6 months of age for halothane<sup>30,31</sup> and isoflurane<sup>32,33</sup> and then decreases steadily thereafter with increasing age (Fig. 43-3). In the case of sevoflurane, the MAC is 3.3% in neonates and 3.2% in infants 1 to 6 months of age.<sup>34</sup> For children 6 months to 12 years, the MAC is constant at 2.4%.<sup>34</sup> In the case of desflurane, the MAC increases throughout infancy peaking in infants 6 to 12 months of age and decreases thereafter with increasing age.<sup>35</sup> The reasons for the peak of MAC in infancy and the age-dependent changes in the MAC remain unclear.

The MAC values of inhalational anesthetics in children have shown several other peculiarities. The MAC of halothane is 25% less in children with cognitive dysfunction, especially those taking anti-seizure drugs.<sup>36</sup> The MAC of desflurane in adult homozygote redheads is 20% greater than in nonredheads<sup>37</sup>; the same response would be expected in children of similar genetic predisposition. The MAC values for halothane and isoflurane show simple additivity with N<sub>2</sub>O in adults and children; however, 60% N<sub>2</sub>O only

contributes 25% to the MAC values for sevoflurane and desflurane in children.<sup>34,38</sup> The reason for this diminished effect of N<sub>2</sub>O on the MAC values of sevoflurane and desflurane is unknown. The MAC also varies with the child's temperature. In children 4 to 10 years of age, the MAC of isoflurane decreases 5%/°C decrease in temperature.<sup>39</sup>

In addition to determining the MAC responses to skin incision, the ED<sub>50</sub> to a number of other maneuvers including insertion and removal of laryngeal mask airways (LMAs), tracheal extubation, and others have been determined in children.<sup>5</sup>

**Figure 43-3** Age and the MAC of isoflurane from premature infants to adults. (Adapted from LeDez KM, Lerman J. The minimum alveolar concentration [MAC] of isoflurane in preterm neonates. *Anesthesiology*. 1987;67:301–307.)

## Respiration

When administered in the absence of surgical stimulation, all anesthetics depress respiration and minute ventilation in a dose-dependent manner, by decreasing tidal volume and increasing respiratory rate.<sup>40,41</sup> Inhalational anesthetics relax intercostal muscles before the diaphragm, resulting primarily in diaphragmatic respiration. Respiratory rate increases during anesthesia, which offsets in part the reduced tidal volume. These effects are most pronounced with halothane; at concentrations 1.4 MAC or higher, sevoflurane depresses respiration to a greater extent than halothane in adults,<sup>42</sup> although the evidence is less clear in children.<sup>41</sup> As the concentration of sevoflurane increases, respiratory rate also diminishes ultimately resulting in apnea. This effect is augmented in the presence of a midazolam premedication. This central effect is offset by manually assisting ventilation. In the case of desflurane, concentrations greater than 1 MAC depress respiration in infants

and children, an effect that exceeds the depression by other inhalational anesthetics.<sup>43</sup>

Inhalational anesthetics also depress the response to carbon dioxide and hypoxia in a dose-dependent manner.

Airway resistance increases during desflurane,<sup>44</sup> and decreases during sevoflurane anesthesia in children.<sup>44,45</sup> Hence, in children with asthma, sevoflurane is preferable. In both children and adults with refractory status asthmaticus, inhalational anesthetics have been effective to break the bronchospasm in the intensive care unit.<sup>46,47</sup>

Upper airway responses to inhalational anesthesia (by mask) depend on both the concentration and the particular anesthetic administered. Halothane and sevoflurane infrequently trigger these reflex responses<sup>40,48</sup> whereas isoflurane and desflurane are quite irritating to the airway, particularly at concentrations exceeding 1 MAC.<sup>49,50</sup> The package insert for desflurane cautions against using it for inhalational inductions in children. The mechanism by which inhalational anesthetics trigger upper airway reflex responses remains unclear.

When a tracheal tube is used, neither desflurane nor isoflurane triggers airway reflexes during maintenance or emergence from anesthesia.<sup>50</sup> When an LMA is used, extubation during deep desflurane anesthesia may increase the incidence of airway reflex responses when compared with extubation awake after desflurane or isoflurane.<sup>51</sup>

### *Cardiovascular*

Inhalational anesthetics depress the heart in a dose-dependent manner. Direct effects of these anesthetics depress the heart rate, contractility, and peripheral vascular tone. Among the inhalational anesthetics, halothane slows the heart rate the most, often sensitizing the myocardium to catecholamines and inducing ventricular dysrhythmias. In the past, anticholinergics were commonly used to prevent bradycardia and arrhythmias in children given halothane; however, this practice is no longer necessary with the newer ether anesthetics that infrequently cause arrhythmias. Sevoflurane and the remaining ether anesthetics exert limited effects on the cardiac conduction system. Sevoflurane maintains or increases heart rate during induction of anesthesia in most instances likely due to withdrawal of vagal tone,<sup>52</sup> although on occasion, nodal bradycardia may occur. This is usually a self-limited effect. Desflurane and isoflurane also tend to increase the heart rate. Desflurane, to a greater extent than isoflurane, causes a sympathetic discharge when the inspired concentration is increased substantively and in a stepwise manner, without pretreatment with opioids<sup>53</sup>; similar responses in children have not been forthcoming. This effect is mediated through the right and left lungs.<sup>54</sup> Sevoflurane and the other inhalational anesthetics prolong the QT

interval, but do not increase the dispersion of repolarization, thus precluding torsades de pointes and other potentially fatal arrhythmias (see later).<sup>55</sup> However, arrhythmias have been reported in children with congenital long QT interval particularly during emergence from anesthesia.<sup>56</sup>

Halothane depresses myocardial contractility to the greatest extent; sevoflurane and the remaining ether anesthetics exert a much more attenuated effect in children. Sevoflurane and halothane decrease cardiac index in children similarly, ~10% at 1 × MAC and 20% to 30% at 2 × MAC, although sevoflurane may depress cardiac index in infants less than after halothane.<sup>57,58</sup> Compared with awake values, systolic blood pressure decreases ~20% to 30% at 1 × MAC of ether anesthetics, an effect that is usually reversed with surgical stimulation.<sup>32,34,35</sup>

Early studies showed that cardiac output depended on heart rate in young children; the calcium-dependent force contraction-rate effect is pronounced in infants and young children.<sup>1</sup> Furthermore, increasing the heart rate reversed the halothane-dependent decreases in cardiac output.<sup>59</sup> More recent evidence suggests that children can increase their stroke volume if needed to augment their cardiac output. Peripheral vascular resistance is reduced in children as evidenced by the absence of a change in blood pressure when a caudal/epidural block is administered.

Sevoflurane is preferred over halothane in children with congenital heart disease as it causes fewer arrhythmias and less hypotension than halothane.<sup>60</sup>

Most anesthetic drugs prolonged the QT interval, which is prolonged when it exceeds 500 milliseconds.<sup>61</sup> When the QT interval is prolonged in the presence of an increased dispersion of repolarization, there is a substantial risk for torsades de pointes. The risk of torsades de pointes is increased when anesthetics that prolong the QT interval are administered to children in the presence of congenital long QT interval (Romano–Ward and Jervell and Lange-Nielsen syndrome), nonanesthetic drugs that prolong the QT interval, several medical conditions (hypomagnesemia, hypokalemia, hypocalcemia, cardiac disease, hypothyroidism), bradycardia, and the female gender.<sup>61,62</sup>

### *Central Nervous System*

All inhalational anesthetics decrease cerebral vascular resistance and cerebral metabolic rate for oxygen. The decrease in vascular resistance increases CBF in the following order: halothane > desflurane > isoflurane > sevoflurane.<sup>3</sup> Sevoflurane and isoflurane decrease oxygen consumption to greater extents than halothane. Hence, the most favorable ratio of CBF to oxygen consumption follows the reverse order: sevoflurane > isoflurane > desflurane > halothane.

The effects of changes in blood pressure as well as carbon dioxide and oxygen tensions on CBF during anesthesia in children have not been fully

elucidated. Autoregulation of CBF in children of all ages is similar to that in adults, although it occurs at greater blood flow rates.<sup>3</sup> The lower limit of autoregulation in children of all ages appears to be similar, that is, the MAP of the 50th percentile for height or ~60 mmHg mean arterial pressure (MAP). However, in infants under 6 months, this limit may be as low as 38 mmHg or at 20% below the baseline MAP. All inhalational anesthetics impair autoregulation, although sevoflurane does not impair autoregulation in children 1.5 MAC or lower.<sup>3</sup> As in adults, hyperventilation restores autoregulation with isoflurane and sevoflurane. Cerebrovasodilatation and CBF increase as carbon dioxide tension increases in children up to ~50 mmHg, but beyond that level, maximum vasodilatation prevents any further response. Changes in CBF in response to changes in PCO<sub>2</sub> during isoflurane anesthesia are greater than during sevoflurane. Hence, hyperventilation may be more effective in attenuating increased intracranial pressure during isoflurane anesthesia than during sevoflurane.

The electroencephalogram during sevoflurane is characterized by sharp, slow waves in the lower frequency range. This pattern differs substantially from that of the isoflurane, the latter comprising the algorithm for the BIS. As a result, the BIS readings in children under 5 years are imprecise, readings decrease 10% to 20% as the child ages from 1 to 12 years, and the BIS values paradoxically increase as the sevoflurane concentration increases from 3% to 4% (see BIS Measurements).<sup>63–67</sup>

Myoclonic movement as well as EEG spike and wave activity (epileptiform) have been reported in a very small number of children during inhalational inductions with sevoflurane, at concentrations between 5% and 8%.<sup>68</sup> In patients with seizures, epileptiform EEG activity has been reported in 58% of those anesthetized with 1 to 2 MAC sevoflurane and in 25% of those with 1 to 2 MAC isoflurane, with hyperventilation and nitrous oxide curiously reducing the epileptiform activity.<sup>69</sup> With sevoflurane, these occurred not only in several patients with a history of seizures but also in the presence of hyperventilation. Indeed, at sevoflurane concentrations approaching 8% during induction of anesthesia, ventilation should be assisted, but not controlled with hyperventilation, if apnea occurs.

## *Renal*

Inhalational anesthetics do not exert substantive effects on the kidneys in children except through their metabolism: the kidney is a site of degradation of inhalational anesthetics. Ether anesthetics, most notably methoxyflurane (no longer in use) and to a lesser extent sevoflurane, are degraded by CYP450 2E1<sup>70</sup> releasing inorganic fluoride into the circulation in similar concentrations, although only the former is known to be nephrotoxic. In part, this has been attributed to the metabolic function of the kidney: specifically

the presence of CYP450 2E1 within the kidney degrades inhaled anesthetics releasing inorganic fluoride, which is toxic to the renal tubules and in the case of methoxyflurane, caused high output renal failure and its withdrawal from the market.<sup>71</sup> The difference in nephrotoxicity between the two anesthetics has been attributed to two factors: The first is that the affinity of methoxyflurane for 2E1 is several fold greater than that for sevoflurane. The second is that methoxyflurane is the only anesthetic to undergo O-demethylation, which produces dichloroacetic acid, a putative cofactor in the pathogenesis of anesthetic-induced nephrotoxicity.<sup>72</sup>

Isoflurane and desflurane are metabolized to small extents. The risk of nephrotoxicity from inorganic fluoride from either anesthetic is remote. Indeed, very small inorganic fluoride concentrations (mean value 11  $\mu\text{M}$ ) have been detected after 131 MAC-hours isoflurane in children.<sup>73</sup>

### *Hepatic*

There are few data regarding the effects of inhalational anesthetics on hepatic function in children. However, isolated cases of hepatic dysfunction in children have been reported after uses of every inhalational anesthetic.<sup>74,75</sup> Most children who develop hepatic dysfunction recover without further treatment. In the case of halothane hepatitis, serologic markers in the form of antibodies to hepatic cell membrane antigens have been detected.<sup>76</sup> Similar immunologic markers have been detected after isoflurane and desflurane, although none have been identified for sevoflurane to date. Although it has been suggested that repeated anesthetics with halothane cause hepatitis, this author asserts there is insufficient evidence to avoid repeated inhalational anesthetics in children.

### *In Vitro Metabolism*

Degradation of inhalational anesthetics in the presence of carbon dioxide absorbents has been the subject of intense research and concern in both adults and children.

Sevoflurane may be degraded via the Cannizzaro reaction in carbon dioxide absorbents. The reaction is accelerated in the presence of increased temperature and barium hydroxide, strong bases (potassium hydroxide), very low fresh gas flow, large sevoflurane concentrations, and dessicated absorbent. The reaction releases five compounds, of which compound A, fluoromethyl-2,2-difluoro-1-(trifluoromethyl) vinyl ether, is the most common.<sup>77</sup> Nephrotoxic concentrations of compound A are more than 100 ppm; in children 1 MAC sevoflurane produces 16 ppm after 5.6 MAC-hours in a circle circuit with a 2 L/min fresh gas flow.<sup>77</sup> To date, there have been no instances of compound A-induced nephrotoxicity in children.

Inhalational anesthetics may also be degraded in the presence of desiccated carbon dioxide absorbent yielding carbon monoxide. Desiccation may occur when a large fresh gas flows through a carbon dioxide absorber for an extended period (>48 hours) without a reservoir bag attached. Subsequently, when a potent inhalational anesthetic encounters the desiccated absorbent, carbon monoxide is produced. The rate of production of carbon monoxide follows the order: desflurane  $\geq$  enflurane > isoflurane > halothane = sevoflurane.<sup>78</sup> This problem can be avoided if the AWS is turned off or the fresh gas is discontinued after each day or if the reservoir bag remains attached. Recently, carbon monoxide ( $\leq 18$  ppm) was detected in the anesthesia breathing circuit in children although the source was unclear.<sup>79</sup>

## Intravenous

IV drugs are distributed first to the VRG, just as inhalational anesthetics are, and then to the muscle, vessel-poor, and fat groups. The primary anesthetic effect occurs when an adequate brain concentration is achieved; thereafter, the anesthetic is redistributed to other tissues and metabolized to terminate its action. The pharmacokinetics of IV anesthetics depends on the dose and rate of drug administered, the binding of the drug in blood, the cardiac output and the distribution of cardiac output, metabolism, and excretion pathways.

## Propofol

Diisopropylphenol is the most commonly used IV induction agent in children. This highly lipophilic drug distributes rapidly to the VRG to affect its anesthetic action. The effect site equilibration half-life ( $t_{1/2keo}$ ) has been estimated at 0.8 or 1.2 minutes, depending on the model.<sup>80</sup> Its action is terminated by redistribution as well as hepatic and extrahepatic metabolism. Volume of distribution and clearance (to a lesser extent) decrease progressively during early childhood.<sup>81</sup> However, clearance increases throughout gestation and the neonatal period, reaching 90% of adult values by 3 months of age.<sup>82</sup> To maintain the 3  $\mu\text{g/mL}$  blood concentration for anesthesia, a 50% greater induction and infusion dosing schedule is required in young children.<sup>83</sup> The net effect is a context-sensitive half-life that increases with time in children more rapidly than in adults.<sup>83</sup>

The ED<sub>50</sub> for loss of the eyelash reflex in children varies with the child's age:  $3 \pm 0.2$  mg/kg in infants 1 to 6 months; 1.3 to 1.6 mg/kg in children 1 to 12 years;  $2.4 \pm 0.1$  mg/kg in children 10 to 16 years.<sup>84</sup> The ED<sub>50</sub> and ED<sub>90</sub> of propofol to insert an LMA in children is 3.5 and 5.4 mg/kg (4.7 to 6.8 mg/kg 95% CI), respectively.<sup>85,86</sup> The dose of propofol to facilitate tracheal intubation in children during sevoflurane anesthesia is 1 to 2 mg/kg.<sup>87,88</sup>

Propofol is an integral part of total IV anesthesia (TIVA) for maintenance of anesthesia in children undergoing medical/radiologic evaluations and surgery. For painless medical or radiologic (e.g., MRI) procedures in young children 2 to 6 years of age, an initial infusion rate of 15 mg/kg/hr (250 µg/kg/min) of propofol is recommended after either an inhalational induction or an IV induction.<sup>83,89,90</sup> This dose may have to be increased to stop spontaneous movement, particularly if the children have neurocognitive impairment or are younger.<sup>91</sup> Conversely, the infusion rate may be reduced in older children. Infusion rates in obese children are far more complex and are discussed under Obesity.

Based on pharmacokinetic modeling to maintain a blood concentration of 3 µg/mL, the infusion rate is decreased during prolonged surgery to facilitate rapid emergence. One recommended stepwise reduction in the infusion rate in children 3 to 11 years of age after an IV induction with 2.5 mg/kg propofol is 15 mg/kg/hr (250 µg/kg/min) for 15 minutes followed by 13 mg/kg/hr (215 µg/kg/min) for 15 minutes, followed by 11 mg/kg/hr (180 µg/kg/min) for 30 minutes, followed by 10 mg/kg/hr (166 µg/kg/min) for 60 minutes, followed by 9 mg/kg/hr (150 µg/kg/min) for the next 2 hours.<sup>83</sup> Target-controlled infusions (TCI) in children are available in Europe, but not in North America.<sup>92,93</sup> These devices use preset algorithms based on the pharmacokinetics that use similar dosing algorithms with modest success.

Propofol causes pain in 70% or more of patients during IV induction of anesthesia<sup>94</sup>; the pain is greater when it is injected into a small vein (as in the hand) than in the arm.<sup>95</sup> This pain is most reliably prevented by administering 70% nitrous oxide before propofol or by applying a mini-Bier block with 0.5 to 1 mg/kg IV lidocaine for 60 seconds.<sup>94-96</sup>

Propofol has profound effects on the airway. After a rapid induction dose, a transient apnea is followed by a return of spontaneous respiration. Propofol reduces the hypopharyngeal dimensions, although upper airway patency is maintained.<sup>97</sup> A jaw thrust maneuver reestablishes a patent airway, should obstruction occur.<sup>98</sup> An important and unique property of propofol is the ease by which an LMA can be inserted. Propofol relaxes the upper pharyngeal muscles to facilitate acceptance of the LMA. Although propofol induces apnea, atelectasis during spontaneous respiration occurs less frequently than with tracheal intubation.<sup>99</sup>

Propofol is the only anesthetic with effective antiemetic properties that may be used for children with a history of postoperative nausea and vomiting (PONV) and in emetogenic surgery.<sup>100</sup>

Although propofol is used for both sedation and general anesthesia, long-term sedation with propofol in infants and children is not recommended, after reports of unexpected death during propofol sedation with greater than 4 mg/kg/hr for more than 48 hours.<sup>101</sup> In the United States, 21 children and 68

adults died in association with propofol administration over a 10-year period.<sup>102</sup> Whether these deaths were the result of the long-chain triglycerides or propofol or both has not been clarified or were less commonly due to other rare disorders such as neonatal adrenoleukodystrophy. Partial exchange transfusions have been effective in preventing death.<sup>103</sup> At least three reports of incipient propofol infusion syndrome (PRIS) have been reported in children after only a few hours of anesthesia.<sup>104</sup> The smallest infusion rate reported to trigger PRIS was 1.9 to 2.6 mg/kg/hr. Currently, long-term sedation with propofol is avoided in infants and children, especially in those with suspected inflammatory responses including sepsis.

Although the original package insert recommended caution when propofol is administered to children with egg and soy allergies this author only avoids propofol in those with documented egg anaphylaxis (see section on Allergies).

## **Ketamine**

Ketamine is a phencyclidine derivative that offers enormous flexibility in the clinical care of children. This anesthetic can be used as a premedication (orally, nasally, rectally, or intramuscularly [IM]), general anesthetic induction agent (IV or IM), and maintenance agent as an infusion, as a sedative (IV or IM), or as a neuroaxial analgesic (caudal/epidural).

Ketamine is available as a racemic mixture, in which the S enantiomer is four times more potent than the R enantiomer. Ketamine is extremely lipophilic with a rapid onset of action, within 30 seconds, and maximum effect by 1 minute; the half-time to equilibrate in the effect site (brain) is 11 seconds.<sup>105</sup> Effective blood concentration of ketamine for anesthesia is 3 µg/mL.<sup>106</sup> Clearance of ketamine is reduced in neonates, but reaches adult levels by 6 months of age.<sup>107</sup> Context-sensitive half-life for ketamine in a 10-kg child increases from 30 minutes after 1 hour to 55 minutes after 5 hours of infusion. Emergence after a prolonged infusion of ketamine, especially when combined with opioids and benzodiazepines, may be delayed. Ketamine is primarily metabolized via CYP450 3A4 to norketamine.

Oral ketamine may be used for premedication in a dose of 5 to 6 mg/kg.<sup>108</sup> It may cause nausea and vomiting postoperatively; nightmares are not common by this route. Ketamine may also be given intranasally, although the porous nature of the cribriform plate raises concern regarding the potential neurotoxicity of ketamine if it reaches the brain directly via this route. The dose of intranasal (IN) ketamine (racemic mixture) is 3 to 6 mg/kg and for S-ketamine 2 mg/kg.<sup>109</sup> The rectal ketamine dose for premedication is 5 to 10 mg/kg, with recovery increasing substantially in duration with larger doses of ketamine. For IM use, 2 to 5 mg/kg ketamine sedates an uncooperative child in 3 to 5 minutes with a duration of action of 30 to 40

minutes.

General anesthesia may be induced with 1 to 2 mg/kg IV, a technique that is useful in children with cyanotic heart disease, septic shock, and conditions in which spontaneous respiration should be preserved (as in a child with an anterior mediastinal mass [AMM]). Ketamine may also be given as a continuous infusion after a single bolus loading dose of 2 mg/kg IV<sup>92</sup>: consisting of 11 mg/kg/hr for 20 minutes followed by 7 and 5 mg/kg/hr for the same periods, then 4 mg/kg/hr for the next hour, and 3.5 mg/kg/hr thereafter. If midazolam and nitrous oxide were added, the same regimen starting at 7 mg/kg/hr would provide adequate sedation.<sup>92</sup>

Ketamine is used occasionally for perioperative analgesia and has made a small resurgence for this indication in children with obstructive sleep apnea (OSA).<sup>110</sup> It is also used for neuroaxial analgesia. S-ketamine is the more potent and preferred enantiomer to administer. If ketamine is administered in a neuroaxial block, a preservative-free formulation should be used. *Caution: The neurotoxic risk of the racemic mixture of ketamine in the epidural space has not been established.*<sup>111</sup>

Side effects associated with ketamine include increased secretions, nystagmus, and nausea and vomiting. The last effect may occur in up to 33% of children. Nightmares and hallucinations have been reported after ketamine but appear to be very infrequent. Coadministration of midazolam and awakening in a dark, quiet environment may reduce the risk of nightmares postoperatively.<sup>112</sup>

Ketamine has been contraindicated in children with increased intracranial pressure and in those at risk for seizures although the evidence for both is weak.<sup>113</sup>

## **Etomidate**

This hypnotic anesthetic is infrequently used in children as its pharmacology has not been understood until recently. It is reserved for those who are hemodynamically unstable (e.g., septic shock). The dose of etomidate is 0.3 mg/kg IV in children. The pharmacokinetics have only recently been estimated: With greater clearance and volume of distribution in young children, larger doses are required in this age group than older children.<sup>114</sup> Although the elimination half-life or context-sensitive half-life of etomidate has not been reported in children, repeated doses or infusions have delayed emergence which limits the use of this drug. Because etomidate causes pain at the site of injection, pretreatment with IV lidocaine and mini-Bier block is advised.

The major impediment to the use of etomidate and to its approval in many countries has been the suppression of adrenal glands, particularly in critically

ill patients.<sup>115</sup>

Recent molecular engineering has yielded changes to the compound that attenuate the adrenal suppression and facilitate emergence even after prolonged infusions although these compounds remain under investigation.<sup>116</sup>

## **Neuromuscular Blocking Agents**

With standard twitch devices readily available, every child who receives a muscle relaxant should be assessed for their twitch response before attempting to antagonize the neuromuscular blockade. The role of neuromuscular agents in children has diminished in the past decade or more with the demise in routine use of succinylcholine and the adoption of propofol as the adjunctive drug to facilitate tracheal intubation after induction of anesthesia with sevoflurane.

In the USA, anaphylaxis to muscle relaxants is quite rare. In contrast, the most common cause of anaphylaxis during anesthesia in adults in Europe is muscle relaxants, with succinylcholine and rocuronium being the most common causes,<sup>117</sup> although in children, latex was the most common cause (42%) followed by muscle relaxants (32%) and antibiotics (9%).<sup>117</sup> The explanation for the frequency of anaphylaxis to relaxants in Europe remained elusive, although regional differences in the use of pholcodine, an over-the-counter cough medicine, suggested that epitopes in pholcodine (and certain cosmetics), which are structurally similar to those in the aminosteroidal relaxants, caused a cross-sensitivity with and anaphylactic reactions to relaxants, even upon first exposure.<sup>118</sup> Indeed, after pholcodine was banned in Norway, the incidence of anaphylactic reactions to muscle relaxants in that country decreased dramatically suggesting that this over-the-counter cough medicine sensitized the population to the relaxants.

### *Succinylcholine*

As the only depolarizing muscle relaxant in clinical practice, succinylcholine remains the agent that provides the most rapid onset and offset of paralysis, without additional drugs to recover the normal twitch response. Succinylcholine comprises two acetylcholine molecules fused together; it acts by depolarizing the acetylcholine receptors of the neuromuscular endplate.

The IV dose of succinylcholine is 3 to 4 mg/kg in neonates and infants, 2 mg/kg in children, and 1 mg/kg in adolescents.<sup>119</sup> The larger dose requirement with decreasing age has been attributed to the larger volume of distribution in younger infants. Paralysis usually occurs within 30 to 60 seconds and lasts approximately 5 minutes.<sup>119</sup> In contrast, an IM dose of 4 mg/kg paralyzes 100% of children within 1 to 2 minutes, although the duration may be as great as 20 minutes.<sup>120</sup> Rarely is it necessary to administer

succinylcholine intra- or sublingually, but this approach may be optimized with digital massage of the injection site.<sup>121</sup> The speed of onset of paralysis when 1.1 mg/kg is administered intralingually is intermediate between IV and IM rates, ~75 seconds.<sup>122</sup> It is imperative to avoid midline sublingual blood vessels to avoid a sublingual hematoma. To administer succinylcholine either IM or sublingually, a 25-gauge needle should be used to minimize vascular trauma. This author routinely administers atropine 20 µg/kg before succinylcholine given via any route to prevent bradycardia and asystole after a single dose in infants and children.

The action of succinylcholine is terminated by pseudocholinesterase (or plasma cholinesterase) which is located on 3q26.1 and 3q26.2.<sup>123</sup> The residual products of metabolism have no neuromuscular activity. Pseudocholinesterase activity may be modified by a number of factors, inherited or acquired (Table 43-6). The inheritance pattern for pseudocholinesterase is autosomal recessive, which yields a host of phenotypes. Four alleles code for most of the genetic variants of pseudocholinesterase (see later): “Usual” (U); “Atypical” (A); “Fluoride resistant” (F); and “Silent gene” (S).<sup>123</sup> Several minor variants (H, J, and K) have also been reported in specific populations. A second gene locus that codes for pseudocholinesterase in only 10% of Caucasians has been identified. It produces a C5 band on electrophoresis that yields 30% more pseudocholinesterase enzyme than normal (Neitlich variant) and rapidly metabolizes succinylcholine.<sup>124</sup> Another gene variant named E Cynthiana has been shown to have increased activity.<sup>125</sup>

The genetics of the pseudocholinesterase activity variant follows simple Mendelian inheritance. The vast majority of the population responds normally to succinylcholine; that is, they are homozygous “Usual” pseudocholinesterase, U/U. The most common allele that prolongs the action of succinylcholine is the “Atypical,” which occurs as heterozygous atypical (U/A) with minimal (~15 minutes) prolongation of action and as 1:3,000 to 1:10,000 in homozygous atypical (A/A) with a prolongation of 1 hour. In the case of fluoride-resistant, the frequency of homozygous F/F is 1:150,000 with a duration of activity of 1 to 2 hours whereas with the homozygous silent gene variant, S/S, the frequency is 1:10,000 patients with a clinical duration of 6 to 8 hours. The other variants H, J, and K (Kalow) are associated with a 90%, 66%, and 30% reduction in pseudocholinesterase activity, respectively. The homozygous H variant yields the greatest duration of action of succinylcholine among these three at 1 to 2 hours. The K variant is thought to occur in 13% of the population and the homozygous K variant occurs in 1.5%, extending the duration of succinylcholine to less than 1 hour. Interestingly, the K variant was present in 89% of A variants suggesting that more than one mutation is often present, for example, U/AK. The C5 and E Cynthiana variants destroy succinylcholine at an ultrarapid speed that may provide such

a brief period of paralysis that the child recovers before laryngoscopy is attempted. Management of delayed recovery from succinylcholine includes sedation/anesthesia and ventilation. Blood should be sent for identification of the specific gene defect and a MedicAlert bracelet ordered.

Identification of the specific gene defect depends on the laboratory analysis of pseudocholinesterase activity and gene identification. When benzoylcholine is added to the blood, dibucaine suppresses the degradation of benzoylcholine by normal pseudocholinesterase by more than 71% (hence a dibucaine number of 71 is normal) whereas the degradation by A/A is only suppressed by 20% (hence the dibucaine number is 20). Intermediate inhibition is a dibucaine number of 60. When fluoride is added to blood, it inhibits normal pseudocholinesterase but the atypical variant to a much smaller extent.

**Side Effects.** The salient side effects associated with succinylcholine include arrhythmias (most notably bradycardia), rhabdomyolysis (with hyperkalemia and myoglobinuria), raised intraocular pressure (IOP), fasciculations, and malignant hyperthermia (MH).

Succinylcholine causes bradycardia via acetylcholine-associated activation of the vagal nerves. Sinus bradycardia is the most common arrhythmia, which may progress to transient asystole after a single IV dose of succinylcholine in a child.<sup>126</sup> Bradycardia can be prevented by pretreatment with an anticholinergic such as atropine (10 to 20 µg/kg) or glycopyrrolate (5 to 10 µg/kg).

**Table 43-6** Pseudocholinesterase Variants

Decreased Activity		Increased Activity	
<i>Congenital Causes</i>	<i>Acquired Causes</i>	<i>Congenital Causes</i>	<i>Acquired Causes</i>
Gene defects	Hepatic insufficiency	Gene defect	Thyroid disease
Usual or E <sup>a</sup>	Renal failure	Cynthiana (C <sub>5</sub> ) or Neitlich	Obesity
Atypical or E <sup>a</sup>	Malnutrition		Nephrotic syndrome
Fluoride resistant or E <sup>f</sup>	Severe burns		Cognitively challenged children
Silent gene or E <sup>e</sup>	Chronic infections		
Rare defects	Pregnancy		
H variant	Neonate		
J variant	Plasmapheresis		
K variant	Drug-induced: organophosphates, cyclophosphamide, echothiophate iodide, oral contraceptives, metoclopramide, glucocorticoids, smolol, chlorpromazine		

Rhabdomyolysis may occur when succinylcholine is administered to children with MH or a myopathy.<sup>127,128</sup> The muscle breakdown releases massive concentrations of potassium as well as myoglobin, both resulting in

potentially fatal consequences.

Hyperkalemia may occur in children with myopathies, upper and lower motor neuron disorders, burns, severe sepsis, and chronic immobilization (e.g., drug-induced, trauma-induced) (usually for weeks).<sup>127</sup> There is no evidence that succinylcholine presents additional risks when administered to patients with renal failure or cerebral palsy.<sup>129</sup> Hyperkalemia causes multifocal premature ventricular contractions that may progress to ventricular tachycardia and fibrillation. This occurs because the potassium concentration increases the resting membrane potential such that it approaches the threshold potential, triggering depolarization of myocardial cells. IV calcium (calcium chloride 10 mg/kg) raises the threshold potential, thus restoring the gap between the resting membrane and threshold potentials to prevent arrhythmias.

Succinylcholine increases IOP 7 to 10 mmHg reaching a peak pressure 1 to 2 minutes after IV administration and returns to the baseline in 5 to 7 minutes.<sup>130</sup> This increase may be attenuated by pretreatment with anesthetics, although none completely eliminates the increase in IOP. In the presence of a lacerated globe, this increase in IOP may increase the extrusion of intraocular contents although greater increases in IOP may occur during crying and coughing.<sup>130</sup>

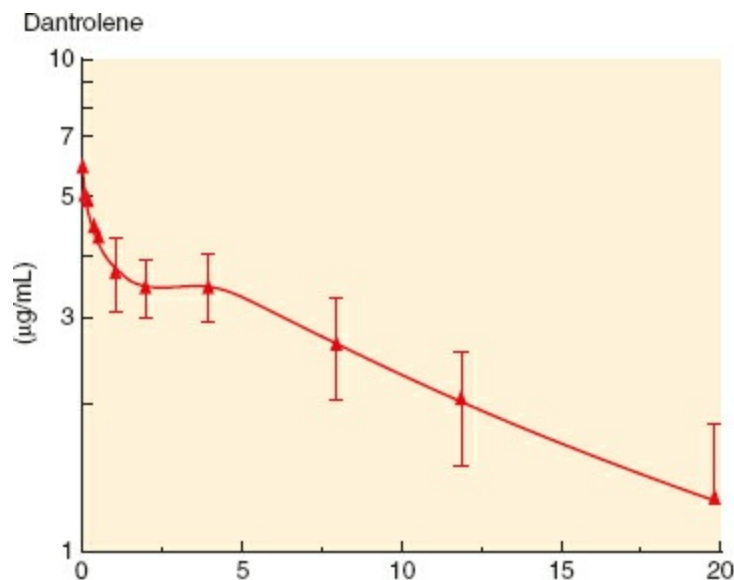

Fasciculations occur immediately after administration of IV succinylcholine. Adolescents with muscular builds are at an increased risk of developing postoperative muscle pain after succinylcholine. To prevent this problem, pretreat with small doses of a nondepolarizing relaxant or simply avoid succinylcholine in this age group. Some assert that fasciculations increase the risk of regurgitation by increasing the abdominal muscle tone. However, the crura of the diaphragm comprise skeletal muscle, also fasciculates, thus preventing any decrease in gastric barrier pressure.

MH is a pharmacogenetic disorder of calcium metabolism in skeletal muscle.<sup>128</sup> The triggers (succinylcholine and/or potent inhalational anesthetics) induce an exaggerated release of intracellular calcium, which causes sustained muscle contractions. These sustained contractions generate heat and muscle breakdown with the release of intracellular potassium, myoglobin, and CPK. The earliest sign of an MH reaction is an increase in end-tidal PCO<sub>2</sub> that is accompanied by an increase in respiratory rate and hemoglobin desaturation. Late signs include increases in core body temperature, disseminated intravascular coagulopathy, and sepsis. Preparation of the anesthetic workstation is discussed later. The definitive treatment for MH is IV dantrolene 2.5 mg/kg, repeated as needed until the reaction abates (Fig. 43-4).<sup>131</sup> (See later and Chapter 24 for further details on MH.)

## Rocuronium

Rocuronium is a steroidal muscle relaxant that is an analogue of vecuronium but differs from the latter by a more rapid onset of action and reduced potency. It is eliminated almost exclusively by the liver; hence liver failure may prolong the duration of action.<sup>132</sup> In contrast, renal failure should have minimal effect on its elimination.

The potency of rocuronium is greatest in infants, least in children, and intermediate in adults. The dose should be adjusted according to the child's age: the ED<sub>95</sub> in infants is 0.25 mg/kg and in children is 0.4 mg/kg.<sup>133,134</sup> In healthy children during sevoflurane anesthesia, 0.3 to 0.4 mg/kg rocuronium provides suitable intubating conditions in 2 to 3 minutes and permits antagonism within 20 minutes. Twice the ED<sub>95</sub> or 0.6 mg/kg IV rocuronium provides relaxation in 1 to 1.5 minutes. Sevoflurane potentiates the effect of rocuronium compared with balanced anesthesia, a pharmacodynamic, not pharmacokinetic effect.<sup>135</sup> The time to 90% recovery of the twitch response after 0.6 mg/kg IV is 46 minutes in children. Recovery after rocuronium in infants is prolonged compared with that in children as a result of the reduced clearance and increased volume of distribution in the former.<sup>134</sup> At 3 to 4 × ED<sub>95</sub>, 0.9 to 1.2 mg/kg IV rocuronium yields similar intubating conditions to succinylcholine within 60 seconds and may be used for rapid sequence induction (RSI), although recovery may be markedly prolonged.<sup>136,137</sup>

**Figure 43-4** Pharmacokinetics of dantrolene in children 2 to 7 years of age. Blood concentrations after 2.4 mg/kg IV dantrolene decreased, leveling off at a therapeutic blood concentration of approximately 3.0 µg/mL between 1 and 4 hours and then decreased after 6.5 hours with an elimination half-life of  $10 \pm 2.6$  hours. (Adapted with permission from Lerman J, McLeod E, Strong HA. Pharmacokinetics of intravenous dantrolene in children. *Anesthesiology*. 1989;70:625–629.)

IM rocuronium (1.8 mg/kg) has been recommended in emergencies when

an IV is not available. However, this dose and route provide poor intubating conditions after 4 minutes and a duration of 80 minutes. The author does not recommend this route and dose of administration.

### *Atracurium*

Atracurium is a benzylisoquinolinium muscle relaxant that undergoes spontaneous degradation in blood primarily by Hofmann elimination yielding the major metabolite, laudanosine, which is devoid of neuromuscular blocking properties.<sup>132</sup> It is comprised of 10 isomers. A typical intubating dose in infants and children is 0.5 mg/kg IV (2 to 3 × ED<sub>95</sub>) with an onset of 2 minutes and duration of 15 to 30 minutes. Complete recovery is usually achieved within 45 to 60 minutes. With its brief half-life, atracurium is suited for use as a continuous infusion in a dose of 6 µg/kg/min during isoflurane anesthesia and 9 µg/kg/min during a balanced IV anesthetic.<sup>138</sup> Neither renal nor hepatic failure affects the duration of action of atracurium. Side effects associated with atracurium include cutaneous erythema, bronchospasm, and wheezing after a rapid large bolus administration; rarely has anaphylaxis been reported.

### *Cis-atracurium*

*Cis-atracurium* is one of the 10 isomers of atracurium that has supplanted atracurium. Its potency is threefold greater than that of atracurium resulting in more specificity for the receptor and fewer side effects such as histamine release.<sup>132</sup> It too is degraded by Hofmann elimination with a typical duration of action of 30 to 50 minutes. Suitable intubating conditions are achieved with 150 µg/kg (3 × ED<sub>95</sub>) by 2 minutes after the dose.<sup>139</sup> Neither renal nor hepatic failure affect the duration of action of *cis-atracurium*. Side effects associated with the administration of *cis-atracurium* are minimal.

### *Neostigmine*

This author strongly recommends antagonizing all neuromuscular blocking agents in infants and children when extubation is planned,<sup>140</sup> provided the time interval from the last dose has not exceeded 2 hours. The train-of-four should be 0.9 or greater before the trachea is extubated.<sup>140</sup> Any child who appears weak, as a “fish out of water,” requires antagonism or a repeat dose of antagonism of the neuromuscular blockade. In order to successfully antagonize the relaxant, vital signs including temperature must be normal.

Neostigmine is an anticholinesterase compound that antagonizes neuromuscular blockade by preventing the degradation of acetylcholine. The acetylcholine competitively displaces the muscle relaxant from the neuromuscular junction. The dose of neostigmine in infants and children is

30% to 40% less than that in adults, or 20 to 40  $\mu\text{g}/\text{kg}$ , which should be administered when at least one twitch is present in the train-of-four. If the recovery of neuromuscular blockade is incomplete, repeat doses of neostigmine may be administered up to 70  $\mu\text{g}/\text{kg}$ . Care must be taken to avoid exceeding 100  $\mu\text{g}/\text{kg}$  as acetylcholine-associated weakness may occur.

Neostigmine should be preceded by an anticholinergic, atropine 20  $\mu\text{g}/\text{kg}$  or glycopyrrolate 10  $\mu\text{g}/\text{kg}$ , to minimize the effect of neostigmine on the nicotinic receptors. Atropine causes a greater increase in heart rate but has a shorter duration of action than glycopyrrolate.

### *Sugammadex*

This  $\gamma$ -cyclodextrin compound is a cylindrical oligosaccharide that uniquely binds rocuronium (and to a lesser extent vecuronium) to eliminate its activity.<sup>141</sup> When administered in the presence of moderate to profound rocuronium-induced neuromuscular blockade, sugammadex restored the twitch response thereby providing a direct intervention for a cannot ventilate, cannot intubate situation. The rocuronium/sugammadex complex is excreted unchanged in the kidney. Sugammadex has been used extensively in Europe but only recently in the United States. In children and adolescents, a single dose of 2 mg/kg or more sugammadex after partial recovery (two twitches of the train-of-four) from rocuronium yielded a train-of-four of 0.9 in approximately 2 minutes.<sup>142</sup> Dose response studies in children have not been forthcoming. In adults, 16 mg/kg can reverse rocuronium 3 minutes after administration for RSI. Most recently, two reports of sugammadex reversal of rocuronium-induced anaphylaxis refractory to vasopressors suggest another possible clinical role for sugammadex.<sup>143</sup>

## **Opioids**

### *Morphine*

Perioperative analgesia is usually accomplished with an intraoperative IV dose of 50 to 100  $\mu\text{g}/\text{kg}$  and postoperative doses of 50  $\mu\text{g}/\text{kg}$  morphine.<sup>144</sup> Perioperative infusions of morphine may also be administered by diluting morphine (1 mg/kg of the child's weight) in 100 mL of a balanced salt solution and infusing at 1 to 4 mL/hr. This provides analgesic blood concentrations of morphine, 10 to 40 ng/mL.<sup>145</sup> Morphine, 33  $\mu\text{g}/\text{kg}$ , may also be administered via the caudal/epidural route with a prolonged duration of action and a small incidence of side effects (vomiting, pruritus).<sup>145</sup> Oral morphine has also been administered, although its bioavailability is 35% due to the first-pass effect.

Side effects after morphine include dose-dependent respiratory depression and incidence of vomiting (particularly at  $>100 \mu\text{g}/\text{kg}$ ). Histamine release

and urticaria at the site of injection are local, nonimmunologic reactions.

### *Fentanyl*

This semi-synthetic opioid is the most widely used intraoperative analgesic in children. This very lipid-soluble opioid, which is bound primarily to  $\alpha_1$ -acid glycoprotein in blood, has a very rapid onset of action, hemodynamic stability, and brief duration of action after a single dose.<sup>146</sup> It may be used via the IV, IM, oral, IN, and caudal/epidural routes. It is 50 to 100 times more potent than morphine, with doses 1 to 3  $\mu\text{g}/\text{kg}$  IV attenuating the sympathetic responses to minor surgical procedures, up to doses of 12 to 50  $\mu\text{g}/\text{kg}$  for neonatal surgery.<sup>146</sup> Fentanyl is infrequently administered IM; oral fentanyl, 10 to 20  $\mu\text{g}/\text{kg}$ , is used in breakthrough cancer pain. IN fentanyl (1 to 2  $\mu\text{g}/\text{kg}$ ) has been used as a premedication and to reduce agitation in children undergoing myringotomy and tube surgery.<sup>109,145</sup> Epidural fentanyl has been administered to children via the epidural space in a dose of 1 to 2  $\mu\text{g}/\text{mL}$  to supplement local anesthetics. There is very little evidence that fentanyl augments the analgesia provided by a lumbar epidural block in a child with an effective local anesthetic concentration (e.g., 0.125% bupivacaine or 0.0625% levobupivacaine)<sup>147</sup>; its addition to these local anesthetics causes pruritus, nausea/vomiting, and urinary retention.

The action of clinical doses of parenteral fentanyl is terminated by redistribution and, secondarily, by clearance in the liver. The initial redistribution is rapid; however, once tissue binding sites become saturated, the elimination half-life of fentanyl increases.<sup>148</sup> Fentanyl is metabolized extensively by CYP450 3A4 to inactive metabolites. The context-sensitive half-life of fentanyl in adults after a brief infusion for 1 hour, 20 minutes, increases dramatically to 4 hours after an 8-hour infusion.<sup>148</sup> Elimination half-life may exceed 20 hours after a prolonged chronic infusion or in some neonates. To offset the increasing context-sensitive half-life with time, the dose of fentanyl must be gradually reduced over time. After a prolonged infusion of fentanyl, it is necessary to slowly taper the dose and monitor for opioid withdrawal.

### *Meperidine*

Meperidine is no longer recommended as an analgesic because of the risk of seizures (from normeperidine) and the accumulation of normeperidine after repeated doses of meperidine. It is currently recommended only for shivering.<sup>145</sup> The dose of meperidine for analgesia is 1 to 2  $\text{mg}/\text{kg}$  and for shivering 25% to 50% of that dose. The elimination half-life of meperidine in children is 3 hours.<sup>145</sup>

### *Remifentanyl*

Remifentanyl is a unique  $\mu$ -receptor opioid that undergoes spontaneous degradation in blood by tissue esterases, with an elimination half-life of approximately 5 minutes that is independent of the duration of infusion.<sup>149</sup> With this brief half-life, remifentanyl is usually administered as a continuous infusion. The context-sensitive half-life (the time to decrease the blood concentration by 50%) of remifentanyl is 3 to 8 minutes. Metabolites of remifentanyl do not effect analgesia.

Remifentanyl is 10- to 60-fold more potent than alfentanil.<sup>149,150</sup> The infusion rate for remifentanyl ranges from 0.05 to 0.25  $\mu\text{g}/\text{kg}/\text{min}$  (although larger doses have been administered), with the dose adjusted according to the presence of concomitant drugs (e.g., inhalational anesthetics). A loading dose (0.1 to 0.2  $\mu\text{g}/\text{kg}$ ) is usually not required as the infusion rapidly establishes an effective target organ concentration and hypotension is possible.

When administered in large doses, remifentanyl may cause hypotension, bradycardia, and chest wall rigidity.<sup>150</sup> Prolonged administration has resulted in tachyphylaxis. Recent evidence suggests that nitrous oxide may attenuate the risk of tachyphylaxis.<sup>151</sup>

### *Hydromorphone*

Hydromorphone (or Dilaudid) is a long-acting opioid analgesic. This  $\mu$ -opioid receptor agonist is 5- to 10-fold more potent than morphine. Bolus dosing is 10 to 20  $\mu\text{g}/\text{kg}$  IV or IM, followed by 1  $\mu\text{g}/\text{kg}/\text{hr}$  IV or epidural continuous infusions.<sup>145,152</sup> Hydromorphone has an elimination half-life of 2.5 hours, similar to that of morphine. Metabolism is extensive (95%) via a single pathway to hydromorphone-3-glucuronide.

### *Codeine*

Codeine has been the mainstay of postoperative analgesia in children for decades. However, it is a prodrug and its analgesic effect depends on its conversion to morphine (10%) and possibly to hydrocodone (11%) via CYP450 2D6.<sup>153,154</sup> Codeine received a blackbox warning from the US FDA for respiratory depression and deaths after tonsillectomy, particularly in children with OSA. This has led to codeine no longer being prescribed for postoperative pain in children in many jurisdictions.

Codeine may be administered IM, PO, and rectal.<sup>145,154</sup> IV codeine is not used as it causes cardiovascular depression and seizures. The dosing range for IM, PO, and rectal routes is similar, 0.5 to 1.5  $\text{mg}/\text{kg}$ . Oral codeine reaches a peak blood level after 1 hour and an elimination half-life of 3 hours. When administered by the IM and rectal routes, the onset of action is more rapid than orally and the elimination half-life is less.

CYP450 2D6 is a noninducible enzyme that increases in activity from

birth, reaching 20% of adult activity by 1 month of age (Fig. 43-1). It is mapped onto chromosome 22. 2D6 metabolizes 25% of the drugs in clinical use. More than 50 polymorphisms of 2D6 have been identified to date resulting in variability in the analgesia conferred from no analgesia (poor metabolizer) to an opioid overdose (an ultrarapid metabolizer), the latter being implicated in postoperative brain damage in one case and death in a second.<sup>155,156</sup> These polymorphisms vary along ethnic lines (e.g., 10% of Caucasians and 30% of Hong Kong Chinese are poor metabolizers whereas 29% of Ethiopians are ultra-extensive metabolizers) resulting in an unpredictable and varied response in children.<sup>157,158</sup> This has prompted some to substitute alternative analgesics postoperatively although few have been investigated in children. Care must be taken to prescribe the appropriate dose based on lean body weight (LBW) and whether the child's opioid receptors have been upregulated as a result of intermittent nocturnal desaturation.<sup>159</sup>

### *Acetaminophen*

This nonsteroidal analgesic/antipyretic has been an effective analgesic for mild to moderate pain in children. Acetaminophen has no anti-inflammatory properties and is also free of platelet-inhibiting properties. Although its mechanism of action is not completely understood, it is believed to act on the peroxidase receptors of prostaglandin H<sub>2</sub> or via *p*-aminophenol.<sup>160</sup>

Oral doses of 10 to 15 mg/kg or rectal doses of 30 to 40 mg/kg yield adequate blood concentrations. Postoperative rectal dosing 20 mg/kg every 6 hours maintains blood concentrations after a rectal loading dose. Absorption after oral administration is rapid (~10 to 15 minutes) whereas after rectal administration it is slow and variable (1 to 2 hours).<sup>161</sup> Rectal suppositories should be lubricated to avoid mucosal tears. With an elimination half-life of 2 to 4 hours after any route, repeat doses may be administered every 4 to 6 hours, while maintaining the maximum 24-hour dose at less than 100 mg/kg confer both analgesia and antipyresis.

The most widely used IV formulations of acetaminophen is paracetamol.<sup>162</sup> An IV dose of 15 mg/kg may be administered every 6 hours.<sup>162,163</sup> Careful attention must be paid to the dosing as three overdoses involved 10- and 20-fold overdoses have been reported in infants, with one requiring treatment with IV *N*-acetylcysteine.<sup>164,165</sup> Furthermore, excessive dosing has occurred when clinicians failed to note previously administered doses on the electronic record. Acetaminophen dosing must be highlighted on the electronic record.

Paracetamol is metabolized via several pathways: the majority is eliminated by conjugation to either the glucuronide (55%) or sulfate (25%), less than 10% is oxidized (by CYP2E1, 3A4, and 2 other isozymes) to *N*-acetyl-*p*-benzoquinone (NAPQI) (toxic metabolite), and 1% to 4% is excreted unchanged by the kidney.

## *Ketorolac*

Ketorolac is a parenteral nonsteroidal anti-inflammatory drug (NSAID) available for use in children. It possesses anti-inflammatory and analgesic properties for mild to moderate perioperative pain<sup>166</sup> and, like other NSAIDs, it also inhibits platelet adhesion by reducing the synthesis of thromboxane.

Ketorolac may be administered in doses of 0.5 to 2 mg/kg, with 0.5 mg/kg being the common dose administered to children.<sup>167,168</sup> The elimination half-life in infants and children is quite variable, 2 to 6 hours, and varies with whether the racemate (standard preparation) or stereoisomers are administered.<sup>167,168</sup>

The side effects of ketorolac have raised concerns limiting its use in the perioperative period. Some surgeons avoid ketorolac during tonsillectomy and adenoidectomy because of the risk of bleeding from COX-2 inhibition of platelet aggregation. Current evidence indicates that ketorolac increases the incidence of bleeding after adenotonsillectomy in adults but not children.<sup>169</sup> There is evidence that ketorolac inhibits bone healing in animals, but not in humans; a decision regarding its use during orthopedic surgery depends on the surgeon. All NSAIDs may trigger severe bronchoconstriction in asthmatics, and ketorolac is relatively contraindicated in this population, although some prescribe ketorolac in children with mild asthma.<sup>170</sup> Rarely, idiosyncratic renal failure has been reported after a single dose, which in most instances resolves spontaneously.

## *Diclofenac*

This NSAID is also a cyclooxygenase inhibitor but with a 20-fold greater affinity for COX-2 rather than COX-1 receptors. Diclofenac may be administered IV, IM, PO, and rectally although in the United States only oral formulation is available. It is a potent analgesic, almost twice as effective for acute pain than acetaminophen during and after surgery.<sup>171</sup> The IV dose in children is 0.3 mg/kg and the oral dose is 1 mg/kg.<sup>172,173</sup> Its bioavailability after rectal administration is twice that of the oral route, hence the rectal dose is half the oral dose, 0.5 mg/kg. It is 99% bound to albumin, eliminated by CYP2C9, 3A4, and 3A5 phase 1 isozymes. Side effects are infrequent, 0.24% of children, with postoperative bleeding being the most frequent. Because of its limited affinity for COX-1 receptors, it is not a potent platelet inhibitor and causes far less risk of bleeding than the other NSAIDs. As with other NSAIDs, it is relatively contraindicated in children with asthma.

## *Ibuprofen*

Ibuprofen is a widely used analgesic, antipyretic, and anti-inflammatory agent in the perioperative period in children. However, its use has been limited as it

is only available in the oral form. A dose of 10 to 15 mg/kg oral q4–6h is widely prescribed for mild to moderate pain postoperatively, although some limit its use when postoperative bleeding may occur.

Recently, an IV formulation has been introduced and is undergoing clinical trials for use in children in the perioperative period.<sup>174</sup> A dose of 10 mg/kg up to max of 400 mg IV q4-6h or a maximum of 2400 mg/d is recommended.

## Sedatives

### *Midazolam*

This benzodiazepine is the most widely used anxiolytic in children in North America. It is water soluble, with a rapid onset of action when administered orally and a brief elimination half-life.<sup>175</sup> Unlike diazepam, it does not cause pain upon parenteral administration. Midazolam may be administered orally, sublingually, nasally, IV, IM, and rectally.<sup>11,175</sup> The oral and nasal doses are discussed under Anxiety, later. The dose for sublingual midazolam is the same dose as for the nasal route, 0.2 to 0.3 mg/kg.<sup>11</sup> Empirical IV dosing of 0.1 to 0.2 mg/kg should be administered, with larger doses being required in adolescence. IM midazolam is infrequently used in children because of the risk of sterile abscess and pain. Rectal dose of midazolam is 0.5 mg/kg, although this route is limited to children under 5 years of age.<sup>11</sup>

Midazolam is metabolized by CYP450 3A4 enzyme system; this enzyme reaches 30% to 40% of adult levels by 1 month and adult levels by 1 year (Fig. 43-1).<sup>176</sup> Approximately 50% of glucuronidated metabolite of midazolam is excreted via the kidneys.<sup>176</sup> Metabolism of midazolam is affected by renal and hepatic failures as well as enzyme systems that interfere with 3A4. The effects of midazolam may be antagonized by IV flumazenil in a dose of 0.01 mg/kg, which may be repeated to a maximum dose of 0.2 mg.

### *Dexmedetomidine*

Dexmedetomidine is an  $\alpha_2$ -agonist sedative whose relative affinity for  $\alpha_2:\alpha_1$  receptors is eightfold greater than clonidine. It may be administered via the oral, nasal, IV, IM, and rectal routes.<sup>177</sup>

The oral dose, which requires 30 to 60 minutes to provide sedation, is 2 to 4  $\mu\text{g}/\text{kg}$ , with increasing doses being more effective but with delayed recovery.<sup>177</sup> The IN dose is 1 to 2  $\mu\text{g}/\text{kg}$  with 1  $\mu\text{g}/\text{kg}$  sedating  $\sim 60\%$  of children within 1 hour. The dose of IV dexmedetomidine may include a loading dose of 1  $\mu\text{g}/\text{kg}$  infused over 10 minutes and followed by an IV infusion of 0.3 to 0.7  $\mu\text{g}/\text{kg}/\text{hr}$ . *This infusion rate must be carefully transcribed because unlike other drugs, the infusion rate is in  $\mu\text{g}/\text{kg}/\text{hr}$ , not  $\mu\text{g}/\text{kg}/\text{min}$ .* When a loading dose is administered before the infusion, the risk of hypotension in the peri-induction period increases.

The pharmacokinetics of dexmedetomidine show a rapid early redistribution phase (half-life of 7 minutes) but a slow terminal elimination half-life, approximately 2 hours in children.<sup>178,179</sup> It is metabolized in the liver primarily via uridine glucuronyltransferase to inactive metabolites.

Unlike other sedative/anxiolytics, dexmedetomidine exerts its clinical effects via  $\alpha_2$  receptors with sedation in the locus coeruleus, hemodynamic manifestations via direct and indirect action on the sympathetic nervous system, and a host of miscellaneous side effects.<sup>177</sup> The unique feature of this sedative/anxiolytic is the *absence* of substantial respiratory depression.<sup>180</sup>

Dexmedetomidine is not a complete anesthetic. It decreases the MAC of inhalational anesthetics approximately 30%, provides suitable sedation for radiologic investigations (although a dose of 0.1 mg/kg IV midazolam is required to prevent movement unless large doses of dexmedetomidine are used),<sup>89,181</sup> facilitates awake fiberoptic intubation and awake craniotomy, provides sedation that is closest to natural sleep, provides analgesia, reduces emergence delirium (ED),<sup>177</sup> and facilitates motor- and sensory-evoked monitoring for spine surgery.<sup>182</sup>

Side effects of dexmedetomidine relate primarily to its hemodynamic effects. Bradycardia has been reported after larger infusion rates (up to 2 to 3  $\mu\text{g}/\text{kg}/\text{hr}$ ) and in younger age infants, with an incidence as great as 16%.<sup>181</sup> Do not treat the bradycardia (heart rates may reach 30 beats/min) with glycopyrrolate as profound hypertension may occur.<sup>183</sup>

Rapid administration of dexmedetomidine has been reported to cause transient hypertension, although this is uncommon in children. Hypotension (>20% decrease from baseline) has occurred during dexmedetomidine infusions.<sup>181</sup> The frequency of hypotension increases with an increasing dose and younger age: The greatest incidence occurs in infants, 8%. IV fluid loading may attenuate the hypotension but awaits additional studies.

## Preoperative Assessment

### Fasting Guidelines

The American Society of Anesthesiologists framed the fasting guidelines for infants and children in 2006.<sup>184</sup> The guidelines, which were based on a consensus panel and a review of the literature, concluded that the fasting intervals before elective anesthesia could be summarized as 2, 4, 6, and 8 hours as delineated in [Table 43-7](#).<sup>184</sup> These guidelines are not age-adjusted. Gastric emptying times after breast milk and formula have only been evaluated in infants<sup>185</sup>; there are no data for comparable emptying times in children ( $\geq 1$  year of age).

The child who presents chewing gum must expectorate the gum or surgery

will be cancelled as aspirated gum will be very difficult to extricate from the airway. Gastric fluid volume after chewing sugar or sugarless gum is doubled, with approximately 50% showing a gastric fluid volume more than 0.8 mL/kg, but without a substantive change in the gastric fluid pH.<sup>186</sup> Hence, the gastric fluid characteristics in the child who is chewing gum are similar to those in the fasted child. Thus, induction of anesthesia does not need to be delayed in the child who has been chewing gum.

Obesity does not increase the risk of pneumonitis should aspiration occur.<sup>187</sup> Gastric fluid volume is increased slightly, but pH is unchanged. Thus, the risk of pneumonitis is unchanged in these children.

**Table 43-7** Fasting Guidelines for Children Requiring Elective Anesthesia<sup>184</sup>

Clear fluids <sup>a</sup>	2 h
Breast milk	4 h
Infant formula and cow's milk	6 h
Solids	8 h

<sup>a</sup>Includes clear tea. If milk is added, we recommend a 6-hour fast. Gum should be expectorated, fasting need not be prolonged.

The risk of regurgitation and aspiration in children who present for emergency surgery is far more difficult to assess. Several factors relate to this risk including the severity and nature of the trauma, existing medical conditions, drugs that were administered, and the timing and nature of the foods ingested. The only evidence upon which to assess the risk of a full stomach relates to the interval between the last food ingested and the trauma or injury.<sup>188</sup> Because gastroparesis and intestinal stasis occur after acute pain, an inflammatory response, and opioid drugs, it is likely that gastrointestinal peristalsis stops after a trauma. There is no evidence in children that administration of a prokinetic drug empties the stomach after trauma. Auscultation of bowel sounds in the abdomen does not ensure gastric emptying, although passing gas does imply peristalsis of the small and large bowels is present but does not ensure return of gastric motility. We consider children who ingested solid foods within 8 hours of a trauma to be at risk for regurgitation and aspiration and take appropriate precautions for managing the airway.

Certain medical conditions delay gastric emptying. Although diabetes mellitus delays gastric emptying, this may require years before the gastroparesis develops. Recent evidence suggests that gastroparesis may be multifactorial.<sup>189,190</sup> Indeed, hyperglycemia alone can delay gastric emptying in both diabetics and nondiabetics.

## Laboratory Testing

Preoperative laboratory testing is infrequently ordered in healthy children without a pre-existing medical condition. A preoperative hemoglobin is indicated in those who are at risk for massive bleeding, those with pre-existing anemia in whom bleeding is highly probable, those with chronic nutritional deficiency, and those with sickle cell disease (see later).

A preoperative pregnancy test is required before anesthesia and sedation in most children of childbearing years in most jurisdictions. The reason for this test is the risk that some drugs that are administered in the perioperative period may cause a miscarriage or, less likely, teratogenicity of an unborn fetus. The incidence of unexpected and unknown pregnancies is approximately 0.3%.<sup>191</sup> Evidence suggests that history alone does not reliably predict pregnancy. Two pregnancy tests are available: urine and blood. The former test yields more rapid results, is cheaper but has a false-negative rate early after conception. Both tests have a known false-positive rate. There is debate regarding the threshold age to begin pregnancy testing. Many institutions and states require preoperative pregnancy testing in females who have reached menarche; some require testing in all females who are older than a specific age. If the pregnancy test is positive and the surgery is elective, the results must be conveyed to the patient. Due consideration should be given to the risk that anesthesia and surgery might pose to the unborn fetus if surgery proceeds. If, however, the surgery is emergent, then the risk benefit ratio of proceeding must be carefully assessed.

## **Medical Conditions**

### **5 Upper Respiratory Tract Infection**

Approximately 65% of children with upper respiratory tract infections (URTIs) have viruses as the cause of their infection; the remaining 34% have bacterial infections. Children who have had a recent URTI should not undergo elective anesthesia for 4 weeks after the infection to ensure resolution of the pathologic effects in the small airways. Because young children have 6 to 7 URTIs per year, most clinicians proceed with anesthesia 2 to 4 weeks after the original infection.<sup>192</sup>

When children present for elective surgery with a URTI, the author recommends canceling the anesthetic if any one of the four criteria listed in [Table 43-8](#) is present.<sup>193</sup> The presence of each of these increases the risk of perioperative airway events. Additional factors that increase the risk of adverse airway events include cigarette smoking in the house, atopy, asthma, prematurity, young age, and secretions.<sup>192,194</sup> If an infant (<1 year of age) presents for surgery with a URTI, the chest should be examined very carefully and a low threshold maintained for cancellation as perioperative respiratory

complications are substantive in this age group<sup>195</sup> including respiratory syncytial virus that may rapidly lead to pneumonia and a protracted recovery possibly involving prolonged tracheal intubation in the intensive care unit.<sup>196</sup>

**Table 43-8** Criteria to Cancel Anesthesia with an Upper Respiratory Tract Infection<sup>194</sup>

- Fever >38.5°C
- Altered behavior (not playing as usual) and habits (not feeding as usual)
- Purulent, productive discharge from the upper airway
- Lower respiratory tract signs (wheezing, rhonchi) that do not clear with coughing

Children who present with clear rhinorrhea, whether due to a mild URTI or allergic rhinitis, should be treated with 1 to 2 drops of oxymetazoline or neosynephrine (0.25%) nose drops per nostril to dry up the nasopharyngeal secretions during anesthesia. Care must be taken to use a dilute solution of neosynephrine, as concentrated solutions may cause a hypertensive crisis. We prefer to manage these children with a face mask if possible in order to minimize the risk of triggering airway reflex responses. However, if the airway must be manipulated, a supraglottic airway is less likely to trigger airway reflex responses than a tracheal tube.

## Asthma

Up to 20% of children have asthma or an asthmatic history, but many fewer present with severe asthma that may complicate anesthesia.<sup>197</sup>

Children with a history of asthma should have their pulmonary condition optimized before surgery and be stable from their chest perspective, without a recent exacerbation or recent hospitalization. In the preoperative assessment, the age of onset of asthma, number and date of the most recent hospital admissions for asthma, treatment ( $\beta_2$ -agonists or steroids by inhalation), and current state of asthma should be recorded. Most children with asthma have never been admitted to hospital because of their asthma. However, if they have, the asthma should be considered severe. If oral steroids have been prescribed recently for an acute exacerbation of asthma, careful preoperative examination of the chest must be performed to ensure that there is no lingering reactive airway component. On the morning of the surgery, the child's lungs should be examined to check for wheezing. If wheezing is present, the child should be instructed to cough deeply to clear any airway secretions present, and bronchodilator therapy should be initiated. Preoperative bronchodilator therapy should be administered to children with mild to moderate asthma even if they are not wheezing, as this reduces airway resistance by approximately 25% during sevoflurane anesthesia and

tracheal intubation.<sup>198</sup> If wheezing persists, the child should be referred to their pulmonologist for reassessment and the anesthetic deferred.

Preoperative bronchodilator therapy should be administered to children who are wheezing and present for emergency or urgent nonairway surgery. If tracheal intubation can be avoided, a face mask or LMA should be used. Equipment should be prepared to administer intraoperative bronchodilator therapy should the need arise.

## **6 Obstructive Sleep Apnea**

OSA is the most serious form of sleep-disordered breathing in children.<sup>199</sup> Children have obstructed airways during sleep that are associated commonly with hypercapnia and intermittent hypoxia. The gold standard for the diagnosis is a polysomnogram, although many children present for surgery with a diagnosis of OSA but without a polysomnogram. In these cases, the diagnosis is made “clinically” by the presence of loud snoring, witnessed apneas, nocturnal enuresis, attention deficit disorder and behavioral problems, and inability to concentrate in school or poor school performance. OSA occurs equally in boys and girls and in asthenic and obese children. Daytime somnolence is not a common feature in children with OSA.

Two important decisions must be made when planning to anesthetize a child with OSA: (1) whether the child requires admission and overnight monitoring postoperatively<sup>159</sup> and (2) whether they are at risk for increased opioid sensitivity, that is those whose minimum nocturnal SaO<sub>2</sub> is less than 85%.<sup>200,201</sup> Although children with OSA may be premedicated with very small risk, those with persistent minimum nocturnal SaO<sub>2</sub> less than 85% are at increased risk for perioperative desaturation and airway events when the usual doses of opioids are administered. Alternative analgesic strategies including local anesthetic, NSAID agents, ketamine, and  $\alpha_2$ -agonists should be considered.<sup>202</sup>

## **Ex-premature Infants**

Infants who were born prematurely (<37 weeks gestational age) and are under 60 weeks postconceptional age (defined as the sum of the gestational and postnatal ages) require 12 to 24 hours of postanesthesia monitoring for apnea and hemoglobin oxygen desaturation, irrespective of the type of surgery (see [Chapter 42](#)).<sup>203</sup> Factors that increase the risk of perioperative apnea in ex-premature infants include age (<60 weeks postconceptual age), anemia (<12 g% Hb), and secondary diagnoses (e.g., intraventricular hemorrhage).<sup>203,204</sup> Opioids are best avoided in these infants; local anesthetic blocks are preferred. Caffeine 10 mg/kg IV may be administered intraoperatively to reduce the frequency of perioperative apneas, but it will

not completely eliminate the risk of apnea.<sup>205</sup> Once the infant has been 12 hours apnea-free, he/she may be discharged home.

In contrast to general anesthesia, regional anesthesia does not increase the risk of perioperative apnea and does not require perioperative monitoring, unless the infant also received sedation, has multisystem disease, or has a history of perioperative apneas.<sup>206</sup> Spinal or caudal anesthesia will provide sufficient anesthesia to perform hernia surgery, the most common surgery in ex-premature infants. If the parents have an apnea monitor at home and have been trained to manage apnea, the child may be discharged home in the parents' care.

## **Malignant Hyperthermia**

Most children who present with an MH diagnosis are offspring of a blood relative with an MH reaction or positive muscle biopsy.<sup>128</sup> The first task in such a case is to verify, as best as possible, the credibility of the past MH reaction from history or records. These children should be scheduled as the first case of the day to minimize their exposure to inhaled anesthetics in both the operating room and the postanesthetic care unit (PACU). If the child is anxious, he/she should be premedicated with oral midazolam (see later) in a dose appropriate for the child's age.

To prepare the AWS for an MH-susceptible child, either a designated inhaled anesthetic-free AWS should be used or a contaminated AWS should be flushed to reduce the anesthetic concentration to less than 10 ppm. In the latter situation, after removing the vaporizers from the AWS, the anesthetic breathing circuit and carbon dioxide canisters should be replaced with new equipment. The fresh gas flow should be set to 10 L/min oxygen/air mixture while the ventilator ventilates an artificial lung or reservoir bag to reduce the concentration of anesthetics in the machine to 10 ppm or less, considered to be the anesthetic threshold to trigger MH reactions. The time required to achieve 10 ppm or less varies amongst the current AWSs (Table 43-9), although there is no way of verifying that the threshold gas concentration was achieved by flushing a particular AWS.<sup>207,208</sup> Some recommend replacing components of the AWS to expedite the washout process whereas others recommend using charcoal absorbent in the inspiratory limb of the breathing circuit.<sup>208</sup> Once the breathing circuit has been flushed, the fresh gas flow should NOT be reduced to less than the flow rate used during flushing (if a charcoal filter is not used), lest a rebound in the anesthetic concentration occurs.<sup>208</sup> Interestingly, MH reactions have not been reported after reducing the fresh gas flow in a flushed AWS.

A trigger-free anesthetic includes propofol, opioids, benzodiazepines, nondepolarizing muscle relaxants, nitrous oxide, and regional anesthesia.<sup>128</sup>

Of the standard monitors, end-tidal CO<sub>2</sub> (the earliest indicator of an MH reaction) and temperature (preferably axillary temperature because it will reflect temperature in the largest muscle bulk in the chest) are essential. IV dantrolene should be available in the facility in sufficient quantity to treat a reaction should it occur (2.4 mg/kg IV as an initial dose, and repeated until the reaction abates). The initial dose should maintain blood concentrations of dantrolene (>3 µg/mL) for 6 hours, after which its elimination half-life is 10 hours (Fig. 43-4).<sup>131</sup>

Ryanodex is a new formulation of dantrolene, which contains 250 mg of dantrolene per vial, only 125 mg of mannitol, and requires only 5 mL of sterile water for dissolution. This is sufficient dantrolene in a single vial for a loading dose in a 100 kg patient, far more dantrolene than is needed to treat the initial reaction in a child. If dantrolene is administered, a urinary catheter may be indicated depending on the dantrolene formulation used.

There is a host of additional strategies that may be used to stabilize the child including cooling strategies, and antiarrhythmics. Refer to [Chapter 24](#) for more on MH.<sup>128</sup>

**Table 43-9** Washout Times for Inhalational Anesthetics from Current Anesthesia Workstations

Ohmeda Machines (min)		Other Machines (min)	
Modulus 1	5–15	Narkomed GS	20
Excel 210	7	Drager Primus	70
AS/3	30	Drager Fabius GS	104
Aestiva (sevo)	22	Kion	>25
Aisys (sevo)	25		

Data from Kim TW, Nemergut ME. Preparation of modern anesthesia workstations for malignant hyperthermia-susceptible patients; a review of past and present practice. *Anesthesiology*. 2011;114:205–212; and Sabouri S, Lerman J, Heard C. Effects of fresh gas flow, tidal volume, and charcoal filters on the washout of sevoflurane from the Datex Ohmeda® (GE) Aisys®, Aestiva®/5, and Excel 210 SE Anesthesia Workstations. *Can J Anesth* 2014;61,935–42.

Children who are MH susceptible may undergo surgery as outpatients provided an MH reaction does not occur and the parents receive detailed instructions regarding how to monitor for possible MH reactions after discharge, as well as who to call and where to go if such a reaction occurs. Discharge times after a trigger-free anesthetic in an MH susceptible child may be similar to that after any other child undergoing similar elective surgery provided signs of an MH reaction do not occur.

## Myopathies

The anesthetic for children with common myopathies, including Duchenne

muscular dystrophy (DMD), Becker muscular dystrophy, and Emery–Dreifuss syndrome, should avoid drugs that are known to disrupt skeletal muscle membranes in children under 8 years of age and excessive cardiac depressants in children 10 years or older with cardiomyopathy.<sup>128</sup> DMD is an X-linked recessive gene in which the underlying defect is the lack of dystrophin (<3% of normal) in skeletal and cardiac muscles. The onset of the disease is 2 to 6 years of age. Becker dystrophy is a milder form of the disease with an onset in the second decade of life. Emery–Dreifuss syndrome is also a milder form of the disease often presenting with cardiac conduction defects, with syncope as the presenting finding.

The dystrophin protein complex is essential for the stability of the cytoskeleton of muscles. Muscle contractions, whether natural or drug induced, may tear the muscle membrane and release intracellular contents including high concentrations of potassium, myoglobin, and CPK. The administration of an inhalational anesthetic (halothane > sevoflurane > isoflurane) as well as succinylcholine may cause skeletal muscle contractions, damaging membranes and releasing intracellular contents.<sup>209</sup> In DMD, most muscle degradation occurs before the age of 10 years during which time this author would prefer propofol.<sup>128</sup> However, by adolescence muscle wasting abates and the predominant anesthetic concern is a progressive cardiomyopathy, which may be managed with careful titration by any anesthetic. In the case of Emery–Dreifuss, heart block may be a complicating finding. Hence, preoperative echocardiogram and electrocardiogram are warranted before anesthetizing adolescents with DMD or Emery–Dreifuss syndrome.

Mitochondrial myopathies are a complex group of disorders that result from defects in the protein complexes of the respiratory chain in mitochondria.<sup>128,210</sup> The protein complexes in the chain are under bigenomic control: 85% arise from nuclear DNA and 15% from mitochondrial DNA. In children, most mitochondrial myopathies result from defects in the nuclear DNA. The distribution of defective DNA in tissues in utero determines the spectrum of the disease.<sup>128</sup> Children with a history of lactic acidosis during infancy should be fasted for brief periods, not receive a lactate-containing solution, and receive an infusion of glucose intraoperatively. Both IV and inhalational anesthetics have been administered to children with mitochondrial myopathies without untoward events.<sup>210</sup>

## **Sickle Cell Disease**

Sickle cell disease (SCD) or sickle cell anemia occurs primarily in children of sub-Saharan descent, with a frequency of sickle cell trait in African Americans of 8% and a form of SCD of 1:600.<sup>211</sup> A point genetic mutation results in the

replacement of the Hb AA (where A is the normal hemoglobin) with Hb SS (S is the sickle hemoglobin) in every red blood cell. Thus, 100% of the cells in children with Hb SS are at risk for sickling; these children chronically have low hemoglobin concentrations (6 to 8 g%), may have had acute vaso-occlusive crises, and may have received multiple red cell transfusions in the past. Vaso-occlusive crises may involve a number of areas including bone, chest, and brain. Some children suffer from repeated vaso-occlusive crises whereas others never experience them. These crises are not related to hypoxia, hypovolemia, or hypothermia, but rather to a systemic inflammatory response, the nature of which remains unclear. Evidence suggests that those with SCD and vaso-occlusive crises have markers of a systemic inflammatory response to the disease that upregulates endogenous factors, including an adhesive factor that traps sickle red cells in arterioles and precipitates occlusive crises.<sup>212</sup> Whether the traditional factors of hypoxia, hypovolemia, and hypothermia exacerbate the initial process or compound the underlying inflammatory process has not been clearly established.

Two other forms of SCD, Hb SC and Hb SD, occur much less frequently than Hb SS and have an equal risk of sickling as Hb SS but have hemoglobin concentrations that are closer to normal values, approximately 10 to 11 g%. These children should be managed in a manner similar to those with Hb SS disease.<sup>211</sup>

Sickle cell may also present in a heterozygote form known as sickle trait, Hb AS. This disorder presents few problems during routine general and regional anesthesia and surgery provided extreme conditions, such as hypothermia and cardiopulmonary bypass, are not employed. Children with Hb AS have normal hemoglobin concentrations.

Preoperatively, a history of the frequency, severity, and precipitating triggers of sickle and vaso-occlusive crises in the child should be elicited. Consultation with the treating hematologist should provide insight into the current local strategies for managing this patient. However, if the child's sickle status has not been clearly established, a sickledex test may be used to diagnose SCD in infants above 6 months of age and in children. This test can be performed rapidly, inexpensively, and reliably. The sickledex test is unreliable in infants under 6 months of age because Hb F interferes with the sickling process and renders the test nonconfirmatory. Infants under 6 months of age rarely sickle because of the presence of Hb F, which gradually wanes in concentration beyond 3 months of age. If the test is negative, the child may still have sickle trait. If the test is positive or if the child is suspected of having sickle hemoglobin from history, then a hemoglobin electrophoresis should be performed to identify the particular hemoglobinopathy that is present. The definitive diagnostic test for SCD is the hemoglobin electrophoresis or high-performance liquid chromatography.

To attenuate the risk of a sickle cell crisis in children with SCD in the perioperative period, many hematologists transfuse the children with packed red cells to a total hemoglobin of 10 g%.<sup>213</sup> Others believe that both prophylactic blood transfusions and the need for transfusions in all children undergoing *minor* surgery are without merit.<sup>214</sup> The disadvantages of frequent transfusions in children who are at risk for sickle crises include sensitizing the recipient to minor antibodies (i.e., Kell and Duffy), iron overload, and transfusion reactions. It is important to consult local hematologists regarding the institutional management of children with SCD before the day of surgery to avoid surgical delays and document that discussion and management plan preoperatively with the parents and in the patient record. Optimal management of these children includes maintaining neutral thermoregulation and adequate hydration and oxygenation throughout the perioperative period.

### **Anterior Mediastinal Mass**

Children with AMM require general anesthesia and/or sedation for a tissue (lymph node) biopsy, CT scan or MRI for diagnosis, or indwelling central line for chemotherapy.<sup>215</sup> Children with these tumors present a significant risk for anesthesia, because cardiac arrest has been reported in the past. Understanding the pathophysiology of the disease enables the clinician to anticipate complications and prepare the anesthetic to avoid them.

Four tissues can be found in AMMs in children: lymphomas, teratomas, thymomas, and thyroid.<sup>215</sup> The most rapidly growing tumor in the anterior mediastinum is the lymphoblastic T cell lymphoma, a non-Hodgkin's lymphoma, which has a doubling time of only 12 to 24 hours. These children may present with minor findings (e.g., night sweats) that rapidly progress over 1 to 2 days to life-threatening problems (e.g., orthopnea, superior vena cava syndrome). In children, anesthesia is usually required to delimit the extent of and tumor effects on mediastinal structures in radiology as well as for tissue biopsy and chronic chemotherapy access in the operating room.

The decision to proceed with local, regional, or general anesthesia depends on the age and level of cooperation of the child, the extent of mediastinal organ compromise, and the accessibility of the node or tumor being biopsied. A multidisciplinary team that includes the surgeon, anesthesiologist, and oncologist should review all radiologic and preoperative data before embarking on the surgery.

Older children often can tolerate the surgery under local anesthesia and sedation. Younger children and those whose tumor severely compromises the airway and/or pulmonary artery may require general anesthesia. In the latter conditions, attempts to shrink the tumor using a 12- to 24-hour course of IV

steroids or a round of radiation should be considered to reduce the perioperative risk of cardiorespiratory complications. However, these alternatives should not be used without first a multidisciplinary discussion with the oncologists<sup>216</sup> because there is a risk of widespread tumor necrosis that may both render the diagnosis of the cell type difficult and/or induce tumor lysis syndrome.<sup>217</sup>

For most children who require a radiologic investigation, tumor biopsy, or chemotherapy access, general anesthesia with spontaneous respiration is preferred. If the child cannot lie flat, anesthesia can be induced and the trachea intubated with the child positioned in the left lateral decubitus or less desirably, in the sitting position. The trachea should be intubated at induction of anesthesia to ensure a patent airway should it become necessary to turn the child prone to reverse circulatory collapse. Tracheal intubation is performed without muscle relaxation to preserve spontaneous respiration. Spontaneous respiration best preserves the negative intrathoracic pressure gradient to suspend the tumor above the mediastinal structures and avoid pressure on the pulmonary artery and right atrium as well as the tracheobronchial tree. It is important to remember that the capnogram may be a very useful monitor to confirm the adequacy of the pulmonary circulation (and cardiac output); the sudden loss of or reduction in the capnogram may herald compression of the pulmonary artery before systemic cardiovascular sequelae occur.

### **Subacute Endocarditis (SBE) Prophylaxis**

In 2007, the American Heart Association significantly revised the indications for SBE prophylaxis.<sup>218</sup> The new recommendations were crafted for dental procedures and adopted by the American Dental Association. The American Heart Association no longer recommends SBE prophylaxis for children undergoing gastrointestinal, urologic, and genitourinary surgeries, although many specialists in these areas continue to request SBE prophylaxis. Accordingly, it is incumbent upon the anesthesiologist to inquire of the specific specialist whether SBE prophylaxis should be administered.

For dental procedures, the indications for SBE prophylaxis are listed in [Table 43-10](#).<sup>218</sup> The antibiotic regimen for SBE prophylaxis has not changed since previously published.

**Table 43-10** Subacute Bacterial Endocarditis Prophylaxis Recommendations by American Heart Association<sup>218</sup>

1. Prosthetic cardiac valve or material used to repair the cardiac valve
2. Previous infectious endocarditis
3. Congenital heart disease:
  - a. Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits
  - b. Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 mos after the procedure
  - c. Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibits endothelialization)
4. Cardiac transplantation recipients who develop cardiac valvulopathy

## Obesity

Obesity in children is an epidemic worldwide. In children, definitions are based on growth curves, not BMI, because height and weight change with age.<sup>219</sup> The definitions in children are as follows: Overweight is a BMI above the 85th percentile, obesity is a BMI above the 95th percentile, and super (morbid) obesity is a BMI above the 99th percentile for age and sex where BMI is defined as  $\text{weight (kg)}/[\text{height (cm)}/100]^2$ . In order to refine drug dosing in obese children, additional scalars should be defined. First, an easy, quick, and simple approach to estimate the IBW based on a child's age is

For children < 8 years:  $\text{Wt (kg)} = 2 \times \text{Age (year)} + 9$

For children  $\geq 8$  years:  $\text{Wt (kg)} = 3 \times \text{Age (year)}$

Second, LBW, which accounts for the excess body muscle and bone masses that results from carrying the excess body fat is estimated to be  $\text{IBW} + 1/3(\text{TBW} - \text{IBW})$ .

Ninety-five percent of obesity is attributable to environmental and lifestyle factors. Fewer than 5% of cases of obesity are attributable to diseases and genes such as Prader–Willi syndrome (Laurence–Moon–Biedl syndrome), inborn errors of metabolism, Cushing disease, and immobility (DMD). The underlying mechanisms for these disorders include leptin mutations (receptor and prohormone convertase 1), proopiomelanocortin mutation, and MCR4 (melanocortin receptor).

Thirty percent of overweight children have restrictive pulmonary pattern results from body fat encasing the pliable chest with decreased chest wall compliance, FRC, and vital capacity. The increased work of breathing compounds the reduced lung volumes as the closing volume approaches the

tidal volume and V/Q mismatch occurs. Nocturnal hypoxemia from the above factors combined with large tonsils (see later) sets the stage for the development of pulmonary hypertension and right heart failure. Sleep-disordered breathing occurs in 17% (up to 33% if BMI >150%) of obese children.

Cardiovascular effects of obesity include systemic hypertension, left ventricular hypertrophy, and premature atherosclerosis. Intermittent hypoxia during sleep apnea may lead to pulmonary hypertension. Both blood volume and cardiac output are increased.

**Table 43-11** Drug Dosing for Obese Children

Drug	Induction Dose Based on	Maintenance Dose Based on
Thiopental	LBW	
Propofol	LBW	TBW
Synthetic opioids (fentanyl, alfentanil, and sufentanil)	TBW	LBW
Morphine	IBW	IBW
Remifentanyl	LBW	LBW
Nondepolarizing neuromuscular blockers	IBW	IBW
Succinylcholine	TBW	
Sugammadex	TBW	

TBW, total body weight; LBW, lean body weight; IBW, ideal body weight.

Insulin resistance and metabolic syndrome are present in 40% of moderately obese children and 50% of severely obese adolescents. Increased abdominal weight predisposes to gastroesophageal reflux, which occurs in approximately 20% of children with severe obesity. Gastric emptying rates and the risk of pneumonitis from aspiration (based on gastric fluid pH and volume) in obese children do not differ from those in normal children. NPO times are the same in obese and nonobese children. Glomerular filtration rate is increased. Fatty infiltration of the liver leads to nonalcoholic fatty liver disease, which leads to abnormal liver function tests and possibly hepatic fibrosis.

Drug dosing in obese children is complex, varying with several factors including lipid solubility, volume of distribution, and the route of elimination, hepatic or renal.<sup>219</sup> The drug dosing for several commonly used drugs in obese children may be estimated on the basis of their weight (Table 43-11).

These children should be positioned 25-degree head-up during preoxygenation to reduce V/Q mismatch and to facilitate tracheal intubation. The tragus should be positioned above the level of the sternal notch to ensure that tracheal intubation will be successful.<sup>220</sup> IV access may be difficult.

Desflurane is preferred for maintenance of anesthesia because it is the least fat soluble of the inhalational anesthetics and has the smallest context-sensitive half-life. However, if the child has asthma or is exposed to smoking, sevoflurane may be preferable. Compression devices should be applied to the legs to prevent stasis and deep vein thrombosis.

Perioperative respiratory events including difficult mask ventilation, greater Mallampati airway class, bronchospasm, rapid hemoglobin desaturation, and prolonged PACU times are more common in obese children.<sup>219</sup>

## *Preoperative History*

Medical, surgical, and family histories including complications should be recorded. The details of all allergies should be carefully elicited in terms of the clinical manifestations and severity. A systems approach should review each organ system including recent URIs recorded.

## *Allergies*

8

Most allergies that are reported in hospital records are of little relevance to the conduct of anesthesia. All allergies reported by patients and families are dutifully transcribed into the hospital record with neither censure nor regard for their relevance or authenticity. Examples of recognized side effects that do not constitute allergies include headaches after epinephrine, vomiting after opioids, and diarrhea or rash after amoxicillin. Only true allergies should be recorded on the anesthetic record: these include anaphylactic reactions and allergic reactions diagnosed and confirmed by an allergist/immunologist. The remainder should be identified as hypersensitivity or idiosyncratic reactions, although this is not the current practice. Cross-sensitivity between penicillin allergy and first-generation cephalosporins is possible; however, there is no cross-reactivity with second or later generation of cephalosporins.<sup>226</sup> If the parents report a possible penicillin allergy or sensitivity to cephalosporin in their child that occurred more than 5 years ago and not confirmed by an immunologist, then this author offers to test the child using a small test dose of the IV antibiotic while monitoring the child and informs the parent of the outcome.

Few, if any, allergies have been reported to propofol. Although the package insert for propofol cautions against the use of propofol in children with egg allergy, the only egg allergy that precludes the use of propofol is possibly egg anaphylaxis.<sup>227</sup> Egg lecithin, a phospholipid in propofol, is not a protein and therefore cannot induce anaphylaxis. However, it may carry trace concentrations of yolk proteins with it into the formulation. The manufacturer

states that no soy protein is present in their North American formulation of propofol. Hence, children with soy allergy (usually <5 years of age) may receive propofol.

Latex allergy should be documented when preparing the operating room for children although its significance is waning.<sup>228</sup> In the past, numerous children with spina bifida, congenital urologic surgery, and multiple surgeries (>5 exposures) were exposed to latex products by repeated bladder catheterizations or latex gloves multiple times and developed IgE-mediated latex anaphylaxis. Children who are latex allergic and who touch toy balloons to their lips or in whom dentists insert a rubber dam, will react with lip or tongue swelling, respectively. Because latex products both in and out of hospital have been replaced with nonlatex substitutes, the prevalence of latex allergy in the children is decreasing; this is an acquired, not a congenital condition. It is imperative to avoid contaminating the surgical (and anesthetic) setup with latex in order to prevent latex anaphylaxis. Removing all latex products from the operating room has eliminated latex anaphylactic reactions and should be adopted worldwide.<sup>229</sup> If the child has latex anaphylaxis, each operating room door should have signage indicating that a latex-allergic patient is present. Epinephrine, in a dose of 1 to 10 µg/kg, is the drug of choice to reverse latex anaphylaxis; 1 to 2 µg/kg reverses isolated bronchospasm (but may need to be repeated), whereas 10 µg/kg is reserved for cardiac arrests.

### *Preoperative Physical Examination*

The airway, respiratory, and cardiovascular systems should be examined preoperatively in every child. The airway examination should include visual inspection of the face in the anterior and profile views to detect any disproportions in facial features that might suggest a congenital facial or airway anomaly. The child should open their mouth fully, stick out their tongue, and extend their neck. Loose teeth should be identified and any removable dental appliances stored. Piercings in and around the mouth should be removed as these may become dislodged and aspirated if they are intraoral. The respiratory examination includes auscultation of the chest (front and back) with full inspiration and expiration through the mouth. If rales or rhonchi do not clear with deep coughing, then a chest x-ray and pulmonary consultation should be ordered. Cardiovascular examination includes auscultation of the heart. If a murmur is detected, then further inquiry regarding the presence of cardiac symptoms (syncope, arrhythmias, tachycardia, heart failure, shortness of breath) should be solicited. If the murmur is heard during diastole, has not been diagnosed previously, or is associated with any cardiac symptomatology, then a cardiology consultation

should be sought. If the child has a history of cardiac surgery, then a recent cardiology note together with an electrocardiogram and echocardiogram should be reviewed.

### **Anesthetic Risks; Consent/Assent**

The mortality associated with anesthesia in healthy children is 1:10,000 or less.<sup>221</sup> Perioperative cardiac arrest rate is greater in children who are young (under 1 year of age), with congenital heart disease, and undergoing emergency surgery. This author does not give a number for the risk of cardiac arrest to parents of healthy children undergoing elective anesthesia (unless specifically requested to do so) but rather uses an analogy that the risk is greater that they would be hit by a car crossing the busy street outside the hospital than to have a serious adverse outcome during general anesthesia. Perioperative morbidity may be greater than the incidence of cardiac arrest, but depends on the child's comorbidities and the severity of the current diseases.

Specific risks discussed preoperatively include the most common complications, pain, nausea, and vomiting. In addition, the author reviews the small risk of unforeseen complications that may result from as yet latent diseases, dental damage, corneal abrasion, aspiration, awareness, allergic reactions, and cardiac arrest.

If asked about awareness, this author informs the parents/guardians that the incidence of awareness in children is extremely rare (1:60,000),<sup>222</sup> although some have reported an ~1% incidence of awareness in their center.<sup>223</sup> The latter may be attributed, for the most part, to inadvertent light anesthesia during periods of stimulation.

If asked about cognitive dysfunction after anesthesia, the author informs the parents/guardians that neuroapoptosis has been reported after almost every anesthetic in neonatal animals and some nonhuman primates.<sup>224</sup> Several studies in children investigated the risk of anesthesia on the maturing human brain; in a sibling cohort study of a single anesthetic before 3 yr, IQ scores in later childhood were similar.<sup>225</sup> In a prospective randomized controlled study of sevoflurane versus spinal anesthesia, neurodevelopmental outcome at the 2-year (preliminary) follow-up was similar.<sup>9</sup> Accordingly, this author advises parents that there is insufficient evidence to suggest that anesthesia causes cognitive dysfunction in young children, but urges parents to consider all of the risks and benefits of anesthesia and surgery for their child when considering whether to proceed with surgery.

### **Induction of Anesthesia**

## Equipment

To ensure that the anesthetizing location is properly and completely prepared, it is useful to use a checklist. Appropriately sized equipment should be available for each child. A range of face mask sizes, oral airways, laryngoscope blades, tracheal tubes, and LMAs should be present. The author prefers cushioned clear face masks that fit the contour of the child's face and permit rapid identification of either fluid or solid material within the mask. Reliance on oral airways in establishing a patent upper airway in children has been supplanted, in part, by an appropriately applied jaw thrust maneuver.<sup>98</sup> The Miller and Wisconsin straight blades are preferred for tracheal intubation in infants and children, although we recently demonstrated that the Macintosh blade provides a similar view to that of the Miller blade in children 1 month to 2 years of age.<sup>230</sup> A range of sizes of laryngoscope blades should be available in every anesthetizing location. For laryngoscopy the child should be positioned flat on the table, with the head stabilized to prevent lateral movement. The large occiput of the child puts the head in the sniffing position naturally. In infants and children with limited oxygen reserve, or when performing tracheal intubation during sedation, the Oxyscope, a straight blade fitted with a source of oxygen at the tip of the blade, may prevent oxygen desaturation.

The classic laryngeal mask airway (cLMA) was introduced to replace face masks in adults and has subsequently proven to be a versatile and useful airway device in some circumstances in children.<sup>231</sup> To fit pediatric airways, the dimensions of the adult cLMA were simply scaled down in size from the adult and unmodified otherwise for infants and children. The cLMA has also proven to be effective in circumstances other than elective anesthesia, including neonatal resuscitation and fiberoptic intubation. A range of sizes of the cLMA should be available.

Although effective, the cLMA does not "protect" the airway from regurgitation and laryngospasm. Because the tone of the gastroesophageal sphincter is reduced in children, compared with adults, children may be at greater risk for regurgitation in the presence of a full stomach or positive pressure ventilation. Hence, it is best to avoid LMAs in these clinical situations. Modifications of the cLMA to include a vent for regurgitant gas or liquid from the esophagus, as in the ProSeal supraglottic airway, may better protect the airway against aspiration.

Complications associated with the cLMA in children are infrequent but may include gastric inflation, aspiration, airway obstruction, and laryngospasm.<sup>232</sup> When compared with tracheal tubes, supraglottic airway devices are associated with fewer postanesthetic complications.<sup>233</sup> The frequency of complications with cLMA in infants under 1 year of age is

greater than that in older children and in infants managed with a face mask. Studies suggested that the epiglottis folds down into the bowl of the cLMA in a majority of children although the LMA is otherwise functioning properly; this finding may simply be moot.

A range of diameters of tracheal tubes appropriate for the child's age, as well as tubes 0.5 mm ID (internal diameter in mm) smaller and larger, should always be available. The appropriate size of the uncuffed tracheal tube is based on the ID of the tube. Guidelines for uncuffed tracheal tube sizes in infants and children are as follows: infant's weight (<1,500 g, 2.5 mm ID; 1,500 g to full-term gestation, 3 mm ID); neonate to 6 months postnatal age, 3.5 mm ID; and 0.5 to 1.5 years, 4 mm ID. For children above 2 years of age, the size of uncuffed tubes may be estimated using the formula: Age (in years)/4 + 4 (or 4.5) mm ID. The size of cuffed tubes (mm ID) may be estimated using the formula: Age (in years)/4 + 3 (for children <2 years) or + 3.5 (for those >2 years).

The length of a tube from the lips to mid-trachea in infants less than 1,000 g in weight is 6 cm, 1,000 to 3,000 g is 7 to 9 cm, in term neonates 10 cm, and for infants and children, 10 + age (years) mm.

In the past, uncuffed tracheal tubes were commonly used to secure the airway of children under 8 years of age. The circular shape of the tracheal tube was suited to the round shape of the lumen within the cricoid ring,<sup>234</sup> which allowed for a good seal without the need for a cuff on the tube. Cuffs were avoided in children out of the concern that compression of the loosely adherent pseudostratified columnar epithelium that lines the cricoid ring would swell and encroach on this narrowest portion of the upper airway and cause stridor. To preclude this potentially serious airway complication, the tracheal tube was carefully selected so that it either passed through the cricoid ring without resistance or did so with an audible leak at a peak inspiratory pressure 10 to 20 cm H<sub>2</sub>O.

Recently, there has been a shift from uncuffed to cuffed tracheal tubes in infants and children. Cuffed tubes contaminate the environment less with anesthetic gases, are associated with fewer laryngoscopies and reintubations, and deliver more consistent tidal volumes (as chest wall and abdominal compliance change during surgery) and positive end-expiratory pressure than uncuffed tubes. This shift in practice has been accelerated by the introduction of the soft, high-compliance cuffed Microcuff tube (Microcuff GmbH, Weinheim, Germany).<sup>235</sup> The latter tubes are uniquely designed as they have no Murphy eye, and the cuff is positioned closer to the tip of the tube (than standard cuffed tubes), is made of polyurethane, and shaped as a cylinder (rather than a sphere), thus mimicking the shape of the larynx. Microcuff tubes seal the airway at much lower cuff pressures (~11 cm H<sub>2</sub>O) than other cuffed tubes.<sup>236</sup> The cost of the Microcuff tube is several fold greater than

that of the uncuffed tube. All cuffs expand when nitrous oxide is used, although the time interval until the cuff pressure in the Microcuff tube reaches 25 cm H<sub>2</sub>O exceeds that with other tubes because the former seals the airway at lower pressures. The cuff pressure should be monitored during surgery to preclude excessive cuff pressures. In a retrospective study, the incidence of post-extubation stridor in neonates whose airways were intubated with these tubes was almost threefold greater than that after uncuffed tubes, suggesting that caution be exercised when using Microcuff tubes in neonates.<sup>237</sup>

Optimizing ventilation during anesthesia and surgery in infants and children has been the subject of much interest.<sup>238</sup> Traditional strategies held that volume-controlled pressure-limited ventilators were effective for most infants and children. However, these ventilators accounted for neither the compliance of the breathing circuit nor the variable leak around the tracheal tube. Further concerns focused on the shape of the pressure tracing during inspiration and the risk of delivering excessive peak airway pressures. In the neonatal intensive care units, pressure-controlled ventilation has been used successfully, in part because the peak inspiratory pressure is restricted and the risk of barotrauma is decreased with the constant inspiratory pressure pattern. The inspiratory pressure pattern also more evenly distributes the inspiratory gas throughout the lungs, reducing the risk of ventilation/perfusion (V/Q) mismatch. Despite the advantages of the pressure-controlled ventilators, many anesthesia ventilators were simply unable to compensate for decreases in abdominal and chest wall compliance that occurred during surgery. The new generation of anesthetic machines offers markedly improved ventilators and ventilation strategies that are hybrids of the best aspects of both volume- and pressure-regulated ventilation. These new ventilators may prove to be ideal for both preterm and term neonates. Ventilation strategies, such as the hybrid pressure-regulated volume-controlled mode, maintain a fixed tidal volume by taking into account the compressible volume of the breathing circuit. This mode is used during controlled ventilation, and a pressure support mode is used once spontaneous respiration commences. For most children, the ventilation strategy will not impact on the outcome, but for those with lung disease, a poor ventilation strategy could result in a panoply of irreversible pulmonary problems. Whichever ventilation mode or strategy is planned for a particular child, it is crucial that the limits on ventilation including peak inspiratory pressure, rate, and positive end-expiratory pressure are set before the child is connected to the ventilator.

## Monitors

The ASA recommends basic patient monitoring during all anesthetics

including electrocardiogram, arterial blood pressure, SaO<sub>2</sub>, capnogram, and temperature, as well as additional monitors specific for the child's medical or anesthetic condition, for example, depth of anesthesia monitor. Many infants and preschool-age children fight the application of monitors while awake. Although induction of anesthesia is usually well-tolerated and safe in expert hands, every effort should be made to apply at least a pulse oximeter before inducing anesthesia. The remaining monitors should be applied as soon as the child loses consciousness. Understanding the role of these monitors in pediatric anesthesia requires a basic understanding of these instruments, although three specific monitors merit further consideration: capnography, temperature, and depth of anesthesia monitoring.

## **Capnography**

Respiratory rate and apnea may be detected by measuring the carbon dioxide tension in the anesthesia breathing circuit. The most commonly used technique is infrared analysis using one of two approaches: sidestream or mainstream capnography. The former requires aspiration of gas into an analyzer whereas the latter detects carbon dioxide with a detector inserted into the breathing circuit.

The accuracy of sidestream capnometry improved dramatically when circle system breathing circuits replaced T-piece circuits because there is less dilution of expiratory gas. Sidestream capnometry using gas obtained from the elbow of the circle breathing circuit provides accurate data, even in neonates who have small tidal volumes. On the other hand, mainstream capnography is infrequently used and is unpopular among pediatric anesthesiologists, particularly for use in infants and neonates, because it increases the dead space of the breathing circuit, must be fitted at the tracheal tube/elbow and is heavy, increasing the risk of kinking or obstructing the tracheal tube.

The end-tidal PCO<sub>2</sub> may also be accurately monitored while the child is sedated and breathing spontaneously through a face mask or through baffled nasal prongs. This noninvasive but accurate measure of capnometry allows continuous assessment of ventilation in remote sites such as the MRI and CT scanners amongst other locations.

## **Temperature**

Thermoregulatory homeostasis requires an understanding of the physiology of heat transfer in the child as well as the effects of anesthesia. Children have large surface areas to body weight and as such are at risk for rapid and extensive heat loss to the environment. In children, heat loss follows the order: radiation (39%) > convection (34%) > evaporation (24%) >

conduction (3%).<sup>242</sup> When anesthesia is induced, heat is redistributed from the central core to the periphery, and from there, it is lost to the environment. There is little that can be done to prevent the redistribution of heat with induction of anesthesia but there are a number of strategies that may attenuate the net loss of heat from the child.

The temperature of the operating room should be increased to about 28°C (80°F) before nonfebrile neonates and infants arrive. Because there may be a substantial (up to 1 hour) lag time between setting the operating room temperature and achieving it, the room temperature should be adjusted as the previous child leaves. The increased temperature warms the walls and the air within the room, thereby reducing both radiation and convection heat losses, respectively.

Several other modalities have been used to maintain thermoneutrality in infants and children during anesthesia including water mattresses, radiant overhead heaters, and forced air warmers. Water mattresses address heat loss primarily through conductive paths and because this accounts for an insignificant fraction of the heat loss, they are unnecessary. Radiant overhead heaters are used primarily in neonates and infants. Feedback control to avoid skin burns is best served using an accurate measure of the distance of the heater from the infant's skin surface as well as continuous surface temperature monitoring on the infant's skin. However, for the majority of infants and children who require temperature control in the operating room, the most important modality is the forced air warmer. These warmers are the single most effective strategy available to minimize heat loss in children who undergo surgery lasting 1 hour or more.<sup>243</sup> Although it is comforting to the child to preheat the air mattress before the child enters the operating room, this practice does not affect the child's temperature at the end of anesthesia. These warmers may predispose to airborne contamination and possible surgical infection, although evidence is conflicting. It remains this author's recommendation to turn the forced air warmer off when the skin is prepped and resume heating after the surgical drapes are in place.

A heat and moisture exchanger may be used to add humidity to the circuit although its efficiency is poor, particularly for surgery less than 1 hour and in infants.

Temperature should be monitored continuously throughout the anesthetic and in the PACU of all children who receive anesthesia or sedation. Core temperature is ideally measured at the level of the mid-esophagus using an esophageal temperature probe. Although alternative sites to measure the core temperature include the rectum, nasopharynx, and axilla, each site has its limitations. Rectal temperature probes may yield inaccurate temperatures if the probe falls out of the rectum or is buried in stool. Nasopharyngeal temperature may detect brain temperature but more likely underestimates the

core temperature by cooler gas passing through the breathing circuit. Axillary temperature may under- or overestimate the core temperature if it is positioned on the ipsilateral arm where the IV fluid is infusing or if the probe is either in the airspace behind the axilla being bathed by cool room air or in the heat from the forced air warmer. The author prefers proper positioning of the axillary temperature probe in the arm without the IV and with the shoulder completely adducted. In this position, an increase in temperature may be detected as an early sign of an MH reaction given the proximity of the large deltopectoral muscle group. Although some use a forehead skin temperature to track temperature, 10 MH reactions occurred in which these devices failed to reflect an increase in temperature.<sup>244</sup>

Temperature monitoring is important not only in MH but also to detect hypothermia. Hypothermia delays emergence from inhalational anesthesia, reduces the rate of degradation of drugs, and increases infectious risks.

### **Depth of Anesthetic Monitoring**

Recent reports of awareness in up to 1% of children who received general anesthesia for elective surgery have attracted considerable attention.<sup>223</sup> Careful review of the studies suggests that many of these episodes may be attributed to local practices that expose the children to concentrations of anesthesia that were insufficient for the level of stimulation. To reduce the risk of awareness, the anesthetic concentration of sevoflurane should be neither interrupted nor dramatically decreased early in anesthesia or during surgical stimulation; at least 0.7 MAC of the inhaled anesthetic should be maintained.

The most widely studied anesthetic depth monitor in children in North America is the BIS, although other monitors such as the cerebral state index and spectral entropy monitor are available. BIS readings are affected by a number of variables that raise questions regarding their validity in children. First, the determinations vary with the anesthetic administered. For example, at equi-MAC values, the BIS measurements during halothane anesthesia are 50% greater than those during sevoflurane.<sup>245</sup> This likely reflects the substantial differences in the EEGs between the two anesthetics. Second, the variability in the BIS measurements during sevoflurane among children precludes precise interpretation of the BIS measurement.<sup>64</sup> Third, age directly affects the BIS readings, because BIS measurements in children under 5 years of age are less reliable than those in children above 5 years of age.<sup>63–65</sup> This likely stems from maturational differences in the EEG from birth to school age, which was not incorporated in the BIS algorithm. Fourth, the BIS readings decrease as the sevoflurane concentration increases but beyond 3%, BIS paradoxically increases.<sup>64</sup> Additional curiosities with the BIS that are not

pediatric specific include the changes in the BIS readings in the presence of nitrous oxide and ketamine and with the onset of paralysis,<sup>246</sup> and finally, the effect of position on the BIS reading with Trendelenburg position (30-degree head-down) increasing the BIS by 20%.<sup>247</sup>

This author's indications for the use of the BIS monitor in children include those who cannot tolerate general anesthesia because of hemodynamic instability, those in whom nitrous oxide is not used, and those who require TIVA.

## **Emergency Drugs**

Emergency drugs should always be available before inducing anesthesia. Syringes with a small gauge (23G or 25G) needle that contain weight-appropriate doses of atropine and succinylcholine should be immediately available to facilitate IM or sublingual drug injection in an emergency. A syringe of propofol (1 to 2 mg/kg) should also be available to facilitate tracheal intubation or insert an LMA, as well as to break laryngospasm and increase the depth of anesthesia quickly.<sup>241</sup> Inotropic drugs are not routinely prepared for children undergoing elective surgery, unless the child has congenital heart disease or is critically ill. In the latter situations, preloaded syringes of phenylephrine (10 µg/mL) and epinephrine (10 µg/mL) should also be available.

## **Full Stomach and Rapid Sequence Induction**

The term full stomach refers to the presence of residual solid or liquid foods in the stomach at induction of anesthesia, a condition that places the child at risk for regurgitation and aspiration. A full stomach is assumed to be present in children who require emergency surgery, in those with gastric dysmotility syndromes, and in those with diabetes. A full stomach may be caused by the trauma, pain, and stress of the injury as well as by the administration of opioids, which increase gastric and intestinal paresis and further delay emptying of food from the stomach. In emergency surgery, the only time interval that correlates with the risk of food remaining in the stomach is the interval between ingestion of food and the trauma or opioid administration.<sup>188</sup>

There are three important principles to remember in such cases: (1) there is no safe time interval after an injury that guarantees the stomach is empty of food; (2) there is no safe time interval after an injury that guarantees that there is no risk of regurgitation of gastric contents; and (3) all children (even those treated with prokinetic motility drugs) are at risk for regurgitation and aspiration during induction of, maintenance of, and emergence from

anesthesia.

To protect the airways of children who are at risk for regurgitation and aspiration during induction of anesthesia, an RSI is widely practiced. Although there is no evidence that an RSI is the best strategy, it seems reasonable to induce anesthesia as quickly as possible and to insert a tracheal tube into the larynx as quickly as possible and inflate the cuff, if a cuffed tube is used. To perform an RSI, a tracheal tube with a stylet as well as tubes 0.5 mm ID greater or less, a functioning laryngoscope, active suction, IV access, and predetermined doses of anesthetic agents should be prepared. Induction of anesthesia may include propofol (2 to 4 mg/kg), ketamine (1 to 2 mg/kg), or etomidate (0.2 to 0.3 mg/kg), with the latter two favored in hemodynamically unstable conditions. We recommend succinylcholine 2 mg/kg (preceded by atropine 0.02 mg/kg) for paralysis, although rocuronium 0.8 to 1 mg/kg has also been used. (Note: *Recent concern regarding unexpected hyperkalemia and ventricular tachycardia in male children with undiagnosed muscle (wasting) diseases who received succinylcholine requires the immediate availability of IV calcium chloride (10 mg/kg IV) or calcium gluconate (30 mg/kg IV) (repeated as necessary to restore normal sinus rhythm).*) If the child has a muscle wasting disorder, succinylcholine should be avoided and rocuronium used to secure the airway. However, if the airway appears to be difficult or precarious, then alternative strategies to secure the airway should be considered, including an inhalational anesthetic or topical local anesthetic and TIVA sedation. If an inhalational induction is performed, unexpected regurgitation may necessitate rotating the child quickly into the left lateral decubitus position and pharyngeal suctioning to prevent aspiration.

There is much debate regarding the importance and relevance of cricoid pressure in an RSI in children.<sup>239</sup> Currently, there is no evidence to support or refute the use of cricoid pressure during RSI. However, there are some concerns regarding the application of cricoid pressure in infants. In both infants and children, the cricoid ring and trachea are mobile and deformable, and as little as 5 N force can compress the infant's airway by 50%.<sup>240</sup> This is one-fourth to one-sixth the force recommended for cricoid pressure in adults.

Cricoid pressure may also increase the level of difficulty of tracheal intubation by distorting tracheal anatomy or compressing the cricoid ring. Very few assistants are trained properly in locating the cricoid ring and in how much force is required to occlude the esophagus. *It remains this author's view that cricoid pressure has not been shown to reduce regurgitation in children at risk for aspiration and is not required for RSI. The practitioner should understand the advantages and disadvantages of cricoid pressure in infants and children in order to make an informed decision regarding its use.*

## Preoperative Preparation

## Anxiolysis

It is important to reduce anxiety in children undergoing anesthesia and surgery. Anxiety is greater when preschool age and withdrawn children are separated from their parents, when anxious parents accompany their children, and when multiple personnel, bright lights, and loud noises are present at induction of anesthesia. Each of these factors should be addressed on an institutional basis to reduce the overall anxiety in young children scheduled for surgery. Goal-directed therapy for the child should primarily attenuate the child's anxiety preoperatively and anticipate more anxiety at induction of anesthesia and, secondarily, address the parental anxiety.<sup>248</sup>

### Parental Presence at Induction of Anesthesia

Two systematic reviews established that parental presence at induction of anesthesia (PPIA) reduced the anxiety of parents but not the children.<sup>249,250</sup> Children 1 to 6 years of age are those for whom PPIA may be most beneficial. Parents who are most insistent on being present at induction of anesthesia are often the most disruptive, least likely to calm their child, and actually promote further noncompliant behavior in their child. Parents should never be invited to accompany their child for induction, lest both the hospital and the medical personnel find themselves responsible for any untoward sequelae that occur. The entire OR team must be like-minded regarding PPIA including detailed plans for escorting the parents out of the OR at the appropriate time. Before entering the OR, the parents must be instructed on the normal behavior of children during induction of anesthesia. If the parent is unable to cope with the OR environment or the child's loss of consciousness, he/she should not be present at their child's induction of anesthesia.

Some cognitively challenged adolescents and children may resist the transfer to the operating room. In such cases, the parents may have to be enlisted to accompany the child to the OR. Those children who resist attempts to bring them to the OR and are physically abusive despite enlisting the parent's assistance may require IM ketamine (see later).

### Distraction Techniques

Preoperative coloring books, stories, videos, and websites may be used to help children of all ages learn about surgery and anesthesia and the equipment that will be used for induction of anesthesia.<sup>250</sup> Some children's hospitals conduct operating room tours during which time the children become familiar and touch the face masks and breathing circuits. Child-life providers may help children defuse anxiety on the day of surgery by having the children play with the mask and flavor the inside using lip balm. Other

distraction techniques including video games, earphones, and portable Internet devices as well as music and clowns all reduce children's anxiety. Once the child enters the operating room, the anesthesiologist should establish rapport (distract) with the child by telling a story, engaging them in conversation about a recent birthday, holiday, or vacation, or by singing as they prepare for induction of anesthesia.

## Pharmacologic Sedation

For some, a premedication may be required to facilitate smooth separation from their parents. In North America, midazolam is the most widely used premedication for children because it can be given orally, nasally, rectally, IM, or IV to provide anxiolysis before induction of anesthesia. It should be noted that most premedications do not delay recovery and/or hospital discharge for surgeries at least 30 minutes in duration.

The dose of oral midazolam increases with decreasing age, although few bother to consider this very important factor.<sup>251</sup> Failure to adequately premedicate the child may lead to parents questioning the practitioner's abilities, but more importantly, may fail to provide adequate anxiolysis for separation from the parents and induction of anesthesia. The bioavailability of oral midazolam is poor, with 27% at 0.15 mg/kg and 15% at 0.45 and 1 mg/kg.<sup>10</sup> This author administers 0.75 to 1 mg/kg (maximum dose 15 to 20 mg) to children 18 months to 3 years of age, 0.6 to 0.75 mg/kg to children 3 to 6 years of age, 0.5 mg/kg to children 6 to 10 years of age, and 0.3 mg/kg to children above 10 years to a maximum of 15 to 20 mg to ensure a 98% success rate of sedating children within 10 to 15 minutes.<sup>252</sup> Because oral midazolam leaves a bitter aftertaste, the current formulation is dissolved in a thick, strawberry flavored-syrup. To minimize the aftertaste, the dose should be swallowed in a single bolus and then followed with a small volume of water. For children too young to swallow midazolam from a cup, it should be instilled into the lateral gutters of the mouth using a needleless syringe to prevent the child from spitting it out. Judgment should be exercised when considering oral midazolam premedication for a child who is crying continuously as few strategies, including parental presence at induction, may provide anxiolysis.

Alternative oral premedications include ketamine (5 to 6 mg/kg),<sup>108</sup> clonidine (2 µg/kg),<sup>253</sup> and dexmedetomidine (2 µg/kg).<sup>254</sup> Ketamine is prepared by suspending it in a thick, flavored syrup. It offers few advantages over midazolam and may cause more postoperative vomiting (POV).<sup>108</sup> Postoperative hallucinations and nightmares are uncommon after oral premedication. Some have combined oral midazolam and ketamine in a 50:50 mixture with good success. Both clonidine and dexmedetomidine take 60 to

90 minutes to effect sedation and anxiolysis. They may produce bradycardia and sedation that persist beyond the duration of the anesthetic.

The IN route is effective in the crying child, although nasal administration of drugs is unpleasant for most.<sup>248</sup> A volume of 0.5 mL is well tolerated and covers adequate mucosal surface for rapid absorption. IN midazolam 0.1 to 0.2 mg/kg causes effective premedication, but older children complain of the bitter burning aftertaste.<sup>255</sup> IN sufentanil 1 to 2 µg/kg is also an effective premedication, although in one study, 23% of patients desaturated to less than 90% after 2 µg/kg of IN sufentanil and 45% developed chest wall rigidity after 4.5 µg/kg.<sup>256</sup> Succinylcholine may be required to resolve chest wall rigidity after IN sufentanil. IN dexmedetomidine (0.5 to 1 µg/kg) also provides anxiolysis and sedation,<sup>257</sup> although it may require up to 1 hour to affect sedation and the sedation may extend into the recovery period.

For older children and adolescents who are cognitively challenged, uncooperative, and/or behaviorally problematic despite their parents' presence, IM ketamine 2 to 5 mg/kg (concentration 100 mg/mL) administered via a small gauge, long needle (large enough to not break off if the encounter became combative) into the deltoid muscle of an arm may be the only means to ensure safe delivery of the child to the OR.<sup>258</sup> These children should be seated on a gurney before administering the ketamine, as they quickly lose consciousness and motor tone, becoming difficult to lift or move onto a gurney. By this route, ketamine has an onset of action of 3 to 5 minutes and a duration of 30 to 40 minutes.

## *Induction Techniques*

### **Inhalational Induction**

In North America, the most common technique for inducing anesthesia in children undergoing elective surgery is an inhalational induction.  Infants and children of all ages, including those who are crying and upset, can be successfully anesthetized using this approach. Distracting upset and crying children using a warm, reassuring, and calm manner often permits a successful induction of anesthesia by face mask. The notion that distraught children should be treated with “brutane” by holding children down and forcing a mask on their face with 8% sevoflurane flowing has no place in pediatric anesthesia and may psychologically scar the child for life. If the child had a poor previous experience with anesthesia, it is important to understand the nature of the past experience and design an anesthetic to minimize their anxiety.

In preschool-age children, distraction techniques and premedication are key strategies to minimize the anxiety associated with separating from their

parents and undergoing induction of anesthesia. The author offers children (>3 years of age) a choice of several flavored lip balms to mark inside the mask. For younger children (<3 years of age), the author flavors the face mask for them. The smell obscures the plastic smell of the mask but more importantly it distracts the child and offers a topic for discussion. Troposmia, which means a distorted perception of an odor, is an interesting strategy in which the child is told that the flavor that was applied to the mask will transform into his/her favorite flavor as anesthesia is induced. Using this approach, 80% of children interviewed postoperatively confirmed that they smelled their favorite flavor as they were anesthetized.<sup>259</sup> Other distraction techniques include music, story and joke telling, magic, video and handheld games, and clowns (see earlier).

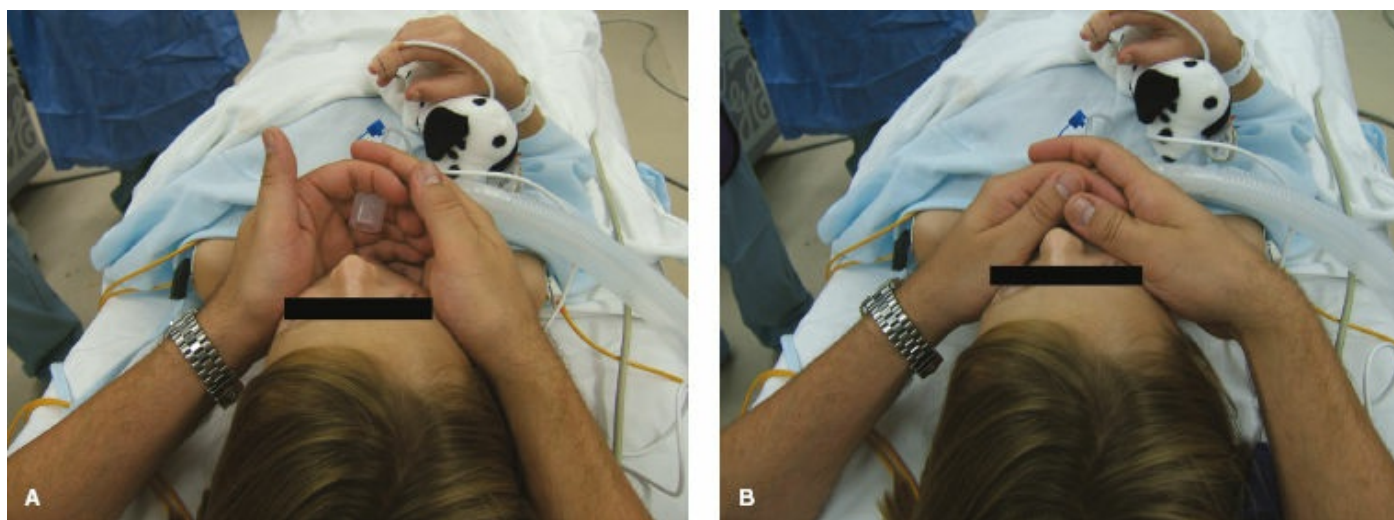

With the child seated on the operating table with his/her back to the anesthesiologist's chest (or on your lap if a diaper is worn) and at least a pulse oximeter (with more monitors as tolerated), a flavored face mask is applied over the mouth and nose with 5 to 7 L/min of a mixture of 70% nitrous oxide and 30% oxygen. The adjustable pressure-limiting valve should be completely open to avoid resistance to exhalation. During this time, the child should be distracted by singing a song or telling a joke or story until the end-tidal N<sub>2</sub>O concentration exceeds ~50% or the child ceases to respond to verbal stimulation. At this point, the inspired concentration of sevoflurane is increased in one step from 0% to 8%. If the sevoflurane concentration is increased in smaller increments, then a protracted period of excitement may ensue. If sevoflurane is introduced at the same time as the nitrous oxide, unmedicated children will reject the mask because of the strong odor of sevoflurane, potentially resulting in an aversion to or fear of face masks, which almost certainly will present difficulties for future anesthetics.

As the child loses consciousness, he/she is placed supine. If apneic or hypopnea occurs (as is common after premedication), ventilation may be assisted manually and gently. To reduce the risk of awareness, this author recommends maintaining 8% sevoflurane and 70% nitrous oxide until IV access has been established. At that time, 1 to 2 mg/kg IV propofol is administered, the nitrous oxide may be discontinued, and an LMA or tracheal tube is inserted.<sup>87</sup> Bilateral air entry in the chest, the presence of a capnogram, and no air entry audible over the upper epigastrium confirm proper placement of the tube. After inflation of the cuff of the LMA, absence of excessive air leak at 20 cm H<sub>2</sub>O confirms proper LMA placement. The inspired concentration of sevoflurane may be reduced to 2% to 3% inspired and nitrous oxide reintroduced.

The child with mask phobia poses a real challenge for those attempting to induce anesthesia by mask.<sup>248,260</sup> Besides refusing a mask, these frightened children often steadfastly refuse needles, leaving few options for induction of

anesthesia. There are many reasons why children may be fearful of face masks, including the unappealing odor of 8% sevoflurane administered to an unmedicated child previously, a partially closed APL valve that prevented the child from exhaling, and claustrophobia. Irrespective of the reason for the mask phobia, if the mask is the focal point of the fear, it should be eliminated. In these cases, anesthesia may be induced without a face mask by inserting the elbow of the breathing circuit between two fingers and interlacing the fingers of his/her two hands (with flavor applied to the gloves) (Fig. 43-5A and B). With the hands cupped under the child's chin and 70% nitrous oxide in oxygen flowing, the hands slowly close in over the child's mouth. Because nitrous oxide is heavier than air, the cupped hands act as a reservoir for the nitrous oxide. Suction tubing may be held in close proximity to minimize spread of anesthetic to those nearby. Although this technique causes OR pollution, this author believes it is the optimal approach for managing children with mask and IV phobias. Once the hands are tight over the mouth, 8% sevoflurane may be introduced. As soon as the child stops responding, the elbow of the circuit is inserted into the mask and the mask is applied to the face to seal the airway.

**Figure 43-5** For the child who fears the face mask, the mask is removed and the elbow of the breathing circuit is inserted between interlaced fingers in the hand. **A:** At this time, the fresh gas comprises 70% nitrous oxide in oxygen. The hands are gradually brought closer to the child's mouth from below the chin (nitrous oxide is heavier than air), until they completely cover the mouth. **B:** At that point, either sevoflurane may be added to the fresh gas or a face mask applied to the face, or both.

If the child is not mask-phobic, the anesthesiologist may deliver sevoflurane from the outset of the anesthetic without the child smelling the sevoflurane by rotating the face mask 90 degrees so the cuff on the mask occludes the nares. This eliminates/decreases the smell of sevoflurane and allows anesthesia to be induced smoothly.

For older children (usually >6 years of age) who understand how to hold their breath, a single-breath induction of anesthesia may be employed.<sup>261</sup> With this technique, the eyelash reflex is lost within 20 seconds of the breath-hold. However, to be successful, the child should practice inhaling maximally through the mouth and exhaling to residual volume (e.g., until there is no air left in their lungs) before the induction. The anesthesia breathing circuit should be primed with 8% sevoflurane (with or without 70% nitrous oxide) as evidenced by the agent analyzer. This is achieved by flushing the circle circuit and a 2- to 3-L reservoir bag three to four times with 8% sevoflurane in 70% nitrous oxide, exhausting the contents of the circuit each time through the scavenging system. Once the child has mastered the breathing maneuver, the child exhales to residual volume, at which point the face mask and the primed breathing circuit is applied and held tightly to the face. The child is instructed to take a single deep breath through the mouth and hold it for as long as he/she can. While the child is holding his/her breath, the anesthesiologist counts aloud slowly to distract the child. The child may be supine or sitting for this induction, but if the child is sitting, an assistant stand behind the child to support him/her when he/she loses consciousness. In general, the child loses consciousness before the count reaches 15 seconds. As discussed earlier, a gradual introduction of the inhaled anesthetics may proceed smoothly in cooperative patients and one variation on that approach is demonstrated in the video.

#### **IV Induction**

For children without IV access, there are several approaches to establishing access. First, a topical local anesthetic cream can be applied to the skin to prevent the pain of the needle puncture. Topical local anesthetic creams that are available include the eutectic mixture of local anesthetics (EMLA) cream (AstraZeneca, Wilmington, DE), which requires a 45- to 60-minute application time to produce topical anesthesia and may cause skin blanching and vasoconstriction; Ametop (4% tetracaine) (Smith and New, Canada); ELA-Max (liposomal 4% lidocaine); and Synera (Zars Pharma Inc., Salt Lake City, UT).<sup>262</sup> Ametop, ELA-Max, and Synera require a 30-minute application time and do not cause skin blanching or vasoconstriction. A meta-analysis of EMLA and amethocaine reported that amethocaine was more effective than EMLA in children.<sup>263</sup> The J-tip injector of powder lidocaine anesthetizes the skin, although it itself causes moderate pain in 20% of children. Investigation of the factors that predispose to painful response to IV placement include young age, more numerous previous painful procedures, greater state and trait anxiety, more active, and the presence of polymorphisms to endothelin receptor A (EDNRA rs5333) compared with those with less pain.<sup>264</sup> Second,

50% to 70% nitrous oxide may be administered for 1 to 2 minutes by a tight mask fit to permit IV insertion, yielding better results than with EMLA.<sup>265</sup> Third, IN sufentanil may be used for IV placement. These approaches may be particularly useful for children with MH and myopathies in whom a potent inhalational anesthetic must be avoided.

Once IV access has been established, IV anesthesia with propofol, ketamine, or etomidate may be used for induction of anesthesia; sodium thiopental is only available outside of the US.

Propofol is the most widely available induction agent. It is available as Diprivan in a 1% solution that includes Intralipid (long-chain triglycerides derived from soybean oil), ethylenediaminetetraacetic acid (EDTA, a bacteriostatic agent), egg lecithin (a phospholipid membrane stabilizer), and propofol (2,6-diisopropylphenol). Because propofol is a phenol derivative, it causes pain when injected into the small peripheral veins of children. Several strategies have been investigated to attenuate or prevent pain, but only two techniques reliably prevent pain associated with IV propofol in small veins: 70% nitrous oxide in oxygen by inhalation or a modified Bier block using 0.5 to 1 mg/kg of 1% lidocaine injected into a vein while the arm is occluded for 45 to 60 seconds.<sup>94-96</sup> Propofol is a very safe induction agent for children. A bolus injection of propofol causes transient hypopnea or apnea with a minor decrease in heart rate and blood pressure.

Ketamine is also used for induction of anesthesia, although it is a second-tier induction agent because of concerns for postoperative nightmares. It is often used in the presence of circulatory instability (shock) or cyanotic heart disease.

Etomidate is only approved for children over 10 years of age in the United States. A recent population pharmacokinetic study of etomidate in children concluded that the dose of etomidate should increase as age decreases because both clearance and volume of distribution increase with decreasing age.<sup>114</sup> However, dosing recommendations have not been forthcoming. In adults, 0.2 to 0.3 mg/kg IV etomidate is effective for induction of anesthesia. Like ketamine, it maintains blood pressure even in the presence of circulatory instability. It decreases CBF by 20% to 30%. Minor side effects include pain on injection and myoclonic jerking. However, a far more serious side effect is suppression of adrenal function for up to 24 hours after both a single dose and a brief infusion of etomidate.

Sodium thiopental has been used for almost half a century as the IV induction agent of choice, but in the past two decades, it was gradually supplanted by propofol as the induction agent of choice and more recently supply was cutoff to the United States out of ethical concerns regarding its use for lethal injection. Thiopental remains available in Europe and Asia. Dosing for induction of anesthesia is 3 to 5 mg/kg IV. It causes no serious side effects

when administered as an IV bolus. However, because it is only metabolized at 10%/hr, emergence is delayed if it is administered as a continuous infusion.

## **IM Induction**

The IM route is infrequently used for induction of anesthesia in children because it is painful, induction is slow, and there is a risk of sterile abscess formation. The only anesthetic currently used for IM injections in children is ketamine.<sup>258</sup> This approach is usually reserved for adolescent children who are cognitively impaired, extremely uncooperative, and large in size. For further details, see IM premedication, earlier.

Rarely do children who require emergent securing of their airways present without IV access. When it does occur, one of several approaches may be undertaken. IV access may be established before induction of anesthesia, after anesthesia is induced with an inhalational agent, or after IM injection of ketamine (3 to 5 mg/kg), atropine (0.02 mg/kg), and succinylcholine (4 mg/kg).

## **Rectal Induction**

Rectal induction of anesthesia has been popular in young children (<5 years of age) in the past, particularly for those who were unwilling to take oral premedication or who were very frightened. Several regimens have been used for rectal induction: methohexital 15 to 25 mg/kg, midazolam 1 mg/kg, ketamine 5 mg/kg, or thiopental 30 to 40 mg/kg.<sup>266</sup> A number of problems were identified with rectal anesthesia inductions, including poor bioavailability of the induction agent (due to unpredictable rectal venous absorption or evacuation of the drug from the rectum), laryngospasm (with methohexital), and delayed recovery from anesthesia. In immune-compromised patients, rectal administration of drugs may lead to sepsis. Today, rectal inductions are rarely employed. Most anesthesiologists prefer to involve the parents in managing the child's behavior at induction of anesthesia rather than administer a rectal medication.

## **Problems during Induction of Anesthesia**

### ***Hemoglobin Oxygen Desaturation***

Pulse oximetry may be the only monitor that remains functional during induction of anesthesia in the restless young child. All current oximeters include motion-artifact compensating software to ensure fairly accurate measurements even when the child is moving. As the child becomes anesthetized, respiration is reduced resulting in hypoventilation. Despite the

use of oxygen-enriched inspired gases, many children, particularly those with a history of a mild URTI or who become deeply anesthetized, hypoventilate or become apneic. This immediately leads to oxygen desaturation, which may be exacerbated if nitrous oxide was coadministered. The primary diagnosis at this time is segmental atelectasis and intrapulmonary shunting, providing upper airway obstruction (often referred to as mild laryngospasm) has been ruled out. To restore the SaO<sub>2</sub>, 10 to 20 cm H<sub>2</sub>O of positive end-expiratory pressure should be applied using the adjustable pressure limit valve. The peak pressure that is delivered should be carefully adjusted to avoid inflation of the stomach. If, however, the lungs are not being ventilated, then laryngospasm should be suspected quickly and the management followed as described later.

### *Laryngospasm*

Laryngospasm is an infrequent, but potentially life-threatening complication that occurs in children during induction and emergence from anesthesia. The frequency ranges from 0.4% to 10% among studies.<sup>267,268</sup> Several factors are known to increase the risk of laryngospasm in children (Table 43-12).<sup>268</sup>

Laryngospasm is defined as the reflex closure of the false and true vocal cords, although the precise pathogenesis of this reflex remains debated. Complete laryngospasm is defined as closure of the false vocal cords and apposition of the laryngeal surface of the epiglottis and interarytenoids. The net effect is complete cessation of air movement and noisy respiration, absence of movement of the reservoir bag, and an absent capnogram. In contrast, incomplete (or partial) laryngospasm is defined as incomplete apposition of the vocal cords with a residual small gap between the cords posteriorly that permits a persistent inspiratory stridor, limited movement of the reservoir bag, and progressively increasing respiratory effort. Some assert that incomplete laryngospasm is not laryngospasm at all, but for treatment purposes this is a moot point.

**Table 43-12** Factors Associated with Laryngospasm<sup>267</sup>

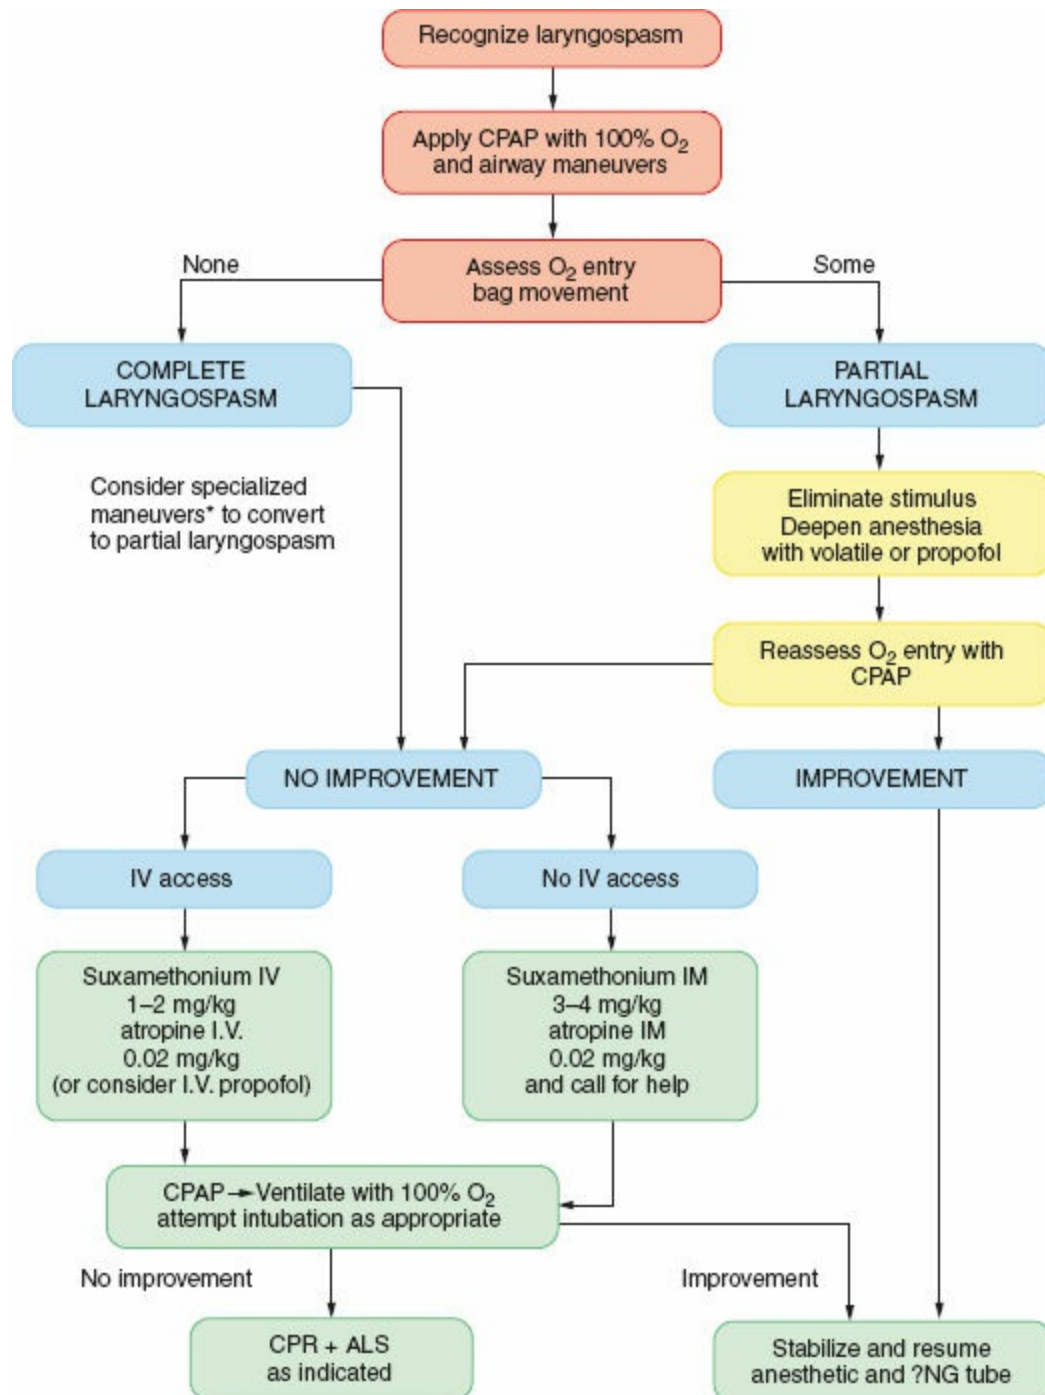

Age: greater in infants than older children and adults; the risk decreases with increasing age
Recent URTI (<2 weeks)
History of reactive airway disease
Exposure to second-hand smoke
Airway anomalies
Airway surgery
Airway devices (tracheal tubes, LMA)
Stimulating the glottis during a light plane of anesthesia
Secretions in the oropharynx (e.g., blood, excess saliva, gastric juice)
Inhaled anesthesia (desflurane and isoflurane)
Inexperienced anesthesiologist

URTI, upper respiratory tract infection; LMA, laryngeal mask airway.

The clinical findings in laryngospasm begin with faint inspiratory stridor, suprasternal and supraclavicular in-drawing due to increased inspiratory effort, increased diaphragmatic excursions, and flailing of the lower ribs. As greater inspiratory effort is expended, the intensity and volume of the stridor increases, and the chest wall movement resembles that of a rocking horse. As laryngospasm progresses, air movement through the almost closed glottis ceases and the inspiratory effort becomes completely silent. This is an ominous sign. If the progression of the laryngospasm is not interrupted, oxygen desaturation will quickly ensue. This may be followed by a decrease in heart rate. This downward spiral must be interrupted as described later.

Management of laryngospasm requires a multifaceted and immediate response (Fig. 43-6).<sup>267</sup> As soon as the diagnosis is suspected, a tight-fitting face mask should be applied to the child's face and 100% oxygen delivered with continuous positive airway pressure (15 to 20 cm H<sub>2</sub>O dialed into the adjustable pressure limiting valve). Pressures in excess of 20 cm H<sub>2</sub>O may cause gastric inflation. Note that the reservoir bag should not be squeezed except during the child's inspiratory efforts, lest gas be driven into the stomach. If the triggering event is blood, secretions, or foreign material in the airway, these should be removed immediately. As soon as the offending agent has been expunged, the jaw thrust maneuver should be applied. This maneuver requires familiarity with the anatomy of the retromandibular notch, an area subtended by the condylar process of the ascending ramus of the mandible anteriorly, the mastoid process posteriorly, and the external auditory canal superiorly.<sup>98</sup> Bilateral digital pressure is applied to the most cephalad point on the posterior edge of the condylar process of the ascending ramus of the mandible, and the force directed toward the frontal hairline. The force should be applied for 3 to 5 seconds at a time and then released for 5 to 10 seconds, while maintaining a tight seal with the face mask against the child's face. By applying and releasing pressure on the condylar processes, the repeated painful stimuli may cause sufficient pain to induce the child to cry,

which opens the vocal cords terminating the laryngospasm. In addition to causing pain, the jaw thrust maneuver serves to relieve upper airway obstruction in the anesthetized child by both translocating the ramus of the mandible anteriorly and rotating the temporomandibular joint so the mouth opens. Together, these maneuvers lift the tongue off the posterior pharyngeal wall establishing a patent upper airway.

**Figure 43-6** Algorithm to diagnose and manage laryngospasm in children. \*Apply the jaw thrust maneuver as described on p. 1247. CPAP, continuous positive airway pressure; CPR, cardiopulmonary resuscitation; ALS, advanced life support; NG, nasogastric tube. (Adapted with permission from Hampson-Evans D, Morgan P, Farrar M. Pediatric laryngospasm. *Paediatr Anaesth*. 2008;18:303–307.)

The jaw thrust maneuver is not as effective when applied at the angle of the mandible as this region contains many fewer pain fibers and does not rotate the temporomandibular joint. Hence, the ability of the maneuver to establish a clear upper airway is not nearly as effective. Remember, laryngospasm cannot develop or persist if the vocal cords are moving and the child is vocalizing or crying. If positive pressure ventilation, 100% oxygen, and jaw thrust maneuver fail to break the laryngospasm, further intervention should be undertaken before desaturation and bradycardia develop. Appropriate treatment would include in the following order: IV or IM atropine (0.02 mg/kg), IV propofol (1 mg/kg), and IV or IM succinylcholine (1 to 2 mg/kg IV or 4 to 5 mg/kg IM).<sup>267-269</sup>

Some suggest that gentle chest compressions effectively break laryngospasm in children. To add chest compressions to the management of laryngospasm requires a pair of free hands. If no free hands are available, do not abandon the maneuvers described earlier to perform chest compressions unless there is a cardiac arrest. The risk associated with this maneuver includes sternal or rib fractures. Currently, the author believes there is excellent alternative treatment for laryngospasm and insufficient evidence to recommend chest compressions to relieve laryngospasm in children.

## **Bradycardia**

Bradycardia is a slowing of the heart rate below age-defined limits. For infants (<1 year of age) this is 100 beats/minute (bpm); for young children 1 to 5 years of age, 80 bpm; and for children above 5 years of age, 60 bpm. Because cardiac output of infants and children is heart rate dependent, a slow heart rate means a reduced cardiac output. If the heart rate decreases below these limits, corrective action should be taken to restore the heart rate, and if necessary cardiopulmonary resuscitation should be initiated.

Although hypoxia is the foremost cause of bradycardia in children, drug-associated causes include halothane and succinylcholine. Because sevoflurane has replaced halothane in developed countries, this cause of bradycardia has all but disappeared.<sup>48</sup> This is not the case in many developing countries. A single dose of succinylcholine remains a cause of bradycardia in children but is a much less common cause today because succinylcholine is not routinely used in children for tracheal intubation. The incidence of bradycardia during the first 6 minutes of sevoflurane anesthesia in children with Down syndrome is fivefold greater than that in matched controls.<sup>270</sup> Children who are rate dependent for cardiac output and develop bradycardia may require treatment with atropine or isoproterenol. Atropine increases the cardiac output not only by increasing the heart rate, but also by increasing contractility through the force frequency response.<sup>1</sup>

**Table 43-13** Causes of Bradycardia in Infants and Children

1. Hypoxia (e.g., laryngospasm, obstructed airway, atelectasis)
2. Vagal reflex response (e.g., laryngoscopy, prolonged stretch on the extraocular muscles)
3. Increased intracranial pressure
4. Medications (e.g., clonidine,  $\beta$ -blockers,  $\alpha$ -adrenergic eye drops, succinylcholine without pretreatment with atropine, sevoflurane [more common with Down syndrome], propofol infusion syndrome)
5. Electrolyte disturbance (e.g., hyperkalemia, hypocalcemia)
6. Congenital heart disease, congenital or acquired rhythm disturbance
7. Hypothermia
8. Air embolism
9. Tension pneumothorax

The causes of bradycardia in healthy children are listed in [Table 43-13](#). To stop progressive slowing of the heart rate, the underlying cause of bradycardia should be corrected (e.g., correct hypoxia when present and administer atropine 0.02 mg/kg). Atropine is only effective when myocardial electrical activity is present and the bradycardia is of vagal origin. If asystole occurs, however, atropine cannot restore the heart rhythm, and the only definitive treatment is IV epinephrine (10  $\mu$ g/kg). Secondary treatment may include isoproterenol.

## Maintenance of Anesthesia

### *Techniques*

Inhalational anesthetics, supplemented with IV analgesics and antiemetics, have been the mainstay of anesthesia although, of late, TIVA has emerged as a reasonable alternative. One key advantage that distinguishes inhalational anesthetics from IV anesthesia is the ability to continuously measure the end-tidal (alveolar) anesthetic concentrations of inhaled agents. This measurement provides invaluable information regarding the accuracy of our delivery system and the anesthetic partial pressures in the VRG of tissues. Currently, isoflurane, sevoflurane, and desflurane are used to maintain anesthesia in children.

TIVA has become the primary anesthetic technique for children with MH, for those undergoing spine surgery with motor-evoked potential monitoring, for those with a history of severe perioperative nausea and vomiting, and, in some institutions, for all children. Propofol and ketamine are the primary general anesthetics used with TIVA, although, unlike propofol, ketamine is emetogenic and associated with prolonged emergence when infused for prolonged periods. Propofol has been proscribed as a continuous sedative for children in ICU because of the risk of PRIS but not in anesthesia. Dosing for

bolus and infusions of propofol is described earlier.

Supplemental analgesics are also used during both inhalational and IV anesthesia to prevent physiologic responses and movement to pain. Remifentanyl (with a 5-minute context-sensitive half-life) 0.05 to 0.1  $\mu\text{g}/\text{kg}/\text{min}$  can be administered as an infusion, whereas other opioids (fentanyl and morphine) are more often administered by IV boluses. Fentanyl (1 to 2  $\mu\text{g}/\text{kg}$ ) or morphine (0.05 to 0.1  $\text{mg}/\text{kg}$ ) can be administered IV; the dose is adjusted up or down depending on the child's exposure to opioids, the severity of the pain, and concomitantly administered analgesics.

## 9 Fluid Management

### General Principles

IV fluid administration sets should be prepared before the child arrives in the operating room. For young children, a 500-mL bag of LR solution with a graduated buretrol is appropriate; for infants (<1 year), a 250-mL bag with a buretrol is preferable. *These recommendations for the use of a buretrol and IV fluid bag are intended to limit the risk of adverse events should the entire bag inadvertently be infused in the child.* All pediatric IV sets should include a manual controller, a one-way valve (to prevent medications from passing retrograde up the IV tubing), and needleless ports and/or three-way stopcocks for medication administration. For children above 8 years of age, the IV infusion set may be prepared with a macro or micro-drip without a buretrol and a 1,000-mL bag of balanced salt solution.

Intralipid infusions from total parenteral nutrition should be discontinued before transfer to the OR to reduce the risk of contaminating the Intralipid and central venous access line by repeated line accessing, although concentrated sugar solutions should be continued.

Most IV fluids administered to healthy children during elective surgery consist of a nonglucose-containing isotonic salt solution, commonly LR solution in North America. These solutions replaced glucose-containing hypotonic solutions that were associated with perioperative seizures, aspiration, and brain damage after large volumes were administered during surgery. LR solution is slightly hypotonic (280 mOsm/L) and contains small concentrations of potassium and lactate. Normal saline (0.9% NaCl) is isotonic (308 mOsm/L), acidic (pH 5), and contains no ionic moieties. Normal saline is not routinely used as the primary maintenance solution because large volumes may lead to a hyperchloremic metabolic acidosis (nonanion gap type). We advocate glucose-containing solutions, such as 1% or 2.5% glucose in LR solution, as a maintenance solution in infants under 6 months of age and for young children who are cachectic, chronically malnourished, tolerate fasting

poorly (maple sugar disease), and suffer from debilitating disease who may be at risk for hypoglycemia.<sup>271</sup> These solutions should not lead to intraoperative hyperglycemia or hyponatremia. Although the shift to isotonic salt solutions dramatically decreased the incidence of perioperative hyponatremia, some specific surgeries (e.g., craniofacial surgery) may warrant perioperative monitoring of serum electrolytes.<sup>272</sup>

Children with specific medical conditions should have tailored IV solutions. For children with renal failure or renal insufficiency, normal saline has been the preferred balanced salt solution because it contains no potassium although evidence suggests it may lead to greater serum potassium concentrations than LR.<sup>273</sup> Children with a mitochondrial myopathy who had lactic acidosis in infancy should be fasted briefly preoperatively (to avoid acidosis and hypoglycemia) and should receive only nonlactate-containing solutions with glucose supplementation as needed.

Infants and children under 2 years of age who may be hypovolemic should be assessed preoperatively to determine the magnitude of their fluid deficit: mild, moderate, or severe. The signs of mild dehydration (5% body weight loss: approximately 50 mL/kg deficit) include poor skin turgor and dry mouth. The signs of moderate fluid dehydration (10% of body weight loss: 100 mL/kg deficit) include sunken fontanel (if present), tachycardia, and oliguria in addition to the signs of mild dehydration. The signs of severe fluid dehydration (15% of body weight loss: 150 mL/kg deficit) include sunken eyeballs, hypotension, and anuria plus the signs of moderate dehydration.

Correction of hypovolemia requires staged infusion of iso-osmolar fluid administration. Approximately 50% of the deficit should be replaced in the first hour, 25% in the second, and 25% in the third. A balanced salt solution should be used to restore euvolemia.

## **Elective Surgery**

For elective surgery, the traditional calculation for the hourly fluid infusion rate has been based on replacing the triad of fluid deficit during fasting, ongoing maintenance, and blood and third-space losses. In children, a hypotonic glucose-containing solution was used as the maintenance solution at the rate of 4–2–1 mL/kg/hr rule where 4 mL/kg is for the first 10 kg, 2 mL/kg is for the second 10 kg, and 1 mL/kg is for the third 10 kg and any additional body weight thereafter.<sup>274</sup> However in the past 25 years, the maintenance solution has shifted to a balanced salt solution to prevent intraoperative hyponatremia. Holliday and Segar reappraised their 1957 recommendation recently,<sup>274</sup> seeking to address the risks associated with both administering hyponatremic solutions to children who were hypovolemic and applying their 4–2–1 fluid infusion rule to isotonic solutions. They reasoned

that the antidiuretic hormone is upregulated in all children who are fasted for elective surgery, presenting with sepsis or an acute inflammatory response, or receiving medications such as opioids and this is the cause of perioperative hyponatremia and water intoxication. To address this problem, they recommended infusing 10 mL/kg/h isotonic solution for each hour for 2–4 h (except for those with cardiac or renal failure) after induction of anesthesia to re-establish euvolemia and downregulate the antidiuretic hormone.<sup>275</sup>

## Blood Transfusion Therapy

Initial blood loss may be replaced with balanced salt solution at a rate of 3 mL of solution for every 1 mL of blood loss. For third-space losses, the replacement volume is based on the severity of the losses: 1 to 2 mL/kg/hr for minor surgery, 2 to 5 mL/kg/hr for moderate surgery, and 6 to 10 mL/kg/hr for major surgery and large third-space losses.

Although most pediatric surgeons are careful to minimize bleeding during surgery, it is important to remain vigilant regarding all blood loss during surgery. For procedures that are likely to result in significant tissue trauma or blood loss, appropriate size IV access must be provided for transfusion of the blood and blood products needed for volume replacement. Packed red cells cannot be rapidly infused through either 24-gauge IV catheters or most peripherally inserted central catheters. A 22-gauge catheter is the smallest IV cannula through which blood can be infused rapidly. Every effort should be expended to insert the largest IV catheter that the child's veins will accommodate. This replacement, together with the maintenance requirement, should be logged on the anesthetic record. As the combined volume of balanced salt solution approaches 75 to 100 mL/kg, it is important to consider the possibility of dilutional thrombocytopenia and dilution of coagulation factors; coagulation indices should be measured at this time.

The threshold for initiating packed RBC transfusions in children has undergone a renaissance in the past decade as evidence that the outcome and complications associated with a transfusion threshold of 7 g% hemoglobin is similar to that of 9 g%.<sup>276</sup>

The estimated blood volume in children decreases with increasing age from 95 to 100 mL/kg in premature infants to 70 mL/kg in adults.<sup>276</sup> Note that the estimated blood volume of obese children is reduced 10% from that of nonobese children of similar age. To estimate the allowable blood loss during surgery, the following equation is used<sup>277</sup>:

$$\text{Maximum allowable blood loss} = \frac{(\text{starting Hct} - \text{target Hct})}{(\text{starting Hct})} \quad (43-3)$$

Some modify Eq. 3 and replace the “starting Hct” in the denominator with

the “average Hct.” This increases the allowable blood loss before transfusion. Irrespective of which equation is used, the actual Hct should be determined before initiating blood transfusion to ensure that the Hct has actually decreased to the desired level. When initiating a blood transfusion in a child, two formulae provide rough estimates of the amount of blood required to increase the hemoglobin concentration by 1 g%: 4 to 5 mL/kg packed cells and 6 mL/kg whole blood.<sup>276</sup> Massive transfusion protocols have also been developed for children and may be accessed at <http://pediatrictraumasociety.org/multimedia/files/clinical-resources/MTP-3.pdf> (accessed January 15, 2017).

## **10** *Prophylaxis for Postoperative Vomiting*

The incidence of POV in children depends on a number of factors that relate to the child (motion sickness history, age), the anesthetic (inhalational anesthetics, nitrous oxide [in specific instances], opioids), perioperative oral fluid ingestion, and the type of surgery (inguinal/orchidopexy, tonsillectomy and adenoidectomy, strabismus, and middle ear surgery).<sup>278</sup>

To reduce PONV after elective surgery, children should be fasted for brief periods and not forced to drink oral fluids postoperatively until they request them (to reduce the risk of vomiting).<sup>279</sup> Intraoperatively, IV fluids should be aggressively administered 20 to 30 mL/kg to reduce PONV.<sup>280</sup> Pain should be controlled using regional anesthesia and NSAIDs or ketamine; opioids should be used only if necessary. If the child is scheduled for emetogenic surgery or has a history of POV, the optimal anesthetic regimen recommended is propofol oxygen/air and two antiemetics, although conflicting evidence exists regarding the role of substituting propofol and nitrous oxide in PONV.<sup>281,282</sup>

The optimal prophylactic antiemetic strategy to administer to children during anesthesia is dexamethasone and a 5-HT<sub>3</sub> receptor antagonist, such as ondansetron.<sup>283</sup> There is no dose–response relationship for dexamethasone: doses between 0.0625 and 1 mg/kg are equally effective, although this author limits the maximum dose to 10 mg.<sup>284</sup> The dose of ondansetron for prophylaxis in children is 0.05 to 0.15 mg/kg.

Although a single study suggested that dexamethasone increases the incidence of postoperative tonsil bleeding, their results are inconsistent with the author’s experience and the subsequent literature.<sup>285,286</sup> A single dose of glucocorticoids has been associated with several reports of tumor lysis syndrome in patients with undiagnosed acute lymphoblastic lymphoma, a very rare but potentially fatal outcome if unrecognized.<sup>217</sup> A single dose of dexamethasone has also been associated with a transient increase in serum glucose concentration that peaked at 2 hours postoperatively, in obese adults with poorly controlled type 2 diabetes. Data in children have not been

forthcoming.

## ***Regional Anesthesia and Pain Management***

There are numerous regional blocks that may be performed to reduce nociception during and after surgery. Three common neuroaxial blocks performed in children today are caudal, epidural, and spinal blocks and these are described later. There has been a shift from neuroaxial to peripheral nerve blocks, both single-dose and continuous local anesthetic administration for perioperative pain management facilitated by the introduction of ultrasound guidance. Morbidity and mortality associated with regional anesthesia in children is exceedingly small and is not considered a substantive argument against its routine use in skilled hands.

### **Caudal Blockade**

This block is useful for both lower abdominal and lower extremity surgeries in infants and children (<5 to 6 years) who are undergoing ambulatory surgery. It is usually performed under general anesthesia although in neonates, awake caudal and spinal blocks have been performed using local anesthetic infiltration and/or sedation. Single-shot caudal blocks with local anesthetic alone are commonly performed in ambulatory surgery. These blocks may last 4 to 6 hours, but if adjuvant medications are added, they may last even longer.

After induction of anesthesia and once that airway is secured, the child is turned onto the lateral decubitus (the side is determined by the anesthesiologist; left-handed anesthesiologists generally prefer the right lateral decubitus position for the child), and the key anatomic sites on the sacrum are palpated: posterior superior iliac spines and the sacral hiatus subtended by the two sacral cornua (see also [Chapter 42](#), Caudal Block section). The sacrococcygeal ligament traverses the space between the two cornua and the coccyx. The skin is then prepared with antiseptic solution and allowed to dry while local anesthetic is prepared. Once the drug has been prepared, the skin site is cut with a blunt needle (to prevent the transfer of epidermis to the caudal space) and the IV catheter (22 gauge for those  $\leq 2$  years or 20 gauge for  $> 2$  years) is passed through the subcutaneous tissue and between or just caudal to the level of the two cornua at a 45-degree angle to the skin. Once the sacrococcygeal ligament has been pierced, the cannula is laid almost flat against the skin (forming a 10-degree angle of the skin) and advanced 2 to 3 mm through the ligament. At that point, the catheter is slipped off the needle and advanced 2 to 3 mm. If any resistance is felt as the catheter is inserted, it is not within the caudal space and the entire cannula

should be removed and the process repeated. If you are not certain the catheter is in the caudal canal, hold your thumb over the sacral hiatus and inject no more than 0.5 mL. If resistance or a bulge is felt, desist from injecting fluid; subcutaneous fluid will obscure the anatomy and preclude a successful caudal block. If the catheter is properly positioned, then remove the needle and examine for blood or cerebrospinal fluid leaking out the catheter. Do not apply negative pressure to the catheter as veins collapse easily. Connect the syringe with local anesthetic and inject slowly 2 to 3 mL every 2 minutes, while observing the electrocardiogram. Peak T waves and an increased ST segment are sensitive indicators of an inadvertent intravascular injection during inhalational anesthesia, although blood pressure increases are more sensitive during TIVA.<sup>287</sup> Once the injection is complete, remove the catheter, clean the caudal skin area, and position the child for surgery.

This author prefers to administer 1 mL/kg bupivacaine 0.175% with epinephrine (1:250,000) for all surgical procedures as a single-shot caudal block. This concentration may be prepared by combining 7 mL of 0.25% bupivacaine with 3 mL of saline to give a total volume of 10 mL. This concentration permits excellent analgesic with motor blockade that resolves within 1 hour of placement. Others use ropivacaine 1 mL/kg of 0.2% or levobupivacaine 1 mL/kg of 0.15%, although a comparative study of 0.2% ropivacaine, levobupivacaine, or bupivacaine concluded that the latter two local anesthetics were more effective than the first. Adjunctive medications have been used to prolong the duration of the caudal block for several hours at best.<sup>111,288</sup>

If a continuous caudal block is planned for the child remaining in hospital for a period, then an 18-ga IV catheter should be used to facilitate passage of a 21-ga epidural catheter. The catheter is inserted exactly as described above for caudal blocks and the catheter threaded to the spinal level necessary for perioperative analgesia. The catheter should be taped away from the anus or, alternately, tunneled under the skin to the side opposite the surgery. This reduces the risk of superficial infections at the catheter insertion site. Catheters that are smaller than 21 ga may not thread to the desired dermatome level. Alternative strategies that may be used to achieve the desired level of block include the Tsui approach<sup>289</sup> and inserting the catheter at an intervertebral space closer to the level of surgery.

Local anesthetics may be infused continuously epidurally for up to 3 days. In infants and young children, 0.2 to 0.4 mg/kg/hr bupivacaine may be administered using 0.3 mL/kg/hr of a 0.1% bupivacaine solution.<sup>290</sup> In older children, 0.4 to 0.5 mg/kg/hr may be administered using 0.3 mL/kg/hr of a 0.1% or 0.125% bupivacaine solution. In neonates 0.2 mg/kg/hr bupivacaine solution may be infused for 3 days as 0.2 mL/kg/hr of a 0.1% solution. To reduce absorption of local anesthetic, epinephrine is routinely added to the

bupivacaine. Fentanyl (1 to 2 µg/mL) is often added to the caudal/epidural solution, although there is no evidence that this improves the quality of the block in children provided the tip of the catheter is properly positioned, 0.2 to 0.3 mL/kg/hr volume of local anesthetic is administered, and at least 0.1% bupivacaine or its equivalent concentration of local anesthetic is used.<sup>147</sup> The addition of fentanyl to the epidural solution yields side effects that include urinary retention, pruritus, nausea, and vomiting. In the case of levobupivacaine, a large study demonstrated no demonstrable benefit from the addition of fentanyl to epidural levobupivacaine in concentrations as small as 0.0625%.<sup>147</sup> Ropivacaine is also suited for continuous epidural infusion for perioperative analgesia using a 0.2% concentration at 0.1 mL/kg/hr for infants under 6 months of age and 0.2 mL/kg/hr for infants above 6 months of age and children, for up to 72 hours.<sup>291</sup>

Careful attention must be paid to the dose of the local anesthetic (although ropivacaine and levobupivacaine are several fold less cardiotoxic than bupivacaine) in infants and children as toxic blood concentrations may cause ventricular fibrillation and cardiac arrest, which, in the case of bupivacaine, is very difficult to successfully resuscitate. The most effective treatment for ventricular arrhythmias from local anesthetics is 1.5 mL/kg (LBW) IV of 20% Intralipid,<sup>292</sup> repeating the bolus up to twice or by continuous infusion of 0.25 to 0.5 mL/kg/min for up to 10 minutes while monitoring vital signs. [NB. Propofol cannot substitute for Intralipid if the latter is unavailable.] The incidence of complications after caudal/epidural block is small, approximately 1.5:1,000.<sup>293</sup> Postoperatively, each child and parents/guardian should be interviewed daily for the efficacy of the block, side effects, and complications from the caudal/epidural block. Side effects of the block include nausea, vomiting, pruritus, urinary retention if opioids were included, and excessive motor blockade or twitching from local anesthetics. Local infection, fluid leakage, and bleeding at the catheter site are important to recognize and treat as indicated.

Local skin infection at the catheter skin site may appear as red and swollen. These superficial infections do not migrate internally causing epidural abscesses; rather abscesses are due to a bacteremia. In any case, the catheter should be removed and the skin cleansed and dressed.

## **Epidural Block**

Epidural anesthesia is performed in the same manner as in adults except that a shorter 5-cm Tuohy 18G needle is more manageable. The distances from the skin to the dura in infants and children, for example, are much smaller as are the doses.

## Spinal Block

This block is useful in preterm infants and neonates who require lower abdominal superficial surgery (see [Chapter 42](#), Spinal Anesthesia section).

## Emergence and Recovery from Anesthesia

As surgery concludes, recovery of neuromuscular function should be assured by monitoring the twitch response and antagonizing the blockade, and the child should be normothermic before contemplating removing the tracheal tube. Equipment including active suction, a face mask, and a source of oxygen should be immediately available to manage the airway and any complications that may ensue. The trachea may be extubated when the child is either fully awake or deeply anesthetized. Evidence suggests that the advantages and disadvantages of the two techniques are similar, notwithstanding confounding effects by comorbidities and concomitant drugs.<sup>294</sup>

The optimal time to extubate the trachea “awake” requires that the child has sufficiently recovered from anesthesia to support his/her own airway, thus minimizing the risk of adverse airway events. For an awake extubation, the practitioner can follow one of two strategies: either the no-touch technique or direct stimulation. With the no touch technique, emergence from inhalational anesthesia follows three distinct phases: early, middle, and late. The early phase may last for several minutes depending on the anesthetic drugs present and the age of the child. During this phase, the child coughs intermittently, gags, struggles, and moves nonpurposefully. This phase passes relatively quickly as the child continues to emerge from anesthesia. During the second or quiescent phase, the child remains generally unresponsive, becoming apneic, agitated, or even breath-holding, straining, and/or desaturating. Desaturation should be treated immediately with continuous positive pressure airway pressure by dialing the adjustable pressure relief valve close until the SaO<sub>2</sub> is more than 95%. As the child enters the third and final phase of emergence, respiration resumes at a regular rate, purposeful movement begins and the child flexes the hips. As these intensify, the child begins to cough and gag on the tracheal tube, and then grimaces and opens his/her eyes spontaneously. Removing the tracheal tube during either the early or middle phase markedly increases the risk of triggering an adverse airway event (e.g., laryngospasm). It is only once the child is in this third phase of emergence that the practitioners should consider extubating the trachea. As I often say: “if you think it is time to remove the tube, don’t! Leave the tube in situ for another minute (or two) until the child is definitely in the late or third phase of emergence. Complications do not occur from leaving a tube in for an extra minute, they only occur when the tube is removed prematurely.”

With the no touch technique, the child breathes 100% oxygen undisturbed and remains unstimulated until the third and final phase of emergence (as described later). The MAC-awake for tidal sevoflurane concentration in children 2 to 5 years is 0.66% and in 5 to 12 years, 0.45%.<sup>295</sup> This author finds that emergence only begins when the anesthetic concentration is empirically less than 0.3% sevoflurane or less than 0.25% isoflurane, depending on the presence of concomitant medications. As the inhaled concentration decreases below these values, the child opens his/her eyes spontaneously and reaches for the tracheal tube, gags, and grimaces, all of which are consistent with a successful extubation. In the case of infants, flexion of the hips indicates good muscle tone. In contrast, with the direct stimulating technique, the anesthetic concentration decreases toward the same concentrations (sevoflurane <0.3% and isoflurane <0.25%) at which time digital pressure may be applied to the most cephalad portion of the ascending ramus of the mandible, to the condylar process (as described earlier in the jaw thrust maneuver), for 3 to 5 seconds while directing the force toward the frontal hairline.<sup>98</sup> The child becomes highly aroused and gags on the tracheal tube for several seconds, but then falls back to a semiconscious state when the stimulation abates. During this quiescent period, the child may breathe shallowly or breath-hold, but if desaturation occurs, positive pressure ventilation with 100% oxygen must be instituted. When the child resumes coughing and gagging, opens their eyes, their respirations are sustained and regular, and they make purposeful movement (e.g., reaches for the tube), then the trachea may be extubated. Both the no-touch and the direct stimulation strategies provide similar outcomes with safe and protected airways in children in experienced hands.

If the tube has been removed prematurely, breath-holding, upper airway obstruction, and laryngospasm may ensue. The child's face mask should be immediately available in order to deliver 100% oxygen through a tight fit to the face with 100% oxygen and dial 10- to 20-cm H<sub>2</sub>O continuous positive airway pressure on the adjustable pressure limiting valve. To force the child through this "light" phase of anesthesia, pressure should be applied to the condyle of the mandible (see jaw thrust) in 3- to 5-second intermittent applications until the child begins to breathe. If laryngospasm develops, see earlier for treatment.

Deep tracheal extubation requires an organized plan. In order to extubate the trachea deep, the depth of inhalational anesthesia must be at least 1.5 to 2 × MAC. In the case of sevoflurane, this means between 3.6% and 5% end-tidal concentration for at least 10 minutes. Some prefer to inspect the larynx at that time for foreign substances and fluids by performing laryngoscopy. Others gently stimulate the airway by moving the tube slightly up and down. The absence of a response and the continuation of regular respirations

indicate an adequate depth of anesthesia is present to remove the tube. If, however, the child coughs or breath-holds, then either a further period of anesthesia is required before a trial laryngoscopy is attempted or the deep extubation approach is abandoned and the child is awakened.

Appropriate airway equipment should be available to transfer the child once the trachea has been extubated. Either a self-inflating Laerdal bag or a T-piece should be available with a source of oxygen. The nurses who manage these children in PACU must have the skills to manage an intubated airway, emergence from anesthesia, and the airway after tracheal extubation.

In children, the primary focus during emergence from anesthesia is the airway, the child's ability to breathe, and whether the child can protect his/her airway should bleeding or regurgitation occur during or after extubation. It is this author's practice to remove the tracheal tube or LMA when the child has fully recovered airway reflexes and is responsive. There are very few surgical or medical indications to remove the airway during a deep level of anesthesia, although opinion varies on this matter. The concern regarding a deep extubation of the trachea is that a child who is deeply anesthetized and transported with an unsecured airway depends on the expertise of the caregiver in the PACU to manage the airway until that child awakens. If the anesthesiologist must return to the operating room and if there is no physician assigned to PACU, then the caregivers may have inadequate backup should an airway emergency arise.

The timing of removing the LMA, either awake or during deep anesthesia, in general, does not affect the incidence of upper airway adverse events. However, the presence of a URTI, specific anesthetics (e.g., desflurane, isoflurane ~ halothane, sevoflurane), and specific surgeries (e.g., airway surgery) increase the risk of perioperative airway events. When the LMA has been removed during deep anesthesia, upper airway reflex responses may only develop when the child begins to emerge from anesthesia, in the PACU. To avoid this potential problem, this author recommends that all LMAs be removed when the children are awake and only then should they be transferred to PACU.

In the vast majority of children, emergence from anesthesia progresses smoothly as described earlier. However, children who do not emerge from anesthesia in a timely fashion must be assessed for possible causes for delayed emergence from anesthesia ([Table 43-14](#)). The most common causes of delayed emergence include drug overdoses, increased sensitivity to drugs (e.g., OSA and opioid sensitivity), failure to taper or reduce the dose of inhalational or IV anesthetic, or the presence of hypothermia. Other, less frequent but potentially catastrophic events should also be considered including hypoglycemia, increased intracranial pressure, and metabolic causes including hyponatremia.

A rare but potentially fatal arrhythmia may develop during emergence in a child with an undiagnosed congenital long QT syndrome.<sup>56</sup> Administering medications (such as 5-HT<sub>3</sub> receptor antagonists) that are known to prolong the QT interval and in the presence of factors known to trigger torsades de pointes may suddenly trigger the arrhythmia.<sup>296</sup> Treatment with IV lidocaine (1 to 2 mg/kg), magnesium (15 to 30 mg/kg), and/or shock may be necessary to convert to sinus rhythm.

## Transport to PACU

Transferring children from the operating room to the PACU requires a stable airway, adequate oxygenation and ventilation, stable heart rate and blood pressure, and adequate pain control. The child must be accompanied by an expert who has been trained to diagnose and manage postoperative problems, most notably airway obstruction.

Most children are transported to PACU without an artificial airway, breathing spontaneously. The optimal position for transfer of a child after surgery is the lateral decubitus position, known as the “recovery position.”<sup>297</sup> In this position, the upper leg is flexed at the hip and resting on the bed in front of the lower leg. The child’s upper hand should be placed under his lower cheek (Fig. 43-7). This position facilitates drainage of secretions, blood, or vomitus out of the mouth rather than onto the larynx, and the tongue falls to the lower cheek or out of the mouth rather than posteriorly onto the larynx. This position permits direct airway monitoring and intervention should the need arise.

**Table 43-14** Causes of Delayed Emergence from Anesthesia in Children

**Figure 43-7** Position of the child after tracheal extubation in preparation for transfer to PACU and the pediatric ICU. This is known as the “recovery position” with the child lying in the lateral decubitus position, neck extended and mouth opened. In this position, oropharyngeal secretions, blood, or vomitus will drain onto the gurney rather than collect in the parapharyngeal region and trigger upper airway reflex responses.

Supplemental oxygen may be administered by nasal prongs or face mask during transport to the PACU to prevent desaturation during the transport. However, in the absence of nitrous oxide and in children whose lungs are normal, the most common reason for desaturation during transport is upper airway obstruction, an emergency that is difficult to detect by pulse oximetry when supplemental oxygen is administered. The reason for this difficulty is that the large reserve of oxygen maintains the oxygen desaturation several minutes even in the presence of complete airway obstruction or hypopnea. Therefore, this author places the child in the recovery position, extends the child’s neck with the base of his hand (thenar and hypothenar eminences) and positions his fingertips over the mouth/nose to feel the warm temperature in the exhaled gases to monitor respiration (but never closes the child’s mouth).

Transporting the recovering child in the supine position predisposes to airway obstruction from posterior displacement of the tongue and facilitates the accumulation of secretions or other fluids in the supraglottic region. Furthermore, opioids depress the hypoglossal motor nuclei centrally, which relaxes the genioglossus muscle allowing the tongue to fall back and potentially obstruct the airway in the supine position.<sup>298</sup>

## **PACU Complications**

Approximately 5% of children have complications in the PACU,<sup>299</sup> with 77% from vomiting, 22% from respiratory causes, and 1% or less from cardiac causes. The age distribution of the complications showed that children above

8 years of age vomited more than twice as frequently as those under 8 years, whereas respiratory complications in infants under 1 year of age occurred twice as frequently as in those above 1 year of age.

### **Laryngospasm, Postoperative Stridor, and Negative Pressure Pulmonary Edema**

Laryngospasm, postoperative stridor, and negative pressure pulmonary edema occur both during induction of anesthesia and during or after emergence from anesthesia. Factors that increase the risk of laryngospasm are enumerated in [Table 43-12](#).

Postextubation stridor may also occur after tracheal extubation. Stridor usually results from the epithelium within the cricoid ring swelling after the tracheal tube is removed. The swelling reduces the internal cross-sectional diameter of the cricoid ring and increases the pressure gradient (and therefore work of breathing) across the ring. Because airflow in the upper airway is turbulent, the resistance to air flow increases as the fifth power of the radius of the cricoid ring decreases. That is, if the radius of the airway within the cricoid ring decreases by 50%, the resistance to airflow increases 32-fold (based on the Fanning equation). In infants with increased oxygen requirements and metabolic rates, residual opioids, muscle weakness, and anesthesia may further compromise their ability to maintain an increased work of breathing during stridor, which could hasten fatigue and respiratory failure. Postextubation stridor is more common in Down syndrome and children with recent URTIs. Treatment for stridor includes humidified oxygen, sitting the child upright, reassurance, light sedation, IV dexamethasone (0.6 mg/kg IV), and nebulized racemic epinephrine (0.5 mL epinephrine in 2 mL saline). Heliox has been effective in reducing the work of breathing, oxygen consumption, and distress although it limits the inspired oxygen fraction. If hypoxemia or respiratory failure occurs, the trachea should be reintubated with a smaller size tube than the one originally used. To avoid further irritating the epithelium, an audible leak should be present after intubation. If a racemic epinephrine treatment is repeated more than twice, the child should be observed for rebound edema in either the PACU or a monitored unit.

Negative pressure pulmonary edema or postextubation pulmonary edema is an infrequent complication that usually occurs immediately or within several minutes after tracheal extubation in healthy, muscular adolescents and young adults, although it has been reported in infants.<sup>300</sup> Shortly after the trachea is extubated, the airway may become increasingly obstructed while the child appears somnolent and unresponsive. The presumptive diagnosis is laryngospasm, which may range in severity from very mild (i.e., hiccups) to severe. Ventilation by mask with 100% oxygen

may be ineffective in restoring vital signs, necessitating tracheal reintubation using propofol and a muscle relaxant. As soon as the tube passes the vocal cords, pink frothy pulmonary edema fluid may appear in the tube or appear upon suctioning the tube. SaO<sub>2</sub> can be restored to more than 94% using positive pressure ventilation with positive end-expiratory pressure and 100% oxygen. Tracheal intubation and positive pressure ventilation are usually sufficient to resolve the pulmonary edema although in some instances, IV furosemide may be required. In a dose of 0.5 to 1 mg/kg, furosemide venodilates the vasculature rapidly resolving the pulmonary congestion and improving oxygenation. Although some may recover from the pulmonary edema very rapidly, others require sedation and tracheal intubation for 12 to 24 hours or more, until the pulmonary edema resolves.

### *Oxygen Desaturation*

Failure to maintain adequate SaO<sub>2</sub> in the recovery room is a common problem. Unrecognized hypoxia may lead to deterioration in the child's clinical status and lead to sudden bradycardia and cardiac arrest. Continuous monitoring of the child's SaO<sub>2</sub> in the PACU is essential to provide an early warning sign of respiratory distress. The minimum acceptable SaO<sub>2</sub> in PACU is 94%. Administration of oxygen by face mask may be required to maintain the SaO<sub>2</sub>, particularly if residual anesthesia or opioids and/or a craniofacial or muscular abnormality is present, or the child is obese or fluid overloaded. In healthy children, oxygen desaturation in PACU is generally indicative of hypoventilation and/or airway obstruction. Because there is no means of assessing ventilation in children in the PACU who do not have artificial airways, we must rely on clinical signs to quickly diagnose and treat airway obstruction and hypoventilation before complications develop.

Children should be weaned from oxygen dependency (assuming they did not require supplemental oxygen preoperatively) before they are discharged to the floor or the step-down unit. Some children remove their face masks themselves when they awake from anesthesia; if their SaO<sub>2</sub> is 94% or more while breathing room air, then no additional oxygen is required. If the SaO<sub>2</sub> is maintained with a face mask, then the oxygen supply can be weaned to nasal prongs and then to room air provided the SaO<sub>2</sub> is maintained at each stage. If the child cannot maintain his/her SaO<sub>2</sub> despite weaning attempts, further investigation may be required (such as a chest x-ray) to rule out aspiration, pneumonia, or pneumothorax.

### *Emergence Delirium*

The introduction of sevoflurane and desflurane anesthesia in children has

caused a recrudescence of emergence agitation (also known as emergence delirium) during recovery from anesthesia. ED, with a prevalence of 20% to 80%, has a peak incidence in children (of both sexes) at 2 to 6 years of age, is more common after certain anesthetics (sevoflurane ~ desflurane ~ isoflurane > halothane ~ TIVA), lasts 10 to 15 minutes, and is terminated either spontaneously or after an IV dose of propofol, midazolam, clonidine, dexmedetomidine, ketamine, opioids, or a host of other medications.<sup>301</sup>

The diagnosis of ED in children has proven difficult for several reasons. First, the presence of pain has proved to be a significant confounding variable in establishing the diagnosis. When ED was assessed in children undergoing MRI with either sevoflurane or halothane, the incidence of ED after sevoflurane was fivefold greater than it was after halothane.<sup>302</sup> Second, the diagnosis of ED has been a challenge without a validated scale. To address this difficulty, we developed the pediatric anesthesia emergence delirium (PAED) score and validated it as an objective measure of ED; a score above 10 or, more recently, above 12 is considered strongly indicative of ED.<sup>303</sup>

## Vomiting

The frequency of vomiting in the PACU and after hospital discharge has decreased dramatically with the introduction of prophylactic antiemetics for children at risk for PONV. Prophylaxis for PONV is recommended for surgeries with the greatest incidence of vomiting: hernia, orchidopexy, tonsillectomy and adenoidectomy, ear surgery, strabismus surgery, and laparoscopic surgery. The incidence of vomiting increases with increasing age, peaking in females 10 to 16 years.<sup>278</sup> IV dexamethasone (0.0625 to 0.15 mg/kg (maximum 10 mg) and ondansetron (0.05 to 0.15 mg/kg) reduce the perioperative incidence of PONV by up to 80% or more.<sup>283</sup> In fact, few children vomit in the PACU; most children who vomit do so after ingesting their first fluids on the ward, in the car on the way home, or at home. Hence, we administer large volumes of IV fluids intraoperatively and in PACU (total 10 to 40 mL/kg over 1–4 h) and recommend oral fluids only when the child requests to drink.<sup>279,280</sup> If the child continues to vomit, there is no magic solution. First, oral fluids should be withheld and IV access should be maintained or restarted and IV balanced salt solution administered. Second, if the child has either the ultrarapid polymorphism of CYP450 2D6 or a polymorphism of adenosine triphosphate-binding cassette subfamily B member 1 (ABCB1) non-TT type (e.g., 2677 or 3435 non-TT type) or both, then ondansetron may be ineffective.<sup>304</sup> Rapid assays are not available for these polymorphisms so we can only speculate as to the reasons for the vomiting. A second dose of ondansetron (0.1 mg/kg) may be given if at least 2 hours have passed since the first dose or IV metoclopramide (0.15 mg/kg)

may be given.

## Postoperative Pain

Management of pain in the PACU and on the ward depends on the origin of the pain, its severity, the medications already administered, and the status of the child. Regional anesthesia with neuroaxial or local blocks (penile, iliohypogastric/ilioinguinal or popliteal nerve blocks) may be used. Regional anesthesia is usually performed during general anesthesia in children (except in older adolescents) using either a direct nerve block or nerve stimulation or more recently ultrasound guidance.<sup>305</sup> When regional block is unsuitable, impractical, contraindicated, or refused by the parents, opioids, NSAID agents (diclofenac, tramadol, ibuprofen, and acetaminophen), and ketamine may be employed (see earlier).<sup>306</sup>

Continuous morphine infusions have been used to manage pain in children.<sup>145</sup> Morphine infusions may be prepared by dissolving the child's weight as milligram of morphine in 100 mL of saline and infused at 1 to 3 mL/hr. These children are best monitored continuously using pulse oximetry.

To tailor the morphine dose to the severity of the pain, patient-controlled analgesia (PCA) was developed for which the patient received morphine upon demand as well continuously for background pain, if needed. PCA has been shown to be effective in children as young as 5 years. For those under 5 years of age and those who are cognitively impaired, caregivers and parents who were educated regarding the use of PCAs have been very effective in controlling the children's pain.<sup>307</sup> A typical morphine PCA may be programmed for a child as follows: PCA bolus 10 to 30 µg/kg; continuous rate of 10 to 40 µg/kg/hr (or in children at risk of apnea, 0 µg/kg/hr); lockout interval 6 to 10 minutes; and a 4-hour limit of 0.25 to 0.4 mg/kg.<sup>145</sup> Smaller doses and background infusions of PCA morphine are used in infants.<sup>145,308</sup> Dilaudid (hydromorphone), which is three- to fivefold more potent than morphine, may be used in place of morphine. The attending nurse should routinely monitor the child's pain and if the pain is not adequately controlled, the pump settings should be reviewed and adjusted accordingly.

#### Postoperative Management

## Conclusion

### KEY POINTS

- 1 Small incisions, decreased postoperative pain, and lower surgical complication rates are some of the benefits of laparoscopy over laparotomy.
- 2 Pneumoperitoneum- and position-related physiologic changes are a significant disadvantage, to the anesthesiologist.
- 3 Risk of perioperative complications may be significant in patients with body mass index  $> 40 \text{ kg/m}^2$  and obesity-related comorbidities.
- 4 Advances in robotic-assisted laparoscopic surgery have expanded its application to multiple subspecialties.
- 5 Access to the patient during robotic-assisted surgery may be seriously limited during an intraoperative cardiopulmonary or airway emergency.
- 6 Severe hypercarbia and acidosis from absorbed carbon dioxide can lead to reduced inotropy, dysrhythmias, and arterial vasodilation.
- 7 High intra-abdominal pressures during hypovolemia can severely impair venous return and cardiac filling.
- 8 Endobronchial intubation can occur during diaphragmatic displacement into the thorax and Trendelenburg positioning.
- 9 Renal blood flow, glomerular filtration, and urine output are reduced during pneumoperitoneum.
- 10 The assessment of neuromuscular blockade during laparoscopic surgery remains highly subjective.
- 11 Major vascular injuries occur rarely during abdominal entry and are associated with significant morbidity and mortality.
- 12 Severe hypotension during pneumoperitoneum should be treated with deinsufflation, and possible conversion to an open procedure.
- 13 Risk factors for complications of subcutaneous emphysema include operative times more than 200 minutes, lower BMI, high intra-abdominal pressure, and Nissen fundoplication surgery.
- 14 Tension capnothorax is a life-threatening condition that requires a high index of suspicion and immediate action from the operating room team.
- 15 Perioperative use of preemptive multimodal strategies and postoperative nausea and vomiting prophylaxis are integral components for optimal patient recovery after laparoscopic surgery.

## Introduction

Over a century ago, laparoscopy was first introduced as a therapeutic alternative to laparotomy. Since then, the field of laparoscopic surgery has evolved and grown tremendously, to the extent that it has now become a conventional approach for many surgical diseases traditionally treated with open procedures. In fact, laparoscopy is now the gold standard approach for cholecystectomy and bariatric surgery. The growth of the specialty has been fueled, in large part, by the benefits of “minimally invasive” surgery (Table 1 44-1). Improved surgical cosmesis, reduced postoperative pain, faster return to work, and lower surgical-related complications continue to make laparoscopy, in many cases, preferable to open surgery.<sup>1-4</sup> Advances in anesthesia have also facilitated the expansion of laparoscopy into noninpatient facilities. Today, a large number of surgeries that once required prolonged hospital stays are now performed in outpatient surgery centers and short-stay facilities.<sup>5-9</sup> The creation of protocolized, fast-track programs that maximize the benefits of minimally invasive surgery has improved surgical outcomes and reduced health-care costs.<sup>10</sup>

Despite its outcome advantages, the practice of traditional laparoscopic surgery has been fraught with technical challenges for the surgeon, derived from the act of operating through small access ports, using long rigid surgical instruments—all while having a limited sense of pressure and depth. Technological advances have now introduced robotics to laparoscopic surgery to address many of its technical issues that affect all laparoscopic surgeons. Robotic-assisted laparoscopic surgery provides surgeons with a close approximation of the fine motor skills and depth of vision used in traditional open surgery, all while positioned comfortably away from the patient’s bedside.

Disadvantages exist in laparoscopy for patients and medical providers alike (Table 44-2). A significant source of intraoperative and postoperative issues during laparoscopy stems from the creation of pneumoperitoneum. 2 Physiologic derangements, particularly affecting the cardiopulmonary system, are common during pneumoperitoneum, and are further aggravated by steep positioning changes common in laparoscopy. A patient’s age and comorbidities can greatly affect the severity of pneumoperitoneum-related changes observed by clinicians. In robotic surgery, long operative time and limited access to the patient, due to prominent robotic equipment, can further complicate management of urgent conditions. As the application of laparoscopy and robotic-assisted surgery continues to expand to more complex patients and diseases, the anesthetist must be increasingly attentive to avoid or minimize serious patient harm.

In this chapter, a general overview is provided regarding the anesthetic management of laparoscopic and robotic-assisted surgery for the adult patient undergoing abdominal and pelvic exploration. For additional discussion on

their application in other areas of surgery, we refer the reader to other relevant chapters within this textbook.

## Laparoscopic Surgery

### *Surgical Approach and Positioning*

Laparoscopic surgery is a minimally invasive surgical technique where specialized tubes are inserted for surgical access. Small skin incisions are made, approximately 1 cm in length, to facilitate insertion of rigid tubes, called trocars. Trocars are sharp, multiport, one-way conduits used to insufflate gas and to guide various specialized surgical instruments. Intraperitoneal viewing is conducted using a video-capable telescopic camera, called a laparoscope. 

Exposure of the intraperitoneal space can be achieved either by intraperitoneal pressurization, called pneumoperitoneum, or by external abdominal wall retraction.

Conventional laparoscopy uses carbon dioxide (CO<sub>2</sub>) for intraperitoneal (e.g., bariatric and cholecystectomy surgery) and extraperitoneal insufflation (e.g., adrenal and inguinal hernia repair surgery). In contrast to other insufflation gases, such as helium and nitrous oxide, CO<sub>2</sub> has a desirable safety profile. CO<sub>2</sub> is highly soluble in blood, facilitating rapid pulmonary removal and minimizing the consequences of inadvertent extraperitoneal or intravascular insufflation. CO<sub>2</sub> is nonflammable, nonoxidizing, and safe to use during electrocautery. Despite its safety profile, CO<sub>2</sub> insufflation has known side effects discussed in subsequent sections of this chapter. 

Intraperitoneal insufflation is generally established by creating a small subumbilical incision, through which a stainless steel, spring-loaded, blunt needle, called a Veress needle, is inserted. An automated, self-regulating insufflator with adjustable preset parameters is connected to the Veress stopcock to deliver low-flow rates of CO<sub>2</sub> until adequate abdominal distention is achieved. Maximal preset intra-abdominal pressures (IAP) above 15 mmHg should be avoided as to minimize CO<sub>2</sub>-related complications and significant cardiopulmonary instability. The Veress needle is replaced with a trocar for laparoscope insertion. Several other incisions are then made through which trocars are sequentially inserted under direct laparoscope visualization and transillumination to avoid inadvertent intra-abdominal injury. The surgery is conducted using a laparoscope for video monitoring, and various long, handheld surgical instruments. If the surgeon's hand is needed for intra-abdominal tissue manipulation or large specimen extraction during laparoscopic surgery, a larger surgical access can be provided for a

laparoscopic hand-assisted approach. A single 5- to 7.5-cm abdominal wall opening is made for insertion of a flexible, self-retaining, circular sleeve used for intra-abdominal hand insertion.

**Table 44-1** Benefits of Laparoscopic Surgery

Patient-specific	Surgeon-specific	Anesthesiologist-specific
Improved cosmetic results	↓Medical risk	↓Incisional stress response
Shorter recovery time	Better clinical outcomes	↓Opioid requirements
Earlier return to work	Earlier return of bowel function	↓Postoperative pain
Faster return to normal activities	↓Postoperative complications	↓Fluid shifts
↓Costs		↓Postoperative respiratory dysfunction

**Table 44-2** Disadvantages of Laparoscopy Surgery

Patient-specific	Surgeon-specific	Anesthesiologist-specific
↑Risk of PONV	Highly-specialized training	Pneumoperitoneum-induced stress response
Referred pain from CO <sub>2</sub> insufflation	Ergonomics	Positioning
	Limited tactile sense	Mechanical ventilatory challenges
	Longer operating times	Extraperitoneal CO <sub>2</sub> -related complications
	Complex equipment and setup	Limited access to patient (robotic surgery)
	Use in reoperation or scar tissue more challenging	

As an alternative to CO<sub>2</sub> pneumoperitoneum, exposure of the intraperitoneal space can be achieved by external abdominal wall retraction, called abdominal wall lift. This technique requires a specialized horizontal lifting apparatus inserted into the abdominal wall for suspension of the anterior abdominal wall away from the abdominal viscera. Gas insufflation is, usually not necessary. Despite the benefits of avoiding gas insufflation and its side effects, abdominal wall lift is generally believed to be inferior to pneumoperitoneum laparoscopy due to longer operative times and an unclear safety profile.<sup>11,12</sup>

Patient positioning during laparoscopic surgery is uniquely affected by several aspects. Long, rigid laparoscopic instruments facilitate minimal access, but limit the ease of tissue manipulation. Bed tilting is usually needed to passively optimize surgical exposure with minimal surgical retraction. Steep, reverse Trendelenburg position (i.e., “head up”) exposes upper abdominal structures, such as in gastric bypass surgery. Steep Trendelenburg position (i.e., “head down”) is used to expose lower abdominal structures, such as in uterine or prostate surgery. The lateral jackknife position is used to expose the retroperitoneal space during radical nephrectomy surgery. Leftward tilting exposes the appendix, whereas rightward tilting exposes the left colon. The addition of lithotomy is dependent on the need for genital, urologic access. An in-depth discussion on patient positioning and potential injuries is discussed elsewhere (see [Chapter 29](#)).

## Ambulatory Laparoscopic Surgery

Laparoscopic surgery performed as day or outpatient surgery has a long history that continues to grow. The earliest reports of outpatient laparoscopy date back to the 1970s, when it was first used in gynecological surgeries.<sup>13</sup> Female sterilization entailed some of the first outpatient surgeries performed with minimal reported complications and low readmission rates.<sup>14,15</sup> Since then, general surgical procedures have surpassed all other outpatient laparoscopic surgery performed worldwide. Laparoscopic cholecystectomy for symptomatic cholelithiasis is now the most commonly performed outpatient laparoscopic surgery. Its safety and dependability has been well established.<sup>5,6</sup> When comparing outpatient versus overnight admission for laparoscopic cholecystectomy, day surgery has been shown to be equally safe with similar pain scores and recovery times.<sup>16</sup>

Ambulatory laparoscopic surgery is also being performed in the bariatric population with increasing frequency. Common laparoscopic weight loss procedures include gastric bypass, sleeve gastrectomy, and adjustable gastric band. Due to its low rates of complications, and readmissions, and predictably short operative time, gastric banding is the most commonly performed outpatient bariatric surgery.<sup>8,17</sup>

The expansion of sleeve gastrectomy and, particularly, gastric bypass into the ambulatory setting, is in large part due to advancements in minimally invasive surgery, patient screening and anesthetic management. Nonetheless, postoperative complications, unanticipated admissions, and readmission rates for these procedures remain concerns for suitability and safety. Based on a comprehensive retrospective review of ambulatory laparoscopic gastric bypass surgery, unplanned admission and readmission rates were 16% and 1.82%, respectively.<sup>9</sup> Causes for unanticipated readmission in both gastric bypass and sleeve gastrectomy surgery include dysphagia, nausea, and uncontrolled pain. More serious complications include unexpected gastric leaks after sleeve gastrectomy, gastrointestinal bleeding, and pulmonary embolism.<sup>9,18,19</sup>

Appropriate patient presurgical screening is ideal for optimizing good surgical results and avoiding unexpected complications. Assessing the body mass index (BMI) and severity of obesity-related comorbidities is important for preoperative risk stratification. Patients with a BMI of less than 40 **3** kg/m<sup>2</sup> and well-optimized comorbid conditions, such as type II diabetes, heart disease, and obstructive sleep apnea, may have acceptable risk for ambulatory surgery. Concerns for greater risk of perioperative complications exist for patients with BMI greater than 40 kg/m<sup>2</sup> and poorly managed obesity-related comorbidities. Ultimately, well-supported recommendations for weight limits in obese patients being screened for ambulatory surgery are

lacking, and may only be based on expert opinion.<sup>19</sup>

Other laparoscopic surgeries routinely performed in an outpatient setting include several general surgical and gynecological procedures, such as inguinal or ventral hernia repair, diagnostic laparoscopy, ovarian cystectomy, and endometrial laser ablation.

An in-depth review on the practice of ambulatory anesthesia (see [Chapter 31](#)) and anesthesia in obesity are presented elsewhere (see [Chapter 45](#)).

## Robotic Laparoscopic Surgery

Robotic laparoscopic surgery is a highly sophisticated, technologic variation on conventional laparoscopic surgery, requiring modification of both surgical and anesthetic management.<sup>1,3,4</sup> The approach was developed to address several limitations of conventional laparoscopy, including reduced range of motion and instrument dexterity, and a two-dimensional view of the operative field. The advanced technology has transformed technically challenging procedures into feasible ones via a minimally invasive approach. Although it was first popularized in urology for radical prostatectomies, **4** robotic-assisted surgery has since gained ground in other fields, in part, due to reports of improved surgical outcomes, lower complication rates, shortened lengths of hospital stay, and improved surgeon ergonomics. It currently has applications and FDA approval in other types of urological surgeries, general laparoscopic surgeries, general noncardiovascular thoracoscopic surgeries, thoracoscopically-assisted cardiectomy procedures, and may be used with adjunctive mediastinotomy to perform coronary anastomosis during cardiac revascularization ([Table 44-3](#)).

**Table 44-3** Examples of Robotic-assisted Laparoscopic Surgery

<b>Cardiac</b>
Coronary artery bypass, valvuloplasty
<b>Thoracic</b>
Lung resection, esophagectomy
<b>Gastrointestinal</b>
Fundoplication, colectomy, gastrectomy, hepatectomy
<b>Urologic</b>
Radical cystectomy, pyeloplasty, prostatectomy
<b>Gynecologic, Oncologic</b>
Hysterectomy, lymph node dissection, oophorectomy

Robotic surgery is performed most commonly employing the Da Vinci Surgical System (Intuitive Surgical Inc., Sunnyvale, CA) that uses a surgeon control console, a robot cart with interactive surgical arms, and a high-definition (HD) 3D video tower ([Fig. 44-1](#)). Similar to conventional

laparoscopy, robotic laparoscopic surgery entails the creation of a pneumoperitoneum, insertion of a video laparoscope, and insertion of trocars for surgical access. From there, the differences in approach far outweigh their similarities. The surgical robot is positioned near the patient with robotic arms inserted into the insufflated cavity. The robotic arms are controlled remotely by a surgeon seated at an ergonomically designed control console. Remote handling of instruments via a specialized control allows for movements that mimic natural maneuvers, improved degrees of freedom, and optimal surgical instrument rotation and pivoting. Surgical visualization is achieved via a goggle viewfinder with an HD, magnified, 3D video display. An assistant near the surgical field provides surgical support, such as robotic arm adjustments, tissue retraction, and suctioning. Other clinicians in the operating room suite visualize the laparoscopic surgical field using 2D HD video screens.

**5** Anesthetic management during laparoscopic robotic surgery requires preparing for patient accessibility limitations and adjusting for patient positioning challenges. Prominent surgical robotic equipment near the patient can greatly limit anesthesia provider access to the patient in case of an emergency. Though newer surgical robotic systems are becoming more compact, with thinner robotic arms, and improved motorized maneuverability functions for steering and engaging, the robotic systems in use today have a large footprint near and above the operating room bed. In the rare event of an airway or cardiopulmonary emergency, the robotic surgical arms must first be carefully disengaged from the trocars, before the robot can be removed safely and the patient positioned in a manner consistent with that needed for airway management or cardiopulmonary resuscitation, respectively.

**Figure 44-1** Robotic surgery room setup. Surgeon at the console (*left*), robot and patient (*center*), and video tower (*right*).

Steep Trendelenburg positioning used in many robotic surgeries requires greater vigilance of the patient. Ocular injury risk in steep Trendelenburg during robotic surgery may be greater than in conventional laparoscopic

surgery (see Complications Related to Surgery). Robotic arms often extend above the patient's face in this position, increasing the potential risk of both accidental endotracheal tube dislodgement and facial injury. Careful endotracheal tube taping and protective foam padding can be placed on the patient's face for extra security.

## Physiologic Impact of Laparoscopy

Laparoscopic surgery induces complex physiologic changes that impact multiple organ systems. Direct mechanical stress placed on the patient, as well as neuroendocrine stimulation during laparoscopy are the primary forces responsible for much of the physiologic derangement observed. The degree of observed effect is modified by a patient's pre-existing comorbidities, positioning, surgical factors, and anesthetic approach.<sup>20,21</sup> Although physiologic changes during minimally invasive surgery are well tolerated in healthy patients, minimizing complications and optimizing conditions for a successful surgical result, require an understanding of the interplay between physiology and laparoscopic surgery.

### Cardiovascular System

The cardiovascular system is exquisitely challenged during laparoscopy by multiple stressors on preload, inotropy, rhythm, and afterload (Table 44-4). In patients, the cumulative effect is an increase in mean arterial pressure (MAP), myocardial oxygen demand, and systemic vascular resistance (SVR). Modifiable factors that affect hemodynamics during laparoscopy include the intravascular volume status of the patient, positioning, baseline comorbidities, and surgical technique.

Carbon dioxide gas is highly soluble and, during insufflation, rapidly moves from the peritoneal cavity into the circulation. Prolonged surgeries and high insufflation pressures can lead to increased CO<sub>2</sub> gas absorption. Systemic CO<sub>2</sub> gas then exerts both direct and indirect effects on the cardiovascular system via adrenergic pathways. Mild hypercarbia (PaCO<sub>2</sub> of 45 to 50 mmHg) alters hemodynamics very little, whereas severe hypercarbia (PaCO<sub>2</sub> 55 to 70 mmHg) and acidosis can lead to myocardial depression, dysrhythmias from catecholamine-induced myocardial sensitization, and peripheral vasodilation. Further complicating the response of the myocardium to transient hypercarbia is the potential for acute elevations in right ventricular afterload from hypercarbia-induced pulmonary vasoconstriction. The potential hemodynamic effects of severe hypercarbia are counteracted by sympathetic nervous system stimulation during laparoscopy, that concurrently produces tachycardia, an increase in MAP, and vasoconstriction from an

increase in SVR.<sup>21,22</sup>

**Table 44-4** Causes of Hemodynamic Changes during Laparoscopy

Determinants of Blood Pressure in Laparoscopy <sup>a</sup>	Effect on Blood Pressure
<b>Preload (venous return)</b>	
IVC compression	↑ or no change
Intra-abdominal organ compression	↑ or no change
Trendelenburg position	↑
<b>Cardiac output or inotropy<sup>a</sup></b>	
Venous return	↑ or no change
Peripheral Vasoconstriction	↑ or no change
<b>Rhythm (brady- or tachyarrhythmia)<sup>a</sup></b>	
Hypercapnia/acidosis	↑ or no change
Hypoxia	↓ or no change
Peritoneal irritation	↑,↓ or no change
<b>Afterload and MAP<sup>a</sup></b>	
Hypercapnia/acidosis	↑,↓ or no change

<sup>a</sup>Autonomic nervous system stimulation and neurohumoral factors, such as catecholamines, vasopressin, and cortisol, released during laparoscopy contribute to physiologic changes. IVC, inferior vena cava; MAP, mean arterial pressure.

The peritoneum and abdominal viscera are highly innervated by autonomic nerve fibers. Stimulation of these autonomic pathways during pneumoperitoneum, typically results in sympathetic nervous system activation, catecholamine release, activation of the renin–angiotensin system, and release of the neurohypophysial hormone vasopressin.<sup>23</sup> This potent endogenous hormone can cause intense vasoconstriction, an increase in MAP, and increases in left ventricular afterload. Left ventricular wall tension and myocardial work needed to maintain intraventricular pressure and cardiac index (CI), respectively, are raised with significant increases in SVR. Mechanical stretch on the peritoneum and abdominal viscera can result in parasympathetic stimulation through the vagus nerve, but sympathetic tone usually predominates.

Intravascular volume status is an important modifier of the mechanical effects of pneumoperitoneum.<sup>22</sup> In instances where low right atrial pressures reflect low cardiac filling volumes, an increase IAP can result in compression of the inferior vena cava (IVC), causing a decrease in venous return and cardiac filling. However, where high right atrial pressures reflect hypervolemia, and not increased intrathoracic pressures from pneumoperitoneum, the IVC can resist collapse resulting in a rapid but transient increase in venous return<sup>2,3</sup> from splanchnic compression.

Patient positioning can further modify the effects of IAP. Steep Trendelenburg positioning during pneumoperitoneum may augment venous return and cardiac filling.<sup>24</sup> In contrast, reverse Trendelenburg position during

pneumoperitoneum can result in an increase in SVR and minor reductions in CI that are soon reversed.<sup>25</sup> Initiating insufflation while supine and maintaining IAP within the recommended range (12 to 15 mmHg) can minimize any reduction in preload.<sup>20</sup> Nonetheless, extremely high IAP, in addition to hypovolemia, can result in severe compression of the venous system, as well as a perilous reduction in venous return and cardiac filling. **7**

Preoperative comorbidities have varying effects on hemodynamics. Morbidly obese patients undergoing laparoscopic gastric bypass surgery show similar hemodynamic changes as nonbariatric patients. It is hypothesized that the morbidly obese better tolerate insufflation because of an intrinsically elevated IAP at 9 to 10 mmHg compared with nonobese patients.<sup>26</sup> Geriatric patients<sup>21</sup> can generally tolerate minimally invasive surgery. However, complex hemodynamic changes in elderly patients with cardiovascular disease may be significant during pneumoperitoneum, despite a lack of observable myocardial ischemia by electrocardiogram.<sup>27</sup> In geriatric patients with at least 1 cardiac risk factor (i.e., history of hypertension, coronary artery disease, heart failure, or myocardial ischemia), the initiation of pneumoperitoneum in the supine position results in an increase in SVR, a reduction in ejection fraction (EF), and CI. Preload and left ventricular stroke work index (LVSWI) remain unchanged. Trendelenburg positioning increases preload, EF, and CI. Return to supine positioning with deinsufflation decreases SVR below baseline and increases EF, CI, and LVSWI—all above baseline.<sup>27</sup> In patients with significant pulmonary hypertension or right ventricular failure, ventricular function may be strained in the setting of changing preload and pulmonary vascular resistance (PVR). Acute increases in preload can strain an already stressed right ventricle. Hypercarbia and acidosis can lead to increased pulmonary vasoconstriction and increased right ventricular afterload, in addition to impaired inotropy. Significant volume loading of a dilated right ventricle can in turn compress the left ventricle through the mechanism of ventricular interdependence leading to reduced global ventricular function.<sup>28</sup>

The type of surgical procedure may also influence the degree of hemodynamic derangement. Surgical disruption of the esophageal hiatus during laparoscopic fundoplication may increase mediastinal and pleural pressures, resulting in a significant reduction in CI.<sup>29</sup> Laparoscopic robotic prostatectomy results in hemodynamics similar to conventional laparoscopic surgery.<sup>30,31</sup> In healthy patients placed in steep Trendelenburg position during robotic prostatectomies, ventricular filling pressure is increased, whereas cardiac markers of ventricular performance remain unchanged.

## **Respiratory System**

Laparoscopic abdominal surgery exerts changes on the pulmonary system by

mechanically displacing thoracic structures, altering lung mechanics (i.e., volumes, compliance, resistance) and disrupting gas exchange through ventilation–perfusion mismatch (Table 44-5). An early effect of 8 insufflation on the pulmonary system is the displacement of the diaphragm into the thorax, which can be further aggravated by Trendelenburg positioning.<sup>20,21</sup> This shifts the carina cephalad, increasing the risk of endobronchial intubation. Elevated IAP and diaphragmatic displacement also lead to compression of the lung bases, atelectasis, ventilation–perfusion mismatch, and hypoxemia. However, abnormally low levels of oxygen are rarely observed in patients with normal preoperative pulmonary function. The change in pulmonary compliance can be observed as an increase in peak inspiratory pressure (PIP) during positive pressure ventilation. Ventilator adjustments may be needed to minimize peak airway pressure, while maintaining acceptable minute ventilation. Hypercarbia from CO<sub>2</sub> pneumoperitoneum frequently requires adjustments in mechanical ventilation.

**Table 44-5** Causes of Pulmonary Changes during Laparoscopy

Anatomic Displacement	VQ Mismatch	Altered Lung Mechanics
Carinal cephalad displacement	Lung volume reduction/ uneven gas distribution	Lung compliance decrease and resistance increase
Diaphragm elevation	↑Alveolar-arterial oxygen gradient	↑Pleural pressure
Endobronchial intubation		↑Airway pressure

**Table 44-6** Causes of Severe Hypercarbia during Laparoscopy

Excessive CO <sub>2</sub> Absorption	Excessive CO <sub>2</sub> Production	Inadequate CO <sub>2</sub> Removal
CO <sub>2</sub> venous embolism	Hypermetabolic conditions (e.g., fever, malignant hyperthermia)	Hypoventilation
Subcutaneous emphysema	Morbid obesity	Endobronchial intubation
Capnothorax (CO <sub>2</sub> pneumothorax)		Atelectasis
Capnomediastinum		Cardiogenic shock
Capnopericardium		Exhausted CO <sub>2</sub> absorber

Hypercarbia routinely develops in all patients from the absorption of intraperitoneal CO<sub>2</sub> into the circulatory system (Table 44-6). The concentration gradient that develops preferentially drives CO<sub>2</sub> from the pulmonary capillaries into the alveolar network, where it is removed during exhalation and measured by capnography as end-tidal CO<sub>2</sub> (EtCO<sub>2</sub>.) Exhaled CO<sub>2</sub> and the degree of gas absorption vary based on the route of insufflation, preoperative comorbidities, and acute intraoperative pathology. In lieu of CO<sub>2</sub> absorption, calculated CO<sub>2</sub> elimination during intraperitoneal and extraperitoneal laparoscopy could increase rapidly then reach a steady state within 30 minutes, regardless of surgery duration.<sup>32</sup> Extraperitoneal insufflation may result in a higher CO<sub>2</sub> elimination than during

intraperitoneal insufflation, due to a greater likelihood of tissue gas accumulation.<sup>32</sup>

In healthy patients undergoing intraperitoneal laparoscopy, hypercarbia and changes in pulmonary mechanics may have limited clinical significance. Compensatory hyperventilation can readily normalize hypercapnia. Despite speculation that a ventilation–perfusion mismatching contributes to hypercapnia during laparoscopy, minimal changes occur in alveolar dead space and pulmonary shunting during prolonged and steep Trendelenburg positioning with pneumoperitoneum used in robotic-assisted hysterectomy and prostatectomy.<sup>33</sup> Elevated EtCO<sub>2</sub> levels with a stable PaCO<sub>2</sub> in these types of surgeries is likely due to insufflated CO<sub>2</sub> absorption and not impaired alveolar ventilation. Furthermore, steep Trendelenburg positioning with pneumoperitoneum can produce close to a 50% reduction in lung compliance while simultaneously producing in an unexpected improvement in oxygenation by mechanisms that remain unclear.<sup>31</sup>

Hypoxia during laparoscopy is usually due to a transient ventilation–perfusion mismatch that is commonly attributed to pulmonary shunting (Table 44-7). Physiologic changes induced during pneumoperitoneum and extreme positioning can reduce the number of ventilated alveolar units being perfused. Nonetheless, this ventilation–perfusion relationship during laparoscopy is still unclear, given the observation in the porcine animal model of hypoxic pulmonary vasoconstriction–mediated improvements in arterial oxygenation (PaO<sub>2</sub>) after pneumoperitoneum, possibly due to perfusion redistribution away from atelectatic areas.<sup>34,35</sup>

Morbid obesity and chronic obstructive pulmonary disease (COPD) are common pre-existing conditions that may complicate ventilation and gas exchange during laparoscopy. Compensating for hypercarbia, managing inspiratory resistance, and maintaining normoxia in morbidly obese patients are common intraoperative dilemmas. The degree of instituted compensatory hyperventilation is a balance between the detrimental effects of extreme hypercarbia and the potential benefits of mild hypercapnia, which can improve tissue oxygenation, vasodilatation, and rightward shift of the oxyhemoglobin dissociation curve.<sup>36,37</sup> Before the induction of pneumoperitoneum under general anesthesia, morbidly obese patients can have an inspiratory resistance about 70% higher than nonobese patients. After Trendelenburg positioning, inspiratory resistance increases significantly. A sizable reduction in functional residual capacity (FRC) from pneumoperitoneum and Trendelenburg positioning in morbid obesity may greatly impair PaO<sub>2</sub>.<sup>38</sup> High BMI alone may also be a stronger predictor of impaired PaO<sub>2</sub>, despite compensatory ventilatory maneuvers.<sup>39</sup> Termination of pneumoperitoneum in morbidly obese patients can result in a prolonged return to baseline exhaled CO<sub>2</sub> compared to healthy patients,<sup>40</sup> potentially

extending the need for ventilatory support. In patients with advanced COPD, severe hypercarbia and limited correlation with standard capnography is expected. A reduced number of intact pulmonary units and decreased effective alveolar ventilation can lead to a rapid and severe rise in PaCO<sub>2</sub> during pneumoperitoneum, that may be refractory to hyperventilation maneuvers. Increased alveolar physiologic space in these patients leads to a wide PaCO<sub>2</sub>–EtCO<sub>2</sub> difference. As a result, EtCO<sub>2</sub> monitoring in COPD may underestimate the actual PaCO<sub>2</sub>. Eventually, PaCO<sub>2</sub> levels return to a baseline values after deinsufflation.<sup>41</sup>

**Table 44-7** Causes of Hypoxia during Laparoscopy

Pre-existing Comorbidities	Inadequate O <sub>2</sub> Supply or Gas Exchange	Low Cardiac Output State
Morbid obesity	Hypoventilation	Vena cava compression
Cardiopulmonary disease (e.g., congestive heart failure, chronic obstructive pulmonary disease)	Atelectasis	CO <sub>2</sub> venous embolism
	Endobronchial intubation	Capnothorax (CO <sub>2</sub> pneumothorax)
	Low inspired oxygen concentration	Capnomediastinum
		Capnopericardium
		Acute dysrhythmias
		Severe hemorrhage

### Regional Perfusion Effects

In healthy patients undergoing laparoscopy the splanchnic, renal, cerebral, and ocular organ systems undergo physiologic changes that are transient and of limited clinical significance (Table 44-8). Nonetheless, the magnitude of physiologic derangement and likelihood of iatrogenic injury are modified by the patients' underlying pathophysiology.

Splanchnic blood flow during laparoscopy may decrease both from external compression during pneumoperitoneum, and systemic vasoconstriction from released neuroendogenous hormones. IAP produced during pneumoperitoneum is known to reduce hepatic vein flow.<sup>42</sup> This physiologic occurrence may be advantageous during laparoscopic hepatic transection surgery, such that CO<sub>2</sub> peritoneum between 10 and 14 mmHg may be used to minimize bleeding.<sup>43</sup> Diminished mesenteric flow during pneumoperitoneum has been implicated in unusual cases of intraoperative mesenteric ischemia in cardiovascularly compromised patients.<sup>44</sup> Although splanchnic vasodilatation from absorbed CO<sub>2</sub> during pneumoperitoneum may offset any potential reductions in mesenteric blood flow in healthy patients, caution should be used in patients with known gastrointestinal coexisting diseases.

**9** Renal function is reduced during pneumoperitoneum. IAP and neurohumoral effects of pneumoperitoneum may partly account for the reductions in renal blood flow, glomerular filtration, and urine output.

Prolonged insufflation times at 15 mmHg IAP have been shown to correlate with reduced urine output without permanent renal sequelae.<sup>45,46</sup> Vasopressin release is induced partially by reduced renal perfusion, resulting in increased renal water reabsorption in the collecting ducts, and oliguria.<sup>47,48</sup> Preoperative risk factors for renal dysfunction may increase the risk of acute kidney injury (AKI) postoperatively. In bariatric surgery, increasing BMI and both insulin- and noninsulin-dependent diabetes mellitus was associated with acute kidney injury within 72 hours of surgery.<sup>49</sup> Though the use of intermittent sequential pneumatic compression devices during bariatric surgery has been shown to improve renal blood flow and urine output,<sup>50</sup> the mechanisms of action remain unclear, as well as its potential future role in AKI prevention.

Both intracranial pressure and cerebral perfusion increase during Trendelenburg positioning and pneumoperitoneum,<sup>51</sup> likely due to diminished cerebral venous outflow and hypercarbia-induced cerebral hyperperfusion. Although the cerebral venous blood fraction is increased from a reduction in cerebral venous drainage, regional cerebral tissue oxygen saturation appears to increase in this setting, possibly due to an increase in cerebral oxygen delivery from an elevated cerebral perfusion pressure and cerebral hyperperfusion.<sup>52</sup> Though these cerebral physiologic changes are usually well tolerated in healthy patients, prolonged steep Trendelenburg positioning with pneumoperitoneum has been associated with acute postoperative cerebral edema.<sup>53</sup> Cerebral physiologic changes during laparoscopy and extreme positioning carry serious theoretical implications for patients with known or occult cerebral vascular disease and intracranial tumors.

Intraocular pressure (IOP) increases during robotic prostatectomy surgery in steep Trendelenburg positioning.<sup>54,55</sup> The determinants of elevated IOP in this setting are theorized to be elevations in CVP from Trendelenburg positioning and increases in choroidal blood volume from absorbed CO<sub>2</sub> during insufflation.<sup>54</sup> Though IOP increases time-dependently and remains elevated during Trendelenburg positioning, postoperative visual function appears to remain unchanged.<sup>54</sup> Nonetheless, the role of IOP and other contributing factors in the development of postoperative ischemic optic neuropathy remains controversial. Rare cases of postoperative blindness after prolonged steep Trendelenburg positioning in laparoscopic prostatectomy<sup>56</sup> and colorectal surgery<sup>57</sup> have been reported. Pre-existing diseases, such as atherosclerotic disease, diabetes, and glaucoma, may lower the threshold of physiologic tolerance to acute intraocular derangements during laparoscopic surgery.

## Intraoperative Management

General anesthesia with endotracheal intubation (GETA), muscle relaxation, and controlled mechanical ventilation remains the preferred anesthetic technique for laparoscopic surgery. Some factors that make laparoscopic surgery best suited for general anesthesia versus other anesthetic techniques include extreme patient positioning, discomfort from pneumoperitoneum, prolonged operative times, and induced cardiopulmonary derangements. Regional anesthesia, if considered, may be suited for brief laparoscopy procedures with minimal positioning changes.<sup>22,58</sup>

**Table 44-8** Causes of Regional Perfusion Changes during Laparoscopy

Cerebral	Splanchnic	Systemic Vasculature
↑Cerebral blood flow	↓ or, unchanged, intestinal flow Hypercapnic mesenteric vasodilatation Pneumoperitoneum bowel compression	↓Femoral vein flow IVC compression
↑Intracranial pressure	↓Hepatic flow Pneumoperitoneum hepatic compression ↓Renal flow Pneumoperitoneum renal compression	

## Monitoring

Electrocardiography, noninvasive blood pressure, capnography, pulse oximetry, and body temperature monitors are mandatory for all laparoscopic procedures. Mechanical ventilation settings and pulmonary mechanics should be modified and measured via the anesthesia machine. Invasive or advanced noninvasive monitoring, such as arterial catheter, pulse contour analysis, pulmonary artery catheter, or echocardiography, may be considered if significant pre-existing cardiopulmonary disease is present. Reliability of CVP monitoring may be misleading, especially during steep Trendelenburg positioning. The role of additional monitors in laparoscopic procedures continue to evolve. Transcutaneous CO<sub>2</sub> monitoring, for example, may provide a close approximation to PaCO<sub>2</sub> in bariatric surgery,<sup>59</sup> and, in the future, may become a complementary device to EtCO<sub>2</sub> monitoring.

## Anesthesia Maintenance

### Inhaled Anesthetics and Propofol

The induction agent of choice in laparoscopy is propofol given its predictable pharmacokinetic profile, and its antiemetic properties.

Anesthesia maintenance with inhaled volatile anesthetics remains the standard anesthetic approach in laparoscopic surgery. Desflurane and sevoflurane are inhaled anesthetics with short-acting and easily titratable properties, ideally suited for ambulatory surgery.<sup>44</sup> Propofol-based total

intravenous anesthesia (propofol-TIVA) has become a common anesthetic approach. Recent popularity of propofol-TIVA has been driven primarily by its associated lower incidence of postoperative nausea and vomiting (PONV), compared to inhaled anesthetics.<sup>60</sup> However, its cost, limited titratability, and infusion equipment set up have limited its broad appeal among anesthesia providers.<sup>25,29</sup> Choice of propofol as a maintenance anesthetic, compared to inhaled anesthetics, remains controversial. The incidence of PONV among patients with low PONV risk factors has been shown to be similar among patients receiving either a propofol-TIVA or an inhaled anesthetic combined with prophylactic antiemetics.<sup>29</sup> On the other hand, compared to balanced anesthesia with desflurane, propofol-TIVA during robotic laparoscopic prostatectomy may reduce the incidence and severity of PONV during the early postoperative recovery period.<sup>61</sup>

## **Nitrous Oxide**

The use of nitrous oxide (N<sub>2</sub>O) during laparoscopic surgery remains controversial. N<sub>2</sub>O during anesthesia is believed to diffuse into air spaces, such as intestinal lumina, leading to adverse pressurization. However, detectable intestinal distension and disruption of laparoscopic surgical conditions does not appear to occur during an N<sub>2</sub>O-based anesthetic.<sup>62</sup> N<sub>2</sub>O is avoided by some practitioners due to a potentially greater risk of PONV. Although the risk of PONV with N<sub>2</sub>O-based anesthetics seems to be greater than non-N<sub>2</sub>O based anesthetics, particularly in young female patients, the overall risk in laparoscopy appears to be equivocal.<sup>63</sup> Additionally, the PONV risk associated with N<sub>2</sub>O appears to be counterbalanced by antiemetic prophylaxis and propofol-based anesthetics. N<sub>2</sub>O is known to support combustion during a spark ignition. During an N<sub>2</sub>O-based anesthetic, N<sub>2</sub>O has been shown to accumulate in the peritoneal cavity to combustion levels as early as 30 minutes<sup>64</sup> to as late as 2 hours.<sup>64</sup> Nonetheless, the incidence of spontaneous intra-abdominal laparoscopic surgical fire with N<sub>2</sub>O is exceedingly rare. This may be explained by the mechanical circulation of peritoneal gases during pneumoperitoneum.

## **Pharmacologic Adjuncts**

Lower postoperative pain is a benefit of laparoscopic surgery over conventional open surgery. A number of pharmacologic adjuncts are available for use during a balanced anesthetic to minimize intraoperative sympathetic stimulation, while optimizing postoperative recovery. Remifentanyl significantly suppresses sympathetic stimulation and the neuroendocrine stress response during pneumoperitoneum<sup>65</sup> without the prolonged respiratory effects of longer-acting opioids. Dexmedetomidine infusion during bariatric

surgery reduces fentanyl use, PONV, and PACU length of stay.<sup>66</sup> Lidocaine infusion administered during laparoscopic abdominal surgery has been associated with significant early postoperative pain reduction, as well as earlier return of gastrointestinal motility.<sup>67–70</sup> Wound infiltration or intraperitoneal instillation with a local anesthetic is routinely performed as part of a preemptive analgesia strategy.<sup>71–73</sup> Improvements in early postoperative pain scores have been shown in both wound infiltration<sup>75,76</sup> and intraperitoneal installation<sup>77,78</sup> of a long-acting local anesthetic. Continuous local anesthetic wound infiltration may have a role in laparoscopic-assisted surgical procedures with longer incisions.<sup>74</sup> Ultimately, controversy remains regarding medication safety, due to unclear concentration and dosing parameters for administered local anesthetics.

## **Neuromuscular Blockade**

Neuromuscular blocking agents are routinely used to improve surgical exposure during pneumoperitoneum. Still, controversy remains about how to best define the role of neuromuscular blockade (NMB) in laparoscopic surgery,<sup>79</sup> while minimizing the potential respiratory complications associated with residual paralysis. Surrounding these concerns remains the topic of how surgeons and anesthesiologists define “optimal surgical working conditions.” Subjective assessments of surgical working conditions during laparoscopy **10** continue to vary between surgeons and anesthesiologists, as well as between surgeons.<sup>82,83</sup> Satisfaction scores from surgeons during laparoscopy are consistently higher during deep NMB than other levels of NMB.<sup>82–84</sup> Small trials show a correlation between deep NMB and improved surgical exposure during laparoscopic cholecystectomy at an IAP less than 15 mmHg,<sup>80,81</sup> thereby supporting the view that more muscle relaxation is invariably better for optimal surgical exposure. A more nuanced view of NMB in laparoscopy, however, might be preferable given that multiple factors, such as BMI, gender, and older age, may play a role in determining expected abdominal wall compliance changes.<sup>81</sup> Ultimately, until more effective reversal agents are widely available, such as Sugammadex, anesthesiologists must continue to balance the task of optimizing perceived operating conditions using NMB while minimizing risks to patients that may be more susceptible to postoperative respiratory complications from residual NMB.<sup>85–87</sup>

## **Mechanical Ventilation**

Volume control (VC) and pressure control (PC) ventilation with positive end-expiratory pressure (PEEP) are the conventional modes of ventilation available during general endotracheal anesthesia (GETA). Both modes of

ventilation are suitable to handle the transient effects of laparoscopy on lung mechanics and to control minute ventilation during pneumoperitoneum.<sup>88</sup> Extreme positioning during pneumoperitoneum creates unique challenges to each mode. During VC in steep Trendelenburg, tidal volume remains constant while peak airway pressure increases and lung compliance decreases. In PC, peak airway pressure remains constant while tidal volume typically decreases. Conversely, reverse Trendelenburg typically induces the opposite ventilatory effects, that is, lower peak airway pressure and increased compliance with VC, and increased tidal volume with PC. Though switching from VC to PC during Trendelenburg may result in dynamic lung mechanic improvements, the effects do not appear to result in significant static lung changes, oxygenation improvements, or any other short-term benefit.<sup>89</sup>

Compensatory hyperventilation and PEEP may be employed if either hypercarbia or hypoxia are suspected. Hypercapnia during laparoscopic cholecystectomies in healthy patients may be normalized by increasing the minute ventilation about 25% above baseline.<sup>90</sup> Ventilation strategies that utilize PEEP can significantly improve ventilation–perfusion matching and preserve oxygenation.<sup>91,92</sup> The use of PEEP during pneumoperitoneum for extended laparoscopy may improve oxygenation.<sup>93</sup> Furthermore, alveolar recruitment maneuvers (RM) with the application of PEEP may have a profound effect in preventing the development of ventilator-induced lung injury by keeping alveoli open, especially in obese subjects.

The role of PEEP as a cause for hypotension in laparoscopy remains controversial. High PEEP levels in the presence of elevated IAP can further increase intrathoracic pressure and can contribute to a decrease in cardiac index.<sup>21</sup> However, a recent meta-analysis concluded that adding RM to PEEP in obese patients improved oxygenation and lung compliance without increasing the risk of hypotension from decreased preload.<sup>88</sup> Furthermore, the postoperative impact of RM and PEEP in the obese population remains controversial. Beach chair position and PEEP improve ventilatory mechanics and oxygenation during pneumoperitoneum.<sup>94,95</sup> Unfortunately, the beneficial effects of PEEP and recruitment maneuvers may only be short term and may induce hemodynamic instability in the hypovolemic patient. Ultimately, caution should be used when using compensatory ventilatory maneuvers because increased peak airway pressure may occur, especially during steep Trendelenburg positioning in morbidly obese patients.

The ideal inspired oxygen fraction ( $\text{FiO}_2$ ) continues to be debated.<sup>96</sup> Oxygen delivery intraoperatively is speculated to have secondary effects in antiemesis, wound healing, and ventilation–perfusion mismatching. Yet, to date, data appear only to support the role of high  $\text{FiO}_2$  in reducing surgical site infection with only a modest effect on PONV. Its role in inducing absorption atelectasis is not well supported. Therefore, judicious use of

oxygen to assure adequate oxygenation, especially in obese populations and those with significant lung pathology, is prudent until more data are available.

Optimal ventilation strategies during GETA continue to be defined in light of limited trials convincingly showing harm with conventional ventilation strategies.<sup>97,98</sup> Nonetheless, rationale for using lung-protective ventilation strategies in the operating room borrows greatly from historical experience managing adult respiratory distress syndrome in the intensive care unit. Low tidal volumes (6 to 8 cc/kg IBW), optimized PEEP (5 to 10 cm H<sub>2</sub>O, or greater), and RM continue to be the key components used to avoid ventilator-induced lung injury.

### **Body Temperature**

Debate continues regarding the effects of CO<sub>2</sub> gas insufflation on heat loss during laparoscopic surgery. CO<sub>2</sub> gas used in laparoscopy is stored in pressurized cylinders in its cold, liquid phase. Phase transition from liquid to gas results in rapid heat extraction from the environment that is associated with release of a cold, desiccated gas. Convective heat losses during insufflation have been theorized to be worse when intraperitoneal contents are exposed to cold and dry CO<sub>2</sub> gas,<sup>99</sup> leading to the practice of actively warming and humidifying insufflated gas with an inline heating device.<sup>100</sup> To date, however, insufflation with heated and humidified CO<sub>2</sub> gas, compared to cold and dry CO<sub>2</sub> gas, for laparoscopic abdominal surgery has not been shown to be superior to conventional hypothermia preventive methods.<sup>101</sup> Temperature control and monitoring should follow standard ASA guidelines.

### **Fluid Management**

Perioperative fluid management (see [Chapter 16](#)) is a controversial topic that in laparoscopy is further complicated by a unique interplay of surgical and physiologic alterations. Moreover, growing acceptance of enhanced recovery protocols in abdominal surgery,<sup>102</sup> which include clear, carbohydrate-rich fluid loading up to the morning of surgery, has changed perceptions of the classic intravascular “volume depleted” preoperative patient. Pneumoperitoneum may create volume shifts that can alter expected perioperative fluid therapy goals. In patients undergoing ambulatory laparoscopic cholecystectomy, intraoperative fluid loading with 40 mL/kg, compared with 15 mL/kg, of Ringer’s lactate resulted in unexpected postoperative improvements in pulmonary function, exercise capacity, and overall well-being. Surgical stress markers were also reduced.<sup>103</sup> These findings suggest a benefit to high volume loading in the healthy patient

undergoing elective ambulatory laparoscopy. In major abdominal laparoscopic surgery, however, perioperative fluid management approaches continue to be defined. In fluid therapy for robotic surgery, increasing age may impart a negative effect on the relationship between length of hospital stay and anastomosis integrity. Geriatric patients (age >70) who received more crystalloid or colloids showed higher rates of anastomotic leaks and longer hospital stays.<sup>104</sup>

Intraoperative fluid therapy based on classic hemodynamic and physiologic indicators may not be reliable. Pneumoperitoneum and steep Trendelenburg positioning, as previously discussed, alter the predictive value of heart rate, blood pressure, and central venous pressure. Pneumoperitoneum dramatically impacts the role of urine output as a surrogate for intravascular volume status. In laparoscopic bariatric surgery, high volume loading (10 mL/kg/h) compared to low volume loading (4 mL/kg/h) of Ringer's lactate resulted in similar rates of oliguria with no difference in renal dysfunction.<sup>105,106</sup> Though restricted fluid therapy approaches have gained momentum recently, insufficient evidence exists regarding the optimal total volume delivery, fluid timing, and role of intraoperative hemodynamic monitoring.<sup>102,107</sup> Intraoperative monitors for goal-directed fluid therapy, such as esophageal Doppler, pulse contour analysis, and bioreactance, are available for use at a clinician's discretion.

Positioning changes may alter fluid management. Steep Trendelenburg positioning may result in more craniofacial edema and airway compromise,<sup>104</sup> which might be ameliorated with intraoperative fluid restriction. A change to steep reverse Trendelenburg position during laparoscopic surgery for morbidly obese patients, compared to healthy normal weight patients, induces a significant change in pulse pressure variation, suggesting a low preload state and a need for rapid volume loading.<sup>108</sup>

## Complications Related to Surgery

In properly selected patients and surgical procedures, laparoscopy continues to be as safe as open surgery worldwide.<sup>109</sup> Nonetheless, perioperative complications during laparoscopic surgery still occur with varying frequency and severity, including those attributable to surgical abdominal entry, pneumoperitoneum, and extreme patient positioning.<sup>110</sup> Greater risk of complications may exist in laparoscopy for upper abdominal procedures, robotic surgery, and in patients with significant preexisting diseases.<sup>111–115</sup> Any recognized life-threatening complication intraoperatively should result in immediate termination of laparoscopy and serious consideration to convert to an open laparotomy, if deemed appropriate.

## Intraoperative

### Intra-abdominal Injuries

**11** Over 50% of complications related to laparoscopy are due to the abdominal entry techniques using the Veress needle and primary trocar insertion.<sup>109</sup> Major vascular injuries are infrequent, but are associated with high mortality rates when they do occur. Furthermore, they occur almost five times more often during blind abdominal entry than during the laparoscopic phase of the surgery. Major vessels at risk for injury during midline abdominal entry include the abdominal aorta, iliac vessels, and IVC. Abdominal entry away from the midline puts other vessels at risk, such as the superior and inferior mesenteric arteries, epigastric artery, and other small vessels of the abdominal wall. Vessels proximal to the site of surgical dissection are at increased risk of injury, such as the cystic and hepatic artery during laparoscopic cholecystectomy, and the dorsal vein complex during robotic prostatectomy. Though frank bleeding may be seen during a major vascular injury, most significant bleeding events during laparoscopy remain occult, requiring clinicians to have a high level of suspicion throughout the procedure. The anesthesiologist should be prepared for immediate surgical conversion to an open laparotomy to control severe bleeding, while managing possible hemodynamic instability due to hemorrhagic shock. Intraoperative testing and interpretation of hematocrit as an assessment of acute blood loss anemia should be performed cautiously, given the confounding effects of preoperative hematocrit collection, active bleeding, and intravascular dilution from crystalloid infusion. Transfusion triggers should be made on an individual basis, taking into account severity of bleeding, hemodynamics, and the patient's coexisting diseases. Preoperative requirement for type and screen testing for laparoscopy continues to be defined.<sup>116</sup> It has become less routine for ambulatory laparoscopy,<sup>117</sup> but continues to be determined by risk of more than minimal blood loss.

Gastrointestinal and urological structures can be injured during both the abdominal entry and the intra-abdominal portion of laparoscopic surgery.<sup>109</sup> Bowel injuries are infrequent but are a major cause of morbidity and mortality, resulting in high rates of laparotomy. Because most intestinal injuries go unrecognized, the risk of postoperative intra-abdominal sepsis is high, making it a common cause of death related to laparoscopy. Deflation of the stomach with an orogastric tube should be routinely performed to minimize the risk of gastric injury during left upper quadrant trocar insertion. Bladder perforation and ureter ligation or transection are also possible during laparoscopy and may present with low urine output, hematuria, and, rarely, pneumaturia. Postoperative hemodynamic instability or unexpected gross hematuria should trigger immediate suspicion of occult injury. Consultation

with the surgeon and critical care specialist may be warranted postoperatively.

## Cardiopulmonary

Acute cardiovascular complications associated with laparoscopy include hypertension, hypotension, dysrhythmias, and rarely cardiac arrest.<sup>21</sup> Hypertension is most common during the initial insufflation when an increase in IAP displaces blood from the splanchnic vasculature and leads to an increase in preload and cardiac output. Catecholamine release further aggravates hypertension by increasing afterload. Hypotension can sometimes be the result of a low cardiac output from vagal stimulation and impaired venous return during insufflation. Preload can be further reduced during positive pressure ventilation and steep reverse Trendelenburg positioning. Hypercapnia can increase PVR. This effect may further impact preload in patients with pulmonary hypertension or right ventricular failure. Tachyarrhythmias during intraperitoneal CO<sub>2</sub> insufflation are commonly due to catecholamine release and hypercapnia. A vagal-mediated cardiovascular reflex triggered by peritoneal stretching can induce bradyarrhythmias, which can range from sinus bradycardia to more life-threatening nodal rhythms. Profound vasovagal reaction to rapid peritoneal distention during insufflation has been implicated in acute cardiovascular collapse and cardiac arrest.<sup>21,118</sup> Treatment of acute cardiovascular disturbances should be based on the cardiophysiologic disturbance. Acute hypertension is often transient, and may be ameliorated by adjusting the depth of anesthesia. More severe cases may require short-acting vasoactive agents. Hypotension is usually responsive 12 to decreasing depth of anesthesia, volume expansion, lower IAP insufflation, and short-acting vasopressors. If treatment of hypotension involves peritoneal deflation, slow re-insufflation with lower IAP should be attempted. Conversion to open laparotomy or termination of surgery may be indicated if there is recurrent hypotension. Refractory hypotension may require immediate abdominal decompression, return to neutral patient position, and exploration of occult life-threatening conditions, such as severe bleeding or capnothorax.

Pulmonary complications that develop during laparoscopy can present as acute hypercarbic (Table 44-6) and hypoxemic (Table 44-7) events. Treatment of refractory hypercarbia usually involves cessation of insufflation. If severe hypercarbia persists during emergence, particularly in the setting of significant pulmonary disease, such as severe OSA, or if airway compromise from subcutaneous emphysema is suspected, persistent ventilator support should be considered. Treatment of hypoxemia should be swift, focusing on confirming O<sub>2</sub> delivery and endotracheal tube positioning. Immediate

pneumoperitoneum release, 100% O<sub>2</sub> ventilation, and neutral positioning should be instituted for refractory hypoxia.

## CO<sub>2</sub> Extravasation

### *Subcutaneous Emphysema*

The inadvertent introduction of CO<sub>2</sub> gas into subcutaneous, preperitoneal, or retroperitoneal tissue leads to trapped gas pockets called subcutaneous emphysema.<sup>119,120</sup> Extension of extraperitoneal CO<sub>2</sub> gas along fascial planes can lead to distant anatomic areas being affected, such as the upper and lower extremities, neck, and face, as well as large cavities, such as the thorax, mediastinum, and pericardium. Risk factors for the development of subcutaneous emphysema include longer operative times (i.e., more than 13

 200 minutes), greater number of surgical ports, lower BMI, older patient age, higher IAP, higher insufflation flow rates, and Nissen fundoplication surgery.<sup>119–122</sup> Subcutaneous emphysema may present as crepitus on physical exam, but remains largely undetected unless a computed tomography or x-ray is performed postoperatively. Unexplained sudden or persistent hypercarbia or acute hypotension may be early signs of subcutaneous emphysema or capnothorax, respectively.<sup>122</sup> The treatment of subcutaneous emphysema is peritoneal deinsufflation; however, no intervention is required in most cases. Reinsufflation at a lower IAP is recommended if pneumoperitoneum must be resumed. Postoperative treatment is supportive. Extravasated CO<sub>2</sub> resolves within 24 hours due to its high rate of diffusion. If concerns for persistent or recurrent hypercarbia from subcutaneous emphysema exist during the postoperative recovery, clinicians should maintain oxygen therapy and monitor for somnolence and acute respiratory acidosis by arterial blood gas. Cervical emphysema should be evaluated with a chest x-ray and the airway should be evaluated for signs of obstruction.

### *Capnothorax*

Carbon dioxide gas accumulation within the pleural space is called capnothorax. It is an unintentional complication of CO<sub>2</sub> insufflation that occurs when CO<sub>2</sub> travels outside the peritoneum, enters the mediastinum, and subsequently dissects along the pleura. Tension capnothorax may occur from uncontrolled pressurization of the thoracic cavity, leading to an increase in intrathoracic pressure, mediastinal shift, decreased venous return, and subsequent right ventricular compression—a potentially life-threatening condition.<sup>110,119</sup>

Insufflated CO<sub>2</sub> can pass from the abdomen and into the thorax through various routes.<sup>123,124</sup> There are several anatomic defects in the diaphragm that connect the abdominal and thoracic cavities, most notably the aortic hiatus,

esophageal hiatus, and caval opening. These defects, in addition to other smaller openings, are believed to serve as channels through which CO<sub>2</sub> can exit out of the abdomen and into the pleural spaces. Risk factors for capnothorax are similar to those for subcutaneous emphysema; however, greater risk exists during procedures near the diaphragm.<sup>111,125</sup> Tension capnothorax can occur during dissection along the diaphragm (e.g., Nissen fundoplication), unrecognized mechanical injury of the diaphragm (e.g., unrecognized trocar injury), or, very rarely, through congenital pleuro-diaphragmatic channels.<sup>119</sup>

Early signs of capnothorax may include palpable subcutaneous emphysema in the upper torso, severe hypercarbia, and changes in electrical axis and reduced amplitude of the ECG. Physical exam findings may include reduced breath sounds bilaterally or unilaterally, as well as reduced chest excursion.<sup>126</sup>

**14** Tension capnothorax may present more acutely with high peak airway pressure, hypoxia, and severe hypotension.<sup>124</sup> Tension capnothorax can be a life-threatening condition that may be difficult to accurately diagnose intraoperatively, therefore, a high index of suspicion and quick communication with the surgical team is often necessary to rescue a patient from harm. Postoperative imaging may be useful to confirm diagnosis of capnothorax. Transthoracic echocardiography is increasingly being used to assess lung pathology, including intraoperative pneumothorax.<sup>127</sup> However, its role in diagnosing capnothorax has not been well defined.

Primary treatment of capnothorax is immediate peritoneal deinsufflation. Hyperventilation can be used to expedite CO<sub>2</sub> reabsorption. Also, the addition of PEEP can reduce the pressure gradient between the abdomen and the thorax during both inspiration and expiration. Close observation is usually adequate for healthy patients with minimal physiologic derangements.<sup>123,124,128</sup> Patients with baseline cardiac dysfunction may be more likely to require supportive therapy. The hemodynamic unstable patient should be supported with fluids or vasoactive agents while the capnothorax is reabsorbed. In severe cases, emergent needle decompression or chest tube insertion may be necessary intraoperatively. If tension capnothorax and hemodynamic instability recur after reinsufflation, termination of laparoscopy and conversion to an open surgical procedure may be indicated.

Other thoracic structures rarely at risk for CO<sub>2</sub> dissection and compression include the mediastinum and pericardium. Severe capnomediastinum and capnopericardium may be associated with severe hemodynamic instability due to excessive pressure of large mediastinal vascular structures and cardiac chambers. Treatment and postoperative management is similar to tension capnothorax.

## *Venous Gas Embolism*

Venous CO<sub>2</sub> gas embolism is a potentially fatal complication of laparoscopy that occurs when large CO<sub>2</sub> gas bubbles enter the venous system, circulate to the heart, and result in right ventricular chamber gas lock and a subsequent venous outflow obstruction.<sup>129</sup> Although the consequence of CO<sub>2</sub> embolism can be severe, clinically significant occurrence is rare. Fatalities from suspected gas embolism occurred in seven patients in a retrospective review of 500,000 closed-entry laparoscopies, over three decades.<sup>130</sup> The reported incidence is varied. According to several case-series, the risk of gas embolism during laparoscopic major hepatectomy may be less than 1.5%, with an unclear correlation to morbidity and mortality.<sup>131</sup> Availability of ultrasound for intraoperative monitoring has allowed clinicians to detect previously undetected gas embolisms during laparoscopic surgery. Clinicians using intraoperative transesophageal echocardiography (TEE) have reported subclinical CO<sub>2</sub> gas embolisms in approximately 20% of laparoscopic radical prostatectomies to almost 100% of laparoscopic total hysterectomies.<sup>132,133</sup>

The etiology of a venous CO<sub>2</sub> gas embolism during laparoscopic surgery, and its degree of hemodynamic impact, is likely multifactorial. Direct Veress needle insertion into a vein or solid organ during insufflation could potentially result in CO<sub>2</sub> entry into the venous system. Open, transected vessels during laparoscopic surgical dissection may result in sudden gas venous ingress and a CO<sub>2</sub> gas embolism. Round ligament transection and broad ligament dissection during laparoscopic hysterectomy have resulted in gas embolisms.<sup>133</sup> The deep dorsal venous complex is a major source of bleeding during radical prostatectomies and a potential source of gas embolism during vessel transection.<sup>134</sup> Patient positioning may play a role in the degree of CO<sub>2</sub> gas entrainment into the right heart chambers. In the animal model, laparoscopic hepatectomies in the reverse Trendelenburg position preferentially resulted in venous gas embolisms.<sup>135</sup> Steep Trendelenburg positioning during robotic radical prostatectomies appears to protect against venous gas embolism compared to open radical retropubic prostatectomies.<sup>134</sup>

Vigilance is important for the early detection of a venous CO<sub>2</sub> gas embolism. Diagnosis is usually dependent on the constellation of clinical signs associated with gas emboli. The severity and presence of these signs vary widely. Acute tachycardia, cardiac arrhythmias, QRS complex widening, hypotension, hypoxemia, and low end-tidal CO<sub>2</sub> may be seen by monitoring. Physical exam findings may include cyanosis and a “mill wheel” murmur by auscultation. TEE is considered the most sensitive method for detecting gas emboli in the heart.<sup>136</sup> A large bolus of CO<sub>2</sub> gas would appear as a near white-out of the right heart chambers, potentially leading to a right ventricular air lock (Fig. 44-2). Because micro air bubbles are present in most peripherally injected solutions, clinicians using TEE must be ready to distinguish CO<sub>2</sub> gas

bubbles from peripherally injected bubbles. This can be facilitated by viewing the IVC during TEE monitoring.

Treatment of a massive CO<sub>2</sub> gas embolism requires immediate action. Pneumoperitoneum should be immediately terminated and the abdomen decompressed. Advanced cardiac life support should be initiated for cardiac arrest. Rapid intravenous fluid may be initiated for hypotension. CO<sub>2</sub> gas removal may be accelerated with hyperventilation and administration of 100% O<sub>2</sub>. If deemed necessary, the patient may be placed in Trendelenburg with a left lateral decubitus position to help minimize the severity of right ventricular air lock.

**Figure 44-2** Venous air embolism of the right atrium visible with transesophageal echocardiographic monitoring.

### **Patient Shifting and Falls**

Extreme positioning and potential for injury are common in laparoscopic procedures, particularly in robot-assisted laparoscopy. Patients undergoing laparoscopy in steep reverse Trendelenburg and steep Trendelenburg are at risk of unexpectedly shifting down or up on the operating room table. Operating rooms table falls are rare,<sup>137</sup> but potentially devastating. The anesthesiologists should actively take part in positioning and ensuring safe securement of the anesthetized patient. A patient in steep Trendelenburg may be secured from moving by using an operating table belt strap. Additional accessories may include an underbody gel pad for skid prevention, lithotomy stirrups with Velcro straps, and a surgical beanbag device. Careful attention should be paid to pressure points created by the securing devices. During steep reverse Trendelenburg positioning, a padded footrest can be attached to the operating room table to keep a patient from shifting down and off the table.

## *Ocular Injuries*

Steep Trendelenburg positioning during laparoscopic robotic surgery alters ophthalmic physiology and may increase the risk of both corneal abrasion and ischemic optic neuropathy–associated blindness.<sup>56,138</sup> The theorized mechanisms of injury may be independent or an interplay between external and internal stressors.<sup>139</sup> The mechanism of corneal abrasion is proposed to be mediated predominately by external risk factors, such as direct ocular trauma, corneal exposure, and corneal dehydration.<sup>140</sup> Eye patches, in addition to eye taping, may further reduce risk of corneal abrasions in robotic prostatectomies.<sup>104</sup> Prolonged steep Trendelenburg position and large volume fluid therapy may increase IOP and venous congestion acutely, thereby potentially leading to optic canal ischemia and subsequent blindness.

## *Peripheral Nerve and Brachial Plexus Injuries*

A large number of nerve injuries acquired intraoperatively are due to patient positioning.<sup>141</sup> The mechanism of injury may involve excessive compression, stretch, and ischemia. Risk factors include prolonged operative times, high BMI, inadequate padding, arm tucking, steep Trendelenburg positioning, and improper beanbag use. The brachial plexopathy is highly associated with steep Trendelenburg and longer operative time in laparoscopic colorectal surgery,<sup>142</sup> and caudad shoulder displacement during robotic prostatectomy.<sup>143</sup> Recommendations for risk reduction continue to evolve. In the meantime careful attention to positioning throughout the operative course is imperative.

## *Airway Edema*

Prolonged steep Trendelenburg position during robotic prostatectomy and large volume fluid resuscitation may induce facial and pharyngo-laryngeal edema,<sup>104</sup> which can result in airway compromise postoperatively. A recumbent sitting position may expedite reversal of any orofacial edema during emergence and postoperative recovery. A cuff leak test may be reasonable to perform prior to extubation; however, its role in ruling out significant laryngeal edema in the intraoperative, noncritically ill, patient is not well defined. If concerns for severe airway edema exist intraoperatively, a plan for continued intubation and ventilatory support should be made.<sup>104</sup>

## **Postoperative Complications**

### *Respiratory Dysfunction*

A significant benefit of laparoscopy over laparotomy is improved pulmonary function and reduced postoperative respiratory complications. Albeit rare, the potential for postoperative respiratory dysfunction after laparoscopy surgery still exists and may be modified by coexisting diseases, surgery specific factors, and any reported intraoperative pulmonary challenges. In bariatric surgery, patients with active reflux disease may be at risk for postoperative aspiration events and exacerbation of reactive airway disease.<sup>144</sup> Significant subcutaneous emphysema in the setting of coexisting lung disease may overwhelm a patient's ability to compensate for severe hypercarbia. Diaphragmatic dysfunction after laparoscopy has been reported<sup>145,146</sup> and can infrequently lead to respiratory dysfunction.<sup>147</sup>

### *Venous Thrombosis*

Coagulation cascade activation and venous outflow obstruction during CO<sub>2</sub> pneumoperitoneum are suspected pathophysiologic factors for acute venous thromboembolism (VTE).<sup>148,149</sup> Prevalence of deep venous thrombosis and pulmonary embolism associated with laparoscopic surgery is low. Still, surgical disease, associated comorbidities, and age modify the patient's risk of VTE in laparoscopic surgery.<sup>151</sup> The prevalence of in-hospital VTE after laparoscopic cholecystectomy increases with age, but overall remains low.<sup>150,151</sup> Obesity is a known hypercoagulable risk factor with a greater negative impact on women than men.<sup>152</sup> Lymph node dissection during radical prostatectomy carries a significant risk of DVT and PE postoperatively, albeit lower if the surgery is performed robotically.<sup>153</sup>

## **Postoperative Management**

### *Acute Pain Management*

**15** Postoperative pain has a significant impact on patient recovery, early mobilization, length of hospital stay, and a return to normal activity. Compared to open abdominal surgery, laparoscopic surgery results in less pain, shorter duration of pain, and less opioid consumption.<sup>154</sup> A number of surgical techniques can reduce the severity of postoperative pain after laparoscopy. These include the use of lower IAP,<sup>11</sup> shorter duration of pneumoperitoneum, and evacuation of subdiaphragmatic CO<sub>2</sub> gas prior to wound closure.<sup>155</sup> Parenteral analgesics and regional anesthesia are common options for postoperative pain management. However, a preferred approach is a preemptive multimodal strategy<sup>71,156</sup> that relies predominately on nonopioids, such as NSAIDs, COX-2 inhibitors,<sup>157</sup> and acetaminophen,<sup>158–160</sup> and minimal weak opioids.<sup>71</sup> These nonopioid analgesics may adequately

control acute postoperative pain, while minimizing adverse effects of opioids. Although the role of transversus abdominis plane block remains unclear, this procedure remains a viable option for postoperative pain management after laparoscopic surgery.<sup>161-164</sup> Neuraxial analgesia is not a routine strategy employed in laparoscopic abdominal surgery,<sup>154,165</sup> unless potential exists for conversion to open laparotomy.

### ***Postoperative Nausea and Vomiting***

Evidence suggests that patients undergoing laparoscopic surgery are at greater risk of PONV than patients undergoing nonlaparoscopic surgery. Cholecystectomy has been reported to be the highest, independent predictor of PONV, followed by laparoscopic surgery.<sup>166</sup> In laparoscopic bariatric surgery, PONV is a common cause of prolonged anesthesia recovery.<sup>167</sup> Several additional PONV risk factors exist for patients undergoing laparoscopic surgery, including inhaled volatile anesthetics, perioperative opioids administration, younger age, female gender, and nonsmoking status. PONV management should be based on assessing level of PONV risk, baseline risk reduction of known PONV triggers, patient consideration, and cost effectiveness.<sup>168</sup> Optimal antiemetic prophylaxis is the key for minimizing prolonged postanesthesia recovery.

### **Conclusion**

Laparoscopic surgery has been a revolutionary alternative to many open surgical procedures. Its ability to provide surgeons the means to operate with minimal surgical trauma while providing patients a shorter postoperative recovery has made it critical to the growth of ambulatory surgery. Advances in technology have introduced robotics as a common and growing feature of minimally invasive surgery. For the anesthetists, “minimally invasive” surgery requires maximally attentive anesthesia. Pneumoperitoneum in conjunction with extreme patient positioning induces transient, but significant, multiorgan derangements that require short-term manipulation of physiology to minimize complications. Because serious complications related to surgery can occur at any stage during the intraoperative and postoperative course, constant vigilance and action are critical to avoiding permanent injury or death. Preemptive multimodal analgesia and PONV prophylaxis strategies in laparoscopy are the keys to optimal postoperative recovery.

## KEY POINTS

- 1 Obstructive sleep apnea (OSA) is common in obese patients and predisposes to airway difficulties during anesthesia.
- 2 Obese patients may appear asymptomatic even when they have

- significant cardiovascular disease because they often have limited exercise tolerance.
- 3 Neck circumference is the single best predictor of problematic intubation in morbidly obese patients. A larger neck circumference is associated with male sex, higher Mallampati score, grade 3 laryngoscopic views, and OSA.
  - 4 Elevated liver function tests (mostly elevated alanine aminotransferase) are seen in many obese patients, but no clear correlation exists between abnormalities of routine liver function tests and the capacity of the liver to metabolize drugs.
  - 5 Morbid obesity is a major independent risk factor for deep venous thrombosis and sudden death from acute postoperative pulmonary embolism. Mobilization in the morbidly obese is often difficult but critically important in the prevention of postoperative complications.
  - 6 Positive end-expiratory pressure is the only ventilatory parameter that has consistently been shown to improve respiratory function in obese patients, but it decreases venous return, cardiac output, and subsequent oxygen delivery.
  - 7 Forearm blood pressure is a fairly good predictor of upper arm blood pressure in most patients, but in obese patients, forearm measurements with a standard cuff may overestimate both systolic and diastolic blood pressures.
  - 8 The head-elevated laryngoscopy position elevates the obese patient's head, upper body, and shoulders above the chest and can improve laryngoscopy and intubation.
  - 9 Larger doses of induction agents may be required by obese patients because blood volume, muscle mass, and cardiac output increase linearly with the degree of obesity. An increased dose of succinylcholine is necessary because of an increase in pseudocholinesterase activity.
  - 10 Prompt but safe extubation reduces the likelihood that the morbidly obese patient will become ventilator-dependent, especially in patients with cardiopulmonary disease.
  - 11 Because of the risk of perioperative hypoxemia and apnea in obese patients, postoperative pain management should include opioid-sparing multimodal analgesic techniques. Regional anesthetic techniques reduce the risk of opioid-related complications.
  - 12 Obese patients who have received either neuraxial or parenteral opioids require careful postoperative monitoring. Delayed respiratory depression with centrally administered neuraxial opioids, when coupled with a potentially difficult airway in the obese patient, suggests that close monitoring is prudent.

# Definition and Epidemiology

## Introduction

The World Health Organization defines obesity as a condition with excess body fat to the extent that health and well-being are adversely affected.<sup>1</sup> Over the past three decades, there has been a sharp increase in rates of obesity worldwide.<sup>2</sup> Estimates suggest that the number of obese individuals now exceeds the number of underweight individuals. More than one-third of Americans (33.8%) and 17% of youth are currently obese.<sup>3</sup> Prevalence of obesity in the United States is unevenly distributed geographically, by race and ethnicity, and by socioeconomic status. The Centers for Disease Control and Prevention (CDC) monitor the epidemiology of obesity and publish periodically updated data at <http://www.cdc.gov/obesity/>.

Obesity-related conditions including diabetes, cardiovascular disease, obstructive sleep apnea, nonalcoholic fatty liver disease (NAFLD), osteoarthritis, and some types of cancer are leading causes of morbidity and mortality in this population.<sup>4,5</sup> Although there has been an exponential increase in the number of bariatric procedures performed, obese and morbidly obese patients undergo all types of surgical procedures. Surgery in this patient population is considered high-risk; however, careful planning, preoperative risk assessment, adequate anesthetic management, strict venothrombotic event prevention, and effective postoperative pain control will all help to reduce the risk. With appropriate perioperative management, obese surgical patients can achieve safe and effective surgical outcomes.

The definition of obesity includes the presence of excessive body weight for the patient's age, gender, and height, and is based or estimated on calculation of the following concepts:

- Ideal Body Weight (IBW) is a concept derived by life insurance companies by referencing height-weight tables. It is the weight associated with the lowest mortality rate for a given height and gender and can be estimated using the Broca index:  
$$\text{IBW (kg)} = \text{height (cm)} - x, \text{ where } x \text{ is } 100 \text{ for adult males and } 105 \text{ for adult females.}$$
- Predicted Body Weight (PBW) is a similar concept as the IBW, and more commonly used in the medical literature. PBW is usually calculated with the following formulas in adults<sup>6</sup>:  
Males:  $\text{PBW (kg)} = 50 + 0.91 \times (\text{height (cm)} - 152.4)$ ; Females:  
 $\text{PBW (kg)} = 45.5 + 0.91 \times (\text{height (cm)} - 152.4)$
- Lean Body Weight (LBW) is the total body weight (TBW) minus the adipose tissue. It is a combination of body cell mass, extracellular water, and nonfat connective tissue. It approximates 80% and 75% of

TBW for males and females, respectively, although more accurate formulas like the following have been proposed<sup>7</sup>:

Males:  $1.10 \times \text{TBW} - 0.0128 \times \text{BMI} \times \text{TBW}$ ; Females:  $1.07 \times \text{TBW} - 0.0148 \times \text{BMI} \times \text{TBW}$

In morbidly obese patients, increasing the IBW by 20% to 30% gives an estimate of LBW. In nonobese and nonmuscular individuals, TBW approximates IBW.<sup>8</sup>

- Body Mass (Quetelet) Index (BMI) is used in clinical practice to estimate the degree of obesity:

$$\text{BMI} = \frac{\text{body weight (kg)}}{\text{height}^2 \text{ (m)}}$$

*Obesity* is defined as having a BMI 30 kg/m<sup>2</sup> or more. Obesity is further classified according to systemic disease risk (Table 45-1). Morbid obesity, defined as a BMI 40 kg/m<sup>2</sup> or more, can also be further classified into super obesity (BMI ≥ 50 kg/m<sup>2</sup>) and super-super obesity (BMI ≥ 60 kg/m<sup>2</sup>).<sup>9</sup> BMI differentiates obese from nonobese adults and it estimates body fat because it adjusts for height while strongly correlating with body weight; however, it cannot distinguish between overweight and overfat, as heavily muscled individuals can be easily classified as overweight using BMI. Therefore, other factors such as age, fat content, and distribution (i.e., waist circumference and waist-to-hip ratio) should be taken into consideration, along with other health risk predictors that use the concept of BMI.

The anatomic distribution of body fat has associated pathophysiologic implications.<sup>10,11</sup> In android (central) obesity, adipose tissue is located predominantly in the upper body (truncal distribution) and is associated with increased oxygen consumption and increased incidence of cardiovascular disease. Visceral fat is particularly associated with cardiovascular disease and left ventricular dysfunction. In gynecoid (peripheral) obesity, adipose tissue is located predominantly in the hips, buttocks, and thighs. This fat is less metabolically active so it is less closely associated with cardiovascular disease. Body circumference indices such as waist circumference, waist-to-height ratio, and waist-to-hip ratio help to classify these patterns of obesity (e.g., android vs. gynecoid obesity) and correlate with mortality and the risk for developing obesity-related diseases. Waist circumference correlates with abdominal fat and is an independent risk predictor of disease (Table 45-1).

## Management of Obesity

### Medical Therapy

Indications for drug treatment include a BMI 30 kg/m<sup>2</sup> or more or a BMI

between 27 and 29.9 kg/m<sup>2</sup> in conjunction with an obesity-related medical complication. Although conventional treatments of obesity including lifestyle changes and medications have demonstrated little success in long-term weight loss,<sup>12-14</sup> medications are often used to treat obesity because of their ability to reduce energy intake, increase energy utilization, or decrease absorption of nutrients. Phentermine, phentermine–topiramate, lorcaserin, bupropion–naltrexone, liraglutide, and orlistat are FDA-approved antiobesity medications.<sup>15</sup> Most pharmacologic therapies target appetite mechanisms with the exception of orlistat. Phentermine (Adipex-P) is primarily a noradrenergic and possibly dopaminergic sympathomimetic amine that decreases appetite. Although it is only approved for 3 months' use, it can induce, tachycardia, palpitations, and hypertension, as well as dependence, abuse, and withdrawal symptoms. It is no longer combined with fenfluramine (Phen-Fen) due to concerns of pulmonary hypertension and valvular heart disease. It is now being combined with topiramate (Topamax).<sup>16</sup> However, this combination often causes dry mouth, paresthesias, constipation, insomnia, and dizziness. Lorcaserin is a serotonin receptor antagonist and stimulates the serotonin type 2c receptor. Bupropion is combined with naltrexone and is a dopamine and norepinephrine reuptake inhibitor,<sup>17</sup> which stimulates pro-opiomelanocortin neurons. In combination with naltrexone, efficacy of bupropion is enhanced due to the release of feedback inhibition of pro-opiomelanocortin neurons that naltrexone potentiates. Liraglutide is associated with weight loss without an effect on appetite. It promotes weight loss by preventing resorption of glucose and water in the renal tubules.<sup>18</sup> Orlistat (over-the-counter Alli, prescribed Xenical) or tetrahydrolipstatin blocks the absorption of dietary fat by inhibiting lipases in the gastrointestinal tract. It leads to weight loss and improved blood pressure, fasting blood glucose levels, and lipid profile.<sup>19</sup> Fat malabsorption causes common complaints of oily spotting, liquid stools, fecal urgency, flatulence, and abdominal cramping. Chronic use of orlistat may result in fat-soluble vitamin deficiency. A prolonged prothrombin time with a normal partial thromboplastin time during orlistat treatment may reflect vitamin K deficiency, and this coagulopathy should be corrected 6 to 24 hours before elective surgery.<sup>20</sup>

**Table 45-1** Classification of Obesity, and Systemic Disease Risk According to Waist Circumference

BMI (kg/m <sup>2</sup> )	Description	Waist Circumference/Risk	
		Male: <102 cm Female: <88 cm	Male: ≥102 cm Female: ≥88 cm
<18.5	Underweight		
18.5–24.9	Normal		
25.0–29.9	Overweight		
30.0–34.9	Obesity (class I)	Average	Average
35.0–39.9	Obesity (class II)	Increased	High
≥40	Morbid obesity (class III)	High	Very high
≥50	Super obesity	Very high	Very high
≥60	Super-super obesity	Extremely high	Extremely high

BMI, body mass index.

Although over-the-counter preparations are widely used as a weight loss strategy, evidence to support their efficacy and safety is limited. Plant extracts or herbs are often used to combat obesity and include: pancreatic lipase inhibitors (e.g., caffeine, green or black tea), appetite suppressants (e.g., hoodia, Korean ginseng, ephedra, sunflower oil), stimulants of energy expenditure (e.g., acai berry, caffeine), and regulators of lipid metabolism (e.g., soybean, fish oil, oolong tea, caffeine).<sup>21</sup> The American Society of Anesthesiologists warns patients to tell their anesthesiologists about medications they are taking, including vitamins, herbs, and other supplements. Since these products can interfere with anesthesia, they can cause complications during surgery.<sup>22</sup>

## Bariatric Surgery

Bariatric surgery is currently the most effective treatment for morbid (class III) obesity. Current guidelines recommend bariatric surgery for patients with BMI above 40 kg/m<sup>2</sup> or below 35 kg/m<sup>2</sup> with obesity-related comorbidities not controlled with medical therapy.<sup>23</sup> However recent calls suggest to alter the threshold for bariatric surgery to BMI 35 kg/m<sup>2</sup> or 30 kg/m<sup>2</sup> with comorbidities in order to reduce the lifetime cost associated with diabetes, hypertension, high cholesterol, colon cancer, and cardiovascular disease.<sup>24</sup> Procedures are classified into malabsorptive (e.g., jejunioileal bypass and biliopancreatic diversion, biliopancreatic diversion with duodenal switch), restrictive (vertical-banded gastroplasty, adjustable gastric banding, sleeve gastrectomy), or combined (Roux-en-Y gastric bypass [RYGB]). The RYGB combines gastric restriction with a minimal degree of malabsorption. RYGB, adjustable gastric banding, sleeve gastrectomy, and vertical-banded gastroplasty can all be performed laparoscopically. Laparoscopic bariatric surgery is associated with less postoperative pain, lower morbidity, faster recovery, and less “third-spacing.”<sup>25</sup> Several procedures (e.g., jejunioileal

bypass) are no longer performed due to the risk for revisions and adverse health effects. RYGB is the most commonly performed bariatric procedure and produces safe short- and long-term weight loss in severely obese patients. With RYGB, patients lose an average of 50% to 60% excess body weight and show a BMI decrease of approximately 10 kg/m<sup>2</sup> during the first 12 to 24 postoperative months. Type II diabetes resolves in a majority of patients. Sleeve or partial gastrectomy is the second most commonly performed restrictive bariatric procedure. Laparoscopic adjustable gastric banding (LAGB) is a restrictive gastric operation that utilizes an adjustable inflatable band to alter stomach capacity for individual weight loss needs. Vertical-banded gastroplasty also restricts food intake.

Less invasive bariatric techniques are being developed. An implantable abdominal vagal nerve stimulator is placed laparoscopically and emits electrical impulses to control gastric emptying and signal the satiety center in the brain.<sup>26</sup> This device can be adversely affected by defibrillation, electrocautery, lithotripsy, magnetic resonance imaging, and therapeutic radiation. Intra-gastric balloons and prostheses, at different stages of development, are placed endoscopically as a temporary measure to increase satiety. They are often considered to be a bridge to more definitive bariatric procedures.<sup>27</sup> Adequate control of postoperative nausea and vomiting is critical to avoid possible stimulator lead or balloon dislodgement.

## Pathophysiology

Obesity comes with adverse health implications of multiple organ systems. [Table 45-2](#) provides a list of the most relevant organ systems with implications for clinical management. These systems will be discussed separately in this section.

1

### *Respiratory System*

Fat accumulation on the thorax and abdomen decreases chest wall and lung compliance. Decreased lung compliance is partially explained by increased pulmonary blood volume because of an overall increase in blood volume. Increased elastic resistance and decreased compliance of the chest wall are further reduced while supine, leading to shallow and rapid breathing, increased work of breathing, and limited maximum ventilatory capacity. Respiratory muscle efficiency is below normal in obese individuals. Decreased pulmonary compliance leads to decreased functional residual capacity (FRC), vital capacity, and total lung capacity. Reduction in FRC is primarily a result of reduced expiratory reserve volume (ERV), but the relationship between FRC and closing capacity, the volume at which small airways begin to close,

is adversely affected (Fig. 45-1). Decreases in FRC and ERV are the most commonly reported abnormalities of pulmonary function in obese patients.<sup>28,29</sup> Residual volume and closing capacity are unchanged. Reduced FRC (due to decreased ERV) can result in lung volumes below closing capacity in the course of normal tidal ventilation, leading to small airway closure, ventilation—perfusion mismatch, right-to-left shunting, and arterial hypoxemia. Anesthesia and supine positioning worsen this situation such that up to a 50% reduction in FRC occurs in the obese anesthetized patient compared with 20% in the nonobese individual. Forced expiratory volume in 1 second and forced vital capacity are usually within normal limits. ERV is the most sensitive indicator of the effect of obesity on pulmonary function.

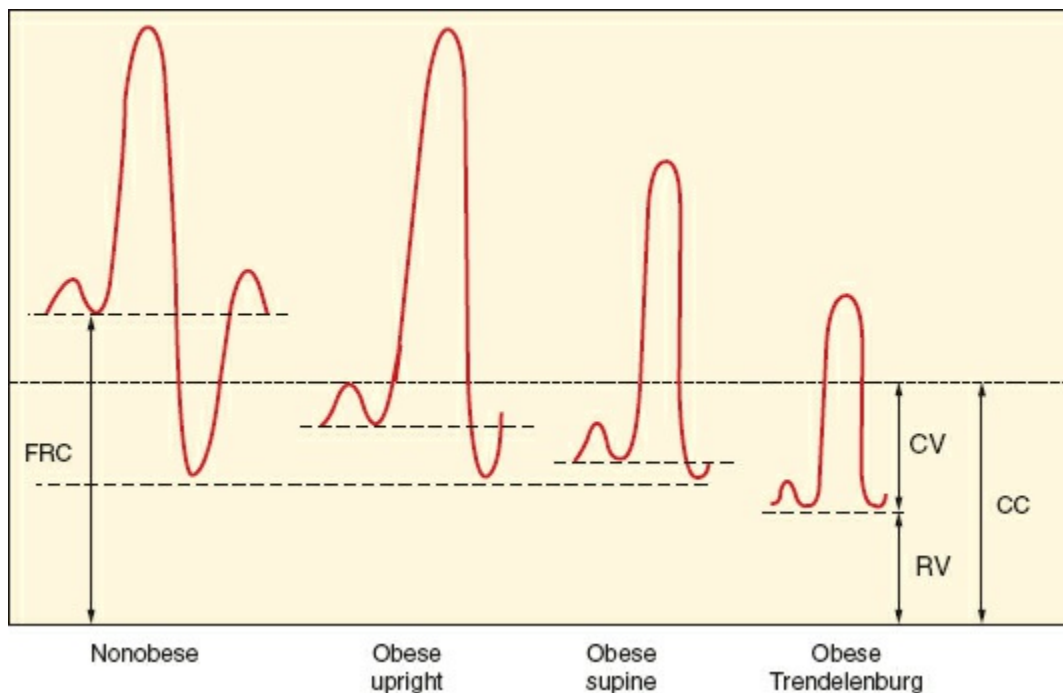

Obesity increases oxygen consumption and carbon dioxide production even at rest. This is because of the metabolic activity of excess fat and the increased workload on supportive tissues. The body attempts to meet these metabolic demands by increasing both cardiac output and alveolar ventilation. Basal metabolic activity is usually within normal limits in relationship to body surface area and normocapnia is usually maintained by an increase in minute ventilation. This requires increased oxygen consumption because most obese patients retain their normal response to hypoxemia and hypercapnia. Arterial oxygen tension in morbidly obese patients breathing room air is lower than that predicted for similarly aged nonobese subjects in both sitting and supine positions. Chronic hypoxemia may lead to polycythemia, pulmonary hypertension, and cor pulmonale.

**Table 45-2** Implications of Medical Consequences of Obesity

System	Practical Anesthesia Key Points
Respiratory	Increased risk of perioperative hypoxemia Careful monitoring needed Use of supplemental oxygen CPAP (when indicated) Nonsupine positioning (if possible) Extreme caution when administering respiratory depressant drugs
Cardiovascular	Increased blood volume, cardiac output, left ventricular wall thickness Increased proinflammatory and prothrombotic mediators Higher perioperative complications related to hypertension, thromboembolic events, and left ventricular diastolic dysfunction
Gastrointestinal	Risk of regurgitation Higher gastric volume and lower pH increases risk of severe pneumonitis should aspiration occur Current preoperative fasting guidelines (6h for solids, 2h for clear liquids) are acceptable Careful assessment of preoperative liver function is recommended
Endocrine/metabolic	High prevalence of hyperglycemia, insulin resistance, and diabetes Careful perioperative glucose monitoring Metabolic syndrome (combination of central obesity, hypertension, dyslipidemia, and impaired glucose metabolism) is frequent and doubles the cardiovascular risk
Genitourinary	Increased risk of renal disease Higher incidence of preeclampsia and eclampsia
Neurologic	Careful positioning with extra padding needed
Hematology	Increased hypercoagulability and risk of perioperative thromboembolic events Preoperative polycythemia suggests prolonged history of apnea
Musculoskeletal	Increased prevalence of osteoarthritis
Psychology/psychiatry	Depression, reduced self-esteem, social stigma

CPAP, continuous positive airway pressure.

Obese patients often suffer from obstructive sleep apnea (OSA)  characterized by periodic, partial, or complete obstruction of the upper airway during sleep. In obese patients, sleep apnea is more likely to  result from airway obstruction produced by excess soft tissue. However, centrally mediated forms of sleep apnea can also occur. Physiologic abnormalities resulting from OSA include hypoxemia, hypercapnia, pulmonary hypertension, systemic vasoconstriction, hypertension, and secondary polycythemia (from recurrent hypoxemia). These result in an increased risk of ischemic heart disease and cerebrovascular disease. Right ventricular failure can occur from hypoxic pulmonary vasoconstriction. Respiratory acidosis is usually limited only to periods of sleep.

**Figure 45-1** Effects of obesity, positioning, and anesthesia on lung volumes. FRC, functional residual capacity; CC, closing capacity; CV, closing volume; RV, residual volume.

The gold standard technique for diagnosing OSA is overnight polysomnography (OPS). The inconvenience, time, and expense of polysomnography lead to a significant fraction of obese patients presenting for surgery with suspicion for but no formal diagnosis of OSA.<sup>30</sup> Screening questionnaires such as the STOP-BANG and others<sup>31</sup> are increasingly used for identifying patients at high risk for OSA. Suggestive signs of OSA include witnessed episodes of apnea during sleep, BMI 35 or more, neck circumference 16 in or more (women) or 17 in or more (men), hyperinsulinemia, and elevated glycosylated hemoglobin. Symptoms of snoring, frequent arousals during sleep and daytime sleepiness, impaired concentration, memory problems, and morning headaches are common but not predictive.<sup>32</sup> Ideally, a thorough preoperative evaluation for OSA should occur long enough before elective surgery to allow preparation of a perioperative management plan. Preoperative initiation of continuous positive airway pressure (CPAP), especially in severe OSA cases, should be considered.<sup>33</sup> A recent study found improvements in blood pressure, glucose, and lipid metabolism in obese OSA patients treated with CPAP in addition to a weight-loss intervention.<sup>34</sup> The frequent lack of compliance or intolerance to CPAP has spearheaded the development of alternative therapies. For example, the implantable hypoglossal nerve stimulator has shown promising results in a selected group of OSA patients. In general, patients with either confirmed or suspected OSA should be considered at high risk for a difficult airway and postoperative pulmonary complications, and managed accordingly.<sup>35,36</sup> To avoid postoperative hypoxemia and hypoventilation in

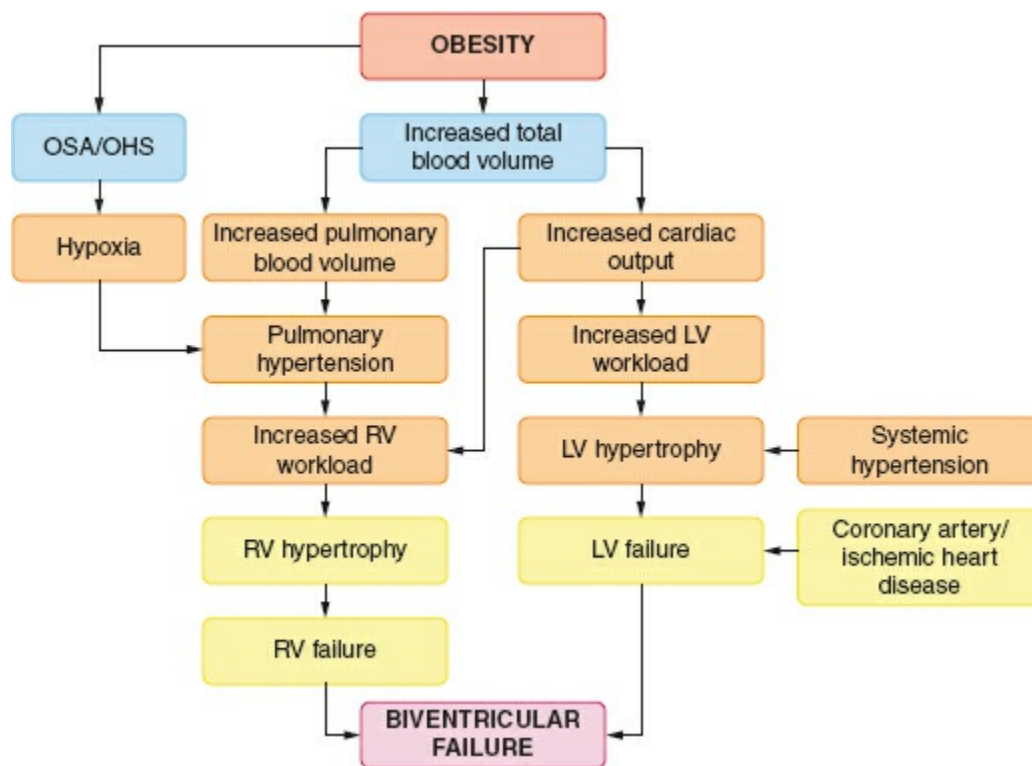

patients either with or at high risk for OSA, experts recommend a semi-upright position, continuous pulse-oximetry monitoring, avoidance of opioid-based analgesia, and therapy with titrated oxygen and/or CPAP as needed.<sup>37</sup>

Obesity hypoventilation (Pickwickian) syndrome (OHS) may result from long-term OSA and is seen in 5% to 10% of morbidly obese patients. OHS is a combination of obesity and chronic hypoventilation that is frequently misdiagnosed and untreated,<sup>38</sup> resulting in pulmonary hypertension and cor pulmonale, increased risk of postoperative complications, and death.<sup>39,40</sup> The presence of both obesity (BMI >30 kg/m<sup>2</sup>) and awake arterial hypercapnia (PaCO<sub>2</sub> >45 mmHg) in the absence of known causes of hypoventilation supports the diagnosis. Prolonged OSA also alters the control of breathing, leading to central nervous system (CNS)-mediated apneic events. This increases reliance on hypoxic drive for ventilation. The main ventilatory impairment of OHS is alveolar hypoventilation independent of intrinsic lung disease in a patient with obesity, daytime hypersomnolence, hypercapnia, hypoxemia, and polycythemia. Right ventricular failure eventually ensues. These patients also have an increased sensitivity to the respiratory depressant effects of general anesthetics.

## **Cardiovascular and Hematologic Systems**

Total blood volume is increased in the obese individual, but on a volume-to-weight basis, it is less than in nonobese individuals (50 mL/kg compared with 70 mL/kg). Most of this extra volume is distributed in adipose tissue. Renal and splanchnic blood flows are increased. Cardiac output increases with increasing weight by as much as 20 to 30 mL/kg of excess body fat because of ventricular dilation and increases in stroke volume. The resulting increased left ventricular wall stress leads to hypertrophy, reduced compliance, and impairment of left ventricular filling (diastolic dysfunction) with elevated left ventricular diastolic pressure and pulmonary edema.<sup>41</sup> When left ventricular wall thickening fails to keep pace with dilation, systolic dysfunction (“obesity cardiomyopathy”) and eventual biventricular failure result (Fig. 45-2).

**2** Obesity accelerates atherosclerosis. Symptoms such as angina or exertional dyspnea occur only occasionally because morbidly obese patients often have very limited mobility and may appear asymptomatic even when they have significant cardiovascular disease.

**Figure 45-2** Interrelationship of cardiovascular and pulmonary sequelae of obesity. OSA, obstructive sleep apnea; OHS, obesity hypoventilation syndrome; LV, left ventricular; RV, right ventricular.

Blood flow to fat is 2 to 3 mL/100 g of tissue. Excess fat requires an increase in cardiac output, to parallel an increase in oxygen consumption. This leads to a systemic arteriovenous oxygen difference that remains normal or slightly above normal. Intraoperative ventricular failure may occur from rapid intravenous fluid administration (indicating left ventricular diastolic dysfunction), the negative inotropism of anesthetic agents, or pulmonary hypertension precipitated by hypoxia or hypercapnia. Cardiac dysrhythmias may be precipitated by fatty infiltration of the conduction system, hypoxia, hypercapnia, electrolyte imbalance, coronary artery disease, increased circulating catecholamines, OSA, and myocardial hypertrophy. Frequent electrocardiogram (ECG) findings seen in morbidly obese patients include low QRS voltage, multiple criteria for left ventricular hypertrophy (LVH), left atrial enlargement, and T-wave flattening in the inferior and lateral leads.<sup>42</sup> In addition, there is a leftward shift of the P-wave, QRS complex, and T-wave axes; lengthening of the corrected QT interval; and prolongation of the QT interval. Substantial weight reduction reverses many of these ECG abnormalities.<sup>43</sup>

Cardiac output rises faster in response to exercise in the morbidly obese and is often associated with a rise in left ventricular end-diastolic pressure and pulmonary capillary wedge pressure. Similar changes occur during the perioperative period, which should prompt a low threshold for performing detailed cardiac investigations. Many obese patients have mild-to-moderate

hypertension, with a 3 to 4 mmHg increase in systolic and a 2 mmHg increase in diastolic arterial pressure for every 10 kg of weight gained. Normotensive obese patients have reduced systemic vascular resistance, which rises with the onset of hypertension. Their expanded blood volume causes increased cardiac output with a lower calculated systemic vascular resistance for the same level of arterial blood pressure. The renin–angiotensin system plays a major role in the hypertension of obesity by increased circulating levels of angiotensinogen, aldosterone, and angiotensin-converting enzyme. As little as 5% reduction in body weight leads to a significant reduction in renin–angiotensin activity in both plasma and adipose tissue, contributing to a reduction in blood pressure.<sup>44</sup>

**Figure 45-3** Adaptation of the heart to obesity and hypertension. (Adapted from Messerli FH. Cardiovascular effects of obesity and hypertension. *Lancet*. 1982;1:1165.)

Obese patients have normal-to-increased levels of sympathetic nervous system activity, which predispose to insulin resistance, dyslipidemia, and hypertension.<sup>41</sup> These obesity-induced comorbidities are responsible for the

increased cardiovascular risk in obese patients.<sup>45,46</sup> Insulin resistance enhances the vasopressor activity of norepinephrine and angiotensin II. Hyperinsulinemia further activates the sympathetic nervous system, causing sodium retention and contributing to obesity-induced hypertension. Hypertension causes concentric hypertrophy of the ventricle in normal-weight individuals but causes eccentric dilation in obese individuals. It is associated with increased preload and stroke work. The combination of obesity and hypertension causes left ventricular wall thickening and a larger heart volume; therefore, there is increased likelihood of cardiac failure (Fig. 45-3).

Obese individuals are also prone to cardiovascular disease because adipose tissue releases a large number of bioactive mediators. These can result in abnormal lipids, insulin resistance, inflammation, and coagulopathies.<sup>45,46</sup> Obese individuals have higher levels of fibrinogen (a marker for the inflammatory process of atherosclerosis), factor VII, factor VIII, von Willebrand factor, and plasminogen activator inhibitor-1 (PAI-1). Increased levels of fibrinogen, factor VII, factor VIII, and hypofibrinolysis are associated with hypercoagulability. High factor VIII levels are associated with increased cardiovascular mortality. Increased fasting triglyceride levels correlate with increased factor VII concentrations, and postprandial lipemia causes activation of factor VII. Endothelial dysfunction induced by insulin increases von Willebrand factor and factor VIII levels, predisposing to fibrin formation. Increased secretion of PAI-1 inhibits the fibrinolytic system and is associated with visceral obesity.<sup>47</sup>

## **Gastrointestinal System**

Gastric volume and acidity are increased, hepatic function is altered, and drug metabolism is adversely affected by obesity. Many fasting morbidly obese patients who present for elective surgery have gastric volumes in excess of 25 mL and gastric fluid pH lower than 2.5 (the generally accepted volume and pH indicative of high risk for pneumonitis should regurgitation and aspiration occur). Delayed gastric emptying occurs because of increased abdominal mass that causes antral distention, gastrin release, and a decrease in pH with parietal cell secretion.<sup>48,49</sup> Abdominal obesity increases intragastric pressure, increasing the frequency of transient lower esophageal sphincter relaxation, and/or hiatal hernia formation. An increase of more than 3.5 kg/m<sup>2</sup> in BMI is associated with a 2.7-fold increase in risk for developing new reflux symptoms.<sup>48</sup> An increased incidence of hiatal hernia and gastroesophageal reflux further increases aspiration risk.

Gastric emptying is faster with high-energy content intake such as fat emulsions, but because of larger gastric volume (up to 75% larger), the residual volume is increased. The combination of hiatal hernia,

gastroesophageal reflux, and delayed gastric emptying, coupled with increased intra-abdominal pressure and high-volume/low pH gastric content, puts the obese patient at risk for increased incidence of severe pneumonitis should aspiration occur. Unmedicated, nondiabetic fasting obese surgical patients who are free from significant gastroesophageal pathology are unlikely to have high volume, low pH gastric contents after routine preoperative fasting.<sup>50</sup> They should follow the same fasting guidelines as nonobese patients and be allowed to drink clear liquids up until 2 hours before elective surgery.<sup>51</sup> Weight loss significantly improves gastroesophageal reflux symptoms.<sup>52</sup>

Peculiar morphologic and biochemical abnormalities of the liver are associated with obesity and include fatty infiltration (high prevalence of NAFLD), inflammation (nonalcoholic steatohepatitis [NASH]), focal necrosis, and cirrhosis. Fatty infiltration reflects the duration rather than the degree of obesity. Histologic and liver function test abnormalities are relatively common, but drug clearance usually is not reduced. Abnormal liver function tests are seen in up to one-third of obese patients who have no evidence of concomitant liver disease. The most common abnormality is an increased alanine aminotransferase (ALT). Despite these histologic and enzymatic changes, no clear correlation exists between liver function abnormalities and the capacity of the liver to metabolize drugs.<sup>53</sup> Morbidly obese patients who have undergone intestinal bypass surgery have a particularly high prevalence of hepatic dysfunction and cholelithiasis. This is also common in the general obese population due to abnormal cholesterol metabolism. The high prevalence of NAFLD, NASH, and cirrhosis necessitates careful assessment for pre-existing liver disease in obese patients scheduled for surgery. Features suggestive of NASH include hepatomegaly, elevated liver enzymes, and abnormal liver histology (steatosis, steatohepatitis, fibrosis, and cirrhosis).<sup>45</sup>

## **Renal and Endocrine Systems**

Impaired glucose tolerance in the morbidly obese is reflected by a high prevalence of type II diabetes mellitus as a result of resistance of peripheral adipose tissue to insulin.<sup>41</sup> Many obese patients have an abnormal glucose tolerance test, and the relative risk of developing diabetes increases by 25% for every 1 kg/m<sup>2</sup> increase in BMI above 22 kg/m<sup>2</sup>.<sup>41</sup> Hyperglycemia, insulin resistance, and diabetes predispose obese patients to wound infections and an increased risk of myocardial infarction. Exogenous insulin may be required perioperatively even in obese patients with type II diabetes mellitus to oppose the catabolic response to surgery.

In addition to these concerns, subclinical hypothyroidism occurs in about 25% of all morbidly obese patients. Thyroid-stimulating hormone levels are

frequently elevated, suggesting the possibility that obesity leads to a state of thyroid hormone resistance in peripheral tissues. Hypothyroidism may be associated with hypoglycemia, hyponatremia, and impaired hepatic drug metabolism.

Obesity is associated with glomerular hyperfiltration as evidenced by increased renal blood flow and increased glomerular filtration rate. Excessive weight gain increases renal tubular resorption and impairs natriuresis through activation of the sympathetic and renin–angiotensin system, as well as physical compression of the kidney. With prolonged obesity, there may be a loss of nephron function, with further impairment of natriuresis and further increases in arterial pressure. However, the increased risk of acute kidney injury by obesity per se is unclear.<sup>54</sup> Obesity-related glomerular hyperfiltration decreases after weight loss, which decreases the incidence of overt glomerulopathy.<sup>55</sup>

*Metabolic Syndrome.* Metabolic syndrome, sometimes referred to as syndrome X and insulin resistance syndrome, is a cluster of metabolic abnormalities associated with an increased risk of diabetes and cardiovascular events. Individuals with this syndrome have up to a fivefold greater risk of developing type 2 diabetes mellitus (if not already present) and are also twice as likely to die from a myocardial infarction or stroke compared with those without the syndrome.<sup>56</sup> Furthermore, patients with metabolic syndrome are more likely to have perioperative adverse events including cardiovascular, pulmonary, and renal complications and wound infections.<sup>57</sup> Although there are several different definitions of metabolic syndrome, the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) definition is the most widely used.<sup>58</sup> It defines metabolic syndrome when three out of the following five conditions exist: (1) Central obesity: Waist circumference 102 cm or more ( $\geq 40$  in) in males, 88 cm or more ( $\geq 35$  in) in females; (2) Dyslipidemia: Triglycerides 150 mg/dL or more; (3) Dyslipidemia: HDL 40 mg/dL or less in males, 50 mg/dL or less in females; (4) Hypertension: at least 130/85 mmHg or use of antihypertensives; (5) Elevated fasting glucose: 100 mg/dL or more ( $\geq 5.6$  mmol/L) or use of medication for hyperglycemia. Weight loss and lifestyle changes can improve metabolic syndrome features.<sup>56</sup> However, bariatric surgery resolves metabolic syndrome in more than 95% of patients who achieve expected weight loss.<sup>59</sup> Because of the increased risk in the metabolic syndrome patient population, anesthesiologists should formulate perioperative management strategies to mitigate perianesthetic and surgical risk.

## Pharmacology

### Pharmacologic Principles

General pharmacokinetic principles dictate, with certain exceptions, that drug dosing should take into consideration the volume of distribution (VD) for administration of the loading dose, and the clearance for the maintenance dose.<sup>60</sup> A drug that is mainly distributed to lean tissues should have the loading dose calculated based on LBW. If the drug is equally distributed between adipose and lean tissues, dosing should be calculated based on TBW. For maintenance, a drug with similar clearance values in both obese and nonobese individuals should have the maintenance dose calculated based on LBW. However, a drug whose clearance increases with obesity should have the maintenance dose calculated according to TBW. Use of LBW and TBW in drug dosing for obese individuals is still under discussion.<sup>61</sup>
